Obesity is defined as a disease where excess body fat has accumulated such that health may be adversely affected.[1] BMI is most commonly used to quantify human adiposity and recent epidemiologic studies suggest that the optimal BMI for nonsmoking adult whites is 20 to 25.[1] Additionally, epidemiologic data confirm that disease and mortality risk progressively increases for people classified as "overweight" (BMI 25 to 30), "obese" (BMI 30 to 40), and morbidly obese (BMI >40).[2] Companion animals are currently classified as overweight when their body weight is more than 15% above their "optimal body weight," and classified as "obese" when their body weight exceeds 20% to 30% of optimal[3]; data suggest that, like in humans, adverse consequences develop when dogs and cats are not maintained in optimal body condition.[3-6]

Prevalence

Recent studies estimate the prevalence of overweight/obesity in the pet population to be between 34% and 41%.[4-9] Although most investigators would agree that, as in humans, the incidence in the pet population is increasing, there are limited data to support this.

Etiology and Pathogenesis

At its simplest, obesity arises from a positive mismatch between energy intake and energy expenditure for a significant period. Most animals are able to maintain a stable body weight despite dramatic fluctuations in caloric intake; however, in those that become overweight, a number of risk factors can be present that alter energy balance toward weight gain.

Risk Factors for the Development of Obesity

Coexisting Health Problems

Concurrent disease can affect energy balance either by increasing energy intake (e.g., by increasing appetite) or reducing energy expenditure (e.g., by decreasing physical activity or slowing the basal metabolic rate). Diseases that can predispose to obesity include endocrinopathies (e.g., hypothyroidism and hyperadrenocorticism), conditions leading to reduced activity levels (e.g., orthopedic and cardiorespiratory diseases), and conditions requiring a medical intervention that might predispose to weight gain (e.g., drug therapy with glucocorticoids or anticonvulsants, and neutering for animals with diabetes mellitus, idiopathic epilepsy, and pyometra).

Although hypothyroidism is commonly cited as an underlying cause of obesity in dogs, such cases are the exception rather than the rule. The prevalence of hypothyroidism is reported to be less than 1%, with less than half of such cases presenting with obesity[10]; this contrasts with the relatively higher prevalence (typically 30% to 50%) of excess body weight.[6-8] Spontaneous hypothyroidism is rare in cats and usually only seen following chemotherapeutic, radiation, or surgical thyroidectomy for hyperthyroidism.

Signalment

The prevalence of obesity, in both species, rises sharply after 2 years of age and is most prevalent in middle age.[5-6] Neutering is an important risk factor for obesity in both dogs and cats, most likely associated with increased food intake and decreased physical activity.[11,12] Sex itself is a predisposing factor in some canine studies, with females overrepresented.[6,8] In contrast, a recent feline study suggested that males might be overrepresented.[9]

Breed

Rare genetic defects are an occasional cause of obesity in humans, but no single-gene disorders have been described in the dog or cat. Polygenic effects predisposing to weight gain in people have been reported.[13] Given that a number of breed predispositions have been reported in both dogs (e.g., Cocker Spaniels, Beagles, Labrador Retrievers, Golden Retrievers, Shetland Sheepdogs, Rottweilers, and mixed-breed dogs) and cats (e.g., Domestic Shorthair),[5,6] genetic influences are also likely in companion animals.

Environment and Activity

Indoor living is a risk factor for canine obesity; indoor dwelling and apartment living have been shown to predispose to obesity in some, but not all, feline studies.[13,14] Furthermore, cats living with dogs or with houses with only one or two other cats may be at more risk.[13,14]

Dietary Factors

The type of diet (prepared pet food vs. homemade) does not predispose to obesity, but the cost of food may.[15] In this respect, obese dogs are more likely to have received inexpensive generic diets rather than more expensive foods, while some studies suggest premium pet foods may increase the risk of feline obesity.[5] This is most likely a result of the potential for a higher fat (and therefore energy) content in premium foods. However, this finding has been contradicted by other studies in which no association was found with a particular type of diet.[13] Although, there have been many anecdotal suggestions that feeding a high-carbohydrate diet to cats predisposes to obesity and diabetes mellitus, there is no evidence to support this assertion either. In fact, increased dietary fat rather than carbohydrate predisposes to weight gain in cats.[16]

Obesity in dogs is associated with the number of meals and snacks fed, the feeding of table scraps, and the animal being present when owners prepared or ate their own meal.[13,14,17,18] Finally, obese cats more commonly have free choice of food intake.[13,14]

Owner Factors and Behavior

Many owners of obese cats tend to anthropomorphize them, and to use them as a substitute for human companionship.[19] Overweight dogs also tend to be anthropomorphized, but a close human–dog relationship is not a factor.[15] Owners of overweight cats also spend less time playing with their pet, and reward with food rather than extra play. Owners of both overweight cats and dogs also observe their pet more closely during eating, are less interested in preventive health, and are more likely to be overweight themselves.[15,19]

However, unlike the owners of overweight dogs who tend to have a lower income,[15,20] there are no demographic differences amongst owners of overweight and normal weight cats.[19]

Behavioral factors also play a part in the development of obesity, especially in cats, and the factors implicated include anxiety, depression, failure to establish normal feeding behavior, and failure to develop control of satiety.[21]

Pathologic Consequences of Obesity

Human Obesity-Associated Disorders

It has long been known that obesity conveys increased risk of mortality in humans (Table 30-2). Most significant is the metabolic syndrome, which comprises a group of metabolic and vascular

Table 30-2 Diseases Associated with Overweight Body Condition and Obesity in Humans, Dogs, and Cats

Disease Category	SPECIES		
	Human	Dog	Cat
Endocrine and lipid	Type II diabetes Metabolic syndrome Dyslipidemias	Hypothyroidism, hyperadrenocorticism Diabetes mellitus; insulin resistance Metabolic syndrome (experimental)	Diabetes mellitus Hepatic lipidosis
Cardiorespiratory	Coronary heart disease, atherosclerosis, hypertension Obstructive sleep apnea, asthma	Tracheal collapse, expiratory airway dysfunction (experimental), hypertension (of doubtful clinical significance), portal vein thrombosis, myocardial hypoxia	
Orthopaedic and impaired mobility	Osteoarthritis Musculoskeletal pain Gout	Osteoarthritis, cruciate ligament disease Humeral condylar fractures Intervertebral disk disease; hip dysplasia	Increased lameness
Oncologic	Various cancers including breast (postmenopausal), renal, endometrial, prostatic, esophageal, colorectal hepatocellular carcinoma	Variable neoplasia risk, transitional cell carcinoma Mammary carcinoma (some but not all studies)	Increased neoplasia risk
Urogenital	(Diabetic) nephropathy	Urinary tract disease, USMI, calcium oxalate urolithiasis,[37] transitional cell carcinoma Glomerular disease (experimental), dystocia	Increased risk of urinary tract disease
Alimentary	Pancreatitis, hepatic steatosis, cirrhosis	Pancreatitis	Increased oral cavity disease and gastrointestinal disease
Other	Depression Postoperative complication Various dermatologic diseases	Reduced immune function	Increased risk of dermatoses

USMI, Urethral sphincter mechanism incompetence.

disorders that increase the risk of an individual developing type II diabetes mellitus and cardiovascular disease.[22] In humans, the prevalence of type II diabetes mellitus has increased dramatically in the last decade, primarily because of the link with obesity.[23] Tissues become "insulin resistant" with excessive caloric intake, and the risk of developing diabetes is known to increase with increasing BMI.[23] Thus, obesity, particularly abdominal obesity, is a major determinant of insulin resistance and hyperinsulinemia.

Obese humans have a higher prevalence of coronary heart disease, atherosclerosis, hypertension, and dyslipidemias.[24] Other comorbidities associated with obesity in humans include renal disease (mainly diabetic nephropathy), osteoarthritis, and respiratory impairment (including obstructive sleep apnea and asthma). There has been a recent recognition that obesity increases the risk of steatosis, cirrhosis, and hepatocellular carcinoma, and is now recognized to be the most prevalent form of liver disease in Western countries.[25] Obesity also predisposes to various types of neoplasia, including postmenopausal breast, prostatic, ovarian, colorectal, renal cell, and esophageal cancer.[26]

Obesity-Associated Disorders in Companion Animals

Table 30-2 summarizes obesity-associated disorders in companion animals.

Longevity

A long-term prospective study recently demonstrated that restricting caloric intake in dogs (to approximately 75% of ad libitum levels) improves longevity.[27] Such a strategy tends to maintain optimal body condition (body conditions scores of 4.5/9 vs. 6.8/9), and can extend lifespan by almost two years (13 years vs. 11.2 years in dogs fed ad libitum).

Endocrine and Metabolic Diseases

In dogs, obesity is reported to be associated with diabetes mellitus, hypothyroidism, and hyperadrenocorticism,[6] whereas obesity in cats is associated with diabetes mellitus only.[5] Cats most often suffer from an "insulin-resistant" form of diabetes mellitus, and there are similarities with "type II" diabetes in humans. Feline obesity is a known cause of insulin resistance in this species,[28] and weight loss in cats improves insulin sensitivity, thereby reducing the requirement for exogenous insulin therapy.

Diabetes in dogs is characterized by progressive β-cell loss and absolute insulin deficiency, such that affected dogs require exogenous insulin therapy and will develop ketoacidosis, if untreated. Although the pathogenesis of β-cell loss is poorly understood, pancreatitis and immune-mediated β-cell destruction are thought to play an important role. The association between obesity and diabetes mellitus in dogs has been shown in epidemiologic studies.[6] One possible explanation for the association is pancreatitis, as the prevalence is known to be higher in overweight dogs.[6] Insulin resistance also may be a contributing factor as it can be induced experimentally (along with other components of the metabolic syndrome) in dogs through weight gain caused by dietary manipulation.[29] Furthermore, dogs fed ad libitum throughout life have worse insulin sensitivity and glucose tolerance.[27] Moreover, a recent study of naturally occurring obesity in dogs demonstrated that the percentage of body fat

correlates with the degree of insulin resistance, and insulin sensitivity is improved significantly upon successful weight loss.[30]

Obese dogs have marginally higher serum total T_4 (thyroxine) and total T_3 (triiodothyronine) concentrations than nonobese dogs, but other parameters (free T_4, canine thyroid-stimulating hormone [cTSH], TSH stimulation) are not significantly different.[31] Thus, although obesity may have some effects on thyroid homeostasis, such changes are unlikely to affect the interpretation of thyroid function tests.

Hyperlipidemia and Dyslipidemia

The association between feline obesity and hepatic lipidosis is well established and was confirmed in an epidemiologic study (see Chapters 32 and 61).[5] Experimental studies in obese dogs have demonstrated mild, but likely clinically insignificant, elevations in serum cholesterol, triglycerides, and phospholipids, while laboratory dogs made obese have increased plasma nonesterified fatty acid and triglyceride concentrations (increased very-low-density lipoprotein [VLDL] and high-density lipoprotein [HDL]; decreased HDL cholesterol).[29] Such changes are associated with insulin resistance. Whether or not lipid alterations account for the increased incidence of pancreatitis in obese dogs requires further study.

Orthopedic Disorders

Obesity is a major risk factor for orthopedic diseases in dogs, with increased prevalence of a variety of orthopedic disorders, including humeral condylar fractures, cranial cruciate ligament rupture, and intervertebral disk disease.[32] There are also reported associations with hip dysplasia and osteoarthritis,[33,34] while weight reduction can lead to a substantial improvement in degree of lameness in dogs with hip osteoarthritis.[34]

As with dogs, obesity may be a risk factor for orthopedic disease in cats. One study suggested that obese cats were five times more likely to limp than cats of normal body condition.[4] However, not all reports have confirmed this association.[5] The lack of association in the latter study may relate to the fact that orthopedic disease is underrecognized, especially as clinical signs are subtle in this species.

Cardiorespiratory Disease and Hypertension

Obesity in dogs can have significant deleterious effects on the functioning of the respiratory system, as shown in a recent experimental study.[35] Although higher BCS did not influence airway function during normal breathing, airway resistance was markedly greater during hyperpnea. Furthermore, there was a tendency toward a lower functional residual capacity in markedly obese dogs compared with other dogs. Such effects are similar to those seen in humans, and may help to explain the link between obesity and certain respiratory conditions in the dog, most notably tracheal collapse, laryngeal paralysis, and brachycephalic airway obstruction syndrome.

Although obesity can affect cardiac rhythm and left ventricular volume, there is no evidence of an association with cardiac disease in dogs.[36,37] However, overweight dogs with heart failure have reduced survival times compared with cats in normal body condition.[37] The effect of obesity on blood pressure is relatively minor and unlikely to be of clinical significance as it is in humans. Finally, obesity may also be associated with portal vein thrombosis, and myocardial hypoxia.

Other Disorders

Some epidemiologic studies in both cats and dogs have reported an increased risk of neoplasia in obese animals.[5,6] However, this association is controversial as it has not been reported in all studies.[38] Overweight dogs are reportedly at increased risk for transitional cell carcinoma of the urinary bladder, but there is controversy over an association between obesity and mammary carcinoma.

Experimentally, the onset of obesity is associated with glomerular pathology in the dog, including increases in plasma renin and insulin concentrations, mean arterial pressure, and plasma renal flow.[39] However, no such association has been reported in naturally occurring obesity. For lower urinary tract diseases, associations between obesity and both urethral sphincter mechanism incompetence (USMI) and transitional cell carcinoma are reported, while obese animals have an increased risk of dystocia. Finally, although the reasons for an association are unclear, obese cats are at increased risk of oral cavity disease, dermatologic disorders, and diarrhea.[5]

Pathogenesis of Obesity-Associated Diseases

When present in excess, white adipose tissue can increase the risk of disease through both "mechanical" and "endocrine" mechanisms. Mechanical effects include excessive loading of weight-bearing structures (exacerbating orthopedic diseases), constriction of collapsible structures (increasing risk of upper respiratory tract and urinary system disorders), inability to groom, and reduced heat dissipation as a result of the insulating effect of fat. White adipose tissue is now understood to be a major endocrine organ, synthesizing a range of cytokines, chemokines, and other inflammation-related proteins, collectively termed *adipokines* (Fig. 30-2).[40] Thus, the endocrine effects of obesity arise through disturbance of its normal function, leading to a state of chronic mild inflammation. In humans, increases in the production of certain "inflammatory" adipokines (e.g., leptin, TNF-α, interleukin [IL]-6, plasminogen activator inhibitor [PAI]-1, and haptoglobin) have been directly linked to the development of the metabolic syndrome and other disorders linked to the obese state.[41] Although information is more limited, inflammatory adipokine gene expression was documented in both canine and feline white adipose tissue samples.[40] Plasma leptin concentrations have been shown to be independently associated with insulin sensitivity in lean and overweight cats, while mildly increased TNF-α, C-reactive protein, and haptoglobin are seen in obese dogs with insulin resistance, and which decrease after weight loss.[40] This suggests that similar pathogenetic mechanisms may exist in companion animal and human obesity.

Clinical Investigation

Upon initial presentation, the patient should be examined thoroughly, with the aim of quantifying the level of obesity, identifying predisposing risk factors, and determining overall health status. All concurrent diseases should be identified, whether they are obesity-associated or not. This enables the clinician to decide upon a plan for weight management, to determine an appropriate target weight, and to choose the safest and most effective approach for weight loss. The exact tests performed will depend upon the individual patient.

History and Physical Examination

The medical history should include details of environment, lifestyle, diet and exercise regimens, as well as a complete medical history including previous or current medical therapy. Physical examination should focus on associated diseases either causing or contributing to weight gain, or present as incidental findings.

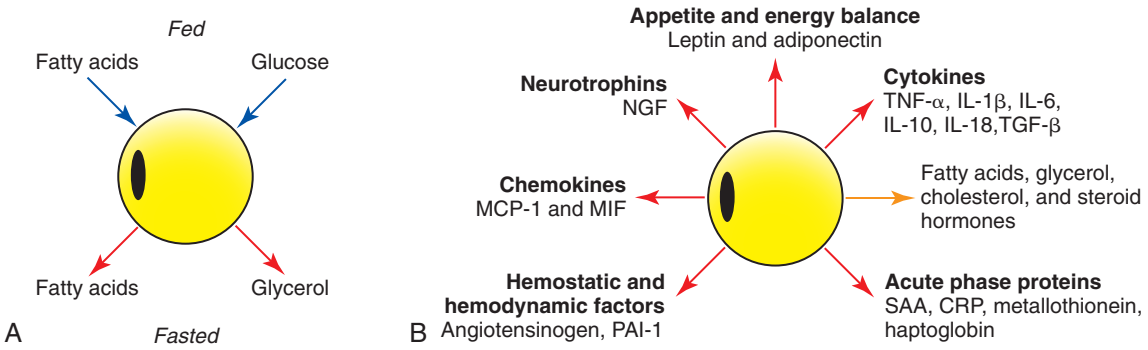

Figure 30-2 Evolving views of the biologic functions of adipose tissue. Adipocytes were previously considered to be inert storage depots releasing fuel as fatty acids and glycerol at times of fasting or starvation. However, it has become increasingly clear that adipocytes are endocrine cells, which secrete important hormones, cytokines, vasoactive substances, and other peptides. **A,** Inert storage depot. **B,** Secretory and endocrine gland. This figure outlines the range of such proteins secreted from white adipose tissue (WAT). CRP, C-reactive protein; IL, interleukin; MCP-1, monocyte chemoattractant protein-1; MIF, macrophage migration inhibiton factor; PAI-1, plasminogen activator inhibitor-1; SAA, serum amyloid A; TGF-β, transforming growth factor-β; TNF-α, tumor necrosis factor-α. Weight Measurement and Body Condition Score

It is advisable to use the same set of electronic weigh scales for weight measurement, and to calibrate these regularly. BCS is useful at the outset to establish the degree of obesity and predict the likely target weight of a particular animal.[42,43] BCS should be calculated periodically during the weight-reduction program to assess progress, and to adjust the target weight if required.

Further Investigations

Although not mandatory in all patients, routine complete blood count, serum chemistry, and urinalysis can provide general information on health. Additional investigations may be required in some circumstances depending upon history, physical examination findings, and clinical suspicions. For example, the further medical investigation might include blood pressure measurement, thyroid and adrenal gland functional assessments (dog), serum fructosamine measurements for diabetes mellitus, survey radiography for suspected orthopedic and respiratory disease, hepatic ultrasonography, and fine-needle aspiration cytology or liver biopsy for suspected hepatic lipidosis. Bacterial culture of the urine, bladder ultrasonography, and radiographic contrast studies for lower urinary tract diseases could also be included in the workup.

Diagnosis

Measurement of Obesity in Companion Animals

Body composition can be assessed in various ways, some more quantitative than others. First, DEXA is known to be precise and reliable, and can be used in a referral setting (Fig. 30-3),[44] but it is unsuitable for general practice, where noninvasive methods are preferred. BCS schemes assess adipose tissue mass through visual assessment and palpation.[42,43] They have shown good repeatability when used by trained individuals, and correlate well with body fat mass measured by DEXA.[42] BCS can determine the approximate degree of excess weight in obese dogs and cats, with each point (in a 9-point system) or half point (for a 5-point system) correlating with approximately 10% to 15% of excess body weight.[43] Finally, bioimpedance is another noninvasive method potentially applicable in general practice. It should be noted, however, that many handheld devices designed for dogs are unreliable, and inferior to the use of BCS.[45]

Treatment and Prognosis

Weight management in cats and dogs can be very challenging for the pet owner as well as for the veterinarian. Rather than simply reducing body weight, the main aims of weight management are to improve quality of life and reduce associated disease risk. In so doing, it is vital that a healthy relationship is established between the pet and its owner, or the weight-reduction program will likely fail over the long-term. The recommended rate of weight loss remains controversial: slow rates of loss can be met with frustration on the part of the owner, while overly rapid rates of loss could enhance fat mobilization and hepatic lipidosis in cats, and excessive lean tissue loss in both species. Weight-reduction rates should be tailored to the nutritional and metabolic needs of each individual cat or dog, but a rate of approximately 1% loss per week is thought to be safe and realistic.[46,47]

There are two phases to any weight-loss program: the weight-loss period itself, which can be of variable length (over many months), and maintenance, which involves stabilization of body weight and preventing rebound weight gain. In humans, the most successful approach for treatment of severe obesity is bariatric surgery, but it is not likely to be practical or ethically justifiable in companion animals. Dietary therapy remains the most common approach to obesity management, although microsomal membrane transfer protein (MTP) inhibitors are gaining increasing acceptability for the treatment of canine, but not feline, weight loss.[48] Whichever strategy is adopted, long-term substantive changes to lifestyle (e.g., increased physical exercise and alterations in feeding behavior) are fundamental to long-term success.

Dietary Management

Diet Formulation

Purpose-formulated weight-loss diets are recommended because they have restricted energy content while at the same time supplemented with protein and micronutrients. Rates of weight loss are principally determined by energy intake. Supplementing dietary protein relative to energy content does not speed up the rate of weight loss, but it ensures that lean tissue lost is minimized. L-Carnitine supplementation is thought to maintain lean tissue mass during weight loss, while supplementation of micronutrients, relative to energy content, ensures that deficiency states do not arise.

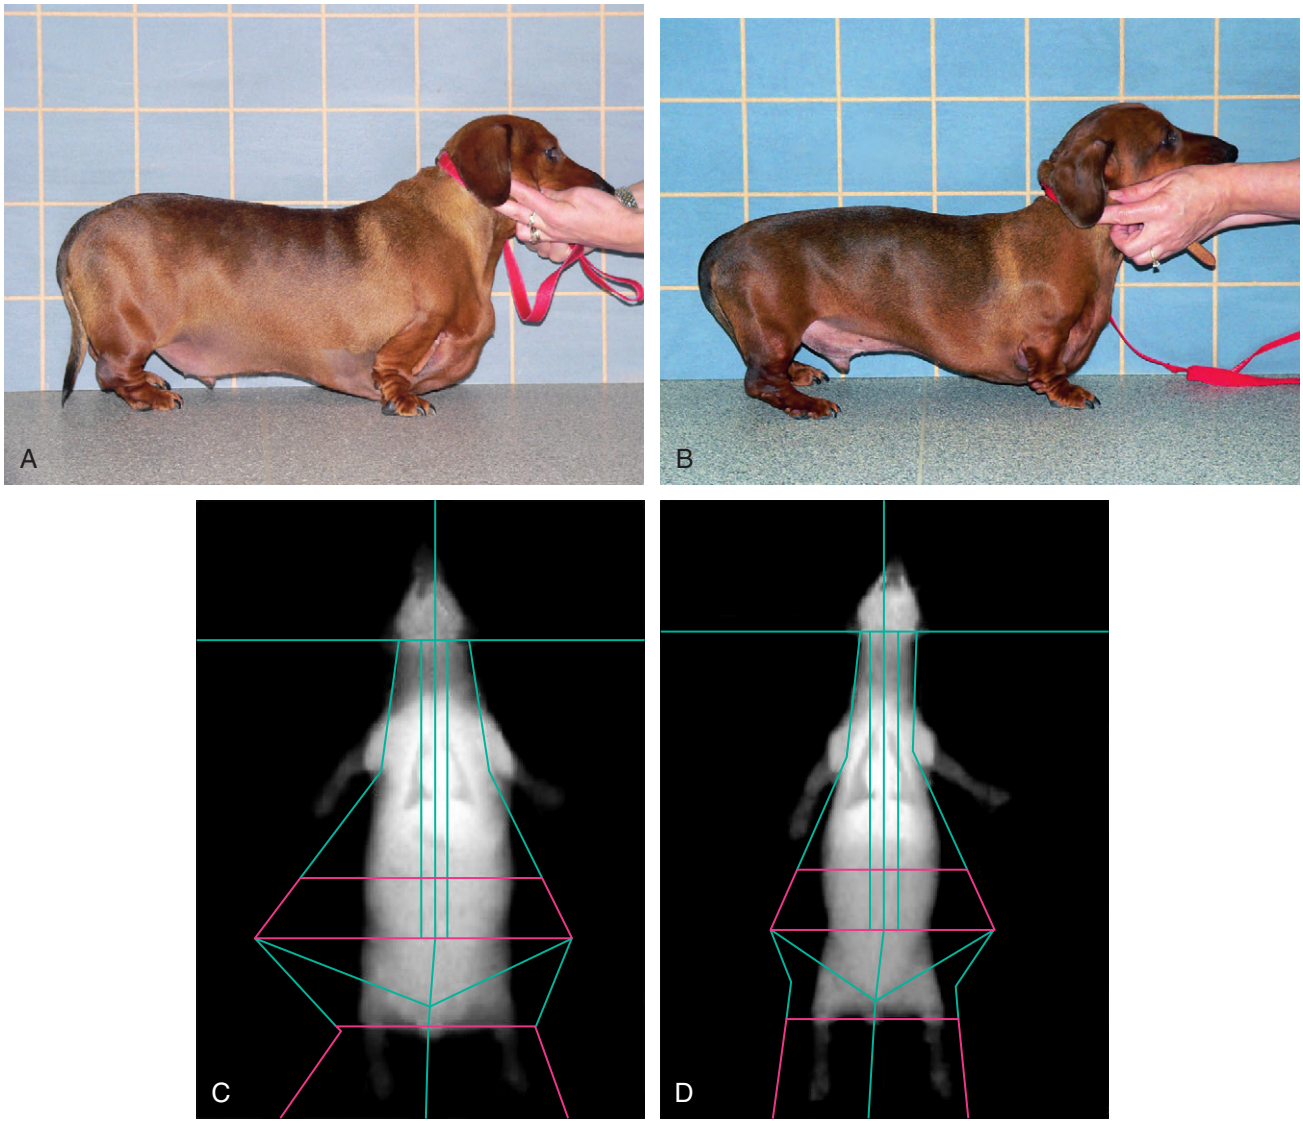

Figure 30-3 **A,** Photograph of an obese 3-year-old neutered male Dachshund, weighing 10.5 kg (23.1 lb), and condition score of 9/9. **B,** Photograph of the same dog, 363 days later, after successful weight loss on a high protein high-fiber diet. Body weight had decreased to 6.5 kg (14.3 lb), and condition score was 5/9. Total weight lost was 38% of starting body weight, at a rate of 0.7%/week. **C,** Dual energy X-ray absorptiometry (DEXA), performed prior to weight loss revealed a body fat mass of 49%. **D,** DEXA, repeated after weight loss, demonstrated that body fat mass had declined to 30%. Based upon the DEXA figures, the estimated composition of the body tissue lost was 81% fat and 19% lean.

Altering the macronutrient content of a weight-management diet can also improve satiety, especially when fiber is supplemented. Supplementing both protein and fiber relative to energy content provides the greatest benefit in dogs,[49] and such a formulation improves the outcome of the weight-reduction program.[50] Because protein content is a key determinant of voluntary food intake in cats, the best effect on satiety is with fiber supplementation, while only modestly increasing protein content.[51]

Energy Intake During Weight Loss

When calculating energy allocation for weight loss, it is essential to base the calculations on the target body weight and not the current weight. Exact recommendations on energy intake vary widely depending upon the diet, species, gender, reproductive status, and concurrent disease. In dogs, a study has suggested a typical starting allocation for weight loss of approximately 60 kcal/kg metabolic body weight (MBW [at target weight (TW)], $kg^{0.75}$),[46] with spayed female dogs requiring less energy than male dogs (either intact or neutered). It should be remembered, however, that the initial allocation is only a starting point, and may need to be modified depending upon response and clinical course. Indeed, in the study described previously, mean energy intake over the entire study period was 57 kcal/kg MBW TW.[46] An average starting allocation of 40 kcal/kg TW and mean energy intake of 32 kcal/kg TW has been recommended for pet cats with naturally occurring obesity.[47] With this degree of restriction, the mean rate of weight loss is 0.8% body weight per week for both species (see Fig. 30-3).[46,47]

Use of measuring cups should be avoided as measurements are imprecise. Electronic kitchen scales are less prone to human error. Close monitoring is required and energy intake must progressively be reduced to ensure continued weight loss.

If at all possible, no additional sources of food should be offered by pet owners to pets during their reduction programs. Healthy treats may be allowed, provided that they are accounted for in the

overall allocation, and provide less than 5% to 10% of total daily requirements. Liquids (e.g., milk) and food used to facilitate oral administration of medications can also be a source of significant caloric intake.

Pharmaceutical Therapy and Weight Loss

Mitratapide and dirlotapide are licensed for use in dogs in Europe, while only dirlotapide is licensed in North America. Neither are licensed nor safe for use in cats. Both drugs are MTP inhibitors, which have local effects at the level of the intestinal epithelial cells in inhibiting the assembly and release of lipoprotein particles into the bloodstream. Dietary caloric intake is decreased both by decreasing lipid absorption and by decreasing appetite. Both drugs are less potent when administered in conjunction with a low-fat (i.e., <10%) diet.

Mitratapide is designed only for short-term use, that is, in the first 8 weeks of a conventional weight-reduction program. Dirlotapide can be used continuously for up to 12 months. Weight loss occurs at a steady rate (0.75% per week on average), but periodic increases in dose are required to maintain weight loss.[48]

The most common side effects of MTP inhibitor treatment are vomiting and diarrhea, and can be seen in up to 20% of patients.[48] Anorexia is also reported in a number of animals and become concerning to many pet owners. If owners are forewarned that it may occur, it is usually better tolerated. Although these drugs can be successful in promoting weight loss, appetite returns rapidly when discontinued and other strategies (feeding and behavioral) may be needed to be successful. Without these additional strategies, rapid and predictable obesity rebound occurs.[48]

Lifestyle Management

Increased physical activity is recommended for most affected animals because, in addition to fat loss, physical activity may assist in lean tissue preservation and possibly help to prevent rapid regain in weight that can occur after a period of successful weight loss. The exercise program should be tailored to the individual, and take concurrent medical conditions into account. Suitable exercise strategies in dogs include lead walking, swimming, hydrotherapy, and treadmill running. Cats can be encouraged to increase their activity through regular play sessions with cat toys (e.g., fishing rod toys), motorized units, and puzzle feeders.

Monitoring of Weight Loss

Regular weight checks should be scheduled during the weight loss program. Initially, a 2-week interval between rechecks is recommended as adjustments are frequent at the start of the program. Thereafter, if weight loss is steady, the interval between rechecks can be increased, but ideally should not exceed 4-week intervals. It is usually best if a dedicated member of the staff takes charge of the weight-management program. In that way a rapport can be established with the client, and this may improve the likelihood of a successful outcome. Given that some clients require intensive support throughout the program, owner coaching may be needed. It is essential to continue to monitor body weight after ideal weight has been achieved to ensure that weight that was lost is not regained; as with humans, a rebound effect has been demonstrated after weight loss in dogs.[49,52]

Prognosis

When an animal is predisposed to obesity, both through individual and environmental factors, many of these predispositions will remain after weight loss. It should also be remembered that the maintenance energy requirements likely will be significantly lower following weight reduction.[53] For these reasons, the obesity can only be managed and never cured, and the prognosis for long-term success is guarded. In the author's experience, approximately two-thirds of dogs and cats successfully reach their TW, while partial success occurs in others. However, for unknown reasons, some dogs and cats fail to lose significant weight or are lost to followup. Also in the author's experience, approximately 50% of cases have weight rebound, although most regain less than half their initial loss. Therefore, as mentioned previously, continued monitoring of body weight during maintenance is recommended. Feeding a purpose-formulated diet (i.e., the one used for weight loss) can help to prevent rebound. Such diets are appropriate for the low-maintenance energy requirements of dogs postweight loss.[53]

Prevention

Given the variable outcome of weight management diets, prevention of obesity is likely to have a more significant beneficial effect on the health and welfare of all dogs and cats, rather than by treating once the problem has developed. Advice on correct nutrition and exercise should be included in all puppy consultations and continued for all dogs throughout their lives. Body weight and BCS should be assessed and discussed at every consultation and during the annual health check. By monitoring body weight and BCS throughout life, increasing adiposity can be more readily identified and rectified. Finally, veterinarians should be alert to the weight gain that can occur as a consequence of neutering. It is advisable to schedule two to three weight-checks in the first 6 to 12 months after neutering to identify those animals at risk of weight gain, and correct it before it becomes a problem.

CHAPTER 31

Adverse Food Reactions

Nick Cave

Definition

An *adverse food reaction* is defined as any abnormal clinical response that occurs following ingestion of a food or food component. Adverse food reactions have been classified according to the underlying pathophysiologic mechanism. These classifications vary from highly specific mechanisms to broad categories. The classification presented in Box 31-1 is based on the mechanism of the reaction, but it should be recognized that in the vast majority of cases, the mechanism of the adverse reaction to food remains undetermined. Thus diagnostic and management principles apply to all clinical cases unless a specific mechanism is identified.

Adverse reactions can be initiated by single chemical elements within a food (e.g., individual protein antigens, histamine, lactose), may be caused by larger components of the food (e.g., the lipid or carbohydrate component), or may only be seen when a whole commercial diet is fed and not if the individual ingredients are fed. Adverse reactions may be seen with very small amounts of food (e.g., in immunoglobulin [Ig] E–mediated hypersensitivity) or may require overfeeding.

The prevalence of adverse food reactions in dogs and cats has not been precisely determined. In a study of 55 cats with chronic signs of gastrointestinal disease (vomiting and/or diarrhea), clinical signs resolved in 27 (49%) of the cats fed an elimination diet.[1] Of those 27 cats, 16 (29%) relapsed when challenged with the original diet. Similar studies have not yet been published in dogs. However dogs with acute vomiting and/or diarrhea are frequently seen in primary practice, and adverse reactions to food are commonly suspected (Box 31-1).

Mechanism and Pathophysiology

Nonimmunologic Adverse Reactions to Food (Food Intolerance)

Nonimmunologic adverse food reactions refer to those in which an innate or acquired immunologic response is not the underlying mechanism for clinical signs. The term *food intolerance* has often been used to describe all nonimmunologic adverse reactions to food. Food "additives" are frequently thought to be responsible for intolerance reactions in dogs and cats. A food "additive" is generally defined as anything that is not directly nutritive but imparts increased nutritional, gustatory, or cosmetic appeal. These include preservatives, humectants (hygroscopic substances), emulsifying agents, flavors, gelling agents, and colors.[2] Despite the wide range of compounds used in commercial pet foods under this term, and in contrast to popular opinion, there is little evidence that food additives are a cause of gastrointestinal disease in dogs and cats.

Food Toxicity

Food toxicity, or food poisoning, generally refers to reactions caused by microbial contamination, but could also include toxins such as benzoic acid or propylene glycol, which have been used in some pet foods. Food toxins include those incorporated into the manufacturing process, and those produced during storage as the result of microbial spoilage. Several mycotoxins have been identified in commercial foods, with corn, grain, and their by-products most commonly incriminated. Aflatoxins (produced predominantly by *Aspergillus* spp.) primarily cause acute hepatocellular necrosis, and dogs or cats may present with anorexia, vomiting, diarrhea that can progress to melena, and other signs of acute hepatopathy.[3,4] Deoxynivalenol (DON, also endearingly termed "vomitoxin") is the most prevalent mycotoxin produced by *Fusarium* spp. Dogs and cats are very sensitive to DON contamination, leading to anorexia, vomiting, bloody diarrhea, and leukopenia, signs that could be easily confused with those of parvoviral enteritis.[5] Enterotoxigenic strains of bacteria can contaminate food and produce acute enteritis, including *Escherichia coli*, *Staphylococcus pseudointermedius*, and potentially *Clostridium* spp. In the majority of these cases, there is usually a clear association between ingestion of a particular food substance and the onset of clinical signs, but pet owners may not present affected animals unless the clinical signs are serious or persistent.

Alterations in the Microflora

Ingested food has a profound effect on the number, species, and metabolic activity of the intestinal microflora. Abrupt dietary change is a common cause of diarrhea, and occasionally vomiting. Most cases are mild and self-limiting, although some will persist until the animal has returned to regular feedings. Persistence of clinical signs following dietary change is reason to suspect a food hypersensitivity or persistent intolerance, but many short-term cases are probably the result of induced disturbances in the enteric microflora. Nondigestible carbohydrate and protein serve as substrates for the microflora, but bacterial species vary greatly in their ability to ferment dietary compounds. In humans, changing from a conventional diet to a highly digestible, fiber-free liquid enteral diet reduces fecal bacterial numbers on a dry weight basis, as well as the fecal concentration of short-chain volatile fatty acids (acetate, propionate, butyrate).[6] The inclusion of fermentable fiber into liquid enteral diets

Box 31-1 Mechanistic Classification for Adverse Reactions to Food

Food intolerance (no primary immunologic basis)
Food toxicity (food poisoning)
Disturbed microflora
Dysmotility
Pharmacologic reactions
Maldigestion/malabsorption ("metabolic")
Physical
Nonspecific dietary sensitivity
Food hypersensitivity (food allergy)
Type I immunoglobulin E mediated
Type IV cell mediated (including gluten enteropathy)

provides substrate for distal ileal and colonic bacteria, and reduces the effect of shifting to highly digestible liquid enteral diets.

In addition to the effect of diet on total bacterial numbers, diet also has an important effect on microbial distribution. Dogs fed a high-protein canned diet have increased numbers of fecal *Clostridium* spp. and reduced numbers of fecal bifidobacteria when compared with dogs fed a lower-protein dry diet, although diet had no effect on fecal *Clostridium perfringens* enterotoxin detection.[7] Human patients placed on a fiber-free liquid enteral diet experienced varied and inconsistent alterations in their fecal microflora.[8] Patients who subsequently developed diarrhea during enteral feeding had higher total numbers of fecal *Clostridium spp*. and lower numbers of *Bifidobacterium* spp. Bifidobacteria have been shown to exert antimicrobial activity against many enteropathogens. Specific strains of bifidobacteria isolated from human feces inhibit the growth of *Salmonella* spp., *E. coli*, *Klebsiella pneumoniae*, and *Staphylococcus aureus* in vitro, and significantly reduce mortality when gnotobiotic mice are infected with *Salmonella typhinurium*.[9]

Similar mechanisms have been proposed to underlie most cases of antibiotic-associated diarrhea. Changes in the enteric microflora are associated with decreased fecal short-chain fatty acid concentrations and decreased concentrations of bifidobacteria species, both of which return to normal following antibiotic withdrawal.[10] Disruption of the commensal population following antibiotic therapy permits pathogen proliferation, which could cause diarrhea through toxin production.

Sources of fermentable carbohydrate have been shown to affect numbers of mucin-degrading bacterial species, which are associated with increased mucosal permeability and diarrhea.[11] A reduction in the specific strains of resident microflora, may reduce the overall pathogen inhibition effect, which then increases the risk of colonization with enteropathogens such as *Clostridium difficile or C. perfringens*. Substantial individual variability is seen in the susceptibility to dietary change. One of several explanations is the variability in an individual's microflora, and even within similar compositions there is variation. For instance, not all *Bifidobacterium* strains possess antibacterial activity, and this contributes to individual variability in response to dietary changes.

When introducing a new diet, a general pragmatic recommendation is to gradually wean the animal from one diet while introducing it to the next. A period of adaptation of intestinal function (e.g., brush-border enzyme expression), as well as microflora, minimizes the risk of diarrhea or vomiting. Clinical experience suggests that for most individuals, a 5-day transition period is adequate, and if clinical signs continue or develop after that time, a persistent adverse food reaction should be suspected.

Dysmotility

Foods that prolong gastric retention, especially high-fat diets and highly viscous diets (soluble fiber), or diets that contain poorly digestible starch may promote vomiting in susceptible patients.[12-14] Predictably, gastric retention times increase with increasing meal size, but also with increased dry matter content.[15] In humans with functional dyspepsia, dietary fat is frequently incriminated as an exacerbating and potentially causative factor leading to an exaggerated sense of fullness, nausea, and vomiting.[16] This is supported by studies that demonstrate symptoms after duodenal lipid infusions, but not after isoenergetic infusions of glucose.[17]

Feeding therefore can have an emetic effect, especially with preexisting gastric disease. Small, frequent feedings have been recommended to limit the duration of acid secretion at each meal and to minimize gastric distention, which can provoke nausea when the stomach is inflamed.

Studies of dietary influences on colonic motility have largely centered on dietary fiber, and their fermentation by-products, the short-chain fatty acids. Constipation is a relatively common presentation, and in the absence of a mechanical obstruction, can develop as a result of excessive dehydration and impaired motility. Dietary variables that lead to constipation have not been well defined in dogs or cats. There is a clear association with the consumption of indigestible material such as bone or wool.[18] In normal humans, colonic transit time is decreased as insoluble fiber is increased, whereas in patients with chronic constipation, increasing insoluble fiber does not speed fecal transit.[19] Whether that reflects a cause or effect is uncertain, as is the significance to canine and feline patients. It is likely that colonic transit time partly determines the response to dietary manipulation, as it does in people.[20] However, determination of colonic motility in dogs and cats is somewhat difficult (see Chapter 26), and there is no definitive evidence for recommending one intervention over another.

Insoluble, nonfermentable fiber increases fecal bulk and increases the frequency of defecation in healthy animals. Increasing fecal bulk may exacerbate constipation in an individual with impaired colonic motility. Perhaps the poorest choice of dietary fiber in constipation is a nonfermentable, insoluble fiber that increases fecal dry matter, but not fecal water content, such as cellulose.[21] Fiber that produces viscous gels (e.g., psyllium husk) will increase the fecal water content, in addition to increasing fecal dry matter. Short-chain fatty acids from colonic fermentation have been shown to stimulate longitudinal colonic smooth muscle contractions in vitro in kittens and adult cats.[22] However highly fermentable fiber may also result in the production of methane. Methane production varies greatly between individuals and depends on the presence of specific organisms.[23] Physiologic concentrations of methane slow small intestinal transit by augmenting circular muscle contractions in the ileum.[24] Constipation, small intestinal dysmotility, and discomfort are aggravated in human irritable bowel syndrome patients with methane production.[24,25] Similarly, the induction of nonpropulsive segmental contractions by methane may be a cause of motility dysfunction in dogs and cats. Consequently, the supplementation of diets with rapidly fermentable purified fiber sources, such as hydrolyzed guar gum, may exacerbate some cases of constipation, irritable bowel syndrome, and other motility disorders.

Pharmacologic Reactions

Methylxanthines. Theobromine and caffeine toxicity is well recognized in dogs. Most dogs will present with signs relating to central nervous system and cardiovascular effects. Anxiety, aggression, tremors, and tachycardia are commonly reported.[26] In other cases,

vomiting and diarrhea are more prominent clinical signs, but still usually accompanied by concurrent neurologic signs.[27]

Histamine. Histamine is found in various home-prepared and commercial foods. Higher concentrations have been detected in foods containing fish by-products, although ingredient lists are not always complete.[28-30] Histamine and other decomposition products are produced in raw fish by bacterial conversion of free histidine. Scombroid fish (e.g., tuna, mackerel, skipjack, bonito) have higher amounts of histamine because of the free histidine content in their muscles.[31] Adverse reactions to the ingestion of raw anchovies that was responsive to antihistamine administration has been reported in cats, and similar signs have been reported in dogs.[30] In those cases, salivation, vomiting, and diarrhea developed within 30 minutes of ingestion.

Some commercial foods contain concentrations of histidine equal to that of raw fish that, if spoiled, might result in high histamine concentrations. That said, the concentration of preformed histamine in unspoiled commercial foods is not that high.[29-31] Ingested histamine is rapidly metabolized by intestinal diamine oxidase (DAO). There is great variation in DAO activity within the human population, rendering some individuals very sensitive to dietary histamine content.[32] Variation in intestinal DAO activity in dogs and cats has not been reported, but large differences in plasma DAO activity do exist in cats.[33] Failure to degrade ingested histamine can result in vomiting and diarrhea that can be hemorrhagic, along with other systemic effects.[32,34]

It has been shown that several drug classifications are capable of profoundly inhibiting the activity of porcine and human intestinal DAO, including the β-lactamase inhibitor clavulanic acid.[34] The clinical significance of this is unknown, but it is conceivable that normally tolerated concentrations of dietary histamine may be sufficient to cause clinical signs when the capacity for intestinal metabolism is reduced during oral treatment with clavulanate.

Maldigestion and Malabsorption

Undigested dietary components can lead to osmotic diarrhea, and rapid fermentation in the distal intestine can lead to flatulence, abdominal pain, and vomiting. Lactose intolerance is the quintessential example of a maldigestive adverse food reaction. Intestinal lactase expression decreases rapidly around the time of weaning in most mammals. In kittens, lactase activity decreases almost tenfold between birth and 6 weeks of age.[35] However, expression in adult cats is highly variable, explaining large individual differences in the ability of the cat to tolerate dietary lactose. Fasting also significantly reduces the expression and specific activity of mucosal enzymes such as disaccharidases, which can lead to impaired digestion following the reintroduction of food.[36] Transient lactase deficiency is common, particularly after rotaviral gastroenteritis.[37] Occasionally it persists, and lactose intolerance may be a cause of postgastroenteritis diarrhea. Undigested lactose can lead to diarrhea by a direct osmotic effect. In addition, colonic and distal small intestinal bacteria rapidly ferment luminal lactose producing gas and volatile fatty acids that can worsen diarrhea, abdominal bloating, borborygmus, and painful intestinal dilation. Healthy adult dogs may tolerate up to 2 g/kg body weight (BW) of lactose, whereas adult cats will not tolerate more than 1 g lactose/kg BW without showing clinical signs.[38]

High-fiber diets may have an effect similar to lactose intolerance in sensitive individuals. High-fiber diets increase gas production by colonic flora and inhibit gas transit leading to gas retention, notable borborygmus, abdominal pain, and flatulence.[39] Ingestion of a "fiber-free" diet for 48 hours significantly reduces the total volume of flatus.[40] Highly purified, highly fermentable fibers such as xylan and pectin predictably cause a greater production of hydrogen, carbon dioxide, and methane than does cellulose or corn bran.[41] The amount of fermentable fiber that can be tolerated without adverse effects varies between individuals, and probably reflects differences in colonic transit time, as well as differences in intestinal microflora.[42]

Physical and Other Effects

Commercial pet foods and most home-prepared diets are unlikely to cause physical irritation, damage, or motility problems in the gastrointestinal tract. However, feeding of fresh carcass meat and "home-kill" often results in the ingestion of significant amounts of bone, wool, and hair, which can predispose to constipation, as well as acute colitis.[43] Dietary indiscretion can result in the ingestion of toxins, indigestible physical abrasives, excessive fat, and compounds that can cause significant gastric fermentation.

Nonspecific Dietary Sensitivity

The term *nonspecific dietary sensitivity* has been used to describe animals that have loose or poorly formed feces when fed particular types of commercial diets.[44,45] The most common cases are seen in large-breed dogs, although the phenomenon can also be seen in small dogs and cats. It has been suggested that reduced colonic capacity for fluid and electrolyte absorption in large-breed dogs makes at-risk individuals susceptible to high-moisture diets.[46] Alternatively, rapid intestinal transit may lead to a degree of malabsorption.[45] Only very mild lymphocytic infiltrates are seen in the small intestine of such animals, and it is not clear if these cases are truly a form of inflammatory bowel disease. To date, abnormal microflora populations have not been shown to be present, and although treatment of affected dogs with the probiotic *Lactobacillus acidophilus* strain DSM 13241 led to clinical improvement in one study, the fecal density of cultured bacteria such as *C. perfringens* and *E. coli* were not significantly altered.[47] In summary, the mechanism of the reaction to food is unclear in these cases, although they will rapidly and readily respond to appropriate dietary manipulation (see below).

Immunologic Adverse Reactions to Food

Complex foods contain a myriad of different proteins, the great majority of which are potentially antigenic, and in a lifetime, an animal will ingest many kilograms of these foreign antigens. Luminal antigens are presented to the largest single collection of T lymphocytes in the body, separated by an epithelial layer within which intraepithelial lymphocytes are directly juxtaposed to this antigen mass. Intact antigens are directly sampled from the intestinal lumen, and a small fraction can even be found in the systemic circulation following a meal.[48] For these reasons, it is perhaps more surprising that detrimental immune responses to dietary proteins do not more commonly occur.

Immune Responses to Dietary Antigens

Dietary antigens interact with the intestinal immune system in such a way as to prevent unnecessary and detrimental immune responses. In so doing, systemic immunity is rendered effectively unresponsive if the same antigen reaches the systemic circulation. This absence of reactivity to orally administered antigens is termed *oral tolerance*.

Peyer's patches are the primary inductive area of the intestinal immune system. Specialized M cells within the epithelium sample

particulate and insoluble antigens, and whole microorganisms.[49] Antigens and organisms are then transported to B cells, macrophages, and dendritic cells within basement membrane invaginations. In the normal intestine these antigen-presenting cells (APCs) lack costimulatory molecules such as CD80 and CD86. Antigens processed by these "unactivated" APCs are then presented to naive B and T cells within the follicle, resulting in the induction of hyporesponsive, T-helper (Th) type 3- or Th2-biased T cells.[50] Activated cells then leave via lymphatics and pass via the mesenteric lymph nodes into the systemic circulation. They then exit at mucosal sites via engagement of cellular adhesion molecules (CAMs) specifically expressed by the high-endothelial venules of mucosal tissues. Activated or memory B and T lymphocytes enter the lamina propria to await a secondary encounter with their specific antigen (Fig. 31-1).

Activated cells may secrete cytokines, but full differentiation into effector T cells or plasma cells may not occur without secondary exposure. For both cell types to be reexposed to antigen, intact antigens must reach the lamina propria. Intestinal epithelial cells are capable of antigen absorption, release to APCs, and limited antigen presentation to cells within the mucosa on major histocompatibility complex (MHC) class II. In the normal intestine, these secondary APCs lack costimulatory molecule expression and contribute to tolerance. Effector T-cell clones resident in the normal intestine secrete a bias toward Th2 and Th3 cytokines, in particular interleukin (IL)-10 and transforming growth factor (TGF)-β, thus directing B-cell isotype switching to produce IgA-secreting plasma cells, while inhibiting the development of Th1 lymphocytes and IgG production.

It is important that the immune system reserves the ability to rapidly respond to pathogens. This ability to recognize pathogenicity is based on the engagement of pathogen-associated molecular pattern (PAMP) receptors, such as Toll-like receptors (TLRs), producing "danger signals." Predictably, expression of TLRs is much greater in mesenteric lymph nodes than in the small intestine, which is generally higher than the large intestine where there is increased potential for deleterious activation by normal microflora.[51] The expression of TLRs is generally lower in the mucosal cells of the normal canine intestine than in the intestines of dogs with inflammatory bowel disease (IBD) or diet-responsive enteropathies, but expression can be rapidly turned on in response to inflammatory cytokines.[51] The absence of these "danger signals" results in relatively inefficient antigen processing by intestinal APCs, markedly reduced or absent tumor necrosis factor (TNF)-α/IL-1/IL-12 production, and the absence of CD80/86 costimulatory molecule expression. T cells activated by such an APC, divide less, with most clones undergoing early deletion by apoptosis, while the surviving memory cells tend to secrete IL-10, TGF-β, or no cytokines.[52] This combination of apoptosis, functional defects in surviving clones, and T cells secreting the antiinflammatory and IgA-supporting cytokines, is the general basis for immunologic tolerance to luminal antigens (Fig. 31-2).

Thus oral tolerance is composed of a delicate balance between induction of IgA, T-cell deletion, anergy, and immunosuppression; and the retention of antigen-specific lymphocytes capable of responding to invasive pathogens through antibody isotype switching to IgM, IgE, or IgG, and the production of inflammatory cytokines such as interferon (IFN)-γ, IL-12, and IL-6.

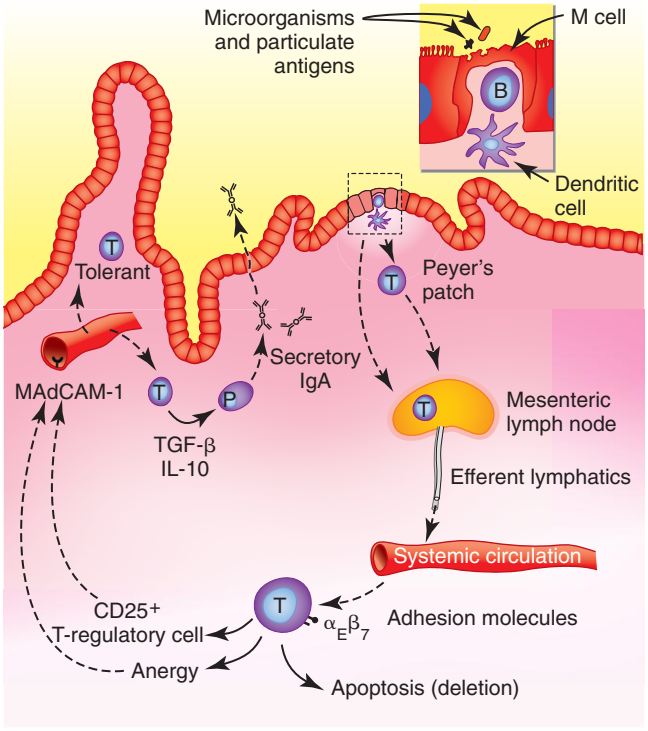

Figure 31-1 Activation and rehoming of intestinal lymphocytes. The primary inductive sites of immune responses to intestinal luminal antigens are the Peyer's patches. Dendritic cells in the Peyer's patch underlying M cells or residing in the mesenteric lymph nodes do not normally express costimulatory molecules (e.g., CD 86) and induce T-cell apoptosis, anergy, or a regulatory function. Lymphocytes activated within the mucosa are induced to express the adhesion molecule ($\alpha_E\beta_7$), which binds to mucosal addressin cell adhesion molecule (MadCAM)-1 expressed by venules within mucosal tissues. In that way lymphocytes activated within mucosal tissues leave to circulate systemically, then exit as effector cells within mucosal tissues.

Food Immunogenicity

In mammals, intact particulate and insoluble antigens are preferentially absorbed across the intestine through M cells overlying the Peyer patches.[53] Classically, such antigens tend to invoke active immunity appropriate for microorganisms. In contrast, soluble antigens are associated with oral tolerance.[54] It has also been shown oral tolerance can be abrogated when soluble proteins are fed in oil-in-water emulsions, resulting in robust systemic humoral responses.[55] This effect may also have relevance to the pet food industry where interactions between dietary proteins and lipids in canned or extruded diets during the cooking and the manufacturing process could feasibly result in novel interactions not present in their native states.

In chickens, particulate antigens induce tolerance, whereas soluble antigens provoke active immunity.[56] If the physical nature of the proteins within the natural diet of a species dictates how the intestinal immune system has evolved, this might have special relevance to species that are commonly fed diets different from their ancestors.

Commercial pet foods are subjected to significant heating during the manufacturing process. The effect of heat treatment on proteins is mostly to change the three-dimensional structure of the protein. Although this may disrupt some antigens, it may equally uncover previously hidden or create new antigenic determinants. Other reactions occurring at high temperatures include the Maillard reactions, which involve the reactions between certain amino acids and reducing sugars to produce less-digestible compounds called *melanoidins*, which give a characteristic brown color. Melanoidins tend to be less digestible and less soluble, and certain melanoidins are more "allergenic" than the original uncooked protein.[57,58]

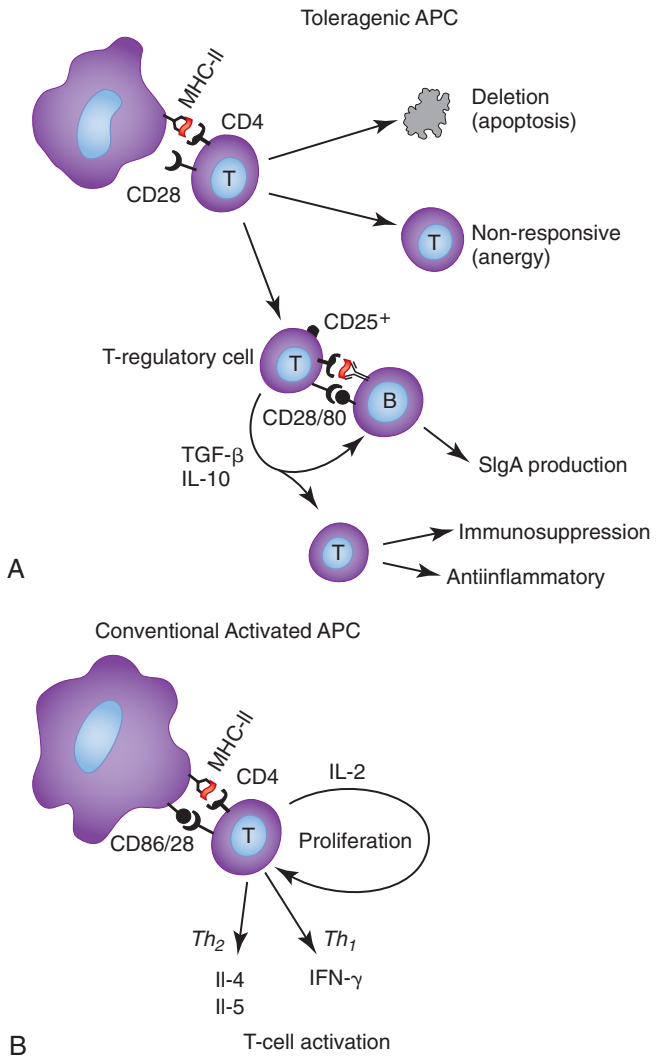

Figure 31-2 Antigen-presenting cells in the intestine are responsible for establishing immunologic tolerance to innocuous dietary antigens. **A,** Intestinal dendritic cells do not widely express costimulatory molecules such as CD86. Antigen presentation leads to tolerance to the antigen through deletion, anergy, or induction of regulatory or suppressor effects in the T lymphocyte. **B,** Elsewhere in the body, conventional antigen-presenting cells activate T cells by presenting antigen in association with costimulatory molecules, inducing either Th1 or Th2 effector functions.

The effect of heating during the canning process on the immunogenicity of dietary proteins has been evaluated in cats.[59] Using soy and casein proteins, the canning process resulted in the creation of new antigens not present in the uncooked product. In addition, a product of heated casein induced a salivary IgA response that was not induced by the raw product. Thus commercial food processing can qualitatively and quantitatively alter the immunogenicity of food proteins. As obligate carnivores, felids have evolved on a highly digestible diet.[60] In keeping with this is the relatively short intestinal tract of the cat, which suggests that they may be poorly suited to poorly digestible diets. It is well established that the commercial canning process decreases protein digestibility and that this has biologically significant effects in cats.[61] Although the significance of this finding is uncertain at present, it emphasizes the need for feeding highly digestible protein sources, or perhaps even more so, hydrolyzed proteins, when enteritis is present.

Loss of Tolerance to Dietary Antigens

The initiating events that lead to loss of oral tolerance, or prevent it from developing have not been described in dogs or cats, and remain poorly understood in any species. Suggested initiating events include the following:

- Increased mucosal permeability, for example, following mucosal injury (e.g., canine parvoviral enteritis) or the neonatal intestine.
- Coadministration of a mucosal adjuvant that activates and changes the phenotype of intestinal dendritic cells, for example, bacterial enterotoxins.[62] Potentially, the introduction of a novel protein at the time of acute bacterial or viral enteritis could lead to temporary or long term dietary sensitization.
- Parasitism. Intestinal parasitism in cats leads to an exaggerated systemic humoral response that includes increased production of food-specific IgE.[63]
- Altered intestinal microflora. The commensal flora are important for establishing normal mucosal immune responses. Lack of commensal flora or TLR-4 signaling augments allergic responses to food antigens in both animal models and humans, and feeding lipopolysaccharide restores oral tolerance in germ-free sensitized mice.[64]

Loss of tolerance to dietary antigens will produce a conventional but detrimental immune response against the dietary antigen. Such an inappropriate response may produce inflammation locally, or at another anatomical site. The response will be characterized by any of the following:

Local Cell-Mediated Inflammation. The resulting chronic stimulus may lead to lymphocytic intestinal infiltration characteristic of IBD. A complete clinical response to an elimination diet has been reported in a cat with duodenal and ileal lymphocytic infiltrates so marked that a histopathologic diagnosis of intestinal lymphoma was made.[65] Alternatively, local inflammatory cytokine release by food-specific T lymphocytes can lead to functional and structural changes leading to loss of absorptive surface area, maldigestion and malabsorption, and vomiting and/or diarrhea.

Local Antibody Production of Isotypes Other Than IgA. The production of IgE will lead to mast cell priming and immediate intestinal hypersensitivity. Following ingestion, mast cell degranulation results causing alterations in transport across the intestinal wall (increased secretory and/or decreased absorptive functions), increased permeability, and altered motility of the intestine.

Systemic Antibody Production. Circulating IgE will lead to priming of mast cells at sites distant to the intestine such as dermal hypersensitivity, that is, food allergy with pruritus as the clinical sign.

The precise nature of the immunologic responses in the vast majority of feline and canine cases is undefined. Although type 1 IgE-mediated hypersensitivities are thought to be present in some, it is likely that other mechanisms exist in a subset of cases. This is especially true for cases where only gastrointestinal signs are present.

Dietary Allergens

Foods contain an enormous variety of proteins, most of which are potentially antigenic (could stimulate an immune reaction if injected), and yet only a few have been shown to be allergenic (capable of stimulating an allergic response). The biochemical

properties that make a particular protein allergenic are not species specific, which is demonstrated by the allergenic potential of immunoglobulins.[66,67] Nonetheless, there are species differences in the relative importance of most allergens. For instance, while beef is the most common allergen in dogs and cats, it is not a common cause of allergy among people living in North America despite it being a significant source of protein in their diets.[68-71]

Mast cell degranulation requires crosslinking of two or more IgE molecules bound by high affinity (FcεR1) IgE receptors on the mast cell membrane. This requirement for divalency places a minimum size limit on molecules that can stimulate IgE-mediated reactions. Most publications refer to this lower limit as being 10 kDa, although smaller peptides could act as haptens, and in humans, peptides as small as 4.5 kDa retain allergenicity.[71-76] Proteins greater than 70 kDa are unlikely to be efficiently absorbed intact through the enteric mucosa and few food allergens are of that size.

Although the majority of the known food allergens are naturally occurring food proteins or glycoproteins, there is evidence that nonprotein molecules can function as allergens. Certain carbohydrates, free of proteins, such as pneumococcal polysaccharides and highly crosslinked dextran, induce allergic reactions in man.[71,77] Carbohydrate determinants have been implicated as protein-binding haptens (e.g., inulin), and as parts of antigenic glycoproteins (e.g., β-fructofuranoside).[78-80] They are also claimed to be responsible for crossreactivity between plant allergies, and are incriminated in false-positive IgE-binding assays, such as used in serum enzyme-linked immunosorbent assay (ELISA) allergy tests.[80] However, the role of true carbohydrate antigens in human allergy is still controversial and poorly defined, and nothing is yet known about their existence in canine and feline patients.

In cases where a dietary carbohydrate is implicated as a source of allergen, for example, maize, it is more likely that there is a protein allergen within the carbohydrate source than the existence of a true hypersensitivity to the carbohydrate molecules. Maize zeins, which are 20- to 23-kDa proteins, have been detected in hydrolyzed casein formulas when corn starch is used as the carbohydrate source.[81] Similarly, lipophilic protein allergens have been isolated in refined vegetable oils.[82] Thus the carbohydrate and lipid sources chosen for incorporation into hydrolyzed protein diets may be an important source of conventional protein allergens and should be considered when evaluating commercial diets.

The most commonly incriminated protein sources in cases of adverse food reactions where dietary hypersensitivity is suspected are the dietary staples. This is an important point that warrants emphasis. Dietary staples within commercial pet foods vary around the world, and to date there does not appear to be one dietary ingredient more likely to cause hypersensitivity than any other when quantity of exposure is considered.

Gluten Enteropathy

A unique dietary hypersensitivity to the storage proteins (gluten) of cereal grains has been described in genetically related Irish Setter dogs.[83,84] In affected dogs, there is reduced brush-border enzyme expression, villous atrophy, diffuse infiltration of the lamina propria and epithelium with increased numbers of lymphocytes, and goblet cell hyperplasia.[85,86] Increased mucosal permeability to macromolecules accompanies these changes, and may precede the development of enteritis in young dogs.[83] Clinical signs of small intestine diarrhea, variable vomiting, weight loss, and, eventually, panhypoproteinemia are characteristic, similar to those reported in other chronic inflammatory enteropathies, such as inflammatory bowel disease. Clinical signs and morphologic changes are reversible when dogs are maintained on a gluten-free diet.[84]

In humans, gluten enteropathy (also known as celiac disease) is a disease of the small intestine, characterized by inflammation in response to the gluten proteins of wheat, barley, and rye in genetically predisposed individuals.[87] Similar to affected dogs, human patients suffer from various degrees of enteritis, ranging from mere intraepithelial lymphocytosis to severe subepithelial (lamina propria) mononuclear cell infiltration resulting in total villus atrophy coupled with crypt hyperplasia.[88] Predictably, clinical signs in people vary from subclinical to severe malabsorption, and even intestinal T-cell lymphoma and other intestinal neoplasia.

In humans, nearly all patients have the MHC II (human leukocyte antigen [HLA]) alleles HLA-DQ2 or HLA-DQ8. Celiac disease in humans results from dysregulation of a usually suppressed T-cell response to gluten in a subset of carriers of HLA-DQ2 or HLA-DQ8. Gluten enteropathy appears to be inherited in Irish Setters as a single autosomal recessive locus.[89] However, genetic analysis of two large families of gluten-sensitive Irish Setter dogs revealed no genetic linkage between the MHC haplotypes and disease.[90] Thus the gluten enteropathy of the Irish Setter dog is not perfectly analogous to celiac disease in humans.

The prevalence of gluten sensitivity among the whole population of dogs has not been reported. A confirmed case of gluten enteropathy has not yet been published in any other breed or in cats. Nonetheless, gluten is suspected to be a common allergen, or as a cause of chronic enteritis, which may be more a reflection of the prevalence of the disease in humans.

Differential Diagnosis

Adverse reactions to food cause a diverse range of gastrointestinal signs, and can be cause for peracute clinical presentations, or a cause of chronic disease. Because of the wide range of clinical signs seen in adverse reactions to food (ARFs), they should be considered in the differential diagnosis of any patient presenting with diarrhea or vomiting. Importantly, ARF should be ruled out early as a differential diagnosis in both acute and chronic gastrointestinal disease unless serious clinical signs are present. This is because of the frequency of diet-responsive disease, the simplicity of diagnosis, and the importance of not pursuing invasive and expensive diagnostic tests (e.g., intestinal biopsy) in patients that would have improved with appropriate dietary manipulation alone.

Evaluation of the Patient

History

ARFs can manifest in any part of the gastrointestinal tract, from the oral cavity to the anus. For that reason, an ARF should be considered as a differential diagnosis for a wide range of gastrointestinal problems. However, the most common presenting problems are vomiting and diarrhea. ARF should be considered more likely if the animal presents with concurrent pruritic skin disease.[1,91] The index of suspicion is increased when there is a temporal association between the feeding of a specific food or ingredient, and the development of clinical signs. Certainly this is helpful in cases of acute ARF where signs develop soon after ingestion. However, even in acute ARF, the timing between ingestion and clinical signs can be misleading as reactions can occur immediately or hours after ingestion. This is particularly important when considering vomiting, which may occur hours after a meal. Moreover, several other gastrointestinal disorders may be associated with clinical signs shortly after

feeding, including acute gastritis, pancreatitis, hepatic failure, and diaphragmatic hernia with gastrointestinal incarceration. Other historical features, like presence or absence of food in the vomitus, large or small bowel-type diarrhea, and length of time the diet has been fed prior to the development of clinical signs, do not readily distinguish ARF from other gastrointestinal disorders. ARFs do not commonly lead to serious clinical signs such as marked weight loss, depression, protracted vomiting, melena, and hematemesis, but several types of ARF may be more severe. Food toxicity, chronic type IV hypersensitivity, gluten enteropathy, and histamine intolerance are examples.

Paramount to the successful diagnosis of ARF is a complete dietary history. Accurate documentation of protein, fat, and carbohydrate sources is essential for conducting appropriate elimination diet trials. For commercial foods, data should include the specific brand, formulation, and flavor variety. When considering the possibility of food toxicity, information should include food purchase date, location of purchase, and storage conditions. All other sources of nutrition should be determined, including treats, table scraps, supplements, food used for administering medications, and edible chew toys (e.g., rawhide). When a home-prepared diet is fed, the specific recipe should be obtained, and special consideration should be given to the potential for microbial contamination (e.g., uncooked meat). Finally, the owner should be questioned about the daily feeding regimen, including other animals in the household, as an indicator for other potential food sources.

Physical Exam

ARFs do not produce classical or pathognomonic physical examination findings. Therefore a physical examination in a patient with suspected ARF focuses on the detection of abnormalities that support other differential diagnoses for the gastrointestinal signs. The reader is referred to Section II of this text for relevant examination findings for each presenting problem. As previously mentioned, the combination of gastrointestinal and cutaneous signs may be present in up to 65% of cases of food hypersensitivity, and that particular combination should raise the index of suspicion of an ARF.[91,92] Thus a careful dermatologic examination should be conducted for signs of cutaneous food hypersensitivity such alopecia, broken hair shafts, papular dermatitis, saliva staining, erythema, pyoderma, and otitis externa.

Elimination and Challenge Diet Trials

A clinical diagnosis of ARF is often based upon the resolution of clinical signs when the offending food is removed from the diet, followed by relapse upon reintroduction of the same food or ingredient. The removal of all potential offending ingredients from a patient's diet is known as an elimination diet trial. The success of an elimination diet trial is dependent upon the correct identification of potential allergens, selection of an appropriate elimination diet, acceptance by the patient, and compliance by the owner. The ideal characteristics for an elimination diet for gastrointestinal disease are the following:

- Intact or hydrolyzed protein sources that are novel to the patient
- A single or limited number of protein sources
- High digestibility
- Restricted fat (dogs <30% of metabolizable energy)
- Avoidance of high protein
- Source of moderate content of fermentable fiber

For cases where gluten sensitivity is suspected, a gluten-free diet is obviously necessary. Animals, especially large-breed dogs, with mild diarrhea that are fed high-moisture canned diets, may benefit from the specific use of a dry diet formulation, in case of nonspecific dietary sensitivity.

The term *hypoallergenic diet* is, at best, an ambiguous one, and has been widely misused. It should be reserved for diets that have, at the very least, been demonstrated to possess a substantial reduction in antigenicity, and preferably been shown to be tolerated by the vast majority of patients known to be hypersensitive to the intact source protein.[93-95] However, defining at which point in the reduction in antigenicity or clinical reactivity a diet could be considered "hypoallergenic" is arbitrary, unless it is absolute, and thus use of the term is discouraged.

A general recommendation for elimination dietary trials is to gradually introduce the elimination diet to allow for intestinal and microbial adaptation to prevent exacerbation of the primary disease, and prevent the misinterpretation of continuing signs (e.g., diarrhea) as evidence of a negative response. In practice, however, when a diet is used with the attributes listed previously, adverse effects of the change are minimal, rarely detectable, and very unlikely to extend beyond the trial period.

Commercial Diets for Elimination Trial

Many commercial diets are suitable for elimination diet trials, and selection is based primarily on which diet is known to be novel to the individual patient, rather than a preconceived and unproven claim of superiority. Intact protein examples include Hill's Prescription Diet d/d (Potato and Duck, Rice and Egg), Royal Canin Veterinary Diet (Potato and Venison, Potato and Whitefish), and Nestle-Purina Veterinary Diets DRM.

Hydrolyzed Protein Diets

Dogs and cats are increasingly exposed to a wide variety of protein sources. The identification of a truly novel protein in patients presented for evaluation of dietary hypersensitivity can be difficult. Hydrolyzed protein diets allow greater confidence in the instigation of an elimination trial where a dietary history is either uncertain or reveals prior exposure to multiple proteins.

The primary aim of a hydrolyzed protein diet is to remove any existing allergens and prevent recognition by a patient sensitized to the intact protein. A secondary aim might be to disrupt the proteins to such an extent that there are no longer any antigens capable of eliciting an immune response and sensitization in a naive individual. Ideally, hydrolysis prevents the mast cell degranulation that would occur in response to the intact protein, and enables a patient hypersensitive to the protein to ingest the hydrolysate without clinical signs. It should be reemphasized that the precise nature of the immunologic response is never defined in the vast majority of cases. Thus, although type I IgE-mediated hypersensitivities are thought to be present in some, it is likely that other mechanisms exist in a subset of cases. The degree of hydrolysis needed to prevent an adverse reaction may be different, when adverse non–IgE-mediated immune responses are present.

Initial selection of a commercial hydrolyzed protein diet for a particular patient should probably be based on the protein source. No currently available diets are sufficiently hydrolyzed to guarantee the complete absence of any allergens. Therefore it is prudent to select a diet that does not contain a protein source known to have sensitized the patient. Secondary consideration should be given to the sources of carbohydrate and lipid, as sources of potential protein allergens, and as unproven as sources of carbohydrate or lipid antigenicity. Table 31-1 lists the hydrolyzed protein diets currently widely available.

Table 31-1 Complete and Balanced Hydrolyzed Protein Diets Available for Dogs and Cats*

Diet	Protein Source	Carbohydrate Source	Lipid Source
Hill's z/d Ultra Allergen Free	Chicken	Maize starch, cellulose	Soybean oil
Hill's z/d Low Allergen	Chicken, potato	Potato, potato starch, cellulose	Soybean oil
Hill's Feline z/d Ultra canned	Chicken	Corn starch	Soybean oil
Hill's Feline z/d Low Allergen dry	Chicken, Brewer's rice	Brewer's rice	Brewer's rice, Soybean oil
Nestle-Purina HA	Soy	Corn starch, cellulose, vegetable gums (gum arabic and guar gum)	Coconut oil, canola oil, corn oil
Royal Canin Hypoallergenic	Soy and poultry liver	Rice, beet pulp, fructooligosaccharides	Poultry fat, soybean oil, borage oil, fish oil

*Ingredients taken from product guides.

Osmolarity increases significantly with hydrolysis, and the high incidence of diarrhea in infants fed extensively hydrolyzed formulas has been attributed to this fact.[96] Although the osmolarity of jejunal contents following a normal meal is mildly hyperosmolar (300 to 350 mOsm/L), feeding high-osmolarity enteral solutions (up to 800 mOsm/L) is associated with diarrhea in humans.[97,98] Even higher osmolarities can cause sloughing of enterocytes.[99] In studies of acute diarrhea in children, an osmolarity of 250 mOsm/L or less is associated with improved rehydration, reduced stool volume, and less vomiting, compared with a solution of 311 mOsm/L.[100] However, the osmolarity of the jejunal contents following a meal of completely hydrolyzed diet is not easily predicted, as it is affected by other ingredients, and by the rate of gastric emptying. Thus a low-fat hyperosmolar solution will produce a different intestinal luminal osmolarity than that obtained with complex extruded dry diet. The osmolarity of the Hill's z/d Ultra diet has been determined to be 682 mOsm/L when mixed 1:1 wt:wt with water, compared with 293 mOsm/L for a standard intact protein maintenance diet.[101] Therefore it is conceivable that the high osmolarity could be detrimental in some dogs. However, in 46 dogs fed the diet for 6 to 8 weeks as part of an evaluation for suspected food hypersensitivity, only four dogs developed soft feces during the trial.[102] Also, of the 46 dogs, 21 dogs had gastrointestinal signs as part of their original presentation, and the feces of all 21 improved on the hydrolysate diet. In the aggregate, these findings would suggest that hyperosmolar diarrhea is not a significant problem with that diet.

Home-Prepared Diets

Home-prepared elimination diets are sometimes suitable alternatives to commercial diets. There are several published sources for suitable recipes, and individual recipe formulation can be made by a veterinary nutritionist.[103] Home-prepared diets offer the flexibility of selecting the desired protein and carbohydrate sources, and the macronutrient proportions, followed by the addition of further ingredients to balance the diet. This gives much greater flexibility than diets available commercially. The high digestibility of home ingredients adds to their efficacy, and they may be less immunogenic than commercial diets. It is often stated that these diets are more palatable than commercial diets. Although such a broad statement cannot be strictly tested, one study that compared home-prepared diets with a commercial hydrolyzed protein diet found that there was no general difference in acceptance.[91] The neophilic effect of offering a home-prepared diet to an animal normally fed a commercial diet may be significant. Likewise, high-moisture foods tend to be more palatable than dry food.

Home-prepared diets can, and should, be formulated to the same standard of commercial diets. However, a combination of inadequate recipes, owner (and veterinarian) ignorance, and the natural tendency for "recipe drift" may conspire to yield a large proportion of inadequate diets. In Europe, a survey of recipes found that energy, fat, and protein were above Association of American Feed Control Officials (AAFCO) recommendations, whereas ratio of calcium to phosphorus, vitamins A and E, and potassium, copper, and zinc concentrations were below recommendations.[104] Relative fatty acid contents of serum phospholipid fractions of home-fed dogs were significantly lower in 18:2(n-6) and 20:4(n-6) than in those from a population of 37 normal dogs consuming commercial dry diets. In the United States, previous studies found that the great majority (>90%) of recipes are nutritionally inadequate.[105] The most common nutritional inadequacy is a deficiency of calcium and a low ratio of calcium to phosphorus, which is an inevitable consequence of an unsupplemented meat-based diet. Other common deficiencies include vitamins B_{12}, E, D, and A, and copper, manganese, and iodine. Common excesses include total fat, 18:2(n-6), and B vitamins.

That dogs and cats do not apparently become ill with short-term feeding of such diets is believed to be a result of:

- The current inability to measure the effects of short-term nutritional inadequacy.
- The uncertainty of absolute physiologic requirements.
- The difference between long-term requirements averaged out as a daily requirement versus true short-term requirements.
- Noncompliance and the pragmatic tendency for a varied diet to be more likely to be completed than a restricted one.

Elimination diets should be fed for as long as it is reasonable to expect improvement in clinical signs. For patients with gastrointestinal disease that appears to be no longer than 3 weeks in duration, and for most patients it may be much shorter. Indeed, cats with proven ARF as the cause of the gastrointestinal signs (vomiting and/or diarrhea) all responded within 7 days of the new diet.[1]

Ideally, a convincing improvement would be followed with challenge of the original diet or individual dietary components to both confirm the diagnosis of an ARF, and identify the specific offending ingredient. In cases where clinical signs are severe, identification may be important to minimize the risk of repeated exposure. However, when a complete and balanced commercial diet is selected as the elimination diet, owners will frequently, and reasonably, decide to continue feeding the novel protein selections.

Food-Specific Serum Immunoglobulin

Several commercial companies offer testing for food-specific antibodies using ELISA and RAST (radioallergosorbent test) techniques, ostensibly to aid in the diagnosis of food hypersensitivity, and in the identification of relevant allergens. Systemic immunoglobulin is commonly produced in response to dietary proteins.[59,106]

This is perhaps surprising in light of the concept of oral tolerance. However the immunoglobulin classes are dominated by IgA and IgG in healthy animals. If the dietary protein is introduced to animals infected with intestinal ascarids, greater quantities of food-specific antibody are produced, and there is a shift toward food-specific IgE.[63] In addition, gastrointestinal disease from a variety of causes, including IBD, is associated with increased food-specific serum IgG.[106] There is, however, no evidence that the food-specific antibody production contributes to disease in these cases. Nor is there any evidence of the diagnostic utility of measuring serum food-specific immunoglobulins either as an aid to diagnosing food hypersensitivity or in identifying offending allergens.[107]

Endoscopic Food-Sensitivity Testing

Even if a single protein source is identified as the cause of an ARF by using elimination and challenge diet trials, differentiation between food intolerance and food hypersensitivity cannot be made as the mechanism for clinical reactivity remains unknown. Direct visualization of a gastric mucosal reaction in response to topically applied antigen solutions can be achieved endoscopically and is used as compelling evidence for an IgE-mediated hypersensitivity. Gastroscopic food-sensitivity testing involves the dripping of a soluble antigen solution onto the gastric mucosa, and the area is observed for up to 5 minutes.[108] Positive changes include focal mucosal swelling and erythema at the site of application, more generalized mucosal erythema, and gastric hyperperistalsis. To assist solution placement, solutions (100 to 500 μL) are applied adjacent to a biopsy site taken at the time of the procedure. A positive control solution of histamine is used to validate an immediate-type response. Biopsies are taken from any reactive sites to support the immunologic mechanism. Difficulty with localization of the solution once applied, and the inability to reliably test more than two or three antigen solutions during one endoscopic procedure, limit the diagnostic utility of this approach. An alternative approach is to inject the solutions (300 μL) directly into the mucosa, allowing better localization, and potentially increasing the number of antigen solutions that can be tested. Injection of solutions around the ileocolic valve during colonoscopy (colonoscopic allergen provocation) has been shown to have a higher sensitivity than gastroscopic food-sensitivity testing, using oral challenge tests as a gold standard in a small number of dogs.[109] However, the practical clinical value of endoscopic food-sensitivity testing has not yet been established. The gold standard of oral challenge testing is cheaper, noninvasive, and in the absence of life-threatening clinical signs, without significant risk. For the time being, endoscopic food-sensitivity testing cannot be recommended in routine clinical practice.

Treatment and Management

Long-term management of ARF, regardless of whether it is an intolerance or specific hypersensitivity, involves avoidance of the incriminated food. To be successful, thorough challenge trials to identify the offending food are required. In practice, once a clinical resolution is apparent, clients are usually understandably reluctant to subject their pet to further investigations. In those cases, empirical recommendations should be made regarding the potential for hypersensitivity to any of the previous diet's ingredients, and avoidance of those in the future is a pragmatic recommendation.

Individualization is required for successful dietary modification in patients with chronic constipation. When colonic motility is known or suspected to be impaired (e.g., megacolon), low-residue diets with moderate (<10% dry matter basis) contents of total dietary fiber are recommended. When colonic motility is still suspected to be reasonable, increasing nonfermentable, gel-forming fiber is likely to be beneficial. A total dietary fiber content of 10% to 20% dry matter basis is reasonable.

CHAPTER 32

Nutritional Strategies in Gastrointestinal Disease

GASTROINTESTINAL TRACT

Sherry Lynn Sanderson

Definition

The gastrointestinal tract (GIT) in dogs and cats is a dynamic organ that performs numerous functions (see Chapter 1) essential for the health and well-being of the animal. A critical function of the GIT is digestion and absorption of nutrients, as well as elimination of potentially harmful substances and waste products. In addition, the GIT is the largest immunologic organ in the body and it also functions as an endocrine organ. Nutrition is important for maintaining a healthy GIT, and it plays a key role in the management of many GIT problems.

Protein

Protein and amino acids are important for synthesis and repair of tissue, and also play a role in energy metabolism. Although all proteins are functional, protein is the second largest potential store of energy in the body after adipose tissue.[1] Energy and protein needs are tied together, and amino acids from protein can be converted to glucose by gluconeogenesis. They serve as a continuing supply of glucose after glycogen is consumed during fasting. The GIT is the primary route by which protein enters the body, and protein balance in the body is dependent on both the availability of dietary protein and the ability of the GIT to digest and absorb protein. Disorders affecting the absorption of protein can rapidly deplete protein stores in the body and lead to protein malnutrition. Protein malnutrition has adverse effects on numerous functions in the body, including muscle strength, organ function, and immune function. Protein malnutrition can also result in mucosal atrophy in the GIT, further impairing protein absorption.

Dietary protein also serves as a source of food allergens. The GIT uses a variety of immunologic and nonimmunologic mechanisms to prevent foreign proteins from entering the body. Under normal circumstances, food antigen exposure via the GIT results in a local immunoglobulin (Ig) A response, activation of regulatory lymphocytes that reside in the gut-associated lymphoid tissue (oral tolerance), and systemic immune response.[2,3] However, in some incidences there is an abnormal interaction between food allergens, the GIT, and the immune system that can result in some GIT disorders such as inflammatory bowel disease (IBD) and acute enteritis. (The reader is referred to Chapter 31 for additional information on adverse reactions to food.)

Glutamine

Specific amino acids play a key role in maintaining a healthy GIT.[4] For example, the amino acid glutamine has traditionally been considered a nonessential amino acid; however, it is now recognized as a conditionally essential nutrient under stress conditions, such as starvation, infection, injury, and recovery from surgery. Glutamine is a fuel for enterocytes lining the small intestinal epithelium, providing as much as 40% of the energy needs for these cells. It is also used by white blood cells and contributes to normal immune system function, as well as being involved in critical processes such as nucleotide synthesis, protein synthesis, and gluconeogenesis. Studies show that dietary glutamine supplementation decreases susceptibility of enterocytes and lymphocytes to apoptosis while enhancing antioxidative function and cell proliferation in the small intestine. It was once believed that only luminal glutamine supported gut function and mucosal integrity. More recent studies show that supplementing total parenteral nutrition (TPN) with glutamine is also an effective route of administration for the gut.[4a]

Arginine

Arginine is important for promoting immune system function. It also serves as a precursor for nitric oxide (NO), polyamines, and creatine, and that it may also activate the mammalian target of rapamycin (mTOR) signaling pathway in the small intestines, which plays a major role in cell growth and proliferation.

Arginine stimulates intestinal fluid secretion through a NO-mediated mechanism, and inhibition of NO synthase (NOS) leads to decreased intestinal secretion and intestinal ischemia. Arginine supplementation is also effective in improving intestinal barrier function and vascular development. Oral arginine decreases the mucosal injury caused by lipopolysaccharide endotoxemia in mice, and pretreatment with arginine enhances survival and intestinal mucosal barrier function after intestinal mesenteric ischemia. Arginine-enriched diets fed to rats also have been shown to protect the gut mucosa from injury caused by radiation-induced enteritis, accelerate healing ability, and prevent translocation of bacteria. However, it is important to keep in mind that the beneficial effects of arginine may be dose dependent. Lower levels of arginine supplementation (0.7%) have beneficial effects on microvascular development, but higher doses of dietary arginine (1.2%) can cause adverse effects, such as gut dysfunction.[4b]

Glycine and Lysine

Both glycine and lysine are directly utilized by the intestine for protein synthesis and other metabolic processes and may have protective effects on the gut.[4] The small intestinal mucosa utilizes glycine to synthesize glutathione (GSH), and it may have powerful cytoprotective effects, such as osmoprotection, scavenging of oxygen free radicals, extracellular signaling, and modification of biologically active molecules. Although research using glycine and lysine supplementation in GIT disorders are just underway, one or both of these amino acids may be useful in the management of some GIT disorders.

Protein Digestibility

Modulation of dietary protein is often very effective in managing many types of GIT disorders. It is very important that protein used in intestinal diets be highly digestible (>87%).[5] This is particularly important in conditions where protein maldigestion or malabsorption is present. Most dietary protein is absorbed in the small intestines, and unabsorbed protein that pass into the large intestines are metabolized by bacteria and produce undesirable metabolites such as gas.

Carbohydrates

Although dogs and cats do not have an absolute dietary requirement for carbohydrates, carbohydrates are a major component of most diets for dogs and cats. The predominant carbohydrate found in pet food is starch. Starch is the storage form of carbohydrates in plants, whereas glycogen is the storage form in animals. The digestibility of dietary starch is dependent upon the source and the degree and type of processing. If properly processed, corn, wheat, rice, and barley can be highly digestible (>90%).[5] Other starches, such as potato and tapioca, are less digestible, especially if undercooked.

Lactose

Lactose is the primary carbohydrate found in milk, and it is broken down by the brush-border enzyme lactase. Puppies and kittens normally have adequate levels of intestinal lactase to permit digestion of lactose in the mother's milk. However, lactase activity often decreases after weaning, and some adult dogs and cats are lactose intolerant. If these animals consume dairy products, such as milk, osmotic diarrhea often results. In humans with lactose intolerance, some studies have shown that the use of probiotics decreases or suppresses symptoms of lactose intolerance.[6-8] Some lactic acid bacteria produce enzymes that hydrolyze lactose, thereby alleviating clinical signs. The majority of the research in this area has been done in humans, and it is unknown at this time whether similar beneficial effects occur in dogs and cats. Carbohydrate intolerance also develops secondary to enteritis, and inadequate disaccharidase activity may be one of the factors responsible for diarrhea associated with rapid changes in the diet.

Fiber

Although the effect of various nutrients on the GIT in dogs and cats has been studied for decades, it is only in the past 10 to 15 years that significant knowledge and understanding of the role that dietary fiber has in maintaining health and preventing diseases has been recognized. Historically, fiber has not been considered essential in the diets of dogs and cats, but the critical role that fiber has in promoting a healthy GIT is increasingly being recognized.

Introduction of Dietary Fiber

Dietary fiber was originally defined as "the remnants of plant cell walls not hydrolyzed by the alimentary enzymes of man," but the definition was subsequently modified to include all plant polysaccharides and lignin, which are resistant to hydrolysis by digestive enzymes.[9] More recently, the definition of fiber has been modified further and is now defined as the composite of all dietary constituents that are not digested by endogenous enzyme secretions in mammals. Although not digestible, dietary fiber is considered to have nutritional value because of its importance in maintenance of the functional integrity of the GIT.[9a]

Dietary fiber consists of material of diverse chemical and morphologic structure. Large differences exist in the physical form and the physiologic effect of various classes of dietary fiber in dogs and cats, and it is now recognized that specific fiber types can be utilized for specific effects on the GIT. Major components of dietary fiber include nonstarch polysaccharides, cellulose, hemicellulose, mixed-linkage β-glucans, pectins, gums, and mucilages. Lignins are also included in the estimates of total dietary fiber because they are plant cell wall constituents that can greatly affect the digestibility of plant-derived foods.[10] Quantitatively, lignins do not make a significant contribution to total dietary fiber intake unless intact seeds are consumed.

The diverse nature of fiber has led to numerous ways of classifying fiber, including by solubility in water, rate of fermentation, digestible and indigestible fractions, water-holding capacity, viscosity, fecal-bulking ability, cation exchange capacity, bile acid–binding ability, and microbial fuel value.[11-14]

In the past, dietary fiber has been classified by its solubility (soluble vs. insoluble). This classification is based on how fiber reacts with water.[11] All fibers hold water to some degree; however, the soluble fibers have a greater water-holding capacity than insoluble fibers, and they may form gels and viscous solutions in the GIT (Table 32-1). In more recent years, this classification of fiber has fallen into disfavor. Categorization of fiber types based on fermentability (Table 32-1) is a more meaningful way to describe certain fiber sources for dogs and cats because the fermentability or the capacity for fiber breakdown by intestinal bacteria more accurately assesses fiber's potential beneficial effects in the GIT than does solubility.

Beneficial Effects of Fermentation of Fiber by Intestinal Bacteria

Fiber usually passes through the stomach and small intestines intact in dogs and cats because they do not endogenously produce the

Table 32-1 Dietary Fiber Fermentation in Dogs[15]

Fiber Type	Solubility	Fermentability
Beet pulp	Low	Moderate
Cellulose	Low	Low
Rice bran	Low	Moderate
Gum arabic	High	Moderate
Pectin	Low	High
CM-cellulose	High	Low
Methylcellulose	High	Low
Cabbage fiber	Low	High
Guar gum	High	High
Locust bean gum	High	Low
Xanthan gum	High	Moderate
Inulin	High	Moderate
Psyllium	Both	Moderate

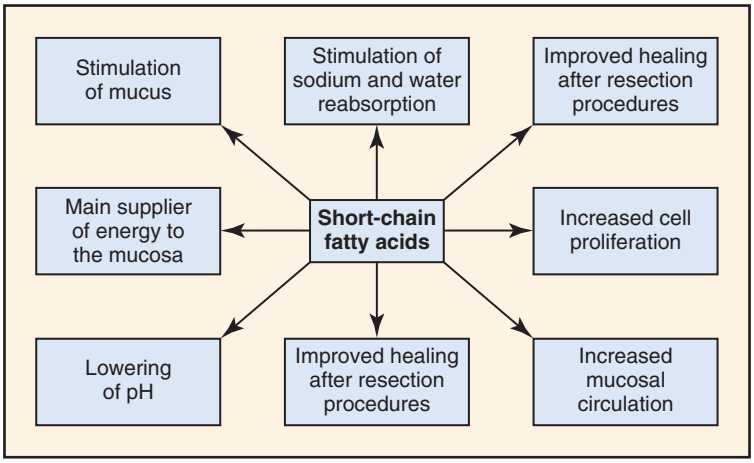

Figure 32-1 Beneficial effects of short chain fatty acids. Adapted from www.nutrition-partner.com

enzymes needed to digest fiber. Until recently, fiber fermentation was thought to be irrelevant in dogs and cats. However, once fiber reaches the large intestines, intestinal bacteria are able to ferment certain types of fiber, resulting in the production of short-chain fatty acids (SCFAs). As a result, fermentation of fiber is very important in dogs and cats. The major SCFAs produced from fermentation are acetate, propionate, and butyrate. In ruminants and herbivorous animals, SCFAs provide a significant source of energy (i.e., up to 75% of daily energy requirement [DER]) in these species. However, dogs and cats have a relatively short and simple structure of the large intestines, and as a result, SCFAs provide less than 5% of energy needs and have little effect on energy balance.[16,17]

Although production of SCFAs in the large intestines of dogs and cats provides very little energy, it does have a number of beneficial effects (Fig. 32-1). Some of the beneficial effects of SCFAs include the following:

1. **An energy source for colonocytes.**[18] Colonocytes derive more than 70% of their energy needs from luminally derived SCFAs. As a result, fermentation of fiber provides a readily available source of energy for colonocytes that aids in maintaining the health and function of these cells. SCFAs are also important for cell renewal and repair. Epithelial cells of the GIT turnover rapidly and must be replaced on average once every 3 days. By providing energy for intestinal cells, SCFAs facilitate the replacement of cells that have been sloughed during the normal process of cell turnover.
2. **Maintenance of normal intestinal electrolyte and fluid balance.**[19] SCFAs facilitate the absorption of sodium, chloride, and water in the colon. For example, a study in dogs showed that sodium and SCFA absorption could account for the entire osmotic absorption of water from the colon. As a result, providing fermentable fiber in the diet is essential in maintaining the normal homeostatic absorptive function of the intestine of dogs.
3. **Maintenance of ileal and colonic motility.**[20] Normal ileal motility appears to be influenced by the presence of SCFA. Kamath et al. infused bolus doses of physiologic concentrations of SCFA into the ileum of dogs. As the dose of SCFA increased, ileal motility increased. Therefore providing fermentable fiber in the diet may be important in maintaining normal ileal and colonic motility.
4. **Amelioration and prevention of pathogenic bacterial overgrowth.**[21] Harmful bacteria (e.g., *Clostridium*, *Salmonella*, enterobacteria) can produce (a) toxins, (b) carcinogens, and (c) putrefactive substances.[22] Beneficial bacteria (e.g., bifidobacteria, lactobacilli) (a) inhibit the presence of harmful bacteria, (b) stimulate immune function, (c) aid in digestion and/or absorption of food, and (d) synthesize vitamins. Maintenance of beneficial indigenous bacterial populations is important in prevention of pathogenic bacterial overgrowth in the intestine. Indigenous bacterial populations in the dog or cat GIT ferment certain fiber sources that result in the production of SCFA.[17,23] The presence of SCFA inhibits the growth of pathogenic bacteria.[24,25] As a result, not only are indigenous bacterial populations necessary for the production of SCFA, but they can also directly inhibit pathogenic bacterial overgrowth in the gut. A growing body of evidence supports the theory that certain dietary fiber sources can modify the composition of the intestinal microflora.
5. **Maintenance of optimal colonic morphology.**[26,27] Dogs fed a fermentable source of fiber had increased colon weight, increased mucosal surface area, and mucosal hypertrophy compared with dogs fed a nonfermentable fiber source (cellulose). These effects on the colon also aid recovery after intestinal surgery.[28]
6. **Amelioration of intestinal inflammation.**[29] Diets containing nonfermentable fiber (cellulose) as the sole source of dietary fiber fed to dogs resulted in a higher incidence of mucus distention and cryptitis when compared with similar diets that contained a fermentable fiber source.

All Fermentable Fibers Are Not Created Equal

Fiber sources can vary in their level of fermentability (see Table 32-1). As fermentation rate of fiber increases, gastrointestinal transit time decreases, fecal bulk decreases, and fecal bile acid excretion increases. Fibers with low fermentability (e.g., cellulose, methylcellulose, oat fiber, peanut hulls, xanthan gum, locust bean gum) are not metabolized well by intestinal bacteria to produce SCFAs. Rather they retain their structure while passing through the GIT intact and act as bulking agents. Highly fermentable fibers (e.g., pectin, guar gum) are rapidly metabolized by intestinal bacteria. One of the products from bacterial

fermentation of fiber is SCFAs. However, less-desirable substances are also produced from bacterial fermentation, including carbon dioxide, hydrogen, and methane. If a fiber source is rapidly fermentable, large amounts of gases will be rapidly produced in the colon, resulting in diarrhea, flatulence, and cramping. Moderately fermentable fiber sources (e.g., beet pulp, rice bran, gum arabic, xanthan gum) produce SCFAs without resulting in rapid production of gases and associated diarrhea. Therefore, moderately fermentable fiber produces the beneficial effects associated with production of SCFAs without the undesirable effects seen with rapidly fermentable fiber. An ideal fiber source for dogs and cats should contain a moderately fermentable portion to facilitate SCFA generation, as well as a nonfermentable portion to provide bulk and enhance peristalsis.[29a]

Fat

Dietary fat can play a very important role in the management of GIT disorders. Some disorders respond best to low-fat diets, whereas others respond best to medium- or high-fat diets. Not only is the quantity of fat in the diet important, but the type of fat is very important in determining its effect in the GIT. To fully understand the properties of various types of fat, it is important to first understand the nomenclature of fat.

Nomenclature of Fat

Fatty acids are classified as short-, medium-, or long-chain fatty acids. SCFAs contain fewer than six carbons, medium-chain fatty acids (MCFAs) contain six to 12 carbons, and long-chain fatty acids (LCFAs) contain more than 12 carbons. LCFAs are the predominant type of fat consumed in the diet by dogs and cats. When LCFAs are absorbed from the GIT, they first enter the lymphatics before eventually making their way to the blood via the thoracic duct. Generally, once SCFAs and MCFAs are absorbed in the GIT, they bypass the lymphatics and instead directly enter the portal vein.[30] However, it has been shown that when dogs are fed low-fat diets (5.35%, as fed) containing 3.2% (as fed) eight-carbon and 1.5% (as fed) 10-carbon length medium-chain triglycerides (MCTs), that some MCT is absorbed into the intestinal lymphatics.[31] Nonetheless, the ability of MCFAs to bypass the lymphatics in most situations make them useful in managing some types of GIT disorders, especially those involving the lymphatics (lymphangiectasia). However, the diet must always contain LCFAs because these provide the essential fatty acids required in the diet of dogs and cats. Diets containing MCTs usually restrict the amount of MCTs to 25% to 30% of the fat in the diet because MCTs are not very palatable, and animals will often refuse to eat diets containing higher quantities of MCTs. Because MCTs are ketogenic, they should be avoided in patients with acidosis or ketosis.

Triglycerides are composed of three fatty acids esterified to a glycerol molecule. Fatty acids can vary in their chain length as well as the number and arrangement of double bonds. Saturated fatty acids contain no double bonds on the carbon chain, and therefore they are fully saturated with hydrogen molecules. Animal fats, such as beef tallow, are dietary sources of saturated fatty acids in dogs and cats. Fats also can be unsaturated, which means they contain one or more double bonds in the carbon chain. The location of the double bond(s) is determined by counting from the terminal methyl carbon (designated as n or ω [omega]). If the first double bond in omega fatty acids occurs either at the three-, six-, or nine-carbon, they are referred to as omega-3 (n-3), omega-6 (n-6), or omega-9 (n-9) fatty acids, respectively. Fats that contain one double bond on the carbon chain are called *monounsaturated fatty acids*, and fats that contain two or more double bonds on the carbon chain are called *polyunsaturated fatty acids* (PUFAs). All of the essential fatty acids for dogs and cats are PUFAs.

Both dogs and cats have a dietary requirement for linoleic acid (LA), which is an n-6 fatty acid.[32] Cats also require arachidonic acid (AA), which is also an n-6 fatty acid. Dogs, however, are able to synthesize adequate amounts of AA from LA and therefore do not have a dietary requirement for AA. Although definitive studies have not been done in dogs and cats, most nutritionists believe that the n-3 fatty acid, α-linolenic acid (ALA), is also necessary in the diet of dogs and cats. Although both dogs and cats have the ability to synthesize eicosapentaenoic acid (EPA) from ALA, their ability to synthesize docosahexaenoic acid (DHA) from ALA is very limited or not present at all. Because DHA is very important for retinal and brain development, DHA is considered a conditionally essential fatty acid. Including DHA in the diet of puppies and pregnant bitches improves learning abilities of the puppy (data on file, P & G Pet Care). Dietary sources of EPA and DHA include fish oils, such as menhaden oil.

Eicosanoid Production from Fatty Acids

PUFAs are important for maintaining membrane fluidity and related cell functions such as transport, metabolic regulation, and the epidermal water barrier in the skin. Cell membrane stability, structure, and function are dependent on having unsaturated fatty acids incorporated into them. The cell membranes from tissues such as adipose tissue, liver, muscle, and kidney tend to be composed predominantly of n-6 fatty acids. Reproductive and neurologic tissues, as well as cell membranes of the rod cells in the eye, tend to be composed predominantly of n-3 fatty acids, in particular, DHA. However, the composition of the cell membranes in many tissues, such as the skin, changes in response to the types of PUFAs provided in the diet.

When PUFAs are metabolized in the body, n-6 fatty acids produce eicosanoids that are different from those produced by metabolism of n-3 fatty acids. These differences can be useful when managing certain types of GIT disorders, especially those associated with inflammation. Eicosanoid synthesis begins with metabolism of AA or EPA by one of two enzyme systems. The first enzyme system is cyclooxygenase, which yield prostaglandins (PGs) and thromboxanes (TXs). The lipoxygenase system yields leukotrienes (LTs), as well lipoxins (LXs), hydroperoxyeicosatetraenoic acids (HEPEs), and hydroxyeicosatetraenoic acids (HETEs). The amount and types of eicosanoids synthesized is dependent upon the availability of the fatty acid precursors, and the activity of the cyclooxygenase and lipoxygenase pathways. The eicosanoids produced from the n-6 fatty acid, AA, are proinflammatory, whereas those produced from n-3 fatty acid, EPA, promote minimal to no inflammatory activity. Because many of the GIT disorders are associated with inflammation, feeding a diet supplemented with n-3 fatty acids may prove useful in reducing the level of inflammation in the GIT. For example, diets supplemented with n-3 fatty acids have been shown to reduce the degree of inflammation in experimental models of colitis.[33]

Fat Malassimilation

Dietary fat is one of the most complex nutrients to process in the GIT. Many steps are involved in the digestion and absorption of lipids (see Chapter 1). In the small intestine, large dietary fat droplets must first be emulsified by bile salts from the liver. This dramatically increases the surface area available for enzyme action. The

resulting smaller fat droplets (triglycerides) are broken down into free fatty acids and monoglycerides by the actions of pancreatic lipase and then incorporated into micelles before absorption through the epithelial membrane. Once both the free fatty acids and monoglycerides are inside the enterocytes, they are repackaged into triglycerides, coated with a lipoprotein to form chylomicrons before entering the lymphatic vessels. Because this process involves multiple organs and multiple steps, disruption of fat digestion and absorption may take place in several gastroenterologic disorders. The resulting fat malassimilation not only interferes with fat absorption, but also interferes with fat-soluble vitamin, mineral, and bile salt absorption. Malabsorbed fat and bile acids are hydroxylated and deconjugated by colonic bacteria to produce potent secretagogues. The deconjugated bile acids and hydroxylated fatty acids are toxic to the colonic mucosa, causing increased mucosal permeability, altered motility, and secretory diarrhea. Dogs and cats with this type of diarrhea can become rapidly dehydrated, develop electrolyte abnormalities, and experience rapid weight loss. The best way to manage these patients is to address the underlying cause of the problem if possible, such as exocrine pancreatic insufficiency, biliary obstruction, and IBD. These animals may also benefit from a lower-fat diet until the underlying cause is addressed. However, it is very important to keep in mind that fat has 2.25 times more energy density per gram than protein or carbohydrate, and if dietary fat intake is reduced, it may be more difficult to meet the energy needs of the patient.

Vitamins and Minerals

Numerous electrolyte and vitamin abnormalities can be associated with GIT disorders, including perturbations in folate and cobalamin (vitamin B_{12}) metabolism. A decrease in serum folate concentrations can be associated with proximal small intestinal disorders, while a decrease in serum cobalamin concentrations can be associated with distal small intestinal disorders and exocrine pancreatic disease. Both serum folate and cobalamin may be decreased with diffuse small intestinal disease. It is particularly important to keep these two vitamin abnormalities in mind for patients with chronic diarrhea and an unthrifty, unkempt appearance, especially cats. Dietary therapy alone is unlikely to resolve these problems. The reader is referred to Chapter 53 for further discussion of folate and cobalamin metabolism.

Folate

Most folate found in pet foods is in the form of folylpolyglutamate and very little is found in the free folate (folylmonoglutamate) form. Liver, animal by-products, and oil-seed meal, such as soybean meal, are the most common sources of folate in pet foods.[34] Dogs reportedly are able to absorb folylpolyglutamates across the small intestines and therefore are much less likely to develop folate deficiency than are cats. However, only the folylmonoglutamate form of folate is actively transported across the small intestines in cats. Folylpolyglutamate in food needs to be deconjugated by the brush-border enzyme, folate deconjugase, to produce folylmonoglutamate. Deficiencies of folate result in impaired biosynthesis of DNA and RNA, and, thus, reduced cell division. The GIT is lined by a rapidly dividing population of cells, and folate deficiency can interfere with this process. Decreased DNA synthesis caused by folate deficiency can also result in megaloblastosis. Treatment of folate deficiency involves identifying and treating the underlying intestinal problem, as well as supplementing the diet with folic acid (200 µg of folic acid per day for 1 month).[35]

Cobalamin (Vitamin B_{12})

Synthesis of vitamin B_{12} is limited almost exclusively to bacteria. As a result, it is found only in foods that have been fermented and those derived from the tissues of animals that have obtained it from their intestinal microflora. Vitamin B_{12} is absorbed in bound form (to intrinsic factor), and it is absorbed only in the ileum. A recent study showed that 61% of 80 cats with clinical signs of chronic gastrointestinal disease had decreased serum cobalamin concentration,[36] and almost all cats diagnosed with exocrine pancreatic insufficiency (EPI) had cobalamin deficiency.[37] Some cats with EPI will respond poorly to pancreatic enzyme therapy unless cobalamin deficiency is concurrently treated. Unfortunately, supplementation to correct cobalamin deficiency requires that it be given parentally and not enterally because cobalamin deficiency causes cobalamin malabsorption. The dose of cobalamin in cats is 150 to 250 µg of cobalamin (cyanocobalamin injection, Elkins-Sinn, Goldline, or others) given subcutaneously once a week.[35] The serum concentration of cobalamin should be rechecked before the fifth and sixth injection. If serum cobalamin concentration has normalized, the dosing schedule can be modified to one injection every 2 to 4 weeks. These animals generally will require lifelong therapy with cobalamin injections.

Prebiotics, Probiotics, and Synbiotics

Companion animals have extensive gastrointestinal bacterial ecosystems. For example, the mammalian digestive system contains more than 500 different species of bacteria.[38] The balance between beneficial and pathogenic bacteria has an effect on the overall health of the animal. As a result, the microbial population in the GIT is recognized to play a substantial role in the health of animals, and its role appears to extend beyond the GIT. Many of the extra-gastrointestinal effects appear to be related to changes in the immune system. Enteric bacteria also contribute significantly to the host's resistance to infectious disease. It is well recognized that a healthy gut bacterial flora is essential for overall health, and this flora is often disrupted during illnesses and may, in some cases, be a precipitating factor.

Establishment of Intestinal Bacterial Flora

Intestinal microflora are established at birth as the neonate passes through the birth canal and after birth through suckling and environmental exposure. Optimal maturation of the gut-associated immune system during the first months of life depends on the development and composition of this native microflora. The most common bacteria with potential to enhance health in pets are the bifidobacteria and lactobacilli. With advancing age, the level and diversity of these beneficial bacteria begin to decline, while less-favorable *Clostridium* spp. bacteria increase.[41] In addition, the bacterial flora composition in the GIT is influenced by many factors including host species, breed, age, dietary history, environmental conditions, geographic locale, intestinal motility patterns, disease, and medication history.

Definitions of Pre-, Pro-, and Synbiotics

Prebiotics are defined as nondigestible food ingredients that beneficially affect the host by selectively stimulating the growth and/or activity of one or a limited number of beneficial bacteria in the colon that improve host health. The most common prebiotic found in diets of dogs and cats is dietary fiber.[22,42]

Probiotics are defined as living beneficial bacteria, which upon ingestion in sufficient numbers exert health benefits to the host.[43] It

is very important that both parts of the definition are met in order to call a product a probiotic.

Synbiotics are defined as a mixture of prebiotics and probiotics that beneficially affect the host. In addition to the beneficial effects of prebiotics alone, in synbiotics, the prebiotic is used to improve the survival of the probiotic organisms.

Prebiotics

Fiber as a Source of Prebiotics

Not all fiber types serve as a source of prebiotics. Three criteria are required for a fiber to serve as an effective prebiotic. First, a prebiotic fiber must be resistant to degradation by stomach acid, mammalian enzymes, and hydrolysis. Second, beneficial bacteria in the intestines must be able to ferment the prebiotic fiber. Third, the prebiotic must selectively stimulate the growth and/or activity of the beneficial bacteria in the intestines. As a result, some fiber sources are ineffective prebiotics.

Prebiotics have received a lot of attention recently as a way to modulate bacterial populations in the colon. Appropriate types of prebiotics can also optimize stool characteristics and reduce fecal odor because fermentation of fiber reduces fecal ammonia, indole, and phenol concentrations, compounds that are implicated as the major malodorous components of feces and as toxins in the colon.

Two fermentable fiber sources that function as prebiotics in the colon are fructooligosaccharides (FOS) and mannanoligosaccharides (MOS). Although both of these fiber sources can have a dramatic effect on the microbial population in the colon, the mechanism by which they accomplish this is different between the two sources.

Fructooligosaccharides

Certain fermentable fiber sources, such as FOS, are good sources of prebiotics for dogs and cats, and the proportion of different bacterial species is related to the type of fermentable substrate available. Fructooligosaccharides are found naturally in many different foods, including plants like beet root (after pulp processing), soy (in the hulls), psyllium, chicory (after hydrolysis), and numerous other fruits, vegetables, and grains.[44] They can also be synthesized commercially. Beneficial intestinal bacteria (e.g., lactobacilli and bifidobacteria) use fermentable fiber as a metabolic fuel, whereas pathogenic bacteria (e.g., *Salmonella*, *Escherichia coli*, *Clostridium perfringens*) cannot metabolize FOS for energy. Production of SCFAs from fiber by beneficial bacteria also lowers colonic pH, further impeding the growth of bacterial pathogens.[45] As a result, in the presence of FOS, beneficial bacteria thrive, multiply, and crowd out pathogenic bacteria. In addition, a study by Willard et al. showed that supplementing the diet of dogs with FOS resulted in a significant decrease in the number of aerobic and anaerobic bacteria in the small intestine of dogs with small intestinal bacterial overgrowth (SIBO).[46] Similarly, FOS supplementation increased numbers of beneficial bacterial and decreased numbers of potential pathogens in the large intestine of healthy cats.[47]

In a recent study, beneficial and pathogenic bacteria in canine feces were cultured and compared while consuming identical diets with various levels of FOS supplementation (data on file, P&G Pet Care). The beneficial bacteria measured was *Lactobacillus*. FOS supplementation resulted in a statistically significant increase in *Lactobacillus* when compared with a diet not supplemented with FOS. In this same study, the pathogenic bacteria *Bacteroides*, *E. coli*, and *Eubacterium* were evaluated. When the diet was supplemented with FOS, there was a statistically significant reduction in the pathogenic bacteria compared with the diet not supplemented with FOS.

Dried beet pulp is another fermentable fiber source in the diet of dogs that beneficially enhance the growth and survival of good bacteria in the gut. Beet pulp is the fiber material that remains after sugar is extracted from sugar beets.[47a] It has been widely used in the livestock industry for many years, and in the last 10 years, the use of beet pulp has expanded into the pet food industry as a source of fiber. It is a safe fiber source and contains no known toxins.

Mannanoligosaccharides

MOS are unique fiber sources similar to FOS. The difference between FOS and MOS is that fructose is the predominant sugar molecule in FOS, whereas mannose is the predominant sugar molecule in MOS. MOS are natural fibers found in yeast cells, and they prevent the growth of harmful bacteria in the GIT through a different mechanism. Pathogenic bacteria establish themselves in the GIT by attaching to the intestinal wall and colonizing the GIT. Pathogenic bacteria are able to attach to the intestinal wall because they have finger-like projections, called *fimbriae*, that allow them to bind to specific residues (e.g., mannose) on intestinal cells. Because MOS contains mannose, fimbriated mannose-specific pathogens can bind to MOS instead of the intestinal wall.[48] By preventing these bacteria from adhering to the intestinal wall, MOS can inhibit the growth of pathogenic organisms, reduce their effects in the GIT and aid in the excretion of these harmful bacteria. They are very effective in preventing diarrhea and contribute to the prevention of digestion-related infectious diseases.

Fructooligosaccharides and Mannanoligosaccharides Enhance the Effectiveness of the Gastrointestinal Immune System

The GIT contains a large population of bacteria, and it is critical to the health of dogs and cats that these bacteria remain in the gut and are prevented from translocating systemically. The GIT is constantly under antigenic stimulation from both bacteria and food, and the integrity of the GIT is essential for maintenance of intestinal health.

The gut contains both nonimmunologic barrier defenses and immunologic barrier defenses. Nonimmunologic barriers include (a) the anatomy of the gut (intact microvilli and tight junctions between cells); (b) peristalsis and mucus, which makes it difficult for pathogens to attach and enter cells; (c) low pH of gastric secretions; and (d) digestive and bactericidal enzymes secreted by the stomach, pancreas, and epithelial cells to inhibit the attachment and growth of bacteria.[49]

The gut is also the largest immunologic organ in the body (see Chapter 3). As a result, immunologic barriers play a critical role in maintaining normal health and function both locally and systemically. Gut-associated lymphoid tissue (GALT) is composed of cells residing in the lamina propria, intraepithelial lymphocytes interspersed between epithelial cells, and immune cells located in organized lymphatic tissue (Peyer's patches and mesenteric lymph nodes).

Fermentable prebiotic fibers, such as FOS, can have a major impact on the gut immune function. In a study by Field et al., dogs were fed isonitrogenous, isoenergetic meat-based diets supplemented with either a combination of fermentable fibers (beet pulp, gum arabic, and FOS) or with nonfermentable fiber (cellulose).[50] Each diet contained similar amounts of fiber but differed in fermentability. The diet supplemented with fermentable fiber significantly ($P < 0.05$) decreased the proportion of Ig^+ cells and increased the CD4/CD8 (i.e., T-helper cell-to-cytotoxic T cell ratio) in peripheral blood. Therefore, adding fermentable fiber to the diet of dogs changes the composition and function of immune cells in GALT.

Probiotics

The most common type of probiotic bacteria are the lactic acid bacteria, such as *Bifidobacterium* and *Lactobacillus*. Probiotics have been used for many years in human medicine. Studies evaluating their potential use in dogs and cats are only in their infancy, but so far they have demonstrated their effectiveness at improving gastrointestinal health in both humans and animals.[50a] The appealing properties of probiotics include their ability to reduce antibiotic use, the apparent high indicator of safety, and the public's continuing positive perception about "natural" therapies.

The mechanisms by which probiotics benefit the host are not completely understood, but may involve immune-enhancing and antiinflammatory activities, modifications to intestinal pH, suppression of pathogenic bacteria through production of inhibitory substances, and competition with pathogens for nutrients and mucosal attachment sites. Bacteria in the gut may also influence the number and distribution of cell types in the GALT and modulate immune response. It is through a combination of these activities that the full range of probiotic benefits is achieved.

When choosing a probiotic, it is important that the product meets both parts of the definition of a probiotic: (a) the supplements containing live (viable) bacteria in sufficient numbers, i.e., billions of organisms; and (b) they have been shown to exert health benefits in the intended species. Unfortunately the veterinary market is flooded with products claiming to be probiotics for dogs and cats. Oftentimes these products contain probiotic bacteria from human preparations. Even if these products are effective probiotics for humans, most have not been demonstrated to exert health benefits in dogs and cats, and therefore these products do not meet the criteria to be called a probiotic. There are only a small handful of probiotic products in the veterinary market that do meet this definition and have research to document clinical efficacy. The following is a list of additional important characteristics that successful probiotics possess.

Stability

A probiotic preparation must be able to withstand commercial processing and storage. Those probiotics that may be stored on a shelf and do not require refrigeration have an advantage in ease of handling from the manufacturing site to the client's possession. A low-moisture environment and avoidance of air are important in the preservation of viable microbes.

Survivability

Survival is the key to a good probiotic supplement. For probiotics to provide a health benefit, adequate numbers of viable organisms must reach the appropriate area of the intestinal tract. For this to happen, probiotic organisms should be selected for their ability to survive transit through the acid environment of the stomach and resist digestion by bile and pancreatic enzymes.

Colonization

An effective probiotic must reside at the desired target sites in the GIT long enough and at sufficient concentrations to elicit probiotic effects. Adherence on the intestinal surface lengthens the retention time of a probiotic, which is important in the small intestine because of the short transient time of intestinal material. Adherence and temporary multiplication of probiotic bacteria at the target site would result in an enhanced concentration of probiotics at the optimal site potentially at a lower dosage. Preferential adherence to the epithelial of the gut helps to maintain gut barrier function and possibly exclude enteric pathogens.

Fermentation of Fructooligosaccharides and Beet Pulp

Among the numerous groups of beneficial bacteria, there are those that can effectively utilize fermentable dietary fibers such as FOS and beet pulp. Bacterial fermentation of these fibers produces SCFAs, which are the preferential fuel for intestinal cells. Health benefits associated with higher densities of bacteria capable of producing SCFAs in the GIT include enhanced intestinal structure and function, stimulation of enteric and systemic immune systems, treatment of gastrointestinal disease, increased absorption of minerals and improved stool characteristics.

Species Specificity

There are inherent differences in the bacterial microflora among species. Probiotics originating from the target species may be better adapted to adhere and possibly colonize the intestinal tract. Adherence and colonization allows greater concentration of the beneficial microbe to help maintain gut barrier function as well as competing with pathogens for sites.

Antipathogen Effects

Probiotic species have protective antipathogen effects by limiting colonization of undesirable bacteria through occupation of certain environmental or nutritional niches; through the production of specific antibacterial products, such as bacteriocins and bactericidal substances; through immune regulation of the host; and/or by inhibition of the production or action of bacterial toxins.

Safety

Probiotics have been widely used for many years in human medicine and overall have an excellent safety record. Potential probiotic bacteria are generally regarded as safe as opposed to antibiotics, which have a number of recognized adverse effects. Concern exists, although insufficiently documented, regarding the possible transfer of antimicrobial resistance from probiotic strains to more pathogenic bacteria in the intestinal microbiota. Newly developed probiotic strains should be evaluated for safety before marketing. There are a limited number of conditions where the use of probiotics is contraindicated until studies document safety.

Contraindications

Patients undergoing long-term immunosuppressive therapy (i.e., patients receiving chemotherapy or those receiving long-term corticosteroids), patients with bloody diarrhea (e.g., parvoviral enteritis patients) and bacterial translocation, and patients with pancreatitis, are a few examples of situations where the use of probiotics would not be advised.

Clinical Benefits of Probiotics in Patients with Gastrointestinal Tract Disorders

Numerous clinical trials have validated the use of probiotics for specific clinical conditions in humans. Although research on probiotic use in dogs and cats lags behind that in humans, it is becoming increasingly clear that probiotics confer many of the same health benefits to dogs and cats. New research has now demonstrated that probiotics can positively affect gastrointestinal conditions in dogs. It is known that the microbial flora of the gut play a role in the normal function and maintenance of health of the GIT. Recent studies have shown that feeding of probiotics to dogs improves stool quality (P&G Pet Care, unpublished research). In one study, young dogs (14 to 16 months old) were fed a probiotic (canine-derived *Bifidobacterium animalis* AHC7; Iams, Prostora Max) or placebo prior to traveling to a training

kennel. Fewer of the dogs that received the probiotic experienced loose stools during the transition to the kennel compared with dogs that received placebo. Another study examined the effects of feeding this same probiotic product to dogs with acute severe watery diarrhea.[51] The time to resolution of diarrhea was approximately 40% less (2.5 days faster) in dogs that received the probiotic than in dogs that received the placebo. Another study examined the effects of this same probiotic in service dogs. Service dogs typically spend the first 14 to 16 months of their lives in a foster home before returning to the service organization for training. It is not uncommon for dogs to develop diarrhea during this transition, which interferes with their training. When compared with dogs that received the placebo, there was a statistically significant reduction in the number of dogs with less-than-ideal fecal scores when probiotics were started 5 weeks prior to this transition. In addition, serum C-reactive protein (CRP) concentrations, which reflect inflammation, were evaluated in both groups. The dogs that received the placebo had elevated levels of CRP above the reference range for at least the first 10 days at the training facility, whereas levels of CRP remained within the reference range the entire time in dogs that received the probiotic. This study illustrates how probiotics not only have beneficial effects in the GIT but systemically as well. These studies indicate that feeding this organism may promote GIT health in dogs, even in the setting of acute diarrhea.

Beneficial Effects of Probiotics on Healthy Dogs

The balance between beneficial bacteria and pathogenic bacteria in the GIT is vital to overall health, and even clinically healthy dogs may have low numbers of pathogenic bacteria, such as *Clostridium* spp., in their GIT. Finding ways to inhibit the growth and reproduction of pathogenic bacteria in the GIT supports overall well-being. In a study conducted by P&G Pet Care, 12 healthy adult dogs were fed either a probiotic product containing canine-derived *B. animalis* (Prostora Max) or a placebo for 6 weeks, and fresh fecal samples were cultured for bacteria prior to any treatment and 5 weeks into either probiotic or placebo treatment. Compared with the control group, the dogs that received the canine-derived *B. animalis* (Prostora Max) had a significant reduction in the total number of fecal *Clostridium* spp. organisms, as well as a significant reduction in a specific clostridial organism (*Clostridium difficile*). Therefore, the probiotic was shown to be effective in reducing the number of pathogenic bacteria, which may reduce the likelihood of disrupting the balance between beneficial bacteria and pathogenic bacteria.

Yogurt as an Alternative to Commercial Probiotics in Dogs

Not all yogurts contain live probiotic organisms because some yogurts are pasteurized, which kills the bacteria. In addition, the two most common probiotic organisms found in yogurt are *Streptococcus thermophilus* and *Lactobacillus delbrueckii* subspecies *bulgaricus*. Neither of these organisms is derived from dogs. As a result, although yogurt that contains probiotic organisms may be beneficial in humans, similar benefits have not been documented in clinical studies when administered to dogs.

An additional hindrance to using yogurt as an alternative to commercial probiotics in dogs is the number of organisms present in yogurt. The generally accepted effective dose of probiotics is a daily dose of 10^9 to 10^{10} organisms. It is estimated that 3.5 cups of yogurt per day would be needed to reach effective levels of organisms, which is not very practical in dogs.[52] When most clinicians have recommended to owners to add yogurt to their dog's food, in most incidences only 2 to 3 tablespoons of yogurt are added to the food, which is too small of a quantity to provide any clinical benefit.

Synbiotics

A two-point approach to maintaining gastrointestinal health can be achieved through the use of synbiotics. When prebiotics and probiotics are administered simultaneously, the prebiotic can be used to increase intestinal survival of the probiotic organism. Beneficial bacteria, such as *Lactobacillus* and *Bifidobacterium*, are able to utilize prebiotics as a source of nutrition, whereas pathogenic bacteria, such as *Salmonella* and *E. coli*, are not.

It is important to demonstrate that the prebiotic fiber selectively stimulates the growth and/or activity of the beneficial bacteria in the intestines because not all fiber sources are effective prebiotics. For example, the effects of various fiber sources were studied to determine their effects on the number of probiotic organisms *B. animalis* AHC7 in healthy dogs (data on file, P&G Pet Care). The fiber sources studied included cellulose, beet pulp, and FOS. At baseline, there was no statistically significant difference in the number of *B. animalis* AHC7 organisms among fiber groups. However, 24 hours after administering the various fibers, there was a statistically significant difference in the number of *B. animalis* AHC7 organisms among fiber groups. Cellulose resulted in the lowest number of *B. animalis* AHC7 organisms, and beet pulp resulted in statistically significant increase in the number of *B. animalis* AHC7 organisms when compared with the cellulose group. FOS resulted in the highest number of *B. animalis* AHC7 organisms and was statistically higher than that seen with both the cellulose and beet pulp groups. As a result, this study demonstrated that there is a symbiotic relationship between the probiotic *B. animalis* AHC7 organism and the prebiotic FOS, and there may be additional benefits of administering synbiotics over administering a prebiotic or probiotic alone.

LIVER AND BILIARY TRACT

Craig G. Ruaux

The liver holds a position of central importance in metabolism (see Chapters 1, 29, and 61). Among the myriad roles of the liver, metabolism of ingested nutrients and toxic compounds is particularly critical. As the source of both the assimilated nutrients and many potentially toxic compounds is either directly from the diet, or from alteration of dietary components by the intestinal microbiota, dietary modification has many potential benefits in animals with hepatic disease.

The traditional approach to management of animals with liver disease has been heavily influenced by a perceived need to protect the patient from hepatic encephalopathy. This emphasis has resulted in the formulation and use of "liver diets" that may be inadequate to meet the caloric and protein requirements of many animals with liver disease. With few exceptions, nutritional interventions should be aimed at optimizing the ability of the liver to heal and regenerate, including provision of sufficient metabolic energy to meet the needs of the patient. In most cases, protection of animals from hepatic encephalopathy is not as important as the provision of dietary energy and preservation of body mass through adequate calorie and protein intake.

Metabolic Energy and Protein Requirements in Chronic Hepatic Disease

Animals with chronic hepatic disease are typically in an advanced catabolic state; consequently, dietary protein restriction may actually slow recovery (as has been shown in studies of human patients).[1,2] To maintain a positive nitrogen balance, protein requirements in animals with acute and chronic hepatitis may be higher than in normal animals.[3] A sizable proportion of this increased metabolic energy and protein requirement is a result of increased protein turnover. In the absence of adequate dietary intake, which is common in animals with liver disease, protein-calorie malnutrition can develop. Protein-calorie malnutrition is associated with loss of lean body mass, blunted immune responsiveness, decreased hepatic albumin synthesis, loss of plasma oncotic pressure, and increased risk of dehiscence of surgical wounds.[4]

Hepatic disease is often accompanied by concurrent malassimilation. Cholestatic liver diseases, for example, are associated with decreased biliary secretion, reduced bile salt availability, incomplete emulsification and micellarization of dietary fat, and steatorrhea. Cats with cholangitis/cholangiohepatitis may have concurrent exocrine pancreatic disease and inflammatory bowel disease (IBD) that may further compromise nutrient absorption through decreased digestive enzyme activity and mucosal dysfunction, respectively.

Patients with liver disease often experience significant nausea and anorexia. As hepatic functional mass declines, less glycogen storage capacity is available within the liver, necessitating the mobilization of lean muscle glycogen stores and protein as substrates for gluconeogenesis. Reduced voluntary intake and increased muscle protein mobilization can lead to rapid weight loss in animals with hepatic disease. Further complicating the management of these cases, skeletal muscle is a storage site for much of the total body pool of ammonia, which is a major toxin of hepatoencephalopathy (see Chapter 17). Failure to meet the animal's metabolic energy requirements and maintain a positive nitrogen balance through provision of adequate dietary protein and fat can thus promote the development of hepatic encephalopathy through release of muscle ammonia stores.

Many clinicians will prescribe protein-restricted diets early in the course of liver disease. This may actually worsen the clinical state of the patient if low dietary palatability leads to insufficient caloric intake. The first aim of nutritional support for most animals with hepatic disease should be to ensure sufficient caloric intake to meet the metabolic energy requirements of the patient.[5] Normal canine maintenance diets utilizing high-quality, readily digestible protein sources are indicated in most dogs with liver disease, unless overt hepatic encephalopathy is present. Provision of adequate calories via dietary fat and carbohydrate spares lean muscle protein, and redirects ingested amino acids for synthesis and repair of muscle mass. Although the actual metabolic energy requirements of animals with hepatic disease are not well defined, clinical experience suggests that most of these patients require at least the same dietary metabolic energy input as healthy, active animals. Unfortunately, many diets utilized for protection of animals from hepatic encephalopathy have reduced palatability, particularly in animals with nausea as a consequence of liver disease, making the provision of adequate caloric intake from these diets difficult.

In obligate carnivores like the domestic cat, the provision of adequate protein intake is even more important to the maintenance of lean body mass. Cats have a minimal dietary protein requirement two to three times greater than that of dogs and other omnivores.[6] The amino acids taurine, arginine, methionine, and cysteine are either essential in cats or become conditionally essential in disease states characterized by decreased voluntary intake. Bile salt conjugation in the cat is dependent exclusively upon taurine,[7] a circumstance which may be further exacerbated if there are disruptions in the enterohepatic recirculation of bile salts.[8] Indeed, total body taurine deficiency readily develops in cats with hepatic disease.

Many diets recommended for use in liver disease cases have a reduced protein content. Although reduced protein content may be protective against hepatic encephalopathy, the use of these diets in animals with nonencephalopathic disease carries the risk of protein-calorie malnutrition. Given that the majority of liver diseases encountered in companion animals do not carry a risk of encephalopathy except in their end stage, the use of unsupplemented "liver diets" with markedly reduced protein content is not recommended in most veterinary patients with liver disease.[3] Diets with mildly reduced protein content, utilizing a high digestibility protein are a preferred choice in most companion animals with liver disease.

Nutraceuticals in Hepatic Disease

A nutraceutical can be defined as a food, food-derived compound, or dietary supplement that is given with the intent to modulate disease or provide health benefits. Many nutraceutical compounds have been suggested as supplements in human beings and animals with hepatic parenchymal disease[9]; however within the veterinary literature only two compounds, *S*-adenosylmethionine and silymarin, have received meaningful attention (see also Chapters 40 and 47).

S-Adenosylmethionine (SAMe) is a compound derived from the essential amino acid methionine and adenosine triphosphate. SAMe is involved in many essential metabolic processes, including hepatic detoxification of drugs and xenobiotics via sulfuration and methylation reactions.[10] Adequate availability of SAMe is critical to the synthesis and reduction of GSH, which is one of the most important early protection mechanisms within the cell against oxidant stress.[10-12] Oxidative stress, with subsequent mitochondrial dysfunction and activation of cell death pathways, is a major cause of hepatocyte death in many disease processes.[13]

SAMe has been assessed prospectively in healthy, untreated cats and in healthy dogs receiving chronic prednisolone therapy.[10,14] In both dogs and cats supplemented with SAMe, hepatic GSH concentrations were increased, with an increase in the ratio of reduced GSH to the oxidized glutathione (GSSG) form. No significant effect was seen on clinicopathologic or histologic manifestations of glucocorticoid-induced vacuolar hepatopathy in the dogs.[14] Apparently successful therapeutic use of SAMe has been reported in a dog with acetaminophen toxicity, severe Heinz-body anemia, and markedly increased aspartate aminotransferase activity; it should be noted, however, that SAMe was only one component of the critical care therapy provided for this patient.[15]

Cats are particularly susceptible to acetaminophen-induced hepatotoxicity, and SAMe appears to be a rational therapeutic application for this condition. Unfortunately, controlled studies of the effect of SAMe therapy on a model of acetaminophen hepatotoxicity in the cat showed little to no effect, with most changes failing to reach statistical significance.[11] At this time, there are no well-controlled evidence-based clinical studies assessing the efficacy of SAMe as a therapeutic agent for chronic liver disease in either dogs or cats.

Silymarin has a potent antioxidant effect in several models of oxidant-mediated liver disease.[16] The use of silymarin has been

investigated in oxidant-mediated pathology in humans, including alcoholic liver disease and viral hepatitis.[17,18] Similar studies in companion animals are lacking, although the oral bioavailability of a silybin-phosphatidylcholine complex has been described.[19] Meta-analysis of clinical trials using silymarin in human beings reveal little evidence for clinical benefit except in *Amanita phalloides* mushroom poisoning.[20]

Although there is a strong theoretical underpinning for the use of many of the available nutraceutical preparations,[21,22] evidence-based medicine studies in support of these compounds is unconvincing. At this time, accurate diagnosis of the primary liver disease and implementation of therapy directed toward this diagnosis are recommended in preference to empirical therapy with nutraceutical compounds.

Copper-Restricted Diets

Hepatic copper accumulation is a feature of several canine liver diseases. Copper retention and hepatopathy is a well-characterized autosomal recessive disorder in the Bedlington Terrier, resulting from a defect in the COMMD1 gene.[23] In several other dog breeds, including the Doberman Pinscher, Cocker Spaniel, West Highland White and Skye Terriers, and the Labrador Retriever,[24,25] there is evidence of excessive hepatic copper accumulation. As copper can accumulate with cholestasis as well as primary hepatocellular disease, the significance of copper retention as a primary pathophysiologic event is less clear in these breeds. Experimental studies of Labrador Retrievers with hepatic copper accumulation, however, show that reduced copper diets are associated with improvement in chronic inflammatory liver disease and slowing of disease progression.[26]

Animals with hepatic copper accumulation sufficient to cause overt hepatopathy are best treated with specific medical therapy using chelating drugs such as D-penicillamine, at least until hepatic copper content is reduced below toxic levels. Dietary copper restriction can then be useful in the maintenance phase of management for dogs with these diseases. Typical maintenance canine diets contain at least 7 parts per million (ppm) copper, while copper-restricted diets may contain as little as 3 ppm on an as fed basis.

Additional dietary manipulations to decrease hepatic copper accumulation include supplementation with ascorbic acid (vitamin C) and elemental zinc. Zinc supplementation increases the intestinal expression of metallothionein, an avid metal-binding protein within the enterocytes.[27] Metallothionein has a higher affinity for copper than zinc. With zinc supplementation and increased metallothionein expression, copper in the diet is bound with high affinity within the mature enterocyte and lost in the feces as the enterocyte is shed.[27] Zinc is given at a loading dose of 100 mg elemental zinc per os twice weekly for 3 weeks, followed by a maintenance dose of 50 mg elemental zinc per os twice weekly. Administration of the zinc with a small amount of food may reduce the side effects of nausea and vomiting. Interestingly, in the previously cited study of dietary copper restriction in Labrador Retrievers with copper-associated hepatic disease,[26] no additional benefit was found with zinc gluconate supplementation.

Vitamin and Mineral Supplementation in Patients with Liver Disease

Liver disease patients often present with vitamin and/or mineral deficiencies. Several factors, including reduced voluntary intake, fat malabsorption, reduced gastrointestinal mucosal function, and loss of reserve stores in hepatic tissue can all contribute to the development of vitamin and mineral deficiencies.

Water-soluble vitamins such as folic acid, thiamine, cobalamin, niacin, and riboflavin are often critical cofactors in enzymatic reactions. It has been suggested that in cats with hepatic lipidosis, deficiencies of these vitamins are common.[28] Most water-soluble vitamins do not have substantial body stores and daily replacement from dietary sources is necessary. Administration of multivitamin supplements is cost-effective and simple, and should be included in any nutritional support plan for patients with liver disease.

Malabsorption of cobalamin has been documented in association with feline liver disease.[29] Cobalamin malabsorption is not easily resolved with dietary supplementation, and parenteral therapy is necessary.[30] A dose range previously described for use in cats with cobalamin deficiency caused by intestinal disease is 250 μg/cat injected subcutaneously, once a week for 6 weeks, once every 2 weeks for 6 weeks, then once a month thereafter.[30] Because the concentration of cobalamin in parenteral multivitamin preparations is typically insufficient to supply this amount of cobalamin in a reasonable injection volume, the use of pure preparations of cobalamin is recommended in dogs and cats with documented cobalamin deficiency.

In animals with long-standing liver disease, particularly those characterized by cholestasis, fat and fat-soluble vitamin (A, D, E, K) malabsorption is a significant problem. Significant elevations in the plasma concentration of proteins induced by vitamin K antagonism (PIVKA) have been documented in both cats with hepatic lipidosis and in cats with cholangitis associated with IBD.[31] Vitamin E deficiency in liver disease patients reduces cellular defenses against oxidant-mediated damage, potentially playing a role in copper-associated hepatoxicity.[32,33] Vitamins E, A, and D supplementation by intramuscular injection at 3- to 4-month intervals has been recommended in companion animals with long-standing liver disease, particularly those complicated by obvious steatorrhea. Cats with hepatic lipidosis should be screened for vitamin K deficiency, particularly if there is any evidence of bleeding tendencies. If detected (ideally via PIVKA assay), subcutaneous vitamin K administration at 1 to 5 mg/kg/day for 2 to 3 days is indicated.

Carnitine and choline are essential cofactors for hepatic cellular fatty acid transport. Carnitine is essential for transport of fatty acids from the cytosol to the mitochondria for β-oxidation of LCFAs, while choline is essential for export of very-low-density lipoproteins (VLDLs) from hepatocytes. Carnitine and choline supplementation are both potentially beneficial in the management of feline hepatic lipidosis.

Nutritional Intervention in Hepatic Encephalopathy

Hepatic encephalopathy (HE) results from loss of hepatic detoxification function and subsequent accumulation of toxic metabolites within the systemic circulation and central nervous system. These metabolites may be directly toxic to neurons and glia (e.g., ammonia), or may act as "false neurotransmitters," interfering with central nervous system function.[34] HE in humans is graded in physiologic and neurologic scoring systems, using the West Haven Criteria.[34] In this scoring system, HE is scored from 0 (no clinical signs) to 4 (hepatic coma). Because subtle neurologic impairments, equivalent to inattention or mild tremor, are more difficult to detect in companion animals, most animals in whom a diagnosis of HE is made will fall within the West Haven Criteria scores of 2 to 4. Most animals with liver disease, however, will not meet these criteria. According to a recent consensus statement of the European

Society of Parenteral and Enteral Nutrition, protein restriction is not indicated in human patients with an HE score of 0 to 2, as negative protein balance and resultant malnutrition are negative prognostic factors.[1] Protein restriction is indicated in human patients with West Haven Criteria scores of 3 to 4 (i.e., severe cognitive impairment, hepatic coma), but this finding is also a strong negative prognostic factor with patient death typically within 1 year.[1] Assuming a similar relationship in animals with a diagnosis of liver disease, most of whom do not present with HE signs consistent with scores of 3 to 4 in the West Haven Criteria, aggressive protein restriction may be counterproductive, even in mild encephalopathy patients.

Although very severe cases of hepatic lipidosis in cats can result in HE and necessitate the use of low-protein diets for a short period of time, encephalopathy is not a consistent feature of most cases of feline hepatic lipidosis, and use of low-protein diets may be associated with an adverse outcome.[35]

Recommendations for dietary protein content in diets fed to animals with severe HE vary within the veterinary literature. Overall, most dogs can be managed with diets containing 3 to 4 g of protein per 100 kcal of diet, whereas cats require at least 6 to 7 g/100 kcal. Note that the recommendation is for protein proportion within the diet, not for protein intake per kilogram of animal.

The amino acid makeup of the diet used in patients with HE is an unsettled controversy. It has been suggested that aromatic amino acid (AAA—tryptophan, phenylalanine, tyrosine)-rich diets are likely to potentiate HE, the AAAs potentially acting as substrates for the production of encephalotoxins.[3] The molar ratio of AAA to branched chain amino acids (BCAAs – isoleucine, leucine, valine) in plasma is increased in veterinary patients with HE.[3] BCAAs are important substrates for gluconeogenesis, thus the presence of protein-calorie malnutrition will lead to depletion of these amino acids in the plasma. Although these changes in the AAA-to-BCAA ratio are well documented in veterinary and human patients, their significance as a direct cause of HE rather than as a epiphenomenon is unclear. Experimental studies using dogs with surgically created portosystemic vascular anomalies found more pronounced HE and higher blood ammonia concentrations in the dogs receiving a low AAA-to-BCAA ratio diet, however the dogs receiving this diet ate more than those receiving a high AAA-to-BCAA ratio diet, resulting in greater total protein intake.[36] Based on metaanalyses of studies in human beings with HE, BCAA supplementation is recommended in patients who develop HE with Westhaven Criteria scores 3 to 4 during enteral nutrition.[1] The situation is much less clear with lower-grade HE human patients and in most veterinary patients. In most cases BCAA supplementation is unlikely to lead to a net negative benefit, unless voluntary intake is reduced. Most veterinary prescription diets specifically labeled for hepatic disease are formulated to achieve a higher BCAA content and derive a significant proportion of metabolizable energy from fats and carbohydrates.

Feeding of several small meals throughout the day is often beneficial for animals with overt HE, reducing the total ammonia load following each meal. Other strategies used to control HE in small animals include antibacterial therapy with neomycin or metronidazole, and the use of enteric lactulose therapy (oral or via enema) to reduce ammonia production and absorption, respectively, from the GIT.

Hepatic Lipidosis in Cats

Appropriate nutritional management is absolutely central to successful resolution of hepatic lipidosis (HL) in cats.[37] Although the underlying pathology of hepatic lipid accumulation in cats has not yet been completely elucidated, several biochemical and nutritional risk factors have been identified (Box 32-1).[38] There is a general consensus that reduced caloric intake and protein-calorie malnutrition are important predisposing factors. Obese cats are commonly thought to be at increased risk,[28,39,40] but this is not exclusively a disease of the overweight cat. Underlying disease is believed to initiate the anorexia and starvation that typify this syndrome. Successful management in the medium- to long-term will require addressing the underlying disease process to permit a return to more normal appetite. In the short-term, diligent attention to restoration of positive caloric balance is necessary. Short-term stabilization may be a necessary precedent to initiating a rational diagnostic workup.

Box 32-1 Factors Predisposing the Domestic Cat, an Obligate Carnivore, to Fat Mobilization and Hepatic Lipidosis

- Essentiality of dietary arginine
- Low levels of hepatic ornithine
- High dietary protein requirements
- Lack of hepatic enzyme adaptation to low protein
- Insufficiency of hepatic glutamate reductase
- Insufficiency of intestinal ornithine transcarbamylase
- Diversion to orotic acid metabolism
- Differences in lipoprotein metabolism (HDLs)

Summarized from MacDonald ML, Rogers QR, Morris JG: Nutrition of the domestic cat, a domestic carnivore. *Ann Rev Nutr* 4:521–562, 1984.

The feline liver has relatively small glycogen stores, thus cats become all too quickly dependent upon systemic lipolysis and hepatic metabolism of triglycerides with the onset of starvation or anorexia. Carnitine, choline, and arginine deficiency are believed to contribute to the development of this syndrome. Healthy cats fed arginine-deficient diets, even if fed in quantities necessary to supply adequate caloric intake, rapidly develop severe HE, as the urea cycle is compromised.[38] Choline and carnitine are important in mitochondrial fatty acid transport and packaging of fatty acids into VLDLs for export from the hepatocyte, thus deficiency of these trace elements may contribute to fat accumulation. Arginine, choline, and carnitine supplementation are commonly recommended in the nutritional management of cats with HL. If the diet used for initial feeding is deficient in arginine, as is the case with most human liquid enteral formulations, this amino acid should be supplemented at dose of 250 mg/100 kcal of diet delivered. The author empirically supplements HL cats with arginine, carnitine, and taurine regardless of the enteral nutrition formula used. Oral administration of L-carnitine, 250 to 500 mg/day, and taurine, 250 to 500 mg/day, are also recommended by several sources.[37,40]

Advances stages of HL are characterized by severe anorexia. Assisted feeding should be implemented as soon as feasible in these patients. Oral forced alimentation is not recommended as many cats will rapidly develop food aversion, while the stress of handling and syringe feeding can precipitate rhabdomyolysis in hypokalemic and hypophosphatemic cats. Medical agents for appetite stimulation in cats are often ineffective in HL cats, may take days to weeks to show benefit, and may require hepatic detoxification. Early placement of a feeding tube, at the minimum an esophagostomy tube, should be considered standard of care. Critically ill cats at risk for anesthetic procedures can be fed initially with a nasoesophageal tube (5 to 8 French). These tubes are more prone to clogging and failure because

of vomiting, regurgitation, or removal by the patient. Nasoesophageal tubes also require placement and maintenance of an Elizabethan collar, and the small lumen of the tube limits diet choice to liquid formulations. Placement of an esophagostomy tube allows use of larger bore tubes (10 to 14 French) that make feeding easier and open up the possibility of blenderized diets. Percutaneous endoscopically placed gastrostomy (PEG) tubes are larger still (up to 20 French), and allow greater movement of the head and neck of the cat (as these areas are not bandaged), which appears to reduce morbidity in some cats by allowing self-grooming. Clinicians experienced in this technique can place a PEG tube in a 10- to 15-minute procedure. If a large-bore PEG tube can be placed, assisted feeding by owners becomes more feasible in the home environment. As some cats require assisted feeding for weeks to months, this can be an important aspect of successful home care. Cats presenting with vitamin K deficiency and elevated PIVKA should receive subcutaneous vitamin K for 1 to 2 days before either esophagostomy or PEG tube placement is recommended. It has been suggested that surgical placement of gastrostomy tubes via celiotomy in cats with hepatic lipidosis is associated with high risk for postoperative morbidity and an unacceptable risk of stomach displacement.[28]

Dramatic, potentially life-threatening electrolyte derangements can occur during initial reinstitution of feeding, particularly in serum potassium (K^+) and phosphate (PO_4^{3-}). These are both predominantly intracellular ions, but during periods of extended malnutrition both K^+ and PO_4^{3-} move into the extracellular space to maintain cellular membrane potentials. With the reintroduction of oral intake and renewed insulin activity, there can be a rapid shift of both ions intracellularly; this shift can be rapid enough to result in rhabdomyolysis and hemolysis in severely affected cats. These changes should be anticipated, and in severely affected cats parenteral administration of PO_4^{3-} and K^+ should begin preemptively. Potassium replacement can be dosed using routine sliding dose scales, whereas PO_4^{3-} is commonly administered intravenously at a rate of 0.01 to 0.03 mmol/kg/h. Phosphate is commonly available with K^+ as a cation, and care should be taken to ensure that the total K^+ input does not exceed 0.5 mEq/kg/h. Oral administration of K^+ as the gluconate salt is also recommended. Twice-daily measurement of serum electrolytes, including magnesium, is recommended during the initial management of critically ill cats with hepatic lipidosis. Electrolyte abnormalities should be anticipated during the first few days of therapy, and should be addressed as early as possible though judicious intravenous fluid supplementation.

Many cats with HL will have water-soluble vitamin deficiencies because of extended periods of anorexia; these are commonly supplemented by adding multivitamin preparations into the IV fluids at a dose of 1 to 2 mL/1 L bag. Fluid bags and lines should be protected from light. Cobalamin deficiency is also common, and can be addressed with subcutaneous cobalamin injections as previously described. Thiamine deficiency is particularly insidious in HL cats. Both thiamine and K^+ deficiencies can result in obtundation, weakness, and ventriflexion of the neck. These signs may be misinterpreted as HE, and these abnormalities should be screened for and corrected before instituting low-protein diets for presumed encephalopathy in hepatic lipidosis patients.

Nutritional Considerations in Diseases of the Biliary Tract

Nutritional management of biliary tract disease has not been discussed in great detail in the veterinary literature. In most cases, management has been limited to medical and surgical approaches.

There is a well-recognized risk of biliary disease in dogs with hypertriglyceridemia.[41] Hypertriglyceridemia has been associated with vacuolar hepatopathy and gallbladder mucocele in dogs, and successful resolution of gallbladder mucocele has been reported in a limited number of dogs using therapies that included low-fat diets and ursodeoxycholic acid therapy.[42,43] Breed-associated predispositions for hypertriglyceridemia have been reported, and many of these breeds are also considered at higher risk for development of gallbladder mucocele.[41] In this context, nutritional interventions directed toward management of hypertriglyceridemia, such as feeding of fat-restricted diets, can be considered a risk-reduction strategy to prevent possible biliary disease.

In clinically healthy dogs, omega-3 fatty acid supplementation has been shown to reduce serum triglycerides significantly and with no perceived adverse effects.[44] Experimental studies in rodents have shown that administration of omega-3 fatty acids reduces the histologic severity of lesions induced by bile duct ligation, suggesting that these compounds may have a role in management of long-term cholestatic disorders such as biliary fibrosis, cirrhosis, and atresia.[45] Controlled studies demonstrating benefit of omega-3 fatty acid supplementation in dogs with preexisting hypertriglyceridemia, however, are lacking.

Chronic cholestasis is associated with fat malassimilation and deficiency of fat-soluble vitamins, as previously discussed. Although successful management of cholestatic diseases will usually require specific medical and surgical therapy, attention to the possibility of fat-soluble vitamin deficiencies and the need for supplementation is indicated.

PANCREAS

Jennifer Larsen

Diseases affecting the exocrine pancreas generally fall into two categories: pancreatic inflammation and/or necrosis and EPI. The pancreas produces a fluid rich in electrolytes, bicarbonate, and enzymes, in addition to antibacterial proteins and cobalamin-binding intrinsic factor (see Chapters 1 and 60). Digestive enzymes include proteases, amylase, and lipase, which carry out the digestion of dietary proteins, carbohydrates, and lipids, respectively. Colipase, nonspecific esterase, and phospholipase are cosecreted and have an important role in triglyceride, cholesterol, lecithin, and fat-soluble vitamin digestion. Digestive enzymes are essential for life; when they are lacking, as in patients with EPI, the outcome is severe maldigestion and malnutrition. To protect the pancreas itself from autodigestion, these same enzymes are incorporated as inactive zymogens into secretory granules following intracellular synthesis. In response to neural and hormonal stimuli, zymogens are secreted into the pancreatic ductal system and small intestine. Inactive trypsinogen, a major component of pancreatic secretion, is catalytically activated by brush-border enterokinase to form active trypsin. Trypsin, in turn, activates other zymogens, thereby initiating the normal process of protein, carbohydrate, and lipid digestion. If activated prematurely, digestive enzymes digest the structural elements of the pancreatic acinar cells resulting in necrosis and inflammation (pancreatitis). The proximate cause of premature activation is believed to be inhibition of secretion and colocalization of digestive zymogens with lysosomal hydrolases (see Chapter 60). The resulting disease process is typically classified as acute or chronic, with recurrences not uncommon. As with EPI, risk factors and clinical signs are well

established; however, individual variation in the clinical picture should be expected. Dietary therapy remains an important component of the management of patients with either pancreatitis or EPI, and recommended strategies have evolved with clinical experience and research data.

Pathogenesis of Pancreatitis

Risk factors for dogs include, but are not limited to, diet history (especially high-fat foods and obesity), breed (including Miniature Schnauzers and Yorkshire Terriers), concurrent disease (including hyperlipidemia and diabetes mellitus), and drugs (phenobarbital, azathioprine, and many others).[1] For cats, risk factors include trauma, infection (including toxoplasmosis), and IBD; however, most cases remain classified as idiopathic.[2,3] Although dogs often show clinical signs of vomiting and/or diarrhea, signs in cats remain elusive, with lethargy and anorexia as the most commonly reported clinical signs.[4,5] In some cases, adverse sequelae and concurrent disease can complicate management; however, supportive medical care and both short- and long-term dietary therapy can help alleviate symptoms and prevent or reduce recurrence.

Approach to Therapy of Pancreatitis

Nutritional Management

The traditional approach to acute pancreatitis is "nil per os" during the immediate period of treatment and hospitalization. Research evidence and clinical experience have suggested that the nil per os approach is not necessary and may not be beneficial. Many patients are hyporexic or anorexic during this time, and intervention is necessary to provide appropriate nutritional support. In particular, animals in poor body condition, those with a history of weight loss, and all cats should have a nutritional management plan in place as early as possible and no later than after 3 to 5 days of anorexia. Longer-term dietary management of patients with either acute or chronic pancreatitis is highly dependent on diet history, concurrent disease, and the fat tolerance of the specific animal.

Role of Nutrition in Pancreatic Secretion

Neural (acetylcholine, substance P, vasoactive intestinal peptide) and endocrine (cholecystokinin [CKK], secretin) mechanisms are responsible for the regulation of exocrine pancreatic secretion (see Chapters 1 and 60 for more details). Secretin stimulates the secretion of a bicarbonate-rich fluid from pancreatic ductal cells as well as from biliary epithelial cells. Not surprisingly, its secretion is stimulated by protons and fatty acids in the duodenal lumen. CCK stimulates pancreatic enzyme secretion as well as gallbladder contraction. The secretion of CCK is stimulated by amino acids, long-chain fatty acids (LCFAs), and gastric protons, but there are some species differences with regard to the relative potency of different nutrients. In humans, amino acids, proteins, and long-chain triglycerides are more potent than carbohydrates in promoting CCK secretion.[6,7] In dogs, fatty acids, amino acids, and peptides stimulate CCK release, but intact proteins do not.[8,9] Cats secrete CCK in response to long-chain triglycerides and proteins,[10] with intact protein being more potent than amino acids.[11]

Management of Acute Pancreatitis

Early Feeding Versus Nil Per Os

The long-standing nutritional strategy of withholding food from patients with acute pancreatitis was based on the erroneous assumption that excessive stimulation of secretion was the underlying pathogenesis of pancreatic acinar cell necrosis, and that fasting (i.e., placing the pancreas at "physiologic rest") should reduce pancreatic secretions. Cell biology experiments of the past decade have shown that pancreatic necrosis and inflammation are instead associated with inhibition of secretion (reviewed in Chapters 1 and 60). These studies further suggest that feeding may help to mobilize prematurely activated enzyme from the inflamed pancreas. Fasting therefore should be restricted to those patients with intractable vomiting and who are at risk for aspiration pneumonia. Recommendations to use the GIT whenever possible are increasingly accepted, with evidence that patients that have been traditionally managed with nil per os orders may actually benefit from early enteral feeding.[12,13] It has been shown that parenteral nutrition, as compared with enteral nutrition, has a negative impact on gut barrier function within 7 days of induction of experimental pancreatitis and is associated with decreased intestinal villi height, mucosal thickness, and total protein and DNA content.[12] Although caution should always be exercised when feeding a patient with suspected gastrointestinal dysfunction (such as protracted vomiting, severe ileus, or malabsorption), early enteral feeding may facilitate more rapid return to function in many gastrointestinal syndromes.[14] The concurrent use of effective antiemetic agents may facilitate earlier return to function. There is no documented benefit to maintaining nil per os orders longer than 1 to 2 days, especially if vomiting is reasonably controlled. Water tolerance should be tested first, and if there is no vomiting, food can then be offered.

Some patients may not be able to tolerate oral or intragastric feeding; however, delivery of enteral nutrients is still possible. Nasojejunal, gastrojejunostomy, and jejunostomy tubes enable postgastric feeding (all detailed in Chapter 33), which may decrease the incidence and severity of vomiting. Historically, nutritional management of acute pancreatitis has been focused on reducing stimulation of pancreatic enzyme secretion,[15,16] but enteral feeding in a dog model of severe acute pancreatitis is associated with decreased endotoxin and bacterial translocation and does not cause worsening of pancreatic pathology.[12]

While parenteral nutrition (PN) is an effective way to deliver nutrients to critically ill veterinary patients, it is advisable to strive for enteral nutritional support as soon as practical. In people with pancreatitis, early enteral feeding via the jejunal route is safe and is recommended in this context because of cost-effectiveness compared to PN.[17] At the author's institution, it is not uncommon to provide at least a small amount of food enterally (approximately 10% of the daily calories including by the gastric route) in patients receiving parenteral nutrition, with the goal of maintaining enterocyte function and gastrointestinal motility.

Dietary Selection: The Role of Dietary Fat

Modification of dietary fat content is a consideration in the management of both acute and chronic pancreatitis. In healthy dogs fed diets with fat concentrations varying from 15% to 38%, there were no differences in pancreatic physiologic responses as measured by serum pancreatic lipase immunoreactivity (PLI), trypsin-like immunoreactivity (TLI), and gastrin concentration,[18] although effects on pancreatic pathology were not reported in these studies. Dogs maintained on 60% fat diets develop more severe pancreatic pathology in induced models of pancreatitis compared with those fed a 20% fat diet.[19] Together with other research data, as well as clinical evidence of efficacy, the practice of dietary fat restriction continues to be the cornerstone of nutritional management of acute pancreatitis.

When PN is not possible, assisted enteral feeding is indicated for patients with acute pancreatitis that will not voluntarily eat adequate calories of an appropriately fat-restricted diet (<20% fat calories). Various diets may be utilized depending on the type of feeding device. If a smaller-diameter nasoenteral, gastrojejunostomy, or jejunostomy tube is placed, liquid diets are necessary. Although liquid veterinary diets are generally high in fat (up to 57% of calories), some human enteral formulations provide comparable energy density while restricting fat (as low as 6% of the calories); these are acceptable alternatives for fat-intolerant patients. For cats, it should be noted that many human enteral liquid diets are not supplemented with taurine, and some contain fructose, high concentrations of which should be avoided in cats because of fructosuria.[20] To reduce the occurrence of maldigestive diarrhea, any diet fed into the jejunum should be "elemental" to resemble the normal characteristics of chyme. Elemental diets provide the basic components of macronutrients such as simple sugars or hydrolyzed starch rather than high-fiber complex carbohydrates, and amino acids or hydrolyzed peptides rather than intact proteins.

For animals with preserved appetite or those fed through an esophageal or gastric tube, several low-fat, highly digestible options exist. Commercially available diets providing 20% or less fat calories can be attempted; however, in many patients, the need for more severe fat restriction necessitates a home-cooked diet. For example, cottage cheese and rice slurries are useful for tube feeding and are generally palatable to dogs and some cats; a volume ratio of 1:1 of 2% fat cottage cheese and white rice provides approximately 10% fat calories. For cats, canned tuna and baby rice cereal is another reasonable option. Both mixtures can be supplemented with a source of essential fatty acids and micronutrients if necessary for longer-term feeding, but many patients can be maintained on a higher-fat diet after recovery.

Diet selection for longer-term management is highly dependent on diet history and disease progression. Some dogs with acute pancreatitis associated with intake of high-fat foods or dietary indiscretion can tolerate the previous diet as long as snacks and treats are more judiciously selected. Other dogs will not tolerate the previous diet and require further fat restriction. In the author's opinion, in those cases, as well as in all dogs with chronic pancreatitis, the initial diet chosen for long-term feeding should provide no more than half of the fat (on a percent-calories basis) as the diet fed previously. A detailed diet history is crucial; in many cases, however, especially if a large amount and variety of treats and snacks are fed, it will not be possible to determine the fat level of the overall diet (or the range of the highest to lowest fat meals). In that case, given the nature of the disease, it is prudent to be conservative and choose a fat-restricted diet (<20% fat calories). In any patient, if the lowest fat commercial diets fail to resolve pancreatitis (or in the case of concurrent disease such as food allergy), or when those diets are not palatable, a customized home-cooked diet can be formulated by a veterinary nutritionist.

Adjunctive Treatments and an Individualized Approach to Pancreatitis

Supportive care and aggressive management of complications is necessary in most cases of acute pancreatitis (see Chapter 60 for details). Generally chronic pancreatitis can be managed on an outpatient basis, with monitoring and intervention as needed. Many patients will have concurrent diseases that may benefit from nutritional management, such as diabetes mellitus, obesity, or hyperlipidemia. In these cases, the patient's diet history as well as all relevant problems should be taken into consideration in a prioritized way when choosing a diet for both short- and long-term feeding.

Pathogenesis of Exocrine Pancreatic Insufficiency

Progressive pancreatic acinar and ductal atrophy is the most common pathogenesis of EPI in dogs. It likely has several underlying etiologies, one of which is presumed to be immune- mediated destruction of exocrine tissue. An important secondary cause is chronic pancreatitis with necrosis of acinar, duct, and occasionally islet cells. This is also the presumed cause of most cases of EPI in cats, but the rarity of the syndrome and the lack of epidemiologic studies prevent establishing a direct cause-and-effect relationship. In both species, and regardless of etiology, clinical signs of EPI are related to severe nutrient maldigestion with resultant steatorrhea, diarrhea, and abnormal intestinal motility. Weight loss with ravenous appetite completes the classic clinical picture. Bacterial overgrowth is an important complication, and antibiotics are often necessary, along with enzyme replacement therapy, dietary management, and other adjunctive treatments.

Approach to Therapy of EPI

Enzyme Replacement Therapy

Enzyme replacement therapy (ERT) has been well established as the principal therapy for long-term management of EPI. Very few patients can be managed without ERT.[21] The concentration and overall potency of enzymes provided by fresh raw pancreas and by commercially available ERT products varies widely. The cost of ongoing management of a pet with EPI is reported to be a common reason for euthanasia,[22] and rapid identification of cost-effective treatment is important in most cases.

As pancreatic enzymes are proteins, they are subject to degradation by exposure to gastric acid, pepsins, and bile acids. To overcome these problems, a variety of approaches has been tried, including pretreatment or coadministration with acid secretory inhibitors (H_2 blockers and proton pump inhibitors) and enteric-coated preparations of ERT. In general, acid secretory inhibitor therapy has not been widely adopted except in refractory cases because of the increased cost, reduction in compliance when additional medications are prescribed, and incomplete evidence of efficacy. Enteric-coated preparations have not typically been recommended; indeed one study showed that these products were less effective than standard ERT therapy.[22] In a more recent study, their use had no impact of survival in dogs with EPI.[21]

Acid-resistant fungal lipase has been investigated with mixed results. In pancreatectomized dogs fed complex meals containing both fat and protein, this product showed promising results, with a similar reduction of steatorrhea, but at a lower lipase dose, compared to treatment with lyophilized porcine pancreatin (a mixture of lipase, trypsin, and amylase).[23] However, in people with pancreatic steatorrhea caused by cystic fibrosis who were fed meals of emulsified long-chain triglycerides, acid-resistant fungal lipase did not result in reductions in steatorrhea.[24] Whether this difference is a result of ERT product preparation, study design, species physiology, or other factors is unclear. Bacterial lipase shows similar dose-dependent effects on fat absorption in dogs with experimental EPI but at a 75-fold lower dose compared with porcine lipase.[25] Most commercially available products are porcine or bovine in origin; for patients with confirmed adverse food response to these antigens,

fungal or bacterial lipase products may be an option assuming availability and financial feasibility.

Nutritional Management

Because of variation in biologic response in the patient population, differences in diet characteristics, composition, and amounts fed, and the dissimilarity among available ERT products, interpreting the impact of dietary strategies is difficult. Dietary strategies have been investigated, and research findings are often conflicting, which may reflect study design and the use of diets varying in multiple parameters but also suggests a need for an individualized approach to management of EPI patients. Unfortunately, there are very little data available for assessing the role of dietary therapy in the management of EPI in cats.

Macronutrients

Role of Dietary Fat

The role of dietary fat (amount and type) is a major focus of interest in the management of canine EPI. Fat is a highly digestible macronutrient, yet digestion depends on a complex interaction of dietary triglycerides, pancreatic enzymes, coenzymes, and bile salts. The presence of fat in the intestinal lumen slows transit by activating the ileal brake and delaying gastric emptying (see Chapters 1 and 60 for more details). This braking mechanism helps to ensure that fat is adequately emulsified and micellarized for successful digestion and absorption, respectively. Traditionally, low-fat diets have been recommended for a number of reasons. Steatorrhea is a major clinical sign in patients with uncontrolled disease, and higher dietary fat concentration is associated with intolerance (diarrhea, visceral pain, and other gastrointestinal signs).[26] Further, maldigested and malabsorbed fat in the intestinal lumen is a substrate for bacterial hydroxylation, leading to osmotic effects. Fat malabsorption can also result from deconjugation of bile salts by intestinal microflora, which produce additional osmotic effects. Antibiotic therapy is important to control bacterial overgrowth, and in some cases it is logical to reduce dietary fat while addressing ongoing diarrhea or during the initial stages of adjusting therapy after diagnosis. Indeed, fat restriction is not uncommonly recommended, and a diet providing 12% to 13% of calories from fat is a successful strategy in the immediate postdiagnosis period, after which most dogs continue to do well on a wider variety of diets.[27]

Despite continued recommendations of low-fat diets for canine EPI patients, their impact on disease progression and outcome remains unclear. Research in this area has been complicated and has not consistently shown benefits of either a low- or high-fat diet. In a recent retrospective study, more than one-third of canine EPI cases were fed "a fat-restricted diet" (dietary fat concentration not reported), which had no negative nor positive effect on survival.[21] Improvement or regression of clinical signs in response to diet change are often difficult to attribute to any one food characteristic. Diets are complex and differ not only in fat content and digestibility, but also in fiber content and type, protein source, and digestibility, and many other factors. A prospective study in untreated pancreatectomized dogs demonstrated lower digestibility of dry matter and fat when dogs were fed a maintenance diet compared with a veterinary-exclusive, lower fiber, highly digestible diet with 18% lower fat. Clinical and laboratory parameters improved but remained statistically insignificant after treatment.[28] Which dietary factor, or combination thereof, had the biggest influence on these findings is unclear. Indeed, a more recent prospective study showed that patient responses to diet changes were highly variable and did not correlate with dietary fat concentration.[29]

Many EPI patients have poor body condition, and could benefit from a palatable, energy-dense diet that is higher in fat content. Research has not shown a clear disadvantage to moderate or high dietary fat concentrations in dogs with EPI. In lipase-treated dogs with experimental EPI, there was no change in fecal scores or in total amount of fecal fat produced each day when fed diets providing 33%, 43%, or 47% of the calories as fat.[30] Additional work by the same group showed that dogs with lipase-treated EPI had increased fat absorption when fed a diet with 43% fat calories compared to one with 18% fat calories.[25] A case series of three dogs with naturally occurring EPI and adverse food reaction showed good clinical response with weight gain and improved fecal scores when fed a hydrolyzed diet with 41% fat calories.[31] It seems prudent to recommend low-fat (<20% of calories) diets for patients with suspected or confirmed bacterial overgrowth or with concurrent fat intolerance (such as lymphangiectasia or hyperlipidemia), whereas other patients may benefit from moderate- (20% to 35% of calories) or high- (>35% of calories) fat diets, especially those in poor body condition.

Digestibility and Fiber

Digestibility is assumed to be an important strategy in the management of dogs with EPI, but this has not been strictly differentiated from the role of other dietary factors. Although veterinary therapeutic diets with high digestibility have been used with success in both experimental[28] and naturally occurring EPI,[32] there may be an influence of fiber type and content on digestibility of a diet. Rigorous research is lacking and generalized recommendations are not warranted at this time. Very-high-fiber diets are less energy dense, which could be a disadvantage for underweight or volume-intolerant dogs and cats. Other patients may have concurrent fiber-responsive diseases, which should be considered in the nutritional management.

Micronutrients

Cobalamin (Vitamin B_{12})

The absorption of cobalamin (vitamin B_{12}) is unique among nutrients, in that both a binding protein and a receptor-mediated process are necessary for transport across the intestinal mucosa. Dietary sources of cobalamin include primarily animal proteins, but enriched cereals are also now widely available, as is free cobalamin in the form of dietary supplements. Cobalamin is bound to dietary proteins and released by the action of gastric acid and pancreatic proteases. Intrinsic factor (IF) is a binding protein necessary for absorption of free cobalamin. In the dog, IF is produced in the pancreas and to a lesser extent by the gastric parietal cells,[33] whereas in the cat the pancreas is solely responsible for synthesis of IF.[34] The IF–cobalamin complex is recognized and absorbed by a receptor-mediated process in the ileum of both species.

As in many malabsorptive diseases, dogs diagnosed with EPI also often present with low serum concentrations of cobalamin. Retrospective studies have shown that 75% to 82% of dogs diagnosed with EPI have low serum cobalamin concentration,[21,22] and this is associated with shorter survival.[21] This appears to be a very common comorbidity in cats with EPI as well, with two studies reporting low cobalamin in all feline EPI patients.[35,36] A prospective study with experimentally induced EPI showed that dogs with ligated pancreatic ducts had decreased cobalamin absorption as evidenced by increased fecal excretion, but the decrease in serum cobalamin concentrations did not reach significance.[37] The B_{12} binding ability of the intestinal microflora is also probably a factor in the absorption of cobalamin in dogs with EPI. Serum cobalamin concentration should be monitored and corrected if necessary in dogs diagnosed

Table 32-2 Nutritional and Medical Management of EPI and Its Complications

Feature	Pathogenesis	Management
Steatorrhea	Fat maldigestion; fat malabsorption	Enzyme replacement therapy; dietary fat modification
Diarrhea	Acid injury	Histamine H_2-receptor antagonists, H^+K^+-ATPase antagonists
	Bacterial proliferation	Oral antibiotics
Mucosal atrophy	Intrinsic factor deficiency	Vitamin B_{12}
Ravenous appetite	Protein-calorie malnutrition	Highly digestible diet
Weight loss	Protein-calorie malnutrition	Highly digestible diet
Refractory clinical signs	Acid inactivation of ERT	Histamine H_2 receptor antagonists

ATPase, adenosine triphosphatase; ERT, enzyme replacement therapy.

with EPI; lifelong parenteral supplementation is generally recommended.

Fat-Soluble Vitamins (Vitamins D, E, A, and K)

Fat-soluble vitamin status is largely dependent on adequate digestion and absorption of dietary fat. Many veterinary patients with steatorrhea caused by EPI may require supplementation.[38]

The degree of control of EPI appears to play an important role in fat-soluble vitamin status in veterinary EPI patients. In one study of dogs with naturally occurring and well-controlled EPI, only 8% (two of 24) had serum 25-OH vitamin D concentrations below the reference range, while 17% (four of 24) had serum hypovitaminosis E.[39] Vitamin A malabsorption was not apparent in this population as serum vitamin A did not differ among dogs with or without EPI when eating the same diet.[39] In dogs with untreated experimental EPI, serum vitamin A concentrations were lower than those of control dogs at baseline and after a single oral dose of vitamin A; however, coadministration of enzyme preparation increased the absorption of vitamin A in the EPI group only, but normal serum concentrations were not achieved.[40]

In addition to the degree of control of EPI, diet composition also appears to play a role in fat-soluble vitamin status. Absorption of vitamin E was higher for both normal dogs and those with controlled EPI when fed diets with 35% of the fat (by weight) provided by MCTs compared to diets fed with 0% MCTs.[39] The authors speculated that the effect may have been a result of enhanced absorption of vitamin E into portal circulation (vs. via lymphatics) as seen in other species when fed MCTs.[41] Higher serum concentrations of fat-soluble vitamins do not necessarily correlate with improved clinical signs or changes in other parameters[39]; consequently, the importance and benefit of maintaining potentially arbitrary serum concentrations with either parenteral or enteral supplementation is unclear.

Although any patient with EPI and clinical signs of coagulopathy should be evaluated for vitamin K deficiency, empirical supplementation does not appear to be warranted. There is one report of vitamin K–dependent coagulopathy secondary to uncontrolled EPI in a cat consuming a balanced commercial diet. Serum fat-soluble vitamins were not assessed and the cat improved with ERT alone.[42] Vitamin E supplementation is often recommended for patients with EPI. Given the wide margin of safety of vitamin E compared with vitamins A and D, empirical supplementation of moderate amounts is unlikely to be harmful but may or may not be helpful. It appears that most canine patients with controlled EPI are unlikely to show clinically significant deficiencies of fat-soluble vitamins. Similar data are not available for cats. Dogs and cats with well-controlled EPI that are consuming complete, balanced diets, appear to be at low risk of fat-soluble vitamin deficiency. In refractory cases with ongoing steatorrhea or for those with concurrent disease that is difficult to manage, supplementation may be warranted.

Adjunctive Treatments and an Individualized Approach to Exocrine Pancreatic Insufficiency

Other treatments may be needed in many patients with EPI (Table 32-2). Many patients need intermittent and recurrent antimicrobial therapy to control "overgrowth" of the intestinal microflora that follows loss of antibacterial secretion in the pancreatic fluid of EPI patients (see Chapters 1 and 60). Diarrhea may persist for several reasons, including bacterial hydroxylation of dietary fat, bacterial deconjugation of bile salts, and gastric acid injury to intestinal villi as a result of loss of pancreatic bicarbonate (HCO_3^-) secretion. Persistent clinical signs of gastrointestinal disease are not uncommon in dogs treated for EPI,[21] but it is unclear whether this represents concurrent disease problems or inadequate control of EPI. Histopathologic changes of the small intestine, including villus blunting and increased cellularity of the lamina propria, have been demonstrated in experimental EPI, which suggests these are direct adverse effects of EPI not attributable to distinct disease processes.[43] Regardless, it is clear that some patients will require adjustments in therapy, as well as investigation and treatment of concurrent disease.

Patients with diabetes mellitus or other concurrent disease will need these problems managed in a prioritized way to maintain a balance of good clinical response, appropriate therapy, and cost. Nutritional, medical, and surgical plans should be coordinated to ensure that control of any one problem is not to the detriment to the others. Although the pancreas plays a critical role in the assimilation of food, processes initiated in the stomach are also important. Hydrochloric acid and pepsinogen for digesting dietary protein, gastric lipase for digesting fat, and intrinsic factor for absorption of cobalamin are all secreted by the stomach. It is possible that variations in absolute or adaptive production of these substances may account for some of the variation among individuals treated for EPI.

CHAPTER 33

Enteral and Parenteral Nutrition

Stanley L. Marks

Nutritional support is aimed at minimizing development of malnutrition in animals at risk, while maintaining or enhancing immunologic and intestinal barrier function. The specific indications for enteral nutrition in people have changed over the years, and it is no longer contraindicated in patients with pancreatitis, ileus, and intestinal dysmotility.[1] Many techniques for obtaining enteral access are available, and the approach depends on several variables, including anticipated duration of enteral support, risk of aspiration, integrity of the gastrointestinal tract, the animal's temperament, the clinician's expertise, and the animal's tolerance of anesthesia.

Rationale for Enteral Nutritional Support

Enteral feeding is indicated for animals unable to ingest adequate amounts of calories, but that have sufficient gastrointestinal function to allow digestion and absorption of feeding solutions delivered into the gastrointestinal tract via an enteral feeding device. The rationale for prescribing enteral nutrition rather than parenteral nutrition (PN) is based on the superior maintenance of intestinal structure and function,[2] reduced infection rates,[3] and reduced cost of enteral alimentation. The average daily cost of total parenteral nutrition (TPN), hereafter referred to as central parenteral nutrition (CPN), for maintaining the caloric requirements of a 20-kg dog at the University of California, Davis, Veterinary Medical Teaching Hospital, is approximately five to 30 times greater (excluding catheter costs) than the cost of a commercial liquid enteral formula, and 60 times greater than the cost of a commercial canned diet for intestinal disorders. The most important stimulus for mucosal cell proliferation is the direct presence of nutrients in the intestinal lumen.[4] Bowel rest as a consequence of starvation or administration of CPN leads to villous atrophy,[5] increased intestinal permeability, and a reduction in intestinal disaccharidase activities.[6] Prolonged fasting in the stressed, critically ill animal can lead to intestinal barrier failure and increased permeability to bacteria and endotoxins. However, enteral nutrition may have shortcomings including underfeeding, perceived intolerance, aspiration, access-related complications, and diarrhea.[7]

Patient Selection for Nutritional Support

Efforts to assess nutritional status and attempts to decide whether nutritional support is required on the basis of a single biochemical measurement or body weight determination are simplistic and of limited value. Objective methods of assessing nutritional status, such as body composition measurement (anthropometry, bioelectrical impedance measurements, dual-energy X-ray absorptiometry) are still in their infancy in clinical veterinary medicine, with the result that a subjective global assessment of an animal's nutritional status needs to be performed. This technique is based on easily collected historical information (changes in oral intake, degree of weight loss, presence of vomiting or diarrhea) and changes found on physical examination (muscle wasting, body condition, and presence of edema or ascites). A technique referred to as subjective global assessment was developed for the nutritional assessment of human patients approximately 30 years ago.[8] The technique relies upon readily available historical and physical parameters to identify malnourished patients who are at increased risk for complications and who would benefit from nutritional intervention. The assessment involves determining (a) whether nutrient assimilation has been restricted because of reduced food intake, maldigestion, or malabsorption; (b) whether any effects of malnutrition on organ function and body composition are evident; and (c) whether the patient's disease process influences its nutrient requirements. The subjective global assessment can be adopted to dogs and cats by determining the following five aspects of the animal's medical history: (a) weight loss, (b) voluntary food intake, (c) the presence of persistent gastrointestinal signs, (d) the animal's functional capacity (e.g., presence of severe weakness or exercise intolerance), and (e) the metabolic demands of the patient's underlying disease state.

The body weight of the animal cannot be equated with its state of nourishment because it does not differentiate between fat, lean tissue, and extracellular water. The animal's serum albumin concentration and total lymphocyte count are insensitive determinants of nutritional status because of the large number of disease processes that influence these parameters unrelated to the effects of malnutrition (see Chapter 30). Nutritional support should be considered for animals that demonstrate recent unintentional weight loss that exceeds 10% of optimal body weight or for those whose oral intake has been or will be interrupted for more than 5 days. Animals with increased nutrient losses from chronic diarrhea or vomiting, wounds, renal disease, or burns should also be considered for nutritional support. Numerous methods exist for quantifying body composition and body fat mass in companion animals. In a clinical setting, the most widely accepted and practical method of body condition evaluation is condition scoring using visual assessment and palpation. This method affords a reproducible and clinically useful assessment of nutritional status. The body condition score is not affected by fluid shifts that can readily impact body weight, facilitating the improved assessment of nutritional status in the hospital or

intensive care environment. The most widely accepted system is the nine-integer scale system, which correlates well with body fat mass determined by dual-energy X-ray absorptiometry.[9] Body condition scoring schemes do not incorporate the loss of lean body tissue, although the recent implementation of a muscle condition score could further enhance the assessment of nutritional status[10] (see Chapter 30).

Calculation of Nutritional Requirements

Nutritional support provides substrates for gluconeogenesis and protein synthesis[11] and provides the energy needed to meet the additional demands of host defense, wound repair, and cell division and growth. The anticipated duration of nutritional support should be determined and factored into the nutritional support plan. In addition, the most optimal route of nutritional support should be determined (enteral versus parenteral) based on the underlying disease process, the integrity of the gastrointestinal tract, and the patient's clinical signs (intractable vomiting or diarrhea, dysphagia, etc.).

The provision of nutritional support should provide sufficient substrates for gluconeogenesis, protein synthesis, and energy to sustain vital physiologic processes such as immune function, wound repair, and cell division.[12] Although energy expenditure has been determined using indirect calorimetry in research populations of dogs, utilization of mathematical formulas remains the most efficient, cost-effective, and practical means of estimating a patient's energy requirement. An estimate of an animal's resting energy requirement (RER) is needed to determine the minimum amount of food necessary to sustain critical physiologic processes. The RER is the animal's energy requirement at rest in a thermoneutral environment and in a postabsorptive state. A linear formula can be applied to determine the RER of dogs and cats weighing between 2 and 45 kg, or, alternatively, an allometric formula (preferred by the author) can be applied to dogs and cats of all weights.

$$\text{Allometric formula: RER (kcal/day)} = 70\ (\text{body weight in kg})^{0.75}$$
$$\text{Linear formula: RER (kcal/day)} = 30\ (\text{body weight in kg}) + 70$$

Until recently, many clinicians multiplied the RER by an "illness factor" between 1.1 and 2 to account for the increased metabolism associated with different disease states and injuries. Veterinary nutritionists discourage the implementation of this extrapolated and subjective practice, and advocate a more cautious approach to minimize overfeeding and potential metabolic complications such as refeeding syndrome.[13] Nutritional support should initially deliver sufficient calories and protein to meet the patient's RER at its current weight, adjusted for body condition. Close observation of changes in body weight, physical examination findings (decreased subcutaneous fat stores, muscle wasting, and presence of edema or ascites), and ongoing losses (diarrhea, vomiting, exudative wounds) will help determine whether to increase or decrease the patient's caloric intake.

Diet Selection

The type of formula to feed the patient depends on the selected route of feeding, the functional status of the gastrointestinal tract, and the animal's nutrient requirements. Other factors, such as cost, availability, and ease of use also may be important. Animals fed via nasoesophageal or jejunostomy feeding tubes are limited to receiving liquid enteral formulas that have a caloric density of approximately 1.0 to 1.3 kcal per mL. Caution should be heeded when using human enteral formulas for longer than 2 weeks, particularly in cats, because most of these formulas contain less than 20% protein calories and they lack the essential amino acids, taurine, and arginine.

Polymeric solutions contain macronutrients in the form of isolates of intact protein (casein, lactalbumin, whey, egg white), triglycerides, and carbohydrate polymers. The carbohydrates are usually glucose polymers in the form of starch and its hydrolysates and the fats are of vegetable origin. The osmolality varies between 300 and 450 mOsm/kg in solutions with a caloric density of 1 kcal/mL; however, the osmolality may reach 650 mOsm/kg in solutions with a greater caloric density. Monomeric solutions contain protein as peptides or amino acids, fat as long-chain triglycerides, or a mixture of long-chain triglycerides and medium-chain triglycerides, and carbohydrates as partially hydrolyzed starch maltodextrins and glucose oligosaccharides. These solutions require less digestion and their absorption is more efficient than regular foods or polymeric solutions; however, the partially digested macronutrients contribute to the higher osmolality, which is between 400 and 700 mOsm/kg.

A variety of disease-specific enteral formulas are available for the management of critically ill human patients with renal disease, liver disease, diabetes mellitus, chronic obstructive pulmonary disease, and food allergies. The hepatic formulas offer increased amounts of branched chain amino acids: valine, leucine, and isoleucine; and reduced amounts of aromatic amino acids: phenylalanine, tyrosine, and tryptophan, compared with standard products. These alterations purportedly promote a reduced uptake of aromatic amino acids at the blood–brain barrier, reducing the synthesis of false neurotransmitters, and thereby ameliorating the neurologic symptoms that occur with hepatic encephalopathy (refer to Chapters 17 and 61).[14,15] Evidence supporting the use of hepatic formulas is very limited and controversial, and there is currently no clear consensus supporting the use of branched chain amino acids supplementation in people with hepatic cirrhosis and encephalopathy.[14,15] Enteral formulas enriched with arginine, omega-3 fatty acids, glutamine, and nucleotides are considered to enhance the immune response, although a systematic review of the evidence by Heyland et al. showed that immunonutrition reduced septic complications in critically ill adults, but this reduction did not result in reduced mortality.[16]

Commercial blended pet food diets are recommended for feeding via esophagostomy or gastrostomy tubes. In select cases, the feeding of a liquid enteral formulation may be indicated for feeding via nasoesophageal or jejunostomy tube. Feeding should be delayed for 12 to 24 hours after placement of a gastrostomy tube, to allow return of gastric motility and allow formation of a fibrin seal. In contrast, feeding can be instituted immediately after esophagostomy tube placement, once the animal has fully recovered from anesthesia. Diet can be administered as bolus feedings or continuous infusion when a gastrostomy tube is used for feeding. Improved weight gain and decreased gastroesophageal reflux have been reported in human patients given continuous feedings,[17] although similar studies are lacking in the veterinary literature. If continuous feeding is employed, it should be interrupted every 8 hours to determine the residual volume by application of suction to the feeding tube. If the residual volume is more than twice the volume infused in 1 hour, feeding should be discontinued for 2 hours, and the rate of infusion decreased by 25% to prevent vomiting. Treatment with metoclopramide (1 to 2 mg/kg/24 h as a constant-rate infusion) may be used to enhance gastric emptying and decrease vomiting.[18]

With bolus feeding, the required daily volume of food should be divided into four to six feedings. Dogs and cats are usually fed

approximately 25% of their caloric requirement on the first day of feeding, with a gradual increase of 25% of the caloric requirement per day. Most animals are able to reach their energy requirement by the fifth or sixth day of feeding. The food should be warmed to room temperature and fed slowly through the tube to prevent vomiting. Flushing the tube with 15 to 20 mL of lukewarm water helps prevent clogging. Before each feeding, the tube should be aspirated with an empty syringe to check for residual food left in the stomach from the previous feeding. If more than half of the last feeding is removed from the stomach, the feeding should be skipped and residual volume rechecked at the next feeding. Jejunal feeding can be started within 6 hours of tube placement if peristalsis is present. Continuous feeding should be used with jejunostomy feeding to avoid abdominal cramping and diarrhea associated with bolus feeding via this route. Continuous infusion is recommended at an initial flow rate of 1 mL/kg/h and increased gradually over 48 hours until the total daily volume can be given over a 12- to 18-hour period.[19]

Enteral Feeding Access Devices

Most feeding tubes today are made of polyurethane or silicone. The main shortcoming of silicone is related to its stiffness and flexibility. Silicone feeding tubes require thick sidewalls to obtain tube-wall integrity or stiffness. Because of this, the internal diameter of a silicon feeding tube is smaller than the internal diameter of a similar-sized polyurethane tube that does not require the degree of sidewall thickness for tube integrity.[20] The flexibility and decreased internal diameter of silicone tubes may lead to clogging or kinking of the tube. In addition, silicone is known for notch sensitivity that is associated with propagation of a defect in the material when the silicone gets a nick or a tear in it.[20] New feeding tube materials are being developed that are copolymers of silicone and polyurethane and other polymer end groups in an effort to mimic the softness of silicone and the durability and wall thickness of polyurethane. The French unit measures the outer lumen diameter of a tube (each French unit is equal to 0.33 mm).

Nasoesophageal Tubes

Nasoesophageal tubes are a simple and efficient choice for the short-term (less than 10 days) nutritional support of most anorectic hospitalized animals that have a normal nasal cavity, pharynx, esophagus, and stomach.[21] Nasoesophageal tube feeding is contraindicated in animals that are vomiting, comatose, or lack a gag reflex. Polyvinylchloride (Infant Feeding Tube, Argyle Division of Sherwood Medical, St. Louis, MO) or red rubber tubes (Robinson catheter, Sherwood Medical, St. Louis, MO) are the least-expensive tubes for dogs and cats, although the polyvinylchloride tubes may harden within 2 weeks of insertion and cause irritation or ulceration of the pharynx or esophagus. Although tubes made of polyurethane (MILA International, Inc., Erlanger, KY) or silicone (Global Veterinary Products, Inc., New Buffalo, MI) are more expensive, they are less irritating and more resistant to gastric acid, allowing prolonged usage. An 8-French, 91-cm tube with or without a tungsten-weighted tip is suitable for dogs weighing more than 15 kg. A 5-French tube is more comfortable for cats and smaller dogs.

The tube should terminate in the distal esophagus to decrease the likelihood of reflux esophagitis,[22] and this is facilitated by ensuring that the length of the tube approximates the distance from the tip of the nose to the seventh or eighth intercostal space. A tape marker is placed on the tube once the appropriate measurement has been made. Desensitization of the nasal cavity with 0.5 to 1 mL of 0.5% proparacaine hydrochloride is recommended. The head is tilted upward to encourage the local anesthetic to coat the nasal mucosa. The tip of the tube is lubricated with 5% lidocaine viscous prior to passage. The tube is passed by maintaining the animal's head in the normal angle of articulation (avoid hyperflexion or overextension of the head and neck) and gently directing the tip of the tube in a caudoventral medial direction. The tube should move with minimal resistance through the ventral meatus and nasopharynx and into the esophagus. Nasoesophageal intubation is more difficult to perform in dogs because of their long, narrow nasal passages and extensive turbinate structures. In addition, the presence of a small ventral ridge at the proximal end of the nasal passage in dogs necessitates directing the tip of the tube dorsally initially to allow passage over the ventral ridge and into the nasal vestibule (Fig. 33-1).[21] The tube is then directed in a caudoventral and medial direction while pushing the external nares dorsally.[23] This maneuver opens the ventral meatus and guides the tube into the oropharynx.

If the tube is unable to be passed with minimal resistance into the oropharynx, it should be withdrawn and redirected because it could be positioned in the middle meatus with the tip encountering the ethmoid turbinate. Once the tube has been passed to the level of the tube marker, it should be secured as close to the nostril as possible, with either suture material (Fig. 33-2A) or glue (Superglue, Loctite Corp., Cleveland, OH), although glue can cause a dermatitis in some animals. A second tape tab should be secured to the skin on the dorsal midline between the eyes (Fig. 33-2B and C). In the cat, the tube must not exit laterally nor come in contact with the whiskers. An Elizabethan collar is usually required for dogs to prevent inadvertent tube removal; most cats, however, do not require such a device. Removal of the tube is facilitated by clipping the hair that is attached to the glue.

After placement, the tube position is checked by injecting 5 to 10 mL of air while ausculting the cranial abdomen for borborygmus, by infusing 3 to 5 mL of sterile saline or water through the tube and observing for a cough response[21] (although a lack of a cough response is not always a reliable indicator of tube placement), or by obtaining a lateral survey thoracic radiograph. Verification of placement can also be done with an end-tidal CO_2 monitor. Tubes placed within the esophagus or stomach should yield no CO_2 when checked with an end-tidal CO_2 monitor. The most common complications associated with the use of nasoesophageal tubes include epistaxis, dacryocystitis, rhinitis, tracheal intubation and secondary pneumonia, and vomiting.[21]

A major disadvantage of nasoesophageal feeding tubes is their small diameter, necessitating the use of liquid enteral formulas. Commercially available canned pet foods that are diluted with water will invariably clog the feeding tube. The caloric density of most human and veterinary liquid enteral formulas varies from 1 to 2 kcal/mL. Diets are fed full strength on continuous (pump infusion) or bolus feeding schedules.

Esophagostomy Tubes

Esophagostomy feeding tubes are easily inserted, require only light general anesthesia with isoflurane or heavy sedation, and intubation with a cuffed endotracheal tube. The technique is minimally invasive and no specialized endoscopic equipment is needed.

The patient should be placed in right lateral recumbency, and the left lateral cervical region clipped and aseptically prepared for tube placement.[24-26] Placement of the feeding tube in the left side of the neck is preferred because the esophagus lies slightly left of midline making left-sided placement more desirable. A 14- to 20-French red rubber catheter (Robinson catheter, Sherwood Medical, St. Louis, MO), silicone catheter (Global Veterinary

Products, Inc., New Buffalo, MI), or polyurethane catheter (MILA International, Inc., Florence, KY) should be premeasured from the midcervical esophagus to the seventh or eighth intercostal space, and marked with a permanent marker to ensure the distal end of the catheter terminates in the distal esophagus.[22] The left midcervical area is aseptically prepared from the angle of the mandible to the thoracic inlet. Three basic techniques for placement of a midcervical esophagostomy tube have been described.[24-26]

Technique Using Curved Carmalt, Mixter, or Schnidt Forceps

Advance the right-angle forceps into the midcervical esophagus from the oral cavity. Use the angle of the jaw and the point of the shoulder for landmarks to help ensure that the tip of the forceps can be palpated externally in the midcervical region. Push the curved tips of the forceps laterally at the midcervical esophagus, so they can be palpated below the skin. A number 11 scalpel blade is used to make a stab incision through the skin only, exposing the subcutaneous tissue and muscle layers of the esophagus, and avoiding the jugular and maxillofacial veins. Exteriorize the tip of the forceps from the esophageal lumen through the skin incision. Guide the advancing forceps through the esophageal muscle layers and carefully dissect the esophageal mucosa off the tip of the forceps with a scalpel blade. Use the tip of the forceps to grasp the distal end of the feeding tube, and draw the tube out of the oral cavity. Secure the distal end of the feeding tube using the forceps to ensure that the tube remains exteriorized while the proximal end of the tube is pulled out of the animal's mouth. Retroflex the proximal tip of the feeding tube and advance it in an aboral direction across the pharynx and down the esophagus, while slowly retracting on the external end of the tube 2 to 4 cm. A guidewire can be used to facilitate pushing the proximal tip of the feeding tube into the esophagus. The exteriorized portion of the tube will be observed to rotate in a cranial direction as the tube moves down the esophagus, indicating correct placement of the tube in the esophagus. Retention sutures (Chinese finger-trap suture) using 2-0 polypropylene are used to secure the distal end of the tube to the skin. An additional method of securing the tube involves passing a heavy suture on a taper needle through the skin next to the tube and into the periosteum of the wing of the atlas. Antibiotic ointment and gauze dressing is placed at the incision site, and the tube and entrance site are loosely bandaged with conforming gauze wrap. The correct placement of the tube in the mid to distal esophagus should be confirmed radiographically. It is important to ensure that the tube does not traverse the gastroesophageal sphincter and predispose the patient to gastroesophageal reflux. Feeding can be instituted immediately following full recovery of the patient from anesthesia. The tube

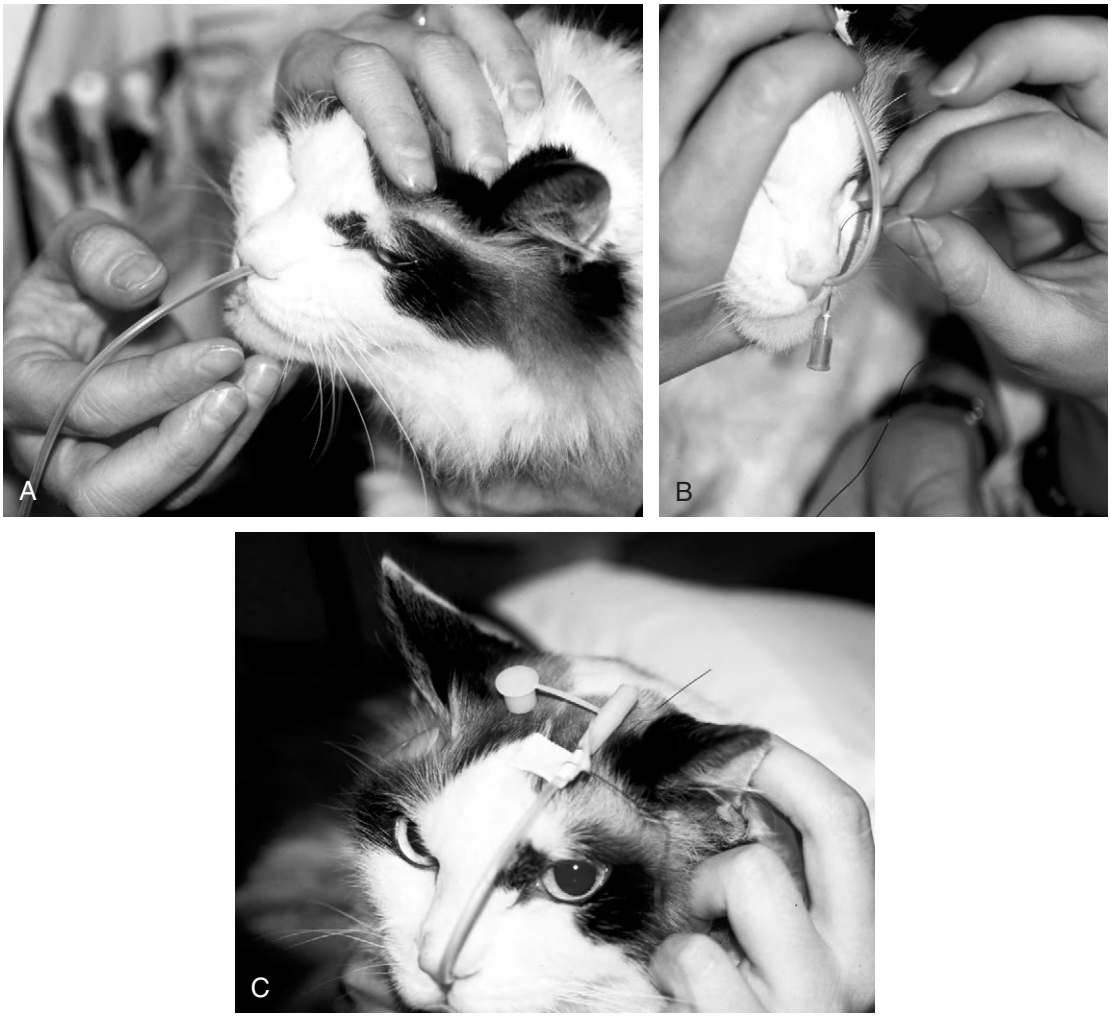

Figure 33-2 **A,** The tip of the nasoesophageal tube has been lubricated and passed into the ventral meatus by positioning the animal's head in a normal angle of articulation. **B,** The tube should be secured as close to the nostril as possible, with either suture material or glue. **C,** The nasoesophageal tube can be secured to the skin on the dorsal midline between the eyes with tape "butterflies."

esophagostomy–skin interphase should be examined at least daily during the first week for evidence of infection or leakage of food or saliva. The stoma site can be kept clean with a topical antiseptic solution (1:100 Betadine solution in 0.9% saline). The tube can be easily removed once nutritional support is no longer needed by cutting the Chinese finger-trap anchoring suture and pulling the tube. The wound should be allowed to heal by second intension.

Percutaneous Feeding Tube Applicator Technique

An alternative tube esophagostomy technique utilizing an ELD percutaneous feeding tube applicator or similar device can be used.[8] The applicator is inserted into the midcervical esophagus via the oral cavity. The distal tip is palpated, and an incision is made through the skin and subcutaneous tissue over the tip of the ELD. Activate the spring-loaded instrument (Fig. 33-3A) to advance the trocar through the esophageal wall and incision (Fig. 33-3B) The distal end of the feeding tube is secured to the eyelet of the trocar with suture material. The ELD device and attached feeding tube are retracted into the esophagus and exteriorized out of the oral cavity. The feeding tube is redirected into the midcervical esophagus after inserting a wire stylet into the distal tip of the feeding tube. The tube is secured to the skin as mentioned above previously.

Percutaneous Needle Catheter Technique

This method incorporates the use of an esophagostomy introduction tube (Van Noort esophagostomy tube set, Global Veterinary Products, Inc., New Buffalo, MI) (Fig. 33-4) that is introduced into the midcervical esophageal area. The slot in the distal portion of the tube is palpated, and a Peel-away sheath needle (Global Veterinary Products, Inc., New Buffalo, MI) is introduced into the distal portion of the tube. The needle is removed from the sheath, and a 10-French catheter is introduced through the sheath to the distal third of the esophagus. The sheath is peeled away and the esophagostomy tube is carefully removed. The feeding tube is secured as described previously. This technique has limitations as the small diameter of the feeding tube (10 French) only allows for the administration of fluids and liquid enteral formulas.

Despite the potential for esophageal scarring and stricture formation, esophageal stricture or a persistent esophagocutaneous fistula have not been reported. The most common minor complication is peristomal inflammation, with peristomal abscessation occurring infrequently.[24-27] Most of the inflammatory reactions are mild and respond to thorough cleansing with topical antibiotics. Other less-common complications include vomiting of the tube into the oral cavity and tube obstruction.[24-27]

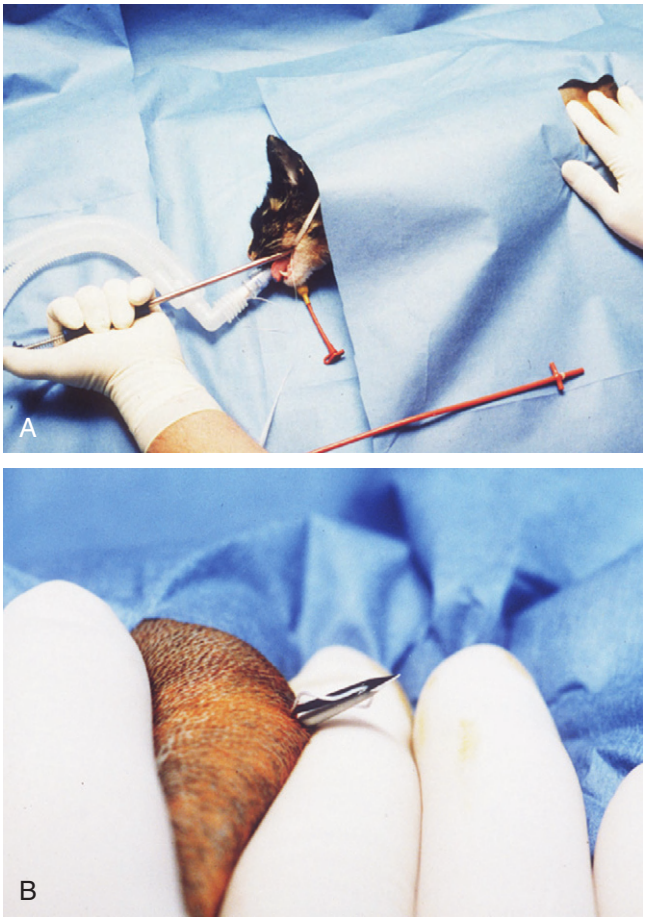

Figure 33-3 **A,** Demonstration of the ELD device for placement of an esophagostomy tube or blind percutaneous gastrostomy technique. Activation of the spring-loaded instrument advances the trocar through the esophageal or gastric wall. **B,** Suture material is attached to the exteriorized eyelet of the trocar, which is retracted into the lumen of the instrument and carefully removed from the esophagus and out the mouth of the animal. The exteriorized suture material is attached to a feeding tube.

Gastrostomy Tubes

Gastrostomy tube feeding is indicated for long-term (weeks to months) nutritional support of anorectic or dysphagic animals that have adequate gastrointestinal function to allow digestion and absorption of feeding solutions. Gastrostomy feeding tubes are of comparatively large diameter (20 to 24 French), allowing the economic use of blended pet foods and the direct administration of medications. Gastrostomy tube feeding is contraindicated in animals with persistent vomiting, decreased consciousness, or gastrointestinal obstruction. Caution should be exercised in conditions under which the stomach cannot be apposed to the body wall (severe ascites, adhesions, space-occupying lesions).

Gastrostomy tubes can be placed percutaneously or during laparotomy. Placement is usually accompanied via a percutaneous endoscopic gastrostomy (PEG) technique,[28,29] or a blind percutaneous gastrostomy technique.[30,31] There are a variety of feeding tubes that can be used for gastrostomy feeding, including latex, polyurethane, and silicon tubes with French-Pezzer mushroom, balloon, bumper, or silicone dome tips (Fig. 33-5). The silicone catheters can be purchased from Global Veterinary Inc., New Buffalo, KY and from US Endoscopy, Mentor, OH; polyurethane from MILA International, Inc., Erlanger, KY; and latex catheters from BARD Urological Division, Murray Hill, NJ. One can modify the catheters by cutting off and discarding the flared open end of the catheter and cutting off two 2-cm pieces of tubing (to be used as internal and external flanges) from the same end of the catheter. The end of the catheter opposite the mushroom tip is trimmed to facilitate its introduction into the larger opening of a disposable plastic micropipette. Make a small stab incision through the center of each flange and fit one flange over the cut end of the catheter, sliding it down until it rests against the mushroom tip. Use the other 2-cm piece of tubing as an external flange that lies against the abdominal wall.

Percutaneous Endoscopic Gastrostomy Technique

Endoscopic and blind placement of gastrostomy tubes necessitates brief anesthesia. The animal should be placed in right lateral recumbency so that the stomach tube can be placed through the greater curvature of the stomach and the left body wall. Patient preparation for both percutaneous procedures is identical and involves a surgical prep of the skin caudal to the left costal arch. The endoscope is introduced into the stomach and the stomach is carefully inflated until the abdomen is distended but not drum tight. The left body wall is transilluminated with the endoscope to ensure that the spleen is not positioned between the stomach and body wall. An

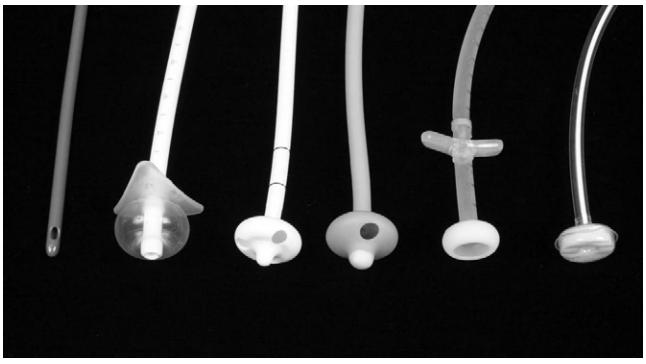

Figure 33-5 Gastrostomy tubes illustrating the various materials and catheter tips. From left to right: French red rubber catheter, silicone balloon catheter, silicone mushroom catheter, latex mushroom catheter, silicone catheter with dome, polyurethane catheter with bumper.

appropriate site for insertion of the tube is determined by endoscopically monitoring digital palpation of the gastric wall. A small incision is made in the skin with a scalpel blade, and an intravenous catheter (16 to 18 gauge, 1.5 to 2 inches) is stabbed through the body wall into the lumen of the stomach (Fig. 33-6A). The stylet is removed and nylon or polyester suture is threaded through the catheter into the lumen of the stomach. The suture material is grasped with the endoscopic biopsy forceps (Fig. 33-6B), and the endoscope and forceps are carefully withdrawn through the esophagus and out of the mouth. The suture material is secured to the feeding tube and gentle traction is applied to the suture material at its point of exit from the abdominal wall (Fig. 33-6C). The feeding tube is pulled out through the body wall allowing the mushroom end to draw the stomach wall against the body wall (Fig. 33-6D). The feeding tube is anchored in this position by the external flange placed over the catheter at the skin surface (Fig. 33-6E). The endoscope is then reinserted into the stomach to verify the correct placement of the mushroom against the gastric mucosa. If blanching of the mucosa is observed, less tension should be applied to the tube, otherwise necrosis of the gastric wall may ensue as a result of ischemia. A plastic clamp is placed over the tube and the tube is capped with a Y-port connector. A jacket made from stockinette (San Jose Surgical Supply, Inc., San Jose, CA) is fitted to protect the tube (Fig. 33-6F).

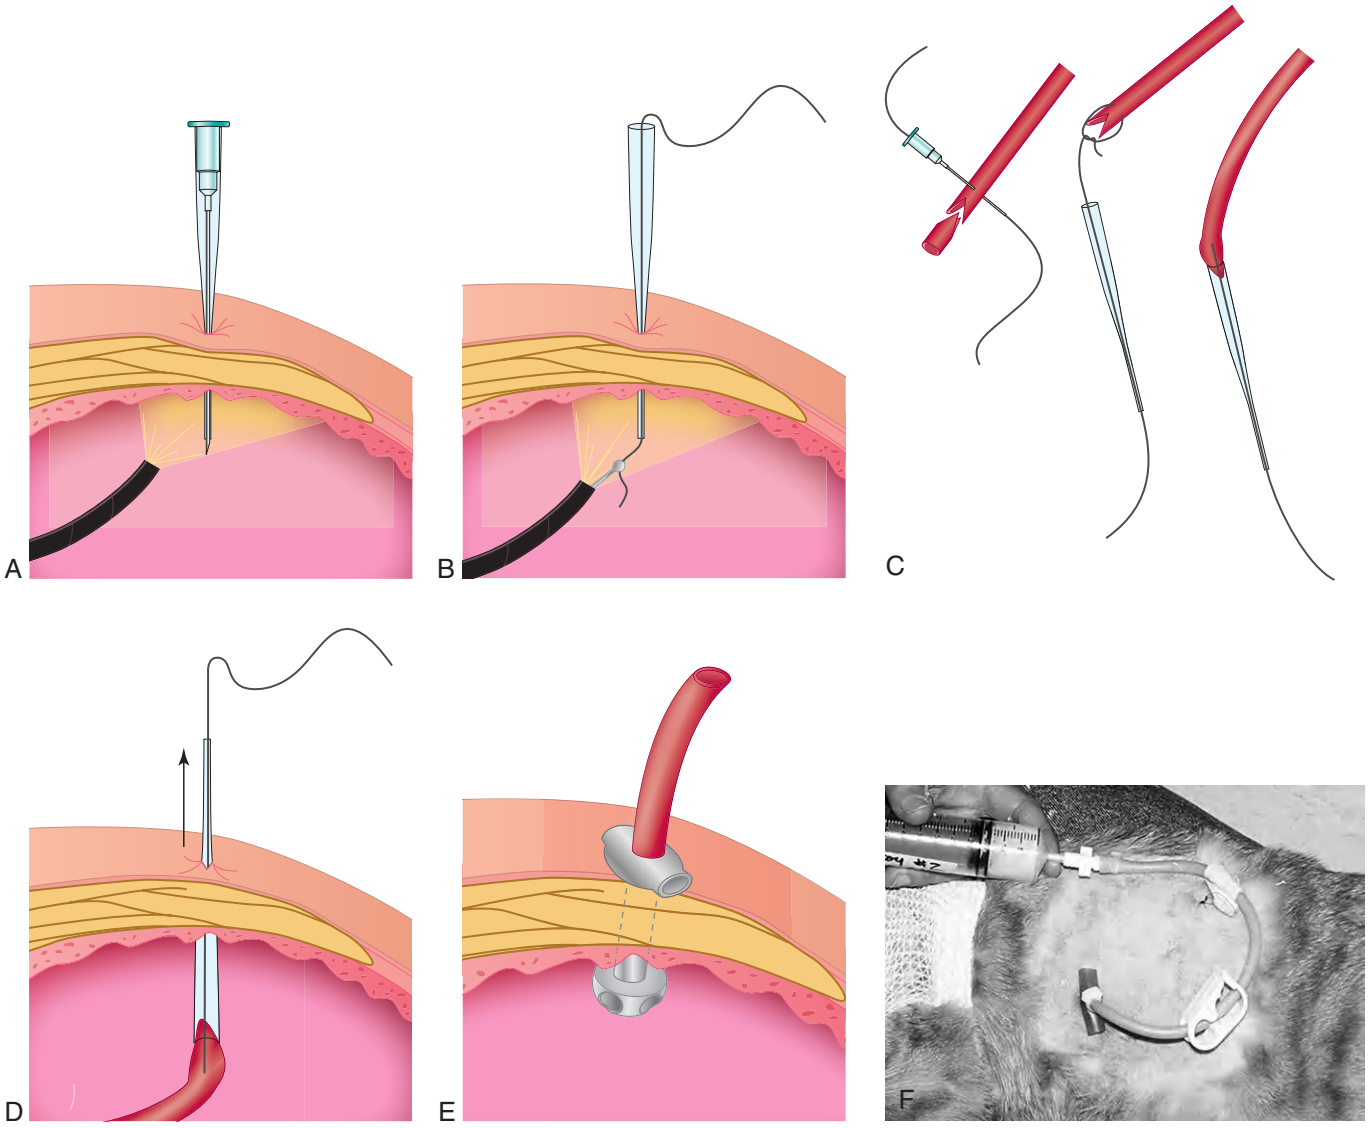

Figure 33-6 Percutaneous endoscopic gastrostomy (PEG) technique. **A,** With the animal in right lateral recumbency, the endoscope is introduced into the stomach, and the stomach is insufflated with air. The left body wall is transilluminated with the endoscope to ensure that the spleen is not between the stomach and the body wall. A 16- to 18-gauge sheathed catheter is pierced transabdominally into the insufflated stomach lumen. **B,** The catheter stylet is removed, and nylon suture is advanced through the catheter until it can be grasped with endoscopic retrieval forceps. The nylon suture is pulled out through the mouth as the endoscope is withdrawn. **C,** The suture material is secured to the feeding tube and water-soluble jelly is applied liberally to the catheter sheath and the mushroom-tip catheter. **D,** The lubricated catheter is drawn down the esophagus and into the stomach as the assistant applies traction on the suture exiting the abdominal wall. **E,** The catheter is advanced until the mushroom tip rests gently against the gastric mucosa. Endoscopy should be repeated to confirm the correct position of the mushroom tip. An external flange is fitted down the tube against the skin to prevent the tube from slipping into the stomach. **F,** Gastrostomy feeding tube in place in a cat, with the clamp in the open position. The stockinette jacket is pulled over the gastrostomy tube once feeding is completed.

Complications related to PEG tubes include those associated with placement of the tube (splenic laceration, gastric hemorrhage, and pneumoperitoneum), and delayed complications such as vomiting, aspiration pneumonia, tube extraction, tube migration, and stoma infection.[28,29,32] Splenic laceration can be minimized by insufflating and transilluminating the stomach prior to placement of the needle or catheter into the abdominal wall. The author has seen a discordant number of large-breed dogs that have had major complications secondary to the stomach falling off the silicone dome at the end of the gastrostomy tube. The stoma appeared normal in all dogs, with the unfortunate consequence that several dogs were fed through the gastrostomy tube. This complication occurred despite the placement of an internal flange between the dome and the gastric mucosa. For this reason, the author recommends that all dogs heavier than 30 kg, particularly those that have delayed wound healing secondary to malnutrition, uremia, or chemotherapy administration, do not have a PEG procedure, and instead have a gastrostomy tube placed surgically or placement of an esophagostomy tube. Minor complications include pressure necrosis at the stoma site and cellulitis.[28,29,32]

Blind Percutaneous Gastrostomy Technique

An alternative technique for nonendoscopic and nonsurgical gastrostomy tube placement has been described.[30,31] The gastrostomy tube placement device can be prepared with a length of vinyl or stainless steel tubing (diameter 1.2 to 2.5 cm) purchased from a hardware store, or an ELD Gastrostomy Tube Applicator (Jorgensen Laboratories, Loveland, CO) or gastrostomy tube introduction set (Global Veterinary Inc., New Buffalo, KY) can be used. The ELD Gastrostomy Tube Applicator is the only device that utilizes an internal trocar, whereas the Cook gastrostomy tube introduction set contains a wire that is threaded through an introduction needle. The distal tip of a stainless steel tube can be flared and deflected 45° to the long axis of the tube to help displace the lateral body wall. The lubricated tube is passed through the mouth and into the stomach. The tube is advanced until the end of the tube displaces the stomach and lateral abdominal wall. Positioning the animal with its head over the edge of the table and lowering the proximal end of the tube will facilitate identifying the tube tip through the body wall. For the Cook gastrostomy introduction set or similarly prepared device, a percutaneous needle is introduced into the lumen of the introduction tube while the assistant firmly holds the distal tip of the tube between two fingers. A skin nick is made over the end of the tube and a 14-gauge needle advanced into the lumen of the introduction tube (Fig. 33-7A). Proper positioning of the needle is confirmed by moving the hub from side to side and feeling the needle tip strike the inside of the tube. A guidewire included in the kit is threaded through the lumen of the needle, into the tube, and out the mouth of the patient. The introduction tube is removed from the patient, and the threaded end of the guidewire is secured to an adapter that fits snugly into the end of a feeding tube (Fig. 33-7B and C). Gentle traction is applied to the guidewire at its point of exit from the abdominal wall, facilitating the placement of the mushroom end of the feeding tube against the gastric mucosa. The feeding tube is secured in an identical fashion to the PEG tube procedure described above.

The reported complication rate for blind percutaneous gastrostomy is similar to that of PEG; however, the risk of penetrating the spleen, stomach, or omentum is greater when the stomach is not insufflated with air prior to positioning the tube against the lateral abdominal wall.[33] Contraindications to using the "blind" technique include severe obesity precluding accurate palpation of the tube against the abdominal wall and esophageal disease. Surgical placement of gastrostomy tubes should be reserved for these patients.

Jejunostomy Tubes

Jejunostomy tubes are indicated in patients unable to tolerate intragastric or intraduodenal feeding, despite having normal distal small

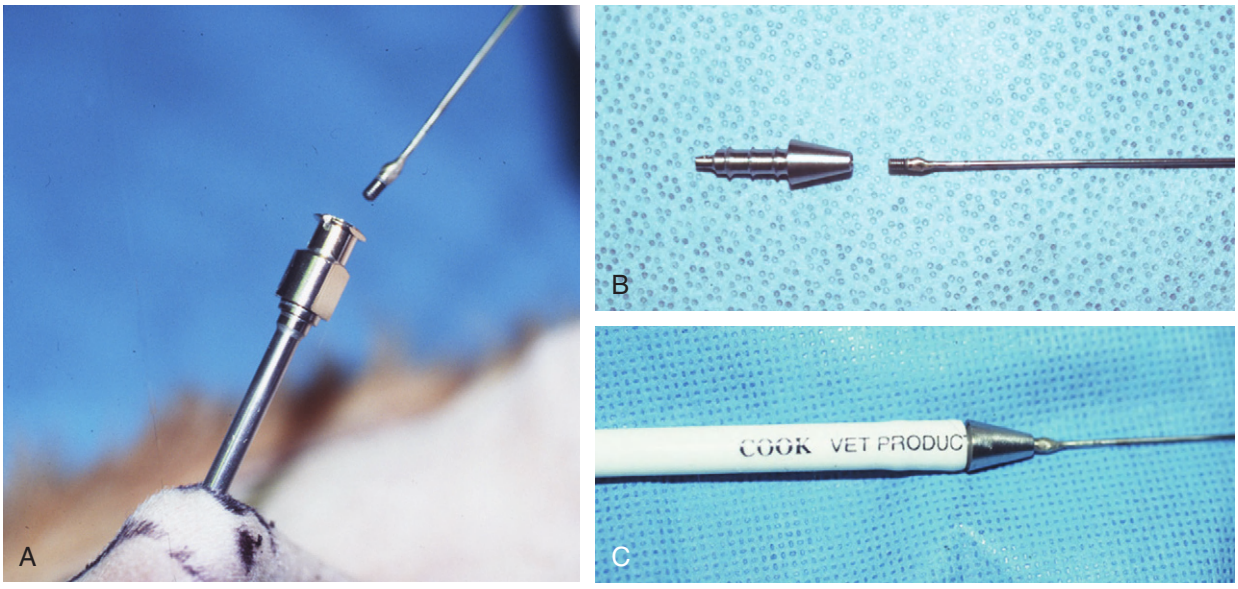

Figure 33-7 **A,** Cook gastrostomy introduction set showing a 14-gauge needle advanced into the lumen of the introduction tube. A guidewire included in the kit is threaded through the lumen of the needle, into the introduction tube, and out the mouth of the patient. **B** and **C,** Following the removal of the introduction tube from the animal, the threaded end of the guidewire is secured to an adapter that fits snugly into the end of the feeding tube. Gentle traction is applied to the guidewire at its point of exit from the abdominal wall to position the mushroom of the tube against the gastric mucosa.

intestine and colon function.[34] Specific indications for feeding via jejunostomy tube include gastric outlet obstruction, gastroparesis, recurrent/potential aspiration, proximal small bowel obstruction, and partial gastrectomy. Jejunal tube feeding minimizes the stimulation of pancreatic secretion and is a viable route for patients with severe pancreatitis.[34] Surgically placed jejunostomy tubes are the most widely used and familiar method for long-term feeding of the small intestine directly. An alternative approach to the surgical jejunostomy technique is the placement of a feeding tube via percutaneous techniques. This includes both percutaneous jejunostomy and percutaneous endoscopic gastrojejunostomy (PEG-J) tubes placed under fluoroscopic or endoscopic guidance. The advantage of the PEG-J technique is that it allows ready access to the stomach for aspiration of gastric luminal contents.

Successful placement of PEG-J tubes has been demonstrated in healthy dogs and cats,[35] according to the method described by Leichus et al.[36] Four sequential steps are followed: (a) routine PEG placement; (b) deep guidewire passage into the small intestine; (c) endoscope retraction leaving the guidewire in place; and (d) jejunostomy feeding tube placement over the guidewire. Briefly, the animal is anesthetized and placed in right lateral recumbency. A PEG tube is routinely placed, and the external portion of the tube trimmed to a length of 6 inches to maximize the amount of jejunostomy tube that can be passed into the small intestine. Placement of a 65-cm jejunostomy tube (Gastro-Jejunal feeding tube, Wilson-Cook Medical Inc., Winston-Salem, NC) works well in cats, whereas a jejunostomy feeding tube 95 cm or larger is recommended for most dogs. A standard loop snare is passed through the PEG tube into the stomach using an endoscope. The snare is opened and the endoscope advanced through the open snare toward the pylorus. The animal is then positioned in left lateral recumbency, and the endoscope is advanced as far down the small intestine as possible. The accessory channel of the endoscope is flushed with water to facilitate rapid passage of a guidewire that is passed down the biopsy channel into the small intestine. As the endoscope is carefully retracted into the stomach, the tip of the endoscope is pulled past the open snare, which is then closed snugly on the guidewire. The endoscope is then removed from the animal with the resultant extension of the guidewire out of the oral cavity. The closed snare is then pulled out through the gastrostomy tube, facilitating the exit of a portion of the guidewire from the opening of the gastrostomy tube. The snare is then released, and an assistant gently pulls on the proximal end of the guidewire. The oral end of the guidewire is pulled through the gastrostomy tube, leaving the distal (aboral) end in the small intestine. The jejunostomy tube is flushed with water, which activates a lubricant on its inner diameter. The jejunostomy tube is threaded over the guidewire under endoscopic guidance until its proximal end is seated in the gastrostomy tube. The guidewire is then removed from the PEG-J tube, and abdominal radiographs are taken to confirm adequate placement of the jejunostomy tube 40 to 60 cm distal to the pylorus. Passage of the jejunostomy tube deeply into the jejunum is deemed critical to prevent retrograde catheter migration into the stomach.

Esophagostomy, Gastrostomy, and Percutaneous Endoscopic Gastrojejunostomy Tube Removal

Unlike gastrostomy tubes, an esophagostomy tube can be removed the same day it is placed if necessary without concern for leakage and development of secondary complications. The dressing and sutures are removed while the tube is held in place. The tube is then occluded by kinking and pulled out using gentle traction. The ostomy site should be cleaned, antibiotic ointment applied, and a light dressing placed around the neck. The dressing should be removed in 24 hours, and the ostomy site inspected. The ostomy site should close within 36 hours. Skin sutures are not needed for closure of the ostomy site. For PEG tubes and PEG-J tubes, it is recommended that the PEG tube be left in place for a minimum of 14 days. Animals receiving immunosuppressive therapy or patients that are severely debilitated may require longer for a peritoneal seal to form. The tube should be removed only when oral food intake is sufficient to meet the patient's caloric requirement. One of two methods of Pezzer PEG tube removal can be applied. The tube can be cut at the body wall and the mushroom tip pushed into the stomach to be passed in the feces. This method is safe in medium- to large-size dogs because the mushroom and internal flange should be easily passed in the stool. Alternatively, a stylet can be inserted into the tube to flatten the mushroom tip, while exerting firm traction on the tube. This method is recommended for cats and small dogs, because the mushroom can cause intestinal obstruction. Removal of the MILA catheter is accomplished by deflating the bumper that occurs once the Y-port adapter is removed. Catheters with a dome (US Endoscopy) are removed by gentle, but firm traction on the tube. The gastrocutaneous tract should seal with minimal or no leakage within 24 hours.

Gastrostomy and Esophagostomy Tube Replacement

The PEG tube may malfunction or be prematurely removed by the patient, requiring replacement. If the gastrostomy tube is removed within 14 days of placement (before establishment of the gastrocutaneous tract), iodinated contrast material can be injected via the stoma site to determine if the gastrocutaneous tract is still intact, or a PEG procedure could be performed to evaluate the gastric mucosa and verify correct positioning of the replacement gastrostomy tube. If the tube is inadvertently removed once the gastrocutaneous tract is well healed, one can replace the original catheter with a balloon-type catheter (Flexiflo Gastrostomy tube, Ross Laboratories, Columbus, OH)[37] or a low-profile gastrostomy device (LPGD, Bard Interventional Products Division, Murray Hill, NJ) (Fig. 33-8A). Both catheter types do not require an endoscopic procedure or anesthesia for placement. The gastrostomy "button" is a small, flexible, silicone device that has a mushroom-like dome at one end and two small wings at the other end that lies flush with the outer abdominal wall (Fig. 33-8B). A one-way antireflux valve prevents reflux of gastric contents through the top of the tube. There are two types of LPGDs: obturated and nonobturated. The obturated device has an enlarged mushroom tip that must be stretched for placement in the stomach by using a special introducer (Fig. 33-8C).[38] The nonobturated tube works like a Foley catheter and does not require forceful entry into the gastrostomy stoma. The length of the gastrocutaneous fistula must be precisely determined to guide correct selection of the appropriate "button" shaft length. This is accomplished with a special stoma-measuring device provided with the kit. The main advantages of the LPGD include their durability because of their silicon material, decreased likelihood of inadvertent removal by the patient, and their aesthetically pleasing appearance to the owners.[39] An alternative low-profile device that can be used in lieu of a regular PEG tube or replacement low-profile device is a one-step or "initial placement" low-profile PEG tube (One Step Button, now renamed as EndoVive Low Profile Percutaneous Endoscopic Gastrostomy kit; Boston Scientific, Natick, MA) (Fig. 33-9A and B). The use of silicon spacers supplied by the manufacturer (Fig. 33-9C) helps ensure that the devices can be adapted to animals with different stoma tract lengths. A recent study evaluating complications

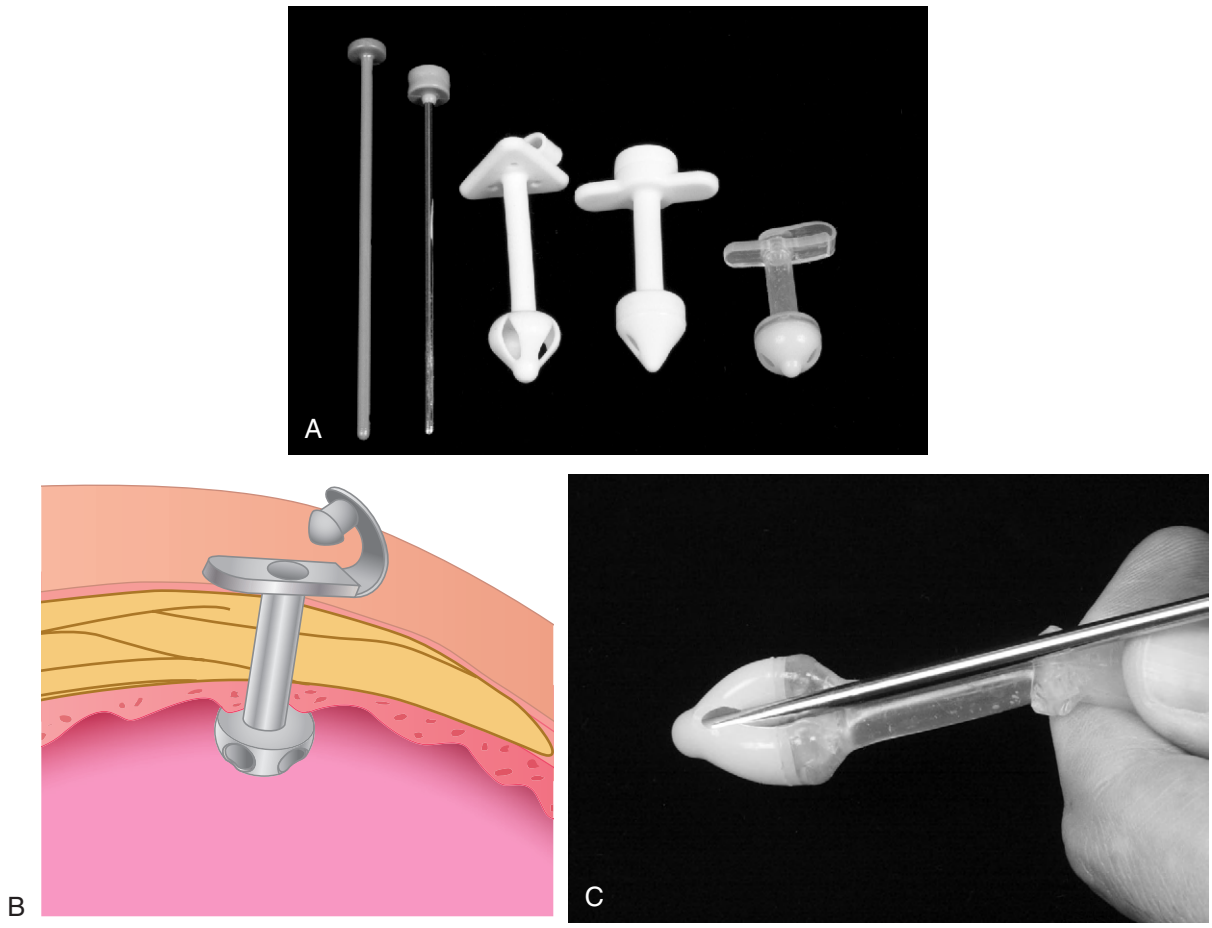

Figure 33-8 **A,** Low-profile gastrostomy devices and obturators used for stretching the dome-shaped tip of the device. From *left*: The Ross Laboratories Stomate low-profile device, the Cook low-profile device, and the Bard "Button" low-profile device. **B,** Low-profile gastrostomy device with small outer wings of the device lying flush against the skin of the abdominal wall. For feedings, the small plastic plug is removed and a feeding adapter is connected to a syringe. **C,** Correct technique for stretching the dome-shaped tip of the low-profile gastrostomy device with an obturator. The dome should not be stretched by passing the obturator through the lumen of the device as it will compromise the integrity of the antireflux valve located adjacent to the dome.

and outcomes of one-step low-profile gastrostomy devices for long-term enteral feeding in dogs and cats found that the devices were well tolerated, with most complications, including peristomal swelling and mucopurulent peristomal discharge, being relatively minor in nature.[40]

Complications of Enteral Feeding

Gastric Pressure Necrosis

Gastric pressure necrosis can occur from either the mushroom of the PEG tube or flange eroding the mucus layer of the stomach because of excessive tension being exerted on the PEG tube during placement. In addition, overzealous traction of the PEG tube followed by placement of the external flange flush against the skin of the patient can also cause pressure necrosis characterized by redness, swelling, and moistness of the skin. To minimize this problem, ensure that the PEG tube can be rotated following its placement and leave a 1-cm space between the external flange and the skin.

Feeding Tube Displacement

This is a relatively common problem, particularly with nasoesophageal and PEG-J tubes. Displacement of the tube can lead to aspiration, diarrhea, or in the case of gastrostomy tubes, peritonitis. Gastrostomy tubes should be marked with tape or a marking pen at the level of the skin to help verify the position of the tube. Detachment of the stomach from the abdominal wall with consequent intraperitoneal leakage of gastric contents can occur in large-breed dogs, and an internal flange should be placed in these animals to minimize dislodgment of the tube.

Tube Obstruction

Obstruction of the feeding tube is one of the most common complications of enteral feeding.[41] Most obstructions are secondary to coagulation of formula, although obstruction by tablet fragments, tube kinking, and precipitation of incompatible medications can also result in tube obstruction. Nasoesophageal tubes are prone to obstruction because of their small diameters, and obstruction also occurs up to three times more frequently in patients fed by continuous versus bolus feedings. Sucralfate and antacids have been reported to precipitate with enteral formulas and cause tube obstruction.[42] Several "remedies" have been advocated to relieve tube obstruction. Warm water injected with gentle pressure and suction will relieve most obstructions. For more unyielding obstructions, carbonated water is instilled into the tube and allowed to sit for

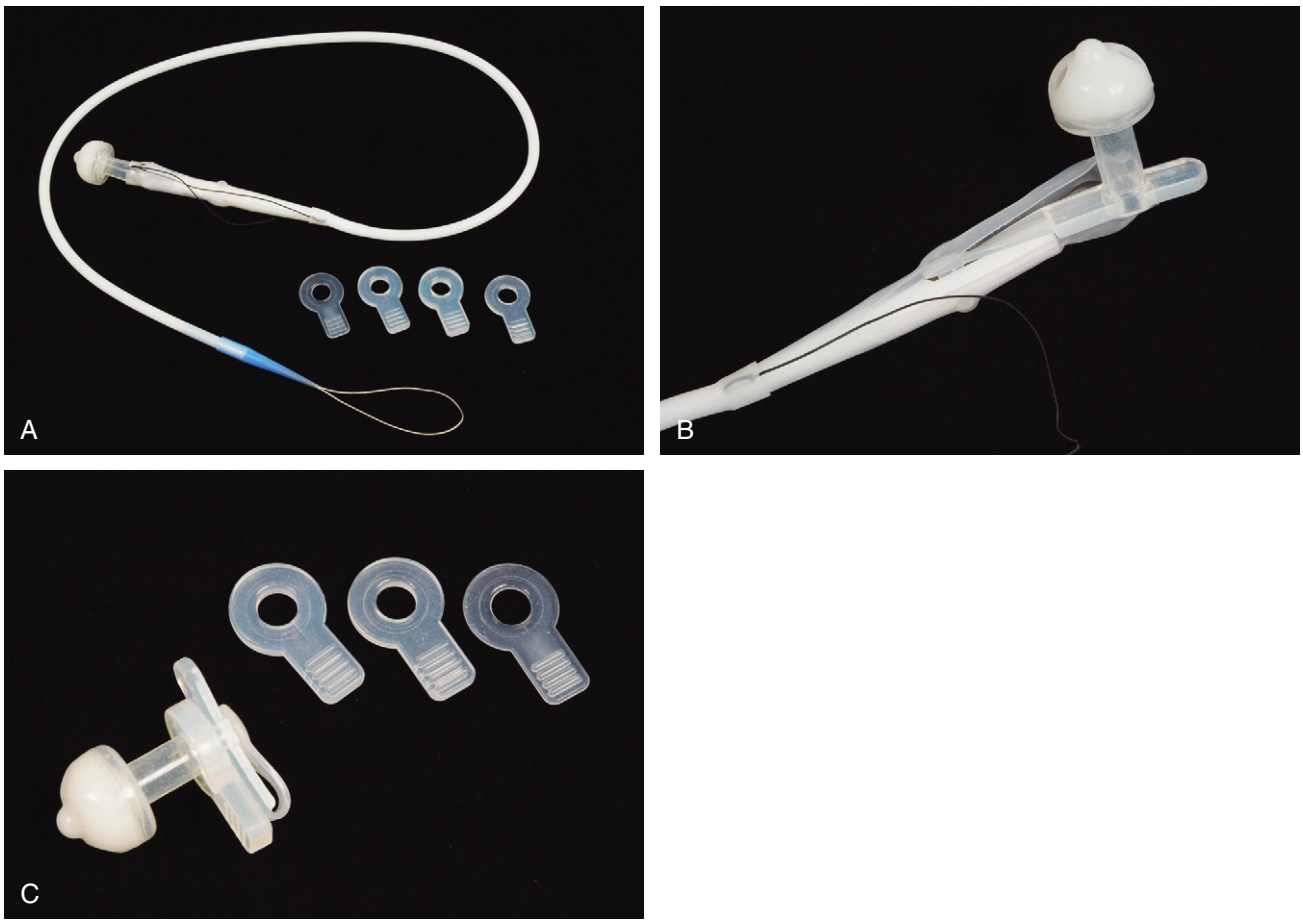

Figure 33-9 **A,** One-step low-profile gastrostomy device with flanges as it comes contained within a catheter sleeve. Four separate silicone spacers are also present. **B,** One-step low-profile gastrostomy device with flanges released after tearing the surrounding catheter sleeve open by pulling on the attached black suture material. **C,** One-step low-profile gastrostomy device separated from catheter sleeve, showing a single 5-mm silicone spacer inserted over the shaft, and three other separate silicone spacers of varying thickness.

1 hour before applying gentle pressure and suction. Pancreatic enzyme infusions[41] and meat tenderizer have also been advocated to dissolve tube obstructions. On rare occasions, the passage of an angiographic wire down the lumen is needed to unclog the tube. Tube obstructions can be minimized by flushing the feeding tube with warm water before and after administering medications or enteral feedings. The tube should also be flushed after checking for gastric residuals, because the acid pH will cause the formula to coagulate in the tube. Elixir forms of medication should be used rather than crushed tablet forms whenever possible. Tablets should be crushed and dissolved in water prior to administration through the feeding tube, if no alternative form of medication is available.

Leakage Through Ostomy Sites

Mild leakage at the stoma site can occur for the first few days following placement of the feeding tube. Persistent leakage may indicate tube dysfunction, peristomal infection, or a stoma site greater than necessary for the tube. Signs of inflammation with or without discharge or fever may indicate infection of the stoma site. These must be differentiated from fasciitis because a simple wound infection can usually be treated locally with dilute Betadine solution and more frequent dressing changes. Systemically administered antibiotics are usually reserved for patients with systemic signs of infection.

Aspiration

Pulmonary aspiration is a common complication of enteral feeding, although the actual incidence of this complication is difficult to determine due to the lack of consistency in how aspiration is defined. Risk factors for aspiration include impaired mental status, neurologic injury, absence of a cough or gag reflex, mechanical ventilation, and previous aspiration pneumonia.[43] The source of the aspirated material should be identified because withholding gastrostomy feedings or placing a jejunostomy feeding tube in a patient will have no benefit if the patient aspirated oropharyngeal secretions. Although controversial, most authors agree that postpyloric feeding reduces the risk of aspiration.[44] In addition, the use of continuous versus bolus feedings has been shown to induce less gastroesophageal reflux than bolus feedings.[45]

Diarrhea

Diarrhea is the most commonly cited complication associated with tube feeding in human and animal patients, with an incidence

ranging from 2.3% to 63%.[46] The clinical implications of enteral feeding–related diarrhea are significant. Severe diarrhea leads to fluid, electrolyte, and nutrient loss, and can cause considerable distress to the patient. Diarrhea in tube-fed patients occurs as a result of multiple factors, including hypoalbuminemia, hyperosmolar or high-fat diets, infected diets, and concomitant antibiotic therapy.[46] The incidence of diarrhea in enterally fed patients taking antibiotics far exceeds the incidence in normally fed patients taking the same antibiotics. Antibiotic-associated diarrhea may arise from overgrowth of enterobacteria (*Klebsiella, Proteus, Pseudomonas*) or from proliferation of *Clostridium difficile*.

Rationale for Parenteral Nutritional Support

CPN refers to the administration of a nutrient admixture into the cranial or caudal vena cava, or directly into the atrium. The term CPN is preferred to the outdated term, TPN, because admixtures used in these formulations are rarely nutritionally complete and balanced for the long-term feeding of patients, even if they supply the full caloric requirement. The indications for CPN have been dramatically altered in people over the past decade following the observation of serious septic and metabolic complications that often worsened patients' outcomes.[47] Deleterious consequences of CPN administration ascertained from results of human and animal studies include intestinal atrophy, decreased mucosal resistance to bacteria, abnormal liver function, increased rate of administration line sepsis, and metabolic complications such as hyperglycemia, blood electrolyte abnormalities, and hyperlipidemia.[2,3] A metaanalysis in which data collected from 27 studies involving 1828 patients were compared, revealed that tube feeding and conventional oral feeding with IV administration of dextrose were associated with a lower rate of infection than that associated with PN in patients with compromised function of the gastrointestinal tract.[3] Administration of CPN to 209 dogs and 75 cats was associated with a high mortality rate of 48% and 52%, respectively.[48,49] The average duration of PN in these studies was between 3 and 5 days, and the poor outcome in these animals was likely a consequence of suboptimal patient selection for PN and the large number of animals with advanced, complex medical disorders. The current use of CPN in people is restricted to the nutritional support of malnourished patients with intestinal failure as a result of extreme short bowel or absolute obstruction, although it might also prove useful to augment nutrition in patients who cannot tolerate sufficient intake by the enteral route. Because of these potential risks and the high cost associated with CPN, veterinary nutritionists have increasingly utilized peripheral parenteral nutrition (PPN) formulations,[50] that contain up to 10% dextrose and are thus not hyperosmolar (osmolality <750 mOsm/L), facilitating their administration via the cephalic or saphenous veins. PPN formulations typically meet 50% to 75% of the animal's RER and are administered for less than 1 week. PPN is thus a practical and beneficial strategy when the clinician anticipates a high likelihood of the patient being able to be weaned onto an enteral formula within days following the initiation of PPN. The major limitation in using PPN is the high incidence of thrombophlebitis.[30]

Parenteral Nutrition Components

The three basic components of parenteral nutrition solutions are amino acids, lipids, and dextrose. Crystalline amino acid solutions, available in concentrations of 3% to 15%, maintain nitrogen balance and replete lean tissue in cachectic patients. The standard amino acid solutions (Travasol 8.5% without electrolytes, Baxter Healthcare Corporation, Deerfield, IL) contain all the essential and dispensable amino acids for dogs and cats, with the exception of taurine. Lipid emulsions provide an intravenous source of fat calories and the essential fatty acids, linoleic and linolenic acid. Cats cannot convert linoleic acid to arachidonic acid, and should thus receive supplementation with an animal fat source if CPN is administered for longer than 2 weeks. Lipid emulsions are isotonic and are available as 10% (1.1 kcal/mL) or 20% (2 kcal/mL) solutions with osmolarities ranging from 270 to 340 mOsm/L, respectively. Lipid emulsions contain soybean oil (Intralipid, Baxter Healthcare Corporation, Deerfield, IL) or a combination of soybean and safflower oil triglycerides (Liposyn II, Hospira, Inc., Lake Forest, IL), egg phosphatides added as an emulsifying agent, and glycerin in water to achieve isotonicity with plasma. Sodium hydroxide is added to these products to adjust the pH to 6 to 9. The emulsified fat particles are comparable in size to chylomicrons and are removed from the circulation via the action of peripheral lipoprotein lipase. A common misconception exists in regards to the use of lipids in cases of pancreatitis. Although hypertriglyceridemia may be a risk factor for pancreatitis, infusions of lipids have not been shown to increase pancreatic secretion or worsen pancreatitis and are therefore considered safe.[51] According to the most recent guidelines provided by the American Society of Parenteral and Enteral Nutrition, human patients with serum triglycerides exceeding 400 mg/dL should have the lipid proportion in PN reduced or eliminated altogether.[51]

Carbohydrate is typically administered in the form of 50% dextrose for CPN, and 10% dextrose for PPN. Providing calories as glucose stimulates insulin secretion, reduces muscle protein catabolism, and inhibits hepatic glucose output, thereby eliminating the need for skeletal muscle protein to provide amino acid precursors for gluconeogenesis. Dextrose is the least expensive intravenous energy source and is available in concentrations ranging from 5% to 70%. The dextrose in intravenous solutions is hydrated, so that each milliliter of dextrose monohydrate provides 3.4 kcal. Standard parenteral maintenance doses of all vitamins should be provided as an additive to the TPN solution. Multivitamin preparations for TPN provide all fat- and water-soluble vitamins with the exception of vitamin K, which may be given subcutaneously once weekly. No formal recommendations are currently available for supplementation of trace minerals to dogs and cats receiving PN.

Parenteral Nutrition Compounding

The preparation and administration of parenteral nutrition solutions may present problems with stability and compatibility. Factors that enhance precipitation include high molar concentrations, increases in solution pH, decreases in amino acid concentration, use of calcium as the chloride salt, increases in temperature, contact with intravenous fat emulsions, and the order of calcium and phosphate addition.[52] Total nutrient admixtures is one term used to describe the combination of dextrose, amino acid, fat emulsion, electrolytes, and multivitamins in one container. These components are aseptically mixed in one bag (up to 3 L) and provide a total nutrient supply for 24 to 48 hours. The advantages of the total nutrient admixture system include decreased nursing time involved in intravenous setup and tubing changes, decreased risk of contamination, and time saved in the pharmacy during preparation. Amino acid solutions should be added to the lipid emulsion before the dextrose solution is added. This prevents deterioration of the emulsion and oiling out that can occur when dextrose (pH approximately

4) is added directly to the lipid emulsion.[52] Ideally, compounding of PN should be done aseptically under a laminar flow hood using a semiautomated, closed-system, PN compounder (e.g., Automix compounder, Clintec Nutrition, Deerfield, IL). Manual compounding can be done in a clean, low-traffic area with strict adherence to aseptic technique using a three-in-one bag if an automated compounder is not available. Formulations of CPN and PPN solutions can be either individualized for each patient according to established worksheets (Boxes 33-1 and 33-2) or, alternatively, preprepared "recipes" are available at many institutions that can save time and prevent the need for calculating individual macronutrients for each formulation. Standardized recipes can be prepared for critically ill dogs and cats with adequate renal and hepatic function (Boxes 33-3 and 33-4) or for hyper- or hypokalemic dogs and cats with altered renal and hepatic function.

Box 33-1 Calculation of Total Parenteral Nutrition in Dogs and Cats

1. Calculate resting energy requirement (RER)
   RER = 70 × (current body weight in kg)$^{0.75}$
   or for animals weighing between 2 and 45 kg:
   RER = (30 × current body weight in kg) + 70 RER
   = _____kcal/day
2. Protein requirements

	Canine (g/100 kcal)	Feline (g/100 kcal)
Standard	4	6
Reduced (hepatic/ renal disease)	2 to 3	3 to 4
Increased (excessive protein losses)	6	6

(RER ÷ 100) × _____ g/100 kcal = _____ g protein required/day
3. Volume of nutrient solutions required
   a. 8.5% amino acid solution = 0.085 g protein/mL
   ____g protein required/day ÷ 0.085 g/mL = _____mL/day of amino acids
   b. Nonprotein calories:
   The calories supplied by protein (4 kcal/g) are subtracted from the RER to get total nonprotein calories needed.
   ____g protein required/day × 4 kcal/g = ____kcals provided by protein
   RER – kcals provided by protein =____total nonprotein kcal/day required
   c. Nonprotein calories are usually provided as a 50:50 mixture of lipid and dextrose
   20% lipid solution = 2 kcal/mL
   To supply 50% of nonprotein calories
   ____lipid kcal required ÷ 2 kcal/mL = ___mL of lipid
   50% of dextrose solution = 1.7 kcal/mL
   To supply 50% of nonprotein calories
   ___dextrose kcal required ÷ 1.7 kcal/mL = ___mL of dextrose
4. Total daily requirements
   ____ mL of 8.5% amino acid solution
   ____ mL of 20% lipid
   ____ mL of 50% dextrose
   ____ total mL of TPN solution to be administered over 24 hours

Note: Given that over 80% of TPN is water, it is important to adjust the IV rates of the patient's IV fluids accordingly.
Rate of administration: Initially start at 25% to 33% of RER, and gradually increase rate over the next 48 hours to meet RER.

Parenteral Nutrition Administration

Cannulation of a large-bore, high-flow central vein, such as the cranial vena cava, permits infusion of hyperosmolar (usually >1600 mOsm/L) nutrient solutions that would not be tolerated by smaller, low-flow peripheral veins. The author prefers to use a multilumen polyurethane catheter for CPN (Arrow International Inc., Reading, PA) that is placed via a surgical cutdown procedure and is dedicated for PN administration. Dressings and tubing connecting the parenteral solutions with the catheter should be changed every 48 to 72 hours. A 0.22-µm filter is inserted between the intravenous tubing and the catheter when lipid-free PN is used and should be changed with the tubing. A 1.2-µm filter should be used when a total nutrient admixture containing a lipid emulsion is infused. Caloric requirements should be based on the animal's RER at initiation of PN. Although some recommendations provide all energy requirements with only dextrose and lipids, others account for the energy provided from amino acids in the calculation and subtract it

Box 33-2 Peripheral Parenteral Nutrition Calculation

1. Calculate resting energy requirement (RER)
   RER = 70 × (current body weight in kg)$^{0.75}$
   or for animals weighing between 2 and 30 kg:
   RER = (30 × current body weight in kg) + 70 RER
   = ____kcal/day
2. Calculate the partial energy requirement (PER)
   Plan to supply 60% of the animal's RER with PPN: PER = RER × 0.60 = ___kcal/day
3. Proportion of nutrient requirements according to body weight:
   (Note that for animals weighing ≤3 kg, the formulation will exceed maintenance fluid requirements.)
   a. Cats and Dogs 3 to 5 kg:
   PER × 0.20 = ____kcals/day carbohydrate required
   PER × 0.20 = ____kcals/day protein required
   PER × 0.60 = ____kcals/day lipid required
   b. Cats and Dogs 6 to 10 kg:
   PER × 0.25 = ____kcals/day carbohydrate required
   PER × 0.25 = ____kcals/day protein required
   PER × 0.50 = ____kcals/day lipid required
   c. Dogs 11 to 30 kg:
   PER × 0.33 = ____kcals/day carbohydrate required
   PER × 0.33 = ____kcals/day protein required
   PER × 0.33 = ____kcal/day lipids required
   d. Dogs >30 kg:
   PER × 0.50 = ____kcals/day carbohydrate required
   PER × 0.25 = ____kcals/day protein required
   PER × 0.25 = ____kcals/day lipid required
4. Volumes of nutrient solutions required:
   a. 5% dextrose solution = 0.17 kcals/mL
   ____kcals carbohydrate required/day ÷ 0.17 kcals/mL = ____ mL/day dextrose
   b. 8.5% amino acid solution = 0.34 kcals/mL
   ____kcals protein required/day ÷ 0.34 kcal/mL = ____ mL/day amino acids
   c. 20% lipid solution = 2 kcal/mL
   ____kcals lipid required/day ÷ 2 kcal/mL = ___ mL/day lipid
   = ____ total mL of PPN to be administered over 24 hours

Box 33-3 Standardized Central Parenteral Formula for Dogs

300 mL	50% Dextrose
500 mL	20% Intralipid
1000 mL	8.5% Travasol without electrolytes
10 mL	Vitamin B complex (by Vedco)
36 mEq	Potassium phosphate
Provides:	1.0 kcal/mL (1129 mOsm/L)

Macronutrient composition: 17% protein (4.9 g protein/100 kcal), 54% lipid and 29% CHO, on ME basis. 20 mEq potassium/L.
1800 mL total volume (sufficient for 30-kg dog at RER for 48 hours or 75-kg at RER for 24 hours)

Box 33-4 Standardized Central Parenteral Formula for Cats

100 mL	50% Dextrose
200 mL	20% Intralipid
500 mL	8.5% Travasol without electrolytes
5 mL	Vitamin B complex (by Vedco)
16 mEq	Potassium phosphate
20 mEq	Potassium/L
Provides:	0.9 kcal/mL (1096 mOsm/L)

Macronutrient composition: 21% protein (6.1 g protein/100 kcal), 55% lipid and 24% CHO on ME basis
800 mL total volume (sufficient for 7-kg cat RER for 48 hours)

from the daily RER to estimate the total nonprotein calories required (see Boxes 33-1 and 33-2). The administration set and fluid bag must be protected from UV light to prevent degradation of B vitamins. The PN solution and entire administration set should be changed every 48 hours regardless of the volume remaining to decrease risk of bacterial growth in the solution and risk of sepsis. The administration line should be dedicated for PN administration and should not be broken (keep attached for walks and client visits) unless changing the administration set. The PN flow rate should be gradually increased over 48 hours to meet the patient's RER. Likewise, PN should be gradually tapered over 48 hours before discontinuation to prevent rebound hypoglycemia.

Monitoring

A complete blood count and serum biochemical profile should be performed prior to initiation of PN support. Body weight, fluid intake, and fluid output should be measured daily, whereas serum electrolytes, phosphorus, and glucose concentrations can be determined every 48 hours until stable and then rechecked weekly. Serum triglyceride concentrations should be evaluated early in the course of parenteral nutrition to document adequate triglyceride clearance. Triglyceride concentrations greater than 400 mg/dL necessitate either reduction of the rate of infusion or complete discontinuation of lipid supplementation. Providing 30% to 40% of total calories as lipid, however, does not stimulate the pancreas and can attenuate the hyperglycemia of pancreatitis.[53]

Complications

A total of 473 complications were recorded in 209 dogs receiving TPN over an 84-month period at the University of California, Davis, Veterinary Medical Teaching Hospital.[48] Metabolic complications were the most commonly encountered problems occurring during TPN administration (70% of complications), with transient hyperglycemia being the most common metabolic complication. Hyperglycemia was also the most commonly identified medical complication in a retrospective study of 75 cats administered TPN, and a significant association was identified between hyperglycemia and increased mortality rate at 24 hours.[49] Effective control of glycemia in critically ill human patients has been associated with a marked reduction in the incidence of bloodstream infections, and intensive insulin treatment in critically ill human patients partially prevents the anticipated postoperative decrease in neutrophil phagocytic function, ameliorates the depression in oxidative function in the alveolar macrophages, and reverses the decreased intracellular bacteriocidal activities in leukocytes.[54,55] Other less-common metabolic complications included hyperbilirubinemia, increased alkaline phosphatase activity, and hyperlipemia. Mechanical complications comprised 25% of the complications observed and included inadvertent catheter removal, catheter occlusion, disconnection or breakage of the line, and venous thrombosis. Mechanical complications can be reduced with meticulous catheter care and close patient monitoring. Catheter or solution-related sepsis was a relatively infrequent complication (5% of complications) because of scrupulous catheter care and insertion technique.

Summary

The field of interventional tube feeding is rapidly expanding, and is being matched by the proliferation of innovative enteral access techniques and the development of specialized feeding tubes. There has been a progressive downward trend in the use of CPN in veterinary institutions, predominantly as a consequence of the cost and recognition that this nutritional modality is no longer the "holy grail" in our nutritional armamentarium. Human and veterinary nutritionists have become increasingly aware of the detriments associated with the withholding of enteral nutrition in our hospital patients, and are more proactive in trickle-feeding patients enterally to preserve the integrity of the intestinal tract, while relying upon PN to augment the patient's energy intake. Peripheral PN represents a practical and relatively safe method for providing the bulk of the patient's nutritional needs for the short-term (<1 week), and can be effectively used alone or combined with enteral nutrition.

CHAPTER 34

Antidiarrheal Agents

Robert J. Washabau

Pathogenesis of Diarrhea

When clinical signs are acute and there are no systemic signs of illness, symptomatic therapy often takes precedence over achieving a precise diagnosis. When the duration of clinical signs is chronic (>3 weeks), or if there are systemic signs of illness, a determined effort should be made to achieve a specific diagnosis. Diarrhea in companion animals may develop through one or more pathophysiologic mechanisms,[1] but one mechanism tends to predominate.[1,2]

Luminal Maldigestion

Small intestinal bacterial overgrowth (SIBO) and Exocrine pancreatic insufficiency (EPI) are the best examples of luminal maldigestion in companion animals. SIBO (or antibiotic-responsive diarrhea) and EPI induce maldigestion, steatorrhea, and diarrhea because of bacterial degradation of pancreatic enzymes (SIBO) or insufficiency of enzyme secretion (EPI). Fat maldigestion and steatorrhea may also result from deficiencies in bile salt secretion (e.g., intra- or extrahepatic cholestasis) or abnormalities in the enterohepatic recirculation of bile salts (e.g., portosystemic vascular shunts).

Villous Atrophy

Atrophy of the villous absorptive surface area occurs with many pathologic processes. Atrophy is caused by accelerated loss of enterocytes or decreased production of enterocytes by stem cells in the crypts. Stem cells retain the ability to reconstitute the overlying mucosa, but regeneration may take days to weeks depending upon the pathologic process. Viral infections (e.g., parvovirus, coronavirus, rotavirus) are the most important causes of damage to villus enterocytes in dogs and cats. Viral enteritides are usually acute, self-limiting infections that resolve over a matter of a few days to 1 to 2 weeks. Villous atrophy may result from immune-mediated processes such as gluten-sensitive enteropathy in the Irish Setter dog,[3] or as a consequence of food sensitivity reactions in both dogs and cats.[4] Food sensitivity reactions are increasingly recognized as an important cause of villous atrophy, malassimilation, and diarrhea in companion animals. Immunosuppressive drugs (e.g., glucocorticoids, vincristine, azathioprine, cyclophosphamide) may also cause severe villous atrophy. Glucocorticoids are frequently prescribed in the management of inflammatory bowel disease (IBD). Antiinflammatory doses of glucocorticoids appear to have minimal effect on epithelial cell turnover, but immunosuppressive doses may abolish epithelial cell renewal. These effects are usually reversible with discontinuation of therapy.

Enterocyte Dysfunction

Enterocyte dysfunction is a common finding in many of the primary gastrointestinal disorders of dogs and cats. Enterocyte dysfunction may be seen with inflammation, infection, malnutrition, malignancy, ischemia, and with certain drug therapies (e.g., misoprostol). Gastrointestinal tract pathology induces enterocyte dysfunction by impeding Cl^- transport, the Na^+/glucose cotransporter, the voltage-dependent calcium channel, or any other component of the cell's signal transduction pathways.[2]

Brush-Border Membrane Maldigestion

SIBO is the major cause of brush-border membrane damage in the canine intestine. Hydrolase and other brush-border transport proteins are degraded by bacteria, particularly anaerobes, during proliferation of small intestinal bacteria. Damage to the brush-border is usually reversible following appropriate antimicrobial therapy. Similar brush-border membrane maldigestion has been documented in canine IBD, but these changes are also readily reversible with resolution of IBD.[1,2] A specific brush-border membrane malabsorption has been documented in Giant Schnauzers with cobalamin deficiency and malabsorption.[5]

Mucosal Barrier Disruption

Just as the stomach has evolved with mucosal barrier properties to reduce the deleterious effects of gastric acidity, the intestine has evolved with mucosal barrier properties to exclude bacterial pathogens and to maintain oral tolerance.[6-9] Barrier disruption may be caused by moderate to severe inflammation, ulceration, ischemia, cytotoxic drugs, and certain protein-losing states. Inflammatory mediators such as interferon-γ, tumor necrosis factor-α, and platelet-activating factor mediate some of the effects on mucosal barrier disruption.[10]

Hypersensitivity

The role of dietary hypersensitivity reactions in the pathogenesis of canine and feline chronic diarrhea is incompletely understood, although recent studies suggest that adverse reactions to food antigens are common in dogs and cats with chronic diarrhea.[4] True allergy or immunoglobulin E–mediated reactions appear to be rare

in companion animals.[4] Food hypersensitivity reactions may evoke more generalized inflammatory responses involving histamine, leukotrienes, prostaglandins, substance P, or 5-HT (serotonin) effects on gastrointestinal absorption, secretion, permeability, and motility.

Mucosal Inflammation

Inflammation is a major cause of chronic diarrhea in both dogs and cats. Although gut inflammation may be induced by many different inciting causes (e.g., dietary antigens, bacterial pathogens, toxins, neoplasia), experimental studies suggest that the immune response is initiated and sustained as a result of exposure to dietary antigens and/or indigenous gut bacteria. Cellular components (T and B lymphocytes, plasma cells, macrophages) and molecular elements (prostaglandins, leukotrienes, complement, platelet-activating factor, nitric oxide, and oxygen-derived free radicals) contribute to the mucosal inflammatory response. The clinical signs of IBD (diarrhea, vomiting, anorexia) are somewhat related to the severity of the mucosal cellular infiltrates and inflammatory mediators.[11,12] (Functional abnormalities, e.g., changes in the permeability or motility of the gut, may contribute to the clinical signs in many animals.)

Neoplasia

Intestinal neoplasia may induce diarrhea by several pathophysiologic mechanisms, including obstruction-induced fluid secretion, release of bioactive substances (e.g., histamine with diffuse mast cell disease, 5-HT with intestinal carcinoid, and gastrin with gastrinoma), bacterial proliferation and overgrowth, protein and lipid exudation, and reduction of the normal villous absorptive surface area.

Lymphatic Transport Disorders

Lymphangitis and intestinal lymphangiectasia are the most common lymphatic transport disorders in the dog. Lymphangiectasia is fairly common in the dog, but rare in the cat. Lymphangiectasia may occur as a primary congenital disorder, or more frequently, it may develop secondarily to IBD,[13] neoplastic infiltration, or right-sided heart failure.

Multiple Pathophysiologic Mechanisms of Diarrhea

Some diarrheal disorders result from one pathogenic mechanism, but others may have several concurrent pathogenic mechanisms, for example, maldigestion, malabsorption, excessive secretion, changes in permeability, protein and lipid exudation, and disordered motility.[2] EPI is often regarded as a classic maldigestive disorder. In the absence of pancreatic enzyme secretion, undigested protein, lipid, or carbohydrate cannot be further absorbed. Affected animals develop diarrhea, steatorrhea, and severe protein-calorie malnutrition. These same animals develop SIBO, gastric acid–induced injury to the intestinal mucosa, cobalamin malabsorption, and hypersecretion of fluid and electrolytes. It is for these reasons that pancreatic insufficient animals may have incomplete response with pancreatic enzyme replacement therapy. Bacterial infection is another example of a diarrheal disorder with multiple pathophysiologic mechanisms. The heat-stable enterotoxin of enteropathogenic *Escherichia coli* stimulates guanylate cyclase production of cyclic guanosine monophosphate (cGMP) and activation of cGMP-dependent protein kinases, culminating in secretory-type diarrhea. At the same time, platelet-activating factor, prostaglandins, and leukotrienes produced during bacterial infection may contribute to the malabsorption and disordered motility of *E. coli* infections.

Specific Therapy of Diarrhea

The best clinical outcomes will be obtained with definitive diagnosis and specific therapy (see Section VI). A cat with intestinal lymphoma, for example, will have a better outcome if it is correctly diagnosed and treated with chemotherapy. Similarly, a German Shepherd dog with diarrhea, steatorrhea, weight loss, and ravenous appetite will have a much better outcome if it is correctly diagnosed with EPI and appropriately medicated with pancreatic replacement enzymes. Table 34-1 outlines other examples of definitive diagnoses and specific therapies.

Nonspecific Therapy of Diarrhea

Definitive diagnosis and specific therapy may not be possible in all cases. This is especially true of cases of IBD in which sequential, nonspecific therapy may be needed to control mild to severe clinical signs (Box 34-1).[2,11,12,14] The pet owner may not permit a detailed medical investigation, or a definitive diagnosis may not be reached despite a detailed and appropriate medical investigation. In these cases, it would be entirely appropriate to consider nonspecific forms of therapy. The criteria for commencing nonspecific therapy should include: (a) the diarrhea is chronic, frequent, and/or severe; (b) definitive diagnosis is not forthcoming; and (c) the client does not desire definitive diagnosis.[2,12,14]

Dietary Therapy

The precise immunologic mechanisms of canine and feline IBD have not yet been determined, but a prevailing hypothesis for the development of IBD is the loss of immunologic tolerance to the normal bacterial flora or food antigens. Accordingly, dietary modification may prove useful in the management of canine and feline IBD. Several nutritional strategies have been proposed for the management of gastrointestinal tract disease including novel proteins, hydrolyzed diets, antioxidant diets, prebiotics, medium-chain

Table 34-1 Examples of Definitive Diagnoses and Specific Therapies

Pathogenesis	Specific Therapy
Food sensitivity reaction	Dietary modification
Bacterial infection	Antibiotics
Parasitic infection	Anthelmintic agents
Fungal infection	Antifungal agents
Pancreatic insufficiency	Pancreatic enzymes
Intestinal cancer	Chemotherapy
Lymphangiectasia	Dietary fat modification
Hyperthyroidism	Chemo- or radiotherapy

Box 34-1 Sequential, Nonspecific Therapy in Inflammatory Bowel Disease

1. Dietary modification
2. Physical exercise
3. Antibiotics
4. Probiotics
5. Antidiarrheal agents
6. Restoration of motility
7. Immunosuppressive agents
8. Behavioral modification

triglyceride supplementation, low-fat diets, modifications in the omega-6-to-omega-3 fatty acid ratio, and fiber supplementation. Of these strategies, some evidence-based medicine has emerged for the use of novel protein, hydrolyzed, antioxidant supplemented, and prebiotic diets.[2,11,14]

Novel Proteins

Food sensitivity reactions were suspected or documented in 49% of cats presented because of gastroenterologic problems (with or without concurrent dermatologic problems) in a prospective study of adverse food reactions in cats.[4] Beef, wheat, and corn gluten were the primary ingredients responsible for food sensitivity reactions in that study, and most of the cats responded to the feeding of a chicken- or venison-based selected-protein diet for a minimum of 4 weeks. The authors concluded that adverse reactions to dietary staples are common in cats with chronic gastrointestinal problems and that they can be successfully managed by feeding selected-protein diets. Further support for this concept comes from studies in which gastroenterologic or dermatologic clinical signs were significantly improved by the feeding of novel proteins.

Hydrolyzed Diets

Evidence is accruing that hydrolyzed diets may be useful in the nutritional management of canine IBD. The conceptual basis of the hydrolyzed diet is that oligopeptides are of insufficient size and structure to induce antigen recognition or presentation.[15] In one preliminary study, dogs with IBD showed significant improvement following the feeding of a hydrolyzed diet, although they had failed to respond to the feeding of a novel protein.[16] Clinical improvement could not be solely attributed to the hydrolyzed nature of the protein source because the test diet had other modified features; that is, high digestibility, cornstarch rather than intact grains, medium chain triglycerides, and an altered ratio of omega-6-to-omega-3 polyunsaturated fatty acids. Additional studies will be required to ascertain the efficacy of this nutritional strategy in the management of IBD.

Physical Exercise

Experimental IBD in the dog is accompanied by significant abnormalities in the normal gastrointestinal motility. Physical exercise has been shown to disrupt the jejunal, ileal, and colonic migrating motor complexes and to increase the total duration of contractions that are organized as non-migrating motor complexes during the fed state. Exercise also induces giant migrating contractions, defecation, and mass movement in both the fasted and fed states. The increased motor activity of the intestine and colon and extra giant migrating contractions that result from physical exercise may aid in normal gastrointestinal motor function.[17]

Antibiotics

Some IBD cases are initiated by true enteric pathogens, whereas others are complicated by SIBO. Some IBD cases may show short-term responsiveness to one or more antibiotics, for example, tylosin, metronidazole, or oxytetracycline.

Probiotics

Probiotics are living organisms with low or no pathogenicity that exert beneficial effects (e.g., stimulation of innate and acquired immunity) on the health of the host. The Gram-positive commensal lactic acid bacteria (e.g., lactobacilli) have many beneficial health effects, including enhanced lymphocyte proliferation, innate and acquired immunity, and anti-inflammatory cytokine production. *Lactobacillus rhamnosus* GG, a bacterium used in the production of yogurt, is effective in preventing and treating diarrhea, recurrent *Clostridium difficile* infection, primary rotavirus infection, and atopic dermatitis in humans.[18] *L. rhamnosus* GG has been safely colonized in the canine gastrointestinal tract, although probiotic effects in the canine intestine have not been firmly established.[19] The probiotic organism, *Enterococcus faecium* (SF68), has been safely colonized in the canine gastrointestinal tract, and it has been shown to increase fecal immunoglobulin A content and circulating mature B ($CD21^+$/major histocompatibility complex class II^+) cells in young puppies.[20] It has been suggested that this probiotic may be useful in the prevention or treatment of canine gastrointestinal disease. This organism may, however, enhance *Campylobacter jejuni* adhesion and colonization of the dog intestine, perhaps conferring carrier status on colonized dogs.[21] *Lactobacillus acidophilus* has also been shown to safely colonize the canine gastrointestinal tract.

Antidiarrheal Agents

The major physiologic functions of the small intestine are luminal and brush-border digestion, secretion, and absorption (see Chapter 1). Other physiologic properties of the small intestine, for example, motility and blood flow, have evolved to regulate digestion, secretion, and absorption. The anatomic structures in support of these functions include the serosa, longitudinal smooth muscle, myenteric or Auerbach's plexus, circular smooth muscle, submucosal or Meissner's plexus, muscularis mucosa, and mucosa. Epithelial cells in the intestinal mucosa are specialized primarily for membrane brush-border enzymatic (e.g., disaccharidases, peptidases) digestion, fluid and electrolyte secretion, and absorption. The crypt is the germinal center of the intestinal epithelium. Crypt epithelial cells are primarily secretory in function—water, solutes, and bicarbonate are secreted into the intestinal lumen to solubilize the chyme, neutralize gastric acid, and reduce the bacterial microflora. As cells migrate up the intestinal villi, they mature into absorptive cells. Villus epithelial cells are primarily absorptive in function—water, solutes, glucose and other monosaccharides; amino acids and small peptides; free fatty acids and glycerol; minerals and vitamins; and other nutrients are absorbed from the lumen into villus epithelial cells. Submucosal plexus neurons innervate the overlying mucosa and regulate absorption and secretion by the villus and crypt epithelial cells, respectively. Myenteric plexus neurons innervate the longitudinal and circular smooth muscle layers and regulate intestinal motility. Contraction of longitudinal smooth muscle stimulates peristaltic type activity and net fluid transit, while contraction of circular smooth muscle mediates segmentation type activity and delay in fluid transit.

In health, villus epithelial cells actively absorb Na^+ and Cl^-, and passively absorb H_2O (see Fig. 1-17). In malabsorptive disorders, Na^+, Cl^-, and H_2O absorption are often markedly reduced in villus epithelial cells. Absorption may be inhibited through a number of mechanisms, including the effects of prostaglandins (e.g., prostaglandin E_2), leukotrienes, cyclic nucleotides (cyclic adenosine monophosphate, cGMP), serotonergic (serotonin or 5-hydroxytryptamine), and vasoactive intestinal polypeptide receptor activation. Stimulation of absorption by these cells, on the other hand, is mediated by noradrenergic (norepinephrine) and opioid (μ,δ-opioid) receptor activation. The pathophysiology of malabsorptive disorders serves as the basis for medical therapy such as prostaglandin synthetase inhibitors, μ,δ-opioid agonists, serotonergic antagonists, and noradrenergic agonists (see Fig. 1-17).

In health, crypt epithelial cells actively secrete Cl^- or HCO_3^-, and H_2O (see Fig. 1-17). In hypersecretory disorders, Cl^- and H_2O secretion is often markedly increased in crypt epithelial cells. The

pharmacology of the secretory crypt cell is remarkably similar to that of the absorptive villus cell. Thus, crypt epithelial cell secretion may be stimulated by prostaglandins (e.g., prostaglandin E_2), leukotrienes, cyclic nucleotides (cyclic adenosine monophosphate and cGMP), serotonergic (serotonin or 5-hydroxytryptamine), and vasoactive intestinal polypeptide receptor activation (see Fig. 1-17). Inhibition of secretion by these cells, on the other hand, is mediated by noradrenergic (norepinephrine) and opioid (μ,δ-opioid) receptor activation. The pathophysiology of hypersecretory disorders serves as the basis for medical therapy, for example, prostaglandin synthetase inhibition, serotonergic receptor antagonism, noradrenergic receptor agonism, and μ,δ-opioid receptor agonism (see Fig. 1-17).

Prostaglandin Synthetase Inhibitors

Sulfasalazine is a highly effective prostaglandin synthetase inhibitor that has proven efficacy in the therapy of large bowel IBD in the dog.[2,14] Sulfasalazine is a compound molecule of mesalamine (formerly 5-aminosalicylate) and sulfapyridine linked in an azo chemical bond. Following oral dosing, most of the sulfasalazine is transported to the distal gastrointestinal tract where cecal and colonic bacteria metabolize the drug to its component parts. Sulfapyridine is largely absorbed by the colonic mucosa, but much of the 5-aminosalicylate remains in the colonic lumen where it inhibits mucosal lipoxygenase and the inflammatory cascade. Sulfasalazine has been recommended for the treatment of canine large bowel IBD at doses of 10 to 30 mg/kg PO q8-12h for 4 to 6 weeks. With resolution of clinical signs, sulfasalazine dosages are gradually decreased by 25% at 2-week intervals and eventually discontinued while maintaining dietary management. Salicylates are readily absorbed and induce toxicity in cats, therefore this drug classification should be used with great caution in cats.[22] If used in cats, some authors have recommended using half of the recommended dog dose (i.e., 10 to 30 mg/kg PO q8-24h). Sulfasalazine usage has been associated with the development of keratoconjunctivitis sicca in the dog, so tear production should be assessed subjectively (by the pet owner) and objectively (by the veterinarian) during usage.[23,24]

Other 5-Aminosalicylates

This drug classification was developed to reduce the toxicity of the sulfapyridine portion of the parent molecule (sulfasalazine) and to enhance the efficacy of the 5-aminosalicylate. Mesalamine (Dipentum, Asacol) and dimesalamine (olsalazine) are available for use in the treatment of canine large bowel IBD. Olsalazine has been used at a dosage of 10 to 20 mg/kg PO q8h in the dog. Despite the formulation of sulfa-free 5-aminosalicylate preparations, instances of keratoconjunctivitis sicca have still been reported in the dog.

μ,δ-Opioid Agonists

These drugs stimulate circular smooth muscle contraction and therefore intestinal segmentation. Loperamide concurrently stimulates absorption, and inhibits secretion of, fluid and electrolytes. Loperamide, at a dose of 0.1 mg/kg PO q8-12h, is the preferred drug in this category.

5-HT_3 Serotonin Antagonists

Antagonists of the neuronal 5-HT_3 receptor inhibit Cl^- and H_2O secretion from intestinal epithelial cells. Examples of drugs in this classification include ondansetron (Zofran, Glaxo) at a dose of 0.5 to 1 mg/kg BID PO; granisetron (Kytril, SmithKline Beecham) at a dose of 0.1 to 0.5 mg/kg PO or IV q12h; tropisetron (Navoban, Novartis) at a dose of 0.5 to 3 mg/kg BID PO; and dolasetron (Anzemet, Sanofi-Aventis) at a dose of 0.6 to 1 mg/kg BID PO, IV, SQ.

α_2-Adrenergic Antagonists

These drugs must be used carefully as they can activate α_2-adrenergic receptors in the chemoreceptor trigger zone and cause vomiting. Clonidine, at a dose of 5 to 10 μg/kg BID-TID SQ/PO, is the best example in this classification.

Restoration of Normal Motility

The mixed μ,δ-opioid agonist, loperamide, stimulates fluid and electrolyte absorption while stimulating segmentation-type intestinal motility. Loperamide (0.1 mg/kg PO q8-12h) may be beneficial in the treatment of difficult or refractory cases of IBD.

Immunosuppressive Therapy

Glucocorticoids

Antiinflammatory to immunosuppressive doses of prednisone or prednisolone may be used to treat IBD in dogs that have failed to respond to dietary management, sulfasalazine, or metronidazole, and as adjunctive therapy to dietary modification in feline IBD.[14] Prednisone or prednisolone are used most frequently, as both have short durations of action, are cost-effective, and are widely available. Equipotent doses of dexamethasone are equally effective but may have more deleterious effects on brush-border enzyme activity. Prednisone should be used for 2 to 4 weeks depending upon the severity of the clinical signs. Higher doses of prednisone (e.g., 2 to 4 mg/kg PO daily) may be needed to control severe forms of eosinophilic colitis or hypereosinophilic syndrome in cats. Combination therapy with sulfasalazine, metronidazole, or azathioprine may reduce the overall dosage of prednisone needed to achieve remission of clinical signs. As with sulfasalazine, the dose of glucocorticoid may be reduced by 25% at 1- to 2-week intervals, while hopefully maintaining remission with dietary modification.

Budesonide

Because of steroid side effects and suppression of the hypothalamic–pituitary–adrenal axis, several alternative glucocorticoids have been developed that have excellent topical (i.e., mucosal) antiinflammatory activity but are significantly metabolized during first pass hepatic metabolism. Budesonide has been used for many years as an inhaled medication for asthma, and an enteric-coated form of the drug is now available for treatment of IBD in humans (and animals). There is little evidence-based medicine in support of the use of this medication in canine or feline IBD, but doses of 3 mg/m^2 Po once daily every other day have been used with some success in anecdotal cases.

Azathioprine

Azathioprine is a purine analogue that, following DNA incorporation, inhibits lymphocyte activation and proliferation. It is rarely effective as a single agent, and it should instead be used as adjunctive therapy with glucocorticoids. Azathioprine may have a significant steroid-sparing effect in IBD. Doses of 2 mg/kg PO q24h in dogs and 0.3 mg/kg PO q48h in cats have been used with some success in IBD. It may take several weeks or months of therapy for azathioprine to become maximally effective. Cats particularly should be monitored for side effects, including myelosuppression, hepatic disease, and acute pancreatic necrosis.

Cyclosporine

Cyclosporine has been used in the renal transplantation patient for its inhibitory effect on T-cell function. In more recent times, cyclosporine has been used in a number of immune-mediated disorders, including keratoconjunctivitis sicca, perianal fistula (anal furunculosis), and immune-mediated hemolytic anemia. Anecdotal reports

suggest that cyclosporine (3 to 7 mg/kg PO daily) may be useful in the treatment of some cases of refractory IBD. Evidence-based medicine studies are needed to establish efficacy, but anecdotal experience suggests that cyclosporine may be useful in some of the more difficult or refractory cases of IBD. Modified formulations of cyclosporine (i.e., cyclosporine-modified) are preferable to the original (unmodified) formulation.

Chlorambucil

Chlorambucil (1.5 mg/m^2 PO every other day) has been used in place of azathioprine in some difficult or refractory cases of feline IBD.

Behavior Modification

IBD and irritable bowel syndrome very likely have underlying behavioral components. Abnormal personality traits and potential environmental stress factors were identified in 38% of dogs in one study. Multiple factors were present in affected households, including travel, relocation, house construction, separation anxiety, submissive urination, noise sensitivity, and aggression.[25] The role of behavior in the pathogenesis and therapy of canine and feline gastrointestinal disorders remains largely unexplored (see Chapter 42).

Prognosis

Most reports indicate that the short-term prognosis for control of IBD is good to excellent.[12,14] Following completion of drug therapy, many animals are able to maintain remission of signs with dietary management alone. Treatment failures are uncommon and are usually a result of (a) incorrect diagnosis (it is especially important to rule out alimentary lymphosarcoma), (b) presence of severe disease such as histiocytic ulcerative colitis and protein-losing enteropathy or irreversible mucosa lesions such as fibrosis, (c) poor client compliance with appropriate drug/dietary recommendations, (d) use of inappropriate drugs or nutritional therapy, and (e) presence of concurrent disease such as SIBO or hepatobiliary disease. The prognosis for cure of IBD is poor, and relapses should be anticipated.

CHAPTER 35

Antiemetic Agents

Robert J. Washabau

Vomiting or emesis is a complex reflex pathway that has evolved to protect animals from ingested toxins, but it holds greater importance because of the large number of medical conditions that may cause or be associated with it.[1,2] Emesis may occur with such diverse conditions as systemic (e.g., septicemia, multiple organ failure), metabolic (e.g., uremia, liver failure), and endocrine (e.g., hyperthyroidism, hypoadrenocorticism) disease, as well as with the inflammatory, infectious, neoplastic, obstructive, and toxicologic disorders of the primary gastrointestinal tract, pancreas, liver, and biliary tract. In each of these circumstances, vomiting is believed to be activated through a neural or humoral mechanism.[3,4]

Physiology of Vomiting: Humoral and Neural Pathways

The first mechanistic studies of vomiting were carried out by Borison and Wang in the early 1950s.[3,4] Those authors postulated a two-component model of vomiting involving activation of a humoral or neural pathway. In the Borison-Wang model, vomiting was postulated to occur through activation of the chemoreceptor trigger zone (CRTZ) by bloodborne substances (*humoral pathway*), or through activation of the emetic center by vagosympathetic, CRTZ, nucleus tractus solitarius, vestibular, or cerebrocortical neurons (*neural pathway*). Through a complicated series of experiments, Borison and Wang showed that activation of the CRTZ by circulating emetogenic substances (e.g., uremic toxins, cardiac glycosides, endotoxins, and apomorphine) could be abolished by CRTZ antagonism, but not by vagotomy, sympathectomy, or emetic center antagonism. At the same time, neural activation of the emetic center by gastrointestinal disease (e.g., inflammation, infection, obstruction, toxicity) could be abolished by vagotomy, sympathectomy, and emetic center antagonism, but not by CRTZ antagonism. Thus, vomiting was most easily explained by two independent mechanisms: one mechanism involving an essentially neural pathway, the other mechanism operating through a humorally dependent pathway.[3,4] The Borison-Wang two-component model has helped to explain many of the vomiting disorders of animals and humans. The model is not without challenge, however, and it has been suggested that there are parallel mechanisms for the initiation of emesis in response to any stimulus, and it is the sum of the inputs that drives the emetic response.[5] In other words, emesis need not be simply an either/or response. The concept of a discrete emetic center has also been seriously challenged. Based on more recent electrophysiologic studies, a model of sequential activation of a series of effector nuclei (e.g., nucleus tractus solitarius, retrofacial nucleus, dorsal motor nucleus of the vagus) has been proposed that doesn't require a discrete emetic center.[5] Despite contemporary reexamination, there still is good agreement on two general patterns of emesis, one humoral and the other neural (Figure 35-1).

The essential component of the *humoral* pathway is the CRTZ located within the area postrema, which is sensitive to activation by bloodborne substances. The CRTZ is located anatomically outside of the blood–brain barrier and is readily perfused by substances in the systemic circulation. Receptors within the CRTZ may be activated by many endogenous (e.g., uremic-, hepatoencephalopathic-, or endotoxins) or exogenously derived (e.g., digitalis glycosides, *cis*-platinum, apomorphine) bloodborne substances. Many pharmacologic approaches to antiemetic therapy are based on receptor interactions at the CRTZ, emphasizing the *humoral* pathway of emesis.[1,4]

Although many antiemetic agents are based on CRTZ pharmacology, many spontaneous vomiting disorders result from activation of the *neural* pathway. Vomiting associated with primary gastrointestinal tract disease (e.g., inflammation, infection, malignancy, toxicity) results from activation of an afferent neural pathway, nucleus tractus solitarius neurons, and the emetic center. Efferent information transmitted back to the gastrointestinal tract stimulates the motor correlates of vomiting; that is, retrograde duodenal and gastric contractions, relaxation of the gastroesophageal sphincter, gastroesophageal reflux, opening of the proximal esophageal sphincter, and evacuation of gastrointestinal contents.[7] A *neural* pathway can also be involved in vomiting associated with motion sickness. Although there are important species differences,[8-10] motion within the semicircular canals is transduced to vestibulocochlear neurons that ultimately synapse in the CRTZ (dog) or emetic center (cat). Finally, a *neural* pathway involving cerebrocortical neurons is very likely involved in vomiting disorders associated with anxiety or anticipation, but its importance in companion animals has not yet been established.

Pharmacology of Vomiting: Neurotransmitters and Receptors

Chemoreceptor Trigger Zone

Neurochemical studies have demonstrated the presence of several neurotransmitters: dopamine, norepinephrine, 5-hydroxytryptamine (5-HT, serotonin), acetylcholine, histamine, substance P, and enkephalins; their respective receptors or binding sites: D_2 dopaminergic, α_2 adrenergic, 5-HT_3 serotonergic, M_1 cholinergic, H_1 and

H_2 histaminergic, NK_1 neurokininergic, and ENK_μ and ENK_δ enkephalinergic; and their respective synthetic or degradative enzymes: DOPA (dihydroxyphenylalanine) decarboxylase, dopamine β-hydroxylase, 5-hydroxytryptophan decarboxylase, choline acetyltransferase, histidine decarboxylase, aminopeptidase N, and enkephalinase (Figure 35-2).[11] Some neurotransmitter-receptor signal transduction pathways are probably more important than others. For example, apomorphine, a D_2-dopamine receptor agonist, is a potent emetic agent in the dog, but it does not readily induce emesis in the cat.[12] This finding has two important implications: (a) CRTZ D_2-dopamine receptors may not be as important in mediating humoral emesis in the cat, and (b) D_2-dopamine receptor antagonists (e.g., metoclopramide) may not be as effective as an antiemetic agent in the cat. Xylazine, an α_2-adrenergic agonist, is a more potent emetic agent in the cat than in the dog.[12,13] Xylazine's effect suggests that α_2-adrenergic antagonists may be more useful antiemetic agents than D_2-dopamine antagonists in the cat.[9] Cancer chemotherapy (e.g., *cis*-platinum, doxorubicin, cyclophosphamide)-induced emesis is mediated by activation of 5-HT_3 receptors in the CRTZ of the cat,[11,14-16] while visceral and vagal afferent 5-HT_3 receptors may be more importantly involved in the dog.[17] Antagonists of the 5-HT_3 receptor are efficacious in the prevention of emesis associated with *cis*-platinum and other chemotherapy in cats[14-16] and dogs.[18] NK_1 receptor antagonists represent a unique new class of antiemetic agents that are based on substance P pharmacology at the CRTZ, as well as the nucleus tractus solitarius. This group of antiemetic agents may have advantages over other antiemetic classifications in that they may inhibit vomiting through both pathways (humoral and neural).[19,20] Finally, although histamine and H_1- and H_2-histaminergic receptors have been demonstrated in the CRTZ of the dog, they have not yet been demonstrated in the cat. Histamine is a potent emetic agent in the dog, but the cat seems resistant to its emetic effects.[11,12] H_1-histaminergic antagonists (e.g., diphenhydramine, dimenhydrinate) are ineffective antiemetic agents for motion sickness in the cat (Table 35-1).[10]

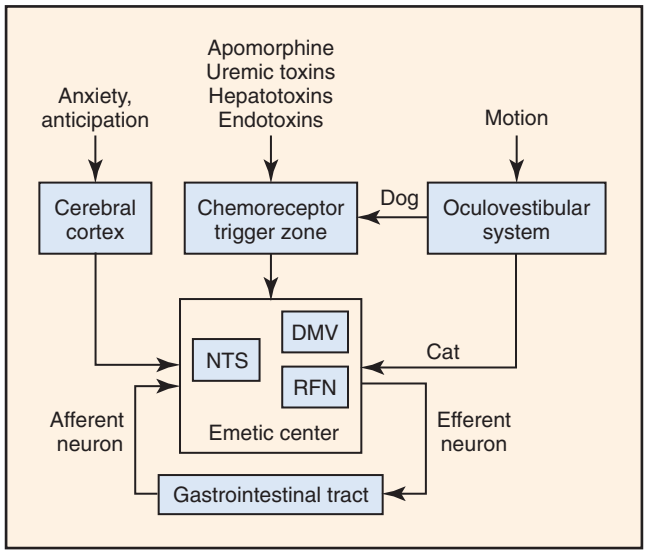

Figure 35-1 Physiology of vomiting: humoral and neural pathways. *Humoral pathway*—Vomiting is initiated through activation of the chemoreceptor trigger zone by bloodborne substances. *Neural pathway*—Vomiting is initiated through activation of the emetic center by a vagosympathetic, chemoreceptor trigger zone, nucleus tractus solitarius, vestibular, or cerebrocortical neurons. NTS, nucleus tractus solitarius.

Emetic Center

Emetic center pharmacology is complicated; indeed, some experimental results may not be reflective of pharmacology at one site. At the present time, the 5-HT_{1A}, α_2-adrenergic, and NK_1 receptors are the only documented receptors involved in the regulation of emesis at the level of the emetic center for which there are clinically available antiemetic agents. It has been shown that 5-HT_{1A} receptor agonists (e.g., flesinoxan, 8-OH-DPAT, buspirone) suppress emesis associated with motion sickness in cats.[21] The emetic center α_2

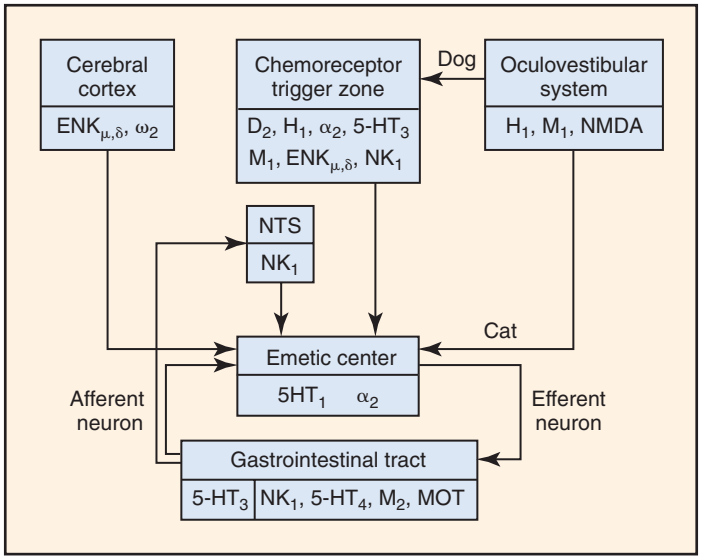

Figure 35-2 Pharmacology of vomiting: neurotransmitters and receptors. α_2, Alpha$_2$-adrenergic receptor; D_2, dopamine$_2$ receptor; ENK$_{\mu,\delta}$, enkephalin$_{\mu,\delta}$ receptor; H_1, histamine$_1$ receptor; 5-HT_{1A}, 5-hydroxytryptamine$_{1A}$ receptor; 5-HT_3, 5-hydroxytryptamine$_3$ receptor; 5-HT_4, 5-hydroxytryptamine$_4$ receptor; M_1, muscarinic$_1$ cholinergic receptor; M_2, muscarinic$_2$ cholinergic receptor; MOT, motilin receptor; NK_1, neurokinin$_1$ receptor; NTS, nucleus tractus solitarius; ω_2, benzodiazepine ω_2 receptor.

Table 35-1 Antiemetic Classifications

Classification	Examples	Site(s) of Action	Dosage	Side Effects
α_2-Adrenergic antagonists	Prochlorperazine	CRTZ, emetic center	0.1 to 0.5 mg/kg q6-8h SQ, IM, IV	Hypotension, sedation
	Chlorpromazine	CRTZ, emetic center	0.2 to 0.4 mg/kg q8h SQ, IV	Hypotension, sedation
	Yohimbine	CRTZ, emetic center	0.25 to 0.5 mg/kg q12h SQ, IM	Hypotension, sedation
D_2-dopaminergic antagonists	Metoclopramide	CRTZ, GI smooth muscle	0.2 to 0.4 mg/kg q6h PO, SQ, IM, IV	Extrapyramidal signs
	Domperidone	CRTZ, GI smooth muscle	0.1 to 0.5 mg/kg q6-8h SQ, IM, IV	Extrapyramidal signs
	Prochlorperazine	CRTZ, emetic center	0.5 mg/kg q6-8h SQ, IM	Hypotension, sedation
	Chlorpromazine	CRTZ, emetic center	0.2 to 0.4 mg/kg q8h SQ, IV	Hypotension, sedation
H_1-histaminergic antagonists	Diphenhydramine	CRTZ	2 to 4 mg/kg q8h PO, IM	Sedation
	Dimenhydrinate	CRTZ	4 to 8 mg/kg q8h PO	Sedation
	Prochlorperazine	CRTZ, emetic center	0.1 to 0.5 mg/kg q6-8h SQ, IM, IV	Hypotension, sedation
	Chlorpromazine	CRTZ, emetic center	0.2 to 0.4 mg/kg q8h SQ, IV	Hypotension, sedation
M_1-cholinergic antagonists	Pirenzepine	Vestibular apparatus, CRTZ	25 to 50 mg q24h PO	None reported
	Aminopentamide	Multiple CNS and PNS sites	0.01 to 0.03 mg/kg q8 to 12 h PO, IM, SQ	GI dysmotility
	Prochlorperazine	CRTZ, emetic center	0.1 to 0.5 mg/kg q6-8h SQ, IM, IV	Hypotension, sedation
	Chlorpromazine	CRTZ, emetic center	0.2 to 0.4 mg/kg q8h SQ, IV	Hypotension, sedation
5-HT_3 serotonergic antagonists	Ondansetron	CRTZ, vagal afferent neurons	0.5-1.0 mg/kg q12h PO	Sedation, head-shaking
	Granisetron	CRTZ, vagal afferent neurons	0.1 to 0.5 mg/kg q12h PO, IV	Sedation, head-shaking
	Tropisetron	CRTZ, vagal afferent neurons	0.5 to 3.0 mg/kg q12h PO	Sedation, head-shaking
	Dolasetron	CRTZ, vagal afferent neurons	0.6 to 1 mg/kg q12h PO, IV	Sedation, head-shaking
5-HT_4 serotonergic agonists	Cisapride	Myenteric neurons	0.1 to 0.5 mg/kg q8-12h PO	Cardiac arrhythmia
$ENK_{\mu,\delta}$ enkephalinergic	Butorphanol	CRTZ	0.2 to 0.4 mg/kg q12h IM	Sedation antagonists
NK_1 neurokinin antagonists	Maropitant	CRTZ, emetic center	1 mg kg q24h SQ	Injection irritant

Abbreviations: CNS, central nervous system; CRTZ, chemoreceptor trigger zone; GI, gastrointestinal; 5-HT, 5-hydroxytryptamine; IM, intramuscular; PNS, peripheral nervous system; SQ, subcutaneous, PO, per os; q, every.

receptor, as well as the CRTZ α_2 receptor, may be antagonized by a pure α_2-antagonist, for example, yohimbine, or by mixed α_1/α_2-antagonists, for example, prochlorperazine and chlorpromazine.[13] It is likely, however, that most of the antiemetic effect of the α receptor antagonists results from antagonism at the level of the CRTZ (Table 35-1).[21,22]

Vestibular Apparatus

Muscarinic M_1 receptors and acetylcholine have been demonstrated in the vestibular apparatus of the cat. Mixed M_1/M_2 antagonists, for example, atropine, and pure M_1 antagonists, for example, pirenzepine, inhibit motion sickness in the cat. It is not clear, however, whether the antiemetic effect of these drugs is solely a result of M_1 receptor antagonism at the vestibular apparatus. Other sites (e.g., cerebral cortex, reticular formation, area postrema) of antagonism are possible.[11] More recently, NK_1 receptors have been shown to be involved in pathogenesis of motion sickness, and NK_1 receptor antagonists (e.g., maropitant) prevent motion sickness in both dogs and cats (Table 35-1).[23,24]

Cerebral Cortex

Opioids, cannabinoids (e.g., nabilone) and benzodiazepines (e.g., diazepam, lorazepam) have been used to reduce anticipatory nausea and vomiting in human beings undergoing cytotoxic drug therapy. Cerebrocortical opioid and benzodiazepine receptors have been implicated but have not been very well characterized pharmacologically. The importance of these receptors in the pathogenesis of nausea and vomiting disorders in the dog and cat has not yet been established.[4,11,12]

Gut Afferents

There are a number of different mechanisms by which stimuli arising from the gastrointestinal tract activate the vomiting reflex. Ingested toxins, cell degeneration or necrosis, inflammation, luminal distention, chemotherapy, and radiation therapy all induce emesis. Of the many receptors found in the gastrointestinal tract, 5-HT_3 receptors likely play an important role in the initiation of emesis.[11] It is now well established that cytotoxic drugs provoke 5-HT release from enterochromaffin cells in the gastrointestinal tract which then activates 5-HT_3 receptors in afferent vagal fibers (dog)[17] or CRTZ (cat).[14,15] Vomiting induced by 5-HT release and 5-HT_3 receptor activation is abolished by pretreatment with 5-HT_3 antagonists, for example, ondansetron, granisetron, tropisetron, and dolasetron.[14,18] Metoclopramide is a weak antagonist of 5-HT_3 receptors but does not seem to be very effective in preventing chemotherapy-induced emesis (see Table 35-1).[25] It remains to be determined whether other gastrointestinal tract pathologies (e.g., inflammation, infection, malignancy, toxicity) are mediated via 5-HT_3 receptor activation.

Gut Efferents

Vagal efferent and myenteric neurons initiate the complex excitation and inhibition of visceral smooth muscle (e.g., retrograde duodenal and gastric contractions, relaxation of the gastroesophageal sphincter, gastroesophageal reflux, opening of the cricoesophageal

sphincter, and evacuation of gastrointestinal contents) that culminates in emesis. A number of receptors have been identified on myenteric neurons and gastrointestinal smooth muscle cells that regulate gastric emptying and/or intestinal transit. These include 5-HT_4 serotonergic (neuronal),[26] D_2-dopaminergic (neuronal),[27] M_2-cholinergic (smooth muscle),[28] and motilin (smooth muscle—dog only)[29] receptors. Cisapride and other 5-HT_4 agonists facilitate gastric emptying by activating presynaptic neuronal 5-HT_4 receptors.[26,20] Metoclopramide is a weak gastric prokinetic agent in the dog and cat, and is believed to facilitate gastric emptying via agonism of 5-HT_4 serotonergic receptors,[26] or via antagonism at D_2 dopamine receptors.[27] Canine gastric emptying is also regulated by motilin, a hormone that is released episodically from gastrointestinal endocrine cells. Motilin initiates phase III of the migrating myoelectric complex and facilitates gastric emptying during the fasting state. Low doses of erythromycin (0.5 to 1 mg/kg q8h PO, IV) stimulate motilin release and facilitate gastric emptying in the dog.[29,31] The role of motilin in the regulation of feline gastric emptying is incompletely understood. Motilin-like macrolide antibiotics increase tone in the feline caudal esophageal sphincter,[32] but their role in the regulation of gastric, intestinal, and colonic motility is incompletely understood (Table 35-1).

Treatment and Management

General Principles

Each vomiting patient will likely have a unique clinical presentation, some that are benign and require little in the way of intervention, others requiring extensive stabilization, therapy, and rehabilitation. Efforts should be made to identify and eliminate inciting agents, sustain blood and plasma volume, restore blood pressure, correct acid–base, electrolyte, and fluid deficits, and treat complications as they develop.

Nutrition

Short periods of fasting are appropriate to reduce the severity and frequency of the central emetic response. Fasting in cats should be implemented only in those instances in which there is severe vomiting and risk of aspiration pneumonia. As obligate carnivores, cats develop fat mobilization and hepatic lipidosis during even short periods of starvation. With chronic vomiting disorders, esophagostomy, gastrostomy, and enterostomy tubes may be placed to facilitate nutrition in anorectic animals (see Chapter 32).

Fluids

Severe vomiting will likely result in serious fluid, electrolyte, and acid/base disturbances. The goal of fluid therapy is to restore the volume and composition of body fluids to normal and, once this is achieved, to maintain external fluid and electrolyte balance so that input by treatment matches fluid losses (see Chapter 49). Electrolyte solutions can be divided into replacement and maintenance solutions. Replacement solutions provide 130 to 147 mEq/L of sodium, similar to values in the extracellular fluid. Maintenance electrolyte solutions provide 40 to 77 mEq/L of sodium, about one-half or less of values in the extracellular fluid. Supplementation of replacement fluids may be required to correct acid/base imbalance and potassium deficits, particularly in animals suffering from vomiting and diarrhea. In the absence of cardiopulmonary disease, intravenous fluids can be safely administered to dogs and cats at 90 mL/kg/h. Animals with mild volume depletion can be treated with lower fluid rates (10 to 20 mL/kg/h, as needed).

Antiemetic Agents

Antiemetic therapy should be formulated on the basis of most likely underlying pathogenesis, that is, neural or humoral pathway. The NK_1 neurokinin antagonists, α_2-adrenergic antagonists, 5-HT_3 serotonergic antagonists, and D_2-dopaminergic antagonists appear to be the most effective antiemetic agents in the dog and cat, although the D_2-dopaminergic antagonists appear to be less efficacious in the cat (see Table 23-1).

Antisecretory Agents

The histamine H_2 receptor antagonists and H^+,K^+-adenosine triphosphatase (ATPase) inhibitors are best clinical examples of gastric acid secretory inhibitors. It may be difficult, if not impossible, to determine the pathogenesis of gastric injury in an individual animal. Most cases will likely result from the combined effects of acid injury and disruption of the gastric mucosal barrier. Acid suppression and restitution of the gastric mucosal defense mechanisms are the cornerstones of treatment (see Chapter 46).

Prokinetic Agents

Gastrointestinal prokinetic agents should be considered in patients that fail to respond to dietary and antiemetic therapy. Combination antiemetic/prokinetic therapy are particularly effective in refractory vomiting patients. The most effective prokinetic agents are the 5-HT_4 serotonergic agonists, of which cisapride, tegaserod, and mosapride are the best examples. D_2-dopaminergic antagonists, motilides, and cholinomimetic agents have also been used to stimulate propagating gastrointestinal motility in companion animals (see Chapter 53).

CHAPTER 36

Antifungal Drugs

Robert J. Washabau

Introduction

Indigenous Fungal Organisms

The gastrointestinal (GI) tract is readily colonized by small numbers of fungal organisms that become part of the indigenous microflora, maintain stable populations, and may even contribute to the nutrient economy of the host. Many of these organisms are undetectable by routine microbiology standards. With the advent of molecular fingerprinting techniques, the role of these organisms in the health of the mammalian host is becoming more readily apparent (see Chapter 2).

Opportunists

Most fungal species, whether transitory or part of the permanent habitat of the gut, appear to be of low pathogenicity. Given appropriate circumstances, however, commensal organisms may become pathogenic to the host. Inflammatory bowel disease, for example, is accompanied by an increase in the number and type of fungal organisms found in the GI tract, although it is still unknown whether this is cause or effect. *Candida* spp. are dimorphic fungi that are normal inhabitants of the GI tract, but they too can become opportunistic infections in some patients.[1] Other opportunistic organisms are sometimes isolated from immunosuppressed patients. Reported opportunists are typically from the Zygomycetes class (zygomycosis), and include members of the Entomophthoraceae (e.g., *Basidiobolus* spp., *Conidiobolus* spp.) and Mucoraceae (e.g., *Absidia* spp., *Rhizopus* spp., *Mucor* spp., and *Mortierella* spp.).[1]

True Pathogens

Rare cases of aspergillosis and mucormycosis involving the GI tract have been reported in the veterinary literature, but the most important pathogens are *Histoplasma capsulatum*, a true fungal organism, and *Pythium insidiosum*, an oomycete.

Pathogenic Fungal Infection of the Gastrointestinal Tract

Histoplasma capsulatum

Etiology

Histoplasmosis is a systemic fungal disease of dogs and cats caused by *H. capsulatum*. In the environment, *H. capsulatum* organisms are mycelial, saprophytic soil fungi. In infected tissue or when cultured at 30°C to 37°C (86°F to 98.6°F), the organism is a yeast. The fungus is endemic throughout most of the temperate and subtropical regions of the world. Most cases of histoplasmosis in the United States occur in the central states, with the geographic distribution following the Mississippi, Ohio, and Missouri Rivers.[2,3]

Pathophysiology

Infection is probably via inhalation or ingestion of infective conidia from the environment. The respiratory system is thought to be the primary route of infection in cats and dogs, although the GI tract may also be an important route in the dog. After inhalation or ingestion, conidia transform from the mycelial phase and are phagocytized by macrophages, where they grow as facultative intracellular organisms. Hematogenous and lymphatic dissemination results in multisystemic disease. Organisms can be disseminated to any organ system, but the lungs, gastrointestinal tract, lymph nodes, liver, spleen, bone marrow, eyes, and adrenal glands are the most common organs of dissemination in the dogs; lungs, liver, lymph nodes, eyes, and bone marrow are most commonly affected in cats. Cell-mediated immunity induces a granulomatous inflammatory response in most infections.[4]

Clinical Examination

Dogs with gastrointestinal histoplasmosis are typically presented with mild fever, anorexia, lethargy, weight loss, vomiting, diarrhea, hematochezia, and tenesmus. Cachexia is a common physical examination finding. Other historical and physical examination findings (dyspnea, cough, ascites, lameness, oropharyngeal ulceration, chorioretinitis, neuropathy) will depend upon organ and tissue involvement.

Diagnosis

Organism identification is required for definitive diagnosis. The most common means of organism identification is cytology. Cytology from affected tissue reveals pyogranulomatous inflammation, often with numerous small, round to oval intracellular yeast cells (2 to 4 μm in diameter) characterized by a basophilic center and a light halo. Exfoliative cytology during colonoscopy (or upper GI endoscopy) is considered useful in diagnosing the disease.[5] Histopathology is helpful if cytology is nondiagnostic or inconclusive. Multiple endoscopic colonic biopsies are usually sufficient to diagnose the disease. The yeast form does not stain well with routine hematoxylin and eosin stains, periodic acid-Schiff and Gomori methenamine silver stain are often used. Fungal culture from affected tissue can be used for diagnosis, but is rarely needed in clinical cases. Currently available serologic tests have poor specificity and sensitivity.[4]

Table 36-1 Antifungal Drug Classifications

Example (Generic)	Trade Name	Mechanism of Action	Dose	Route	Frequency
Amphotericin B	Fungizone	Binds cell membrane sterols; activates tissue macrophages	Dog: 0.5 to 0.1 mg/kg	IV	q48h
			Cat: 0.25 mg/kg	IV	q48h
Lipid amphotericin B	Abelcet complex		Dog: 1 to 3 mg/kg	IV	q48h
Ketoconazole	Nizoral	Inhibits 14-α-demethylase and ergosterol biosynthesis	Dog: 10 to 30 mg/kg	PO	divided q12h
Itraconazole	Sporanox		Dog: 5 to 10 mg/kg	PO	q24h
			Cat: 10 mg/kg	PO	q24h
Fluconazole	Diflucan		Dog/Cat: 2.5 to 10 mg/kg	PO	q12h
Posaconazole	Noxafil		Dog/Cat: 5 mg/kg	PO	q24h
Voriconazole	Vfend		Dog/Cat: 5 mg/kg	PO	q12h
Flucytosine	Ancobon	Inhibits DNA & RNA synthesis	Dog: 25 to 50 mg/kg	PO	q6h
Terbinafine	Lamisil	Inhibits squalene epoxidase and ergosterol biosynthesis	Dog/Cat: 10 to 20 mg/kg	PO	q24h
Caspofungin	Cancidas	Glucan synthase inhibition	Dog/Cat: Safe and effective doses not yet established		

Treatment

Itraconazole (5 mg/kg PO BID for 2 to 4 months) is considered the treatment of choice (Table 36-1) for feline histoplasmosis. In one study, itraconazole therapy cured histoplasmosis infections in all eight study cats.[6] Ketoconazole and amphotericin B have been described as the treatments of choice for canine histoplasmosis. With GI tract involvement, additional GI therapy may be useful in affected dogs, for example, dietary modification, treatment for small intestinal bacterial overgrowth, and direct antidiarrheal therapy. Corticosteroids may have been used successfully in the treatment of airway obstruction secondary to hilar lymphadenopathy in chronically infected dogs.[7]

Prognosis

There may be important species differences in prognosis although the paucity of reports, especially of prospective clinical trials, makes it difficult to generalize. It would seem that the prognosis is guarded in dogs, but fair to good in cats.

Oomycete Infection

Pythium insidiosum

Etiology

P. insidiosum is an aquatic oomycete that causes severe GI pathology in a range of hosts in tropical and subtropical climates.[8] Based on ribosomal RNA gene sequence data, members of the class Oomycetes are phylogenetically distinct from the kingdom Fungi, and are more closely related to algae than to fungi.[9] The oomycetes differ from fungi in two important properties: cell wall and cell membrane composition. Chitin is an essential component of the fungal cell wall, but it is generally lacking in the oomycete cell wall. Oomycetes also differ from fungi in that ergosterol is not a principal sterol in the oomycete cell membrane. This difference may explain why ergosterol-targeting drugs like the azoles (e.g., itraconazole) are less effective in the medical treatment of pythiosis.[9]

Pathophysiology

The infective state of *P. insidiosum* is thought to be the motile zoospore, which is released into stagnant water in warm environments, and likely causes infection either by encysting in the skin, or by being ingested into the GI tract. Ingested zoospores encyst and adhere to the gastric, jejunal, and colonic epithelium with a polarity oriented toward the submucosa for rapid tissue penetration following germ tube eruption. *Pythium* induces a chronic pyogranulomatous response in the GI tract and mesenteric lymph nodes. The gastric outflow tract and ileocolonic junction are the most frequently affected portions of the GI tract, and it is not uncommon to find two or more segmental lesions in the same patient.[10] Inflammation in affected regions is typically centered on the submucosa, with variable mucosal ulceration and occasional extension of disease through serosal surfaces, resulting in adhesion formation and peritonitis.

Clinical Examination

Weight loss, vomiting, diarrhea, and hematochezia are the most important clinical signs. Physical examination often reveals emaciated body condition and a palpable abdominal mass. Signs of systemic illness such as lethargy and depression are not typically present unless intestinal obstruction, infarction, or perforation occurs.

Diagnosis

Ileocolonic wall thickening, obliteration of the normal layered appearance, and regional lymphadenopathy are common ultrasonographic features of canine intestinal pythiosis.[11] Of course, these findings cannot be readily differentiated from those associated with intestinal malignancy. Definitive diagnosis requires histologic demonstration or immunohistochemical labeling of the organism and/or positive enzyme-linked immunosorbent assay (ELISA) or polymerase chain reaction (PCR) assays. The histologic findings associated with pythiosis generally are characterized by eosinophilic granulomatous to pyogranulomatous inflammation with fibrosis. Affected tissue typically contains multiple foci of necrosis surrounded and infiltrated by neutrophils, eosinophils, and macrophages. Discrete granulomas composed of epithelioid macrophages, plasma cells, multinucleate giant cells, and neutrophils and eosinophils may also be observed. *Pythium* zoospores may be cultured directly from affected tissue in antibiotic-containing (e.g., streptomycin and ampicillin) media. More recently, sensitive and specific ELISA and PCR assays were developed for the accurate diagnosis of pythiosis in dogs.[12-14]

Treatment

Aggressive surgical resection remains the treatment of choice (see Table 36-1) for pythiosis in dogs. Because it provides the best opportunity for a long-term cure, complete resection of infected tissue should be pursued whenever possible. Segmental lesions of the GI tract should be resected with 3- to 4-cm margins whenever possible. Medical therapy for the oomycetes has not been very promising. This may relate to the absence of ergosterol (cell membrane target of most currently available antifungal drugs) in the oomycete cell membrane. Clinical and serologic cures have been obtained in a small number of dogs following therapy with amphotericin B lipid complex (2 to 3 mg/kg QOD administered to a cumulative dose of 24 to 27 mg/kg) or itraconazole (10 mg/kg q24h for 6 to 9 months).

Prognosis

Unfortunately, most dogs with GI pythiosis are not presented to the veterinarian until late in the course of the disease, when complete excision is not possible. The anatomic site of the lesion (e.g., pylorus or ileocolic sphincter) may also prevent complete excision. Consequently, the prognosis is usually grave in most animals.[9]

CHAPTER 37

Anthelmintic Agents

Michael R. Lappin

There are a number of cestodes, nematodes, and trematodes that are associated with gastrointestinal disease in dogs and cats. Chapters 55 to 58 provide an in-depth discussion of the clinical applications of anthelmintic drugs for these disease states. Some helminths can also be associated with clinical illness in humans and therefore management of infections in dogs and cats is part of a comprehensive public health program. This is particularly important for some of the hookworm (e.g., *Ancylostoma* spp., *Uncinaria* spp.) and roundworm (e.g., *Toxocara* spp., *Baylisascaris procyonis*) species. Approximately 3% to 5% of client-owned dogs and cats in the United States are currently shedding roundworm or hookworm eggs, with much higher shedding rates being detected in specific regions.[1-5]

This chapter provides information concerning the drugs most frequently used to remove or control helminth infections in dogs and cats. The majority of the compounds discussed are available in multiple countries. However, formulations and combinations of drugs may vary between countries. In addition, some of the drugs are used off-label for some parasites and label claims and dosages may change. Thus readers should always consult recent publications for potential changes. The majority of the comments in this chapter are written using resources and experiences from practice in the United States. Information is also drawn from the recommendations of the Companion Animal Parasite Council in the United States (www.capcvet.org) and the Compendium of Veterinary Products (CVP) drug label database in the United States.

Benzimidazoles

Historically, many drugs in the benzimidazole class (albendazole, fenbendazole, flubendazole, mebendazole, oxibendazole, thiabendazole) or probenzimidazole drugs (febantel) have been used as broad-spectrum anthelmintics in dogs and cats.[6-11] There is no information available to suggest that albendazole, flubendazole, mebendazole, oxibendazole, or thiabendazole are more effective against gastrointestinal parasites in dogs or cats than fenbendazole or febantel. Mebendazole is associated with hepatic necrosis in dogs and albendazole is associated with bone marrow suppression in dogs and cats, which are additional reasons fenbendazole and febantel are prescribed more frequently.[12,13] These drugs are considered among the best broad-spectrum agents because of activity against a variety of different parasites of the gastrointestinal system and other systems (Tables 37-1 and 37-2).

Mechanism of Action

The benzimidazole and probenzimidazole drugs are believed to inhibit energy metabolism in susceptible parasites leading to energy exchange breakdown and inhibition of glucose uptake. The drugs also bind to tubulin molecules, which binding inhibits microtubule formation and cell death of susceptible parasites through disruption of cell division.

Dose and Toxicity

If a labeled product containing fenbendazole or febantel is available, the label should be followed for each respective parasite. In general, fenbendazole at the dosage of 50 mg/kg, PO, daily for 3 days, is considered safe and effective against most of the target helminths of both dogs and cats (see Tables 37-1 and 37-2). In the United States, febantel is labeled only for oral administration in dogs. However, the drug has been administered safely to cats in several studies at dosages as high as 56.5 mg/kg (adult cats).[11,14] Side effects at the recommended dosages in dogs and cats are rare, and if side effects occur, generally salivation or vomiting, they are usually mild and self-limiting.

Clinical Application

Fenbendazole and febantel are prescribed frequently for the target helminths as discussed (see Tables 37-1 and 37-2). However, neither compound is effective for the treatment of *Dipylidium caninum* or *Echinococcus* spp. infections. Febantel is combined with praziquantel (see "Isoquinolones" section), which effectively treats the other tapeworms and pyrantel (see "Tetrahydropyridimines" section), which increases its activity against hookworms and roundworms (Drontal Plus, Bayer Animal Health). Benzimidazoles also treat *Trichuris vulpis* infections, which is an advantage over some of the drugs in other classes with anthelmintic activity.

Fenbendazole or febantel are also commonly prescribed to dogs or cats with small bowel diarrhea for potential activity against *Giardia* spp. (see Chapter 57).[14-17] Fenbendazole is one of the anthelmintics that is believed to have activity against the trematodes that can be associated with gastrointestinal disease (*Alaria* spp., *Nanophyetus salmincola*, *Heterobilharzia americana*, *Platynosomum fastosum*).[18] However, optimal protocols have not yet been established and fenbendazole is not labeled for this use.

Table 37-1 Drugs Used in the Management of Common Helminth Infections of the Gastrointestinal System of Dogs

	NEMATODES			CESTODES		
Drug and Class	**Hookworms**	**Roundworms**	**Whipworms**	***Dipylidium***	***Echinococcus***	***Taenia***
Benzimidazoles						
Febantel	Yes	Yes	Yes	No	No	Yes
Fenbendazole	Yes	Yes	Yes	No	No	Yes
Cyclic depsipeptide

Hookworms = *Ancylostoma tubaeforme;* roundworms = *Toxocara cati* and *Toxascaris leonina.*
[#]The dose of ivermectin used in heartworm preventatives controls hookworm infections but not roundworms. Higher doses may be effective for roundworms.

Cyclic Depsipeptide

Emodepside is the only drug in this class currently prescribed to dogs or cats. It has been evaluated for oral (dogs) or topical (cat) administration and is considered safe and effective for use in the management of several nematode infections in dogs or cats (see Tables 37-1 and 37-2).[19-23] Emodepside is combined with praziquantel (Profender, Bayer Animal Health). The oral formulation for use in dogs is not currently available in the United States.

Mechanism of Action

The emodepside mechanism of action is considered unique to the drugs with anthelmintic activity. The drug binds to the latrophilin receptor presynaptically, which activates a complex signal transmission cascade that eventually results in the release of inhibitory neuropeptides into the synaptic gap. The resulting ion influx that occurs postsynaptically results in the inhibition of pharyngeal pump function that leads to paralysis and death of susceptible nematodes.

Dose and Toxicity

Based on the label in the United States, the emodepside-containing topical solution should be applied to cats older than 8 weeks of age and greater than 1 kg of body weight. The drug has been applied to small numbers of pregnant queens and 4-week-old kittens in a research study without apparent side effects.[19] Adverse effects associated with administration of the topical solution to 606 cats in a controlled, double-masked field safety study reported by Bayer Animal Health were infrequent, mild, and self-limited. The reactions reported were licking/excessive grooming in 18 cats (3.0%), scratching treatment site in 15 cats (2.5%), salivation in 10 cats (1.7%), lethargy in 10 cats (1.7%), alopecia in eight cats (1.3%), agitation/nervousness in seven cats (1.2%), vomiting in six cats (1.0%), diarrhea in three cats (0.5%), eye irritation in three cats (0.5%), respiratory irritation in one cat (0.2%), and shaking/tremors in one cat (0.2%).[21-23] Salivation, vomiting, and mild neurologic effects induced by administering the topical solution orally to cats were self-limited. Side effects induced by administration of the oral preparation to dogs have also been minimal.[21-23]

Clinical Application

In addition to the label indications, administration of emodepside to a small number of pregnant queens that were experimentally infected with *Toxocara cati* apparently blocked lactogenic transmission to the kittens.[19] Combining emodepside with praziquantel expands the spectrum of activity to include cestodes and, potentially, trematodes (see "Isoquinolones" section).[23] Emodepside also has effects against helminths of other body systems like feline lungworm.[24]

Isoquinolones

Praziquantel and epsiprantel are the isoquinolones currently used for the treatment of a number of cestode and trematode infections in dogs and cats.

Mechanism of Action

The exact mechanisms of action of the isoquinolones are unknown but may relate to inhibition of organism attachment. At low concentrations in vitro, praziquantel appears to impair the function of the cestode suckers and stimulates parasite motility. At higher concentrations in vitro, praziquantel increases the contraction of the worm's strobila, which can be irreversible at very high concentrations. Isoquinolone administration may cause damage to the integument of susceptible cestodes and trematodes, which may impart increased vulnerability to digestion by the host.

Dose and Toxicity

In dogs and cats in the United States, epsiprantel (Cestex, Pfizer) is labeled for use at 5.5 mg/kg or 2.75 mg/kg PO once, respectively. The company recommends use of the epsiprantel in dogs and cats older than 7 weeks of age. Praziquantel is available alone for oral administration, alone for injection, combined with pyrantel (see "Tetrahydropyridimines" section) for oral administration, combined with pyrantel and febantel for oral administration (see "Benzimidazoles" section), or combined with emodepside for topical administration to cats (see "Cyclic Depsipeptides" section). For treatment of susceptible cestodes, the label dosage of praziquantel based on the formulation used should be followed. Side effects, even at extremely high doses, are unusual for epsiprantel or praziquantel. Discomfort may occur during administration of praziquantel for injection.

Clinical Application

Praziquantel and epsiprantel are commonly prescribed by veterinarians for the treatment of current infections by susceptible cestodes. Some praziquantel-containing products are also labeled for the removal and control of *Echinococcus granulosa* and *Echinococcus multilocularis* in dogs in some countries. In *E. multilocularis* endemic areas, dogs continually exposed to wild rodents can be administered praziquantel every 21 to 26 days to lessen potential for shedding infective eggs into the human environment.

Praziquantel is one of the anthelmintics with activity against the trematodes that can be associated with gastrointestinal disease (*Alaria* spp., *N. salmincola, H. americana, P. fastosum*).[18] Praziquantel administration after fenbendazole administration has also be used successfully to treat peritoneal larval cestodiasis.[25] However, optimal protocols are unknown and praziquantel is not labeled for these infections.

Macrolides

There are several macrolides (macrocyclic lactones) with toxic effects against gastrointestinal nematode infections of dogs and cats and these include ivermectin, milbemycin oxime, moxidectin, and selamectin.[6,26-31] These drugs also have the advantage of preventing *Dirofilaria immitis* infections and some also can be used in the management of *Ctenocephalides felis* and other external parasite infections (see Clinical Application).

Mechanism of Action

The macrolides are antibiotics produced by *Streptomycetes* and the basic mechanism of action of action is likely similar for each of the drugs. Contact of the drugs with susceptible nematodes triggers a calcium ion influx that results in hyperpolarization of the nematode neurons. This ultimately prevents initiation and propagation of normal action potentials and results in paralysis and death.[6]

Dose and Toxicity

There are multiple products containing ivermectin, milbemycin oxime, moxidectin, or selamectin for use in the removal or control of some nematodes in dogs or cats (see Tables 37-1 and 37-2). Some products are for oral administration (ivermectin and milbemycin), injection (moxidectin; dogs only), or topical administration (moxidectin and selamectin). The drug label for each product should be consulted for specific dose recommendations and toxicity. Accidental high doses of macrocyclic lactones can cause toxicity.[32] Some dogs are at increased risk for ivermectin toxicity (in particular, Collies and Shelties) and this risk is genetically determined.[33,34] In general, this drug class is considered extremely safe when used as directed, even in ivermectin-sensitive dogs.[34,35]

Clinical Application

Tables 37-1 and 37-2 list the usual indications for the macrolide drugs for gastrointestinal helminth infections in dogs and cats. When used monthly for heartworm prevention, some of the

products also can be used as strategic deworming for hookworms and roundworms. Heartworm preventatives that contain ivermectin alone do not have a high enough concentration to effectively treat or prevent roundworm infections in dogs or cats or hookworm infections in dogs. Consequently, ivermectin is combined with pyrantel in some products to achieve this purpose (see "Tetrahydropyridimines" section). Some of the macrolides have effect against some external parasites at the heartworm prevention doses (selamectin); others are combined with other drugs like imidacloprid (Advantage Multi, Bayer Animal Health) or lufenuron (Sentinel, Novartis Animal Health).

Some of the macrolides are also being evaluated for the management of other less common gastrointestinal helminth infections. For example, milbemycin has been shown to be effective for the treatment of *Baylisascaris procyonis* in dogs, and moxidectin has been shown to be effective for prevention of *Spirocerca lupi* in dogs.[36,37]

Piperazines

Piperazine and the piperazine analogue diethylcarbamazine have activity against some helminths. Diethylcarbamazine administered by mouth daily can be used as a heartworm preventive, but has no activity against helminths associated with gastrointestinal disease when used alone. The anthelmintic spectrum of piperazine is narrow, but the drug has been used widely for the treatment of ascarid infections in dogs and cats because of wide availability and minimal side effects.

Mechanism of Action

Piperazine is thought to paralyze susceptible nematodes by disrupting acetylcholine or γ-aminobutyric acid neurotransmission.

Dose and Toxicity

Although multiple doses have been recommended over the years for the treatment of adult roundworms, a dose range of 45 to 65 mg/kg of the base drug is frequently prescribed and given orally to dogs or cats. As there is no effect of tissue stages, treatment is usually recommended at 2-week intervals. Clinical side effects are almost never recognized at recommended doses. However, self-limiting vomiting, diarrhea, and ataxia have been reported in some dogs and cats. If a massive overdose occurs, clinical signs related to anticholinergic effects may be noted and include depression, weakness, ataxia, muscle fasciculations, hypersalivation, slowed papillary light responses, and nystagmus.

Clinical Application

Piperazine should be used exclusively for the treatment of adult roundworm infections in dogs and cats. As coinfections with other helminths are common in dogs and cats, many veterinarians now recommend the use of other products with a more broad spectrum of activity.

Tetrahydropyridimines

Pyrantel is the only tetrahydropyridine currently used in dogs and cats. The drug is safe, effective, and tolerated by most dogs and cats and so is currently one of the most frequently used anthelmintics in small animal practice.[38]

Mechanism of Action

Susceptible parasites are paralyzed by pyrantel, which acts as a depolarizing, neuromuscular-blocking agent owing to cholinesterase inhibition.

Dose and Toxicity

Pyrantel is available in several products labeled for dogs or cats around the world. For labeled indications, the product label can be followed. Published oral doses used for roundworms and hookworms in dogs have varied from 5 to 15 mg/kg and in cats have varied from 5 to 10 mg/kg orally. Treatments are usually repeated several times in infected animals and in puppies and kittens during strategic deworming programs because of minimal effects on tissue phases (see Chapter 38 and www.capcvet.org). Side effects are almost never reported at clinical doses and when they occur generally consist of mild, self-limited vomiting. Overdoses result in clinical signs consistent with excess cholinergic stimulation (increased respiratory rate and ataxia). Because of competing mechanisms of action, pyrantel should not be administered with piperazine.

Clinical Application

Pyrantel is widely used in hookworm and roundworm strategic deworming protocols in puppies and kittens (www.capcvet.org). The drug is also well tolerated by dogs and cats and is used frequently when hookworm or roundworm infections are suspected based on clinical signs of disease. Some products have pyrantel combined with praziquantel (Drontal for Cats, Bayer Animal Health) or with febantel and praziquantel (Drontal Plus, Bayer Animal Health). Pyrantel has also been used to treat *Physaloptera* infections in vomiting dogs or cats at 5 mg/kg PO once (see also Chapters 55 to 58).

Miscellaneous

Other drugs with anthelmintic activity that were used historically in dogs and cats include dichlorophene, *N*-butyl chloride, toluene, levamisole (imidazothiazole), and dichlorvos (organophosphate). Some products containing these substances are still available in the United States but are less commonly prescribed by small animal veterinarians than the other drugs discussed in this chapter because of issues associated with safety or efficacy.

CHAPTER 38

Nonsteroidal Antiinflammatory Analgesics

Karol Mathews and Sarah Boston

Nonsteroidal antiinflammatory analgesics (NSAIAs) are a group of pharmaceutical agents that possess both analgesic and antiinflammatory properties. The NSAIAs are frequently used in human and veterinary medicine to relieve mild, moderate and severe pain associated with surgery, inflammatory conditions, and osteoarthritis. The efficacy of many NSAIAs are equal or superior to the pure μ-opioid agonists (e.g., oxymorphone, morphine, hydromorphone, meperidine), and butorphanol or buprenorphine in managing postoperative pain.[1-15] When used in combination with opioids, a synergistic effect is achieved and may allow for reduced dosing of the opioid in mild to moderate, but not in severe, pain states where higher opioid dosages may still be necessary. In addition to their centrally acting antinociceptive effect, NSAIAs concentrate in inflamed joints and tissues with a duration of effect of 12 to 24 hours.[16] The duration and efficacy of the NSAIAs make them ideal for treating acute[1-15] and chronic pain[17-28] in veterinary patients; however, because of their potential for harm, patient and NSAIA selection must be considered prior to administration. More detailed reviews of NSAIAs have been published elsewhere.[29-39]

Pharmacology of Eicosanoid

Cyclooxygenase (COX) enzymes oxidize arachidonic acid to various eicosanoids and related compounds—prostanoids, prostacyclin, thromboxanes, and leukotrienes (Fig. 38-1).[40] COX-1 and COX-2 are constitutively expressed throughout the body. Their functions are determined by the specific sites and locations within tissues and cells, and the stimulus triggering their production. Canine and human COX-1 and COX-2 isoenzymes share 96% and 93% DNA sequence homology, respectively. The isoenzyme distribution does differ amongst the species, therefore extrapolation to specific anatomic function may not be appropriate.

COX-1, present in all tissues, ultimately converts arachidonic acid into prostanoids, thromboxanes, and prostaglandins (PGE_2, PGF_2, PGI_2, and PGD_2), which are involved in many homeostatic functions and which are organ specific.[46] For example, prostaglandin (PG) activity throughout the body is important in maintaining smooth muscle tone, modulation of vascular tone, and regulation of body temperature[46,52]; PGE_2 maintenance of the gastric mucosal barrier properties; and thromboxane A_2 (TXA_2), released by platelets in response to vessel injury is responsible for primary plug formation, thrombosis, and primary hemostasis.

COX-2 is involved in many pain and inflammatory states, and as an essential enzyme in many constitutive functions. Prostacyclin (PGI_2) is a COX-2 metabolite that, when released from the endothelium, is antithrombotic in modulating TXA_2 and maintains a nonthrombotic barrier between the vessel wall and the blood. Prostacyclin is a potent vasodilator that is regulated in several organ systems. In the kidney, for example, this includes the structures that play an essential role in renal blood flow associated with renin activity, fluid–electrolyte homeostasis,[31,53,57] and nephron maturation.[53,56] COX-2 enzyme also has important constitutive functions in bone metabolism; nerve, brain, ovarian, and uterine function; and intestinal mucosa healing.[52,55]

COX-3, a COX-1 variant, is expressed in the brain and its microvasculature in the dog.[46,49,50] Its importance in humans has not yet been established. The COX-3 isoenzyme is associated with generation of fever and appears to be more sensitive to NSAIAs that are analgesic and antipyretic, but which have low antiinflammatory activity.[44]

PGs serve as both inflammatory and antiinflammatory mediators where COX-2–derived PG (the PGJ_2) functions in resolution of inflammation.[47,50,51] PGJ_2 interacts with nuclear receptors that comprise the peroxisome proliferator-activating receptor (PPAR) family, particularly PPAR-γ. Activation of PPAR-γ transrepresses the activation of many transcription factors, including nuclear factor κβ (NF-κβ), an important promoter in many inflammatory responses. PPAR-γ is found in macrophages, dendritic cells, and B and T lymphocytes with potential roles in regulating inflammation and immunomodulation.[50,51]

Leukotrienes produced in the 5-LOX (5-lipoxygenase) cascade are also involved in the inflammatory response. Arachidonic acid is converted in a two-step process into the conjugated triene epoxide leukotriene (LT) A_4, the most biologically important form of LT (see Fig. 38-1).[47,62-64] LTA_4 is subsequently metabolized to LTB_4, LTC_4, and LTD_4. Cells known to express 5-LOX include circulating polymorphonuclear leukocytes (PMNs), monocytes, basophils, eosinophils, tissue macrophages, and mast cells. These cells release LTA_4 and participate in the transcellular biosynthesis of either LTC_4 or LTB_4.[65] As with the prostanoids, it is impossible to list all the activities of the LTs as their function is also dependent on organ involvement. With inhibition of COX-1 or COX-2 by NSAIAs, there is the potential of conversion of arachidonic acid into leukotriene B_4 via the 5-LOX pathway.[39,47,66-68]

In addition to the antiinflammatory functions of the PGs, endogenous antiinflammatory mechanisms in the LOX pathway also exist. These consist of small chemical mediators, or autacoids, that play a key role in controlling inflammation by inhibiting PMN recruitment

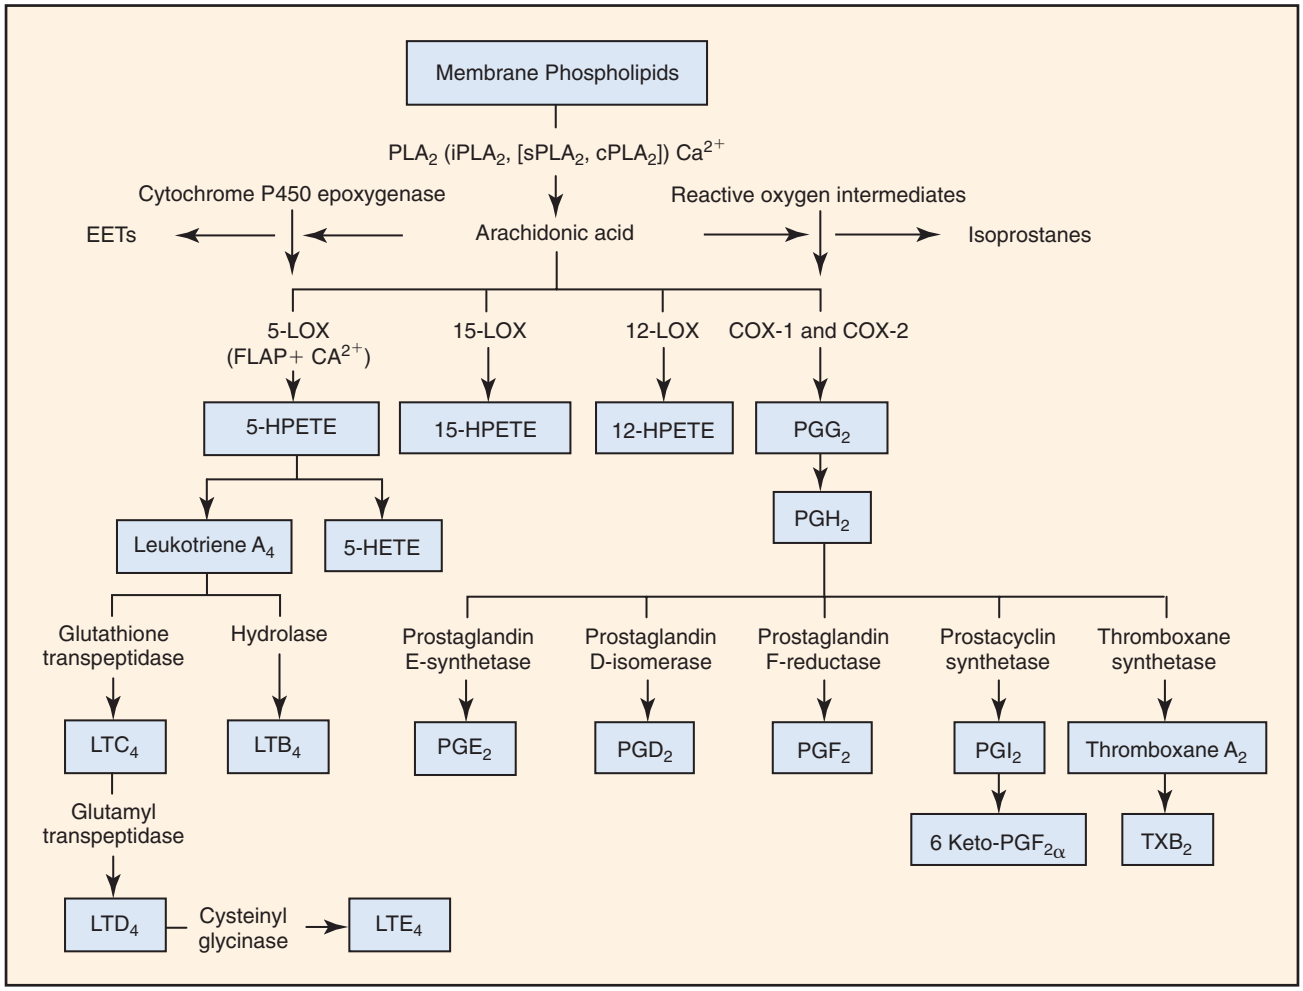

Figure 38-1 The arachidonic cascade. COX, cyclooxygenase; EETs, epoxyeicosatrienoic acids; FLAP, 5-lipooxygenase-activating protein; HETE, hydroxyeicosatetraenoic acid; HPETE, hydroperoxyeicosatetraenoic acid; LOX, lipoxygenase; LT, leukotriene; PG, prostaglandin; PLA_2, phospholipase A_2; TXB_2, thromboxane B_2. (From Mathews KA, Nonsteroidal anti-inflammatory analgesics. In: Ettinger SJ, Feldman EC, eds. *Textbook of Veterinary Internal Medicine*, ed 7, St. Louis, Saunders, 2010.)

and enhancing monocyte activity.[64] Arachidonic acid–derived lipoxins (LXs), particularly LXA_4, have been identified as antiinflammatory mediators, illustrating that the LOX pathway also has a dual proinflammatory and antiinflammatory role. These endogenous "antiinflammatory" products are also referred to as resolvins.[51] Resolvins, by definition, are endogenously generated within the inflammatory resolution phase and downregulate leukocytic exudate cell numbers.[51,82]

Cyclooxygenase and the Gastrointestinal Tract

Chapters 45 and 56 describe the mechanisms of gastric and intestinal mucosal protection. The prostaglandin-conferred component is extremely important in the overall protection of the gastrointestinal tract. Many of the effects of the prostaglandins in the gastric mucosa were discovered retrospectively as a result of the side effects associated with NSAIA administration.

Cyclooxygenase-1

The COX-1–derived prostaglandins are responsible for gastric mucosal protection through vasodilation, stimulation, and secretion of gastroduodenal mucus and bicarbonate, and forming a protective barrier to acid injury. These prostaglandins help protect the stomach's mucosal integrity during periods of vasoconstriction and the daily "trauma" of ingestion, digestion, and emptying. The cytoprotective and trophic functions are important in wound healing secondary to mucosal damage of foods transiting through the stomach. Exogenous administration of prostaglandins have been shown to inhibit gastric acid secretion, stimulate gastroduodenal mucus and bicarbonate secretion, maintain or enhance gastric mucosal perfusion, and have a trophic effect on the gastric mucosa.[51a]

Cyclooxygenase-2

Some studies also show a protective role for COX-2 in the maintenance of gastrointestinal integrity. For example, upregulation of COX-2 is identified in the duodenum in response to mucosal injury.[52,54]

Pathophysiology of Nonsteroidal Antiinflammatory Analgesic–Induced Gastritis and Gastric Ulcers

NSAIA gastropathy describes the subepithelial hemorrhages, gastroduodenal erosions, and ulcerations that can occur secondary to NSAIA administration.[54a] Lesions range from simple erosions affecting only the mucosal layer of the stomach to ulceration affecting the submucosa and deeper layers. There are several studies in dogs

reporting gastric ulceration associated with aspirin, flunixin meglumine, phenylbutazone, meclofenamic acid, piroxicam, naproxen and ibuprofen,[54b] and more recently in association with combination or sequential therapy, or inappropriate dosing of deracoxib[73] and meloxicam.[74] The inhibition of COX-1 is the principal mechanism responsible for the development of gastric lesions. When a synthetic PGE_1 (misoprostol) and an NSAIA (aspirin) with known COX-1 selectivity were administered concurrently, dogs developed significantly fewer gastroduodenal lesions than dogs receiving aspirin alone, but mild gastroduodenal lesions still developed in some of the dogs despite the administration of misoprostol.[54c,54d] Despite the importance of COX-1, COX-2 inhibition may also contribute to the pathophysiology of gastric ulceration. A study evaluating the effects of various COX inhibitors (a selective COX-1 inhibitor, a selective COX-2 inhibitor, a preferential COX-2 inhibitor, and nonselective inhibitor) showed that prolonged healing and a decrease in gastric blood flow were noted in all treatment groups compared with controls. The effect was most profound in the selective COX-1 and nonselective inhibitor treatment groups. The coadministration of synthetic PGE_2 in similar treatment groups facilitated healing. Analysis of mucosal (COX-1) and (COX-2) of the saline-treated group revealed stable levels of COX-1 at all times during the study; but COX-2 levels were not detectable in intact mucosa. In the ulcerated mucosa of the NSAIA-treated rats, COX-2 was present at all times and peaked on day 7 of a 14-day test period.[54e] This study suggests that COX-2 may play an important role in protection during response to inflammation. In a later study COX-2 was found to be constitutively expressed in canine pyloric and duodenal mucosa. NSAIAs may amplify or decrease the endogenous antiinflammatory response. Aspirin is more COX-1 selective and can impair many components of mucosal defense and enhances leukocyte adherence within the gastric and mesenteric microcirculation.[54f] However, with chronic use of aspirin there is an adaptation of the gastric mucosa, which occurs at approximately 14 days, and is associated with a marked upregulation of COX-2 expression and lipoxin production. This lipoxin is termed *aspirin-triggered lipoxin* (ATL). Aspirin is unique among current therapies in that it acetylates the COX-2 enzyme thereby enabling the biosynthesis of 15(R)-hydroxyeicosatetraenoic acid (15[R]-HETE), which is converted to ATL by 5-LOX. Inhibition of either of the COX-2 or 5-LOX enzymes results in blockade of ATL synthesis. LXA_4 and ATL (a carbon-15 epimer of LX) attenuates aspirin-induced leukocyte adherence, whereas selective COX-2 inhibitors augment aspirin-induced damage and leukocyte adherence to the endothelium of mesenteric venules in rats.[54f]

NSAIAs are excreted at varying rates, depending upon the metabolic pathway and extent of enterohepatic circulation. There are many species differences in drug elimination among the NSAIAs. For some drugs, the enterohepatic cycling may increase the risk of toxicosis because of the persistent local effects of the drug on the intestinal mucosa through repeated cycling in the biliary system.[34]

For NSAIAs that are administered orally, a topical or local effect on the gastric mucosa may also be responsible for the development of erosions/ulcers. In the acidic environment of the stomach, NSAIAs exist in a nonionized form, which are relatively lipophilic and will readily permeate gastric mucosal cells. Here the NSAIA is effectively trapped and can lead to an increase in osmotic pressure causing swelling and cell lysis. The disruption of the gastric mucosal barrier, may allow the diffusion of gastric acid into the submucosa, contributing to further damage.[54b] The effect of NSAIAs on the microcirculation to the stomach may be another component of the pathogenesis of gastropathy. Aspirin has been shown to cause a focal decrease in mucosal blood flow at the sites of subsequent ulcer formation.[54g] Some of these alterations in blood flow are likely mediated through the systemic inhibition of PG synthesis, or local effects of NSAIAs. Another potential mechanism affecting the microcirculation is the increase in neutrophil adherence to the vascular endothelium after NSAIA administration resulting in direct obstruction of the microvasculature, or by causing damage to the endothelium and epithelium by releasing proteases and free radicals.[54b]

Signs of Gastric Ulceration

Clinical signs of gastric ulceration in dogs include vomiting, hematemesis, melena, abdominal pain, pallor of the mucous membranes, lethargy, weakness, collapse and anorexia. Interestingly, experimental studies of NSAIAs reported clinical signs of gastric ulceration to be inconsistently present in dogs with endoscopic or gross evidence of gastrointestinal lesions.[54h] Some dogs remained bright and alert with no signs of abdominal pain. These findings are consistent with reports in humans where most cases of NSAIA-induced gastric ulceration go undiagnosed until they are life-threatening, complicated ulcers. The delay between the development of gastric ulceration and the observation of clinical signs may be related to unique properties of the NSAIA, or clinical signs may not develop until a deep ulcer erodes into a large blood vessel. Poor correlation between gastrointestinal lesions observed by endoscopy and clinical signs following treatment with carprofen, ketoprofen, or meloxicam have been reported in other studies. These lesions were mild to moderate in severity and did not differ statistically from placebo. The initial signs of vomiting and anorexia are frequently due to gastric irritation or inflammation. Because of the requirement of a severe lesion prior to the presence of hemorrhage or acute kidney injury, it is essential that owners be warned to stop NSAIA administration and seek immediate advice from the family veterinarian should the dog or cat develop vomiting or anorexia.

Role of Prostaglandins and Antiprostaglandins in Nociception

Nonsteroidal antiinflammatory analgesics inhibit COX-1, COX-2, or both, or COX-3 resulting in reduced PG synthesis. COX-2 is inducible and synthesized by macrophages and inflammatory cells, potentially increasing by 20-fold over baseline, especially in injured tissue and inflammatory conditions such as osteoarthritis.[42] Increased COX expression stimulates prostanoid production and these compounds serve as mediators of inflammation and amplifiers of nociceptive input in the peripheral and central nervous systems.[42] By this mechanism, COX-2 is responsible for a significant amount of pain and hyperalgesia following tissue injury. COX-1 is increased approximately two- or threefold during tissue injury, and may also generate PGs at sites of inflammation (e.g., joints, skin, gastrointestinal tract). COX-1 is present within the central nervous system and active in pain transmission. In addition to the peripheral effect, a significant part of the NSAIA antinociceptive effect is exerted at the spinal cord and supraspinal levels.[41-47] This action, in addition to pain relief, may account for the observed overall well-being and improved appetite of patients receiving injectable NSAIAs for relief of acute pain.

Pain management should be considered in its physiologic context as pain pathways involve COX-1 or COX-2 genes predominantly, both of which are differentially expressed. COX-1 selective NSAIAs, for example, are superior to COX-2 selective NSAIAs at inhibiting visceronociception and visceronociception is also greatly reduced in COX-1 but not COX-2 knockout mice. Visceral pain may be mediated by intraperitoneal receptors on sensory fibers by COX-1–produced prostacyclin. These studies concluded that peripheral COX-1 mediates nociception in slowly developing pain in mice,

such as in visceral pain, and central COX-1 may be involved in rapidly transmitted, nonvisceral pain, such as that caused by thermal stimulation. Interestingly, there may be gender differences, as in Ballou's mouse model, COX-2 was also found to mediate visceral nociception, but only in female mice.[47a] The analgesic potency of a range of NSAIAs in relieving tooth-extraction pain in humans correlates closely with increasing selectivity toward COX-1 rather than COX-2. These findings highlight the importance of both COX-1 and COX-2 contributing to pain and the selectivity of NSAIAs in treating painful conditions. The veterinary COX-2 preferential (COX-2 inhibition with some COX-1 sparing) NSAIAs may have similar activity.

Early research emphasis was placed on development of medications that inhibit COX-2 activity and spare constitutive COX-1 function. Theoretically, COX-2–selective NSAIAs should be effective, with potentially fewer adverse effects in the management of pain. Unfortunately, this complex biologic system is still not clearly defined and current knowledge indicates a role for both in nociceptive transmission and constitutive functions,[47,48] and the notion of "good versus bad COX" is probably too simplistic.[34] In addition to the COX-2 role in inflammation, aberrantly upregulated COX-2 expression is increasingly implicated in the pathogenesis of a number of epithelial cell carcinomas, including those of the colon and esophagus.[58,59] COX-2 inhibitors are being studied as potential anticarcinogenic agents. Although glucocorticoids are not analgesics, the COX-2 gene is glucocorticoid sensitive, in that it is reduced following administration of glucocorticoids, which may partially explain the antiinflammatory and analgesic effects of this class of medications.[47,58,60]

The COX-3 isoenzyme has been proposed as a target of the analgesic/antipyretic agents acetaminophen and dipyrone.[46,49,50] Both acetaminophen and dipyrone have minimal effect on COX-1 and COX-2,[46] and are frequently used to reduce fever in animals with little gastrointestinal or renal adverse effects. The COX-3 isoenzyme is more sensitive to NSAIAs that are analgesic and antipyretic, but which have low antiinflammatory activity. This fact emphasizes the different niche for NSAIA therapy in managing pain of differing etiology. As the COX-3 isoenzyme is derived from the COX-1 gene, this suggests that the COX-1 gene plays an integral role in pain and/or fever depending on the physiologic context.[44]

Adverse Effects of Nonsteroidal Antiinflammatory Agents

The breadth and severity of organ dysfunction depends on the COX selectivity of the NSAIA (Table 38-1). All NSAIAs require accurate dosing to avoid potential adverse effects, especially when used long-term. The recommended dosages for the various NSAIAs rarely compromise these functions; however, should a patient be in a prostaglandin-dependent pathologic state, administration of NSAIAs frequently result in adverse effects. However, even in health, the NSAIAs may result in gastrointestinal, renal, or hepatic abnormalities, or rarely coagulopathy (predominately non-selective NSAIAs). Some patients may be receiving other medications and NSAIA interaction with these must be considered prior to administration.[71]

Gastrointestinal Tract

COX-2–specific inhibitors appear to have fewer GI adverse effects than COX-1 inhibition, but long-term use in some people has resulted in gastrointestinal problems similar to those experienced with the COX-1 inhibitors, thereby identifying individuals intolerant to NSAIAs. Although the incidence of gastrointestinal signs may be reduced with COX-2–specific targeted NSAIAs, adverse effects may also occur in dogs and cats, as COX-2 is protective in the intestinal mucosa. COX-2 expression has been identified in the duodenum of dogs, which increased significantly following 3 days of aspirin (10 mg/kg q12h for 3 days), when compared with carprofen and deracoxib.[72] Duodenal ulceration has been identified in dogs receiving appropriate dosing of deracoxib and meloxicam; therefore it cannot be assumed that COX-2–specific inhibitors will be a "safe" treatment for all dogs with chronic administration. Frequently, dosages higher than those recommended or in association with corticosteroids resulted in gastric or duodenal ulceration.[73,74] This highlights the importance of contraindications for NSAIA administration. Some reports of meloxicam toxicity have been associated with the use of Mobicox, the human formulation.[74]

When given per os, NSAIAs should be given with food to protect the gastric mucosa from high, localized drug concentrations. Another potential cause for gastric ulceration is the fact that most NSAIAs that inhibit COX have been shown to result in diversion of arachidonate to the 5-LOX pathway (see Fig. 38-1). This results in an excessive production of leukotrienes, which have been implicated in many pathologic states, including hyperalgesia and the formation of NSAIA-induced ulcers.[46,61-64]

Liver

An elevation in serum alanine aminotransferase (ALT) can potentially occur with all NSAIAs, and is usually reversible with NSAIA withdrawal. Rare, acute, idiosyncratic hepatic necrosis after carprofen administration has been recognized in dogs.[75] Hepatotoxicity occurs in cats where acetaminophen has been administered. *N*-Acetylcysteine 140 mg/kg initially, then 70 mg/kg IV q4h × 12 to 24 h with IV fluid support is recommended.

Kidney

Where malaise, inappetence, and vomiting occur, serum creatinine should be measured to rule out renal injury as a cause of signs. As both the COX-1– and COX-2–selective NSAIAs deplete PG production in the kidney there is potential for renal injury where a PG-dependent state exists. Animals with renal disease, various degrees of volume depletion, hypotension, and increased sympathetic tone could experience an increased release of angiotensin II and norepinephrine. Renal PGs modulate such vasoconstrictive influences of the renal vessels thereby preserving renal blood flow and glomerular filtration rate (GFR).[76] In a study assessing potential alterations in GFR, serum urea and creatinine, following NSAID administration to young healthy dogs; carprofen, meloxicam, or saline was administered one hour prior to anesthesia and painful stimulus.[78] The findings of this study showed that meloxicam or carprofen produce no clinically significant alteration of renal function when compared with a saline placebo. However, should an unrecognized or untreated ischemic event occur, this may result in injury to the proximal tubule, increased solute delivery to the distal nephron, which in turn stimulates tubuloglomerular feedback and further vasoconstrictive effects. Damage to endothelial cells and subsequent activation of leukocytes also contribute to impaired GFR by physically impeding blood flow.

Table 38-1 Nonsteroidal Analgesic Dosing Regimen Per Lean Body Weight*

Drug	Indication	Species, Dose, Route	Frequency
Ketoprofen	Surgical pain	Dogs: ≤2 mg/kg, IV, SC, IM, PO	Once postoperative
COX-1 & COX-2 selective		Cats: <2 mg/kg, SC	Repeat q24h
	Chronic pain	Dogs: & cats <1 mg/kg	cats; no more than 5 days dogs: 1 mg/kg PO up to 5 days, 0.25 mg/kg for up to 30 days
		Dogs: & cats ≤2 mg/kg, PO ≤1 mg/kg	Repeat q24h
Meloxicam	Surgical pain	Dogs: <0.2 mg/kg IV, SC	Once
COX-2 preferential		<0.1 mg/kg IV, SC, PO	Repeat q24h
	Chronic pain	Dogs: <0.2 mg/kg PO	Once
		<0.1 mg/kg PO	Repeat q24h
	Surgical pain	Cats: <0.2 mg/kg SC, PO	Once
		0.05 mg/kg SC, PO	Daily × 2 to 3 days
	Chronic pain	Cats: ≤0.05 mg/kg SC, PO	Once daily
		Titrate reduction to comfort ~0.025 mg/kg ASAP	Daily or 3 to 5× weekly
Carprofen	Surgical pain	Dogs: <4 mg/kg, IV, SC	Once upon induction
COX-2 preferential, however, mechanism not clear		<2.2 mg/kg PO	Repeat q12h-24h PRN
	Chronic pain	Cats: <2 mg/kg SC	Once upon induction
		Dogs: <2.2 mg/kg PO	q12 to 24h
Etodolac	Chronic pain	Dogs: <10 to 15 mg/kg PO	Once daily
Deracoxib	Perioperative pain	Dogs: 3.0 mg/kg PO	Once daily × ≤7 days
COX-2 selective	Chronic pain	Dogs: 1 to 2 mg/kg PO	Once daily
Firocoxib	Chronic pain	Dogs: 5 mg/kg PO	Once daily
COX-2 selective			
Tepoxalin	Chronic pain	Dogs: 10 mg/kg PO	Once daily
Dual LOX-COX inhibitor			
Tolfenamic acid	Acute & chronic pain	Cats: <4 mg/kg SC, IM	SC, IM dose: once
COX-1 COX-2 selective		Dogs: <4 mg/kg PO	Oral dosing: once daily for 2 to 4 days consecutive days per week, repeat weekly cycle
Flunixin meglumine	Pyrexia	Dogs & cats: 0.25 mg/kg SC	Once
COX-1 COX-2 selective	Ophthalmologic procedures	Dogs & cats: 0.25 to 1 mg/kg SC	q12 to 24h PRN for 1 or 2 treatments
Ketorolac	Surgical pain	Dogs: 0.3 mg/kg PO	Twice daily along with misoprostol
		Cats: 0.25 mg/kg IM	q12h for 1 to 2 treatments
COX-1 COX-2 selective	Panosteitis	Dogs: 10 mg/dog >30 kg, PO 5 mg/dog >20 kg but <30 kg, PO	Once daily for 2 to 3 days
Piroxicam	Inflammation of the lower urinary tract	Dogs: 0.3 mg/kg, PO	q24 to 48h
		Cats: 0.3 mg/kg, PO	q24 to 72h
Acetaminophen	Acute or chronic pain	Dogs: only 15 mg/kg PO	q8h
weakly inhibit both COX-1 and COX-2 but have greater inhibition of COX-3			
Aspirin	Acute or chronic pain	Dogs: 10 mg/kg PO	q12h
COX-1 COX-2 selective			
Dipyrone	Antipyresis	Dogs & cats 10 mg/kg IV	q12h
weakly inhibit both COX-1 and COX-2, but have greater inhibition of COX-3	Analgesia	Dogs & cats 25 mg/kg IV	q12h

*See text for details on the contraindications for use.
PRN, As required.

Hemostasis and Cardiovascular

Alteration of COX-1 and COX-2 disrupts vascular homeostasis. Platelets contain solely COX-1. NSAIAs with COX-1 selectivity have anti-TXA_2 activity thereby reducing platelet aggregation. Poor platelet function results in hemorrhage in susceptible patients. Conversely PGI_2, a modulator of thrombosis, is affected by the NSAIAs with COX-2 selectivity resulting in a reduction in vasodilation and antithrombosis.[84] A study examining the effect on coagulation in dogs with osteoarthritis and receiving aspirin, deracoxib, carprofen, or meloxicam revealed changes in platelet aggregation and the thrombelastogram associated with the COX selectivity of these NSAIDs.[75a]

Because of the opposing effects of prostacyclin and TXA_2 on hemostasis, the degree of hemorrhage in any individual patient may vary. Patients with occult von Willebrand disease have been

identified by severe hemorrhage following a single dose of a non-selective COX inhibitor. In this setting, the effects of COX-1 inhibition were demonstrated in the vulnerable patient. The potential for proliferation of thrombi due to unopposed TXA_2 activity may be a potential problem in specific situations in dogs taking highly selective COX-2 inhibitors. This, in addition to unopposed vasoconstriction, was the reason for withdrawal of some COX-2–selective NSAIAs implicated in myocardial infarction and stroke in humans.

Summary of Adverse Effects

When summarizing the common adverse effects noted in animals following administration of NSAIAs (e.g., gastrointestinal ulceration, hepatic necrosis, renal perturbations, and hemorrhage), hemorrhage is the only one that appears to be spared with COX-2–selective and COX-2–preferential NSAIAs in animals with normal platelet numbers and function. The majority of reported adverse effects secondary to NSAIA administration appear to be iatrogenic and other pre-existing pathology and drug usage should have been considered.

General Considerations

As a group, NSAIA effects are not reversible, making it imperative that the general health of the patient be considered prior to prescribing NSAIAs. With large-animal formulations, dilutions and estimations are ill-advised, as a very small volume may easily result in serious overdose. Dosing should be calculated based on the ideal weight of a patient. Overdose requires short-term, gastric protection and IV fluids to support renal function. Because cats and dogs are more susceptible to the adverse effects of NSAIA administration, the reported safety of any NSAIA approved for the human patient is not easily transduced to the veterinary patient. The potential for toxicity with certain NSAIAs is greater in cats than other species as a result of their limited ability to glucuronidate NSAIAs, resulting in a prolonged duration of effect.[38] Therefore, only NSAIAs approved for use in cats should be administered to this species (see Table 38-1).[77] Of note, meloxicam (Metacam) is approved for use in cats in many countries. A single dose of 0.3 mg/kg is approved in the United States; however, it is the opinion of this author and others[38] that a loading dose of no more than 0.1 or 0.2 mg/kg IV, SC, PO, depending on degree of surgical pain, and lower for chronic pain, is effective, allowing repeated daily dosing. In general, NSAIAs should be restricted to animals older than 6 weeks of age. If a particular NSAIA appears ineffective in managing pain, prescribing a different NSAIA may be effective because of individual variation in response to the different analgesics. However, caution is advised when switching from one NSAIA to another as COX-2 dysregulation within the duodenal mucosa may predispose to ulceration. Currently it is difficult to predict in the individual patient what is a "safe" time to wait prior to starting a different NSAIA. In a recent study where the COX-2 inhibitor firocoxib was administered to dogs after a wash-out period from 1 to 7 days (most commonly >2 days) following discontinuation of another NSAIA, there was no increased risk when compared to a longer washout period.[81] The study examined only administration of firocoxib after another NSAID; therefore, the results cannot be extrapolated to other NSAIDs. In another study where dogs were administered injectable carprofen followed by oral deracoxib within 24 hours, there was no evidence of NSAIA treatment–related lesions in the gastrointestinal tract.[83] Again, based on the individual intolerance and susceptibility to adverse effects of the NSAIAs, veterinarians and owners must be aware of the potential for gastrointestinal pathology when switching from one NSAIA to another, especially where intolerance to one is the reason for change, and not efficacy.

Contraindications for the Use of Nonsteroidal Antiinflammatory Analgesics

There are many potential interactions between NSAIAs and other medications.[71] Prior to prescribing an NSAIA to a patient receiving other medications, it is essential to review the interactions to ensure there are no contraindications for coadministration. Concurrent use of any other NSAIAs or corticosteroids has resulted in gastroduodenal perforation. NSAIAs should not be administered to patients in shock, trauma cases upon presentation or where hemorrhage is evident (e.g., epistaxis, hemangiosarcoma, head trauma). Likewise, those animals with acute renal insufficiency, hepatic insufficiency, dehydration, hypotension, conditions associated with low "effective circulating volume," coagulopathies (i.e., factor deficiencies, thrombocytopenia, von Willebrand disease), or evidence of gastrointestinal pathology, should not receive NSAIAs. NSAIAs must be avoided in animals with spinal injury, including herniated intervertebral disk, as most of these patients receive corticosteroids with medical or surgical management. A study using healthy beagles simulated such a scenario where dexamethasone (0.25 mg/kg q24h) and meloxicam (0.1 mg/kg q 24h) were administered for 3 days pre- and post-sham surgery. When compared with lesions in dogs receiving saline, dexamethasone, or meloxicam combined with saline, the total endoscopic score of the dexamethasone-meloxicam group was significantly greater than the other groups. Scores for the dexamethasone group were significantly greater than the scores for the saline and meloxicam groups, with no significant difference found between the saline and meloxicam groups. The location of lesions were consistent with previous findings where the pylorus and pyloric antrum appear more susceptible to the effects of combination NSAIAs and corticosteroids.[71a]

NSAIAs should not be administered to patients with severe or poorly controlled asthma, or other moderate to severe pulmonary disease, as they may deteriorate with COX-1–inhibiting NSAIAs, especially aspirin. As COX-2 induction is necessary for ovulation and subsequent implantation of the embryo,[52] NSAIAs should be avoided in breeding females during this stage of the reproductive cycle. NSAIAs also block PG activity in pregnant animals resulting in cessation of labor, premature closure of the ductus arteriosus in the fetus, and disruption of fetal circulation.[52] If administered prior to birth, or during lactation, a permanent nephropathy may result.

Over several years, many studies have reported the safety and efficacy of NSAIAs in various clinical settings. The NSAIAs are very effective analgesics in both the acute and chronic clinical settings. Millions of dogs and cats worldwide benefit from these analgesics on a daily basis. Due diligence on behalf of the veterinarian will reduce the potential for harm.

CHAPTER 39

Antimicrobial Drugs

Mark G. Papich

Antimicrobial drugs used for gastrointestinal disease are primarily used to treat infections of the intestine and occasionally stomach (e.g., treatment of *Helicobacter*-like organisms). These drugs are used to treat a primary infection of the gastrointestinal tract (GIT) or prevent a more serious systemic infection disseminating from the GIT. Once an infection of the GIT has disseminated, producing sepsis and a general inflammatory reaction, systemic antimicrobials are needed. Although antimicrobial drugs technically also include antiviral drugs, antiprotozoal drugs (anticoccidial drugs), and anthelmintic drugs—all of which can be important to treat diseases of GIT—these drugs are discussed in other sections of this book. More detailed information about the pharmacology of these drugs and prescribing information can be found in other publications.[1,2] Principles of antibiotic therapy can be found in another chapter.[3]

Antimicrobial Drugs

Macrolide Antibiotics

The macrolide antibiotics include erythromycin and tylosin. More recent derivatives include clarithromycin and azithromycin. The macrolide antibiotics are protein synthesis inhibitors that bind to the 50-S ribosomal subunit and interfere with the translocation reaction necessary for RNA-dependent protein synthesis in bacteria. The macrolides may be bactericidal for some Gram-positive bacteria, but for other bacteria these drugs are bacteriostatic. Their action is considered time-dependent. Their pharmacokinetics favor a time-dependent action because many in this class have long half-lives that produce drug concentrations above the minimum inhibitory concentration (MIC) in plasma, cells, or tissue for an extended time after dosing.

The activity of these drugs is better for Gram-positive bacteria than Gram-negative bacteria. Gram-positive bacteria accumulate macrolides to a greater extent than Gram-negative bacteria (as much as 100× for erythromycin). Subsequently, activity is almost nonexistent against Gram-negative bacteria, especially those of the Enterobacteriaceae (e.g., *Escherichia coli*). Their activity also includes GIT pathogens such as *Campylobacter jejuni* and *Clostridium* spp.

The clinical use of macrolides involves the use of erythromycin, tylosin, and occasionally azithromycin, administered orally. In some instances, such as with tylosin-responsive diarrhea this chapter (see "Tylosin-Responsive Diarrhea" section), the pathogens that are the target of successful treatment are not known.

Macrolide pharmacokinetics have been studied in most animals. Oral absorption of erythromycin is inconsistent because it is not stable in the stomach. Oral absorption is less than 20%. Various attempts have been made to improve stability in the stomach, including salts of erythromycin, poorly soluble esters, and enteric coating. Azithromycin requires some buffering of oral formulation, but its oral absorption is much higher than for erythromycin.

The poor oral absorption of erythromycin is probably responsible for one of its most common adverse effects; that is, diarrhea. This has obvious importance when treating diseases of the GIT. Usually, gastrointestinal adverse effects in small animals are fewer following administration of tylosin or azithromycin, but this is based on anecdotal experiences and has not been investigated in a controlled study.

The most common adverse effect reported from administration of erythromycin is vomiting in dogs. This may be caused either by irritation of the stomach, or stimulation of stomach contraction. In one study, erythromycin oral administration produced the most frequent adverse effects in comparison with other drugs.[4] Stimulation of gastric motility occurs via an increase in activation of motilin receptors, via release of endogenous motilin, or via cholinergic mechanisms in the upper GIT and gallbladder.[5,6] This effect has been utilized therapeutically (see "Other Uses for Antimicrobials" section).

Lincosamides

Clindamycin and lincomycin are the most common drugs from this class. They are not related to the macrolides by chemical structure, but there are many overlapping properties such as pharmacokinetics and antimicrobial activity. Clindamycin differs from lincomycin by only the addition of chlorine on the parent molecule. This addition produces a more active drug against bacteria and some protozoa. Because clindamycin is the most often used from this group in small animals, lincomycin is not discussed further.

Like macrolides, these drugs are inhibitors that bind to the 50-S ribosomal subunit and interfere with protein synthesis. They are traditionally considered bacteriostatic (time-dependent in action), but more recent evidence shows that there is some bactericidal activity as well.

Susceptible bacteria important for the GIT include streptococci, *C. jejuni*, *Clostridium* spp., and some mycobacteria. There is little activity against most Gram-negative organisms, particularly the enteric bacteria (Enterobacteriaceae). Clindamycin has good activity against most anaerobic bacteria, but resistance has been documented among bacteria of the *Bacteroides fragilis* group.

For clindamycin, tablets, capsules, and an oral liquid (clindamycin hydrochloride) are available for small animals (Antirobe and generic) and clindamycin palmitate liquid (Cleocin), an ester that must be hydrolyzed in the GIT. Oral absorption of clindamycin hydrochloride is high in small animals.

The adverse effects are noteworthy because they predominantly affect the GIT. Clindamycin usage has been associated with bacterial overgrowth (especially *Clostridium difficile*) in the colon. Serious and fatal diarrhea has been reported in humans, rabbits, ruminants, and horses from oral administration. In people, clindamycin-associated diarrhea is common and a serious disease known as *pseudomembranous colitis* can occur as a consequence of clindamycin administration. Fortunately, such serious adverse effects have not been reported in dogs and cats, although mild diarrhea certainly is possible.

The other adverse effect that may affect the GIT in cats is esophageal injury caused by the oral administration of the hydrochloride formulation.[7] Hydrochloride formulations of other drugs (e.g., doxycycline hyclate) also have been reported to produce esophageal injury to cats (see "Tetracyclines" section).

Fluoroquinolone Antibiotics

These drugs include enrofloxacin, marbofloxacin, orbifloxacin, and difloxacin. This class also includes ciprofloxacin, which is an approved human drug that is frequently administered to dogs. (Enrofloxacin is partially metabolized to ciprofloxacin in most animals.) For treatment of GIT disease, the fluoroquinolones owe their usefulness to the high activity against Gram-negative bacilli, particularly the Enterobacteriaceae. These drugs also have the favorable property of weak activity against anaerobic bacteria. Without anaerobic activity, these drugs are less likely than other oral antimicrobials to disrupt the anaerobic intestinal bacterial population.

The fluoroquinolones have a unique mechanism of action. They inhibit the DNA gyrase enzyme (also called topoisomerase type II), which catalyzes the conversion of relaxed closed circular DNA to the superhelical form. There are A and B subunits of this enzyme and quinolones usually inactivate the A subunit. As a result of this activity, the fluoroquinolones are highly bactericidal.

The fluoroquinolones are highly absorbed after oral administration. A summary of their individual pharmacokinetics is available in a recent book chapter.[8] The exception to this generalization is the human drug ciprofloxacin. In cats the oral absorption of ciprofloxacin is low, and in dogs it is highly variable, ranging from approximately 30% to 80%. An advantage of fluoroquinolones is that they are excreted both by hepatic and renal mechanisms. Renal or hepatic insufficiency is not a contraindication to their use nor requires a dose adjustment.

The fluoroquinolones have a good safety record and can be used in a wide range of patients. The most notable adverse effects are arthropathy in young dogs (ages 4 to 28 weeks are the most susceptible) with high doses, and blindness in cats if the dose of enrofloxacin exceeds 5 mg/kg per day. Other adverse effects such as neurologic problems (seizures, tremors) are rare at the doses used for GIT diseases.

The formulation most often used is the tablet, which is available for every drug listed previously. Enrofloxacin is also available in an injectable formulation, which may be necessary in animals that cannot tolerate oral medications. When oral treatments are used, drug interactions are possible. The fluoroquinolones can be inactivated by di- and trivalent cations, producing poor oral absorption. This may be important for treatment of some GIT diseases because drugs known to contain these cations include antacids (magnesium, aluminum, and calcium), sucralfate (aluminum), and nutritional supplements (supplements containing magnesium or iron).

Tetracyclines

The tetracyclines include tetracycline, oxytetracycline, doxycycline, and minocycline. For small animals, the use is almost exclusively that of doxycycline. Tetracyclines are protein synthesis inhibitors. They bind to the 30-S ribosomal subunit and block the aminoacyl-transfer RNA from binding to the messenger RNA (mRNA) ribosome complex.

The tetracyclines are broad-spectrum drugs that are active against Gram-negative and Gram-positive bacteria, as well as *Chlamydia*, rickettsia, spirochetes, mycoplasma, L-form bacteria, and some protozoa (e.g., *Plasmodium, Entamoeba)*. The family Rickettsiaceae includes *Rickettsia* and *Ehrlichia* and tetracyclines, particularly doxycycline, are considered the drug of first choice for these infections.

The oral route is the most common method of administration and doxycycline hyclate tablets, and occasionally doxycycline monohydrate, are the formulations most often administered to small animals. Oral absorption is sometimes erratic and unpredictable, but high enough for oral treatment in most animals. Calcium and other divalent cations will chelate tetracyclines and inhibit oral absorption (note that in "Fluoroquinolone Antibiotics" section, drugs were listed to treat GIT diseases contain these cations), although this is less of a problem for doxycycline than for other tetracyclines.

Most tetracyclines are metabolized minimally and rely on glomerular filtration for elimination. However, doxycycline and minocycline are metabolized more than the other tetracyclines and the renal excretion may not be as high as for other tetracyclines. Doxycycline and minocycline differ from the other tetracyclines because they are excreted into the intestinal lumen, which may be important for treatment of some intestinal diseases.

Tetracyclines can produce changes in the gastrointestinal microflora. This has been a problem in some animals (horses especially), but less so for small animals. Nevertheless, diarrhea can occur from oral administration. The other important adverse effect related to the GIT is esophageal injury. Doxycycline entrapped in the esophagus from a broken tablet or incompletely dissolved capsule can cause injury to the esophagus and stricture. In cats, a capsules or broken tablets can lodge in the esophagus unless administered with water. Therefore, one should be cautious about giving oral doxycycline medications to cats. This problem has been primarily associated with doxycycline hyclate (the form most common in the United States), rather than doxycycline monohydrate.

Ampicillin and Amoxicillin

Ampicillin and amoxicillin are aminopenicillins, derived semisynthetically from the parent drug penicillin. They have advantages over penicillin that include better oral absorption (although amoxicillin is better absorbed than ampicillin in small animals), and slightly better activity against Gram-negative bacilli. They are also active against many of the anaerobic bacteria and some enterococci.

The aminopenicillins are available in a variety of formulations, including tablets, capsules, liquid oral suspensions, and injectable forms. Their absorption is variable. In dogs the systemic availability for ampicillin is 30% to 40%, and for amoxicillin it is approximately 60% to 80%. A relatively high amount remains in the intestinal lumen and this forms the basis for the oral use of these drugs for

treating GIT diseases. These drugs may also produce diarrhea in animals by disrupting the oral flora.

Chloramphenicol

Chloramphenicol is highly active against many pathogens that cause GIT disease. Chloramphenicol is a protein synthesis inhibitor that acts by binding to the 50-S subunit of the ribosome. This is the same site of action as macrolide antibiotics, therefore antagonism is possible. Binding to this subunit is reversible and results in inhibition of protein synthesis.

Chloramphenicol has been considered bacteriostatic, but some evidence suggests a more bactericidal action. Chloramphenicol has a wide spectrum of activity that includes both Gram-positive and Gram-negative bacteria, as well as some atypical organisms. The bacterial spectrum includes organisms that are important for GIT disease, including *Salmonella*, anaerobes (including *Bacteroides*), and enterococci.

Adverse effects must be considered whenever prescribing chloramphenicol. Dose-related anemia and pancytopenia may be associated with chronic treatment. This effect has been well-documented in cats and can occur after 14 days of therapy with standard dosages.[9] Because of the potential injury to bone marrow cells, use in neonatal animals or pregnant animals should be avoided. The more serious effect of idiosyncratic aplastic anemia has been described in humans only. The incidence is rare but the consequences are severe. This can potentially occur by direct exposure from handling the medication; therefore, pet owners should properly be advised when receiving a prescription for their pets. Chloramphenicol also can be involved in drug–drug interactions. It decreases the clearance of other drugs that are metabolized by the same metabolic enzymes (e.g., barbiturates).

Florfenicol (Nufluor) is a chloramphenicol derivative used as an injectable formulation in pigs and cattle. It has been examined only experimentally in small animals. The requirement for frequent administration and poor absorption make it an impractical choice for treating dogs. The lack of a palatable oral formulation and inexperience with clinical use is a disadvantage for the use in cats.

Metronidazole

Metronidazole (Flagyl and generic) is of the group of nitroimidazoles. Metronidazole is the most common drug prescribed from this group. Tinidazole (Tindamax) tablets are approved in people for treating *Giardia*, *Trichomonas*, and *Entamoeba*. Similar drugs, not available presently in the United States, are nimorazole (Naxogin), ornidazole (Tiberal), ronidazole, and benznidazole (Rochagan). Ronidazole is not a registered drug in the United States, but compounded formulations have been used in the United States to treat infections caused by intestinal *Tritrichomonas* in cats.

Metronidazole is a unique antimicrobial in that it has very little effect on aerobic Gram-positive and Gram-negative organisms, but is highly effective against anaerobic bacteria (e.g., *Bacteroides, Fusobacterium, Clostridium, Peptococcus*, and *Peptostreptococcus*). It is not effective against bacteria that may be facultative anaerobes. It has good activity against many protozoa (e.g., *Giardia lamblia, Entamoeba, Trichomonas*). Metronidazole has been used in people, in combination with other drugs, to treat *Helicobacter pylori*.

Metronidazole is rapidly taken up by bacteria, followed by a reaction in the cell in which it is metabolized by a reduction process to cytotoxic derivatives (short-lived free radical compounds). These cytotoxic compounds damage DNA and other critical intracellular bacterial macromolecules. Aerobic bacteria lack the reductive pathway necessary to produce a cytotoxic compound.

Metronidazole is rapidly and highly absorbed in small animals (59% to 100% in dogs) following oral administration. An injectable preparation is available, but seldom used. Peak concentrations occur 1 to 2 hours following oral administration. The related drug, ronidazole, is also highly absorbed. In cats, the oral absorption of ronidazole is rapid and complete (almost 100%).

The most significant adverse effect is neurotoxicity. The reactions appear to be caused by inhibition of the γ-aminobutyric acid neurotransmitter. At high doses (67 to 129 mg/kg/day) that exceed the recommended dose, metronidazole has caused ataxia, lethargy, proprioceptive deficits, nystagmus, and seizure-like signs in dogs. Dogs have recovered if drug administration was discontinued, but recovery may take 1 to 2 weeks.[10,11] Recovery is much faster if diazepam is administered.[12] Neurotoxicosis also has been observed in cats with high doses.

Metronidazole has caused nausea, vomiting, and diarrhea in animals, but it is rare. Palatability is a problem in most animals because of its bitter taste. Cats are particularly susceptible to the unpleasant taste of broken or crushed tablets. This problem can be alleviated by administration of the ester metronidazole benzoate.[13]

Aminoglycosides

The aminoglycosides are administered orally. They are used occasionally for diseases of the GIT because they retain their activity in the lumen of the GIT without systemic absorption and risk of systemic adverse effects.

Aminoglycosides are protein synthesis inhibitors. They irreversibly bind to the 30-S ribosomal subunit and cause misreading of the genetic code and inhibit bacterial protein synthesis. The aminoglycosides are rapidly bactericidal. They are concentration-dependent drugs for which the activity is predicted by the peak concentration (C_{MAX}) in relation to the MIC. The clinical protocols that administer these drugs orally retain high concentrations in the GIT lumen; therefore, their pharmacodynamics are ideally suited for this application.

Aminoglycosides are active against most Gram-negative bacteria, including Enterobacteriaceae. Their action against streptococci and enterococci is limited unless they are combined with a β-lactam antibiotic. Anaerobic bacteria are inherently resistant because drug transport into bacteria is oxygen dependent.

Oral absorption of aminoglycosides is poor, but if any systemic absorption occurs, these drugs rely almost exclusively on renal clearance, primarily glomerular filtration. If there is any risk of systemic absorption caused by a compromised GIT mucosa (e.g., severe enteritis), systemic absorption may occur, and dosage adjustments must be considered in patients with renal insufficiency or failure. If systemic absorption occurs, the most serious toxic effect associated with aminoglycoside therapy is renal tubular injury. These drugs are actively taken up by proximal tubular cells. Animals that are dehydrated have electrolyte imbalances (e.g., low Na^+ or K^+), have endotoxemia, or have existing renal disease, are at a higher risk for toxicity than are healthy animals.

Drugs used for GIT disease in this class include gentamicin oral formulations (developed for pigs), neomycin oral (e.g., Biosol), and paromomycin. Paromomycin has been administered orally to people and small animals for treatment of intestinal infections. Its primary use has been in oral treatment of enteric protozoa and aerobic bacteria. It has also been used as a treatment for cryptosporidiosis, but efficacy is questionable. Caution is advised when using paromomycin for intestinal disease because it has caused acute renal failure in cats at high doses.[14]

Antimicrobial Drugs for Treatment of Diarrhea

The routine use of antimicrobials to treat diarrhea has been questioned by gastroenterologists. Therapy for diarrhea should include fluid therapy, electrolyte replenishment, maintaining acid–base balance, and control of discomfort. But drugs are sometimes used such as antimicrobials, motility modifiers, and intestinal protectants. Drugs used to treat diarrhea caused by intestinal parasites are covered in another section. In most cases of diarrhea in small animals, a bacterial etiology cannot be identified. A recent review[15] provides a critical overview of the lack of proven efficacy for many antimicrobials that are FDA-approved for treating diarrhea. In those patients, fluid therapy and supportive measures are often the most widely recommended treatment.

The preferred drugs for treatment of diarrhea are those that are poorly absorbed or nonabsorbed antibiotics, because the goal of treatment is to restrict the drug activity to the gastrointestinal lumen. For treatment of diarrhea, these drugs have been combined with motility modifiers, adsorbents, and intestinal protectants. These drugs have been combined in commercial preparations, but some of these are irrational combinations and no longer have a place in companion animal medicine.

Important points that are essential to understanding the use of antimicrobial drugs for treatment of diarrhea include: (a) sometimes administration of oral antibiotics can be a *cause* of diarrhea.[16,17] (b) Selection of drugs is often empirical and based on anecdotal experience, reports by experts, or extrapolated from the use of the drug in human medicine. (c) It is unusual for therapy to be guided by culture and susceptibility testing. In addition to the challenges of culturing and isolating bacteria that may be the cause of diarrhea, standardized susceptibility testing methods are not available. Ordinarily, when bacteria are cultured a susceptibility test can be performed according to standards developed and published by the Clinical Laboratory Standards Institute (CLSI).[18] However, these standards, and particularly the breakpoints that define susceptibility and resistance, only apply to the systemic use of the agents. The antibacterial MICs for organisms isolated from the intestine may not apply to drugs that are delivered locally (i.e., orally). Therefore, a susceptibility test may not correlate to the efficacy of the drug when used to treat the diseases discussed in this section, unless the treatment is targeted to a systemic infection.

Campylobacter Enteritis

This disease is caused by C. *jejuni*, which has public health significance because it may be transmitted to people. This organism is the most common cause of foodborne infectious diarrhea in people. The treatment is aimed primarily at maintaining fluid and electrolyte balance. If antimicrobials are considered, the following drugs have been used: erythromycin (10 to 20 mg/kg q8h for 5 to 7 days), azithromycin (7 to 10 mg/kg once a day × 3 days), fluoroquinolones, tylosin, clindamycin, tetracycline, or chloramphenicol (40 to 50 mg/kg PO q8h). Although erythromycin has been cited as the treatment of choice, bacterial shedding may resume once therapy is stopped.[19]

Intestinal Bacterial Overgrowth Caused by *Escherichia coli or Clostridium* spp.

Treatments that have been used include antimicrobial treatment and administration of probiotics. Probiotics are formulations of specific bacteria that will restore a healthy population of bacteria in the intestine (discussed in more detail elsewhere). When antibiotics are considered, one should administer an oral drug that is active in the gastrointestinal lumen. For treatment of infections caused by *Clostridium* spp. the drug should have activity against anaerobic bacteria and may include metronidazole or clindamycin. Oral ampicillin or amoxicillin also has been used. Vancomycin is used orally in people when resistance to other drugs is suspected, but this use has not been described for small animals. For *E. coli*, fluoroquinolones are recommended.

Tylosin Responsive Diarrhea

Because some forms of chronic diarrhea in animals have been responsive to the antimicrobial tylosin (Tylan), the disease has been characterized as "tylosin-responsive chronic diarrhea in dogs."[20,21] This disease, affecting both large and small bowel, is most likely caused by a bacterial pathogen, but the specific etiology has not been identified. C. *jejuni* and *Clostridium perfringens* have been identified in some of the affected animals. Tylosin has been effective at improving clinical signs that occur with or without organisms being identified. When administered at 7 to 15 mg/kg/q12-24h (average dose) response was prompt.[20] Some dogs respond within 24 hours; others respond within 3 days. Other studies by the same investigators showed that a dose of 20 mg/kg/day was effective, but other drugs (metronidazole, trimethoprim-sulfonamides, doxycycline, or prednisolone) were not.[21]

Sources of Tylosin

The powdered form for livestock (Tylan) has been mixed with the animal's food at a dosage of 40 to 80 mg/kg/day. One teaspoon contains approximately 3 g (3000 mg); consequently, one-quarter teaspoon contains 750 mg, enough for many dogs. Because some animals may find the bitter taste unpleasant and refuse their food, the administration should be tested to identify the method of administration that is best tolerated. Tablets for small animals are available in other countries.

Metronidazole Responsive Diseases

Metronidazole (Flagyl) is active against the protozoan *Giardia* and it is for this use that metronidazole has traditionally been administered to treat diarrhea in small animals. Veterinarians discovered that metronidazole also was effective in patients that did not have giardiasis. Bowel inflammation may be caused by metronidazole-sensitive bacteria, which act as a chemoattractant for neutrophils. The efficacy of metronidazole may be related to this antibacterial activity. Oral administration of metronidazole at 20 mg/kg to cats decreased the number of anaerobic and aerobic bacteria and altered the indigenous bacterial population.[22] In addition, metronidazole may have an immunosuppressive effect on the gastrointestinal mucosa (decreased cell-mediated response). Metronidazole (with and without combination with ampicillin) has been effective for histiocytic ulcerative colitis in dogs.[23] Doses have been as high 60 mg/kg/day for 2 to 4 weeks, but many animals will respond to low doses of 30 mg/kg/day (in divided doses). Cats can receive one-quarter of a 250 mg tablet, two to three times daily (10 to 25 mg/kg). Cat owners should be cautioned that broken tablets have an unpleasant taste.

Ronidazole

Ronidazole, from the same chemical group as metronidazole, has greater in vitro activity against, and is the preferred treatment for, intestinal infections in cats caused by the organism *Tritrichomonas foetus*. It has been administered at a dose of 30 mg/kg once or twice daily for 14 days, and studies in cats demonstrate

that is one of the few drugs associated with eradication of this organism.[24]

Although central nervous system reactions are associated with ronidazole treatment in cats, these are usually associated with high doses. Because of the long half-life, it may be possible to administer this drug once daily and avoid adverse effects.

Ulcerative Colitis in Dogs

In some dogs, particularly Boxer dogs, ulcerative colitis is associated with *E. coli* infection of the colonic mucosa.[25] In these dogs there is evidence of mucosal infiltration with large numbers of macrophages that induce an inflammatory reaction, leading to ulcerative colitis. The invasive bacteria evoke production of inflammatory reactions and produce cytokines that are responsible for clinical signs. Successful treatment has been accomplished with oral administration of fluoroquinolones, which are highly active against *E. coli*. One of the regimens includes enrofloxacin at 7 mg/kg, once a day × 9 weeks.

Salmonellosis

The primary goal when treating *Salmonella* is to maintain fluid balance and prevent electrolyte losses. The patients should be isolated to prevent spreading of infection and strict containment procedures should be instituted in the hospital. Antibiotics are discouraged unless absolutely necessary for patients with salmonellosis. Antibiotic therapy may prolong shedding. In animals in which oral therapy is possible, drug choices include the following: fluoroquinolones, chloramphenicol, ampicillin or amoxicillin or amoxicillin-clavulanate, trimethoprim-sulfonamide, or a cephalosporin (the activity against *Salmonella* is highest with third-generation cephalosporins).

Bacterial Septicemia Secondary to Diarrhea

When it is suspected that there may be a loss of the protective epithelial barrier, the intestinal mucosal integrity is compromised. In these cases, bacteremia and septicemia can occur because of translocation of bacteria. Signs accompanying septicemia include a severe, bloody diarrhea, fever, and leukocytosis. This may progress to signs of endotoxic shock. If septicemia is suspected, systemic antibiotics are clearly warranted.

The choice of antibiotics will vary depending on the species and the animal's age. Neonates with diarrhea will deteriorate rapidly and treatment cannot wait for culture and sensitivity results. Therefore broad spectrum antimicrobials often are used.

Recommended antibiotics include ampicillin or amoxicillin (with or without a β-lactamase inhibitor); combination of a β-lactam (penicillin, aminopenicillin, or cephalosporin) with an aminoglycoside (gentamicin or amikacin); aminoglycoside alone; cephalosporin (extended-spectrum cephalosporin); carbapenem (meropenem or imipenem); or fluoroquinolones (enrofloxacin, marbofloxacin, difloxacin, orbifloxacin). If the animal shows signs of sepsis, systemic antimicrobials should be used. Antibiotics that are poorly absorbed and confined to the gastrointestinal lumen may be of little benefit (e.g., neomycin, ampicillin).

Other Uses for Antimicrobial Drugs

Erythromycin to Increase Gastrointestinal Motility

Erythromycin, as discussed previously, is a macrolide antibiotic widely used to treat bacterial infections. It is associated with vomiting and regurgitation in small animals as an adverse consequence of treatment. This effect is caused by stomach contraction and expulsion that is most prominent at high doses. But at low doses, it can produce a beneficial stimulation of gastrointestinal motility. Not all macrolide antibiotics exhibit this property because it requires a unique chemical structure that not all drugs in this class possess (erythromycin has a 14-carbon structure, but other macrolides that are less effective—tylosin and tilmicosin—have a 16-carbon structure). In people, erythromycin has been used to promote gastric motility and increase emptying in patients with diabetic gastroparesis and in conjunction with enteral feeding in critical care patients.[26]

Erythromycin stimulates gastrointestinal motility via activation of motilin receptors, via release of endogenous motilin, or via cholinergic mechanisms in the upper GIT.[5,6,26] Motilin is a 22-amino-acid peptide released from endocrine cells of duodenal mucosa. It increases the motor contractions—housekeeper wave—during the interdigestive period. Motility is stimulated specifically in the pyloric antrum or the smooth muscle cells of the proximal intestine.[27,28] Because most of the motilin receptors are on the stomach and proximal small intestine, there is a weak response to erythromycin in the distal GIT. The effective dose in animals is 0.5 to 1 mg/kg q8h or less, much lower than the antibacterial dose.

Treatment of *Helicobacter* Gastritis

Treatment of gastritis and ulcers caused by *H. pylori* and *Helicobacter*-like organisms has gained interest in veterinary medicine. These organisms have been identified in biopsy specimens from dogs and cats, but their definitive role in gastritis and ulcers of companion animals has yet to be established.[29,30] Some studies have found no association between *Helicobacter* infection and gastritis.[31,32] However, in some animals with gastritis, treatment with ampicillin, metronidazole, and famotidine, or the combination of metronidazole, amoxicillin, and bismuth subsalicylate has helped decrease signs.[29] Triple antibiotic therapy for *Helicobacter* also decreased clinical signs in dogs with chronic vomiting.[31a] Role of *Helicobacter* as a cause of gastritis in animals has been reviewed.[32a,33] One author recommends that animals with clinical signs of gastritis and positive for *Helicobacter* or *Helicobacter*-like organisms should be treated. The oral treatment for animals that has been the most widely used is a 2-week course of the combination of metronidazole and/or clarithromycin plus amoxicillin, and a proton-pump inhibitor or H_2-receptor antagonist.

In people, *H. pylori* gastritis has been treated with the simultaneous use of metronidazole, omeprazole, and clarithromycin.[34] One regimen uses clarithromycin (Biaxin) and omeprazole (Prilosec). A product called Tritec combines ranitidine with bismuth citrate and is designed to be administered concurrently with clarithromycin (Biaxin). Some regimens also use amoxicillin or metronidazole. Some synergism is achieved with these combinations. For example, H_2-antagonists or omeprazole enhance the antibacterial activity of metronidazole and perhaps other antibiotics.

CHAPTER 40

Antioxidant Drugs

Craig B. Webb

Definitions

Oxidative Stress

Oxidative stress is an imbalance between prooxidant compounds and antioxidant defenses.[1,2] Another term used to describe this summation of pro- and antioxidant molecules is the *redox state*.

Free Radicals

A *free radical* is any molecular species capable of independent existence and containing one or more unpaired electrons.[1,2] Examples include the hydrogen radical ($H^{\bullet}$), the superoxide free radical ($O_2^{\bullet -}$), and the hydroxyl ($OH^{\bullet}$) and peroxyl radicals ($RO_2^{\bullet}$). Metabolic processes taking place within the liver constitute a major source of free radical production. The superoxide free radical, for example, is produced by hepatic oxidative reactions and by "uncoupling" of the cytochrome P450 enzyme system. Free radicals are formed during hepatic metabolism of endogenous substances or xenobiotics such as acetaminophen.[5]

Reactive Oxygen Species

The term reactive oxygen species (ROS) is used to describe free radicals containing oxygen.[1,2] These are molecules that are formed by the reduction of oxygen and encompass both free radicals and nonfree radicals such as hydrogen peroxide (H_2O_2), hypochlorous acid (HOCl), and peroxynitrite (ONOO, which is also a reactive nitrogen species). ROS are produced under normal circumstances during normal mitochondrial respiration, and during disease processes such as inflammation, necrosis, and ischemia.

Reactive Nitrogen Species

Nitric oxide synthase (NOS) in hepatocytes and Kupffer cells produces nitric oxide ($NO^{\bullet}$), a reactive nitrogen species (RNS)[1,2] in the reaction:

L-Arginine + O_2 + NADPH → $NADP^+$ + $NO^{\bullet}$ + citrulline

where NADPH is nicotinamide adenine dinucleotide phosphate (reduced form) and $NADP^+$ is nicotinamide adenine dinucleotide phosphate.

Nitric oxide is also produced by neutrophils as part of the inflammatory process, and from the reaction of glutathione with peroxynitrite. Nitric oxide binds reversibly to free thiol groups, including reduced glutathione (GSH) through the action of glutathione-*S*-transferase. Nitric oxide is a powerful vasodilator, and acts as an antioxidant through its ability to scavenge lipid peroxyl radicals. Conversely, nitric oxide forms nitrogen-containing reactive intermediates such as nitrotyrosine, which can lead to liver necrosis, inhibit mitochondrial function, and deplete cellular pyridine nucleotides causing breaks in DNA strands. Nitric oxide can also combine with the superoxide anion free radical to form the RNS peroxynitrite. Peroxynitrite produces cell injury through lipid peroxidation, inhibition of mitochondrial respiration and Na^+/K^+-adenosine triphosphatase (ATPase) activity, and protein oxidation.

Pathophysiology[1,2]

DNA Damage

ROS cause DNA base-pair modifications, strand breaks, crosslinking, and mutations resulting in uncontrolled growth and malignant transformation. Free radicals are also implicated as initiators of apoptosis, or programmed cell death.

Lipid Peroxidation

Polyunsaturated fatty acids in cell membranes react with oxygen to produce peroxyl radicals, the primary free radical intermediate of lipid peroxidation. Change in the structure of membrane lipids will change cell membrane fluidity and significantly alter membrane functions such as ion transport, receptor recognition and signaling, and osmotic gradients. Initially a hydroxyl radical removes hydrogen from lipid molecules in the cell membrane, transforming that lipid molecule into a free radical and starting a cycle of reactions whereby a newly formed membrane lipid peroxyl radical extracts a hydrogen molecule from the next lipid molecule and the cycle is repeated.

Protein Damage

Oxidative modification of endogenous proteins causes unfolding of the tertiary and quaternary structure. Intracellular signaling pathways rely on normal protein structure and function, and ROS can oxidize amino acids within enzymes, rendering them inactive and/or antigenic.

Altered Redox State

Intracellular changes in ROS cause changes in the redox balance and second messenger signal transduction that may affect cell function, cell proliferation, and gene expression. The upregulation of matrix metalloproteinases, kinases, and transcription factors, such as nuclear factor kappa B (NF-κB), by free radicals may result in the production of mediators, such as tumor necrosis factor (TNF)-α and interleukin-1, in chronic diseases, such as inflammatory bowel disease.[2]

Drug Classifications and Mechanisms of Action

Antioxidant defenses consist of both enzymatic and nonenzymatic processes.[3] Antioxidant enzymes include superoxide dismutase, catalase, glutathione peroxidase, and glutathione reductase. These antioxidant enzymes catalyze chemical reactions that utilize ROS. The end-product of their reactions is often a much less harmful compound such as water, or a metabolite that is subject to further antioxidant reactions, such as hydrogen peroxide.

Sulfur-containing glutathione is the most important of the nonenzymatic antioxidants. Thiols exert their antioxidant action through oxidation of the sulfhydryl bond of cysteine. In this way, they scavenge free radical unpaired electrons. The inhibition of lipid peroxidation by α-tocopherol (vitamin E) is another example of a scavenging antioxidant property. These antioxidants are replaceable substrates because they can be returned to their reduced form through simple chemical reactions.

Enzymatic and nonenzymatic antioxidant defenses often work synergistically. For example, after the superoxide dismutase enzyme generates hydrogen peroxide from the superoxide anion, the glutathione peroxidase enzyme converts hydrogen peroxide to water by oxidizing GSH to the disulfide form GSSG. The glutathione reductase enzyme completes the process by returning GSSG to GSH:

$2\ O_2^{\bullet -} + 2\ H^+ \rightarrow H_2O_2 + O_2$

Superoxide dismutase enzyme

$2\ GSH + 2\ H_2O_2 \rightarrow 2\ H_2O + GSSG$

Glutathione peroxidase enzyme (selenium cofactor)

$GSSG + NADPH + H^+ \rightarrow 2\ GSH + NADP^+$

Glutathione reductase enzyme (riboflavin cofactor)

Much like glutathione, the thioredoxins are ubiquitous thiol-containing antioxidant polypeptides that are oxidized to a disulfide form while they undergo redox reactions with multiple proteins. Thioredoxins are returned to their reduced form by an NADPH-dependent reaction driven by the thioredoxin reductase enzyme, and along with GSH, are critical to cellular redox (oxidative) potential.

The Fenton reaction uses metals (copper or iron) as a cofactor during the generation of ROS: $Fe^{2+} + H_2O_2 \rightarrow OH^{\bullet} + OH^- + Fe^{3+}$

The liver serves as the major organ for iron and copper transport and storage. Hepatic copper accumulation is both cause and consequence of chronic hepatitis. Proteins that bind these metals are considered antioxidant. The liver is abundant in metallothioneins or cysteine-rich proteins that bind to various hepatic metals such as copper and zinc. Iron is bound in the hepatocyte to the protein ferritin or hemosiderin. Some of the more important of the metal-binding transport molecules are transferrin and lactoferrin, which bind iron, ceruloplasmin, and albumin, which bind copper, and the exogenous copper-chelating agent penicillamine.

Rational Use of Antioxidants in the Veterinary Patient

Therapies of oxidative stress in dogs and cats have been directed primarily at the tripeptide glutathione (γ-glutamylcysteine-glycine).

During normal hepatic metabolism, glutathione can be directly conjugated to a variety of metabolites and drugs to increase their water solubility and enhance their excretion through the kidney. This process is particularly important in the cat because hepatic glucuronidation is virtually absent in that species. Glutathione is abundant in gastrointestinal mucosa and undoubtedly serves a similar antioxidant role in that tissue.

Reduced GSH concentrations have been reported with hepatic disorders, including inflammation, cholestasis, lipidosis, copper retention, and acetaminophen toxicity.[4-6]

These studies support the role of glutathione as an antioxidant in dogs and cats and a number of glutathione precursors have been developed.

S-adenosyl-L-methionine (*S*-adenosylmethionine)

S-adenosyl-L-methionine (SAMe) is a key component of several metabolic pathways, including methylation, sulfuration, and aminopropylation reactions, but it is perhaps most important clinically as a glutathione precursor.

Oral administration of SAMe (48 mg/kg q24h) increases plasma SAMe concentrations, hepatic GSH concentration, and hepatic GSH-to-GSSG ratio in healthy cats.[7] These same doses have been shown to diminish erythrocyte peroxidation and osmotic fragility. SAMe conserves red blood cell and hepatic GSH concentrations in dogs with experimentally induced steroid hepatopathy,[8] and limit Heinz body formation and erythrocyte destruction in cats and dogs exposed to acetaminophen.[9,10] Although *N*-acetylcysteine (NAC) is traditionally considered the antioxidant of choice, comparative efficacy studies show that SAMe may be a more effective treatment of acetaminophen toxicity in mice.[9] SAMe also may be useful in the treatment of pancreatitis and gastric ulceration.[11,12]

N-acetylcysteine

NAC is the thiol donor most frequently used in emergency cases. The oral bioavailability of NAC is limited, but when given intravenously it results in a rapid increase in GSH synthesis and has direct antioxidant activity. NAC is still considered the standard of care in cases of acetaminophen toxicity, and is useful in the detoxification of hepatotoxins, as well as in cases of ischemia–reperfusion injury.

Vitamin E (α-Tocopherol)

Vitamin E inhibits lipid peroxidation, thereby stabilizing cell membranes, and preventing changes in membrane fluidity and function. Supplementation with vitamin E reduces the production of the proinflammatory mediators NF-κB and TNF-α, and decreases collagen production associated with hepatic inflammation. Vitamin E concentrations are depleted in several forms of liver injury, including hypoxia.[13] Vitamin E and cysteine supplementation ameliorates acetaminophen, but not onion powder, toxicity in cats.[14] Vitamin E plus selenium combinations also have been used for tetracycline-induced hepatotoxicity in the cat.[15] Dogs treated with vitamin E for 3 months demonstrated an increase in serum and hepatic vitamin E concentrations and an improved hepatic GSH-to-GSSG ratio.[16]

Vitamin C may help to recycle vitamin E to a useful antioxidant form, but because vitamin C can act as a prooxidant and promote hepatic iron storage, supplementation is generally not recommended.

Milk Thistle (Silymarin, Silibinin)

Silymarin is an extract of the milk thistle plant that contains a mixture of bioactive flavonolignans, the most powerful of which is silibinin. Silymarin reduces hepatic iron accumulation, collagen deposition, and fibrosis following severe hepatic injury, and has been reported to improve survival in cirrhosis,[17] but not in hepatitis C or alcohol-induced hepatitis.[18] Silibinin administered at a dosage of 50 mg/kg reduces elevations in alanine aminotransferase, alkaline phosphatase, and total bilirubin, as well as the hepatic hemorrhagic necrosis following amanita mushroom or CCl_4 poisoning in the dog.[19,20]

Table 40-1 Antioxidant Agents Used in Dogs and Cats

Drug Classification	Dose	Indications	Side Effects	Trade Names
S-adenosyl-L-methionine	20 mg/kg PO q24h	Acetaminophen toxicity, xenobiotics, hepatotoxins	Nausea, emesis	Denosyl (Nutrimax) Zentonil (Vetoquinol)
N-acetylcysteine	140 mg/kg initial dose IV, 70 mg/kg BID-QID	Acetaminophen toxicity, xenobiotics, hepatotoxins	Hypotension, allergic reactions	Mucomyst (Apothecon) Mucosil-10 (Day Labs)
Vitamin E	10 to 15 units/kg PO, BID, q24h (for liver disease)	Cholestatic liver disease, hepatitis, cirrhosis, copper-associated hepatopathy, hepatotoxins	Platelet aggregation	
Silibinin	5 to 15 mg/kg q24h, upto 30 mg/kg q24h	Amanita mushroom poisoning, other hepatotoxins, hepatitis, cirrhosis, cholestatic disorders	Suppression of cytochrome P450	Marin (Nutramax)
Ursodeoxycholate	10 to 15 mg/kg PO q24h	Cholestatic disorders, cholangitis, hepatitis, copper-associated hepatopathy	Anorexia	Actigall (Watson)

A recent study evaluated the therapeutic efficacy of combining silymarin with metronidazole for treating canine giardiasis.[21] Although the silymarin dose (3.5 mg/kg/day combined with 50 mg/kg/day of metronidazole) was quite small, a positive response was noted earlier in the silymarin-supplemented dogs.[21]

Ursodeoxycholic Acid (Ursodiol)

Ursodiol differs from other antioxidants in that it is a prescription medication and it is normally prescribed for its choleretic, not antioxidant, properties. In a rat model of alcoholic steatohepatitis, ursodeoxycholic acid (UDCA) treatment improved liver morphology; decreased aspartate aminotransferase, γ-glutamyltransferase, and liver triglyceride content; and normalized cytochrome P450 enzyme content and markers of oxidative stress.[22] UDCA administration (10 mg/kg) is safe, and is currently being used in a number of canine hepatopathies, including copper retention and chronic hepatitis.[23] Ursodiol appears to have no prokinetic effect on the biliary system.

Other Diseases

Feline intestinal ischemia–reperfusion injury is classically associated with oxygen free radical generation, and can be prevented by treatment with superoxide dismutase.[24] Canine gastric dilation-volvulus is another example of an ischemia–reperfusion injury in which the iron-chelator deferoxamine reduces the severity of injury during the period of reperfusion.[25] The free radical scavenger, fullerenol, was found to ameliorate changes in GSH in a canine experimental model of ischemic bowel syndrome.[26] None of these antioxidant strategies have become best practice standards in cases of gastrointestinal ischemia–reperfusion injury.

Combination Therapy

The first step in designing an effective antioxidant treatment plan is to define the oxidative damage that is most important in disease progression. Lipid peroxidation, DNA damage, or the signaling of inflammatory cytokines are just a few of the consequences of free radical production. A combination of these effects is likely to require a combination of antioxidants to return to homeostasis. Combination antioxidant therapy has been used to beneficial effect in racing sled dogs and in cats with renal insufficiency.[27-29]

In the meantime, logical choices for antioxidant treatments in dogs and cats can be made based on the species, the disease, evidence from studies in other animal species, the small number of veterinary studies currently available, theory, lack of toxicity, and best practice standards. Table 40-1 lists antioxidant agents used in dogs and cats.

CHAPTER 41

Antispasmodic Agents

Robert J. Washabau

Definitions

Brain–Gut Axis

The term *brain–gut axis* refers to the bidirectional neural processing of information between the central nervous and digestive systems. The brain–gut axis plays an essential role in the regulation of gastrointestinal (GI) motility, secretion, digestion, absorption, and blood flow; in the regulation of appetite, energy balance, and metabolism; and in the modulation of mucosal immunity (see Chapter 1). In turn, the brain receives interoceptive input (i.e., endogenous stimuli) from the GI tract, integrates this information with other systems input, and transmits integrated feedback back to the end-organs of the GI tract. The brain–gut axis is designed to optimize homoeostasis during minor physiologic perturbations and to adapt GI function to the overall state of the animal.[1] In health, the great majority of interoceptive input does not reach the level of consciousness in the brain, but serves primarily as input to an autonomic reflex pathway. Brain–gut dysfunction underlies the clinical signs of the functional GI disorders such as irritable bowel syndrome, and it might mediate the development of stress-induced relapses in inflammatory bowel disease (IBD).[1]

Irritable Bowel Syndrome

Irritable bowel syndrome (IBS) is a human chronic GI tract disorder of unknown origin that is characterized by abdominal pain and altered bowel habits in the absence of detectable biochemical or structural abnormalities.[2] IBS is one of the most common functional GI disorders with an estimated prevalence of 10% to 15% in Western adult populations. Direct and indirect costs of IBS reach up to $30 billion per year in the United States alone.[2] IBS is commonly subdivided into different phenotypes, depending upon the most prevalent bowel habit: diarrhea-predominant IBS (IBS-D), constipation-predominant IBS (IBS-C), and mixed features IBS (IBS-M).[3] Symptom complex differentiation is an important strategy in the diagnosis and treatment of the disorder. Because of the inability of animal species to describe clinical signs such as abdominal pain and discomfort, IBS is not as well-defined in veterinary medicine. Nonetheless, recurring vomiting and diarrheal disorders are seen in companion animals, abdominal discomfort is readily detected on physical examination, the clinical features are unaccompanied by mucosal morphologic change, and the pathogenesis is assumed, therefore, to be of functional or physiologic origin.[4]

Antispasmodic Agents

Antispasmodic agents are drugs designed to relieve or prevent spasms of the GI tract. They are used primarily in patients with clinical signs consistent with a diagnosis of constipation-predominant IBS.

Pathophysiology of Irritable Bowel Syndrome

The pathophysiology of IBS is incompletely understood, although it is considered to have both peripheral and central mechanisms.[1]

Peripheral Mechanisms

Primary Afferent Pathways

Acute inflammation is associated with peripheral sensitization and visceral hyperalgesia. Inflammation-induced peripheral sensitization is usually transient and resolves after inflammation subsides. The role of sensitized primary sensory afferents in the symptoms of persistent or chronically recurrent abdominal pain states is not known. Evidence from mucosal biopsies of IBS patients, however, suggests neuroplastic remodeling of the epithelium. Such neuroplastic changes may affect the response properties of spinal and vagal afferent neurons.[1,5]

Infection and Microflora

A bacterial etiology of persistent abdominal pain has long been suspected (including a relationship between *Helicobacter pylori* infection of the stomach and functional dyspepsia, and the development of IBS-like symptoms following infectious gastroenteritis). Although in the great majority of patients a causal relationship between abdominal pain and acute or chronic infection cannot be established, it has been suggested that host–microbial interactions in vulnerable individuals during the early phase of the disorder may result in permanently altered immune or host cell responses, which then continue to play a role in the persistence of symptoms in the absence of the infection or inflammation. Several studies have reported the onset of IBS-like symptoms following established bacterial or viral infections of the GI tract. This so-called postinfectious IBS occurs in 10% of human patients with bacterial gastroenteritis.[1,6]

Epithelial-Immune Activation

Leukocyte infiltration and mucosal inflammatory cytokines are generally not found in the GI mucosa of the IBS patient. Instead,

enhanced release of neuropeptides from primary sensory nerve endings (such as substance P and calcitonin gene-related peptide), as well as the release of mast cell mediators (including serotonin, histamine, and proteases), has been implicated in the sensitization of primary afferent pathways. The release of nerve growth factor has also been impugned in the neuroplastic and morphologic changes of sensory and motor neurons of the colon. Such neuroplastic changes may play a role in the long-term symptoms of IBS long after the initial immune activation subsides.[1,5]

Mast Cells

Increased mast cell numbers or density, alterations in mast cell–nerve interactions, and increased release of mast cell mediators have been reported in the epithelial biopsy samples of IBS patients.[1,7] Mast cells can be activated by immunoglobulins, neuropeptides, and cytokines to secrete mediators without degranulation. They can release many signaling molecules, including histamine, serotonin, corticotropin-releasing factor (CRF), and proteases. Alterations in these signaling systems have been implicated in the pathophysiology of IBS, and mediator-specific receptor antagonists have been suggested as possible therapies. A particularly interesting aspect of mast cell regulation is the close juxtaposition of mast cells with noradrenergic, cholinergic, and peptidergic nerve endings in the villus epithelium (see Fig. 1-17). Persistent alterations in the spatial and functional relationships between mast cells and nerve endings are a plausible mechanism for recurrent abdominal pain.[1,7]

Epithelial Permeability

Increased epithelial permeability has been reported in many IBS patients, including animal species.[8] Multiple mechanisms of increased permeability have been proposed with differing underlying trigger mechanisms, including stressors and mucosal inflammation. Mast cell mediators, such as CRF and proteases, have been implicated in mediating permeability changes in the GI tract and in pain sensitization.[1,9]

Dysmotility

The concept that exaggerated and dysregulated contractile activity of the GI tract plays a role in the pathophysiology of chronic abdominal pain states has long been a central theme of IBS pathophysiology.[1] Colonic motor dysregulation has been unequivocally demonstrated in experimental canine IBD,[10] but not yet IBS.

Central Mechanisms

Enhanced Stress Responsiveness

First-symptom onset or symptom exacerbation in IBS has been linked to psychosocial stressors and enhanced visceral perception. Upregulation of central stress and arousal circuits has been postulated.[1,11] Central CRF-CRF_1 receptor signaling has been impugned in mediating some forms of acute and chronic stress-induced visceral hyperalgesia. Increased responsiveness of stress and arousal circuits is likely to contribute to the increased activity of the sympathetic nervous system observed in IBS patients, and may play a role in altered mast cell function.[7]

Central Pain Amplification

There are multiple mechanisms by which the central nervous system can modulate afferent signals from the viscera, including increased activity of endogenous pain facilitation and reduced engagement of endogenous pain inhibition. Endogenous pain modulation systems are likely to mediate the effects of affect, mood, and environmental context on pain perception.[11]

Neuroimmune Activation in the Spinal Cord

Visceral hyperalgesia is associated with activation of the glia following a psychological stressor. Activation of the glia can produce proinflammatory cytokines, such as tumor necrosis factor-α, and can result in the downregulation of the glutamate transporter on astrocytes, which, in turn, may lead to elevated synaptic glutamate. Both effects may result in an upregulation of the glutamate/*N*-methyl-D-aspartate receptor signaling system, thereby contributing to the development of central sensitization.[1,12]

Enhanced Brain Responses to Visceral Distention

In IBS patients, evidence for both increased engagement of endogenous pain facilitatory mechanisms and compromised engagement of endogenous pain inhibitory mechanisms have been reported.[1,13]

Enhanced Brain Responses to Expectation of Visceral Pain

Future-oriented worry and anxiety about abdominal symptoms play a prominent role in many human IBS patients. Alterations in prefrontal modulation of stress and arousal circuits may comprise the neurobiologic substrate underlying anxiety.[1,14]

Structural Brain Changes

Even though IBS by traditional definition excludes the presence of detectable structural changes, there is a growing body of evidence of structural (e.g., gray matter) abnormalities in patients with IBS. The mechanisms underlying such structural changes remain unclear, but excitotoxicity (related to enhanced glutamate signaling) and apoptosis (related to increased cytokine release) have been implicated.[1,15]

Clinical Manifestations of Irritable Bowel Syndrome

Humans

The main symptom of IBS is chronic or recurrent abdominal pain or discomfort associated with altered bowel habits. In general, women report IBS symptoms more often than men. Women are more likely to report IBS, bloating, constipation, chronic functional abdominal pain, sphincter of Oddi dysfunction, fecal incontinence, and pelvic floor dysfunction. Women and men report similar rates of functional esophageal symptoms and dyspepsia, while aerophagia and functional diarrhea are reported more often in men.[3] The Rome III criteria for the diagnosis of IBS were published in 2006,[16] the major categories of which are outlined in Box 41-1. The Rome III system is still largely based on symptom complexes rather than pathophysiologic parameters,[17] which has generated both enthusiasm and derision.[18,19] A general consensus has emerged around the need to validate disease-specific biomarkers as surrogate endpoints for drug development for a selective group of functional gastrointestinal disorders.[20,21]

Experimental Animal Studies[22,23]

Immobilization Stress

Restraint or immobilization procedures are the most extensively used models to study the physiologic and behavioral effects of stress exposure in laboratory animals. Immobilization procedures activate the hypothalamic–pituitary–adrenal (HPA) axis and the development of a pathophysiologic response in the brain and gut. Restraint procedures in mice and rats, for example, have been demonstrated to induce GI ulcers, altered GI motility, and altered epithelial permeability.[22,24]

Box 41-1 Rome III Classification of Functional Gastrointestinal Disorders

Functional Esophageal Disorders
Functional heartburn
Functional chest pain of presumed esophageal origin
Functional dysphagia
Globus

Functional Gastroduodenal Disorders
Functional dyspepsia
Postprandial distress syndrome
Epigastric pain syndrome
Belching disorders
Aerophagia
Unspecified excessive belching
Nausea and vomiting syndromes
Chronic idiopathic nausea
Functional vomiting
Cyclic vomiting syndrome

Functional Bowel Disorders
Irritable bowel syndrome
Functional bloating
Functional constipation
Functional diarrhea
Unspecified functional bowel disorder

Functional Abdominal Pain Syndrome
Functional gallbladder and sphincter of Oddi disorders
Functional gallbladder dysfunction
Functional biliary sphincter of Oddi disorder
Functional pancreatic sphincter of Oddi disorder

Functional Anorectal Disorders
Functional fecal incontinence
Functional anorectal pain
Chronic proctalgia
  Levator ani syndrome
  Unspecified functional anorectal pain

Functional defecation disorders
Dyssynergic defecation
Inadequate defecatory propulsion

Functional Disorders: Neonates and Toddlers
Infant regurgitation
Infant rumination syndrome
Cyclic vomiting syndrome
Infant colic
Functional diarrhea
Infant dyschezia
Functional constipation

Functional Disorders: Children and Adolescents
Vomiting and aerophagia
Adolescent rumination syndrome
Cyclic vomiting syndrome
Aerophagia
Abdominal pain–related functional gastrointestinal disorders
Functional dyspepsia
Irritable bowel syndrome
Abdominal migraine
Childhood functional abdominal pain
Constipation and incontinence
Functional constipation
Nonretentive fecal incontinence

Source: Abstracted from references 3 and 16.

Captivity

Cotton-top tamarins (*Saguinus oedipus*) develop a spontaneous ulcerative colitis that bears resemblance to the human disorder. The frequency and severity of colitis in this species is significantly higher in animals in captivity compared with animals living in their natural environment. Psychological stress because of captivity is believed to play an important role in the pathogenesis of ulcerative colitis in this species.[22,25]

Water Avoidance

Water avoidance is a model of chronic mild stress used primarily in rodents. Water avoidance procedures activate the HPA axis inducing a reduction in food intake and weight loss, as well as several GI pathophysiologic changes including increased intestinal ion secretion, increased intestinal and colonic permeability, and hyperplasia and activation of GI mucosal mast cells.[22,26]

Sleep Deprivation

Partial sleep deprivation is another model of psychological stress in rodents that has been shown to induce bacterial translocation, and to the development of gastric ulcers by decreasing mucosal blood flow.[22,27]

Neonatal Maternal Separation and Early Weaning

Neonatal maternal separation is a model of IBS in that it activates the neonatal HPA axis and increases colonic secretion and permeability leading to impaired host defense to luminal bacteria. Early life trauma increases the risk of GI dysfunction in adulthood. It predisposes adult rats to spontaneous and mild stress-induced visceral hypersensitivity and intestinal barrier dysfunction, as well as increased susceptibility to chemical-induced colitis.[22,28]

Thermal Injury

Burn injury is associated with intestinal damage, which ranges from mild transient ileus to lethal necrotizing enterocolitis. Burn injury–induced intestinal barrier dysfunction permits bacterial translocation to mesenteric lymph nodes and systemic circulation. Thermal injury also triggers activation of the HPA axis.[22,29]

Companion Animals

A large bowel diarrheal syndrome similar to IBS in humans has been reported in the dog.[4] Affected animals have clinical signs of diarrhea, excessive fecal mucous, hematochezia, and tenesmus. Abdominal pain and weight loss are occasionally reported by pet owners. Multiple diet changes and empirical medications fail to relieve clinical signs. Medical investigation is negative for bacterial and other pathogen infections, colitis-type inflammatory bowel disease, and colonic neoplasia, and the term *chronic large bowel diarrhea* has been applied to the disorder. Dogs affected with this syndrome respond to the feeding of a highly digestible diet supplemented with soluble fiber.[4]

Table 41-1 Outline of Medical Management for Irritable Bowel Syndrome in Companion Animals

Medical Principle	Clinical Sign	Classification	Examples	Dose
Antidiarrheal agents	Diarrhea	Prostaglandin synthetase inhibitor	Sulfasalazine	Cats: 10 to 20 mg/kg q12h Dogs: 10 to 40 mg/kg q8h
	Diarrhea	μ,δ-opioid agonists	Loperamide	Dogs: 0.08 to 0.2 mg/kg PO Cats: 0.08 to 0.16 mg/kg PO, q6 to 8h PRN
	Diarrhea	5-HT_3 serotonergic antagonists	Dolasetron	0.6 to 1.0 mg/kg PO, q12 to 24hr (as antiemetic)
	Diarrhea	α_2-Noradrenergic agonists	Clonidine	5 to 10 μg/kg PO, q8 to 12h PRN
Antibiotics	Diarrhea	Macrolide antibiotics	Tylosin	7 to 15 mg/kg q12 to 24h
		Nitroimidazole antibiotics	Metronidazole	Dog: 12 to 15 mg/kg PO q8 to 12h Cat: 10 to 25 mg/kg per day PO
Probiotics	Diarrhea	Lactobacillus	*Lactobacillus rhamnosus*	Many formulations, label recommendation
		Bifidobacterium	*Bifidobacterium* spp.	Many formulations, label recommendation
Laxative agents	Constipation	Bulk laxative	Psyllium	1 to 4 tsp mixed with food, q12 or 24h
		Emollient laxative	Docusate	50 mg PO, q24h
		Lubricant laxative	Petrolatum	1 to 5 mL PO, q24h
		Hyperosmotic laxative	Lactulose	1 ml per 4.5 kg PO q8h to 24h
		Stimulant laxative	Bisacodyl	5 mg PO, q24h
Prokinetic agents	Constipation	5-HT_4 serotonergic agonists	Mosapride	0.25 to 1.0 mg/kg PO, q12h
			Prucalopride	0.01-0.2 mg/kg PO q8 to 12h PRN
Antispasmodic agents	Pain, spasm	Muscarinic cholinergic antagonists	Aminopentamide	0.01 to 0.03 mg/kg PO, q8 to 12h
Antigas agents	Bloat, eructation, flatulence	Antifoam surface-acting agents	Simethicone	5 mL (liquid form) PO PRN

Medical Management

The treatment of IBS is largely dependent upon the predominating clinical sign, for example, diarrhea or constipation (Table 41-1).[2,30]

Diet

In the study of chronic idiopathic large bowel–type diarrhea in 37 dogs, most had an excellent or very good response to supplementation of soluble fiber (psyllium) in a highly digestible diet.[4] The median initial dose of psyllium was 2 tablespoons per day, with a median of 1.33 g of psyllium per kilogram of body weight per day. Fiber has multiple effects on gastrointestinal function, including increasing the fecal water content, decreasing the intestinal transit time, and increasing the frequency of defecation. Short-chain fatty acids (acetate, butyrate, propionate) derived from fiber fermentation have been shown to act as metabolic fuel for the colon, and to directly stimulate colonic motility.

Antidiarrheal Agents

Antidiarrheal agents (e.g., prostaglandin synthetase inhibitors, μ,δ-opioid agonists, 5-HT_3 serotonergic antagonists, and α_2-noradrenergic agonists; see Chapter 34) may be useful in the treatment of diarrhea-predominant IBS. Of these four drug classifications, loperamide may be the most effective in restoring smooth muscle segmentation, prolonging intestinal transit time, and improving fecal consistency.

Laxative Agents

The bulk, emollient, lubricant, hyperosmotic, and stimulant laxative agents (see Chapter 50) are generally safe, well tolerated, and effective in the treatment of constipation-predominant IBS.

Antispasmodic Agents

The antispasmodic agents include the musculotropic antispasmodics (mebeverine and pinaverine) and muscarinic cholinergic antagonists (dicyclomine and hyoscyamine). Safe and effective doses have not been established for any of these drugs in any of the companion animals. Aminopentamide, a nonselective muscarinic cholinergic antagonist, has been used in dogs at a dose of 0.01 to 0.03 mg/kg BID-TID, and may be useful as an antispasmodic agent.

5-HT_3 Serotonergic Antagonists

Alosetron and cilansetron are selective 5-HT_3 serotonergic antagonists that were developed for treatment of human diarrhea-predominant IBS. Because of severe side effects, specifically ischemic colitis and severe constipation, they are no longer available or recommended for the treatment of IBS. Ondansetron, granisetron, tropisetron, and dolasetron are members of the same classification that have been used for their antiemetic and antidiarrheal properties in companion animals.

5-HT_4 Serotonergic Agonists

Tegaserod was approved by the FDA for the treatment of constipation-predominant IBS in women. Following reports of untoward cardiac effects, it, like cisapride, was removed from most

international markets. Mosapride and prucalopride are the two most effective currently available 5-HT_4 agonists. They accelerate transit through binding of presynaptic 5-HT_4 receptors and depolarization of cholinergic neurons. Their role in reducing visceral sensation is less well understood.

Antibiotics

Small intestinal bacterial overgrowth (SIBO) has been theorized to play a role in some IBS patients. Bacterial overgrowth has long been known to disrupt epithelial absorption and secretion, but recent data also suggest that SIBO may be an important activator of mucosal-based immunity.[31] Activation of proinflammatory cytokines by bacteria may alter epithelial cellular function, enhance nociceptive pain signaling, and alter intestinal motility—all purported pathophysiologic mechanisms in IBS. Antibiotics most effective in the treatment of SIBO include tylosin, metronidazole, and tetracycline.

Probiotics

Probiotics are hypothesized to work IBS by several different mechanisms. These include a shift from a proinflammatory cytokine profile to an antiinflammatory cytokine profile, reduction of bile acid delivery to the colon, and restoration of GI motility.[2,30] Treatment with *Lactobacillus* sp. or *Bifidobacterium* spp. is associated with a reduction in abdominal pain and discomfort.[2,30]

CHAPTER 42

Behavioral Intervention

Diane Frank

Physiologic Translation of Stress into Gastrointestinal Signs in Dogs

Moberg states that the term *stress* has been used so broadly in biology that no clear definition of stress has emerged.[1] Stress is defined as the biologic response elicited when an individual perceives a threat to its homeostasis. Threats may be real (physical) or perceived (psychological),[2] and may originate from the outside world or from within. Interoceptive stressors (e.g., gut infection, mucosal inflammation, or internal hemorrhage) may be seen as simple reflex responses, mediated at a subcortical level by the system involved in the processing of visceral information. Exteroceptive stressors (psychological), on the other hand, engage circuits in the limbic forebrain including the lateral and medial prefrontal cortex, hippocampus, and amygdala.[2] These responses are adaptive and serve to maintain the stability of the internal environment and ensure the survival of the organism. In the healthy individual, the physiologic response systems are rapidly turned on and off, synchronizing the physiologic stress response to the duration of the stressor, and limiting exposure time of the organism to potentially harmful effects of the stress response.[2] There are situations, however, in which the severity or duration of the stressor and resulting physiologic responses can cause damage, exacerbate existing disease processes, or predispose the individual to acquire new disease. These responses become maladaptive.

Researchers have relied on a variety of endocrine, behavioral, autonomic nervous system, and immunologic parameters to assess stress.[3-11] In fasted dogs, 90-dB music produces inhibition of gastric motility along with increases in heart rate and plasma cortisol,[12] and is therefore considered an example of acoustic stress. One hour of acoustic stress, associated with a fourfold increase in plasma cortisol, delays the appearance of the next gastric, but not jejunal, migrating motor complex (MMC) by 75%. Acoustic stress–induced inhibition of the gastric MMC is completely abolished with prior administration of diazepam (0.2 to 0.5 mg/kg IM) or muscimol (10 μg/kg IV) and partially abolished with lower doses of diazepam (0.1 mg/kg). Gastric MMC inhibition is unaffected by naloxone (0.1 mg/kg IM), phentolamine (0.2 mg/kg IV), or propranolol (0.1 mg/kg IV) treatment. Muscimol, a GABAergic receptor agonist, and diazepam (a benzodiazepine that interacts at the receptor level and potentiates the effects of endogenous γ-aminobutyric acid [GABA]) may act at the central or peripheral level to block the effect of noise on gastric motility. In a different study,[13] intracerebroventricular administration of ovine corticotropin-releasing factor (CRF) (100 ng/kg) in dogs also delayed the appearance of gastric MMC without affecting jejunal motility and this effect was not antagonized by previous administration of diazepam or muscimol. The effects of acoustic stress and CRF on gastric motility were both abolished after bilateral thoracic vagotomy. Consequently, the suppressive action of diazepam and muscimol on noise-induced gastric hypomotility may be related to blockade of the acoustic stress–induced CRF release.

A high prevalence of gastric lesions have been reported in racing Alaskan sled dogs.[14] Endoscopic examination of 70 dogs that participated in the 2001 Iditarod race revealed that 34 dogs (48.5%) had gastric ulceration, erosion, hemorrhage, or some combination of these findings. Gastric disease in racing sled dogs has been attributed to bacterial pathogens, ingested foreign bodies, ulcerogenic drugs (usually banned during races), exercise-induced ischemia (although mesenteric blood flow was unchanged during vigorous exercise in one study[15]), and stress. Exercise on a treadmill at low and high intensity (4.2 miles/h with a 6% or 20% incline) has been shown to increase serum cortisol concentrations in dogs.[16]

Interaction of Corticotropin-Releasing Factor and Monoaminergic Systems

CRF is the principal neuroendocrine substance regulating adrenocorticotropic hormone secretion, and is involved in inflammatory responses of the gut via vagal and peripheral pathways.[17] CRF mediates stress influences on the gastrointestinal (GI) tract either centrally (hypothalamic–pituitary–adrenal [HPA] axis) or peripherally via local CRF-based paracrine activity. CRF is also implicated in many behavioral responses. Physiologic and behavioral responses observed during stress can be induced by exogenous administration of CRF and α_1-adrenergic agonists.[18] Psychological stress triggers sympathetic activation and favors inflammatory reactions, which is associated with concurrent activation of the HPA axis. To date, it is unclear whether stress is the cause or consequence of inflammatory bowel disease development in humans.[17]

CRF immunoreactivity has been demonstrated in the raphe nuclei and the locus coeruleus, two areas of origin of the major serotonergic and noradrenergic pathways in the brain. Thus CRF may play a role in modulating these monoaminergic systems that have been implicated in the pathophysiology of depression and anxiety.[19] Dysregulation of signaling by CRF may contribute to the etiology and pathophysiology of stress-related neuropsychiatric disorders in people. Activation of serotonergic systems plays an important role in several behaviors that are influenced by CRF, including behavioral arousal, motor activity, and facilitation of anxiety-related

behaviors. In a recent study in rats,[20] intracerebroventricular injections of CRF (1 μg) increased several measures of behavioral activity, including total activity, locomotion, and spontaneous nonambulatory motor activity such as visual scanning of the environment, head movements associated with sniffing, shifts in body position, and lateral or vertical movements of the forelimbs. Treatment with fluoxetine,[20] a selective serotonin reuptake inhibitor (SSRI), prevented CRF-induced increases in spontaneous nonambulatory motor activity at all doses (0.1 mg/kg; 1 mg/kg; 10 mg/kg). These effects were most apparent during a 40- to 70-minute time period when CRF-induced behavioral activity was most pronounced. The data of this study support an interaction between CRF and serotonergic systems in the regulation of emotional behavior. These data do not exclude a role of other brainstem neuromodulatory systems such as the noradrenergic systems. Given that the behavioral consequences of CRF are similar to the behavioral consequences of anxiogenic drugs,[21] therapeutic effects of fluoxetine and other SSRIs may involve attenuation or prevention of the effects of aversive or anxiogenic stimuli on CRF-induced stress- or anxiety-related emotional states and behavior.[20]

Anecdotal Information

Marion,[22] a private practitioner, compiled retrospective data on 20 dogs with intermittent recurring bouts of vomiting and 20 control dogs without vomiting. Minimal medical workup was obtained for all vomiting dogs (serum chemistry, abdominal radiography, upper GI endoscopy and biopsies). Between episodes of vomiting, dogs were clinically normal, as is observed in people suffering from cyclic vomiting syndrome.[23] Diagnosis in all cases was assumed to be a functional GI disorder. Vomiting dogs relapsed regularly regardless of treatment, including highly digestible diets and antisecretory medication (e.g., cimetidine). The author completed a grid entitled Emotional Disorder Evaluation in Dogs (EDED)[24] for assessment of emotional disorders in all 40 dogs. Marion found that dogs in the vomiting group had significantly higher scores than the control group suggesting that these dogs were more likely to have concurrent behavioral anxiety disorders than control dogs. The EDED scale has not yet been validated in other studies. Marion also reported that she had treated some vomiting dogs with anxiolytic medications; however, she did not specify duration of treatment, drugs, or dosages.

Future Research

Stress responses may result from anxiety.[25] Anxiety is an emotional state associated with adaptive physiologic and behavioral responses and only becomes pathologic when it is exhibited in contextually inappropriate situations or in more natural ones but to a level that impairs effective adaptive responses.[21] Anxiety disorders (separation anxiety, noise phobia, generalized anxiety) have been described in companion animals.[26] Development of a validated anxiety scale would be a valuable tool to objectively score anxiety in dogs and cats. Placebo-controlled crossover studies in which a particular antianxiety medication could be given alone or concurrent with other treatments for specific GI disorders in "anxious" and "not anxious" canine patients could generate new information. Medications that could be considered would include SSRIs (fluoxetine,[20] sertraline, fluvoxamine), tricyclic antidepressants (amitriptyline,[23] clomipramine), benzodiazepines (alprazolam,[19] diazepam,[12] clonazepam), and perhaps even α_2-adrenergic agonists (clonidine[23,27]).

CHAPTER 43

Chelating Agents

David C. Twedt

A chelating agent is a ligand (or drug) that binds to a metal ion through two or more sites to form a metal chelate that is removed from the body, usually through renal excretion. Copper (Cu) chelators are used in veterinary gastroenterology for the treatment of abnormal Cu accumulation in the canine liver.[1]

Pathophysiology of Copper

The liver is the central metabolic organ for the regulation of Cu body stores.[2] Cu enters the body through the diet and approximately 30% is absorbed by the upper small intestine with the majority of the Cu passing out through the feces. Although the exact details of intestinal Cu absorption are not completely understood, Cu is passively taken up by intestinal epithelial cells, bound to the cytosolic protein metallothionein, and actively transported into the circulation bound to either albumin or transcuprein. Cu is then transported to the liver where it is stored, mobilized to peripheral tissues, or excreted from the body.[2] Hepatic Cu is either complexed with ceruloplasmin a transport protein, incorporated in hepatic cellular pathways, or bound with metallothionein within the liver. Metallothioneins are cysteine-rich, cytosolic proteins that function to store Cu and protect the hepatocyte from Cu toxicity.[2] In health, approximately 80% of the Cu that is absorbed is eventually excreted into the bile.

Normal hepatic Cu concentrations in dogs are maintained at approximately 200 to 400 μg/g dry weight liver.[3] When Cu concentrations increase to levels exceeding hepatic metallothionein's complexing capabilities, direct hepatic damage results, primarily through formation of oxygen free radicals causing either hepatocellular necrosis or apoptosis.[4] The abnormal accumulation of hepatic Cu in the dog results from either a primary metabolic defect in hepatic Cu metabolism or secondary to cholestatic liver disease resulting in impaired biliary Cu excretion.[1] Box 43-1 lists dog breeds documented or suspected of having a hereditary defect in Cu metabolism. Thus far, only the affected Bedlington Terrier has been identified as lacking a specific gene on chromosome 10 encoding a small cytosolic protein termed COMMD1 (MURR1) that is involved in hepatic Cu transport and biliary excretion.[5] The other breeds listed in Box 43-1 do not accumulate hepatic Cu to the same extent as the affected Bedlington Terrier and most likely have a different genetic alteration in Cu metabolism. Regardless of the cause of Cu accumulation, therapy is directed at reducing hepatic Cu concentrations into the normal reference range using Cu-chelating agents. Depending on the breed, hepatic Cu concentrations, and extent of liver pathology, the choice of chelators and the dose and duration of therapy vary.

Copper Chelators

Cu-chelating agents are drugs that have a high affinity for Cu and when bound as the metal-chelator complex are excreted through the urine. When given for prolonged periods of time, chelating agents are effective in depleting hepatic Cu concentrations. Cu-chelating agents used clinically or experimentally in dogs include penicillamine, the tetramines (trientine and 2,3,2-tetramine), and tetrathiomolybdate.

Penicillamine

Penicillamine is a thiol, a compound with a sulfhydryl group, making the molecule an active metal-chelating agent with a high affinity for Cu.[6] Penicillamine was first discovered in the early 1950s when J.M. Walshe identified this unusual urinary metabolite in a human patient treated with penicillin.[7] Walshe dosed himself with penicillin and found that he also excreted penicillamine in his urine. He quickly discovered that this compound had chelation properties with the thiol group because it would bind to iron. Following a dose of penicillamine, Walshe discovered he had an increase in urinary Cu excretion. Those early studies also found that the L isomer of penicillamine was toxic to growing rats but the D isomer did not have this effect.[8] Once an adequate supply of the D-penicillamine was obtained, a patient with Wilson's disease, a hereditary disease in which Cu accumulates in the tissues, was treated and showed a positive response to therapy with increased urinary Cu excretion. Over the last 50 years D-penicillamine has been the primary Cu chelator used in the treatment of Wilson's disease.[9]

Mechanism of Action

By virtue of its sulfhydryl groups, penicillamine chelates a number of heavy metals, including Cu. It forms a stable water-soluble complex with Cu that is excreted through the kidneys. In vitro studies show 1 atom of Cu combines with 2 molecules of penicillamine, which in theory means 1 g of penicillamine would be followed by a maximum excretion of 200 mg of Cu.[9] Clinically, Cu excretion from a 1-g dose results in the loss of only several milligrams of Cu. Prolonged penicillamine therapy in Wilson's disease patients eventually results in a decline in urinary Cu excretion in spite of continued elevations in hepatic Cu concentrations. However, these patients for some reason continue to improve both clinically and in their liver histology.[10] There is now speculation that there may actually be several pools of hepatic Cu in Wilson's disease, some of which may not be removed by the drug. It is postulated that penicillamine may detoxify the remaining Cu in the liver, either by

the formation of a hepatic chelate that is nontoxic or more likely by inducing the synthesis of hepatic metallothionein proteins that then bind and sequester Cu in the liver in a nontoxic form. Penicillamine has also been reported to have a greater affinity for Cu in tissues than in the blood.[10]

Penicillamine will also decrease cystinuria and has been used to prevent the formation of cystine calculi in dogs.[11] It combines chemically with cystine to form a stable, soluble, readily excreted complex. Penicillamine also interferes with the formation of crosslinks between procollagen molecules, thereby exerting some weak, antifibrotic activity.[10] Penicillamine may also have immunomodulatory effects and has been demonstrated to reduce immunoglobulin M rheumatoid factor and T-cell activity in human patients with rheumatoid arthritis.[10] The clinical relevance of penicillamine immunosuppression in dogs is unknown.

Dosage and Toxicity

For management of Cu-associated hepatopathies in the dog, a dose of 10 to 15 mg/kg q12h of D-penicillamine (Cuprimine [capsules] or Depen [tablets]) is given orally.[1] It should be administered on an empty stomach, at least 1 hour before meals or 2 hours after meals, and at least 1 hour apart from any other drug or food. This permits maximum absorption and reduces the likelihood of inactivation by chelating substances within the gastrointestinal tract.

Side effects from penicillamine therapy are common in humans, with an incidence estimated as high as 30% to 50% of untoward reactions, the most common being dermatologic (Box 43-2).[11] There may be some cross-sensitivity between penicillin and penicillamine in some patients. In dogs, nausea and vomiting are the most common side effects and are observed in approximately 30% of patients. These clinical signs may be minimized by reducing the dose or dividing the daily dose into three or four smaller doses. The reduced dose can usually be increased gradually over time. Alternatively, the drug can be given with a small amount of food; however, this may reduce absorption as a consequence of intestinal chelation. Very few other adverse effects have been observed or reported in dogs. The author observed skin hypersensitivity reactions (Figure 43-1 *A* and *B*) in several dogs that all have resolved with discontinuation of therapy. The author is also aware of a few anecdotal reports of renal disease following therapy. Penicillamine is reported to cause depletion of the vitamin B_6 (pyridoxine) in humans. Although this has not been observed in dogs, B-vitamin supplementation during long-term therapy may be advisable.

Figure 43-1 **A,** A 5-year-old female Doberman Pinscher with perioral and periocular dermatitis that developed 1 month after starting therapy with penicillamine. **B**, There is resolution of the dermatitis 2 months after discontinuation of penicillamine therapy.

Long-term Cu-chelator therapy given to a dog that is incorrectly diagnosed as having Cu hepatotoxicity can result in adverse side effects. This has been reported with trientine therapy in one dog and the author has observed similar findings in one Bedlington Terrier treated with penicillamine.[12] Anorexia, vomiting, and weight loss was observed clinically with marked elevations in serum liver enzyme activity. Both dogs had marked reductions in hepatic Cu concentrations. Discontinuation of chelation therapy resulted in clinical improvement. Consequently, it is imperative to correctly diagnose a Cu storage disease based on biopsy and hepatic Cu quantitation before starting therapy and to measure hepatic Cu concentrations during therapy.

Clinical Application

Penicillamine is the treatment of choice for Bedlington Terriers with Cu-associated hepatopathy and this therapy has been documented to be effective in removing hepatic Cu. One study of affected Bedlington Terriers treated with either placebo, penicillamine, trientine, or 2,3,2-tetramine for a 6-month period found the

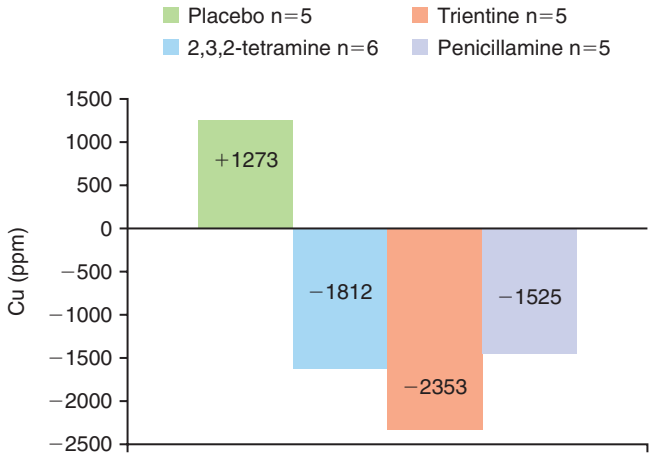

Figure 43-2 Changes in hepatic copper concentrations (µg/g dry weight) in affected Bedlington Terriers in a randomized placebo-controlled study treating with placebo, penicillamine, trientine, or 2,3,2-tetramine for 6 months. (Twedt DC: Diagnosis and management of copper associated liver disease in dogs. *Eur J Comp Gastroenterol* 2:7, 1997.)

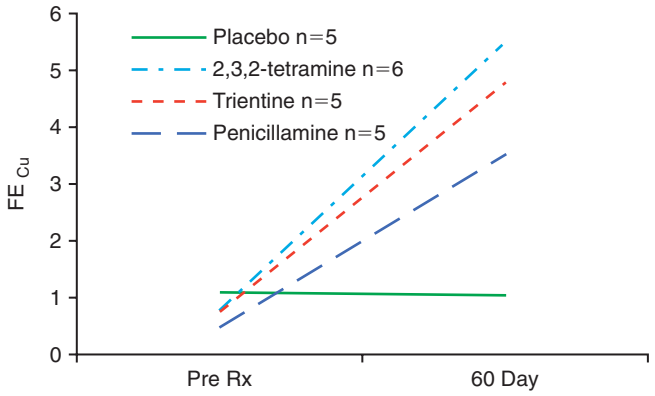

Figure 43-3 Changes in urinary fractional excretion of copper (FE_{Cu}) in affected Bedlington Terriers in a randomized placebo-controlled study treating with placebo, penicillamine, trientine, or 2,3,2-tetramine for 6 months. FE_{Cu} = urine copper/serum copper × serum creatinine/urine creatinine. (Twedt DC: Diagnosis and management of copper associated liver disease in dogs. Eur J Comp Gastroenterol 2:7, 1997.)

penicillamine treatment group had a mean decrease in hepatic Cu of 1529 µg/g dry weight liver, while the placebo group had a mean increase in hepatic Cu of 1273 µg/g dry weight liver (Fig. 43-2).[13] There was also a significant increase in urinary fractional excretion of Cu in the penicillamine group at 2 months posttreatment (Fig. 43-3).[13] A second, unpublished, long-term study was performed by the author to evaluate the effectiveness of penicillamine therapy in affected Bedlington Terrier littermates throughout their life (Fig. 43-4). Four dogs were treated with penicillamine and for two dogs the owners elected no further therapy. The treated dogs had a significantly lower hepatic Cu concentrations at death (mean: 1633 µg/g dry weight liver), whereas the two untreated dogs died having approximately four times higher hepatic Cu concentrations (mean: 6444 µg/g dry weight liver). The treated dogs died from other causes and had minimal inflammatory hepatic changes on histology. The concentrations of Cu in the treated dogs would be toxic to most other dogs. This is a similar finding in humans with Wilson's disease treated long-term with penicillamine. It appears

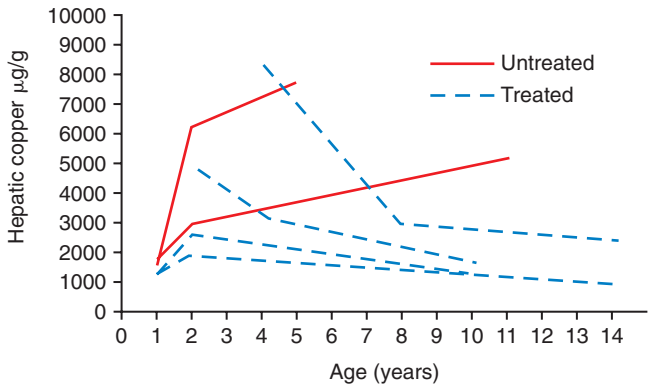

Figure 43-4 Effects of long-term penicillamine therapy in Bedlington Terrier dogs. Each line represents an individual dog.

hepatic Cu concentrations decline to a certain level after which penicillamine's "de-coppering" effect becomes diminished despite the apparent protective effect of the drug. This effect is thought to be the result of penicillamine's induction of hepatic metallothionein that sequesters the Cu. Bedlington Terriers appear to require lifetime Cu-chelation therapy to maintain that protective effect.

Penicillamine therapy has been reported in other breeds having Cu-associated hepatotoxicity. The author believes chelation therapy should be instituted in those dogs when hepatic Cu concentrations approach 750 to 1000 µg/g dry weight liver. In one 4-month study of therapy using penicillamine in five Doberman Pinschers having subclinical hepatitis and abnormal hepatic Cu concentrations (mean concentration: 1036 µg/g dry weight liver), affected animals had a significant decrease in mean hepatic Cu concentration of 407 µg/g dry weight with a significant improvement in liver pathology.[14] In another, larger, placebo-controlled study of 40 affected Labrador Retrievers with Cu-associated hepatitis, treatment resulted in a mean reduction of 863 µg/g dry weight Cu in the treated group (mean pretreatment Cu concentration was 1511 µg/g), whereas the placebo-treated group had no significant change in Cu concentrations.[15] Twenty-three percent (5/12) of the treated dogs in this study had gastrointestinal side effects, with three requiring dosage changes or administration of the drug with a small amount of food.

It appears that affected breeds other than the Bedlington Terriers do not accumulate hepatic Cu to such high concentration and consequently may not require long-term chelator therapy. Chelation for 4 to 6 months may be adequate to de-copper the liver of other breeds such as the Labrador Retriever and Doberman Pinscher, but the length of therapy should only be determined following repeated liver biopsies and Cu quantitation. Following clinical improvement, intermittent chelation therapy or oral zinc therapy to prevent further intestinal absorption of Cu may be sufficient.

Trientine

Trientine is a triethylene tetramine or 2,2,2-tetramine used as an alternative Cu chelator in humans that do not tolerate penicillamine therapy.[16]

Mechanism of Action

The exact mechanism of action of trientine is poorly understood and data on the pharmacokinetics of trientine is not available. Dosage adjustment recommendations are based upon clinical use of the drug and response to therapy. In experimentally Cu-loaded rats, trientine and penicillamine induced a similar cupruresis.[17] Trientine

appears to have a cupruretic effect similar to penicillamine in humans although trientine may mobilize a different Cu pool.[10] Trientine is thought to have a greater affinity for serum Cu, whereas penicillamine may be more effective in mobilizing Cu from tissue sites. Following trientine therapy, urinary Cu excretion increases in humans with Wilson disease.[10] It is not clear if trientine has other hepatoprotective properties beyond Cu chelation. Trientine and zinc are frequently combined in the therapy of Wilson's disease patients. Trientine has been shown to suppress of angiogenesis in animal studies and might be useful clinically as a chemopreventive agent.[18]

Dosage and Toxicity

Trientine (Syprine) is administered in dogs at a dose of 10 to 15 mg/kg q12h PO. It should be given on an empty stomach, at least 1 hour before meals or 2 hours after meals, and at least 1 hour apart from any other drugs or food. This permits maximum absorption and reduces the likelihood of inactivation by metal binding within the gastrointestinal tract. In Europe, trientine is currently available only as a designated orphan drug.

Reported side effects of trientine therapy are few and most humans and dogs seem to tolerate the drug without problems. The author has seen nausea and vomiting develop in a few dogs following therapy. The gastrointestinal signs can be alleviated by decreasing the dose with increased frequency of administration or by giving the drug with a small amount of food.

Clinical Application

Trientine is often prescribed for dogs that cannot tolerate penicillamine. When trientine was given to normal dogs at a dose of 300 mg per day for 23 days, there was a significant cupruresis without changes in serum Cu, urine zinc, or iron concentrations.[19] Trientine was also compared with penicillamine in a placebo-controlled study in affected Bedlington Terriers and showed a significant decrease in hepatic Cu concentrations and a significant increase in urinary fractional excretion of Cu with both drugs compared with placebo (see Fig. 43-2).[13] Trientine caused a mean Cu reduction of 2353 µg/g dry weight liver and no side effects were observed in seven treated Bedlington Terriers over the 6-month course of therapy.[13]

Experimental Chelators

2,3,2-Tetramine

2,3,2-Tetramine is an experimental drug having a similar structure to trientine but reported to be a more potent Cu chelator.[20] As compared with trientine therapy in normal dogs, 2,3,2-tetramine resulted in a four to nine times greater cupruresis.[21] In five treated Bedlington Terriers there was a significant (3000 µg/g) dry weight reduction in hepatic Cu over a 200-day course of therapy and a 12 times increase in 24-hour urine Cu output with no significant change in serum Cu, zinc, or iron levels.[22] These dogs showed a reduction in hepatic lysosomal Cu content based on rhodanine stain and improvement in the distribution and severity of morphologic damage. In a second study treating affected Bedlington Terriers, there was a significant mean reduction in weight liver Cu concentration of 1812 µg/g over 6 months of therapy (see Fig. 43-2).[13] There was no observed evidence of toxicity using this drug in these dogs. Because of the drug's solubility characteristics, the author treated two critical Bedlington Terriers with Cu-associated hemolysis using an intravenous formulation with good success. This compound is not commercially available.

Tetrathiomolybdate

As an experimental drug, tetrathiomolybdate appears be beneficial in the treatment of Wilson's disease patients; however, information on long-term therapy and toxicity studies are limited.[23] It is considered the drug of choice for Wilson's disease patients having Cu-associated neurologic signs. The drug acts by forming a tripartite complex with Cu and proteins. Given with food, tetrathiomolybdate binds dietary Cu and endogenously secreted Cu with food proteins and prevents absorption of the complexed Cu. Given without food, tetrathiomolybdate is absorbed into the blood where it complexes Cu to albumin making the Cu unavailable for cellular uptake. It also is believed to mobilize hepatic metallothionein-bound Cu promoting bile excretion but not urinary Cu excretion. Generally, humans with Wilson's disease are dosed by both giving the drug with meals and also between meals.[23]

There are no reported dog studies using tetrathiomolybdate. Because it is recommended for Cu-associated neurologic signs, and because dogs do not develop Cu-associated neurologic disease, it may have limited benefit. This drug may also not be beneficial in treating Bedlington Terriers or other breeds having defects in biliary Cu excretion as biliary Cu excretion is one of the drug's modes of action.

Other Chelators

Other chelators used in veterinary medicine include disodium calcium ethylenediamine tetraacetate (EDTA) used to treat lead poisoning, dimercaprol (BAL) used for arsenic and mercury toxicity, and deferoxamine used for iron toxicity and ischemia–reperfusion injury. Experimental animal studies evaluating these chelators found no appreciable increase in urinary Cu excretion.[24,25] Consequently, these drugs are not likely beneficial in the management of Cu-associated hepatotoxicity.

Iron chelators are indicated in conditions associated with hemochromatosis, a disease associated with abnormal hepatic iron concentrations. Hepatic iron overload results in inflammatory hepatic change and cirrhosis similar to the mechanisms caused by Cu. In humans, hemochromatosis is either a genetic based abnormal iron metabolism disorder or an acquired condition observed with certain types of chronic anemia in which patients require many blood transfusions. Deferoxamine is the primary drug used for iron chelation. A primary genetic hemochromatosis has not been documented in the dog; however, secondary acquired hemochromatosis has been reported associated with multiple blood transfusions, in Basenji dogs with pyruvate kinase deficiency, and from iatrogenic iron administration.[26] One dog that had been treated with chronic blood transfusions for aplastic anemia subsequently developed iron-associated liver cirrhosis and failed to respond to deferoxamine therapy.[26] It is not uncommon to identify elevations in hepatic iron concentrations in dogs with chronic inflammatory hepatic changes or portal systemic shunts.[3] In inflammatory liver disease, iron accumulation is thought to be caused by the release of iron from necrotic hepatocytes with its sequestration in macrophages. The sequestered iron is thought to be relatively inert and specific iron chelation therapy does not appear to be necessary.

Adjunct Therapy

Zinc Therapy

Zinc therapy decreases intestinal absorption of dietary Cu by inducing synthesis of an intestinal epithelial cell protein metallothionein. Cu binds more tenaciously to the increased metallothionein than does zinc and prevents its intestinal movement into the blood.[10]

Metallothionein-bound Cu is eventually lost into the feces when intestinal epithelial cells die and are sloughed into the lumen. In essence, there is a mucosal block in Cu absorption. There is also evidence that zinc therapy decreases hepatic stores of Cu and induces production of hepatic metallothionein which may be hepatoprotective.[27,28] Zinc therapy in two West Highland White Terriers and two Bedlington Terriers with Cu hepatotoxicity resulted in a significant reduction in hepatic Cu concentrations.[29] The response was slow with the process taking several years to achieve a maximal therapeutic response. Early human studies involving a combination of zinc and chelator therapy found no benefit over single therapy suggesting that chelator most likely binds the zinc in the intestinal tract. More recently, however, patients with Wilson's disease and penicillamine intolerance are sometimes treated with a combination of trientine and zinc with apparently good results.[28] The author's current recommendation is to treat affected dogs with the fast-acting Cu chelator, and when hepatic Cu concentrations approach normal levels, to switch to zinc therapy alone to prevent further Cu accumulation.

The initial report of zinc therapy described use of 100 mg of elemental zinc acetate BID for 1 to 2 months during an induction phase followed by a maintenance dose of 50 mg of elemental zinc BID thereafter.[29] Serum zinc concentrations were monitored with a goal of approximately a twofold increase in serum concentrations (<200 μg/mL). In this study, serum zinc levels remained in the suggested therapeutic range and there was no evidence of toxicity. When serum zinc concentrations become significantly increased (>750 μg/mL) hemolysis can occur. Zinc can be given either as an acetate, sulfate, gluconate, or methionine salt, but should be administered on an empty stomach to assure adequate absorption. Common problems encountered with zinc therapy include anorexia, nausea, and vomiting shortly following administration of the drug. If concurrent chelator therapy is used, the dosing should be staggered to assure adequate absorption of the chelator.

Other Therapies

Affected dogs should be placed on a low-copper diet and one should assure that dietary supplements do not contain Cu. The pathogenesis of Cu hepatotoxicity is in part related to factors associated with cellular oxidative damage and membrane lipid peroxidation.[4] Consequently, it may be prudent to also provide antioxidants to the patient as a form of liver support. Antioxidants such as vitamin E (D-α-tocopherol), *S*-adenosylmethionine (SAMe), or silibinin (milk thistle derivative) may all be helpful. Vitamin C has been shown to act as a prooxidant in the presence of increased concentrations of Cu and should not be supplemented in these animals.[30]

CHAPTER 44

Chemotherapy

Antonella Borgatti

Principles of Chemotherapy

Significant advances have been made in the chemotherapeutic management of neoplastic conditions. Unfortunately, a large proportion of cancer patients still fails to respond to therapy, or relapses following an initial response, underscoring the need for new anticancer drugs and better integration of conventional treatment modalities (e.g., surgery, radiation therapy, and chemotherapy).

Chemotherapy kills rapidly dividing cancer cells by targeting DNA, RNA, and protein synthesis. Some cell-cycle nonspecific chemotherapeutic agents damage DNA by preventing cellular replication and/or inducing apoptosis, while other cell-cycle specific agents interfere with a specific phase of the cell cycle. Cell-cycle phases include the *S-phase* (DNA synthesis); the G_1*-phase* (RNA-synthesis); the *M-phase* (mitosis); the G_2*-phase* (second period of protein and RNA synthesis); and the G_0*-phase*, characterized by resting cells that are unaffected by chemotherapy as a result of their lack of replication.

Gompertzian growth kinetics have been used to describe tumor growth.[1] In the Gompertzian model, the tumor growth fraction increases exponentially over time. Once the limit of clinical detection is reached, tumor growth progressively slows down and eventually plateaus. Response to chemotherapy highly depends on the location of the tumor on its growth curve. For example, tumor cells in the latent growth phase (i.e., prior to clinical detection) are more sensitive to chemotherapy than cells in subsequent phases because the growth fraction is greater during latency. In general, smaller tumors have higher growth fractions compared with larger tumors; consequently, they are more susceptible to chemotherapy.

Chemotherapy is indicated for patients with a measurable tumor mass known to be susceptible to a particular therapeutic modality (e.g., lymphoma) and patients likely to have micrometastatic disease. It is also used to reduce the size of an inoperable tumor to allow subsequent local therapy; as a radiosensitizer; and, as a palliative treatment modality to alleviate clinical signs associated with metastatic or bulky disease.

Several factors influence the ability of chemotherapeutic agents to kill cancer cells. These include (a) intrinsic or acquired resistance to a chemotherapeutic agent; (b) impaired drug delivery across cell membranes; (c) duration of exposure to an effective concentration of the drug; (d) upregulation of glutathione, glutathione-*S*-transferases, or other detoxification pathways; (e) dysregulation of apoptotic (cellular death) pathways; or (f) activation of survival pathways by growth factors, such as epidermal growth factor. Acquired resistance to chemotherapy is often associated with overexpression of P-glycoprotein, a transmembrane pump encoded by the multiple-drug resistance gene.[2]

The P-glycoprotein extrudes xenobiotics from the cell cytoplasm. Overexpression of P-glycoprotein leads to a resistance to various drugs, including anthracyclines, vinca alkaloids, and taxanes. Dogs with a defective multiple-drug resistance gene have greater susceptibility to drugs affected by the P-glycoprotein and are more likely to experience toxicity following administration of these drugs.

It is unclear as to whether any tumor cell or only stem cells develop resistance. Tumors develop intrinsically resistant cell lines (or clones) because of genetic instability that cause a susceptible tumor to become subsequently unresponsive to chemotherapy and to relapse.[3] Based on this theory, induction chemotherapy should consist of a combination of drugs rather than a single agent.[4]

Resistance can also be explained by the "tumor stem cell theory," according to which committed cancer cells are killed by induction chemotherapy whereas stem cells survive and repopulate the tumor.[5]

Chemotherapeutic agents are generally administered at the maximum tolerated dose and at the highest dose intensity (i.e., shortest dosing interval). In addition, they are commonly dosed based on the estimated body surface area. As a result of the increased toxicity observed with this dosing scheme in cats and small dogs receiving drugs such as doxorubicin and carboplatin, it is currently recommended, that the dose of specific chemotherapeutic agents be calculated on an mg/kg basis for animals weighing less than 10 kg rather than on the estimated body surface area.[6] The author applies the mg/kg dosing scheme to dogs weighing less than 15 kg.

Classes of Chemotherapeutic Agents

Alkylating Agents

The first nonhormonal chemical found to have antitumor properties was a nitrogen mustard alkylating agent (sulfur mustard gas). When used as a weapon during World War II for its vesicant effects, the gas resulted in bone marrow suppression among the victims. This led to the development of a nitrogen mustard compound (mechlorethamine or Mustargen) and to its clinical application for the treatment of various cancers, primarily lymphomas.[7] Alkylating agents react with DNA strands by inserting an alkyl group (thus the term *alkylating*), and changing the DNA structure. Some agents are monofunctional (i.e., they react with only one strand of DNA), some are bifunctional (i.e., they react with both DNA strands to produce a "crosslink"), and they are cell-cycle nonspecific. The most commonly utilized alkylating agents in veterinary oncology are chlorambucil (Leukeran), cyclophosphamide (Cytoxan),

Table 44-1 Classification of Chemotherapy Drugs for Treatment of Gastrointestinal Disease

Drug	Indications	Toxicity	Dosage and Route of Administration
Alkylating Agents			
Cyclophosphamide	Lymphoma, sarcoma, carcinoma	Sterile hemorrhagic cystitis, BM, GI	Typically 200-250 mg/m^2 IV or PO
Chlorambucil	Lymphoma (lymphocytic) CLL, MCT, to replace cyclophosphamide if sterile hemorrhagic cystitis occurs	Bone marrow (mild)	Variable, PO
CCNU (Lomustine)	Lymphoma, MCT	Bone marrow, liver	Dogs: 60-90 mg/m^2 PO q3wk Cats: 50 to 60 mg/m^2 PO or 10 mg/cat PO q3 to 4wk
Melphalan	MM, plasma cell tumors	Bone marrow	0.1 mg/kg/day PO × 10 days, then 0.05 mg/kg QOD; pulse dose at 7 mg/m^2 daily for 5 days q3wk
Anthracyclines			
Doxorubicin	Lymphoma, sarcoma, carcinoma	Bone marrow, GI, hypersensitivity reaction, perivascular damage with extravasation, cumulative myocardial toxicity (dogs), nephrotoxicity (cats)	Dogs: ≥15 kg: 30 mg/m^2 IV q2 to 3wk Dogs: <15 kg: 1 mg/kg IV q2 to 3wk Cats: 1 mg/kg or 25 mg/m^2 q3wk
Mitoxantrone	Lymphoma, carcinoma	Bone marrow, GI, perivascular damage with extravasation	Dogs: 5 to 6 mg/m^2 IV q3wk Cats: 6 to 6.5 mg/m^2 IV q3wk
Platinum Drugs			
Carboplatin	Sarcoma, carcinoma	Bone marrow, GI	Dogs: 300 mg/m^2 IV q3wk Cats: 240 to 260 mg/m^2 IV q3 to 4wk
Cisplatin	Sarcoma, carcinoma	Bone marrow, nephrotoxicity, emesis, diuresis). Fatal pulmonary edema (cats)	Dogs: 70 mg/m^2 IV q3wk (saline Do not use in cats
Antimetabolites			
Methotrexate	Lymphoma	Bone marrow (mild), GI	0.8 mg/kg IV once weekly
Cytosine arabinoside	Lymphoma	Bone marrow (mild), GI	Variable; SQ, IM, IV
Gemcitabine	Lymphoma, MM, carcinoma, feline SCC	Bone marrow	Limited studies Dogs: 100 to 1000 mg/m^2 IV; 50 mg/m^2 twice/wk with RT Cats: 25 mg/m^2 twice/wk with RT
5-FU	Sarcoma, carcinoma	Bone marrow, GI, neurotoxicity, fatal neurotoxicity in cats	Dogs: 150 mg/m^2 once/wk IV, topically Do not use in cats
Antimicrotubule Agents			
Vincristine	Lymphoproliferative cancer, sarcoma	Bone marrow, GI, constipation (ileus), peripheral neuropathy, perivascular tissue reaction	0.5 to 0.75 mg/m^2 IV weekly or every other week
Vinblastine	Lymphoma, MCT	Bone marrow, GI, perivascular tissue reaction	2 to 2.2 mg/m^2 IV weekly
Miscellaneous			
L-Asparaginase	Lymphoma	Hypersensitivity reaction	400 IU/kg or 10,000 IU/m^2 SQ or IM (10,000 IU maximum) weekly
Procarbazine	Lymphoma	GI, bone marrow	Variable; dogs: 50 mg/m^2/day

BM, bone marrow; CLL, chronic lymphocytic leukemia; GI, gastrointestinal; MCT, mast cell tumor; MM, multiple myeloma; RT, radiation therapy; SCC, squamous cell carcinoma.

mechlorethamine (Mustargen), melphalan, and lomustine (Table 44-1). A unique toxicity to cyclophosphamide is the possible development of sterile hemorrhagic cystitis, an irritation of the urinary bladder caused by the inactive metabolite acrolein.

Anthracyclines

Anthracycline antibiotics are derived from the bacteria *Streptomyces peucetius*. Doxorubicin, a hydroxylated daunorubicin derivative, is widely utilized in human and animal patients for a variety of malignancies, including lymphoma, sarcomas, and carcinomas. It is cell-cycle nonspecific and exerts its cytotoxic effect through different mechanisms, including free radical formation, DNA intercalation, and inhibition of protein synthesis. It also inhibits topoisomerase, leading to the formation of cleavable complexes, DNA damage, and cellular death. It is metabolized by the liver and eliminated primarily in the feces. Doxorubicin can promote oxidative reactions, forming

highly reactive oxidative species, including superoxide anions, hydrogen peroxide, and hydroxyl free radicals that can damage lipid membranes. Cellular defenses against free radical formation (e.g., catalase, glutathione) become saturated and because catalase levels are low in cardiac muscle of humans and dogs, cardiotoxicity is a potential side effect of this drug. Nephrotoxicity has been observed in cats treated with doxorubicin, but the pathogenesis is unclear.[8]

Mitoxantrone is a synthetic antitumor antibiotic that was originally developed as a noncardiotoxic alternative to anthracycline compounds. It inhibits topoisomerase IIα by stabilizing topoisomerase IIα–cleavable complexes. Unlike doxorubicin, mitoxantrone does not result in free radical formation, which may account for its reduced cardiotoxic potential. Mitoxantrone is metabolized in the liver and is eliminated via feces and urine. In humans, it is used for the treatment of non-Hodgkin lymphoma and acute leukemias, as well as for the treatment of breast cancer and hormone-refractory prostate cancer (see Table 44-1).[9]

Platinum Drugs

The antitumor activity of platinum coordination complexes was first recognized by Rosenberg and colleagues in 1961. They observed that cisplatin induced filamentous growth in bacteria without affecting RNA or protein synthesis (suggesting DNA as the primary target of the drug).[10] Platinum drugs act preferentially at the N7 position of guanine and adenine residues, forming mono- and bifunctional adducts. Initially, monofunctional adducts form and these may subsequently form intra- or interstrand crosslinks. The toxicity profile of cisplatin, as observed in early clinical trials, led to the development of platinum analogues (carboplatin, oxaliplatin) with less toxicity and potentially greater efficacy against various tumor types. They are cell-cycle nonspecific, and elimination occurs through the kidneys (see Table 44-1).

Antimetabolites

Methotrexate

Methotrexate (MTX) is a commonly used antifolate agent that has activity against hematopoietic malignancies and various solid tumors in people. In dogs, this agent has been incorporated primarily in combination chemotherapy protocols for the treatment of lymphoma. MTX is an inhibitor of dihydrofolate reductase, an enzyme responsible for maintaining the intracellular folate pool of the reduced form of tetrahydrofolates that is critical for the synthesis of certain amino acids and purine nucleotides. It is primarily eliminated via renal excretion.

Cytarabine

Cytarabine (Ara-C, Cytosar) is a cell-cycle phase-specific pyrimidine analogue that targets cells undergoing DNA synthesis in S-phase. Maximum cytotoxicity is observed during periods of rapid DNA synthesis. The duration of cytarabine exposure is an important determinant of the degree of cytotoxicity (a higher proportion of cells enters the S-phase with prolonged exposure of the drug). Intracellular activation of the drug is necessary for cytotoxicity to occur. It is primarily used for the treatment of hematologic malignancies. The drug is eliminated in the urine.

Gemcitabine

Gemcitabine is a deoxycytidine analogue that requires the nucleoside transporter system for entry into cells. Similarly to cytarabine, it requires intracellular activation to exert its cytotoxic effect. Gemcitabine has a broader spectrum of activity compared with cytarabine with recognized activity against human solid tumors, including pancreatic cancer.

5-Fluorouracil

5-Flourouracil (5-FU) is a fluoropyrimidine that requires intracellular activation to exert cytotoxicity. It enters the cells through a facilitated uracil transport mechanism and is subsequently converted into the active metabolite 5-fluoro-2′-deoxyuridine monophosphate (FdUMP), which interferes with DNA synthesis and repair. Elimination occurs through the lungs and the kidneys (see Table 44-1).

Antimicrotubule Agents

Microtubules are cellular organelles that can be targeted by a variety of natural anticancer drugs, primarily vinca alkaloids (vincristine, vinblastine) and taxanes (paclitaxel). These agents interfere with the microtubules that form the mitotic spindle, inhibiting cellular division and proliferation. Microtubules are also involved in chemotaxis, membrane transport, secretion, adhesion, and signaling.

While the vinca alkaloids bind to microtubular proteins involved in the mitotic spindle during metaphase (thus preventing cell division), the taxanes decrease the availability of tubulin to be used for microtubule formation.

The vinca alkaloids and paclitaxel are metabolized by the liver and excreted in the feces (see Table 44-1).[11]

Miscellaneous Agents

L-Asparaginase is a bacterial-derived enzyme that depletes the circulating pool of L-asparagine. Although normal cells are able to synthesize L-asparagine from aspartic acid through asparagine synthase, cancer cells lack this enzyme and their survival depends on exogenous sources of this amino acid. Elimination occurs in the urine and feces.

Hydroxyurea interferes with the activity of the ribonucleoside diphosphate reductase enzyme and prevents the conversion of ribonucleotides to deoxyribonucleotides in an S-phase specific manner. Hydroxyurea is metabolized by the liver and eliminated in the urine.

The mechanism of action of procarbazine is unclear, although inhibition of DNA, RNA, and protein synthesis has been described, and the drug has possible activity through DNA alkylation and methylation. Procarbazine is metabolized by the liver and eliminated in the urine.

Imatinib mesylate (Gleevec) is a tyrosine-kinase inhibitor that occupies the adenosine triphosphate (ATP) binding site of the Bcr-Abl tyrosine kinase and of other tyrosine kinases, platelet-derived growth factor, c-kit, and stem cell factor. In humans, imatinib is considered the first-line therapy for chronic myeloid leukemia and for gastrointestinal stromal tumors (GISTs) expressing the c-kit tyrosine kinase (see Table 44-1).[12]

Corticosteroids

Prednisone is a catabolic steroid frequently incorporated in chemotherapy protocols used for lymphoproliferative disorders, mast cell tumors, and plasma cell tumors. It binds to cytoplasmic receptors, thereby inhibiting DNA synthesis. Prednisone is converted in the liver into its active form (prednisolone).

Metronomic Chemotherapy

Blood vessel formation plays a pivotal role in the process of tumor growth and metastasis. Some of the antitumor effects of standard

chemotherapeutic agents resides in their ability to target the vascular endothelium. The observation that the functional impairment of a single capillary negatively impacts a high number of cancer cells, and the fact that endothelial cells, unlike cancer cells, are "genetically stable" and thus less likely to develop resistance, makes the endothelium a desirable target for cancer therapy.[13,14] Metronomic (antiangiogenic) chemotherapy strategies are being developed and include small, continuous, daily dosing of chemotherapy that results in targeting and inhibition of vascular endothelial cells, with decreased potential for systemic toxicity, reduced risk for resistance, and longer-lasting effects compared with standard chemotherapy regimens.[15]

This approach, although promising in rodent tumor models, has not yet been validated through clinical trials in animal or human cancer patients.

Chemotherapy in the Treatment of Gastrointestinal Cancer

Adjuvant therapy for gastrointestinal cancer, particularly gastric, pancreatic, and colorectal cancer, has been explored extensively in human oncology for the past 30 years. To date, the only treatment option potentially able to cure gastrointestinal neoplasia is surgery, but the vast majority of patients have unresectable or metastatic tumors that cannot be cured by means of surgery alone. Furthermore, even patients whose tumors are completely excised often develop metastatic disease following surgery. Although chemotherapy is generally unsuccessful in providing long-term tumor control in these cases, it is often indicated as an adjunctive treatment to surgery to prevent or delay the onset of metastatic disease and local tumor recurrence, often resulting in amelioration of quality of life and extended survival times.[16]

Oral Cancer

Although surgery and radiation therapy are used to achieve local and regional tumor control, chemotherapy is often indicated as an adjunct to standard local treatment modalities for highly metastatic tumors, including oral melanoma and tonsillary or lingual squamous cell carcinoma.

Oral melanoma has historically been described as a chemoresistant malignancy, but measurable responses have been reported for dogs treated with melphalan,[17] carboplatin,[18] and intralesional cisplatin chemotherapy.[19] Because melanoma is a highly immunogenic tumor, biologic response modifiers[20] and immunotherapy approaches, including the recently developed canine melanoma vaccine,[21] have emerged as promising strategies for the treatment of this disease.

The use of nonsteroidal antiinflammatory medications, such as piroxicam, has not been consistently beneficial in the management of feline oral squamous cell carcinoma (SCC), despite the overexpression of cyclooxygenase-2 in this malignancy.[22,23] However, piroxicam appears to have potential efficacy against canine oral SCC. In fact, increased response rates were noted when piroxicam was combined with cisplatin or carboplatin chemotherapy.[24] However, because of the high incidence of renal toxicity, the combination of piroxicam with cisplatin is not recommended.[25,26] In cats, mitoxantrone chemotherapy has yielded encouraging results when combined with radiation therapy.[27]

Some chemotherapeutic drugs also play a role as radiosensitizing agents. For example, platinum drugs have been used in dogs with oral melanoma while gemcitabine has been combined with radiation therapy for the treatment of feline oral SCC.[28,29]

Gastric Cancer

Gastric cancer accounts for only 1% of all malignancies in dogs and 70% to 80% of these tumors are adenocarcinomas.[30] In cats, lymphoma is the most common gastric malignancy whereas adenocarcinomas are rarely reported.[31]

With the exception of disseminated lymphoma, for which chemotherapy remains the treatment of choice, surgery is the first-line therapeutic modality recommended for most gastric cancers. There is currently no effective chemotherapy for the treatment of adenocarcinomas and, in general, the effectiveness of chemotherapy as an adjuvant to surgery for the treatment of gastric cancer is unknown.

In humans, c-*kit* inhibitors have shown efficacy in the treatment of GISTs, with approximately 80% of these responding to the small molecule imatinib.[32] Because approximately 75% of canine GISTs are characterized by c-*kit* mutations, it is conceivable that c-*kit* inhibitors may have efficacy in the treatment of canine GISTs, but this hypothesis has yet to be fully evaluated. London et al. reported on the use of toceranib phosphate (Palladia, SU11654), a small-molecule tyrosine kinase inhibitor recently approved by the FDA for the treatment of pet dogs with cutaneous mast cell tumors, which, similarly to GIST, often have an activating mutation of c-*kit*. Toceranib phosphate has antitumor and antiangiogenic properties through the inhibition of c-*kit*, platelet-derived growth factor receptor-β, and vascular endothelial receptor factor 2.[33]

Salivary Gland, Esophageal, and Pancreatic Cancer

Primary neoplastic conditions of the salivary gland, the esophagus, and exocrine pancreas of dogs and cats are rare.

Adenocarcinomas are the most common cancers affecting the salivary gland of dogs and cats; other reported tumor types include malignant fibrous histiocytoma, osteosarcoma, mast cell tumor in dogs, and sebaceous carcinoma in cats.[34] Surgical excision should be performed whenever possible and radiation therapy considered in cases of incomplete resection or inoperable masses. Chemotherapy is not reported widely in veterinary oncology because of the lack of effective chemotherapeutics and the local disease control afforded by surgery and radiation therapy.

The most common esophageal tumors include carcinomas (primarily SCC), but sarcomas including leiomyosarcoma, osteosarcoma, and fibrosarcoma also have been reported. *Spirocerca lupi* infestation has been implicated in the pathogenesis of esophageal sarcomas.[35,36] With the exception of lymphoma, chemotherapy has rarely been utilized for the treatment of esophageal cancer. Surgery is considered the treatment of choice, but often times it is not feasible because of location and advanced stage of disease (intrathoracic resections are particularly difficult). Likewise, radiation therapy can result in unacceptable toxicity to the surrounding normal tissues when directed to intrathoracic lesions, but it can be applied to cervical locations.[36]

The vast majority of cancers affecting the exocrine pancreas are adenocarcinomas of ductal origin, which are characterized by a high metastatic potential. Surgery (total pancreatectomy or pancreaticoduodenectomy, also called Whipple's procedure) has been reported in humans and dogs, but cure rates are low while morbidity and mortality are high.[37] Charney and colleagues reported the use of intracavitary carboplatin and/or mitoxantrone chemotherapy in 12 dogs with carcinomatosis, sarcomatosis, and mesothelioma. The median survival time of treated dogs was 332 days, compared with only 25 days for seven untreated dogs included in the retrospective evaluation.[38] In humans, amelioration has been achieved with chemotherapy alone (gemcitabine, paclitaxel, docetaxel) or in combination with local treatment modalities, but survival times are still woefully short.

Hepatobiliary Cancer

Hepatic tumors are rare in pet animals. In dogs, the liver is more commonly a secondary (i.e., metastatic) site from nonhepatic neoplasias whereas in cats primary hepatobiliary tumors occur more commonly than metastatic disease.

Liver lobectomy is the recommended approach for all canine and feline resectable liver masses, including localized hepatocellular carcinoma (HCC). Surgical excision is, however, not possible in the diffuse and nodular forms of HCC, and the role of chemotherapy in the treatment of liver neoplasia has not been investigated.

In humans, HCC is considered a chemoresistant tumor with response rates no greater than 25% with single-agent therapy or combination of various chemotherapeutics, including 5-fluorouracil, interferon, cisplatin, and doxorubicin. Chemoresistance may be caused by P-glycoprotein expression and by the detoxification biochemistry of hepatocytes. Aside from the disappointing results provided by the use of systemic chemotherapy for the treatment of HCC, encouraging reports have emerged regarding various regional chemotherapies for the treatment of nonmetastatic HCC.[39]

Liver lobectomy can be performed in case of hepatic sarcomas. However, the prognosis associated with these tumors is poor because of the presence of metastatic disease at the time of diagnosis. Doxorubicin-based protocols have yielded promising results when applied to the treatment of canine and feline sarcomas located elsewhere in the body, but they have not yet been investigated for primary hepatic sarcomas in these species.

Intestinal Cancer

In a retrospective study evaluating 46 cats with malignant colonic neoplasia, a significant survival advantage was found for cats treated with surgery and adjuvant doxorubicin compared with cats treated with surgery alone (280 days vs. 56 days, respectively).[40]

In another study evaluating 14 dogs with gastrointestinal leiomyosarcoma, two dogs received adjuvant doxorubicin chemotherapy following surgery; one developed metastatic disease 4 months following completion of the chemotherapy regimen, whereas the other dog was lost to follow up 2 years later.[41]

Doxorubicin was also used following surgical resection in two dogs with intestinal adenocarcinoma and survival times greater than 17 months were reported.[42]

Although the addition of chemotherapy could provide a potential survival advantage, the usefulness of adjuvant chemotherapy in the treatment of intestinal nonlymphoid malignancies is unclear and further research and prospective clinical trials are greatly needed.

Less controversial is the role of chemotherapy in the treatment of intestinal lymphoid malignancies. In a recent prospective clinical trial, dogs with gastrointestinal lymphoma were treated with a 20-week combination chemotherapy protocol consisting of induction and consolidation phases. Thirteen of the dogs studied had primary gastrointestinal lymphoma and five had multicentric lymphoma with gastrointestinal involvement. The overall remission rate was 56% with nine dogs achieving a complete remission for a median of 86 days (range: 22 to 420 days) and one dog achieving a partial remission for 26 days. The overall median survival time was 77 days (range: 6 to 700 days). Although long-term survival times were noted in this study, results suggest that dogs with gastrointestinal lymphoma treated with multiagent chemotherapy have poor response rates and survival times compared to dogs without gastrointestinal involvement treated with similar cyclophosphamide, hydroxydaunorubicin, methotrexate, prednisone (CHOP)-based protocols. Significantly shorter survival times were found in dogs that failed to achieve a remission or had diarrhea at the time of the initial presentation.[43]

In cats with intestinal lymphoma, median survival times ranging from 6 to 9 months have been reported, with some cats living 2 years or longer. Long-term survivors are typically cats with inflammatory bowel disease or low-grade lymphocytic lymphoma (often indistinguishable histopathologically, see Chapter 57) whose median survival time is significantly longer than that of cats with the lymphoblastic form of the disease (22.8 months vs. 2.7 months).[44] In a study by Zwahlen and colleagues, the addition of surgery to chemotherapy did not provide any survival advantage over chemotherapy alone.[45] It must be noted, however, that the number of cases included was small and it was not a randomized, prospective clinical trial. In the author's opinion, surgery may be a beneficial addition to chemotherapy in cats and dogs affected by lymphoma, manifesting as a solitary intestinal lesion.

Interestingly, the nonsteroidal antiinflammatory piroxicam resulted in considerable amelioration of clinical signs when used in dogs with rectal tubulopapillary polyps. Furthermore, its use has been postulated for the adjunctive treatment of surgically excised colonic tumors, but randomized, prospective studies evaluating the role of piroxicam or adjuvant chemotherapy following surgical resection for the treatment of intestinal tumors in dogs, cats, and humans are lacking.

CHAPTER 45

Gastric Cytoprotective Agents

Caroline S. Mansfield and Tim Hyndman

Introduction

Gastric cytoprotective agents are used when normal gastric defense mechanisms are disrupted, thereby exposing submucosal layers to damage from gastric acid, or when there is another need for reducing gastric acidity, such as esophageal disease. Signs of significant gastric ulceration are hematemesis and melena. Hematemesis refers to the vomiting of blood, which, when digested, may have the appearance of coffee grounds. Gross melena (digested blood in the feces) only occurs after significant volumes of blood have been lost into the intestinal lumen.

The gastric mucosa has several intrinsic properties that protect it from autodigestion, including intact apical cell membranes, tight junctions, bicarbonate secretion, mucus production, rich blood supply, active cell renewal, surface active phospholipids, and endogenous prostaglandins. Gastric ulceration is believed to have its origins in the disruption of the mucosal barrier, or as a result of excessive acid secretion (Box 45-1), and is more commonly reported in dogs than in cats.[1-4] History and physical examination, as well as full metabolic assessment, will help to rule out systemic disease and drug administration as the underlying cause. Strenuous exercise, particularly in sled dogs, is associated with increased intestinal permeability and gastrointestinal ulceration.[5,6] The use of corticosteroids in dogs with intervertebral disk disease has been associated with severe gastrointestinal ulceration.[7] If no underlying cause is identified abdominal ultrasound combined with further testing, such as endoscopy or gastric biopsy, may be required.

For many of the conditions listed in Box 45-1 the true incidence of ulceration is unknown, especially with regards to nonsteroidal antiinflammatory drug (NSAID) toxicity. NSAIDs (particularly aspirin) are reported to exert their adverse effects by direct toxicity to the gastric mucosa as well as by inhibition of the cyclooxygenase pathways, thereby reducing endogenous prostaglandin and mucus production.[8] It may well be that the superficial gastric erosions reported and identified in animals given NSAIDs are not clinically significant.

In addition to the conditions detailed in Box 45-1, gastric cytoprotective agents have been used in the treatment of gastroesophageal reflux disease. Gastroesophageal reflux may occur secondary to general anesthesia (especially when the animal has not been fasted),[7] protracted vomiting disorders, or physical defects such as hiatal hernias.[9] Ingestion of caustic substances such as clindamycin or generic doxycycline capsules in cats may cause severe esophagitis requiring gastric antisecretory therapy.[10,11]

It is important to bear in mind that ideal treatment goals for specific gastric conditions have not been established in veterinary medicine. In human medicine it is recommended that the gastric pH should be increased to more than 4 for approximately 16 to 22 hours per day in the treatment of gastroesophageal disease, as well as in critically ill patients, whereas for conditions of gastrointestinal hemorrhage the pH should be as high as 6 to promote hemostasis.[12] Similar standards have not yet been developed for most companion animal disease conditions.

Classification

Drugs used for gastric protection are classified according to their mechanism of action and are discussed under the following sections:

- Oral Antacids
- Chemical Diffusion Barriers
- Prostaglandin Analogue(s)
- Histamine H_2-Receptor Antagonists
- $H,^{+}K^{+}$-ATPase (Proton Pump) Inhibitors

Oral Antacids

Mechanism of Action

Antacids react chemically with gastric acid to reduce the overall acidity of the stomach. Antacids do not directly decrease acid secretion. The most commonly used antacids are aluminum hydroxide ($Al[OH]_3$), magnesium hydroxide ($Mg[OH]_2$), and calcium carbonate ($CaCO_3$). Many of these are available as over-the-counter formulations for the symptomatic relief of gastroesophageal reflux and dyspepsia, and are often formulated with other drugs (see Box 45-1). They are given orally as tablets or liquids and are often flavored for palatability. There is little absorption from the gastrointestinal tract so the risk for adverse systemic effects is minimal.

The use of antacids for stomach ulceration is based on the premise that buffering or decreasing gastric acid will permit ulcer healing.[13] However, ulcer healing seen with aluminum hydroxide may not be related to gastric acidity,[14] as it may also release prostaglandin (PG) E_2 into the gastric lumen and submucosa.[15] The significance of this finding requires further investigation. There is very little scientific literature assessing the efficacy of local antacids for dog and cat gastric ulceration.

Box 45-1 Differential Diagnoses of Gastric Ulceration

Primary Gastrointestinal Disease
Helicobacter-like organisms*

Renal failure
Hypoadrenocorticism
Shock
Liver disease†

Miscellaneous
Parasitic disease
Hypereosinophilic syndrome

*The most common potential underlying causes of gastric ulceration in dogs.[1]
†The most common potential underlying causes of gastric ulceration in cats.[4]

Dose

The onset and duration of antacid effect in humans is rapid and extends from 20 minutes to 3 hours, depending on the preparation that has been used.[16] Antacids act locally so the presence of food will delay gastric emptying, thereby prolonging the effect of these drugs.[17] This short duration of action, which presumably also occurs in dogs and cats, necessitates that these drugs be taken often. Dose recommendations are estimations only and have not been scientifically determined for dogs or cats (Table 45-1).

Rational Use

These drugs are an unattractive option for the management of stomach ulceration and more appropriate alternatives usually should be used. They are likely more appropriate for mild to moderate gastric disease.

Contraindications and Side Effects

The cations in antacids are capable of binding to fluoroquinolones and tetracyclines and may decrease the systemic absorption of this drug class. Ketoconazole and itraconazole, which depend on gastric acidity for oral absorption, will show decreased systemic absorption when given concurrently with any drug capable of reducing gastric acidity. Recommendations to prevent decreased bioavailability of these drugs that are based on controlled animal studies do not exist, but human recommendations are that these drugs be given parenterally (if appropriate) or orally a few hours before or after administration of the antacid.[16] In dogs, the bioavailability of oral propranolol in the presence of aluminum hydroxide or magnesium hydroxide is reduced.[18]

Table 45-1 Commonly Used Gastric Cytoprotective Agents in the Dog and Cat

Generic Name	Trade Name	Dose (dog)	Dose (cat)	Comments
Aluminum hydroxide-magnesium hydroxide combination	Mylanta	5 to 10 mL PO q4h	5 to 10 mL PO q4h	Give with food.
Calcium carbonate	TUMS	5 to 10 mL PO q4h	5 to 10 mL PO q4h	Give with food.
Bismuth		1 to 3 mL/kg PO q24h	1-3 mL/kg PO q24h	May cause black feces
Sucralfate	Carafate	0.5 to 1 g PO q8 to 12h	0.25 to 0.5 g PO q8 to 12h	
Misoprostol	Cytotec	2 to 5 µg/kg PO q8 to 12h†	3 to 5 µg/kg PO q8h*	
Cimetidine	Tagamet, Zitac	5 to 10 mg /kg PO, SC, IV q6 to 8h	5 to 10 mg /kg PO, SC, IV q6 to 8h	Reduce dose by 50% in animals with renal impairment. Use with care with concurrent administration of drugs with extensive hepatic metabolism.
Ranitidine	Zantac	1 to 2 mg/kg PO, SC, IV q12h	2.5 to 3.5 mg/kg PO, SC, IV q12h	Reduce dose by 50% in animals with renal impairment.
Famotidine	Pepcid	0.1 to 0.2 mg/kg PO, IV q12 to 24h	0.1 to 0.2 mg/kg PO, IV q12 to 24h	Reduce dose by 50% in animals with renal impairment.
Nizatidine	Axid	2.5 to 5 mg/kg PO, q12 to 24h	2.5 to 5 mg/kg PO, IV q12 to 14h	Reduce dose by 50% in animals with renal impairment.
Omeprazole	Losec (USA: Prilosec)	0.7 to 1 mg/kg PO q24h	0.7 to 1 mg/kg PO q24h	Do not crush enteric-coated granules inside tablets or capsules. Increased benefit may be seen with 1 mg/kg q12h dosing.
Pantoprazole	Somac (USA: Protonix)	0.5 to 1 mg/kg PO, IV q24h	0.5 to 1 mg/kg PO, IV q24h	Intravenous doses should be given over at least 15 minutes or given as an infusion spread over 24 hours.

*This drug has not been assessed for safety, efficacy, or pharmacokinetics in cats.
†Efficacy in dogs has only been shown against aspirin-induced damage to gastrointestinal mucosa.

Magnesium hydroxide has mild laxative effect whereas aluminum hydroxide has a mild constipating effect. These two salts are often given together in the same formulation such that changes in fecal consistency are uncommon. It has been suggested that magnesium-containing antacids should be avoided in patients with renal failure to avoid hypermagnesemia that may lead to central nervous system toxicity.[19] Calcium carbonate reacts with stomach acid to liberate carbon dioxide, and belching may be noted.[19] Aluminum hydroxide is capable of binding to phosphates and is sometimes used for cases of hyperphosphatemia.[20] Aluminum toxicity to with aluminum hydroxide antacids has been reported.[21]

Antacids have sometimes been singled out as drugs that produce significant rebound gastric acid hypersecretion once therapy has stopped, however, this hypersecretion may simply be a function of gastric hypoacidity caused by many of the gastric acid-lowering drugs.[22]

Prostaglandin Analogues

Mechanism of Action

Gastric prostaglandins play an important role in gastric mucosal defense in that they increase mucosal blood flow, mucus production, and bicarbonate secretion.[23,24] The most commonly studied and used prostaglandin analogue in veterinary medicine is misoprostol, an analogue of prostaglandin E_1.[25-28]

Dose

Beneficial effects have been reported at a dose of 3 µg/kg body weight every 8 to 12 hours in dogs,[8] with a half-life of approximately 30 minutes, and a duration of action of 3 to 6 hours.[29] Only oral formulations for this purpose are available. No known pharmacokinetic or safety studies have been performed in cats, but the anecdotal dose is recommended to be 2 to 5 µg/kg body weight every 12 hours.[8]

Rational Use

The veterinary application of this drug originated from its use in people to prevent NSAID-induced gastric injury, although it is not clear how superior it is to other gastric cytoprotective agents.[30,31] NSAIDs are frequently used in older animals and may inhibit tissue cyclooxygenase pathways.[2,32] In most in vivo veterinary assessments of this drug, misoprostol was given along with a nonsteroidal drug, usually aspirin, and compared with placebo. Despite slight variation in study design, it has been shown that there was significantly less gastroduodenal hemorrhage and vomiting in the misoprostol group over 14-day[25] to 30-day[26] periods. The benefit of misoprostol is less convincing in studies of dogs given corticosteroids because of intervertebral disk disease.[7,33] This may be due to differences in the pathogenesis of glucocorticoid-induced gastric ulceration or additional neurogenic factors. Based on these studies, it would seem prudent to only recommend the prophylactic use of misoprostol in dogs receiving NSAID therapy that are at high risk of developing gastric ulceration. However, its use is not generally supported in healthy animals receiving cyclooxygenase-2–specific antagonists or animals receiving glucocorticoids alone.

Contraindications and Side Effects

The use of this drug is contraindicated in dogs receiving gentamicin or other nephrotoxic drugs, as it has been shown to potentiate nephrotoxic effects.[27] Side effects that have been reported include intestinal cramping and diarrhea, caused by the stimulation of migrating motor complexes. The incidence of diarrhea is dose dependent, especially when the recommended dosage is exceeded.[28] Because of the potential to induce abortion, the drug should not be handled by women who are pregnant or trying to conceive.

Chemical Diffusion Barriers

Mechanism of Action

This class of drugs provides physicochemical barriers between the gastric epithelium and the acidic content of the gastric lumen. These drugs are seen as a replacement or support for the mucus layer of the gastric epithelium. The two drugs most commonly used in small animal medicine from this class are bismuth and sucralfate. US formulation is bismuth subsalicyclate, and its use is cautioned against in cats due to potential for salicylate absorption and toxicity.

Bismuth is capable of binding to an ulcer bed, providing a protective coating. In addition, it can enhance bicarbonate secretion and local prostaglandin synthesis, and adsorb the proteolytic enzyme pepsin.[34]

Sucralfate is a complex of sucrose octasulfate and aluminum hydroxide that in the presence of acid dissociates into these two components. Sucrose octasulfate will polymerize into a sticky, viscous, yellow-white gel that is strongly anionic and electrostatically binds to cationic tissue proteins of ulcerated mucosa. The ulcerated site covered by this "liquid band aid" is protected from backward diffusion of hydrogen ions. It seems likely that both the sucrose octasulfate and aluminum hydroxide components contribute to cytoprotection.[35] Sucralfate has additional cytoprotective roles that may involve mucosal synthesis of protective prostaglandins, secretion of mucus and bicarbonate, and increases in epidermal growth factor. It has little effect on stomach acidity.

Dose

In humans, approximately 30% of the polymerized viscous paste of sucralfate remains in the stomach 3 hours after administration. In one study in dogs, radiolabeled sucralfate could still be detected bound to acetic acid–induced gastric ulcers 8 hours after oral administration.[36] Anecdotal reports suggest 8- to 12-hour dosing at 0.5 to 1 g for dogs and 0.25 to 0.5 g for cats.

Rational Use

Bismuth has shown efficacy as an antiulcer medication in rats,[37] but is largely ineffective against NSAID-induced ulceration in people.[38] Most of the attention given to bismuth as an antiulcer drug has been in humans for its use in cases of *Helicobacter pylori*-gastritis. The interaction between bismuth, stomach ulcers, and *Helicobacter*-like organisms in small animal medicine requires further investigation. Because of the limited information concerning the efficacy of bismuth as an antiulcer medication in dogs or cats, its use in these species for this indication cannot be recommended at this time.

Despite the widespread use of sucralfate in dogs and cats for stomach ulceration and esophagitis, there are few data demonstrating efficacy for these indications. The use of sucralfate to prevent NSAID-induced ulceration in people appears to be poor.[39] It has been shown that sucralfate does not provide any benefit when used prophylactically to prevent methylprednisolone-induced gastrointestinal tract bleeding in dogs.[33] Liquid sucralfate is able to prevent acid-induced esophagitis in cats and, in this role, outperformed a PGE_1 analogue[40] and cimetidine.[41]

Contraindications and Side Effects

Similar to the cationic antacids, sucralfate is capable of binding to fluoroquinolones and tetracyclines, and will likely decrease their systemic absorption when given orally. Also, the absorption of digoxin, theophylline, and phenytoin is decreased when given concurrently with sucralfate. All these drugs should be given orally at least 2 hours prior to sucralfate. It would seem logical that concurrent use of antacids or H_2-histamine antagonists would neutralize stomach acid and therefore decrease the efficacy of sucralfate, but one study in dogs showed the concurrent administration of these drugs did not affect sucralfate's ability to bind to gastric ulcers.[36] Bismuth will create blackened stools that do not represent melena; the owner should be made aware of this.

H_2-Histamine Antagonists

Mechanism of Action

These drugs competitively inhibit H_2-histamine receptors in the gastric parietal cells and cause approximately 70% to 90% reduction in gastric acid and pepsin secretion. H_2-histamine antagonists have significant popularity in human medicine, and in many countries are sold over the counter. Despite differences in the degree of gastric acid inhibition between the different drugs of this group, no study shows one to be superior to the other in a clinical setting.

In a recent study of healthy Beagles, intragastric pH was measured before and after feeding during 7 days of treatment with ranitidine, famotidine, pantoprazole, omeprazole, or saline at therapeutic doses.[12] Generally, pH was higher for longer periods after treatment with famotidine, pantoprazole, or omeprazole. Only twice-daily administration of omeprazole reached the therapeutic criteria as established in people.

Rational Use

Potential reasons for using an H_2-antagonist include treatment of gastric ulceration, prevention of gastrointestinal ulceration in critically ill animals, and treatment of gastroesophageal reflux. There is insufficient evidence to support their use for prevention of NSAID-induced gastric damage,[42,43] although in one pharmacokinetic study cimetidine reduced the half-life of piroxicam in healthy cats,[44] and famotidine increased gastric blood flow in healthy dogs administered diclofenac sodium.[45]

Each drug may have additional effects and contraindications, and is discussed separately.

Of the H_2-histamine receptor antagonists, historically cimetidine was commonly used, but is reported to be least effective in reducing gastric pH. It is also without effect on gastrointestinal motility. Cimetidine has important effects on drug metabolism by inhibiting hepatic microsomal enzymes and decreasing hepatic blood flow.[46] Other effects of cimetidine relate to immunomodulatory benefits, mainly by dampening cell-mediated immunity.

Dose

A dose of 5 to 10 mg/kg either intravenously or orally every 6 to 8 hours is recommended in both dogs and cats. If given orally with food there is a delay in drug absorption, and there should be at least 2 hours between administration of cimetidine, ketoconazole, antacids, or digoxin.

Contraindications and Side Effects

Care should be used if giving this drug intravenously in animals with impaired renal function. Most of the drug is excreted through the kidneys and the dose should be reduced by 50%. Care should also be used in giving this drug to animals receiving drugs that require extensive hepatic metabolism (e.g., phenobarbital, metronidazole, theophylline, calcium channel blockers, and benzodiazepines). Other drugs in this class have less of an effect on hepatic microsomal enzymes and should be used preferentially in animals receiving concurrent medications such as these.

Ranitidine

Ranitidine has less of an inhibitory effect on the hepatic microsomal enzyme system. It has a prokinetic property through an anticholinesterase effect that has been shown to stimulate gastrointestinal motility.[47] This motility effect has been shown to occur in the gastroesophageal sphincter and the gastrointestinal tract in dogs and cats, and is one drug recommended for therapy in feline megacolon.[48] Despite its safety, little is known regarding its efficacy and, as mentioned earlier, in one recent study of healthy dogs it was shown to be significantly less effective than famotidine, omeprazole, or pantoprazole at increasing intragastric pH.[12]

Dose

The dose is 1 to 2 mg/kg (dogs) and 2.5 to 3.5 mg/kg (cats) orally, subcutaneously, or intravenously every 12 hours in both dogs and cats. Absorption is not affected by feeding.

Contraindications and Side Effects

As for all H_2-antagonists, the dose should be reduced by 50% in animals with renal impairment.

Famotidine

Famotidine is more effective at reducing gastric acid secretion than ranitidine.[49] It is preferred to omeprazole in the treatment of *H. pylori*–associated gastroesophageal reflux in people.[50] Like cimetidine, it has no effect on gastrointestinal motility or gastroesophageal sphincter tone.

Dose

Famotidine has minimal hepatic first-pass metabolism and limited oral bioavailability. Absorption is not affected by feeding or fasting, a fact that has made this drug preferable to omeprazole in endurance dogs during racing.[51] The dosage in dogs and cats is 0.1 to 0.2 mg/kg orally or intravenously every 12 to 24 hours.

Contraindications and Side Effects

Famotidine should be reduced by 50% in animals with impaired renal function. It may exacerbate cytopenias if given in conjunction with other myelosuppressive agents. Anecdotal cases of hemolytic anemia in cats have been reported.[52]

Nizatidine

Nizatidine is the least-studied drug in animals from this group. It has similar effects on gastrointestinal motility to those of ranitidine, also at antiulcer therapeutic doses.[48]

Dose

Food improves oral bioavailability, but this is not thought to be clinically important. There is minimal hepatic first-pass metabolism and rapid and virtually complete oral absorption.[53] Administration of 2.5 to 5 mg/kg orally or intravenously every 12 to 24 hours is recommended for both prokinetic and H_2-antagonistic effects.

Contraindications and Side Effects

Dosage should be reduced by 50% in animals with significant renal impairment.

Theoretically, the use of any H_2-antagonist may induce cardiac side effects because of the presence of type 2 histamine receptors on cardiac myocytes, but only transient arrhythmias seem to occur. Long-term usage has resulted in bacterial overgrowth in humans because of acid hyposecretion, but clinical cases in dogs and cats have not been reported.

H^+,K^+-ATPase (Proton Pump) Inhibitors

Mechanism of Action

Proton pump inhibitors covalently bind and irreversibly inhibit the proton pump (H^+,K^+-adenosine triphosphatase [ATPase]) on the luminal surface of the parietal cell. New synthesis of H^+,K^+-ATPase enzyme is continuous, so the pharmacologic effect of a proton pump inhibitor is not permanent. All afferent pathways that culminate in the basal or stimulated secretion of hydrogen ions from the parietal cell (gastrin, histamine, and acetylcholine) are inhibited. The two drugs from this class most commonly utilized in small animal medicine are omeprazole and pantoprazole.

Dose

These drugs should be given on an empty stomach as the presence of ingesta will decrease oral bioavailability. Proton pump inhibitors are absorbed in the small intestine and arrive at the parietal cell through the vascular system and resecretion. They are weakly alkaline and therefore will concentrate and persist in the acidic parietal cell, prolonging their duration of action. The inhibition of acid secretion from a single dose may extend for longer than 24 hours in the dog.[54] However, their onset of activity is slower than drugs that act locally. In humans, the antisecretory effect is first seen within 1 hour of oral administration and maximal effects usually occur within 4 days of therapy. The antisecretory effect continues after therapy is discontinued (3 to 4 days) as acid secretion is dependent on the synthesis of new protein. Dogs and cats are often treated with oral omeprazole at a dose of 0.7 to 1 mg/kg daily.

Human preparations of omeprazole are formulated as tablets or capsules containing enteric coated granules of the drug. Omeprazole is labile to protonation in the acidic environment of the stomach, which will decrease gastrointestinal absorption. Disrupting the enteric coating by crushing the granules should therefore be avoided. It has been suggested[54] that once acid secretion has decreased, subsequent doses will not be affected. Enteric-coated omeprazole paste preparations registered for use in horses (e.g., Gastrozol) have not been assessed for use in dogs and cats. The recruitment of compounding pharmacies to produce compounded omeprazole should be treated cautiously as pharmaceutically equivalent preparations may not be bioequivalent to their commercial counterparts.[55]

Rational Use

Metaanalysis in people reveals that omeprazole is the "gold standard" for treatment of acute gastric ulceration.[56] Omeprazole outperformed placebo in the prevention of exercise-induced gastritis in sled dogs[57] and, as mentioned previously, was the only drug capable of increasing gastric pH in healthy dogs to levels that are considered optimal for the treatment of gastroesophageal reflux disease and duodenal ulcers in people.[12] In another study, however, omeprazole did not demonstrate any statistically significant benefit compared with a negative control in the prevention of gastric mucosal lesions in glucocorticoid-treated dogs with intervertebral disk disease.[7]

Proton pump inhibitors may provide support in the prevention of rebleeding from sites of gastric ulceration. It has been suggested that clot formation is impaired in acidic environments (pH <6).[12] To elevate gastric pH to greater than 6 requires an almost complete inhibition of acid secretion. In dogs and cats, studies to determine the dose necessary to achieve these levels are nonexistent.

Contraindications for Use and Side Effects

Proton pump inhibitors are capable of causing complete cessation of gastric acid secretion. There is no direct evidence in dogs and cats that achlorhydria is harmful, but long-term data are lacking. Currently, there is no evidence that bacterial overgrowth occurs in either dogs or cats with long-term therapy. Long-term use of proton pump inhibitors (>8 weeks) may lead to increased levels of gastrin following inhibition of negative feedback pathways. Posttherapy rebound hypersecretion of gastric acid has been seen with proton pump inhibitors in humans,[22] but rebound hypersecretion was not reported in one dog study.[58] Overall, side effects from proton pump inhibitors are considered uncommon.

As with all drugs capable of decreasing gastric acidity, concurrent administration of ketoconazole or itraconazole with proton pump inhibitors may result in decreased bioavailability of these two antifungal azoles. Proton pump inhibitors have the ability to mask some of the symptoms associated with gastric cancer.

CHAPTER 46

Hepatobiliary Cytoprotective Agents

Cynthia R. L. Webster

Natural Hepatobiliary Defense Mechanisms

The liver is uniquely susceptible to damage as a consequence of its role in the metabolism of endogenous metabolites and xenobiotics, and its position as a filter for portal blood. These processes expose the liver to high levels of oxidative stress from free radicals generated not only in hepatobiliary cells but also in activated Kupffer cells (resident macrophages in the liver) and infiltrating neutrophils. The liver has developed strong cyto- and hepatoprotective mechanisms, including enzymatic (catalase, superoxide dismutase, glutathione peroxidase, glutathione transferase) and nonenzymatic (glutathione, vitamin E, beta-carotene, bilirubin) antioxidant systems. Glutathione (GSH), a tripeptide of cysteine, glycine, and glutamine, is a major free radical scavenger in the liver. It is synthesized in the cytosol and transported into intracellular organelles. The rate-limiting step in GSH formation is the intracellular availability of cysteine.

Hepatobiliary cells also respond to toxic signals by initiating intracellular prosurvival biochemical pathways. These pathways, which protect against necrotic and apoptotic cell death, are controlled by hormones, such as glucagon, and growth factors, such as hepatocyte growth factor, and work through the modulation of survival kinases, including phosphoinositol-3-kinase (PI3K) and Akt.[1]

Hepatoprotective Agents

A summary of the hepatoprotective agents discussed in the following section can be found in Table 46-1.

Ursodeoxycholate

Chinese black bear bile has been used for its hepatobiliary healing power for centuries. The major bile acid in this bear is ursodeoxycholate (UDCA). Bile acids, a family of molecules synthesized exclusively in the liver, are formed when a hydroxyl group (OH) is added to cholesterol's steroid nucleus. The simplest bile acids are thus the di-OH bile acids, chenodeoxycholate and UDCA. Additional hydroxylation creates the tri-OH bile acids in the cholate group. Bile acids are conjugated to either taurine or glycine in the liver. In cats and dogs, the tri-OH bile acid, taurocholate, is the major circulating bile acid. Some bile acids, unlike UDCA, are hepatotoxic.[2] The structural basis for the differential cytotoxicity of bile acids is not fully understood but is roughly correlated with their degree of hydrophobicity. Toxic bile acids damage hepatocytes by disrupting biologic membranes and stimulating apoptosis.[2]

UDCA's cytoprotective effect is associated with several factors.[3] First, UDCA can replace more hydrophobic hepatotoxic bile acids from the circulating bile acid pool. This effect is of limited value in dogs and cats in which the major circulating bile acid is the relatively nontoxic, taurocholate. A major cytoprotective action of UDCA lies in is its ability to inhibit apoptosis. Mitochondria are key regulators of apoptotic pathways and UDCA can stabilize mitochondrial membrane function, increase mitochondrial stores of glutathione, and prevent the mitochondrial-mediated generation of free radicals, all of which contribute to mitochondrial instability and the initiation of apoptosis. UDCA's antiapoptotic action also involves stimulation of cellular survival signaling through activation of protein (Akt, mitogen-activated kinases) and lipid kinases (PI3K). UDCA is a choleretic agent and this action promotes the excretion of potentially toxic endogenous metabolites retained during cholestasis. UDCA induces choleresis by (a) direct stimulation of a bicarbonate-rich bile flow in the bile ducts (followed by the osmotic movement of water) and (b) increasing the membrane expression of transport proteins necessary to generate bile flow. Emerging evidence suggests that UDCA also works as a biologic response modifier of the glucocorticoid receptor. UDCA can activate the glucocorticoid receptor by interacting with a distinct region of the receptor (not the same binding site as cortisol), inducing nuclear translocation of the glucocorticoid receptor, and suppressing transcription of inflammatory mediators.

Following oral administration, UDCA is absorbed primarily in the small intestine. Absorption is enhanced in the presence of food. UDCA has high hepatic first-pass metabolism (70%). In the liver, UDCA is conjugated to taurine or glycine and then undergoes enterohepatic circulation. UDCA that escapes enterohepatic circulation is metabolized to lithocholate in the colon and eliminated in the feces or urine. The bioavailability of UDCA may decrease with advanced cholestasis because of decreased hepatic extraction and increased renal elimination. Thus in severe cholestasis, twice daily administration of UDCA may be beneficial.

There is little information in the literature on the use or efficacy of UDCA in small animals. The recommended dose (10 to 15 mg/kg/day PO), has been extrapolated from human medicine. One study each in the cat and the dog shows that oral administration of this dose results in the appearance of UDCA in the serum.[4,5] In the dog case report, this dose was associated with biochemical and clinical improvement of chronic hepatitis.

UDCA is well tolerated. Diarrhea and vomiting may occur rarely. Extensive toxicologic studies performed in healthy dogs did not

Table 46-1 Hepatoprotective Agents

Drug	Mechanism of Action	Dose	Indication	Side Effects
Ursodeoxycholic acid	Choleretic Upregulates survival pathways Replaces hepatotoxic bile acids Immunomodulatory	10 to 15 mg/kg/day PO Absorption enhanced in the presence of food	Cholestatic, inflammatory, and metabolic hepatopathies	Rarely vomiting May increase the bioavailability of vitamin E and cyclosporine
S-adenosylmethionine	Transmethylation reactions Increase glutathione levels Increases polyamine synthesis	20 mg/kg/day PO Do not give with food	Cholestatic, inflammatory, and metabolic hepatopathies	None
Silymarin (milk thistle)	Antioxidant Antifibrotic Choleretic	Silymarin: 5 to 15 mg/kg/day PO Siliphos: 3 to 6 mg/kg/day PO	Inflammatory, cholestatic, and metabolic hepatopathies	None Inhibits drug-metabolizing enzymes
Vitamin E	Antioxidant Antiinflammatory	10 to 15 IU/kg/day PO of α-tocopherol acetate	Inflammatory, cholestatic, and metabolic hepatopathies	None
N-acetylcysteine	Antioxidant Restoration of capillary dynamics in acute liver failure	140 mg/kg IV once then 70 mg/kg q6h	Acetaminophen toxicity Acute liver failure Feline hepatic lipidosis syndrome	Vomiting with oral preparations
Carnitine	Necessary for transport of fatty acids into mitochondria Detoxifies toxic intermediates that accumulate in disorders of β-oxidation May retard lipid accumulation	250 mg/cat/day PO	Feline hepatic lipidosis syndrome	None
Zinc	Inhibits intestinal absorption of copper Antifibrotic Antioxidant	100 mg/kg elemental zinc/day q12h	Copper-associated hepatopathies Inflammatory hepatopathies	Vomiting Iron deficiency Hemolytic anemia Monitors serum values, goal is 200 to 500/mg/dL
Colchicine	Inhibits microtubule function and thus secretion of collagen into extracellular matrix	0.01 to 0.3 mg/kg/day PO	Noninflammatory fibrotic hepatopathies	Diarrhea

reveal any serious side effects. No adverse effects were noted in normal cats treated with 10 mg/kg/day PO for 3 months or with 15 mg/kg/day PO for 8 weeks.[4,6] UDCA can increase the bioavailability of cyclosporine and vitamin E.

Currently, this author uses UDCA as ancillary therapy in a variety of acute and chronic hepatopathies in the dog and cat. In some chronic inflammatory hepatopathies in dogs, particularly where corticosteroids are contraindicated, UDCA is used a sole therapy. UDCA is also used to promote bile flow in acute and chronic cholestatic disorders in the absence of bile duct obstruction.

The effect of UDCA on serum total bile acid concentrations has been investigated in normal dogs and cats. In cats given 15 mg/kg/day, pre- and postprandial serum bile acid concentrations increase but are not out of the normal range.[4] In normal dogs, one study showed that 15 mg/kg/day UDCA increased postprandial serum bile acids in only one of 16 dogs whereas another study using the same dose showed that six of 14 dogs developed increased serum total bile acids 1 to 6 hours after oral dosing.[7,8] The effect of UDCA administration on serum bile acid profiles in animals with hepatic disease has not been reported.

S-Adenosylmethionine

The liver is the major site of *S*-adenosylmethionine (SAMe) synthesis and degradation. Methionine is actively transported into the liver and converted to SAMe by the enzyme, methionine adenosyltransferase. The activity of methionine adenosyltransferase is impaired in experimental models of liver injury in laboratory rodent and in human patients with alcoholic cirrhosis. Thus, in the setting of severe liver disease, SAMe becomes a conditionally essential nutrient.[9,10]

In the liver there are three metabolic pathways for SAMe metabolism: (a) transmethylation, (b) transsulfuration, and (c) aminopropylation, and all three are implicated in the compound's hepatoprotective effects.[9,10] In transmethylation reactions, SAMe donates a methyl group to a large number of molecules, including proteins, DNA, and membrane phospholipids. Through methylation of the latter two, SAMe can decrease the expression of

inflammatory cytokines and stabilize mitochondrial membranes. Once SAMe has donated its methyl group, it is converted to *S*-adenosylhomocysteine. In the transsulfuration pathway, *S*-adenosylhomocysteine can be converted by a series of enzymatic steps to cysteine. Because the availability of cysteine is the rate-limiting step in the synthesis of glutathione, SAMe administration can increase hepatic glutathione levels in normal dogs and cats.[11,12] It also ameliorates acetaminophen-induced red blood cell and hepatic damage in cats and dogs, respectively.[13,14] In the third major pathway, SAMe can be decarboxylated to polyamines that can stimulate protein synthesis. Methyladenosine, an intermediate in this pathway, is antiapoptotic in hepatocytes.

Two stable salts of SAMe are available for oral administration.[15] The 1,4-butanedisulfonate salt is marketed for veterinary use as Denosyl-SD4 (Nutramax Laboratories, Inc.) and the tosylate salt is marketed as Zentonil (EVSCO Pharmaceutical). The dose is 20 mg/kg/day. SAMe tablets must be enteric coated and stored in a blister pack. The tablets should not be split or crushed. Because food interferes with absorption, SAMe should be given in the fasting state. SAMe has low oral bioavailability (approximately 3%) because of a significant hepatic first pass effect and rapid metabolism within the liver. SAMe crosses the blood–brain barrier[16] and there is a significant body of literature to support an antidepressant effect in humans.[17] SAMe is rapidly metabolized intracellularly, but that portion not metabolized undergoes renal and fecal excretion. Limited pharmacokinetic studies in dogs show that peak plasma concentrations occur within 1 to 4 hours.[12] No side effects have been reported in human trials and the LD_{50} (median lethal dose for 50% of test subjects) in laboratory rats is greater than 4650 mg/kg/day. Cats given four times the recommended dose for 3 months had no adverse effects.[11]

In a study of prednisone-treated dogs, SAMe did not prevent the development of hepatic vacuolar changes or the induction of serum hepatic enzyme activity.[12] In this study, concurrent prednisone use did not adversely affect the pharmacokinetics or pharmacodynamics of SAMe administration.

In human clinical trials, SAMe has shown beneficial effects in alcoholic and cholestatic liver disorders.[18,19] The therapeutic potential of SAMe in veterinary medicine is unknown as limited clinical studies have been published. Because glutathione levels are decreased in some animals with hepatic disease,[20,21] particularly cats with hepatic lipidosis, SAMe supplementation may be beneficial. SAMe may also be useful as adjunctive therapy in dogs and cats with inflammatory liver disease. This author often uses SAMe in combination with corticosteroids and/or ursodeoxycholate. There is some evidence that the concurrent use of SAMe and ursodeoxycholate may be synergistic.[19] Typically, animals are given a 3-month trial of SAMe to evaluate whether addition to the therapeutic protocol provides symptomatic or biochemical improvement. Because SAMe crosses the blood–brain barrier and there is a considerable body of evidence to suggest that SAMe is effective in the treatment of depression in humans, the possibility of "mood elevating" effects in symptomatic control of hepatopathies cannot be overlooked. SAMe therapy may be useful in the recovery phase of hepatotoxic drug reactions.[22]

Silymarin

The active ingredient in milk thistle, silymarin, is a mixture of flavonoids (silibinin, silidianin, and silichristin), all of which have antioxidant properties.[9,23] Their antioxidant effects are a result of inhibition of lipid peroxidation and inactivation of inflammatory transcription factors and cytokines. Silymarin also promotes protein and DNA synthesis, inhibits collagen synthesis, and restores normal glutathione stores. Because silymarin inhibits the uptake of *Amanita* toxin in dogs, it can be used as an antidote for mushroom hepatotoxicity.[24] Silymarin also promotes choleresis by increasing the insertion of transporters into the apical membrane of hepatocytes.[25] Silymarin inhibits drug-metabolizing enzymes including P-glycoprotein, glucuronyltransferases, and cytochrome P450, so coadministration with other drugs metabolized by these systems should be closely monitored.

Silymarin's bioavailability is low as a result of erratic absorption from the gastrointestinal tract. It has a short plasma half-life in humans (6 hours), but is preferentially accumulated in the liver. It is excreted in the biliary tract as a glucuronide and sulfoglucuronide conjugate, and undergoes some enterohepatic circulation. Bile concentrations are 100 times those in serum. Silymarin appears to be safe and well tolerated. It has been difficult to show clinical benefit of silymarin in randomized control trials in human liver disease.[26] Metaanalyses show that available studies suffer from poor study designs, including a heterogeneous cohort of patients with differing etiology and/or extent of liver disease, small sample sizes, and variation in formulation, dosing, and duration of silymarin therapy. Extrapolation of dose from these studies is difficult, but suggests that 5 to 15 mg/kg/day divided into two to three daily doses might be in the therapeutic range. Typical formulations of milk thistle should contain 70% to 80% silymarin. Siliphos, a formulation of silymarin complexed with phosphatidylcholine, is four to five times more bioavailable than silymarin itself in dogs.[27,28] It is currently marked as a combination product with vitamin E and zinc (Marin, Nutramax, USA) or SAMe (Denamarin, Nutramax, USA).

Vitamin E

The term *vitamin E* refers to a family of eight related, lipid-soluble, antioxidant compounds that are widely distributed in plants.[29,30] α-Tocopherol is the most active form of vitamin E. Vitamin E is important in protecting membrane phospholipids from oxidative damage. In addition to its membrane-protective effects, vitamin E also modulates signal transduction and gene expression. Vitamin E analogues can modulate the activity of lipooxygenases, cyclooxygenases, and protein kinase C, and inhibit activation of the proinflammatory transcription factor, nuclear factor-kappa B. In some instances different synthetic derivatives of vitamin E are more effective than others; for example, the α-tocopherol succinate ester is better at nuclear factor-kappa B inhibition than α-tocopherol acetate. The former analogue also has the unique ability among the vitamin E family members to stimulate selective apoptosis of cancer cells.

There is considerable experimental evidence of the therapeutic benefit of oral administration of vitamin E in chronic hepatic disease in humans and experimental models.[30] A small pilot study in 20 dogs with chronic hepatitis treated with a vitamin E supplemented diet for 3 months showed an increase in serum and liver vitamin E levels and some indication of increased antioxidant protection.[31] The diet provided a low daily dose of vitamin E (0.58 IU α-tocopherol acetate/kg body weight/day) so it is not surprising that no effect was seen on biochemical indicators of hepatic disease. The recommended oral formulation of vitamin E is the acetate form of α-tocopherol. It is used at a dose of 10 to 15 IU/kg PO once a day. Because cholestasis can interfere with the intestinal absorption of this fat-soluble vitamin, an emulsified formulation of vitamin E for parenteral administration has been developed. In a recent study, administration of this emulsified vitamin E ameliorated acute hepatobiliary injury that was induced by administration of hydrophobic

bile acids.[32] This formulation may prove to be useful in the management of acute cholestatic hepatopathies such as idiopathic hepatic lipidosis in cats.

N-acetylcysteine

N-acetylcysteine (NAC) is a stable formulation of the amino acid L-cysteine that can be given parenterally to replenish intracellular cysteine, and thus glutathione, levels.[33] It is a well-recognized antidote for acetaminophen-induced red blood cell and hepatocyte toxicity. NAC restores intracellular GSH levels that result in the detoxification of the reactive intermediate generated by cytochrome P450 metabolism of acetaminophen. The dose is 140 mg/kg IV initially, then 70 mg/kg q6h for seven treatments. NAC has additional beneficial effects, particularly in acute liver failure, where it is cytoprotective to endothelial cells and can improve blood flow and oxygen extraction in microcapillary beds. A high incidence of gastric irritation and vomiting limits the use of oral formulations of NAC.

Colchicine

Colchicine is a microtubular inhibitor that is used in hepatobiliary disease primarily for its antifibrotic effects. Colchicine's main mechanism of action is to inhibit collagen secretion, but it can also suppress inflammation by inhibiting neutrophil migration and degranulation and promote collagen degradation by stimulating collagenase activity. In isolated case reports, colchicine has shown variable efficacy in canine chronic hepatitis when used at 0.01 to 0.3 mg/kg/day PO.[34,35] In human medicine, metaanalysis of several large, randomized clinical trials of patients with chronic hepatitis/cirrhosis have not shown a beneficial effect of colchicines, and some studies actually have shown increased morbidity/mortality in the colchicine-treated patients.[36] Colchicine use should be limited to those canine patients with noninflammatory fibrotic hepatopathies. The major side effect is hemorrhagic diarrhea, although bone marrow suppression and peripheral neuropathies have been reported in humans. The use of colchicine has not been reported in cats.

Zinc

Zinc, a trace mineral that is an essential cofactor for a number of enzymes, has antifibrotic, antiinflammatory, and antiapoptotic effects in the liver.[37] Zinc is also used to treat copper-associated liver disease.[38] Zinc deficiency accompanies some chronic hepatopathies in humans, and there are anecdotal reports of low hepatic zinc levels in canine chronic hepatitis. Zinc is available as zinc acetate, sulfate, and gluconate salt. The suggested dose is 100 mg/kg of elemental zinc per dog q12h. The percentage of elemental zinc in the various salts is: Zn acetate, 30%; Zn gluconate, 14%; and Zn sulfate, 23%. Zinc should be administered on an empty stomach. Side effects include anorexia, vomiting, and hemolytic anemia. Plasma zinc levels should be monitored and kept below 800 µg/dL.

Carnitine

Carnitine is a cofactor in the transport of long-chain fatty acids across the inner mitochondrial membrane into the mitochondrial matrix where they can be utilized for energy production. Carnitine is also important in removing excess mitochondrial acetylcoenzyme A, the accumulation of which can impair β oxidation. Carnitine is derived from dietary sources (meat and dairy sources) or synthesized by the liver. Studies suggest that carnitine supplementation in obese cats undergoing weight loss increases the β-oxidation of fatty acids and decreases hepatic lipid accumulation.[39] Thus carnitine supplementation (250 mg/cat/day) has been advocated in the management of cats with liver failure as a consequence of hepatic lipidosis. This is despite the fact that cats with this syndrome have liver and skeletal muscle carnitine levels that are greater than those seen in control cats.[40] Carnitine supplementation can also improve neurologic status in human cirrhotic patients with hepatic encephalopathy.

CHAPTER 47

Enzyme Supplementation

Elias Westermarck

The exocrine pancreas has great reserve capacity; consequently, the clearly recognizable signs of failure emerge only when up to 90% of the exocrine gland tissue has been compromised. Replacement therapy with enzyme supplementation is then needed to compensate for the lack of endogenous enzyme production.[1]

Pancreatic enzyme replacement therapy was first attempted in human medicine at the turn of the twentieth century and it was shown that nutritional status could be significantly improved with such therapies. One challenge to this therapy is the sensitivity of pancreatic enzymes to gastric acid. Amylase and lipase are the most susceptible and are destroyed at a pH below 4.5. Trypsin can withstand a pH of 3.5, thus remaining unaffected by most pH conditions in the stomach. In humans, only 17% of ingested lipase can be recovered intact from the duodenum.[2] To improve passage of pancreatic enzymes through the acidic environment of the stomach, pharmaceutical companies have developed porcine, enteric-coated pancreatic enzyme preparations. The manufacturing process must be gentle to ensure that enzymes are not destroyed. Although much is already known about pancreatic enzyme supplementation, modern replacement therapy has significant room for improvement. Despite adequate enzyme supplementation, digestion capacity does not return to normal in humans or dogs with exocrine pancreatic insufficiency (EPI). Only a small portion of the orally administered enzyme is delivered intact and functional to the small intestine.[1] For maximum digestive efficiency, pancreatic enzyme preparations should be formulated to (a) protect acid-labile enzyme from gastric inactivation, (b) provide concomitant gastric emptying of the enzyme with the ingested meal, and (c) deliver maximal enzyme activity to the proximal duodenum. To fulfill these criteria, formulation of a sustained-release preparation of pancreatic extract that releases enzymes over a prolonged period of time to a site favorable for their function would be highly desirable. Unfortunately, this preparation is not yet commercially available.[3]

The gastric-emptying rates of nondisintegrating forms of enzyme have been reported in several studies. Early studies reported that particles reduced to a size of 2 mm or less are emptied rapidly from the canine stomach.[4] More recently, however, in normal dogs and in one dog with EPI, the majority of multiunit preparations (diameter, 1 to 1.7 mm) have been shown to remain in the canine stomach for up to 8 hours before being emptied into the duodenum by the interdigestive migrating motility complex.[5] The majority of pancreatic enzymes prepared in granule form obviously would never be emptied from the stomach simultaneously with food. Even a reduction of granule size to 0.3 mm had no clear effect on the gastric-emptying time of these preparations. It can be concluded, therefore, that smaller granules (<0.3 mm) will be needed to optimize gastric emptying of multiple-unit preparations in pancreatic replacement enzyme therapy. It should be recognized, however, that this could aggravate existing problems in manufacturing associated with granulation and particle coating.[3] In humans with chronic pancreatitis or cystic fibrosis, encapsulated enteric-coated microspheres and minimicrospheres (diameter <1.7 mm) are considered the enzyme treatment of choice. Even so, full recovery from the catabolic state of EPI with enzyme replacement therapy is never achieved in all patients.[6]

To study the effect of different enzyme preparations in the treatment of dogs with EPI, experimental studies were carried out in two dogs with cranial jejunal cannulation.[7] Food was supplemented with commercial enzyme preparations in the following sequences: powder, granules, capsules, enteric-coated tablets, and finely chopped raw pig pancreas. Jejunal ingesta were sampled at 30-minute intervals for 6 hours after feeding. Protease, amylase, and lipase activities were determined in jejunal samples and in feces. The control subjects comprised 14 healthy dogs and one subclinical EPI dog. This dog had approximately 90% pancreatic atrophy, but did not yet have clinical signs of maldigestion. In normal dogs and in the EPI dog, the highest lipase activities in the jejunal samples were achieved using raw pig pancreas. Powder achieved the second highest activities, but the other commercial porcine enzyme preparations yielded activities that were only one-tenth of those attained with the raw pancreas. Raw pancreas and commercial enzyme preparations increased the activities of proteases and amylase well beyond those found in the jejunum of the subclinical EPI dog. With the commercial powder preparation and with the raw pancreas, jejunal enzyme activity was detected immediately after feeding. Capsules and granules delayed the appearance of jejunal enzymatic activity by 1 to 2 hours and enteric-coated tablets by 5 hours. It should be noted that measuring enzymatic activity in feces was not reliable for evaluating the potency of pancreatic enzyme preparations added to food. Lipase activity was seldom found in the colon, and amylase and protease activities showed substantial variation.

The effect of the two uncoated enzyme supplements—raw chopped pancreas and porcine pancreatic powder preparation—were compared in a long-term clinical study.[8] The study included 76 dogs with an EPI diagnosis: 40 dogs were fed powdered enzymes and 36 dogs were fed raw chopped pancreas. When comparing the prevalence of clinical signs, there were no significant differences between the two groups. The study showed that in practice, the prescription of one of these supplements was largely based on economics and practicality. The raw chopped pancreas was only one-fourth as

expensive, but practical difficulties, mainly in availability, handling, and storing, were considerable compared with powdered enzyme supplements. The most common source of raw chopped pancreas was from pigs (72%), followed by cattle (19%) and lambs or reindeer (9%). The mean amount of raw chopped pancreas was 87 g/meal. It has been shown that raw pancreas can be stored frozen for several months prior to feeding. All dogs treated with powdered enzyme supplements were fed the same product (Viokase V, Fort Dodge Laboratories, IA), and the mean amount was 3 g/meal. No correlation was found between body weight and amount of enzyme fed.

Because raw chopped pancreas is not available in many countries, powder enzyme supplementation is the most common treatment for dogs and cats with EPI. Widely accepted treatment recommendations for dogs include feeding of a dose of 1 to 2 tsp of powdered pancreatic extract per 20 kg body weight at each meal.[9] For cats, a starting dose of 0.5 to 1 tsp should be administered with each meal. Enzymes should be mixed with food 20 minutes before feeding. Thereafter, pet owners are counseled to decrease the dose of pancreatic enzymes based on their pet's initial response. Most dogs require at least 1 tsp of enzymes per meal. Little additional improvement was observed after doubling or quadrupling this dose in EPI dogs with experimental pancreatic ductal ligation.[10] Side effects of porcine pancreatic extracts are rare, but it has been reported that high doses of pancreatic enzyme supplements can cause oral bleeding in dogs with EPI. Oral bleeding can be successfully managed by dose reduction in most dogs.[11]

Numerous attempts have been made to increase the efficacy of enzyme supplementation in dogs. Antacids or histamine H_2-receptor antagonists have been recommended in the therapeutic regimen to reduce gastric acid–induced destruction of orally administered enzyme. This practice is, however, costly and does not necessarily increase the efficacy of pancreatic enzyme supplementation.[9,12] In humans, a double-blind, placebo-controlled crossover study was conducted to measure the effect of acid suppression (ranitidine or omeprazole) on fat absorption in patients with cystic fibrosis. No overall significant improvement in fat absorption could be demonstrated with adjuvant therapy.[13] Concurrent oral administration of bile salts and preincubation of the meal with pancreatic enzymes for 20 to 30 minutes before feeding also did not improve the response.[14]

Besides porcine pancreatic extracts, bacterial lipase has been reported to be effective in correcting steatorrhea in dogs with experimental EPI.[15] Bacterial lipase is secreted by *Burkholderia plantarii* during fermentation. It is resistant to acid denaturation and protease digestion and does not require colipase activation for lipolytic activity. Bacterial lipase maintains activity even in the presence of bile acids. The effects of bacterial lipase were compared with those of a powdered porcine pancreatic enzyme preparation (Viokase powder, A.H. Robins Co., Richmond, VA) in alleviating steatorrhea in EPI dogs. The results of that study revealed that correcting steatorrhea required 75 times more porcine lipase than bacterial lipase by weight (240 mg vs. 18 mg). Improved fat absorption with use of bacterial lipase does not, however, improve absorption of the other nutrients, and thus, proteases and amylase are still necessary to correct protein and carbohydrate malabsorption, if present. These studies further showed that in using bacterial or porcine lipase to treat dogs with experimental EPI, a high-fat and high-protein diet improved fat absorption more efficiently than a low-fat, low-protein diet.

Enzyme preparations of vegetable origin have also been launched alongside ordinary pancreatins; these are extracted from molds or contain a protein-cleaving papain from the tropical papaya tree. Nevertheless, preparations obtained from an animal (porcine) pancreas have been demonstrated to be the ideal replacement enzymes and can in no case be replaced by vegetable ferments.[16] An experimental study in dogs has, however, shown that fungal lipase may prove to be useful in treating dogs with EPI.[17]

CHAPTER 48

Fluid Therapy

Rance K. Sellon

Dogs and cats with gastrointestinal (GI) disease commonly need fluid therapy. The most basic reasons for fluid therapy in patients with GI disease are replenishment or maintenance of intravascular fluid volumes and correction of specific metabolic deficits, such as electrolytes, serum protein concentrations, and others, that arise secondary to GI disease. As such, there is no "one-size-fits-all" approach to fluid therapy in patients with GI disease; rather, fluid therapy should be tailored to the needs unique to the individual patient. Provision of appropriate fluid therapy requires an inventory of a variety of fluid types, access to laboratory and other technologies for patient monitoring, and a staff trained in the monitoring and care of patients receiving fluid therapy.

Pathophysiology

The need for fluid therapy in patients with GI disease arises from a number of pathophysiologic conditions. Because of malaise and anorexia, dogs and cats with GI disease may have fluid intake reduced to a level unable to offset sensible and insensible fluid losses. Patients with GI disease are also susceptible to increased fluid losses as a result of vomiting, diarrhea, and, in some cases, polyuric states. Lastly, some types of GI disease put patients at risk for fluid redistribution into third spaces, such as edema or effusion caused by hypoalbuminemia and peritonitis. These pathophysiologic processes are not mutually exclusive, and all three mechanisms could be operative in a given patient. This chapter is a broad overview of fluid therapy in patients with GI disease. Readers interested in more in-depth information regarding fluid therapy are referred to other references.[1,2]

Goals of Fluid Therapy

Some important goals of fluid therapy, and the general types of fluids commonly used to meet these goals, include the following:[1,2]

- Restoration and maintenance of circulating volume for tissue perfusion: crystalloid and colloidal fluids
- Correction of abnormalities of electrolytes, glucose: crystalloids, electrolyte, and glucose supplements
- Provision of oncotic support: synthetic and natural colloids
- Restoration of oxygen-carrying capacity: whole blood and blood products
- Provision of nutritional support: enteral and parenteral nutritional solutions

Drug Classifications

Crystalloids and colloids are the fluid types most commonly used in the treatment of dogs and cats with GI disease. Crystalloids are compositions of fluid and electrolytes in varying proportions that are divided generally into replacement fluids and maintenance fluids. Box 48-1 provides examples of each of these types of fluids. Replacement fluids, as the name suggests, are designed to replace water and electrolytes lost as a consequence of GI (or other) disease, and are characterized by higher concentrations of sodium than maintenance fluids, which have proportionally more water than replacement solutions. Colloids can be synthetic or natural. Box 48-1 also outlines examples of synthetic and natural colloids.

Rational Use in the Diagnosed Patient

Indications for Fluid Therapy

Determined by History and Physical Exam

The decision to administer fluids to a patient with GI disease should take into account historical elements (e.g., is the patient voluntarily eating and drinking?), physical examination findings, results of laboratory or other diagnostic tests, and the underlying disease process. Patients that are unwilling, or unable, to drink emerge as more likely candidates for fluid therapy than those patients that can and will drink. Dogs or cats that are dehydrated, as suggested by the physical examination and/or laboratory results, also become candidates for fluid therapy. The physical examination assessment of hydration status has potential errors in interpretation. Animals that have lost considerable body weight commonly have reduced skin turgor, prolonged skin retraction, and ocular recession even if normally hydrated. Heart rates can be elevated for reasons other than dehydration. Nausea may contribute to a degree of mucous membrane moistness in the dehydrated patient, and mucous membranes may be overly dry in the patient that has been panting. Capillary refill times may be prolonged as a result of marked sympathetic stimulation and constriction of peripheral vascular beds, or may be very rapid in patients with peripheral vasodilation or hyperdynamic states of cardiovascular shock (as occurs, e.g., with sepsis).

Determined by Laboratory Data

Laboratory abnormalities that could suggest the need for fluid therapy include hemoconcentration, prerenal azotemia for reasons

- VetStarch

Natural
- Plasma (fresh or fresh frozen)
- Concentrated albumin solutions
  - Human
  - Canine

other than heart failure or reduced cardiac output, and abnormalities in electrolytes such as hyper- or hyponatremia, hyper- or hypokalemia, and acid–base disorders. Electrolyte abnormalities are nearly impossible to predict in patients with GI disease, so baseline laboratory evaluations should be obtained to guide choices in fluid therapy. Some volume-depleted patients may have a small cardiac silhouette or small pulmonary vessels evident on thoracic radiographs. It is common for abnormalities of hydration status to mask laboratory abnormalities—for example, the dehydrated and anemic patient may initially have a normal packed cell volume—so the clinician needs to be mindful of all the pathophysiologic processes that influence a given laboratory result and assess the patient for the presence of multiple pathophysiologic processes that could confound laboratory interpretation.

Determined by Underlying Disease and Severity

The underlying disease process may also influence fluid therapy decisions. For example, adult animals with acute, self-limiting gastroenteritis without physical examination or laboratory data abnormalities may be fine without fluid therapy, or with minimal fluid therapy, whereas puppies with acute parvoviral enteritis are likely to die without fluid therapy.

Fluid Selection

The type of fluid administered to a dog or cat with GI disease is based on history, physical examination, and diagnostic test results. Patients that are dehydrated are usually candidates for replacement-type crystalloid fluids; patients that are profoundly hypotensive or hemodynamically unstable may benefit from boluses of colloid fluids in addition to initial replacement fluids. Patients with effusions from inflammatory disease, or hypoalbuminemic patients, commonly need colloidal support to help maintain a degree of effective circulating vascular volume. Patients that are not dehydrated, but for which a need for fluid supplementation is anticipated, may require little more than a maintenance type of fluid. Moderate to marked hypoalbuminemia, or hypotension/shock are often indications for colloidal fluid administration.[3]

Route of Administration

Fluids may be administered orally, intravenously, subcutaneously, or occasionally intraosseously. For most patients with GI disease, the most commonly employed routes are oral, intravenous (IV), and subcutaneous (SC). For animals, dogma has long held that patients with vomiting and diarrhea should receive fluids through routes other than oral.[4] Dogma has been challenged, however, as Mohr and colleagues[5] demonstrated that parvovirally infected puppies fared no worse, and were discharged from the hospital sooner, when oral nutrition solutions were administered. In people, oral electrolyte-containing fluids are commonly administered to diarrheic patients as the ability to absorb sodium, and thus water, remains intact in most diarrheal illnesses (see Chapter 1). Similar studies demonstrating a benefit of oral rehydration therapy in diarrheic dogs have not yet been performed, but it is likely that many would benefit from oral fluid therapy. IV fluids should be the prime consideration for patients that need rapid fluid volume replacement (e.g., shock, hypotension) and for patients with persistent vomiting. Fluids given subcutaneously may suffice for the normally hydrated patient that needs short-term fluid support, but this route is not ideal for volume replenishment given the comparatively small volumes of fluid that can be successfully given via this route. Intraosseous and intraperitoneal routes of fluid administration are typically reserved for those patients for which venous access is not possible. For a description of the technique of intraosseous fluid administration, the reader is referred to other sources.[1]

Monitoring of Fluid Administration

Once fluid therapy has been initiated, monitoring becomes an important element of the therapeutic strategy, particularly for those patients with complicated or long-term fluid needs. Assessment of therapeutic responses should be based on changes in physical examination findings; for the GI disease patient for which changes are taking place rapidly, physical examination assessments may have to be done frequently to best monitor fluid therapy responses. Attention to general attitude and appearance, heart rate, pulse quality, capillary refill time, mucous membrane color, and blood pressure are among the simplest of physical examination parameters that can be used to judge responses to fluid administration. Other parameters that are particularly useful for assessing responses to fluid therapy include urine output (may require a urinary catheter), body weight, and central venous pressure (increased with increased vascular fluid volume). Urine output in an adequately hydrated patient should be at least 1 mL/kg/h and values less than that could reflect insufficient rehydration, or oliguria/anuria secondary to renal injury. Body weight should increase in patients that are rehydrated. Increases in body weight in the face of physical examination or laboratory parameters that suggest continued volume depletion likely reflect third-space losses (interstitial edema, peritoneal or pleural effusion, GI tract fluid accumulation). Conversely, patients losing weight in the face of fluid therapy likely have had an underestimation of GI, urinary, or insensible fluid losses. Central venous pressure, if measured, should be between 5 and 10 cm water.

A number of laboratory values are likely to change with fluid therapy, and become part of the monitoring equation. Special attention should be paid to erythrocyte mass, serum total protein, serum albumin, blood urea nitrogen (BUN), serum creatinine, electrolytes, and acid–base status, typically as reflected by changes in total CO_2 and anion gap. Adjustments in fluid rate, composition (e.g.,

electrolyte or other additives), or fluid type (e.g., addition of a colloid) are all potential outcomes of monitoring of fluid therapy responses.

Contraindications and Side Effects

Although fluid therapy is often important, even lifesaving, in the patient with GI disease, fluid therapy is not without potential adverse effects. Adverse effects can be seen following administration of either crystalloids or colloids.

Administration of excessive amounts of fluids, particularly if administered intravenously, can lead to overhydration. Overhydration increases the risk of edema or effusion formation as a result of increased hydrostatic pressure. In patients with underlying cardiac disease, excessive fluid administration can provoke overt signs of heart failure (pulmonary edema, pleural or peritoneal effusion). Additionally, overhydration can dilute serum albumin concentrations and oncotic pressure, creating an additional risk factor for edema or effusion formation. A common complication of crystalloid fluid therapy is hypokalemia, particularly if potassium supplements are not added to the fluids.

Complications of colloid administration include coagulation disorders, which are more of a concern with synthetic colloids. Administration of natural colloids (plasma, albumin) can be associated with hypersensitivity reactions.[6-8] The risk of transfusion reactions associated with plasma administration can be reduced by minor crossmatching (donor serum to recipient erythrocytes), but febrile reactions associated with plasma transfusion are still possible, likely mediated through leukocyte–platelet aggregates.

Concentrated human albumin solutions have been used, primarily in dogs, for the provision of oncotic support. Although available literature suggests that hypersensitivity reactions in clinical patients are not common, deaths in normal dogs have developed secondary to administration of concentrated human albumin.[6-8] Thus, this product should be used with caution in dogs. Albumin products given to dogs with protein-losing enteropathies are likely to be of only short-term benefit because of ongoing losses, but these products can be quite helpful in perianesthetic/perioperative periods when anesthetic and surgical interventions are likely to exacerbate hypoalbuminemia and attendant consequences.

In addition to the physiologic complications that can be seen with fluid therapy, other complications are possible. Catheter or catheter site infections are possible if aseptic technique is not followed when placing IV catheters. Thrombophlebitis can be a consequence of IV catheterization, and administration of hypertonic or irritant fluid types. Blood loss can arise if patients chew connections on catheter ends. Extravasation of fluids can also occur if catheters are not secured to the patient.

CHAPTER 49

Immunosuppressive Drugs

Rance K. Sellon

When aberrant or uncontrolled immune responses either target directly, or indirectly affect, the gastrointestinal (GI) tract, immunosuppressive drugs may be prescribed. When used for the treatment of GI disease, immunosuppressive therapy is typically administered with the goal of suppressing antibody and/or cell-mediated immune responses. A number of GI diseases of dogs and cats have either demonstrated, or suspected, pathophysiologic attributes of immune-mediated disease or dysregulated immune responses. Among the most common of GI diseases treated with immunosuppressive therapy are idiopathic stomatitis, megaesophagus secondary to myasthenia gravis, chronic enteropathies, anal furunculosis, and chronic hepatitis.

When treating dogs and cats affected by such disorders with immunosuppressive drugs, commonly accepted goals of therapy should be kept in mind. First and foremost, immunosuppressive therapy is given to control clinical signs. In some cases, control of clinical signs will be accompanied by improvements in other hallmarks of the disease being treated, for example, hypoalbuminemia in patients with protein-losing enteropathy. However, improvements in laboratory or other diagnostic features will not be appreciated in all patients despite improvements in clinical signs.[1] Thus, for patients with resolution of clinical signs of GI disease, increasing or altering immunosuppressive therapy with the specific goal of improving a laboratory or other parameter may be met with unwanted side effects or increased cost of therapy or monitoring, and should be carefully considered. The clinician should also keep as a goal of immunosuppressive therapy control of clinical signs with the lowest possible dose of drugs and longest dosing interval. Such goals also help the clinician attain a last objective of immunosuppressive therapy, which is minimization of side effects. For some clients, keeping cost to a minimum will also be a goal of therapy, and such client-driven restrictions will often dictate the immunosuppressive options possible.

Drug Categories, Mechanisms of Action, and Formulations

For dogs and cats, there are a limited number of drugs used for immunosuppressive treatment of GI disease. The most commonly used classes of drugs are glucocorticoids, calcineurin inhibitors, antimetabolites, and alkylating agents. Because of different mechanisms of action, different classes of immunosuppressive drugs are often given in combination. For most of the diseases treated, there is little high-quality (blinded, placebo-controlled) clinical evidence that supports the use of any given immunosuppressive protocol.

Glucocorticoids

Glucocorticoids are the mainstay of immunosuppressive therapy for most GI diseases needing such treatment. There are many formulations of glucocorticoids, but some of the most commonly used in the treatment of gastrointestinal disease, and their dosage suggestions, are presented in Table 49-1. It is expected that most clinicians will have an appreciation for the common side effects of glucocorticoids in dogs and cats.

Glucocorticoids have wide-ranging effects on the immune system and are beneficial for suppression of both antibody and cell-mediated immune responses. The mechanisms underlying the immunosuppressive effects of glucocorticoids are complex, and the level of understanding of these mechanisms is still evolving.[2,3] Some of the immunosuppressive effects are mediated through the interaction of glucocorticoids with cytoplasmic glucocorticoid receptors (GRs). The steroid–GR complex interacts with specific DNA sites termed *glucocorticoid-response elements*. Glucocorticoid-response elements are able to suppress, either directly or indirectly, the transcription of genes that encode proteins with proinflammatory and immune-stimulating activity. There is evidence that the antiinflammatory/immunomodulatory effects of glucocorticoids are also mediated by interaction of the glucocorticoid-GR complex with the regulatory factor nuclear factor-kappa B (NF-κB). With appropriate stimuli, NF-κB migrates from the cytoplasm to the nucleus and binds to key sites on DNA to initiate transcription of a variety of inflammatory and immune mediators. In the presence of the glucocorticoid–GR complex, NF-κB is not able to translocate to the nucleus.

Most glucocorticoids used in the treatment of canine and feline GI disease exert their effects systemically. A potential exception is the glucocorticoid budesonide. In people, budesonide has extensive first-pass hepatic metabolism and therefore is associated with fewer systemic effects than other orally administered glucocorticoids. Budesonide is used in the management of human inflammatory bowel disease (IBD).[4] A reduction of systemic effects would hold obvious appeal in the treatment of dogs or cats with IBD; however, the pharmacokinetics of budesonide have not been extensively investigated in these species. Available studies of budesonide administration to normal dogs and dogs with IBD have shown suppression of the hypothalamic–pituitary–adrenal axis, suggesting some systemic absorption of biologically active drug. However, these studies did note fewer of the other common side effects of systemically active glucocorticoids, such as polyuria, polydipsia, and increased liver enzymes.[5,6]

Table 49-1 Formulations and Dosages of Glucocorticoids Commonly Used in the Management of Small Animal Gastrointestinal Tract Disease*

Formulation	Immunosuppressive Dosage	Comments
Prednisone/prednisolone	1 to 2 mg/kg PO q12h (D, C)	Prednisolone is preferred by some clinicians for cats.
Dexamethasone	0.2 to 0.5 mg/kg PO, IV, SC q24h	Dosage suggested on the premise that dexamethasone is 4 to 5 times as potent as prednisone; may have less sodium and water retentive properties than prednisone.
Methylprednisolone acetate	20 mg SC q2wk (C)	Depo forms not recommended. If there is a need for empirical glucocorticoid therapy, use shorter-acting forms.
Methylprednisolone sodium succinate	30 mg/kg IV initially, then 15 mg/kg IV every 2 to 6 h	Immediate-acting formulation
Budesonide	3 mg/m^2 (D) 1 mg/day for "small" dogs; 2 mg/day for "medium" dogs; 3 mg/day for "large" dogs 1 mg/cat once or twice daily	Considered to have approximately 15 times the potency of prednisone; pharmacokinetic studies that establish optimal dosage guidelines have not been done in dogs or cats.

C, cat; D, dog; IV, intravenous; PO, per os; SC, subcutaneous.
*Readers are referred to chapters on the specific diseases for more details regarding therapy. Clinicians should familiarize themselves with any drug (dosing, routes of administration, adverse effects) before administration to a patient.

Calcineurin Inhibitors

Calcineurin inhibitors are a potent class of immunosuppressive drugs that includes cyclosporine and tacrolimus (FK506). Although these two drugs are structurally different, their mechanism of action depends on inhibition of the protein calcineurin. Calcineurin has serine-threonine phosphatase activity, and substrates of this enzyme include transcription factors that lead to cytokine gene activation. Inhibition of calcineurin activity causes decreased production of key cytokines, such as interleukin-2 and others that support the development of T-cell–dependent immune responses. The immunosuppressive effects of the calcineurin inhibitors encompass both B- (humoral) and effector T-cell (cell-mediated) responses.[7]

Cyclosporine is available in several proprietary and generic oral formulations. The practitioner must be aware of the different properties of the formulations as there is substantial variability in GI absorption and hepatic metabolism between formulations. Some of the available proprietary formulations include Sandimmune, Neoral, and Atopica; the latter is the only formulation specifically licensed for use in dogs and cats. Sandimmune requires more bile salt-mediated emulsification for GI absorption, and oral bioavailability is unpredictable, making Neoral, Atopica, or another microemulsified preparation preferable. Parenteral (for intravenous administration) formulations are also available, but have seen limited use in dogs and cats. Cyclosporine also comes in topical formulations, but use of these preparations has not been reported, to the author's knowledge, in dogs or cats with GI disease. Plasma trough levels of cyclosporine can be measured to determine if they are within a therapeutic window, but a common clinical practice is to evaluate drug levels if a desired clinical response is not achieved and adjust dosages if below a therapeutic level.

Evidence in the veterinary literature supports the use of calcineurin inhibitors, especially cyclosporine, in patients with stomatitis, myasthenia-induced megaesophagus, IBD, and anal furunculosis. Tacrolimus comes in formulations for both oral and topical (Protopic) administration; topical tacrolimus (0.1%) has been used successfully in the treatment of dogs with anal furunculosis.[8,9]

Antimetabolites

The antimetabolite drug most commonly used for immunosuppression in dogs is azathioprine. Azathioprine is metabolized to the active compound 6-mercaptopurine, a purine analogue that causes feedback inhibition of enzymes that synthesize purine nucleotides, essential building blocks for DNA. Incorporation of 6-mercaptopurine into DNA results in faulty DNA synthesis and messenger RNA (mRNA) transcription, and impaired T- and B-cell immune responses.[10] The most common side effect of azathioprine administration in dogs and cats is bone marrow suppression causing neutropenia, thrombocytopenia, or, rarely, anemia.[11,12] Pancreatitis is a documented complication of azathioprine administration in people, but evidence for azathioprine-induced pancreatitis in dogs is limited. Likewise, azathioprine can cause hepatic toxicity in people, but reports of dogs developing hepatotoxicity as a result of azathioprine administration are anecdotal. Azathioprine can be given to cats, albeit at much lower dosages than dogs because of an increased risk of toxicity (see Table 49-2).

Alkylating Agents

The mechanism of action of the alkylating agents involves the formation of reactive intermediates that attach alkyl groups to DNA to interfere with DNA replication and mRNA transcription. Alkylating agents impair both T- and B-cell immune responses. Chlorambucil is the most common alkylating agent used for immunosuppressive purposes in patients with GI disease, and is often used in cats when glucocorticoid responses are insufficient, or if there are reasons to avoid glucocorticoids (e.g., diabetes mellitus). Cyclophosphamide, another alkylating agent, has been used for treatment of immune-mediated hematologic diseases, but has seen little use in the management of canine and feline GI diseases (see Table 49-2).

Other Immunosuppressive Drugs

Other immunosuppressive drugs occasionally used in the treatment of immune-mediated diseases of dogs and cats are mycophenolate mofetil and leflunomide. Mycophenolate mofetil (MMF), a product of *Penicillium* spp., is converted to the active metabolite mycophenolic acid. Mycophenolic acid inhibits inosine monophosphate dehydrogenase, a critical enzyme in the synthesis of the purine guanosine. Impaired guanosine synthesis leads to decreased production of guanosine triphosphate (GTP), a nucleotide incorporated into DNA. Because lymphocyte proliferation requires de novo synthesis of GTP, MMF has a selective effect on lymphocytes, and impairs production of $CD4^+$ and $CD8^+$ lymphocytes. MMF

Table 49-2 Dosages and Side Effects of Non-Glucocorticoid Immunosuppressive Drugs Commonly Used in the Treatment of Gastrointestinal Tract Disease*

Drug	Dosage	Side Effects	Other Comments
Azathioprine	1-2 mg/kg PO q24h; often given daily for 10 to 14 days then decreased to every other day (D) 0.3 mg/kg PO q48h (C)	Neutropenia, thrombocytopenia; potential for pancreatitis, toxic hepatopathy	Believed that clinical benefits not appreciated for 2 to 3 weeks.
Cyclosporine	3 to 5 mg/kg PO q12 to 24h	Inappetence, vomiting, diarrhea, gingival hyperplasia	Expensive; better, more predictable absorption with modified formulations
Chlorambucil	2 to 6 mg/m^2 PO q24 to 48h (D) 2 mg/cat PO q48 to 72h	Neutropenia, thrombocytopenia	Does not require hepatic conversion to active metabolites
Cyclophosphamide	250 mg/m^2 PO or IV q7days 50 mg/m^2 PO q48h, or 2.2 mg/kg once daily for 4 days per week	Neutropenia, thrombocytopenia, sterile hemorrhagic cystitis	Routine evaluation of CBC is mandatory; if hemorrhagic cystitis develops, administration of the drug should cease
Mycophenolate mofetil[26]	10 mg/kg PO q8h or 20 mg/kg PO q12h (D)	Diarrhea, which can be bloody	Expensive; optimal dosing schedules have not been established
Leflunomide[27,28]	2 mg/kg PO q12h (D) 4 mg/kg PO q24h (D) 10 mg/day (C)	Anorexia, lethargy, possibly anemia	Expensive, but based on available information; a well-tolerated drug in dogs; dosing information is limited in cats

C, cat; CBC, complete blood count; D, dog; IV, intravenous; PO, per os.
*Readers are referred to chapters on the specific diseases for more details regarding therapy.

has a substantial history as an antirejection drug in canine transplantation models, including bone marrow and kidney, and has shown an ability to inhibit mitogen-stimulated proliferation of feline lymphocytes in vitro.[13,14] There are no published studies regarding the use of MMF in the treatment of animals with GI disease, but anecdotal reports of its use in dogs with myasthenia gravis–induced megaesophagus abound. MMF has been used in the treatment of human IBD,[15] and it could be of benefit in dogs refractory to other therapeutic approaches. Side effects in dogs are common and include lethargy, anorexia, and diarrhea.[16]

Leflunomide is metabolized to an intermediate that inhibits a critical enzyme in the synthesis of uridine. Like guanosine, lymphocytes synthesize uridine de novo, and impediments to uridine synthesis lead to lymphocyte death. Leflunomide has seen use in people with IBD,[17,18] but use in dogs or cats with IBD has yet to be reported.

Rational Use of Immunosuppressive Drugs in Patients with a Definitive Diagnosis

Given the immunosuppressive drug options available to the small animal clinician, an often encountered initial dilemma is deciding which drug or drugs to use in the early treatment period. As previously noted, there are no clinical studies that compare results of treatment of canine or feline GI disease with various single-agent immunosuppressive drugs, or that compare combinations of drugs. Thus, the initial selection of immunosuppressive therapy is often influenced by direct experiences, experiences of others, and owner tolerance of cost and side effects. When deliberating over the menu of drugs available, consideration of the goals of immunosuppressive therapy as discussed previously, in concert with discussions with owners to gauge tolerance for cost and adverse effects, can be useful for guiding the initial choices.

General efficacy, combined with low cost, make glucocorticoids attractive as an initial, or often sole, treatment for GI disease needing immunosuppressive therapy. When treating GI diseases that have an immunopathologic basis, immunosuppressive dosages are needed, and the clinician should not hesitate to administer such dosages in a well-evaluated patient. A common approach to immunosuppressive therapy with glucocorticoids is to administer prednisone at 2 to 4 mg/kg/day for approximately 2 weeks before a dose reduction is considered. Dosage reductions are considered after this if the desired responses have been achieved. As discussed previously, the clinician needs to carefully weigh the merits of using laboratory results over clinical features when evaluating responses to immunosuppressive therapy. The author's approach, assuming the desired clinical response has been seen after 2 weeks, is to make a dose reduction of 20% to 25%. Additional 20% to 25% reductions are prescribed typically every 2 to 3 weeks thereafter, assuming the patient's disease remains in clinical remission. A relapse usually demands reinstitution of the starting high prednisone dose. The clinician should try to find the lowest dose and greatest dosing interval needed to control clinical signs.

Because of the side effects of glucocorticoids and clients' frequent complaints about those side effects, the author is an advocate of starting azathioprine at the same time that glucocorticoids are initiated in dogs. The rationale for this approach is the use of azathioprine as a "safety net" in the event that side effects of glucocorticoids demand changes to the planned treatment approach. Azathioprine is generally well-tolerated, adds nominally to expense, and in the author's experience, often allows disease to remain in clinical remission without glucocorticoids. Azathioprine has an established history of use in patients with IBD, anal furunculosis,[19,20] and myasthenia gravis,[21] although published reports of its use in these diseases are not always placebo-controlled or blinded clinical studies.

Cyclosporine could be considered as part of the initial treatment protocol for GI disease, although the expense of the drug will limit its use in some patients. Cyclosporine is accepted as an initial line of treatment for canine anal furunculosis, although approaches using glucocorticoids or azathioprine have been described. Cyclosporine has been used successfully in the treatment of steroid-refractory IBD in dogs,[22] and has been used as part of the treatment approach to dogs with myasthenia gravis-induced megaesophagus.[23]

For patients that receive combinations of immunosuppressive drugs, another decision is the order of drug cessation. The author largely leaves such decisions to clients who will make choices based on tolerance for side effects or cost. The author does not typically taper cyclosporine, but will instead simply stop the drug. In the author's hands, azathioprine is often the last drug stopped if the drug is otherwise well-tolerated.

Responses of patients to immunosuppressive therapy can be variable. Reasons for treatment failure in the face of immunosuppressive drugs could include inappropriate dosages or dosing regimens, incomplete therapeutic regimens (i.e., the patient needs additional therapy beyond immunosuppressive drugs), poor client compliance, an incorrect diagnosis, or potentially the inherent refractoriness of the disease being treated. The intestinal epithelium is capable of upregulating expression of P-glycoprotein, a membrane protein that can pump some drugs out of a cell, in response to treatment with glucocorticoids. A potential consequence of increased P-glycoprotein expression could be poor response to glucocorticoids as was demonstrated in one study of dogs.[24]

Empirical Immunosuppressive Therapy in the Absence of a Definitive Diagnosis

Owner financial constraints commonly relegate the practitioner to empirical immunosuppressive therapy, often with glucocorticoids as first-line drugs. For most clients, empirical therapy offers the immediate advantage of reduced cost of veterinary care, particularly if favorable responses are appreciated. However, the provision of empirical immunosuppressive therapy warrants additional considerations not often needed for empirical therapy with other drugs. For some diseases, particularly lymphoma, empirical glucocorticoid treatment carries the potential risk of reduced chemotherapy responses should an owner choose at a later time to pursue chemotherapy. Some infectious diseases (e.g., pythiosis, histoplasmosis) can have features similar to idiopathic inflammatory disease of the gastrointestinal tract and could be made worse by immunosuppressive therapy. Although not commonly recognized in dogs and cats, for any given patient receiving immunosuppressive therapy there is a risk of acquisition of opportunistic infections. Poor responses to empirical immunosuppressive therapy do not rule out idiopathic inflammatory GI diseases as immunosuppressive therapy may be only one component of a given patient's therapeutic needs, and some patients require different immunosuppressive approaches to achieve clinical improvement. Lastly, empirical therapy risks delays in diagnosis of diseases that, when treated inappropriately, progress to the point of being more difficult to treat or untreatable (e.g., GI neoplasia). Empirical immunosuppressive treatment of GI disease should only be done after careful examination of the patient, elimination of as many other differentials as possible, and a conversation (ideally documented in the medical record) of the risks and benefits of such treatment. If using immunosuppressive doses of glucocorticoids in an empirical manner, shorter-acting formulations (prednisone, prednisolone, dexamethasone) are favored over intermediate or long-acting forms in case adverse events are appreciated.

Contraindications and Side Effects of Immunosuppressive Therapy

Fortunately, there are few absolute contraindications to immunosuppressive therapy in dogs and cats. It is generally accepted that immunosuppressive drugs should be avoided in patients with known infections, and should be used with caution in patients for which infectious disease is suspected. Short-term administration of immunosuppressive drugs may not exacerbate infections, but there are very few investigations in dogs and cats that specifically address this concern. Glucocorticoids should be used with caution, particularly in cats, where there is preexisting heart disease as glucocorticoids can increase intravascular fluid volume.[25] A known history of adverse reactions or toxicities to certain drugs would typically render a given patient ineligible for additional therapy with that drug, or would provoke extreme caution with additional treatment.

For patients that experience side effects, some (e.g., cytopenias) will resolve with temporary cessation of the drug; often the drug can be reinstituted at a lower dose to avoid the observed side effect. Some side effects (e.g., hepatotoxicity) may require permanent cessation of treatment with the drug. Occasionally, side effects are severe enough so as to require short-term supportive care (e.g., antibiotics for neutropenia, or fluid therapy for GI signs), which should be provided if clinically indicated.

CHAPTER 50

Laxative Agents

Robert J. Washabau

Definition of Constipation

Constipation is an important pathophysiologic condition of both cats and dogs, but primarily of the cat. Constipation is defined as difficult, painful, or reduced defecation over a period of time ranging from days to weeks or months.[1] Physical examination findings depend on the severity and pathogenesis of constipation. Dehydration, weight loss, abdominal pain, and mild to moderate mesenteric lymphadenopathy are common findings in cats with idiopathic constipation. It is important to consider an extensive list of differential diagnoses in an individual animal, but it should be kept in mind that most cases are idiopathic, orthopedic, or neurologic in origin (see Chapters 10 and 58).[2] Left untreated or poorly monitored, constipation may progress to obstipation (permanent loss of function) and megacolon (permanent loss of form and function).[3]

Therapeutic Strategies for Constipation

Four main strategies are utilized in the management of constipation (see Fig. 10-1 in Chapter 10)[4]:

- Removal of impacted feces
- Laxative agents
- Prokinetic agents
- Surgical resection

Chapter 58 discusses each of these strategies in detail.

Established Laxative Agents

Laxatives promote evacuation of the bowel through stimulation of fluid and electrolyte transport or increases in propulsive motility. Established laxative agents are characterized as bulk-forming, emollient, lubricant, hyperosmotic, or stimulant laxatives, according to their mechanism of action (Table 50-1).[3] Newer laxative agents are more specific in their mechanism(s) of action, and include chloride channel activation, guanylate cyclase activation, μ-opioid receptor antagonism, 5-HT_4 serotonergic receptor agonism, and neurotrophin-3 activation.[5-7]

Bulk-Forming Laxatives

Most bulk-forming laxatives are dietary fiber supplements of poorly digestible polysaccharides and celluloses derived principally from cereal grains, wheat bran, and psyllium. Some constipated cats will respond to supplementation of the diet with one of these products, but many require adjunctive therapy (e.g., other types of laxatives or colonic prokinetic agents). Dietary fiber is preferable because it is well tolerated, more effective, and more physiologic than other laxatives. Fiber is classified as a bulk-forming laxative, although it has many other properties. The beneficial effects of fiber in constipation include increased fecal water content, decreased intestinal transit time, and increased frequency of defecation.[8,9] Short-chain fatty acids derived from fiber fermentation in the gut have been shown to directly stimulate colonic motility.[8,9] Fiber supplemented diets are available commercially, or the pet owner may wish to add psyllium (1 to 4 tsp per meal), wheat bran (1 to 2 tbsp per meal), or pumpkin (1 to 4 tbsp per meal) to canned cat food. To maximize the therapeutic effect, cats should be well hydrated before commencing fiber supplementation. Fiber supplementation is most beneficial in mildly constipated cats, prior to the development of obstipation and megacolon. In obstipated and megacolon cats, fiber may in fact be detrimental. Low-residue diets may be more beneficial in obstipated and megacolonic cats.

Emollient Laxatives

Emollient laxatives are anionic detergents that increase the miscibility of water and lipid in digesta, thereby enhancing lipid absorption and impairing water absorption. Dioctyl sodium sulfosuccinate and dioctyl calcium sulfosuccinate are examples of emollient laxatives available in oral and enema form. Anecdotal experience suggests that dioctyl sodium sulfosuccinate therapy may be most useful in animals with acute but not chronic constipation. As with bulk-forming laxatives, animals should be well-hydrated before emollient laxatives are administered. It should be noted that clinical efficacy has not been definitively established for the emollient laxatives. Dioctyl sodium sulfosuccinate, for example, inhibits water absorption in isolated colonic segments in vitro, but it may be impossible to achieve tissue concentrations great enough to inhibit colonic water absorption in vivo. Dioctyl sodium sulfosuccinate at a dosage of 30 mg/kg/day had no effect on fecal consistency in Beagle dogs.[10] Further studies are required to determine the clinical efficacy and therapeutic role of dioctyl sodium sulfosuccinate in the management of constipated cats.

Lubricant Laxatives

Mineral oil and white petrolatum are the two major lubricant laxatives available for the treatment of constipation. The lubricating

Table 50-1 Classification, Examples, and Doses of Established and Newer Laxative Agents

Drug Classification and Example	Dose
Rectal Suppositories	
Dioctyl sodium sulfosuccinate	1 to 2 pediatric suppositories
Glycerin	1 to 2 pediatric suppositories
Bisacodyl	1 to 2 pediatric suppositories
Enemas	
Warm tap water	5 to 10 mL/kg
Warm isotonic saline	5 to 10 mL/kg
Dioctyl sodium sulfosuccinate	5 to 10 ml/cat
Dioctyl calcium sulfosuccinate	250 mg (12 mL) given per rectum
Mineral oil	5 to 10 mL/cat
Lactulose	5 to 10 mL/cat
Established Laxative Agents	
Bulk Laxatives	
Psyllium	1 to 4 tsp mixed with food, every 24 or 12 hours
Canned pumpkin	1 to 4 tsp mixed with food, q24h
Coarse wheat bran	1 to 4 tsp mixed with food, q24h
Emollient Laxatives	
Dioctyl sodium sulfosuccinate	50 mg PO, q24h
Dioctyl calcium sulfosuccinate	50 mg PO, q12 or 24h as needed
Lubricant Laxatives	
Mineral oil	10 to 25 mL PO, q24h
Petrolatum	1 to 5 mL PO, q24h
Hyperosmotic Laxatives	
Lactulose	1 mL per 4.5 kg PO
Polyethylene glycol	25 mL/kg PO q24h as needed
Stimulant Laxatives	
Bisacodyl	5 mg PO q24h
Newer Laxative Agents	
Chloride Channel Activators	
Lubiprostone	Safe and effective doses not yet established
Guanylate Cyclase Activators	
Linaclotide	Safe and effective doses not yet established
μ-Opioid Antagonists	
Methylnaltrexone	0.15 mg/kg SQ q24 to 48h
Alvimopan	Safe and effective doses not yet established
Serotonergic 5-HT$_4$ Agonists	
Prucalopride	0.01 to 0.2 mg/kg PO q8 to 12h as needed
Neurotrophins	
Neurotrophin-3	Safe and effective doses not yet established

properties of these agents impede colonic water absorption, as well as permit greater ease of fecal passage. These effects are usually moderate, however, and, in general, lubricants are beneficial only in mild cases of constipation. Mineral oil usage should probably be limited to rectal administration because of the risk of aspiration pneumonia with oral administration, especially in depressed or debilitated cats.

Hyperosmotic Laxatives

This group of laxatives consists of the poorly absorbed polysaccharides (e.g., lactose, lactulose), the magnesium salts (e.g., magnesium citrate, magnesium hydroxide, magnesium sulfate), and the polyethylene glycols. Lactose is not effective as a laxative agent in all cats.[11] Lactulose is the most effective agent in this group. The organic acids produced from lactulose fermentation stimulate colonic fluid secretion and propulsive motility. Lactulose administered at a dosage of 0.5 mL/kg body weight q8 to 12h fairly consistently produces soft feces in the cat. Many cats with recurrent or chronic constipation have been well managed with this regimen of lactulose. The dosage may have to be tapered in individual cases if flatulence and diarrhea become excessive. Magnesium salts are not recommended in the treatment of feline constipation and idiopathic megacolon. Anecdotal reports of therapeutic successes have been reported with the polyethylene glycols.

Stimulant Laxatives

The stimulant laxatives (bisacodyl, phenolphthalein, castor oil, cascara, senna) are a diverse group of agents that have been classified according to their ability to stimulate propulsive motility. Bisacodyl, for example, stimulates nitric oxide–mediated epithelial cell secretion and myenteric neuronal depolarization.[12] Diarrhea results from the combined effect of increased mucosal secretion and colonic propulsion. Bisacodyl, at a dosage of 5 mg q24h PO, is the most effective stimulant laxative in the cat. It may be given individually or in combination with fiber supplementation for long-term management of constipation. Daily administration of bisacodyl has been linked to enterocyte injury, but this is of uncertain functional significance (see "Laxative-Induced Colonic Injury" section).[12]

Newer Laxative Agents

Chloride Channel Activators

Chloride channels are voltage-gated anion channels that allow the transport of chloride ions across cell membranes and play a critical role in fluid transport, maintenance of cell volume, and intracellular pH.[5,6]

Lubiprostone

Lubiprostone is a member of a group of compounds referred to as prostones.[13] Prostones are naturally occurring bicyclic fatty acids formed by enzymatic oxidation of the 15-hydroxyl group of prostaglandins to the keto form. Lubiprostone is approved by the U.S. Food and Drug Administration for the treatment of chronic idiopathic constipation in humans. Lubiprostone activates type 2 chloride channels in the apical membrane of intestinal epithelial cells. This activity stimulates chloride secretion, followed by passive secretion of sodium and water (see Fig. 1-17 in Chapter 1). The fluid–induced bowel distention secondarily induces peristalsis, but lubiprostone has no direct stimulatory effect on gastrointestinal smooth muscle. Insufficient safety and efficacy data are currently

available to recommend the routine use of lubiprostone in dogs and cats.

Guanylate Cyclase Activators

Activation of the guanylate cyclase-C (GC-C) receptor increases cyclic guanosine monophosphate, thereby inducing signaling pathways that stimulate chloride and bicarbonate secretion through cystic fibrosis transmembrane regulator (CFTR) chloride channel–dependent mechanisms and, to a lesser extent, CFTR chloride channel–independent mechanisms, and inhibit sodium absorption by a sodium-proton exchanger.[5,6]

Linaclotide

Linaclotide is a GC-C receptor agonist and intestinal secretagogue that improves bowel symptoms and accelerates colonic transit in chronic constipation.[14] Linaclotide has also been shown to attenuate nociceptive reflexes in response to colonic distention in three rodent models of visceral hypersensitivity.[14] Dosage is 0.15 mg/kg SQ q24 to 48h.

μ-Opioid Antagonists

Postoperative ileus has multiple pathogenetic mechanisms. A dominant theme is the activation of enteric μ-opioid receptors resulting in inhibition of enteric nerve activity.[5,6]

Methylnaltrexone

Methylnaltrexone is a quaternary derivative of the μ-opioid receptor antagonist naltrexone.[7] *N*-terminal methylation reduces lipid solubility and prevents the drug from crossing the brain–blood barrier. Methylnaltrexone's reversal of opioid-induced inhibition of enteric nerve activity increase propulsion and secretory activity. Methylnaltrexone is clearly beneficial in the treatment of opioid-induced constipation; its efficacy in the treatment of postoperative ileus has not yet been definitively established. Insufficient safety and efficacy data are currently available to recommend the routine use of methylnaltrexone in dogs and cats.

Alvimopan

Alvimopan has all of the same properties as methylnaltrexone; additionally, alvimopan accelerates colonic transit in healthy individuals, suggestive of a direct prokinetic effect.[7] Insufficient safety and efficacy data are currently available to recommend the routine use of alvimopan in dogs and cats.

Serotonergic 5-HT_4 Agonists

Serotonergic 5-HT_4 agonists bind 5-HT_4 receptors on smooth muscle cells, enterochromaffin cells, myenteric plexus neurons, and intrinsic pathway primary afferent neurons, resulting in stimulation of gastrointestinal motility (see Chapter 52).[5,6,15] Some of the 5-HT_4 agonists also have effects on secretion and visceral sensitivity.

Prucalopride

In addition to its motility effects, prucalopride also modulates cyclic adenosine monophosphate–mediated chloride secretion and visceral sensitivity. Safety and efficacy data have been reported for its use in both dogs and cats (see Table 52-1 in Chapter 52).

Neurotrophins

Neurotrophins play an important role in the development and maintenance of the central, peripheral, autonomic, and enteric nervous systems.[5,6]

Neurotrophin-3

Neurotrophin (NT)-3 reduces fluid absorption, thereby increasing the fluidity of the stool and facilitating defecation. NT-3 has also been shown to accelerate colonic transit. Insufficient safety and efficacy data are currently available to recommend the routine use of NT-3 in dogs and cats.

Laxative Withdrawal Rebound Constipation

Physical dependence is a state of adaptation that is manifested by a drug class specific withdrawal syndrome that can be produced by abrupt cessation, rapid dose reduction, decreasing blood level of the drug, and/or administration of an antagonist.[17] A small percentage of human patients with chronic constipation are dependent upon laxatives to achieve bowel movements without complaints such as severe straining, but several studies have now shown that this is not the result of prior laxative intake. There is no indication for the occurrence of "rebound constipation" after stopping laxative intake in humans,[17] and thus is not likely in dogs and cats either.

Laxative-Induced Colonic Injury

Stimulant laxatives (bisacodyl, phenolphthalein, castor oil, cascara, senna) do cause structural damage to surface epithelial cells that appears to be reversible and of uncertain functional significance. There is no current convincing evidence that chronic use of stimulant laxatives causes structural or functional impairment of enteric nerves or intestinal smooth muscle cells.[18]

CHAPTER 51

Probiotic Agents

Mary Bowles

Probiotic agents are living organisms with low or no pathogenicity that exert beneficial effects on the health of the host. The use of probiotic agents (Box 51-1) has been advocated for general health as well as the prevention and treatment of many disorders in humans and in domestic and nondomestic animals.[1] Although controlled studies documenting the efficacy of probiotics in dogs and cats are relatively lacking, the strongest and most consistent evidence of beneficial effects resulting from probiotic administration has been related to prevention and therapy of disorders of the digestive system (Table 51-1).[2-4] Probiotics have been used as single-agent therapy or in conjunction with prebiotics as synbiotic therapy (Box 51-1).[5,6]

Probiotic Mechanisms of Action

Multiple mechanisms have been proposed to explain the beneficial effects of probiotic therapy, but most theorize an interaction between probiotic organisms and the indigenous gastrointestinal (GI) flora. Colonization of the intestine, particularly the colon, with bacteria from the environment occurs in the neonate during the first few days of life.[2,7,8] Depending upon the specific organism and the host, these bacteria may preferentially and permanently establish residence in the lumen, mucous gel layer, crypts, or epithelial cell surface of the GI tract.[9] Some bacteria provide benefit to the host through enhancement of immune responses and protection against potentially damaging agents.[2] With few exceptions, probiotic agents establish only short-term residency in the GI tract following consumption by the host. Probiotic organisms bind to epithelial Toll-like receptors thereby triggering specific innate immune responses, depending upon the particular receptor, anatomic site, and host.[10,11] Box 51-2 outlines other proposed mechanisms.[12-14]

Prebiotic Effects on Probiotic Therapy

Fiber-containing prebiotic agents can augment probiotic therapy, although the simple addition of fiber to the diet or as a supplement does not automatically guarantee effective prebiotic activity as the effect varies with fiber type. Two classes of oligosaccharides, oligofructose (fructooligosaccharide) and inulin, are soluble fibers that are considered classic and effective prebiotic agents.[15] Both classes of oligosaccharides are fermented in the colon. Oligofructose, which can be found naturally in soybeans, oats, beets, and tomatoes, undergoes rapid fermentation in the colon and provides the most benefit to bacteria residing in the proximal colon. Inulin, which is found naturally in plants such as Jerusalem artichoke, jicama, and chicory root, undergoes slower fermentation in the colon, and provides benefit to bacteria residing in both the proximal and distal colon. Although the dog and cat small intestines have minimal ability to digest prebiotic oligosaccharides, ileal and colonic bacteria are quite capable of fermenting these soluble fibers to short-chain fatty acids (acetate, butyrate, propionate) that provide metabolic fuel for colonic epithelial cells. Short-chain fatty acids decrease colonic pH resulting in pathogen inhibition, stimulation of sodium and water absorption, and suppression of abnormal colonocytes.[16]

Selection of a Probiotic Preparation

Labeling

When selecting a probiotic preparation for use in the dog or cat, a number of factors should be considered. One of these factors is the lack of regulation by the Food and Drug Administration (FDA) because probiotics are not presently classified as pharmaceutical products. Despite the advances of the past decade, most of the commercially available probiotic preparations, whether marketed for use in humans or animals, do not have adequate studies supporting manufacturer claims. Moreover, product labels have been shown in some instances to be inaccurate or incomplete in their identification and quantification of viable microorganisms.[17] Consequently, it is advisable to start the selection of a probiotic agent by using a product marketed by a reputable, science-based company. By observing this principle, the preparation selected is more likely to satisfy basic criteria for safety and efficacy (Box 51-3).[12,13,17,18] In addition to safety and efficacy data, the manufacturer's label should have information on content, handling, and advisory statements (Box 51-4).[12]

Specific Probiotic Agents

Specific identification of the organism and strain, is valuable because responses of the GI tract and immune system may vary widely depending upon the organism and strain eliciting the response. The lactic acid bacteria *Lactobacillus*, *Bifidobacterium*, and *Enterococcus* species, along with the yeast *Saccharomyces boulardii* are widely believed to be of benefit in cats and dogs with GI disorders.[2,19] Available literature indicates more specifically that *Lactobacillus acidophilus* strain DSM13241 and *Enterococcus faecium* strain SF68 are immunomodulatory bacteria capable of surviving in the canine and feline GI tract.[20,21] In a recent study of acute idiopathic diarrhea, dogs receiving *Bifidobacterium animalis* strain AHC7 as a dietary supplement experienced more rapid resolution of clinical signs compared with similarly affected dogs receiving placebo.[22] Clinical signs resolved more rapidly in dogs fed *L. acidophilus* strain NCC2628, *L. acidophilus* strain NCC2766, and *Lactobacillus johnsonii* strain NCC2767 in

Table 51-1 Canine and Feline Gastrointestinal-Related Disorders Most Likely to Benefit from Probiotic Therapy

Iatrogenic V/D	Stress D	Dietary V/D	Infectious	Miscellaneous
Medication-induced • Antibiotics • NSAIDs • Glucocorticoids	Boarding Travel Weaning Shelter/colony populations Working dogs Environmental changes	Change Indiscretion Intolerance (eg., lactose) Allergy	Viral Bacterial Protozoal	Inflammatory bowel disease Maldigestion/malabsorption SIBO Idiopathic diarrhea Hepatic encephalopathy Exocrine pancreatic disease

D, diarrhea; SIBO, small intestinal bacterial overgrowth; V, vomiting.

Box 51-1 Term Definitions

Probiotic–live microorganisms, which when administered in adequate amounts, confer a health benefit on the host.
Prebiotic–indigestible oligosaccharides that benefit the host by stimulating growth and/or activate the metabolism of a limited number of health-promoting bacteria in the GI tract.
Synbiotic–combination of a probiotic and a prebiotic for the purpose of producing a synergistic beneficial effect.

Box 51-2 Probiotic Mechanisms of Action Related to the Gastrointestinal Tract

Immunomodulation
Stimulate innate protective immune responses of host GI tract
Upregulation or downregulation of GI immune responses through Toll-like receptors
Initiate production of antiinflammatory cytokines
Suppress production of proinflammatory cytokines
Alteration of GI epithelial cell function
Promotes repair of damaged epithelial cells
Aids in epithelial cell production of antibacterial substances and protective proteins
Inhibits epithelial cell apoptosis induced by cytokines
Competitive inhibition of GI attachment of pathogens and toxins

Box 51-3 General Safety and Efficacy Criteria for Probiotic Agents in Commercial Preparations

Stable in product storage
Present in large numbers (>1 × 10^8 colony-forming units)
Resilient to technical processing
Able to survive gastric acidity and bile during GI transit
Capable of establishing temporary residence within the GI tract
Nonresistant to antibiotics
Nonpathogenic, noncarcinogenic, and nontoxic
Incapable of absorption into the systemic circulation following consumption
Capable of providing an obvious health benefit to the host

Box 51-4 Important Probiotic Product Labeling Information

Product Contents
Specific genus, species, and strain of microorganisms identified by current, scientifically recognized nomenclature
Number of live, colony-forming units per unit weight of product for each probiotic agent listed
Identification of fermentable fiber types if prebiotic agents included in product

Product Handling and Advisory Information
Storage requirements
Shelf-life
Recommended dose
Accurate description of effect on host following consumption
Warning information regarding potential adverse drug or medical condition interaction with product
Manufacturer contact information

addition to an elimination diet, compared with a control group fed an elimination diet alone.[23] Shedding of GI pathogens is also influenced by probiotic administration, and responses may vary depending upon host species and type of microorganism administered. In one study, *Enterococcus faecium* NCIB 10415 was administered to dogs, resulting in a decrease in fecal *Clostridium* species shedding, and an increase in *Salmonella* and *Campylobacter* species shedding.[24] Another study, however, reported reduction in shedding of *Campylobacter* by infected cats receiving *L. acidophilus* DSM13241.[25]

Concentration of Microorganisms

In addition to specific microorganism identification, the number of live, microbial organisms (colony-forming units [CFUs]) per unit weight of probiotic product is an important parameter that should be disclosed by the manufacturer. Ideally, the manufacturer has determined that the number of microorganisms included in a product will result in an adequate quantity of viable organisms available to the host throughout the shelf life of the preparation. Although optimal concentrations have yet to be determined, current information suggests that the number of microorganisms for each agent included in a probiotic preparation should be in the range of 1 × 10^8 to 1 × 10^{12} CFUs/g of product to achieve colonization and efficacy.[20,21,26]

Storage and Handling

Probiotic product storage and handling information should be included in the manufacturer's label. Product efficacy is directly tied to organismal viability, so product stability is of particular concern. Avoiding excessive heat, keeping the product dry, and refrigerating after opening are standard manufacturer recommendations. Even when handling instructions are strictly followed, the viability of many probiotic agents declines to an unacceptable level after 6 months of storage, or is adversely affected because of microorganism turnover during GI transit. Consequently, some manufacturers employ processing techniques such as freeze drying,

Table 51-2 Recommended Probiotic Preparations for Dogs and Cats

Product Name (Manufacturer)	Product Form	Product Probiotic Content	Oral Dose	Comments
Culturelle (Amerifit)	Capsule	*Lactobacillus rhamnosus GG* (1×10^{10} CFUs per capsule)	Dog: 1 capsule/day Cat: ½ capsule contents BID	Human product
FortiFlora Canine FortiFlora Feline (Purina Veterinary Diets)	Packet	*Enterococcus faecium SF68* (1×10^{8} CFUs per packet)	1 packet/day of cat or dog formulation Contents sprinkled on food	Veterinary product Antioxidant vitamins included Taurine included in cat product Contents of packet microencapsulated
Prostora MAX (Procter & Gamble Pet Care: Iams)	Chewable tablet	*Bifidobacterium animalis AHC7* (1×10^{8} CFUs per tablet)	Dog: day 1: 2 tabs in the AM + 1 tab in PM Days 2 to 7: 1 tab BID	Veterinary product for dogs Canine-derived probiotic agent
Proviable (Nutramax)	Proviable KP paste Proviable DC capsules	*E. faecium* *Streptococcus thermophilus* *Lactobacillus acidophilus* *Lactobacillus bulgaricus* *Lactobacillus casei* *Lactobacillus plantarum* *Bifidobacterium bifidum* (Total bacteria: minimum of 5×10^{8} CFUs per mL of paste or 5×10^{9} CFUs per capsule)	Proviable KP: Cat: 1 mL PO, BID-TID Dog: <20 lbs: 1 to 2 mL; 21 to 50 lbs: 3 to 4 mL; >50 lbs: 5 mL, PO BID-TID Proviable DC: Dog and cat: 1 capsule PO daily	Veterinary product Same formulation used in cat and dog Probiotic agents microencapsulated Prebiotics included Proviable KP paste: includes kaolin and pectin and should be administered separately from other medications by 1 to 2 hours Recommended to use for ≤72h Proviable DC capsules can be administered alone or with paste

CFUs, colony-forming units.

microencapsulation, or protective coatings to achieve sustained viability during storage and administration.[20,26]

Microorganism Species of Origin

In the future it may be beneficial for label information to include the microorganism species of origin. Until recently, probiotic agents used in dogs and cats have been derived from species other than cat or dog. A few commercially available probiotic preparations now contain canine-derived organisms. Given the specific host interactions that seem to be associated with particular strains of bacteria, it seems reasonable that same species-derived microorganisms would have the potential to enhance the therapeutic and prophylactic value of probiotic products. Future studies in dogs and cats should help determine if such enhancement actually occurs with administration of canine- and feline-derived probiotic agents.

Commercial Probiotic Products

Commercial products containing probiotics include pet foods and yogurt. Problems with microorganism content and viability limit the usefulness of these products as reliable sources of probiotic agents. To further complicate matters, current commercial pet food claims for probiotic content are not always accurate.[27] Although nonpasteurized yogurt has long been advocated as a source of probiotics, it is doubtful that viable organisms survive GI transit in sufficient numbers to reliably confer desired health benefits to the host.[27] In addition, organisms frequently contained in nonfortified yogurt, for example, *Lactobacillus bulgaricus* and *Streptococcus thermophilus*, have questionable probiotic activity. Fortified yogurt, which commonly has *L. acidophilus* and *Bifidobacterium* species added to it, may be a more scientifically sound source of probiotics.[28] Some evidence exists to support the use of yogurt fortified with *Bifidobacterium animalis* DN 173010 (e.g., Activia-Dannon),[29] but variation in viability and concentrations of microorganisms even in fortified yogurt limits the usefulness of these types of products.

Numerous commercial probiotic preparations are available that are manufactured for human or animal use. Selection of a beneficial preparation is not easily accomplished because of the minimal regulation of these products, relative lack of controlled studies, and uncertainties regarding dosing and microorganism–host interactions. Based on manufacturer reputation, product content, availability of evidence-based literature, and personal experience, Table 51-2 summarizes information for a limited number of probiotic products believed by the author to have the greatest potential for beneficial effects in the dog and cat. Two of the products listed in Table 51-2 have some unique aspects that distinguish them from other available probiotics. Prostora MAX contains canine-derived microorganisms, potentially enhancing the ability of the probiotic agent to interact with the canine gastrointestinal microenvironment. Proviable offers a somewhat different approach to probiotic therapy in that seven different probiotic agents are incorporated into one product. The potential, but not yet proven advantage, of this strategy is that multiple microorganisms expand the opportunity for beneficial interactions between the probiotic and the host microenvironment. In addition, Proviable may be offered with a prebiotic agent to help achieve more rapid resolution of acute diarrhea.

Therapeutic Regimens

Although ideal therapeutic dosing regimens have not yet been established, the products and protocols outlined in Table 51-2 all meet or exceed the minimum daily oral dose of 1×10^{8} CFUs/unit of product that is suggested by currently available information.[20] Duration of administration can range from a few days for acute GI disturbances to months for chronic disorders such as inflammatory bowel disease. For sustained effect, most microorganisms must be administered continuously as a consequence of the transient nature of probiotics in the GI tract.[2] Depletion or alteration of

the indigenous microflora as a result of antibiotic therapy is an indication for long-term probiotic therapy extending over a course of several days to weeks while the normal microflora becomes reestablished. If given concurrently with an antibiotic, the probiotic should be administered at a different time of day than the antibiotic.

As indicated in Table 51-1, probiotics have the potential for aiding in the treatment of a variety of companion animal GI disorders. The ability of probiotic agents to inhibit pathogens and parasites as well as to limit bacterial overgrowth through competition and immunomodulation supports the use of probiotic products for therapy and prevention of GI disease.[13] At the same time, traditional therapies should not be overlooked when treating specific disorders. For the time being, probiotic agents are best employed as *ancillary* therapeutic measures. At present, diarrhea-related disorders, especially those induced by medication, diet, or stressful situations, are conditions that may have the greatest potential for management and prevention with probiotics.

Contraindications and Adverse Effects

In general, adverse effects are infrequently encountered with the use of probiotic agents. Efficacy issues are more commonly encountered than safety issues or undesirable side effects. Although probiotic preparations are not subject to the stringent safety review undertaken with most pharmaceutical products, probiotic agents can receive FDA designation of "Generally Recognized As Safe" (GRAS). Because live microorganisms are being administered to the host, one of the greatest concerns is the introduction of bacteria with antibiotic resistance and plasmids conferring antibiotic resistance that can be transferred to other bacteria residing in the GI tract of the host. Although some lactic acid bacteria have antibiotic-resistant plasmids, antibiotic resistance related to the lactic acid bacteria more frequently used in probiotic preparations appears uncommon and generally does not occur because of a transmissible characteristic. In some instances, as is the case with *E. faecium* SF68, specific probiotic strains neither acquire nor transmit antibiotic resistance.[12] Because potential opportunistic, systemic infection remains a source of concern when administering live bacterial preparations, probiotic products should be used with caution or withheld from patients with weakened immune defenses. These individuals include neonatal patients (especially those ≤3 weeks of age), patients markedly debilitated as the result of a disease process, patients afflicted with severe clinical signs of intestinal infections such as canine parvovirus or feline panleukopenia, and immunosuppressed individuals in general.[4,20]

CHAPTER 52

Prokinetic Agents

Robert J. Washabau

Gastrointestinal motility disorders represent a diagnostic and therapeutic challenge. Disorders of gastrointestinal motility may result in delayed transit, accelerated transit, impaired relaxation, or inappropriate relaxation. The delayed transit disorders are the most important motility disorders of companion animals and may involve the esophagus (hypomotility and megaesophagus), stomach (delayed gastric emptying), small intestine (postoperative ileus and intestinal pseudoobstruction), or colon (constipation and megacolon) (see Section VI).

Dopaminergic D_2 Antagonist Drugs

Metoclopramide and Domperidone

The dopaminergic D_2 antagonists are a group of drugs with gastrointestinal prokinetic and antiemetic effects at peripheral (prokinetic) or central (antiemetic) dopamine D_2 receptors (Table 52-1, Figure 52-1).[1] The best representatives in this classification, metoclopramide and domperidone, reverse gastric relaxation induced by dopamine infusion in dogs, and they abolish vomiting associated with apomorphine therapy. Although the role of dopamine receptors in chemoreceptor trigger zone–induced vomiting is fairly well established, there is no definitive evidence that inhibitory dopaminergic neurons regulate gastrointestinal motility. The prokinetic effects of metoclopramide and domperidone thus may not be readily or exclusively explained by dopamine receptor antagonism. Some dopaminergic antagonists (e.g., metoclopramide) have other pharmacologic properties, for example, 5-HT_3-receptor antagonism and 5-HT_4-receptor agonism. Domperidone also has α_2- and β_2-adrenergic receptor antagonistic effects. The characterization of these drugs as dopaminergic antagonists is convenient but may not properly describe their overall in vivo effects.

Gastroesophageal Sphincter Disorders

The gastroesophageal sphincter prevents reflux of gastrointestinal contents into the esophageal body.[2,3] Reflux of gastric H^+ and pepsins, and of duodenal bicarbonate, bile salts, and proteases, induces chemical injury and inflammation of the esophageal mucosa.[3] Gastroesophageal sphincter tone appears to be under the regulation of dopaminergic neurons as both metoclopramide and domperidone increase sphincter tone. The gastric prokinetic effect of metoclopramide, although moderate, may also help to reduce the frequency, severity, and duration of reflux episodes.

Gastric-Emptying Disorders

Metoclopramide increases the amplitude and frequency of antral contractions; inhibits fundic receptive relaxation; and coordinates gastric, pyloric, and duodenal motility, all of which result in moderate acceleration of gastric emptying.[4,5] Metoclopramide appears to have continuing clinical application as a gastric prokinetic agent in the dog and cat, although the serotonergic agonists are clearly more potent. Domperidone appears to be less effective as a gastric prokinetic agent. Although effective in humans, domperidone actually decreases the frequency of corporeal, pyloric, and duodenal contractions and deteriorates antropyloroduodenal coordination in the dog by decreasing the frequency of contractions spreading from the antrum or pylorus to the duodenum.[5]

Small Intestinal Transit Disorders

Metoclopramide and domperidone are generally considered less effective in the management of the small intestinal transit disorders. Metoclopramide enhances antropyloroduodenal coordination in the dog and may be effective when delayed gastric emptying is a result of poor antropyloroduodenal coordination.[6] Domperidone has no documented effects on small intestinal transit.

Chemoreceptor Trigger Zone–Induced Emesis

The antiemetic effects of metoclopramide and domperidone are attributed to their central effects at the chemoreceptor trigger zone.[7] The antiemetic effect of metoclopramide is more important than its prokinetic effect.[1,7] Despite long-standing usage by small animal veterinarians, metoclopramide is not a very potent gastrointestinal prokinetic agent. Domperidone is 12 to 25 times more potent than metoclopramide and 50 to 60 times more potent than prochlorperazine in attenuating apomorphine-induced vomiting.

Serotonergic 5-HT_4-Agonist Drugs

Drugs acting on gastrointestinal 5-hydroxytryptamine (5-HT or serotonin) receptors have potent motility effects (see Table 52-1, Figure 52-2).[8] Serotonergic drugs that bind 5-HT_4 receptors on enteric cholinergic neurons induce depolarization and contraction of gastrointestinal smooth muscle. These drugs are not entirely selective for the 5-HT_4 receptor, however. Some of the putative 5-HT_4-receptor agonists also have 5-HT_1 and 5-HT_3 antagonistic effects on enteric cholinergic neurons, and direct noncholinergic (perhaps 5-HT_{2a}) effects on colonic smooth muscle. Cisapride,

Table 52-1 Mechanisms, Sites of Activity, Indications, and Doses of Currently Available Gastrointestinal Prokinetic Agents

Drug Classification/ Mechanism	Sites of Activity	Indications	Dose	Other Properties
Dopaminergic D_2-Antagonist Drugs				
Metoclopramide	GES, stomach, intestine, CRTZ	Vomiting disorders, gastroesophageal reflux, delayed gastric emptying, ileus/pseudoobstruction	0.2 to 0.5 mg/kg PO, IV TID; 0.01 to 0.02 mg/kg/h infusion	α_2-adrenergic antagonist β_2-adrenergic antagonist 5-HT_4-serotonergic agonist 5-HT_3-serotonergic antagonist
Domperidone	GES, CRTZ	Vomiting disorders, gastroesophageal reflux	0.05 to 0.1 mg/kg PO BID	α_2-Adrenergic antagonist β_2-adrenergic antagonist
Serotonergic 5-HT_4-Agonist Drugs				
Cisapride	GES, stomach, intestine, colon, CRTZ	Gastroesophageal reflux, delayed gastric emptying, ileus/pseudoobstruction, constipation, chemotherapy-induced vomiting	0.1 to 0.5 mg/kg PO TID (doses as high as 0.5 to 1 mg/kg have been used in some dogs)	5-HT_3-serotonergic antagonist 5-HT_1-serotonergic antagonist 5-HT_2-serotonergic agonist
Mosapride	Stomach	Delayed gastric emptying	0.25 to 1 mg/kg PO BID	None
Prucalopride	Stomach, colon	Delayed gastric emptying, constipation	0.01 to 0.2 mg/kg PO BID	None
Tegaserod	Intestine, colon	Constipation, ileus/ pseudoobstruction	0.05 to 0.1 mg/kg PO or IV, BID	5-HT_1-serotonergic antagonist
Motilin-like Drugs				
Erythromycin	GES, stomach, intestine, colon	Gastroesophageal reflux, delayed gastric emptying, constipation (dogs)	0.5 to 1 mg/kg PO IV TID	5-HT_3-serotonergic antagonist
Acetylcholinesterase Inhibitors and Cholinomimetic Agents				
Ranitidine	Stomach, colon	Delayed gastric emptying, constipation	1 to 2 mg/kg PO BID-TID	H_2-histaminergic antagonist
Nizatidine	Stomach, colon	Delayed gastric emptying, constipation	2.5 to 5.0 mg/kg PO SID	H_2-histaminergic antagonist
Bethanechol	Esophagus	Canine idiopathic megaesophagus	Dog: 5 to 15 mg/dog PO TID	
Nitric Oxide Donors				
AMU-301		Stomach	Diabetic gastroparesis	Not yet established
Prostanoids				
Misoprostol		Colon	Constipation	Dog: 2 to 5 μg/kg PO TID-QID

CRTZ, chemoreceptor trigger zone; GES, gastroesophageal sphincter; SID, standardized ileal digestible.

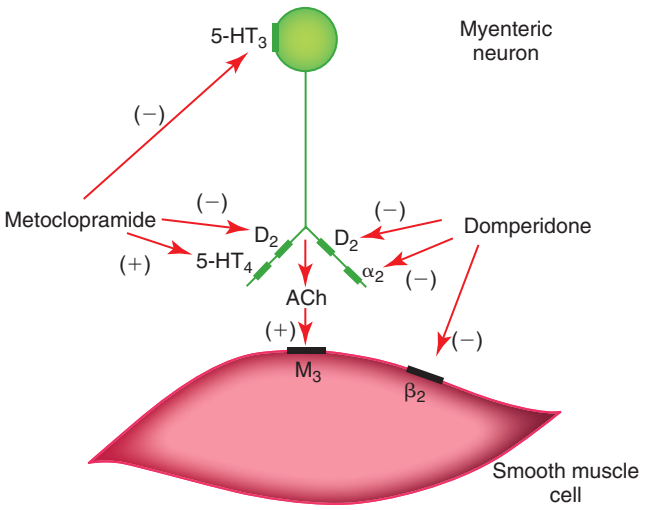

Figure 52-1 Dopaminergic regulation of gastrointestinal motility and sites of action of metoclopramide and domperidone.

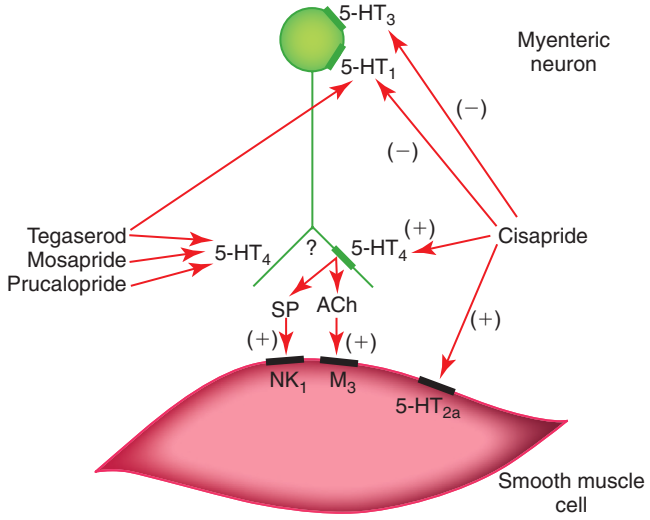

Figure 52-2 Serotonergic regulation of gastrointestinal motility and sites of action of cisapride, mosapride, prucalopride, and tegaserod.

mosapride, prucalopride, and tegaserod are the best examples in this classification. Cisapride and tegaserod have been withdrawn from several international markets because of their effect(s) on myocardial Q-T interval prolongation, although both remain available through compounding pharmacies. Mosapride is available in Japan (Pronamid, DS Pharma) and prucalopride is available in Europe (Resolor, Movetis).

Cisapride

Cisapride was widely used in the management of canine and feline gastric emptying, intestinal transit, and colonic motility disorders throughout most of the 1990s.[9,10] Cisapride was withdrawn from the American, Canadian, and certain West European markets in July 2000 following reports of untoward cardiac side effects in human patients. Cisapride causes Q-T interval prolongation and slowing of cardiac repolarization via blockade of the rapid component of the delayed rectifier potassium channel (I_{Kr}).[11] This effect may result in a fatal ventricular arrhythmia referred to as *torsades de pointes*.[11] Similar effects have been characterized in canine cardiac Purkinje fibers, but in vivo effects have not been reported in dogs or cats. The withdrawal of cisapride has created a clear need for new gastrointestinal prokinetic agents, although cisapride continues to be available from compounding pharmacies.

Gastroesophageal Sphincter Disorders

Cisapride is indicated for the treatment of gastroesophageal reflux because it stimulates gastric emptying and increases gastroesophageal sphincter pressure. Comparative studies have shown that cisapride is more potent than metoclopramide in stimulating gastric emptying and increasing gastroesophageal sphincter pressure. Cisapride can be used in conjunction with chemical diffusion barriers (e.g., sucralfate) and gastric acid secretory inhibitors (e.g., H_2-receptor antagonists; H^+,K^+-adenosine triphosphatase [ATPase] inhibitors) in the treatment of gastroesophageal reflux.[12-14]

Cisapride stimulates distal esophageal peristalsis in those animal species (e.g., cat, human being, guinea pig) in which the distal esophageal muscularis is composed of smooth muscle. The obvious exception is the dog, a species in which the entire esophageal body is composed of striated muscle. It has been suggested that cisapride might improve esophageal peristalsis in dogs affected with idiopathic megaesophagus. This would not appear to be a rational clinical application of the drug, because a smooth muscle prokinetic agent would not be expected to have much effect on striated muscle function. Indeed, the prokinetic effect of cisapride in the esophagus of human beings or cats is confined to the distal esophageal body at the transition zone from striated muscle to smooth muscle. Cisapride has no effect on proximal esophageal peristalsis in these species. Furthermore, 5-HT stimulates contraction of canine gastroesophageal sphincter smooth muscle, but is without effect on canine esophageal body striated muscle.[15] Thus, cisapride cannot be recommended for the treatment of idiopathic megaesophagus in dogs. Indeed, cisapride-induced increases in gastroesophageal sphincter pressure could diminish esophageal clearance and worsen clinical signs in dogs affected with idiopathic megaesophagus.

Gastric-Emptying Disorders

Cisapride accelerates gastric emptying in dogs by stimulating pyloric and duodenal motor activity, by enhancing antropyloroduodenal coordination, and by increasing the mean propagation distance of duodenal contractions.[5,16] Cisapride appears to be superior to metoclopramide and domperidone in stimulating gastric emptying. Dosages of cisapride in the range of 0.05 to 0.2 mg/kg enhance gastric emptying in dogs with normal gastric emptying. Dosages in the range of 0.5 to 1 mg/kg are needed to enhance gastric emptying in dogs with delayed gastric emptying induced by α_2-adrenergic agonists, dopamine, disopyramide, or antral tachygastria.[9,10]

Small Bowel Motility Disorders

Cisapride stimulates jejunal spike burst migration, jejunal propulsive motility, and antropyloroduodenal coordination following intestinal lipid infusion in the dog.[6,17] Thus, cisapride would appear to have a rational place in the treatment of postoperative ileus and intestinal pseudoobstruction. Well-designed clinical trials and evidence-based data are required to determine the effectiveness of cisapride in the treatment of these disorders.

Colonic Motility Disorders

Cisapride stimulates colonic motility,[18,19] and would appear to have a rational place in the treatment of idiopathic constipation. Disruption of the normal colonic motility patterns results in constipation in domestic cats. Cisapride improves colonic motility in cats that are mildly or moderately affected with idiopathic constipation; cats with long-standing hypomotility and dilation are usually less responsive. A recent evidence-based data review of cisapride's efficacy in the treatment of human constipation and constipation-predominant irritable bowel syndrome was carried out by the Cochrane Collaboration.[20] These authors concluded, "no clear benefit could be demonstrated with cisapride."[20]

Cis-*Platinum–Induced Emesis*

Cis-Platinum-induced emesis is mediated by 5-HT_3 serotonergic receptors, either in the chemoreceptor trigger zone (cat) or in vagal afferent neurons (dog). Selective antagonists of the 5-HT_3 receptor (e.g., ondansetron, granisetron, tropisetron, dolasetron) abolish vomiting associated with *cis*-platinum chemotherapy. Cisapride antagonizes these 5-HT_3 receptors and inhibits vomiting associated with *cis*-platinum chemotherapy. The potency of cisapride's 5-HT_3 antiemetic effect (median effective dose [ED_{50}] = 0.6 mg/kg IV; ED_{100} = 2.6 mg/kg IV) is less than its 5-HT_4 gastric prokinetic effect. Thus, cisapride could be recommended as an antiemetic agent for the cancer chemotherapy patient only if ondansetron, granisetron, tropisetron, or dolasetron were not immediately available or were too cost prohibitive.[7] Metoclopramide is equipotent with cisapride in inhibiting *cis*-platinum emesis, but it has the distinct disadvantage of adverse central nervous system side effects, for example, drowsiness, extreme weakness, and body tremors. Cisapride has no effect on nausea and vomiting mediated by dopaminergic D_2 receptors (e.g., apomorphine, uremia) or histaminergic H_1 receptors (e.g., motion sickness).

Mosapride

Mosapride citrate, a substituted benzamide, is a novel 5-HT_4-receptor agonist that increases gastric emptying in rats and dogs, and increases electrically evoked contractions in the isolated guinea pig ileum.[21,22] Mosapride stimulates acetylcholine release from the myenteric plexus via activation of 5-HT_4 receptors, but has no real affinity for D_2 dopamine, 5-HT_1, 5-HT_2 receptors, or α_1-adrenoceptors. Mosapride restores gastric motility in dogs with vincristine-induced gastric hypomotility,[23] and therefore may be clinically useful in other gastric-emptying disorders. Mosapride is apparently without effect on distal gastrointestinal tract motility. Mosapride is marketed as Pronamid by DS Pharma Animal Health in Japan.

Prucalopride

Prucalopride is a potent partial benzamide agonist at 5-HT_4 receptors, but is without effect on other 5-HT receptors or cholinesterase enzyme activity. Prucalopride dose dependently (0.02 to 1.25 mg/kg) stimulates giant migrating contractions and defecation in the dog.[24-26] The prucalopride effect is observed most prominently in the first hour after administration, suggesting that the prucalopride effect is a direct effect on the colon rather than on total gut transit time. Oral and intravenous doses appear to be equipotent, again implying a high oral bioavailability. Prucalopride also enhances defecation frequency in healthy cats.[27] Cats treated with prucalopride at a dose of 0.64 mg/kg experience increased defecation within the first hour of administration. Fecal consistency is not altered by prucalopride at this dosage.

Prucalopride also appears to stimulate gastric emptying in the dog.[28] In lidamidine-induced delayed gastric emptying in dogs, prucalopride (0.01 to 0.16 mg/kg) dose dependently accelerates gastric emptying of dextrose solutions. The prucalopride effect is equipotent following oral and intravenous administration suggesting that prucalopride may have a high oral bioavailability. Prucalopride is marketed as Resolor by Movetis in Europe.

Tegaserod

Tegaserod is a potent partial nonbenzamide agonist at 5-HT_4 receptors and a weak agonist at 5-HT_{1D} receptors.[29,30] Tegaserod has prokinetic effects in the distal gastrointestinal tract. Intravenous doses of tegaserod (0.03 to 0.3 mg/kg) accelerate colonic transit in dogs during the first hour after intravenous administration.[29] The highest doses of tegaserod (0.1 and 0.3 mg/kg) have no greater efficacy than lower doses (0.03 mg/kg), suggesting the possibility that tegaserod may stimulate canine colonic motility through a receptor-independent mechanism, or that tegaserod may act at sites other than 5-HT_4 receptors at higher doses.

The motor mechanisms responsible for tegaserod-induced canine colonic propulsion are unclear. High-amplitude propagated phasic contractions are thought to be responsible for mass movements, but they were not observed during tegaserod infusion. Contraction, amplitude, and motility indices were not different postprandially among treatment groups, so the mechanism of the tegaserod effect requires more detailed investigation in the dog.

Gastric effects of tegaserod have not been reported in the dog, so this drug may not prove as useful as cisapride in the treatment of delayed gastric-emptying disorders. Tegaserod at doses of 3 to 6 mg/kg PO normalizes intestinal transit in opioid-induced bowel dysfunction in dogs,[31] and it may be useful in other disorders of intestinal ileus or pseudoobstruction.

Tegaserod was approved by the U.S. Food and Drug Administration in September 2002, but was removed from the American market in 2007 because of reports of prolongation of the Q-T interval and delayed cardiac repolarization. Tegaserod is marketed as Zelnorm by Novartis in Europe.

Future Research in 5-HT-Receptor Pharmacology

The 5-HT_4 receptor appears to hold the most interest and promise for future drug development. 5-HT_4-receptor activation can cause relaxation or contraction depending on the region, cell type, and animal species. In the dog, the effects of selective 5-HT_4-receptor agonists suggest that these receptors are present on jejunal mucosa, ileal mucosa, gastric cholinergic neurons, and circular colonic smooth muscle cells. Development of 5-HT_4 ligands is somewhat constrained by the effects these drugs have on cardiac 5-HT_4 receptors and the delayed rectifier potassium channel (I_{Kr}). Some, but not all, 5-HT_4 agonists prolong the Q-T interval and delay cardiac repolarization. Molecular biology experiments have revealed differences in the carboxyl terminus of smooth muscle and cardiac muscle 5-HT_4 receptors, but these amino acids differences are distant from the receptor binding site. Thus, receptor subtypes may exist but they may not be important from a functional or therapeutic standpoint.

Motilin-Like Drugs

Erythromycin

The antibiotic properties of erythromycin and other macrolides were discovered in the early 1950s. Since that time, erythromycin has been widely used in treating patients with Gram-positive and Gram-negative bacterial and mycoplasmal infections. Physicians and veterinarians noted that erythromycin therapy was accompanied by frequent gastrointestinal side effects, including nausea and vomiting. This occurrence suggested to researchers that erythromycin might have effects on gastrointestinal motility. It was subsequently demonstrated that microbially effective doses of erythromycin stimulate retrograde peristalsis and vomiting in dogs, and that lower microbially ineffective doses of erythromycin stimulate migrating motility complexes and antegrade peristalsis similar to that induced by the endogenous gastrointestinal hormone, motilin (see Table 52-1, Figure 52-3).[32-34]

Gastroesophageal Sphincter Disorders

Motilin, erythromycin, and erythromycin analogues (e.g., LY-267108) increase gastroesophageal sphincter pressure in cats and dogs.[35] Erythromycin also increases gastroesophageal sphincter pressure in cats in which the basal pressure has been lowered experimentally by esophageal acid perfusion or following intravenous isoproterenol administration.[35] These studies suggest that erythromycin should be useful in treating cats, and perhaps dogs, with gastroesophageal reflux and reflux esophagitis.

Gastric-Emptying Disorders

Erythromycin accelerates gastric emptying by inducing antral contractions similar to phase III of the interdigestive state.[36-39] The strong contractions associated with phase III normally occur only

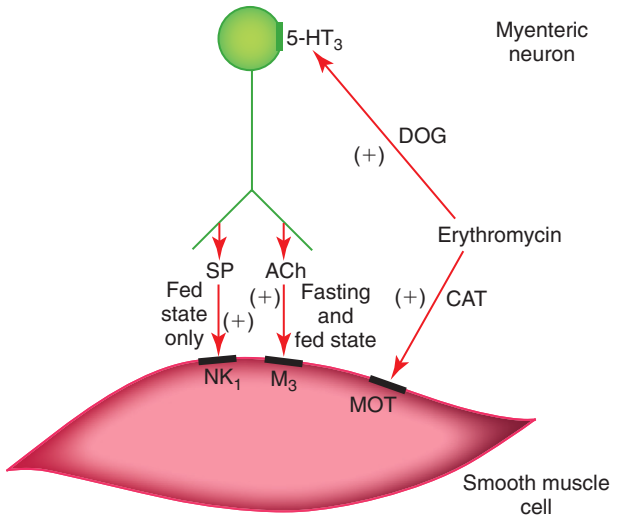

Figure 52-3 Motilin regulation of gastrointestinal motility and sites of action of erythromycin.

during the fasted state when they clear the stomach of large indigestible solids. After meals, intravenous or oral erythromycin accelerates gastric emptying of solid meals in dogs. EM574 is 250 times more potent than erythromycin in inducing phase III contractions in dogs and it has no antibacterial activity.[37,38] EM574 is as effective as cisapride in normalizing gastric contractility and emptying in dogs with clonidine-induced gastroparesis in dogs.[37,38]

Colonic Motility Disorders

Erythromycin accelerates regional colonic transit in the dog.[40] Erythromycin has been shown to stimulate canine but not feline colonic smooth muscle contraction in vitro.[41] These results suggest that erythromycin may be useful in the treatment of canine colonic motility disorders.

Acetylcholinesterase Inhibitors and Cholinomimetic Agents

Ranitidine and Nizatidine

Ranitidine and nizatidine, classic histamine H_2-receptor antagonists, stimulate gastrointestinal motility by inhibiting acetylcholinesterase activity (see Table 52-1, Figure 52-4).[42-44] As parasympathetic potentiating agents, ranitidine and nizatidine stimulate gastric emptying and small intestinal and colonic motility. The prokinetic effects of ranitidine and nizatidine appear to be more prominent in the proximal gastrointestinal tract (i.e., gastric emptying). Other members of this classification, for example, cimetidine and famotidine, apparently have no effect on gastrointestinal motility.

Bethanechol

Bethanechol is a cholinomimetic agent that binds muscarinic cholinergic receptors and stimulates motility throughout the gastrointestinal tract.

Esophageal Motility Disorders

Smooth muscle prokinetic agents, for example, cisapride and metoclopramide, have limited clinical application in the treatment of canine idiopathic megaesophagus. Cisapride and metoclopramide stimulate distal esophageal peristalsis in those animal species (e.g., cat, human being, guinea pig) in which the distal esophageal muscularis is composed of smooth muscle. The domestic dog has evolved with a purely striated muscle esophageal muscularis, which has a different regulation and therapeutic responsiveness.[13] Bethanechol stimulates esophageal propagating contractions in some dogs affected with idiopathic megaesophagus and is therefore a more appropriate prokinetic agent for the therapy of this disorder.[45]

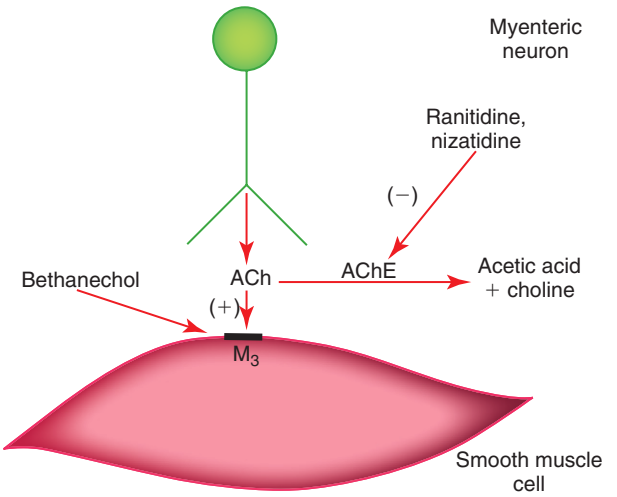

Figure 52-4 Cholinergic regulation of gastrointestinal motility and sites of action of ranitidine, nizatidine, and bethanechol.

Gastric-Emptying Disorders

Ranitidine and nizatidine stimulate gastric antral contractions at gastric antisecretory dosages (ranitidine, 1.0 to 2.0 mg/kg PO BID; nizatidine, 2.5 to 5.0 mg/kg PO BID) and may be useful as gastric prokinetic agents in dogs and cats.[43,44,46]

Colonic Motility Disorders

Infusions of ranitidine at doses of 3 mg/kg induce canine colonic propagating contractions in vivo.[46] Ranitidine and nizatidine also stimulate feline colonic smooth muscle contraction in vitro.[47] These data suggest that ranitidine and nizatidine may be useful in the treatment of feline or canine colonic motility disorders.[42]

Nitric Oxide Donors

Delayed gastric emptying is recognized as an important cause of upper gastrointestinal tract pathology (e.g., anorexia and vomiting) in companion animals.[14] Delayed gastric emptying has been reported in infectious and inflammatory gastric diseases, diabetes mellitus, and radiation injury in the dog.[48,49] Delayed gastric emptying is also associated with several secondary conditions, including electrolyte disturbances (e.g., hypokalemia, hypocalcemia), metabolic disorders (e.g., hypoadrenocorticism, hypergastrinemia, uremia), concurrent drug usage (e.g., cholinergic antagonists, β-adrenergic agonists, opiates), acute stress (e.g., sympathetic stimulation, spinal cord injury), and acute abdominal inflammation.[48,49]

Diabetes mellitus is the most common endocrinopathy of the domestic dog.[50] Long-standing undiagnosed or untreated diabetes mellitus is associated with significant gastroparesis in the dog,[51,52] just as it is in humans. The pathogenesis of gastroparesis in diabetes mellitus is complex and probably multifactorial, involving one or more of the cellular elements (neurons, smooth muscle cells, interstitial cells of Cajal) regulating gastric motility.[53] An important pathophysiologic mechanism appears to be the loss of neuronal nitric oxide synthase, the enzyme responsible for the production of nitric oxide, an inhibitory neurotransmitter that is required for relaxation of smooth muscle and therefore a critical component of normal gastrointestinal motility. In the absence of nitric oxide, the stomach cannot relax, resulting in bloating, satiety, nausea, and vomiting.[54]

Cisapride, metoclopramide, and erythromycin have all been used with variable effect in diabetic gastroparesis. Therapy aimed instead at restoring nitrergic neurotransmission could have intrinsic beneficial effects in canine diabetic gastroparesis. AMU-301, a nitric oxide (NO) donor, is recognized as an effective treatment for diabetic gastroparesis in streptozotocin-induced (STZ) diabetic rat models of delayed gastric emptying,[55] and may eventually prove useful in spontaneous canine diabetes mellitus (see Table 52-1, Figure 52-5).

Prostaglandin E_1 Analogues

Misoprostol is a prostaglandin E_1 analogue that reduces the incidence of nonsteroidal antiinflammatory drug–induced gastric injury. The main side effects of misoprostol therapy are abdominal discomfort, cramping, and diarrhea. Dog studies suggest that prostaglandins

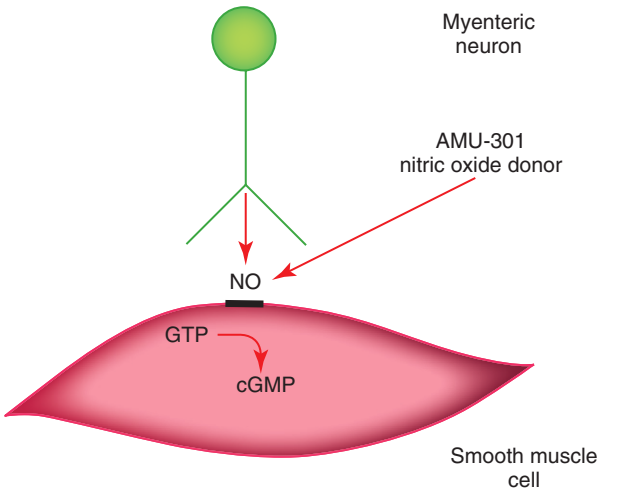

Figure 52-5 Nitric oxide regulation of gastrointestinal motility and sites of action of nitric oxide donors.

may initiate a giant migrating complex pattern and increase colonic propulsive activity.[56] In vitro studies of misoprostol show that it stimulates feline and canine colonic smooth muscle contraction.[57] Given its limited toxicity, misoprostol may be useful in dogs and cats with severe refractory constipation.

CHAPTER 53

Vitamins and Minerals

Craig G. Ruaux

Definition

Vitamins and minerals are components of the diet that are necessary for normal cellular physiology but do not provide any significant caloric input. In a dietary context, the term *minerals* refers to the ionized form of predominantly low-molecular-weight alkali metals or transition metals such as magnesium, cobalt, selenium, and zinc. Vitamins, by comparison, have more complex molecular structures. Vitamin and mineral malabsorption and systemic deficiencies are common consequences of gastrointestinal disease.

Formulations and Doses

Vitamin and mineral supplements are available in a variety of over-the-counter formulations, for both human and animal use. Many of these products contain a substantial variety of vitamin and mineral compounds in combination with various amino acids, fatty acids, and putative micronutrients. There is a distinct lack of objective, peer-reviewed literature to support the need for or use of these complex mixtures of vitamins and minerals, particularly in the otherwise healthy companion animal consuming a well-formulated, balanced diet. Many of the components of these multivitamin supplements have rational uses in gastrointestinal diseases; however, the doses necessary to achieve therapeutic effect are often substantially higher than is feasible using multivitamin preparations. Therapeutic formulations of vitamins for parenteral use in companion animal species are available from several manufacturers in a variety of formulations.

Rational Use in the Diagnosed Patient

Vitamin and Mineral Deficiencies in Gastrointestinal Disease

Vitamin and mineral deficiencies are commonly recognized in human patients with inflammatory bowel disease.[1] The mechanisms whereby micronutrient deficiencies may come about include reduced voluntary intake because of inappetence, increased losses as a result of diarrheal disease, compromised uptake as a consequence of loss of absorptive surface area, loss of specific mucosal receptors, or compromised fat absorption in diseases characterized by steatorrhea. In the veterinary literature, the greatest attention has been paid to (a) vitamin deficiencies resulting from fat malassimilation and (b) deficiencies in cobalamin (vitamin B_{12}) and folic acid or folate (vitamin B_9) as a result of loss of specific receptors. Hypovitaminosis D, with concurrent disorders of calcium homeostasis, has been reported in dogs in association with protein-losing enteropathies,[2,3] while in the cat severe organic acidemias have been recognized in patients with gastrointestinal disease and subnormal serum cobalamin concentrations.[4,5] Hypocobalaminemia has been identified as a negative prognostic factor in dogs with chronic enteropathies.[6]

Recent studies have focused on the prevalence of cobalamin deficiency in the cat and dog with gastrointestinal disease.[7,8] In both species, cobalamin deficiency was common in patients with gastrointestinal disease. In an open-label, uncontrolled study, cobalamin supplementation in cats with gastrointestinal disease and severe hypocobalaminemia was associated with positive clinical benefit and normalization of biochemical parameters.[9]

Cobalamin malabsorption because of intestinal disease cannot be successfully treated with dietary supplementation. Parenteral therapy is essential in deficient patients.[9] A dose range previously described for use in cats with cobalamin deficiency as a consequence of intestinal disease is 250 µg/cat injected subcutaneously, once a week for 6 weeks, once every 2 weeks for 6 weeks, and once a month thereafter.[9] The concentration of cobalamin in standard injectable multivitamin preparations (5 µg/mL) is insufficient to supply this amount of cobalamin in a reasonable injection volume. Therefore a pure preparation of cobalamin is recommended, in addition to multivitamin products, in dogs and cats with documented cobalamin deficiency.

Reduced serum concentrations of folic acid/folate most commonly occur in companion animals because of loss of specific duodenal mucosal receptors. Although subnormal serum folate concentrations have been recognized cats with gastrointestinal disease,[10] the clinical significance of this finding, or of similar findings in dogs, is currently unclear. At the time of writing there is no well-defined threshold for folic acid supplementation in either species, and no peer-reviewed literature that specifically addresses the benefit, if any, of folate supplementation in adult patients with gastrointestinal disease. Empirically, treatment with oral or injectable folic acid (1 to 5 mg/dog or 1 mg/cat PO daily) results in dramatic increases in serum folate concentrations in most animals (unpublished data).

Vitamin and Mineral Deficiencies in Liver Disease

Liver disease patients often present with vitamin and/or mineral deficiencies. Several factors, including reduced voluntary intake, fat malabsorption, reduced gastrointestinal mucosal function, and loss of hepatic reserves, all contribute to the development of vitamin and mineral deficiencies.

Water-soluble vitamins such as folic acid, thiamine, cobalamin, niacin, and riboflavin are cofactors for many enzymatic reactions carried out in hepatic cells. Deficiencies in these vitamins are detected frequently in cats with hepatic lipidosis.[11] Most water-soluble vitamins do not have substantial body stores and daily replacement from dietary sources is necessary. Administration of multivitamin supplements is cost-effective and simple, and should be included in any nutritional support plan for patients with liver disease. In the cat, cobalamin malabsorption because of small intestinal disease is commonly documented in association with liver disease.[5]

In animals with long-standing liver disease, fat malabsorption and subsequent deficiencies of fat-soluble vitamins can occur. Vitamin E deficiency may reduce cellular defenses against oxidant-mediated damage, potentially playing a role in copper-associated hepatoxicity.[12,13] Empirically, regular supplementation of vitamins E, A, and D by intramuscular injection at 3- to 4-month intervals is recommended in companion animals with long-standing liver disease, particularly if this is complicated by steatorrhea. Cats with hepatic lipidosis should be screened for vitamin K deficiency, particularly if there is any evidence of bleeding tendencies. If detected (ideally via protein-induced vitamin K absence [PIVKA] assay), subcutaneous vitamin K administration at 1 to 5 mg/kg/day for 2 to 3 days is indicated.

Niacin Therapy for Hyperlipidemia

Niacin therapy has been recommended in humans and companion animals with hyperlipidemia syndromes, particularly when dietary fat restriction has failed.[14,15] Niacin acts through several different mechanisms to reduce circulating lipids. These mechanisms include inhibition of hormone-sensitive lipase, thus reducing fatty acid mobilization, stimulation of hepatic high-density lipoprotein catabolism, and direct inhibition of hepatic fatty acid synthesis.[16] Taken alone in high doses, niacin is associated with pruritus and skin flushing in many human patients.[17] When used for control of hyperlipidemia in dogs, niacin is administered at 25 to 100 mg/dog/day.[14] As with many other nutritional interventions in animals, large-scale controlled studies documenting benefit of niacin therapy are lacking.

Elemental Zinc Therapy in Copper-Accumulation Hepatopathies

Hepatic copper accumulation is a feature of several diseases in dogs. Copper accumulation hepatopathy is well recognized as an autosomal recessive disorder in the Bedlington Terrier.[18] In several other breeds, including the Doberman Pinscher, Cocker Spaniel, West Highland White, Skye Terrier, and Labrador Retriever, there is evidence of excessive copper accumulation in some liver diseases.[19,20] In addition to chelation therapy and the feeding of a low-copper diet, micronutrient interventions to decrease hepatic copper accumulation include supplementation with ascorbic acid and elemental zinc.

Administration of zinc between meals leads to increased metallothionein expression in the enterocytes. Copper in the diet is bound with high affinity within the mature enterocyte and lost in the feces as the enterocyte is shed.[21] Zinc is given at a loading dose of 100 mg per os twice daily for 3 weeks, followed by a maintenance dose of 50 mg orally twice daily. Vomiting and nausea may both occur as side effects of zinc therapy; administration with a small amount of food may reduce these side effects. Ascorbic acid supplementation increases urinary excretion of copper and zinc, as well as increasing the intestinal synthesis of metallothionein.

Rational Use in the Undiagnosed Patient

Water-soluble vitamin B-complex formulations are commonly used empirically in the management of many chronic disease conditions. To the best of the author's knowledge, no peer-reviewed publications directly address the utility of multivitamin supplementation in any disorder of companion animal species. Most water-soluble vitamins have minimal potential for toxicity or adverse effects, thus water-soluble vitamin supplementation in companion animals with gastrointestinal disease can be considered safe and of potential, but unproven, benefit.

Empirical use of cobalamin supplementation in companion animals with chronic gastrointestinal disease is becoming increasingly common. Although mild symptomatic improvement may be seen in some patients with empirical cobalamin supplementation, all efforts should still be made to achieve a definitive diagnosis and appropriate therapy for the primary gastrointestinal disease.

Contraindications and Side Effects

Empirical use of fat-soluble vitamin supplements, particularly formulations containing more than one vitamin, should be approached with caution because of the potential for hypervitaminosis syndromes, particularly hypervitaminosis A in the cat and hypercalcemia as a result of hypervitaminosis D.[22-24] Empirical use of water-soluble vitamins, particularly B-complex preparations, carries minimal risk of side effects at appropriate doses.

CHAPTER 54

Oropharynx

STRUCTURE AND FUNCTION

Kendall Taney

Structure of the Oropharynx

Oral Cavity

The oral cavity extends from the lips to the oropharynx, or more specifically to level of the palatine tonsils.[1] The lateral boundaries are the cheeks and the dorsal boundary is the hard palate and part of the soft palate.[1,2] The ventral boundary is the tongue and floor of the mouth. The oral cavity encompasses the vestibule and the oral cavity proper. The vestibule is the potential space between the lips or cheeks and the teeth and gums. The oral cavity proper extends from the alveolar ridge and teeth to the oropharynx.[1] The oral cavity proper contains the teeth, hard palate and part of the soft palate, portions of the osseous tissue of the skull and mandible, and the tongue.

Dogs and cats have anisognathic jaws as the mandible is narrower than the maxilla and the teeth of the maxilla and mandible do not meet directly in occlusion.[1] The dentition and jaw structure in carnivores facilitate capture of prey and tearing of tissue versus the grinding and crushing action of the teeth and jaws in humans and other omnivores. The dentition of the dog is described as diphyodont, heterodont, and thecodont.[1] Diphyodont means having two sets of teeth, such as a primary set that erupts soon after birth followed by a permanent set that remains in place for the remainder of life. Heterodont refers to having more than one shape of tooth, such as the pointed canines, which are used for grasping and holding food and the more blunt caudal molars that are used for grinding and crushing food. Thecodont teeth are held firmly within the sockets or alveoli by a type of fibrous, nonmobile joint termed a *gomphosis*.[1-3] The fibrous structure that anchors the teeth to bone is more commonly referred to as the periodontal ligament. The alveolar processes of the paired maxillary and mandibular bones surround the roots of the teeth. It is composed of a cortical plate, cribriform plate, and trabecular bone. The cortical plate forms the outer wall of the alveolus. The cribriform plate is a thin layer of bone within the alveolus, which appears radiographically as the lamina dura. Trabecular bone is the supportive hard tissue between the cortical plate and the lamina dura.[1]

The hard and soft palates separate the oral and nasal cavities. The bony structure of the hard palate is composed of the paired incisive bones, palatine processes of the maxilla, and palatine bones. These bones are covered by cornified stratified squamous epithelial soft tissue, called the *hard palate mucoperiosteum*. The mucosa of the hard palate is nonelastic and has six to 10 transverse ridges or rugae. Located just caudal to the maxillary incisors on midline is a mound of tissue called the *incisive papilla*. On either side of the papilla are the incisive ducts, which travel through the palatine fissures of the incisive bones to communicate with the vomeronasal organ.[1-5] The greater palatine branch of the maxillary branch of the trigeminal nerve (cranial nerve [CN] V) supplies sensory innervation to the hard palate. The main arterial supply is from the paired greater palatine arteries that branch off from the maxillary arteries.[2,4] The soft palate begins at the caudal termination of the hard palate and continues into the pharyngeal region; it is discussed further with the oropharynx.

An important structure within the oral cavity is the tongue, which is responsible for prehension and manipulation of a food bolus during mastication and deglutition. It is also involved in grooming and intake of fluids. The tongue is divided into four sections: tip, margin, body, and root. It becomes thicker caudally toward the root. Arterial blood supply to the tongue is provided by the paired lingual arteries.[2] Motor innervation of the tongue is from the hypoglossus. Sensory innervation is provided by the lingual branch of the trigeminal (CN V), facial (CN VII), glossopharyngeal (CN IX), and vagus nerves (CN X).[2,4] The dorsal surface of the tongue is covered by cornified lingual papillae. The papillae can be mechanical or may contain taste pores which provide information to the sensory nerves.[2] Five types of papillae are present in the tongue of the adult dog: filiform, fungiform, vallate, foliate, and conical. A sixth type, called *marginal papillae*, is a functional type present only in neonates. The marginal papillae are located on the margins of the tongue and help create an airtight seal in the mouth during nursing. They begin to disappear soon after weaning. Filiform papillae are numerous and are located on the rostral two-thirds of the tongue. They are heavily cornified and may aid in grooming; thus they are mostly mechanical in function. The filiform papillae in the cat are especially stiff and long, and are oriented in a caudal direction.[4] The fungiform papillae are also located on the rostral two-thirds of the tongue but are mostly concentrated on the tip and sides of the tongue. Each fungiform papilla may contain up to eight taste pores. There are anywhere from three to six total vallate papillae in the dog. They are arranged in a V shape at the base of the tongue. Vallate papillae may also contain taste pores. The foliate papillae do contain taste buds and are located on the caudal third of the tongue immediately rostral to the palatoglossal folds. Finally, the conical papillae are located on

the caudal third of the tongue. Their function is mainly mechanical and tactile and they do not contain taste pores.[1,2] A visible median groove divides the most rostral two-thirds of the dorsal tongue. The ventral surface is covered by a smoother, less cornified mucosa.[1] A band of tissue called the *lingual frenulum* extends from the floor of the mouth to the base of the tongue.

The tongue is able to prehend and manipulate food as a result of its composition of intrinsic and extrinsic skeletal muscles. The intrinsic propria lingua muscle is innervated by the hypoglossal nerve (CN XII) and serves to retract and depress the tongue. It has four types of muscle fibers: superficial longitudinal, deep longitudinal, perpendicular, and transverse. These muscle fibers allow the tongue to perform complex movements during prehension, fluid intake, mastication, bolus formation, and deglutition and also function to prevent the tongue from being bitten. The extrinsic muscles are the styloglossus, hyoglossus, and genioglossus. These extrinsic muscles are also innervated primarily by the hypoglossal nerve (CN XII). The origin of the styloglossus muscle is the stylohyoid bone. The styloglossus muscle has three heads and the tongue can be pulled backward when all three heads are contracting together.[2] Each head can also act to depress the tongue. The hyoglossus muscle originates from the basihyoid and thyrohyoid bones to the root and caudal two-thirds of the tongue. Its action is to depress and retract the tongue. The genioglossus muscle lies beneath the tongue in the intermandibular space and its origin is on the medial surface of the mandibles. A portion of the genioglossus makes up the lingual frenulum. The caudal fibers can act to draw the tongue forward and the rostral fibers can curl the tip of the tongue downward.[2]

Other important structures involved in the function of the oropharynx are the salivary glands. These accessory digestive organs secrete a serous and mucous fluid (saliva) that is important for lubrication of a food bolus for transport to the upper digestive tract. Many different salivary glands contribute to saliva formation and they are regulated by the autonomic nervous system (see Chapter 1). There are several groups of numerous, small, disseminated glands that secrete small amounts of saliva. These are the lingual, labial, buccal, and palatine salivary glands. The larger salivary glands contribute to the bulk of saliva formation and are the paired parotid, mandibular, sublingual, zygomatic, and, in cats only, the molar glands.[1] The parotid gland is located close to the surface of the masseter muscle. The parotid duct exits into the vestibule on the buccal mucosa at the level of the maxillary fourth premolar. The zygomatic salivary gland, which is located ventral to the rostral portion of the zygomatic arch, has a duct that exits in the vestibule just caudal to the parotid duct. There may also be several small minor zygomatic duct openings in addition to the major opening.[1-4] The parotid duct termination is commonly called the *major papillae* and the larger zygomatic duct opening is called the *minor papillae*. The mandibular gland is located just caudal to the angle of the mandible between the linguofacial and maxillary veins. The sublingual gland is divided into monostomatic and polystomatic portions. The monostomatic portion of the gland is located primarily within the capsule of the mandibular salivary gland with a few lobules of tissue located close to the mandibular and sublingual ducts near the root of the tongue. The polystomatic portion is a group of small, scattered lobules that empty through several minor sublingual ducts into the oral cavity between the tongue and mandible.[1] The mandibular and sublingual salivary glands are intimately associated with one another as they share a common capsule. Their ducts are adjacent to one another and terminate in the same location. The openings of the ducts of the mandibular and the monostomatic portion of the sublingual gland are located beneath the tongue in a fold of mucosal tissue called the *sublingual caruncle*. Salivary mucoceles are most commonly caused by a defect in the sublingual gland or duct. Because of the close proximity of the mandibular and sublingual glands, treatment for salivary mucoceles requires excision of the mandibular and sublingual gland ducts to the level of the lingual nerve.[6-8] Buccal and lingual molar glands are present only in the cat. The buccal molar gland is located below the mucous membrane of the lower lip and empties into the vestibule through several small ducts. The lingual molar gland is located just lingual to the mandibular first molar in a fold of tissue. This gland also has several small openings unlike a common duct.[1]

Oropharynx

The pharynx is the common passageway for the respiratory and digestive systems. It provides a connection between the nasal and oral cavities to the trachea and esophagus and is pivotal in directing air, food, and fluids into the correct system. The pharynx encompasses the nasopharynx, oropharynx, and laryngopharynx. The nasopharynx is part of the respiratory system. It is located dorsal to the soft palate and extends from the choanae to the caudal free edge of the soft palate and the palatopharyngeal arches.[3] This caudal border is where the laryngopharynx begins. The oropharynx is part of the digestive system and lies between the soft palate, the base of the tongue, and the epiglottis. The laryngopharynx receives air from the nasopharynx and directs it to the trachea, and accepts food and water from the oropharynx and directs it to the esophagus. It is a part of both the respiratory and digestive systems and extends from the base of the epiglottis to the esophagus.[3]

The anatomic borders of the oropharynx are indistinct but can be correlated with certain structures. The dorsal border of the oropharynx is the ventral surface of the soft palate. The soft palate is the muscular continuation of the hard palate and is covered by stratified squamous epithelium on the ventral surface. Dorsal to the epithelium there are numerous palatine glands, which open on the ventral surface of the soft palate. The next layer is the muscular layer and includes the paired palatine muscles and the end portions of the paired tensor and levator veli palatini muscles. The arterial vascular supply of the soft palate includes the minor palatine arteries, the ascending pharyngeal artery, and the major palatine arteries. Venous drainage occurs through the palatine plexus.[2] The right and left pterygopharyngeal muscles originate from the pterygoid bones and pass laterally and dorsally along the pharynx and the caudal part of the soft palate to form the base for the palatopharyngeal arches. These arches are the caudal continuation of the soft palate and also demarcate the nasopharynx from the laryngopharynx.[2,4] The paired palatoglossal arches or folds are located at the rostral border of the soft palate and demarcate the end of the oral cavity and the beginning of the lateral borders of the oropharynx. These arches are not well-defined structures compared to humans because dogs and cats lack a palatoglossus muscle. When the tongue is pulled rostrally and laterally the fold is more visible and extends from the body of the tongue to the rostral border of the soft palate.[2] Soft palate defects are caused by disturbances during development of the secondary palate. These defects can occur on midline between the palatine muscles, or less commonly can be unilateral or bilateral and are located lateral to the palatine muscles. In bilateral defects of the soft palate, a remnant of tissue remains that is composed of portions of the levator and tensor palatini muscles, connective tissue, and mucosa.[9] In contrast to an abnormal or absent soft palate, brachycephalic breeds commonly have an elongated soft palate, which can interfere with the function of the glottis and epiglottis or the normal passage of air.[2,10]

The lateral walls of the oropharynx are termed the *fauces*. The fauces contain the palatine tonsils that reside within the tonsillar fossa. The tonsils are aggregates of lymphoid tissue located in the pharyngeal mucosa. They are not encapsulated like typical lymph nodes. The tonsils function as host defense at the mucosal level. Only efferent lymphatic drainage occurs as tonsillar tissue does not filter lymph.[2,4] The palatine tonsils are the only discrete bodies of lymphoid tissue. The other tonsils such as the pharyngeal and lingual are more diffuse. The pharyngeal tonsil is unpaired and is known as the adenoid in humans. The lingual tonsils are distributed over the entire surface of the base of the tongue.[11] The palatine tonsils arise from the second branchial cleft epithelium. The palatine tonsils often increase in size over time as an increase in lymphatic tissue and the system of crypts occurs, likely as a consequence of antigenic stimulation.[2,11] These crypts serve as physical antigen traps and the tonsils themselves form immunocompetent lymphocytes.[8] The palatine tonsils can be visible in some animals or they may be completely within the tonsillar fossa. Everted tonsils are more often seen in brachycephalic breeds, perhaps as a result of increased negative airway pressure causing eversion of the tonsils and laryngeal saccules.[10] The medial wall of the fossa is formed by the tonsillar fold that comes from the ventral surface of the lateral portion of the soft palate.[2] The deep portion of the tonsil is attached to the lateral wall of the pharynx. Efferent drainage of the palatine tonsils is into the medial retropharyngeal lymph node. Blood supply is derived from the tonsillar artery, which is a branch of the lingual artery. The palatine plexus provides venous drainage.[2]

Function of the Oropharynx

Prehension and Mastication

The most important functions of the oral cavity and oropharynx are their roles in prehension, mastication, bolus formation, and deglutition or swallowing. Prehension is the grasping and manipulation of food. In dogs and cats, prehension is generally achieved with the use of the tongue, teeth, and mandible. The lips play a very minor role in prehension and act more to keep food and fluids in the oral cavity. The olfactory nerve (CN I), optic nerve (CN II), trigeminal nerve (CN V), hypoglossal nerve (CN XII), and the cerebral cortex control the voluntary act of prehension.[12,13] Vertebrates with complete cheeks, such as pigs, sheep, and horses, use suction to draw liquid upward and use their tongue to transport it intraorally. In contrast, vertebrates with incomplete cheeks, including most carnivores, are unable to seal their mouth cavity to generate suction and must instead rely on their tongue to move water into the mouth. The cat accomplishes this through a rapid lapping mechanism that differs in function from the scooping mechanism of the dog.[14]

Mastication is the process of breaking down food into smaller pieces and coating it with saliva to prepare a food bolus for deglutition. The masticatory muscle group is composed of the paired temporalis muscles, masseter muscles, lateral and medial pterygoid muscles, and the digastricus muscles. The masseter, pterygoids, and temporalis muscles contain special type 2M skeletal muscle fibers, sometimes referred to as *superfast fibers*.[4,15] Masticatory muscle myositis, a disease characterized by painful inflammation, scarring, and contracture of the masticatory muscles, can be diagnosed by measuring serum 2M antibody. Autoantibodies against this specific type of myosin in these fibers are responsible for the immune-mediated process.[16] An increase in titer along with clinical signs confirms the diagnosis.[17] The muscles of mastication are innervated by the mandibular branch of the trigeminal nerve (CN V) except for the caudal belly of the digastricus muscle, which is innervated by the facial nerve (CN VII).[2] All of the muscles, except for the digastricus, act to close the jaws. The digastricus muscle contracts to open the jaws. The large size of the masseter and temporalis muscles and the action of the pterygoid muscles act to keep the jaws closed even at rest. Prehension, mastication, and bolus formation are voluntary whereas deglutition is strictly involuntary.

Deglutition

Deglutition is the transport of a bolus of food or liquid from the mouth to the stomach.[12] Normal deglutition requires precisely timed contraction and relaxation of numerous muscles of the oral and pharyngeal regions (Table 54-1).[18] After prehension and mastication the food bolus stimulates sensory receptors in the oropharynx that inhibit the muscles of mastication and allows swallowing to occur. The structures involved in deglutition include the tongue, hard and soft palate, pharyngeal muscles, esophagus, and gastroesophageal junction.[19] Coordination of swallowing is controlled by the trigeminal (CN V), facial (CN VII), glossopharyngeal (CN IX), vagus (X), and hypoglossal (CN XII) nerves and their nuclei. These nerves and nuclei are themselves controlled by areas of the reticular formation known as the swallowing center.[20] All of these nerves provide sensory and motor innervation except for the hypoglossal (CN XII), which provides only motor innervation.[21] The trigeminal nerve (CN V) carries sensory fibers from the oral cavity and motor fibers for the muscles of mastication and the soft palate muscles. The facial nerve (CN VII) contains sensory fibers from visceral receptors in the soft palate and nasopharynx, and motor fibers to the stylohyoid and omohyoid muscles. The glossopharyngeal nerve (CN IX) contains sensory fibers to the pharynx and some areas of the tongue. The vagus nerve (CN X) and the motor fibers of the glossopharyngeal nerve (CN IX) innervate nearly all of the muscles of the pharynx. The vagus nerve carries both visceral efferent and visceral afferent fibers to the pharynx. The visceral sensory nerves of the vagus nerve transmit impulses from the base of the tongue, pharynx, and esophagus to the medulla oblongata.[19]

Deglutition is divided into three phases: oropharyngeal, esophageal, and gastroesophageal. The oropharyngeal phase is controlled by the trigeminal (CN V), facial (CN VII), glossopharyngeal (CN IX), vagus (CN X), and hypoglossal nerves (CN XII). The oropharyngeal phase is further subdivided into three stages: oral, pharyngeal, and pharyngoesophageal.[12,13,19] The oral phase is voluntary and is controlled by cranial nerves V, VII, and XII. The food bolus is transferred into the oropharynx by the base of the tongue.

Once the food bolus reaches the pharynx, the involuntary pharyngeal phase begins. Sensory receptors in the oropharynx are stimulated and transmitted by cranial nerves V, IX, and X. The swallowing center in the medulla oblongata initiates the deglutition reflex and causes progressive contraction of the pharyngeal muscles to continue to propel the food bolus. To prevent aspiration the soft palate is elevated to seal off the nasopharynx and the entrance to the trachea is covered by the glottis and epiglottis (Figure 54-1). The pharyngeal phase is controlled by cranial nerves V, VII, IX, X, and XII. The final stage of oropharyngeal deglutition is the pharyngoesophageal phase. Cranial nerves IX, X, and the swallowing center control this stage. The cricopharyngeus and thyropharyngeus muscles of the cranial esophageal sphincter relax to allow the food bolus to pass into the cranial portion of the esophagus. The sphincter closes after passage of the bolus to aid in retention and to prevent aerophagia. A primary peristaltic wave in the esophagus is initiated after passage of the bolus (see Chapter 55).[12,13,19,20]

Table 54-1 Muscles and Motor Nerves Involved in Prehension, Mastication, and Deglutition

Muscle	Innervation	Action
Lingua propria, intrinsic tongue muscle (P, D)	Hypoglossus	Protrude the tongue, coordinate complex movements, prevent tongue from being bitten
Hyoglossus, extrinsic tongue muscle (P, D)	Hypoglossus	Retract and depress the tongue
Styloglossus, extrinsic tongue muscle (P, D)	Hypoglossus	Draw the tongue backward or depress the tongue
Genioglossus, extrinsic tongue muscle (P, D)	Hypoglossus	Depress the tongue, draw the tongue forward, curl the tip downward
Temporalis muscle (P, M)	Mandibular branch of trigeminal nerve	Closing the jaws
Masseter muscle (P, M)	Mandibular branch of trigeminal nerve	Closing the jaws
Medial and lateral pterygoid muscles (P, M)	Mandibular branch of trigeminal nerve	Closing the jaws
Digastricus muscle–rostral belly (P, M)	Mandibular branch of trigeminal nerve	Opening the jaws

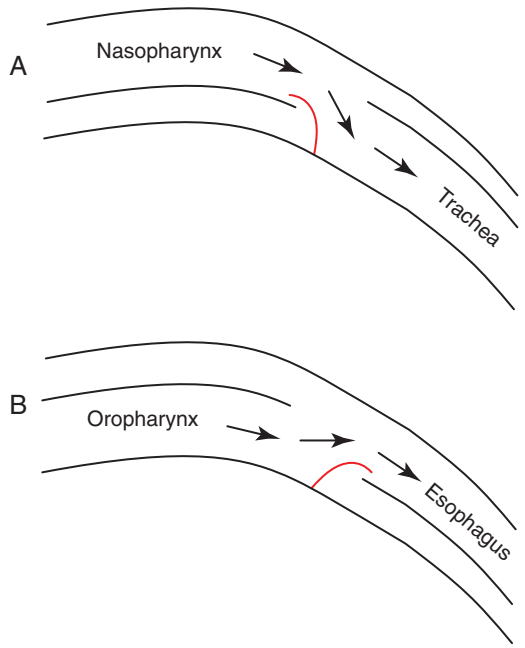

Figure 54-1 Diagram showing the changing position of the epiglottis (highlighted in the red zone) during inspiration (**A**) and deglutition (**B**). During inspiration, the epiglottis moves forward to close off the oropharynx and prevent food or liquids from entering the trachea. During deglutition the epiglottis moves caudally to cover the entrance to the trachea and again prevent movement of food or liquid into the trachea.

The beginning of the gastrointestinal tract is a complex group of structures that all act to promote nutrient intake, provide immunologic protection, and prevent aspiration and aerophagia, as well as other functions such as grooming and defense. The precise coordination of nerves, muscles, and other structures is very complicated. Any abnormality in these structures or their function can result in significant morbidity for the animal if alimentation is not precisely coordinated. Diagnosis of dysphagia requires intimate knowledge of the anatomy of the oral cavity and oropharynx as well as the neurologic control of this region.

INFLAMMATION

Linda DeBowes

Stomatitis

Clinical Manifestations

Stomatitis refers to inflammation within the oral cavity and clinical manifestations depend on the site(s), extent of inflammation, amount of pain, and the interference with normal function. Inflammation may range from superficial mucosal inflammation, erosion, and shallow to deep ulceration. Stomatitis includes inflammation of the gingiva; the buccal, vestibular, and sublingual mucosa; the tongue; and the palate.

The major clinical sign often is halitosis. Depending on the severity of stomatitis, there may be hypersalivation, drooling, decreased food intake, dysphagia, lethargy, depression, and weight loss (Figure 54-2). Patients with extensive inflammation and ulcers are often in pain and are apprehensive about being touched around their head or mouth. Oral examination should be attempted with

Figure 54-2 **A,** A dog with severe stomatitis showing drooling. **B,** Proliferative and ulcerated buccal mucosa in this patient.

Figure 54-3 Inflammation and rounding of the gingival margin in a dog with gingivitis.

these patients; however, when the lesions are too painful, this is done under anesthesia unless anesthesia is contraindicated.

Gingivitis is inflammation of the gingiva and may be limited to the marginal gingiva or include the attached gingiva (Figure 54-3). Focal areas of gingival hyperplasia may result from chronic inflammation. Contact ulcers are focal areas of inflammation and ulceration located on the buccal mucosa where it contacts plaque biofilm (Figure 54-4). Periodontitis involves the gingiva as well as the other tissues of the periodontium (i.e., cementum, periodontal ligament, alveolar bone). Oral examination may reveal gingival

Figure 54-4 Contact ulcer on the buccal mucosa opposite calculus on the canine tooth.

Figure 54-5 Gingival bleeding, recession, and exposed roots in a dog with periodontitis.

recession, gingival hyperplasia, root exposure, and mobile teeth (Figure 54-5).

Patients with stomatitis may have severe inflammation and ulceration of the gingiva, buccal mucosa, tongue, and palate (Figure 54-6). Inflammation of the tongue is often along the lateral margins and there may be ulceration are severe cases (Figure 54-7). Palatal inflammation and ulceration is usually linear or focal and range from superficial to deep ulceration. Patients with severe stomatitis may be in significant pain. Clinical signs may be severe halitosis, hypersalivation, drooling, and changes in behavior. The patients often refuse dry food and will eat only soft food. In very severe cases they refuse soft food as well. When cats with caudal stomatitis open their mouths to eat or yawn this can trigger intense pain, and they may vocalize, aggressively rub or scratch at their face, run away from their food, and have activities that the owners describe as a seizure. On physical examination there may be minimal external signs. In severe cases there is blood-tinged or thick-yellowish saliva, and saliva may adhere to the fur around the lips and on the front legs. Cats often have a matted and unkempt appearance. The inflammation of the mucosa is often disproportionately severe compared with the minimal amount of plaque and calculus on the teeth.

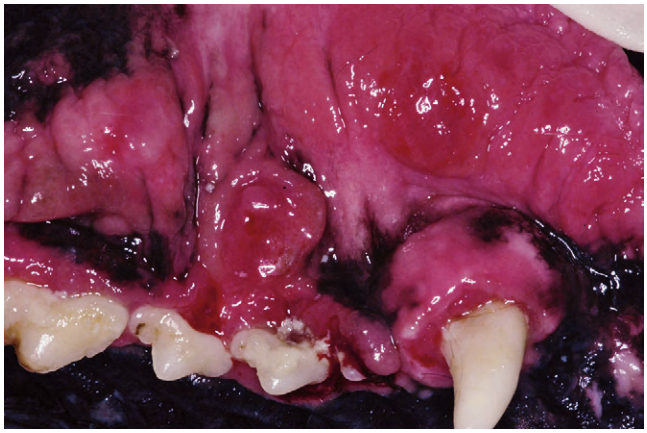

Figure 54-6 Dog with severe stomatitis, buccal and gingival inflammation, and ulceration.

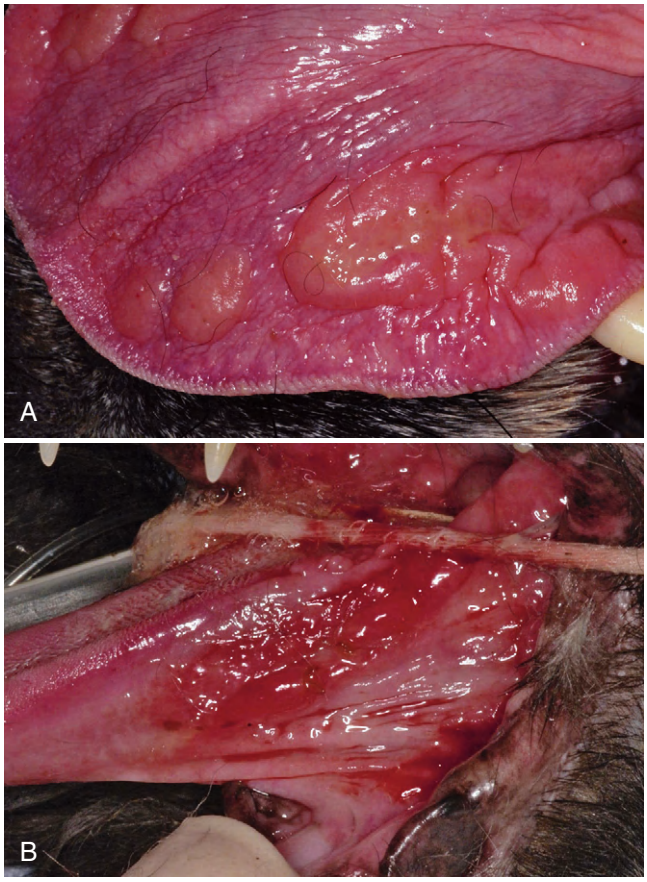

Figure 54-7 **A,** Lingual inflammation in a dog with periodontal disease. **B,** Lingual inflammation in a cat with caudal stomatitis.

The inflammation in cats with caudal stomatitis initially may be limited to the pterygomandibular raphe (Figure 54-8). Over time many cats with caudal stomatitis will also develop anterior stomatitis (Figure 54-9). Pharyngeal hyperplasia, in severe cases, can result in a narrowing of the pharyngeal opening, contributing to pain on swallowing (Figure 54-10). Oral examination of cats with severe caudal stomatitis may be difficult, but visualization is often possible if the mouth is opened very slowly and carefully. Inflammation of the tongue may be local or generalized and present as erythematous areas, erosions, or ulcers. Cats with lingual ulceration may have

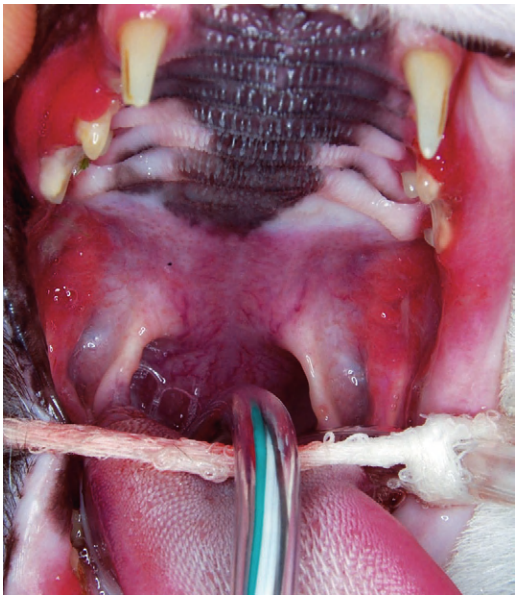

Figure 54-8 Caudal stomatitis in a cat.

Figure 54-11 **A,** Lingual ulcers in a cat with feline calicivirus infection. **B,** Oral ulceration in a cat with lingual oral neoplasia (hemangiosarcoma).

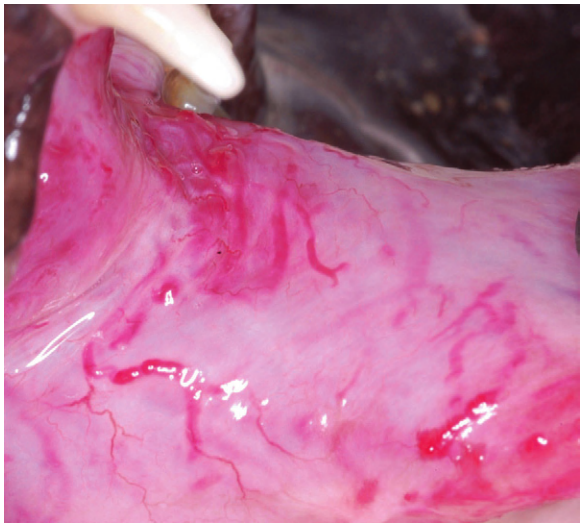

Figure 54-12 Sublingual hemangiosarcoma in the cat shown in Figure 54-11.

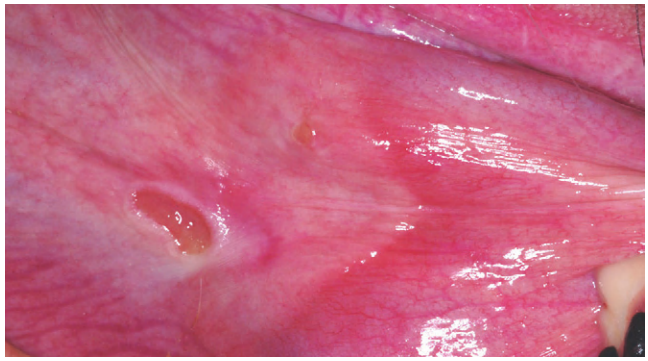

Figure 54-13 Sublingual eosinophilic granuloma in a dog.

clinical manifestations of upper respiratory tract infection. Lingual ulcers may be located anywhere but the most common areas are the rostral one-third of the tongue (Figure 54-11). Lingual ulcers associated with feline calicivirus (FCV) and feline herpesvirus (FHV)-1 are seen with the acute phase of the infection and when there is a recurrence of signs in a carrier cat.

Sublingual masses generally occur at the base of the tongue with varying degrees of inflammation, ulceration, and proliferation. When a lingual mass is present, especially if the base of the tongue is involved, the patient may have difficulty eating or drinking (Figure 54-12).

Eosinophilic diseases affecting the oral cavity occur more frequently in cats than in dogs.[1] The canine breed reported most commonly with eosinophilic granulomas is the Siberian Husky. Affected dogs have lesions primarily on the palate or tongue.[2,3] Eosinophilic granulomas have also been reported in Cavalier King Charles Spaniels.[4-6] Clinical signs may not be present and the lesions may be found incidentally on physical examination. Lesions on the palate or tongue are usually linear with raised margins, and a reddish color in the center but no ulceration (Figure 54-13). Eosinophilic granulomas in cats occur primarily at the base of the tongue, are proliferative with varying degrees of ulceration, and may have a similar appearance to sublingual squamous cell carcinoma. Clinical signs may include excessive licking and abnormal tongue movement with difficultly in eating or drinking.

Oral candidiasis may result in single or multiple erosions or ulcers of the mucocutaneous junctions and oral mucosa. Ulcers are nonhealing and erythematous, and are covered by whitish-gray plaques.[2,7]

Pemphigus vulgaris in dogs may be associated with severe inflammation and ulceration of the gingiva and oral mucosa. Ulcerated tissues are very erythematous and friable. Patients are usually in pain, are depressed, have difficulty eating, and prefer soft food. The severity of the inflammation is more than is expected with the minimal amount of plaque and calculus and inflammation is present even in edentulous areas.

Lymphoma in the oral cavity may be seen as raised, inflamed gingival tissues, or as a mass lesion.[8]

Patients with systemic diseases may have oral lesions as part of the presenting clinical signs. Vasculitis as a consequence of systemic disease may lead to oral lesions including ulcers and necrosis of oral mucous membranes and the tongue. Additional oral lesions that may be associated with systemic diseases include congestion, hemorrhage, glossitis, uremia-related oral ulceration, and lingual necrosis, especially at the tip of the tongue.[2]

Pathogenesis

Inflammation of the oral tissues is a common pathologic response when disruption of the normal oral mucosal barrier allows an inflammatory response in the epithelium or connective tissues.[9]

The depth and severity of an ulcerative lesion depend on the severity of the insult and inflammatory response. Erosion involves only the epithelium, ulceration occurs when the epithelium is lost, and deep ulcers occur when there is sloughing of inflamed necrotic material.

The masticatory mucosa of the gingiva, hard palate, and the dorsal surface of the tongue is a tough layer of keratinized stratified squamous epithelium that provides protection from compressive and shear forces.[10] This protective layer is less likely to be damaged with resulting inflammation compared with other areas in the oral cavity.

The lining of the oral mucosa is composed of nonkeratinized stratified squamous epithelium that is attached to underlying structures by loose, elastic connective tissue. The tightly adherent epithelial cells and intercellular ground substance compose the primary mucosal barrier and protect the underlying tissues against fluid loss and the ingress of potentially harmful environmental agents (e.g., microbial toxins and antigens). This permeability barrier also isolates organisms in the epithelial layer from larger molecules (e.g., antibodies, complement) in the subepithelial tissues. When antigens penetrate the mucosal barrier, antigen–antibody complexes, complement activation, and infiltration of inflammatory cells result in tissue destruction. Oral organisms on the surface of the epithelium do not penetrate the mucosal barrier unless the organism acquires a greater virulence or the host defenses are compromised.[10]

The protective function of the mucosal barrier may be damaged by trauma, immune-mediated disease, soluble toxins, altered mucosal barrier, and xerostomia.[10] When the mucosal layer is damaged or there is a decrease in cell renewal, epithelial and subepithelial inflammation may occur. Xerostomia and dehydration may result in ulceration and infection because of the role of salivary mucins in maintaining healthy epithelium.

Epithelial cell renewal is affected by age, stress, inflammation, chemotherapy, and radiation treatments. Mild epithelial inflammation stimulates cellular proliferation while severe inflammation suppresses cell proliferation.[10] Chemotherapeutic agents and radiation treatments limit the proliferative ability of the epithelium and connective tissue. Depending on the neoplastic disease and planned cancer treatment, the oral cavity should be evaluated and oral disease (e.g., dental) managed prior to treatment to prevent complications associated with mucositis.[11]

Oral ulcers occur in some forms of pemphigus. Autoantibodies are directed against components of the epidermis or subdermal tissues and the level at which cell separation occurs determines the depth of the ulceration.

In addition to limiting the proliferative ability of the epithelium and connective tissue, ionizing radiation has a direct effect on the large molecules that make up intercellular ground substance. These changes allow for an increase in vascular permeability, resulting in tissue edema and an inflammatory infiltration.

Secondary bacterial infections occur commonly when the mucosal tissues are compromised. When the normal endogenous microflora is altered, such as following prolonged broad-spectrum antibiotic therapy, oral candidiasis can occur.

The pathogenesis of periodontal disease depends on microbial plaque stimulating an initial inflammatory response. The host defense cells are stimulated to produce and release mediators capable of destroying the alveolar bone and periodontal connective tissue. Genetics plays a role in determining the host inflammatory response.[12,13]

Patients infected with *Cryptococcus neoformans* occasionally have oral involvement as part of the clinical manifestations of local or systemic disease. The lesions may include diffuse ulceration of the buccal mucosa, tongue, gingiva, hard palate, and lips as well as gingival proliferation. The more common clinical signs of cryptococcosis include sneezing, snuffling, nasal discharge, skin lesions, and a nasal mass.[8,14,15]

Vasculitis as a manifestation of systemic or local disease affects the circulation and oxygenation of tissues and may lead to destruction or necrosis of these tissues.[16]

Etiology and Differential Diagnosis

Stomatitis is defined as the inflammation of soft tissues of the oral cavity occurring as a result of mechanical, chemical, thermal, bacterial, viral, electrical, or radiation injury, or as a reaction to allergens or as a secondary manifestation of systemic disease.[17]

Mechanical causes of stomatitis include swallowing, chewing, or biting on abrasive substances (e.g., pinecones, sticks, plants, rocks). An object may become lodged in the mouth causing continuous mechanical trauma, inflammation, and infection until it is removed.

Caustic and irritating substances that come into contact with oral soft tissues cause inflammation, primarily on the dorsal one-third of the tongue, but inflammation can occur in other places as well. Examples of caustic and irritating materials are certain plants with small spikes, household products (e.g., cleaning supplies, bleach), foreign bodies (e.g., grasses, bark, wood, fertilizers, embedded hair), and medications (e.g., pancreatic enzymes). Biting on electrical cords can cause severe palatal and lingual inflammation and necrosis of soft tissues.

Focal areas of inflammation and ulceration of the maxillary or mandibular mucosa are common signs associated with squamous cell carcinoma, osteomyelitis, or other neoplasms. Inflammation and draining fistulas at the mucogingival line may be from endodontic infection or less commonly periodontal infection.

Caudal stomatitis in cats is secondary to altered immune function; however, the etiology has not been determined.[18] Various theories have been presented, including associations with FCV and *Bartonella henselae*.[19] FCV does appear to be associated with caudal stomatitis.[19-21] The role of FHV-1 in caudal stomatitis is unknown; however, in one study the majority of cats with caudal stomatitis were shedding both viruses.[21]

Eosinophilic diseases in most cases are attributable to hypersensitivity reactions to insects (e.g., fleas and mosquitoes), environmental antigens (e.g., atopic dermatitis, foods), or other antigenic stimulation. Eosinophilic granulomas in some cats may be a result of imbedded insect parts; in many cases, however, the specific etiology remains unknown.[1] Pemphigus vulgaris, bullous pemphigoid, and pemphigus foliaceus may have oral manifestations. Of these, pemphigus vulgaris is most likely to have oral manifestations and up to 75% to 90% of dogs with this disease have involvement of the oral cavity. Oral lesions are the initial clinical signs in 50% of cases.[2]

Painful oral ulceration and inflammation may occur following radiation treatment or chemotherapy.

Extension of diseases such as neoplasia (e.g., squamous cell carcinoma) and infection into the oral cavity can occur, resulting in inflammatory lesions within the oral cavity.[22]

Systemic diseases also may have oral manifestations. Renal failure and vasculitis (e.g., rickettsial diseases) from any cause may result in oral manifestations (Figure 54-14).[16] Mucosal erosion and ulceration may be present in patients with systemic lupus erythematosus. Bacterial (e.g., *Francisella tularensis*, *Leptospira canicola*), fungal

Figure 54-14 Oral squamous cell carcinoma in a cat.

(e.g., *C. neoformans*), and viral infections, neoplasia, and drug reactions all have the potential for oral manifestations.[8,23,24]

Diagnosis

Diagnosis of stomatitis begins with a complete history and physical examination. It is usually possible to determine when oral lesions may be a manifestation of a systemic disease. Diagnosis of systemic diseases is beyond the scope of this chapter.

Stomatitis caused by irritating or inflammatory materials may be diagnosed based on the history and oral examination. Contact irritants (e.g., rubber toys, chemicals) may be suspected based on history and response to removal. Traumatic stomatitis is often identified based on the history and oral examination; however, an oral examination under anesthesia may be required to identify the cause (e.g., penetrating foreign body) and consequences of the trauma. Embedded materials (e.g., plant materials) may not be visually apparent and biopsy and histopathology should be performed if embedded materials are suspected.

Caudal stomatitis in cats is a clinical diagnosis and is present only when there is inflammation of the pterygomandibular raphe. This is important because there are specific treatments for caudal stomatitis that do not apply to stomatitis elsewhere in the mouth. Histologic examination reveals inflammation and does not add to the diagnosis; however, when neoplasia is suspected based on the clinical appearance, histological examination should be undertaken (see Figure 54-14).

Periodontal disease and the extent of disease are diagnosed by oral examination and dental radiography. Buccal and lingual inflammation associated with periodontal disease (e.g., contact ulcers) is also a clinical diagnosis.

Eosinophilic granuloma (complex) is diagnosed by histopathology (rules out other problems); the underlying etiology, however, may require additional evaluation (e.g., dietary trials).[1]

Histopathology is necessary for the diagnosis of pemphigus vulgaris, oral candidiasis, and neoplasia.[7]

Treatment

Initial treatment is removal of any topical substances that may have caused the stomatitis. Oral hygiene to reduce bacterial load, pain management, treatment of secondary bacterial infections, and nutritional support should be considered. Oral manifestations of systemic diseases are treated as for any stomatitis in addition to the treatment of the primary systemic disease.

Pain management is especially important initially when there is severe inflammation and ulceration. Oral antimicrobial rinses (e.g., 0.12% chlorhexidine gluconate) are often used until the epithelium has healed. Secondary bacterial infections may occur in cases that do not rapidly resolve and systemic antibiotics may be necessary in addition to the topical rinses.[25]

Periodontal disease treatment planning is based on the extent of disease. Complete periodontal treatment planning is beyond the scope of this chapter.[13]

Eosinophilic granuloma complex may be treated with short courses of glucocorticoids if the lesions are mild and occur only once to twice a year.[1] If lesions are progressive in severity or frequency, a more complete evaluation for the cause should be undertaken. Higher doses and longer durations of glucocorticoids, antibiotics, and cyclosporin may be used in the more severe cases.[1]

Treatment of caudal stomatitis has been widely debated over the years; however, the first treatment should be extraction of all premolar and molar teeth. In some patients with severe anterior stomatitis accompanying the caudal stomatitis, extraction of the canine and incisor teeth may also be necessary. Medical treatment following surgical extractions may include antibiotics, glucocorticoids, or cyclosporin. Medical management should not be used in place of extractions for long-term management. Clindamycin, amoxicillin-clavulanate acid (Clavamox), and metronidazole are commonly used oral antibiotics. If glucocorticoids are used as an adjunct to extraction, they should be used at the lowest doses necessary. Cyclosporin has been used for the management of cats with persistent clinical signs following extractions. Cats should be treated for at least 8 weeks to assess the clinical response.[26] Potential side effects of cyclosporin are gingival hyperplasia, excessive shedding, and hypertrichosis.[27,28] The immunosuppressive effects of cyclosporin may result in development of infections or the emergence of an existing subclinical infectious disease (e.g., toxoplasmosis).[29-31] Although lactoferrin, gold salts, and other miscellaneous treatments have been recommended, there is no evidence that they have any clinical benefit. Newer therapies that have been proposed are omega interferon (Virbagen Omega, Virbac) and T-cell receptor (TCR) peptides (TCR Vax). Anecdotally, cats with an incomplete response to extractions have improved with Virbagen Omega; however, this product is not licensed in the United States. The administration of a TCR vaccine for treatment of caudal stomatitis in cats has been proposed (www.imulan.com). TCR Vax is undergoing field trials and is not yet commercially available.

Pemphigus vulgaris is difficult to treat and multidrug therapy is often necessary. High-dose glucocorticoid administration either alone or in combination with another immunomodulatory medication is usually recommended. Azathioprine is the secondary immunomodulatory medication most commonly used.[32] Gold salts, chlorambucil, and tetracycline-niacinamide are other options for the treatment of pemphigus. Alternative therapeutics may be tried when the response to the commonly used drugs is not adequate. Intravenous immunoglobulin (IVIg) has been suggested as an alternative therapeutic for treating dogs.[32] IVIg used in humans for the treatment of pemphigus has shown beneficial results and a better quality of life when compared with other therapeutics.[33]

Mucositis secondary to chemotherapy or radiation treatment is managed with palliative care. Pain medications, topical rinses (e.g., CET rinse), and soft foods are used during the healing phase. Infections (e.g., candidiasis) and systemic complications may occur during treatment or after treatment.[25]

Prognosis

The prognosis for resolution of clinical signs in cats with caudal stomatitis is dependent on the treatment, severity of disease, concurrent viral (e.g., FCV) infection, and duration of disease. An excellent response following extraction may be achieved, especially when treated at an early stage. Extraction of the premolars and molars carries the best long-term prognosis for resolution.[34] The prognosis is poor to guarded when extractions are not done and when tooth roots have not been removed. Cats that do not have a successful or significant improvement in clinical signs following extraction are medically managed. There is a varied response in these cats and some may have excellent responses. In one study, cyclosporin treatment resulted in remission in four of eight cats and fair to good improvement in the other cats.[26]

Eosinophilic granuloma, especially in dogs, may spontaneously regress. Eosinophilic granulomas in cats may respond well to three monthly subcutaneous injections of a long-lasting glucocorticoid. Cyclosporin for treatment and maintenance is reported to be beneficial.[26]

Radiation mucositis is an acute reaction and should start to heal by 10 to 14 days after treatment has ceased. However, the prognosis depends on the amount of radiation that the tissue was exposed to. The prognosis is guarded in patients with severe mucositis and poor healing.[25] Postradiation osteonecrosis has a poor prognosis and a comprehensive assessment and oral care should be done before radiation therapy.[35]

Pemphigus vulgaris has a guarded prognosis because of the potential for secondary infections, high doses of medication necessary to control the disease, and the difficulty of maintaining the patient in remission.

Pharyngitis

Clinical Manifestations

The pharynx is divided into three areas: nasopharynx, oropharynx, and laryngopharynx. Clinical manifestations vary depending upon the location and extent of the inflammation, the etiology, and the involvement of adjacent structures. The most common clinical manifestations include dysphonia (voice change), snoring, coughing, gagging, dysphagia, inappetence, and hypersalivation. When stomatitis occurs concomitantly with pharyngitis there may be clinical signs of each. Secondary tonsillitis is often present in association with pharyngitis. Clinical manifestations of tonsillitis are similar to those of pharyngitis (Figure 54-15).

Nasopharyngeal foreign bodies can cause coughing, sneezing, epistaxis, gagging, discomfort on pharyngeal palpation, and open-mouth breathing.[36] Obstructive masses may result in dyspnea, stridor, open-mouth breathing, snoring, and gagging.[36-38]

Disease involving extrapharyngeal sites have additional clinical manifestations and signs of disease (e.g., neurologic signs, ocular discharge, repeated head shaking) depending on the involved site, disease process, and extent of disease.[38]

Pathogenesis

The pharyngeal tissues have the same mucosal barrier as in the oral cavity. Therefore pharyngitis has the same pathogenesis for inflammation as stomatitis.

Etiology and Differential Diagnosis

Pharyngeal inflammation can occur from trauma, caustic or irritating substances, infectious diseases, obstructive masses, foreign bodies and as an extension of rhinitis, sinusitis, caudal stomatitis, and drainage of a local abscess (e.g., retrobulbar abscess) (Figure 54-16).[36,39] Caustic or irritating substances are similar to those causing stomatitis. Pharyngitis caused by chronic coughing, regurgitation, or vomiting may cause irritation resulting in pharyngitis. Severe cases of caudal stomatitis in cats can extend into the oropharynx. Sino-orbital aspergillosis may extend into the palate and nasopharynx resulting in clinical signs of pharyngitis.[21,40,41]

Nasopharyngeal diseases include lymphoma and inflammatory polyps.[40,41] Feline inflammatory polyps that expand into the nasopharynx as well as other obstructive masses in the oral cavity or nose, may obstruct the flow of air and the exaggerated respiratory efforts result in laryngeal inflammation (Figure 54-17).[38] The etiology of feline inflammatory polyps has not been determined.[38] Tissue from 41 inflammatory polyps was evaluated by polymerase chain reaction for the presence of FCV and FHV-1; negative findings

Figure 54-15 Bilateral tonsillar enlargement with histologic evidence of chronic inflammation and fibrosis.

Figure 54-16 Focal area of inflammation and drainage from a retropharyngeal abscess.

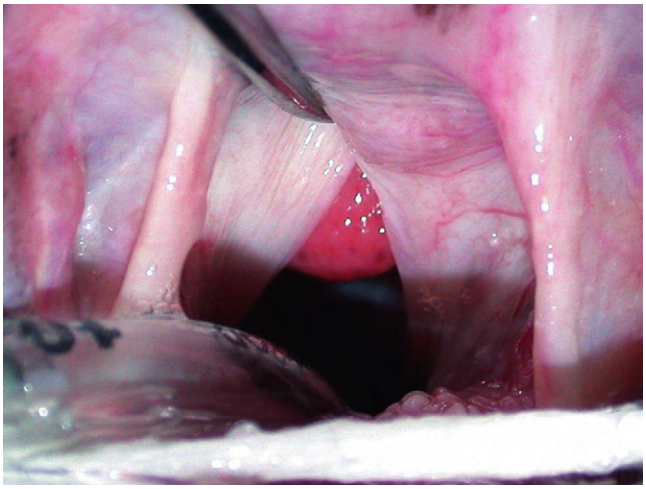

Figure 54-17 Feline inflammatory polyp.

suggested that these viruses are not involved with the pathogenesis of inflammatory polyps.[38]

Diagnosis

History and oral examination will lead to the clinical diagnosis of pharyngitis. Direct oral examination may be sufficient in diagnosing topical contact with caustic or irritating substances, trauma, foreign bodies, or mass lesions. Rhinoscopy and retroflex nasopharyngoscopy may be required for adequate visualization and collection of tissue for histopathology.

Radiography is generally not necessary in diagnosing the etiology of pharyngitis. Radiography may be necessary for diagnosing pharyngitis from a radiodense penetrating foreign body (e.g., needle) or pharyngitis secondary to extrapharyngeal disease.

Treatment

Removal or treatment of the primary etiology applies to all patients with pharyngitis. In addition, pain management, topical antimicrobial rinses, systemic antimicrobials, and fluid and nutritional support should be considered for each patient.

Topical irritants, depending on the source, should be removed as much as possible by rinsing the mouth. Foreign bodies are removed using direct visualization.[36]

Nasopharyngeal inflammatory polyps in cats with normal bulla may be treated (removed) by traction avulsion.[38] A novel approach to removal of polyps using an endoscope passed into the nasopharynx via a gastrotomy has been described.[42]

Nasopharyngeal stenosis in cats may be treated by balloon dilation under general anesthesia.[43,44] Restenosis may occur and it may be treated with another balloon dilation. When retreatment is necessary, the application of topical steroids or an antifibrotic agents may be tried to decrease the degree of another restenosis.[43]

Prognosis

There is an excellent prognosis in acute primary pharyngitis when the source of topical trauma or irritant can be removed. Nasopharyngeal foreign bodies may have a varied prognosis depending on the ability to remove the foreign body atraumatically and manage local complications that can occur from a perforation of the nasopharynx. The prognosis is worse when there has been a perforation.

Feline inflammatory polyps have an excellent response to removal. Feline nasopharyngeal stenosis has a good to excellent response following balloon dilation.[43] The prognosis for other problems that may cause pharyngitis depends on the underlying disease and its response to treatment.

Sialadenitis

Clinical Manifestations

Enlarged, painful salivary glands, hypersalivation, dysphagia, repeated attempts at swallowing, pain on opening the mouth, xerostomia, decreased food intake, and depression are all potential manifestations of sialadenitis.

Pathogenesis

The pathogenesis of salivary gland inflammation may be idiopathic, infectious (e.g., bacterial, viral, mycotic), traumatic, secondary to xerostomia or dehydration, ductal obstruction, or organic disease of the gland (e.g., Sjögren syndrome). Acute bacterial infections of the salivary gland are usually a result of an ascending infection. Xerostomia or dehydration may contribute to the development of ascending bacterial infection by decreased salivary flow and alteration of the normal oral flora.[45,46] Hematogenous spread of infection from other areas also may cause a bacterial sialoadenitis.[47]

Etiology and Differential Diagnosis

Ascending bacterial infections are most likely to be caused by anaerobic periodontal pathogens.[48] Decreased salivary gland flow may occur secondary to dehydration, salivary duct obstruction, or decreased saliva production. Acute salivary gland inflammation or chronic inflammation with fibrosis may decrease salivary gland production. Systemic disorders that may lead to inflammation include autoimmune sialadenitis (e.g., Sjögren syndrome) and vasculitis.[49] Sialadenitis is uncommon in dogs and cats. Differentials for enlarged salivary glands include sialadenitis, sialadenosis, and infiltrative disease.

Diagnosis

Diagnostic tests may include fine-needle aspirate cytology, culture and sensitivity, histopathology, ultrasound, and radiography (e.g., films and contrast sialography). Fine-needle aspirate cytology of enlarged salivary glands is the initial diagnostic test and may reveal the presence of salivary gland inflammation.[50] Bacterial culture and sensitivity of exudate from the orifice of the salivary duct or the salivary gland is recommended.[47] Ultrasound of the salivary gland can help to differentiate obstructive from nonobtrusive sialadenitis and identify masses and abscess formation.[51] Radiography, including plain films and contrast sialography, may identify radiopaque salivary calculi and ductal or glandular changes. Histopathology may reveal neutrophils in the ducts and small abscesses in the interstitium.[47]

Treatment

Sialadenitis is treated with supportive care, antiinflammatories, and antibiotics.[52] Abscesses may be treated by antibiotics in addition to drainage using ultrasound guidance.[51]

Prognosis

Ascending bacterial infections and acute sialadenitis may be treated very successfully if there are no ductal or glandular obstructions. Salivary duct obstruction generally has a good prognosis, especially in acute cases.

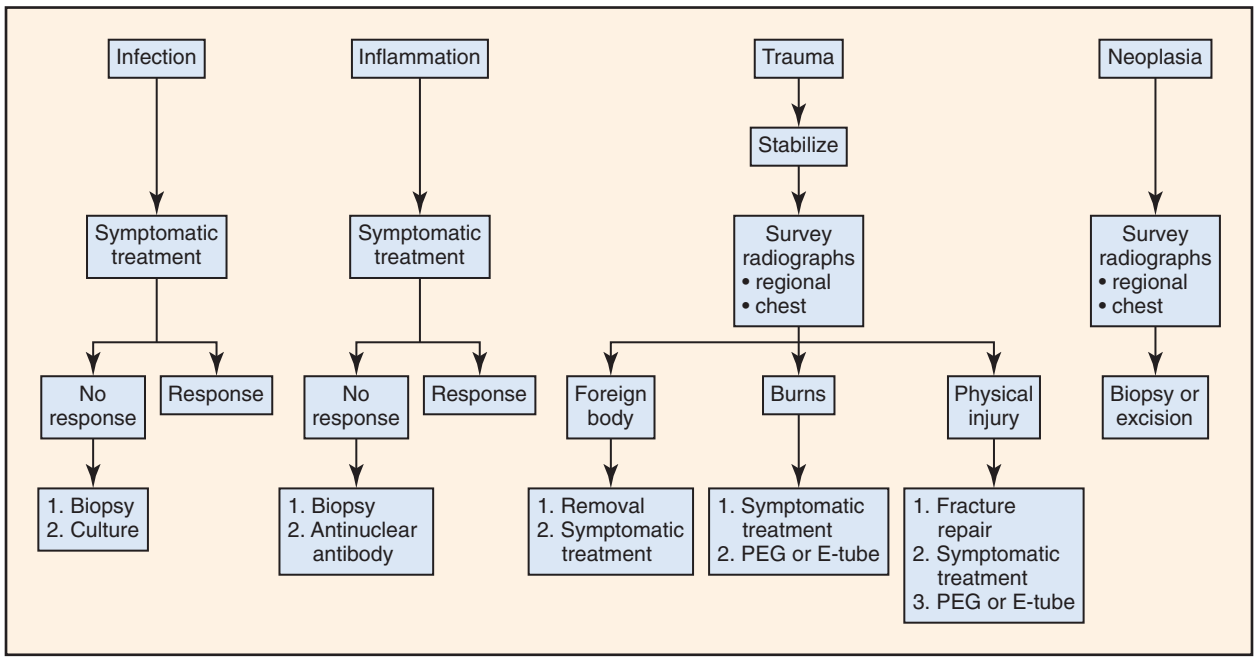

Figure 54-18 Medical investigation of a morphologic oropharyngeal motility disorder. E, Esophageal; PEG, percutaneous endoscopic gastrostomy.

DYSMOTILITY

Robert J. Washabau

Etiology

Oropharyngeal motility in health requires the highly coordinated propagation of food and water in the oral, pharyngeal, and cricopharyngeal stages of swallowing.[1-4] Oropharyngeal dysmotility is associated with the primary clinical signs of dysphagia, gagging, and salivation (see Chapter 13).[5] Dysmotility syndromes are broadly classified as anatomic or functional in origin. The anatomic disorders are those processes that interfere with oropharyngeal motility because of infection, inflammation, trauma, and neoplasia (Figure 54-18). The functional disorders are of three main types: oropharyngeal dysphasia, cricopharyngeal dysphagia, and cricopharyngeal achalasia (Figure 54-19).

Physiology and Pathophysiology

The oropharyngeal phase of feeding is entirely under voluntary control. Feeding is guided by social conditions for domesticated animals, and by the fight-or-flight response for animals in the wild. The oropharyngeal phase of feeding consists of three stages: prehension, mastication, and deglutition (swallowing).[5] see Structure and Function section for more detail on the process of swallowing.

The first stage of oropharyngeal motility begins with the prehension of food and water with teeth and tongue. Land animals have evolved diverse means to acquire water, including absorption through the skin and the extraction of moisture from food, but most rely on drinking. Vertebrates with complete cheeks, such as pigs, sheep, and horses, use suction to draw liquid upward and use their tongue to transport it intraorally. In contrast, vertebrates with incomplete cheeks, including most carnivores, are unable to seal their mouth cavity to generate suction and must rely on their tongue to move water into the mouth. When the tongue sweeps the bottom of a shallow puddle, the process is referred to as *licking*.[6,7] When the puddle is deeper than the tongue excursion into the liquid, it is called *lapping*. The domestic cat and dog lap by a subtle mechanism based on water adhesion to the dorsal side of the tongue. Fluid inertia is exploited to defeat gravity and pull liquid into the mouth. The competition between inertia and gravity sets the lapping frequency.[6,7]

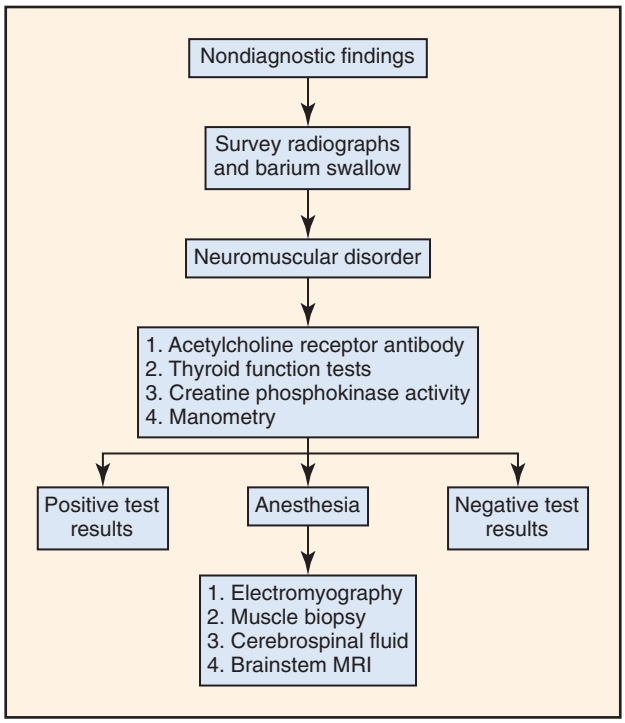

Figure 54-19 Medical investigation of a functional oropharyngeal motility disorder. MRI, Magnetic resonance imaging.

Table 54-2 Differentiation of Clinical Signs: Diseases of the Oral Cavity, Esophagus, and Stomach

Clinical Sign	Oral Cavity	Esophagus	Stomach
Dysphagia	Always present	Sometimes present	Absent
Regurgitation	Absent	Present	Absent
Vomiting	Absent	Absent	Present
Salivation	Usually present	May be present	May be present
Gagging	Often present	Usually absent	Absent
Ability to drink	Abnormal	Normal	Normal
Bolus formation	Abnormal	Normal	Normal
Dropping food	Present	Absent	Absent
Ejection time	Immediate	Delayed (minutes to hours)	Delayed (minutes to hours)
Character of food	Undigested	Undigested	Digested, bile stained, acidic pH
Odynophagia	Occasional	Frequent	Absent
Swallowing	Multiple	Single to multiple	Usually single

Mastication is the next stage in the process of breaking down food into smaller pieces and coating it with saliva to prepare a bolus for deglutition (swallowing).

In the final stage, rostral to caudal pharyngeal contractions propel the bolus from the base of the tongue to the cricopharyngeal or cranial esophageal sphincter opening. The cricopharyngeus relaxes during the final stage, and the bolus passes into the cranial esophageal body. Following bolus passage, the cricopharyngeus subsequently contracts, pharyngeal muscles relax, and the oropharyngeal phase is repeated until the completion of feeding.[1-4]

Prehension, *mastication*, and *deglutition* are controlled by the hypoglossal nerve (tongue movement), trigeminal and facial nerves (jaw movement), and glossopharyngeal and vagus nerves (pharynx constriction and relaxation, and soft palate movement) (see Table 54-1).[8] Disorders of the cranial nerves, neuromuscular junction, and striated musculature can result in significant oropharyngeal dysphagia.

Dysphagia, gagging, and hypersalivation are the most important clinical signs with oropharyngeal disorders. Other signs include difficulty in drinking water or forming a solid bolus; excessive mandibular or head motion; persistent forceful ineffective swallowing efforts; dropping of food from the mouth; nasal discharge because of misdirection of food into the nasopharynx; excessive salivation; foaming from the mouth; coughing; failure to thrive; and reluctance to eat (Table 54-2). Regurgitation, a common sign of esophageal disease, is less frequently reported with diseases of the oropharynx.

Clinical Examination

Physical examination findings are dependent upon both pathogenesis and disease severity. Many anatomic abnormalities (e.g., neoplasia, stricture, inflammation, foreign body) are readily apparent on physical examination alone. Animals with functional disorders, on the other hand, may have few anatomic abnormalities. Focal or generalized muscle atrophy and diminished or absent gag reflex may be the only abnormal findings in animals with functional disorders of the oropharynx. Figures 54-18 and 54-19 outline an approach to the diagnosis oropharyngeal dysmotility. The diagnosis of an anatomic abnormality is usually straightforward and, except for tissue biopsy or culture, does not usually require any additional diagnostic testing. (Examples of each of the anatomic disorders may be found in: "Inflammation", "Neoplasia", "Granuloma", and "Trauma" sections.) Survey radiography, ultrasound, computerized tomography, and magnetic resonance imaging (MRI) may be performed to assess for either the severity of local traumatic injury or for distant metastasis.[4] The diagnosis of the functional motility disorders is more difficult and likely requires the use of videofluoroscopy[3,5,9] and/or electrophysiology.[2] If these techniques are not readily available in the private practice setting, cases could be referred to a specialty center.

Diagnosis

Videofluoroscopy is useful in the further classification of the functional disorders.[3,5] The videofluoroscopy findings of *oral* stage dysphagias are typified by weak tongue-thrust action, retention of contrast medium in the oropharynx, and loss of contrast medium from the mouth. Aspiration pneumonia is not a typical finding in oral stage dysphagias. Videofluoroscopic findings consistent with a *pharyngeal* stage dysphagia include incomplete pharyngeal contraction with adequate cricopharyngeal relaxation, slow induction and slow progression of peristaltic-like contractions from the rostral to the caudal pharynx, and laryngotracheal aspiration. Aspiration pneumonia is a typical finding in pharyngeal stage dysphagias. In *cricopharyngeal* stage dysphagia, the cricopharyngeus fails to relax (achalasia) or relaxes at an inappropriate time (incoordination) following pharyngeal contraction.

Electromyography may be useful in distinguishing oropharyngeal dysphagia and cricopharyngeal dysphagia from cricopharyngeal achalasia. Fibrillation and positive sharp waves observed in oropharyngeal musculature suggest that the disorder involves the structures of the oral cavity and pharynx instead of the cricopharyngeus.

Other diagnostic tests that may be warranted after an oropharyngeal dysphagia or cricopharyngeal dysphagia has been diagnosed are serology for nicotinic acetylcholine receptor antibody, antinuclear antibody, thyroid function test, serum creatine phosphokinase activity, muscle biopsy, and brainstem magnetic resonance imaging (see Figure 54-19). Esophageal disorders are the major differential diagnoses for the oropharyngeal dysmotility syndromes.

Oropharyngeal Dysphagia

Oropharyngeal dysphagia represents a disruption in the coordinated transport of food and water from the oropharynx to the hypopharynx. If morphologic abnormalities (e.g., infection, inflammation, trauma, neoplasia) can be excluded, neuromuscular disease is the likely underlying pathogenesis. The precise etiology is often more difficult or impossible to identify. Some cases are associated with

Table 54-3 Treatment of the Functional Oropharyngeal Motility Disorders

Disorder	Diagnostic Test	Therapy
Myasthenia	Ach R Antibody	Pyridostigmine
Myositis	Antinuclear antibody	Glucocorticoids
Hypothyroidism	TSH, T_4/T_3	Thyroid hormone
Brainstem disease	MRI, CSF tap	Nutritional support

Ach R, acetylcholine receptor antibody; CSF, cerebrospinal fluid; T_4/T_3, thyroxine/triiodothyronine; TSH, thyroid-stimulating hormone.

brainstem disease (e.g., meningioma), cranial nerve neuropathy, myasthenia gravis, polymyositis, muscular dystrophy, and hypothyroidism. A unique form of oropharyngeal dysphagia bearing some resemblance to muscular dystrophy has been described in the Bouviers des Flandres breed.[10-12] Fluoroscopy demonstrates absence of aboral pharyngeal contraction, incomplete bolus transport, and dropping of food and water. Differentiating between oropharyngeal dysphagia, cricopharyngeal dysphagia, and cricopharyngeal achalasia is crucial, as the treatment for cricopharyngeal achalasia (myotomy or myectomy) could significantly exacerbate clinical signs in dogs affected with more proximal oropharyngeal dysphagia. Table 54-3 outlines treatments for each of the causes of oropharyngeal dysphagia. For those of known or unknown etiology, long-term management may require permanent gastrostomy or enterostomy tube feedings. Consequently, the prognosis for the oropharyngeal dysphagias is guarded at best, and affected animals will require significant home care.

Cricopharyngeal Dysphagia

Cricopharyngeal dysphagia is a rare swallowing disorder of the cricopharyngeus (cricoesophageal sphincter) characterized by cricopharyngeal asynchrony or dyssynchrony. Affected animals have many of the same clinical signs as seen with oropharyngeal dysphagia. Cricopharyngeal dysphagia or asynchrony is an incoordination between contraction of the dorsal cranial and middle pharyngeal contractor muscles (i.e., the hyopharyngeal, pterygopharyngeal, and palatopharyngeal muscles) and relaxation of the cricopharyngeus.[13,14] Cricopharyngeal dysphagia likely represents an abnormality of the central pattern generator with incomplete coordination of the contraction–relaxation cycle of oropharyngeal and cricopharyngeal motility. Cricopharyngeal myotomy or myectomy have been recommended in the treatment of this disorder. Although some animals have improved with this therapy, others have not.[14-16] The prognosis for this disorder is guarded as well, and the patients may be at increased risk for aspiration pneumonia.

Cricopharyngeal Achalasia

Cricopharyngeal achalasia is a neuromuscular disorder of young dogs characterized by (a) hypertension of the cranial esophageal sphincter (cricopharyngeus) and (b) inadequate relaxation of the sphincter with swallowing. In this disorder, the lesion is purely sphincteric. Proximal oropharyngeal motility is entirely normal. The underlying pathogenesis has not been elucidated, but a dysfunction in the inhibitory neuron mediating sphincteric relaxation has been postulated. To reduce sphincteric hypertension, calcium channel antagonists have been used to treat this disorder, but without success.[17] (Calcium channel antagonists are more effective in smooth muscle sphincters versus the striated muscle of the cricopharyngeus.) Myotomy or myectomy should be considered and will usually resolve the dysphagia seen in this disorder.[14-16] The cricopharyngeal and thyropharyngeal muscles can be approached through a standard, ventral midline approach, with 180-degree rotation of the larynx on its longitudinal axis, or through a lateral approach, with 90-degree rotation of the larynx. Cricopharyngeal myotomy involves transecting the cricopharyngeal muscles to the level of the pharyngeal mucosa. Several authors have combined cricopharyngeal myotomy with partial or complete thyropharyngeal myotomy. Cricopharyngeal myectomy entails removal of a portion of the cricopharyngeal muscles, rather than simple incision. The muscle fibers are separated from the mucosa and excised. Both procedures (myotomy and myectomy) appear to be effective. Myectomy may be more permanent in its effect.

Treatment/Management

General Principles

Except for cricopharyngeal achalasia, which is treated surgically by cricopharyngeal myotomy or myectomy, oropharyngeal and cricopharyngeal dysphagias are best treated medically. Cricopharyngeal myotomy appears to be of no benefit in oral, pharyngeal, or cricopharyngeal stage dysphagias; indeed, more proximal dysphagias may be worsened by cricopharyngeal myotomy.

Medical (Drugs and Diet)

The medical therapy for oropharyngeal and cricopharyngeal dysphagias is mostly supportive and consists of nutritional support (e.g., gastrostomy tube feeding) on a temporary or permanent basis. Elevated feedings and different food consistencies may be attempted, but these efforts are often of little clinical benefit. In early cases of myasthenia gravis, acetylcholinesterase inhibitors (e.g., pyridostigmine, 1 to 3 mg/kg PO, BID-TID) may yield substantial clinical improvement.[18,19] Glucocorticoid therapy (prednisone, 1 to 2 mg/kg PO, BID) also improves clinical signs in many myasthenic and polymyositis patients, although many cases of canine myasthenia gravis appear to resolve spontaneously without immunosuppressive therapy.[20] Thyroid hormone replacement therapy (levothyroxine, 22 µg/kg PO, BID) should be attempted in animals with documented hypothyroidism.

NEOPLASIA

Antony S. Moore

Most oral tumors are diagnosed at an advanced stage of growth and therefore many pets show similarly advanced clinical signs. Regardless of the tissue of origin, cats and dogs with oral tumors present for drooling, halitosis, and (occasionally) dysphagia. Most patients have shown signs for 3 months or less, but some may show signs for 6 to 12 months before diagnosis. With more routine dentistry performed, some tumors are diagnosed at an earlier stage, and this has been reflected in recent changes to prognosis (specifically, early diagnosis of oral melanoma in dogs may confer a reasonable chance for long survival). Loose teeth at dentistry may be the first signs of oral squamous cell carcinoma (SCC) in cats. Biopsy of any ulcerated mucosal tissue is warranted in older cats with dental disease.

Before obtaining a biopsy or attempting surgical resection of an oral tumor, all dogs and cats should have their general good health confirmed with a minimum database, including hematology and

urinalysis. Thoracic radiographs should be obtained to rule out macroscopic pulmonary metastases or other intercurrent disease. Fine-detail radiographs of the affected area, including the dental arcade, provide information on tumor infiltration. Radiographs should not be relied on for surgical margins because more than 50% of the bone must be replaced by tumor before lysis is evident radiographically. Computed tomography (CT) is a more accurate method of delineating the margins of a tumor and will allow planning of surgical margins or radiation therapy. Local lymphadenopathy should be further investigated by fine-needle aspiration (FNA) or biopsy performed at the same time as tumor biopsy. In one study of 100 dogs with oral melanoma, 60% of enlarged lymph nodes had cytologic evidence of metastases, but metastases were also detected in 40% of normal-size lymph nodes.[1] Thus, even normal-size lymph nodes should be aspirated. A preoperative biopsy of the primary tumor will guide the veterinarian as to the type of surgery needed and the prognosis.

The first surgical excision is the most likely to result in tumor control. The tumor should not be scraped or peeled from underlying bone, as recurrence is certain and the tumor bed will be enlarged. A definitive aggressive first surgery, such as maxillectomy or mandibulectomy, should be performed.

General Comments about Surgery

In general and regardless of the tissue of origin, incomplete surgical resection is commonly associated with recurrence, which emphasizes the importance of early diagnosis and obtaining wide surgical margins by mandibulectomy or maxillectomy at the first surgery. In two studies 65% of oral tumors treated by maxillectomy with incomplete margins recurred, compared with 22% of tumors with complete histologic margins.[2] Similarly 62% of oral tumors treated by mandibulectomy with incomplete margins recurred, compared with 15% of tumors with complete histologic margins.[3]

Surgical techniques for mandibulectomy and maxillectomy have been described in detail, and the reader is referred to surgical texts for descriptions beyond the scope of this chapter; newer techniques for resection of large oral masses have been published.[4,5]

Although the mandibular lymph nodes are regularly assessed when examining a dog with an oral tumor, metastases may involve other lymph nodes in the neck without involving the mandibular nodes. A single surgical approach was described that allowed biopsy of ipsilateral parotid, mandibular, and medial retropharyngeal lymph nodes. Lymph nodes that would have been considered difficult to evaluate by FNA (parotid and medial retropharyngeal) provided useful diagnostic and prognostic information.[6] The surgeon should also be aware that lymphatic drainage from the cranial mandible is commonly bilateral to mandibular nodes.

Both mandibulectomy and maxillectomy are tolerated well by dogs, with median hospitalization times ranging from 2 days for simple excision to 8 days for total hemimandibulectomy. Owner satisfaction with aggressive oral surgery remains a concern for veterinarians and their patients' families. In a telephone survey of caregivers for 27 dogs with oral tumors that had been treated with either aggressive surgical resection, satisfaction with the surgical procedure was assessed.[7] Overall, 85% of owners were pleased with their decision to treat their dogs, and the longer the dog had lived, the more likely the caregiver was to be satisfied. Although difficulty in eating was noted for 44% of the dogs (most commonly after maxillectomy; 64%), pain was thought to be less after surgery for most animals. All clients found the cosmetic appearances of their dogs acceptable after facial hair regrew. The quality of the pets' lives was perceived by the owners to be most improved after rostral mandibulectomy (100%) and least improved after partial mandibulectomy.

Mandibulectomy and maxillectomy are poorly tolerated in cats compared with dogs. One study reviewed 42 cats treated with mandibulectomy for oral cancer. Tumor control was seen in 56% of cats at 1 year after surgery and in 49% of cats 2 years after surgery; in addition, 60% and 57% of the cats were alive during the same time periods. Cats with SCC (43% were alive 2 years after surgery) had shorter survival than cats with fibrosarcoma (67%) or osteosarcoma (83%). Morbidity was high in cats compared with reports from dogs, with 72% of cats dysphagic or inappetent immediately after surgery and 12% never regaining the ability to eat. Despite acute morbidity in 98% and long-term morbidity in 76% of cats, 83% of the owners surveyed were satisfied with the outcome of mandibulectomy.[8] Cats that have undergone mandibulectomies need to have special attention paid to dental care, and teeth may need to be removed if they are causing abrasion. Nutritional support should be considered mandatory in cats with oral tumors, particularly if they are undergoing extensive treatment. A gastrostomy or esophagostomy tube should be placed during aggressive surgery or for the duration of radiation treatment and until the cat is able to eat by itself. Antibiotics, corticosteroids, and analgesics should be administered as needed to minimize discomfort.

Benign Oral Tumors

Epulides and Ameloblastomas

Dogs

A number of different terms have been used to describe tumors arising from the components of teeth. Some tumors retain the ability to induce reactive proliferation of connective tissue, and thus odontogenic tumors are often described as "inductive." Reclassification of what used to be termed *epulides* has resulted in the term *epulis* being reserved only for fibromatous epulis of periodontal ligament origin. Fibromatous epulides are slow-growing gingival masses that rarely exceed 2 cm in diameter. In dogs, they may be single or multiple but are always discrete and located near teeth, particularly the premolars; they are most common in the maxilla. Poor oral hygiene may be a predisposing factor for these tumors. One study found that dental plaque deposition was common in dogs with fibromatous epulides; approximately half the affected dogs had severe dental tartar, and a further 30% had moderate dental tartar.[9]

Acanthomatous ameloblastoma (previously acanthomatous epulis) occurs in dogs, but not cats. It is a rapidly progressive tumor that has a high epithelial component and infiltrates readily into bone. It is usually found in the mandible, particularly around the canine teeth, and should be considered malignant.

Cats

Epulides, arising from the periodontal ligament, are rare in cats.[9a] In this species, giant cell epulides have a more aggressive clinical behavior compared with the fibromatous type, including rapid growth, presence of ulceration, and rapid recurrence after surgery; all of which combined confer a worse prognosis. The most common noninductive tumor in cats is the calcifying epithelial odontogenic tumor, which contains amyloid deposits within its stroma and may be pigmented. Inductive fibroameloblastomas have almost exclusively been described in cats age 18 months or younger and appear as a rapidly growing fleshy mass, usually located rostrally in the mouth.

Treatment

Dogs

Local excision of a fibromatous or ossifying epulides may be all that is required. In one study, 104 dogs with fibromatous epulides were treated by marginal excision; only six dogs had a slow-growing regrowth between 6 and 7 months after surgery.[9]

Local gingival excision of an acanthomatous epulis is rarely curative, as these tumors deeply invade bone in a similar manner to SCC and other oral malignancies. Of 23 dogs with a marginal excision, the tumor recurred in 21 (91%) within 1 month.[9] Wide surgical margins that include a section of normal bone encompassing the tumor (maxillectomy or mandibulectomy) should be curative for small acanthomatous epulides. Similarly aggressive surgical excision should be curative for larger acanthomatous epulis; however, adequate margins may be difficult to obtain.

Radiation therapy is very effective for the treatment of acanthomatous epulis. In one series of dogs with acanthomatous epulis, 80% were free of tumor 3 years after ^{60}Co radiation therapy.[10] Where the tumor was located within the oral cavity, and whether bone was involved were not important to outcome.

Chemotherapy is not warranted, as systemic spread has not been reported for any epulis. Cryosurgery has been used for treatment of epulides, but recurrence is common, presumably because of poor ability to freeze bone. This modality should not be used if it will delay more definitive treatments.

Cats

In cats, radiation therapy appears to confer similar long-term tumor control for cats with epulides, calcifying epithelial odontogenic tumors, and fibroameloblastomas and may be preferred to surgery for tumors that are large and would require significant portions of bone to be removed.

Malignant Oral Tumors

The most common malignant neoplasm in the oral cavity of dogs is melanoma, which accounts for approximately 35% of tumors. The next most common is SCC (25%), with fibrosarcoma as the third most common (16%). Other less common tumors encountered include osteosarcomas and nerve sheath tumors. In cats, SCC accounts for 60% to 80% of all oral tumors. Fibrosarcoma is the only other commonly reported malignant tumor, and accounts for 10% to 20% of feline oral tumors; all other individual tumor types account for less than 3% of oral tumors.

Oral Melanoma

Dogs

Oral melanoma is the most common oral malignancy in dogs. Unlike cutaneous melanomas, which are often benign, melanomas of the canine oral cavity are uniformly malignant. Aggressive local growth and distant metastasis are common. These tumors are most common in Poodles, Dachshunds, Scottish Terriers, and Golden Retrievers. This is a disease of older dogs. In one study, the median age of affected dogs was 11 years.

Most melanomas arise in the gingiva. In descending order of frequency, melanomas are also found on lips, tongue, and hard palate. Although masses are frequently pigmented, amelanotic tumors are common. Because these tumors often surround the bony structures and invade bone, surgical excision is often difficult.

In general oral melanomas should be considered to be potentially malignant regardless of their histologic appearance. On the other hand, a recent study found that shorter survival times were seen for dogs with oral melanomas that were larger, had high numbers of mitotic figures per 10 high-power fields, had marked nuclear atypia, and had more inflammation or necrosis (these characteristics were added into a numerical score). In that study six of the nine dogs alive at the end of the study had a score of less than 10, and only one of the 46 dogs that died had a score of less than 10 (so the system is not perfect).[11] Melanomas of the lips appear to have less aggressive behavior, with lower metastasis rates after local therapy. In one study, dogs with melanoma of the lips had a median survival of 22 months with a 30% death rate caused by melanoma, compared with a median survival of 5 months with a 68% death rate caused by melanoma for dogs with oral mucosal melanoma.[11]

Metastasis of oral melanoma is probably an early event; however metastases are often not detected until long after the primary melanoma is resected. The growth rate of metastases may vary, and it is this variation, rather than when metastasis occurs, that determines survival time.

Cats

Although oral melanoma is common in dogs, it is rare in cats, accounting for less than 3% of oral cancers. Oral melanomas in cats have a similar clinical appearance to those in dogs and are often ulcerated. Based on case reports, and anecdotal information, the metastatic rate for this tumor approaches 100% (usually lymph nodes and lungs but also to other systemic sites) and progression is usually rapid.

Treatment

Dogs

Surgery remains the mainstay of treatment for oral melanoma and should consist of mandibulectomy or maxillectomy. Radiation has a role in local tumor control. Chemotherapy with platinum compounds, perhaps combined with immunotherapy, may offer the best adjunctive treatment for metastatic disease.

Most dogs with oral melanoma are euthanized because of progression or recurrence of local disease. If surgery is aggressive from the outset, it may prolong survival as well as provide palliation. Aggressive local therapy should include resection of underlying bone. Mandibulectomy or maxillectomy should be the first surgery used to treat oral melanoma in dogs. Less aggressive surgeries do not prolong survival and make subsequent surgery more difficult. Most studies report local recurrence rates ranging from less than 15% for melanomas treated by mandibulectomy to 48% for tumors treated by maxillectomy. In three studies, dogs treated with aggressive surgery had a median survival time of 7 to 9 months compared with seven dogs that did not have surgery and survived a median of 2 months. Lingual melanomas may have a lower rate of metastasis than mucosal melanomas, and are often of a lower histologic grade. Regardless of the surgery performed, most dogs with oral melanoma develop metastases; consequently, adjuvant chemotherapy is recommended.

Radiation therapy has a role in the treatment of melanoma, particularly when surgery is not possible. Melanoma responds best when radiation therapy is delivered in large doses per fraction, and because metastatic disease is often the cause of death in dogs with melanoma, a palliative course of radiation is also appealing from a quality of life perspective. For dogs that have tumors that cannot be treated by surgery, coarsely fractionated radiation therapy causes a complete response in 50% to 75% of patients. If the melanoma can be reduced to microscopic disease, then the prognosis is much better. For dogs with small, rostrally located melanomas the risk of late effects of radiation therapy becomes greater as their survival times are likely to be long. For these dogs the use of small doses per

fraction, as used in more conventional radiation therapy, could be considered. In one study, dogs with microscopic disease, those with no bony lysis on radiographs, and those with rostrally located tumors all had a lower chance of recurrence and lived longer. Overall median survival was 7 months. Dogs with no poor prognostic factors lived longer than those with increasing numbers of negative factors.[12]

Metastatic disease occurs in the majority of patients and often occurs within 6 months of treatment, although metastases may not be visible for longer than 1 year after surgery. After metastases develop, dogs may still survive a long time, depending on the growth rate. Dogs may tolerate pulmonary metastatic disease with very little apparent effect on their quality of life.

Chemotherapy may improve survival times in dogs with oral melanoma when used as an adjunct to surgery but rarely when used to treat gross or metastatic disease. Platinum compounds appear to be the most efficacious. Carboplatin caused responses in 28% of dogs with unresectable oral melanoma, including one dog with a complete response lasting nearly 3 years. Overall response duration was 5.5 months.[13] Higher dosages, and the occurrence of gastrointestinal toxicity were associated with a higher likelihood for response.

Combinations of chemotherapy with either surgery or radiotherapy appear to make the most therapeutic sense for dogs with oral melanoma. One study reported weekly radiotherapy for 6 weeks (also given with weekly low doses of carboplatin or cisplatin before treatment) to dogs that had been treated surgically to microscopic disease. In this group of 39 dogs recurrence was seen in six dogs (15%) a median of 4 months after treatment, and metastases were seen in 20 dogs (51%) a median of 10 months after treatment. The median overall survival was more than 1 year.[14] Survival times were longer than previously reported for dogs with oral mucosal malignant melanoma. The implication is that surgical debulking to microscopic disease may improve local control, and allow the benefit of chemotherapy in treating metastatic disease to be seen.

Immunotherapy has a role in treating melanoma in dogs. In early 2010, the USDA gave full licensure to a xenogeneic human tyrosinase DNA vaccine to treat dogs with melanoma, following a period of conditional licensure starting in 2007 in which the vaccine was available to veterinary oncologists in the US for treatment trials in spontaneous melanoma in dogs. The vaccine is now available in the US as Oncept (produced by Merial) for use by veterinary oncology specialists. The vaccine is given as an initial series of four treatments, using a specifically designed needleless transdermal injector, 2 weeks apart, and then a booster every 6 months. Recent data analysis of 58 dogs with stages II and III oral melanoma treated by surgical excision and Oncept showed that dogs that received vaccine had a longer median survival time (median not reached) compared with historic controls. 75% of dogs were alive 15 months after surgery, compared with 5 months for dogs treated by surgery alone.[15]

Cats

All cats that had surgical excision of oral melanoma developed metastatic disease within 5 months of surgery. In two of these cats metastases were diffuse throughout the body. Radiation therapy appears to be helpful in local tumor control as it is in dogs; however, even though responses are reported in approximately 60% of cats, metastasis is common and survival times are similar to those with surgery. Carboplatin may have efficacy against metastases but is unproven. With the exception of one report,[16] the use of Oncept in cats has been reported anecdotally that one macroscopic anti-tumor response was seen. The safety and toxicity appears to be the same as for canine patients. The Bioject transdermal device can be used on feline skin, but the angle of injection is different, using the skin of the caudal thigh and injecting cranially into the semimembranosus/tendinosus muscles.

Squamous Cell Carcinoma

Dogs

Most oral SCCs are found rostrally within the mouth; most occur in the maxilla. SCC is usually found in the gingival tissue, although the tongue and tonsils can be affected. Gingival tumors may extend to cause lysis of underlying bone. SCC usually occurs in older dogs with no apparent breed or gender predilection. Tumors of the tonsil and tongue behave more aggressively than SCC arising at other sites. Papillary SCC occurs more often in young dogs as a progressive disease with a high rate of lytic bone involvement; however metastases are rare.[16a]

Metastasis of gingival SCC is uncommon, and metastasis to the lungs at time of diagnosis is rare. Regional lymph nodes are frequently enlarged at diagnosis and should be sampled for cytology or histopathology; however, they usually do not contain metastases. Regional lymph node metastasis is uncommon both before and after therapy, occurring in 10% of dogs in a five-case series.

Tonsillar SCC is considerably more aggressive than gingival SCC and occasionally may occur bilaterally. Most dogs present with dysphagia, anorexia, and pain, and clients may have noticed a cervical swelling, which is usually lymph node metastasis that occurs very early in the course of disease. In fact, the primary tumor may be quite small but lymphadenopathy may be marked. Most dogs have shown these signs for 1 month or less. SCC of the tongue has a similarly high metastatic rate to tonsillar SCC.

Cats

SCC is the most common oral tumor of cats. White coat color appears to increase the risk of developing cutaneous SCC, but there is no influence of coat color, gender, or breed on the occurrence of oral SCC. Affected cats have an average age of 12 years. Although SCC in cats can affect any mucosal surface in the mouth, the tongue is most commonly involved. The frenulum and ventral surfaces are often ulcerated, and although the tumor is deeply invasive it is rare for the dorsum of the tongue to be affected. This site predilection has been suggested to be because of increased carcinogen exposure caused by coat grooming in cats and the risk is higher in cats exposed to insecticidal collars and certain foods.[17] The mucosa adjacent to the caudal maxilla or mandible is the next most commonly affected site. SCC may invade the underlying bone and extend to involve the palate, pharynx, or angle of the jaw occasionally invading the periocular space causing exophthalmos as well as nasal and ocular discharge. Invasion of mandibular bone can cause a marked periosteal reaction that mimics a primary bone tumor both clinically and radiographically. Although oral SCC may progress to invade the tonsillar area, it is uncommon for the tonsil to be the primary site in cats.

Treatment

Dogs

In dogs the relatively low metastatic rate of gingival SCC makes this malignancy a good candidate for local therapies, such as surgery and radiation. Aggressive surgery is necessary to obtain adequate surgical margins, and with this approach median survival in reports ranged from 9 to 18 months. Recurrence is more frequent than metastasis after surgery. Incomplete surgical resection is commonly associated with recurrence, which emphasizes the importance of confirming wide surgical margins by histopathology after mandibulectomy or maxillectomy. Adjunctive radiation therapy may improve tumor control when complete excision cannot be achieved at

surgery. Dogs with rostrally located tumors and dogs with smaller tumors appear to have longer remissions following either surgery or radiotherapy. Median progression-free survival in one study of radiotherapy was approximately 17 months. Local mucositis is the most common acute side effect of radiation therapy, and dogs may require antiinflammatory medications, antibiotics, pain relief (opioids, such as codeine or fentanyl), and appetite stimulants. It may be necessary to place a feeding tube in a dog undergoing radiation therapy for an oral tumor. For small dogs, or dogs with a large radiation field, prophylactic tube placement is recommended. It is rare for acute side effects to persist beyond 3 weeks after therapy.

A combination of radiation and surgery gives the best control for gingival SCC, and postsurgical radiation should be considered for dogs with large tumors or for dogs with tumors that have incomplete margins on histopathology. This combined modality approach is the treatment of choice for larger, caudal or incompletely excised SCC. Chemotherapy is rarely warranted for rostral gingival SCC in dogs because of the low metastatic rate for this tumor. Chemotherapy should always be considered for SCC of the tongue, tonsil, and caudal location of the mouth because of the high metastatic rate of such tumors. Platinum compounds are probably the drugs of choice for metastatic SCC. Piroxicam, a nonsteroidal inhibitor of cyclooxygenase-2 (COX-2), showed efficacy against canine oral SCC although the duration of response may be in the order of 6 months. The mechanism by which piroxicam exerts its antitumor effects on SCC is still unclear, although it may affect tumor angiogenesis. Combination carboplatin and piroxicam may have increased efficacy over either drug itself.

The prognosis for dogs with tonsillar SCC is very poor. Surgery alone is not generally effective for treating tonsillar SCC because of their high metastatic rate, which manifests early in the course of the disease. The best survival rates for this tumor have come when dogs were treated with a combination of surgery, radiation therapy, and chemotherapy. Even with this approach, the median survival was still only 8 months. Piroxicam also shows efficacy against canine tonsillar SCC, with similar response rates and duration as for oral mucosal SCC.

Surgery for lingual SCC in dogs has variable outcome, and recurrence is common unless wide surgical margins are obtained. In one study, dogs with small tumors were treated with surgery alone and had a median survival time of 8 months. In some cases, complete removal of the tongue is indicated and requires that dogs have food supplemented with water to maintain hydration, or they learn to suck water as a horse would. This surgery was well tolerated by owners and dogs. Recurrence of tongue tumors is also common after radiation therapy. Metastatic disease usually determines survival; 43% of dogs in one study developed metastasis to lymph nodes, lung, or bone, so chemotherapy is indicated.

Cats

The best treatment for oral SCC in cats has yet to be decided. In one study comparing surgical treatment with radiation either alone or in combination with hyperthermia or platinum drug, there was no influence of treatment modality on survival.[18] Surgical removal of visible tumor is rarely successful as oral SCC is deeply invasive into both soft-tissue stroma and sometimes bone, thus often making local excision incomplete. CT scanning prior to surgery may assist the surgeon in deciding on the extent of surgery needed to obtain appropriate margins. Maxillectomy or mandibulectomy may allow the surgeon to obtain tumor-free margins but recurrences are still common. Cats treated in this way rarely live longer than untreated cats. Recurrence or metastases occur in cats within a median of 2 months after resection of all visible tumor tissue. For SCC limited to the mandible, mandibulectomy may delay recurrence to between 4 and 9 months after surgery. Still the major indication for surgical excision is as an adjunct to multimodality therapy.

Because recurrence is still a problem following even radical surgery, radiation therapy either alone or following surgery has been used to treat oral SCC. Tumor response to radiation is often dramatic initially, but usually of short duration, and the reported median survival is still only about 3 months. To date, the addition of chemotherapy or cell sensitizers does not seem to improve on these figures.

The best results have been reported in a small series of seven cats with SCC limited to the mandible; they were treated with a combination of mandibulectomy, lymph node resection, and radiation that included the surgical site of regional lymph node resection. The median disease-free period for this group of cats was 11 months and the 1-year survival rate was 57%. All cats developed recurrence.

Chemotherapy alone or in combination with radiation therapy has done little to improve survival in cats with oral SCC, and further trials are needed to further define the role of this modality. Response rates to platinum drugs, mitoxantrone, doxorubicin, or cyclophosphamide have been approximately 20%. Piroxicam, a nonsteroidal antiinflammatory agent, appears to have limited efficacy in cats as oral SCC has a very low rate of COX-2 expression; however, this treatment remains unexplored in the cat.

Other treatment modalities, such as cryosurgery or photodynamic therapy, do not appear to be successful, in part because of the increased sensitivity of the oral mucosa to toxicity, and because the tumor invades bone or deep into tissue, preventing adequate light or cold penetration.

Nutritional support is mandatory for cats with oral SCC. Clients should be counseled about care and nursing, and a gastrostomy or esophagostomy tube should be placed for the duration of treatment and until the cat is able to eat by itself. In one study, half of the cats required a gastrostomy tube for 2 weeks or less. Antibiotics and antiinflammatory drugs may be necessary to treat secondary bacterial infection and inflammation in these cats, and analgesics should be administered as needed to minimize discomfort.

Fibrosarcoma

Dogs

Fibrosarcoma is the third most common oral malignancy in dogs and occurs at an average age of 7 years. These tumors arise most commonly in the gingiva and are equally likely to be located around the maxilla or the mandible. The hard palate is uncommonly involved except by extension of a maxillary tumor. Tumors are usually large, with diameters of greater than 4 cm.

Histologic reports of these tumors should be interpreted cautiously. Occasionally, a tumor may be termed a *fibroma*, which implies that the process is benign. In fact, all sarcomas encompass a spectrum of disease and fibromas of the oral cavity should be treated as aggressively as fibrosarcomas. One report described tumors that were histologically diagnosed as fibromas, nodular fasciitis, or granulation tissue. Although all of these lesions are considered histologically benign, they invade bone and metastasize in some dogs and should therefore be termed *histologically low-grade, biologically high-grade fibrosarcomas*. Bony invasion should be interpreted as a sign of malignancy regardless of the pathology report.

Metastasis is uncommon in fibrosarcoma, particularly at the time of diagnosis, but is reported in approximately 25% of patients in the latter stages of disease, most commonly to regional lymph nodes.

Especially in young dogs, which may have more aggressive tumors, mandibular lymph nodes should be palpated and subjected to FNA or biopsy. Systemic metastases from oral fibrosarcoma may be a late event, so the incidence may prove higher than has been reported as local tumor control improves.

Cats

Fibrosarcoma is the second most common oral malignancy in cats, but unlike oral SCC, which has a predilection for the sublingual tissues, there does not appear to be a site predilection for feline oral fibrosarcoma. Fibrosarcoma is invasive when it occurs in the oral cavity, just as it is at other sites in cats; advanced lesions may invade surrounding bone and muscle. Lesions may be ulcerated causing dysphagia and other signs similar to oral SCC, and most cats are presented because an owner noticed swelling or a mass.

It is rare for metastases to be noted at the time of presentation, and no cat has been reported to have metastatic disease after surgery. Many of these cats had short survival following surgery before any subclinical metastases become apparent, therefore the reported low metastatic rate may not be accurate.

Treatment

Dogs

The treatment of choice for fibrosarcoma of the oral cavity in dogs is complete surgical excision. Maxillectomy and mandibulectomy are well tolerated by dogs and are necessary to obtain adequate surgical margins. In series of dogs treated with aggressive surgery, the median survival was 12 months. Even after such surgery, local recurrence is seen in nearly 40% of dogs, although this appears to depend on surgical expertise. Incomplete surgical resection is commonly associated with recurrence, which emphasizes the importance of early diagnosis and confirming wide surgical margins by histopathology.

The response of oral sarcomas to radiation therapy is not as good as for soft-tissue sarcomas at cutaneous sites, but still good compared with incomplete surgery alone. In one study the median survival for dogs with oral sarcomas was 18 months compared with 75 months for dogs with tumors at other sites.[19] In another study, the median progression-free survival was 26 months.[20] As with melanomas and carcinomas, dogs with smaller tumors had longer remissions.

Little has been reported regarding chemotherapy in the treatment of oral fibrosarcomas, although the metastasis rate of nearly 30% documented in one study shows that with local control rates improving with more aggressive surgery and radiation therapy, metastasis is the cause of death in as many dogs as is local recurrence.[20] Doxorubicin has been noted to produce objective responses in soft tissue sarcomas, and metronomic cyclophosphamide in combination with piroxicam appears to delay regrowth of sarcomas at other sites.

The optimum treatment for oral fibrosarcoma probably involves combined surgery and radiation therapy to dosages that exceed 50 Gy. Chemotherapy is investigational but may improve survival rates through control of metastases. Control rates similar to those seen with soft-tissue sarcomas at other locations could be expected with this combined approach.

Cats

In cats, as in dogs, surgical excision should be as aggressive as possible. Adequate postsurgical nursing care and nutritional support should be provided as described for cats with oral SCC. Survival times after surgery are generally higher than for cats with oral SCC, with 67% of cats with fibrosarcoma and 83% of cats with osteosarcoma alive 2 years after complete excision.

Radiotherapy improves local control of soft-tissue sarcomas at other sites in cats, and should be considered for cats with unresectable or histologically incompletely resected oral sarcomas.

Salivary Gland Tumors

Dogs

These tumors occur in older animals with no obvious gender predilection. Poodles and possibly Spaniel breeds are at higher risk for developing this disease. Malignant salivary gland tumors are more common than benign tumors and account for more than 95% of reported cases. On the other hand, enlargement of the salivary gland in a dog is more likely to be an inflammatory process than a tumor. Most owners notice a swelling or mass in the neck. Signs may include anorexia, dysphagia, and pain on opening the mouth. The most commonly affected salivary gland is the parotid gland (50% of dogs), with mandibular (30%), sublingual (12%), and zygomatic glands less frequently affected.

Lymph node metastasis may occur, and metastases to nodes were confirmed in approximately 20% of affected dogs at presentation in one study.[21] Dogs with enlarged nodes should have a biopsy or a FNA. Pulmonary metastases are rare, occurring in less than 10% of dogs at presentation in one study. Staging has proven prognostic for dogs with salivary carcinoma; the occurrence of metastases to lymph nodes or systemically gives a worse prognosis with a median survival of approximately 6 months following surgery alone. On the other hand, in one large study, histologic features did not appear to be prognostic; approximately 60% of tumors were poorly differentiated, and most showed more than 50% necrosis and vascular emboli, but this had no effect on outcome.

Cats

Approximately 5% of salivary tumors in cats are adenomas. Little is reported about salivary adenocarcinoma in cats. The average age of affected cats is 11 years but ranges from 2 months to 20 years. Siamese cats are predisposed to this tumor. Commonly, cats are presented for an enlarging mass on the side of the face or below the ear. Less commonly the mucosal gingiva or other oral site may be ulcerated. Oral tumors that are "undifferentiated" adenocarcinomas are usually of salivary derivation. Ulceration of the overlying skin is common, possibly a result of pruritus. Pruritus may be exacerbated by secondary otitis externa from parotid tumors, and deeper invasion may result in facial nerve damage or vestibular signs. Salivary adenocarcinomas can be very invasive into surrounding musculature and may even extend along the skin of the neck to involve the thoracic wall and scapula.

Approximately 80% of cats have metastases to regional lymph nodes at the time of first diagnosis. However; fewer than 20% have distant metastasis at the time of diagnosis. Interestingly, clinical stage (i.e., whether the tumor had metastasized to nodes) was not prognostic in a study of 31 cats with salivary carcinomas, although the multiple methods of treatment reported probably confuses the issue. This implies that the finding of metastasis should not necessarily preclude treatment.

Treatment

Dogs

Surgery alone and radiation therapy with surgery were the most successful modes of treatment in a study of 24 dogs. Both groups had median survival times of 2 years, with a number of animals alive

beyond 4 years. Chemotherapy is rarely reported. In one study a plethora of protocols was reported, but none improved survival.

Cats

Cats with salivary adenocarcinoma that were not treated lived between 5 and 6 months and were euthanized because of weight loss and enlargement of the tumor. Surgery is considered the primary treatment for salivary adenocarcinoma; however, surgical cure is often difficult because of deep invasion into the oral cavity and around the jugular vein and associated structures. Complete excision may be associated with long-term control in cats, particularly if used in combination with radiotherapy or chemotherapy. The primary surgery should be as aggressive as possible, however, so that a minimal amount of tumor tissue is present when adjunctive therapy is instituted.

Good local control of these tumors has also been seen when radiation therapy was used, but metastases are common, and therefore adjunctive chemotherapy is usually necessary. Chemotherapy for salivary adenocarcinoma has not been evaluated in a controlled clinical trial; however, based on one study where chemotherapy was used in combination with surgery, adjunctive therapy should be considered. Combination therapy using surgery, radiation therapy, and chemotherapy is the treatment most likely to be successful in cats with salivary adenocarcinomas. The median survival for 31 cats treated with any combination of these modalities was 17 months.[21]

TRAUMA

Kevin Stepaniuk

Etiology

Oropharyngeal trauma includes trauma of the soft (oral mucosa and underlying connective tissue, muscles, tongue, tonsils) and hard tissues (teeth and maxillofacial bone) of the oropharynx.

Soft Tissue

Trauma secondary to wooden sticks, plant material, sharp dental chews, projectiles, insects, chemicals, electricity, blunt and crushing trauma, and self-trauma secondary to behavioral problems is common. *Stomatitis* is the term used to refer to generalized inflammation of the oral cavity. Regional areas of inflammation such as caudal mucositis, buccal mucositis, gingivitis, periodontitis, glossitis, and the like are more descriptive and provide better clues to underlying pathogenesis and etiology.[1]

Oropharyngeal Foreign Body

Oropharyngeal foreign bodies are common. Breeds that commonly carry wooden sticks in their mouth can suffer oral lacerations, punctures, abrasions, and impalement.[2] Puncture wounds from sticks introduce bacteria into deeper tissues and may cause retrobulbar abscesses or cellulitis, glossitis, and actinomycosis cervicofacialis.[3] Foreign plant material can migrate and cause trauma, draining tracts, and granulomas.[4] Sticks and bones may lodge across the palate between contralateral dental arcades resulting in oral ulcerations, gingival recession, and periodontal disease.[5] Foreign bodies in or under the tongue lead to chronic inflammation, ulceration, granuloma formation, and sublingual edema.

Chemical and Pharmaceutical Trauma

Chemical injury secondary to ingestion of caustic substances leads to erosions and ulcerations of the oral mucosa.[6] Cleaning chemicals, batteries, and disinfectants are common sources of chemical injury to the oropharyngeal mucosa (Figure 54-20). Erroneous Internet information may lead owners to attempt home remedies that result in further chemical trauma.[7]

Insect bites and stings damage the oral mucosa and induce local inflammatory reactions.[8] Venom found in the mucosa of toad skin may also cause acute oral inflammation. With some species of toad, death of the patient within minutes to hours results from cardiovascular and systemic collapse.[9,10]

Medical prescriptions often have unanticipated side effects if they are retained in the oral cavity. Pancreatic enzyme supplementation, for example, causes oral mucosal ulceration and hemorrhage if not properly adminstered.[11,12] Differentials for traumatic and chemical ulcers includes chronic ulcerative paradental stomatitis (Figure 54-21), inflammatory diseases secondary to trauma, and autoimmune diseases.

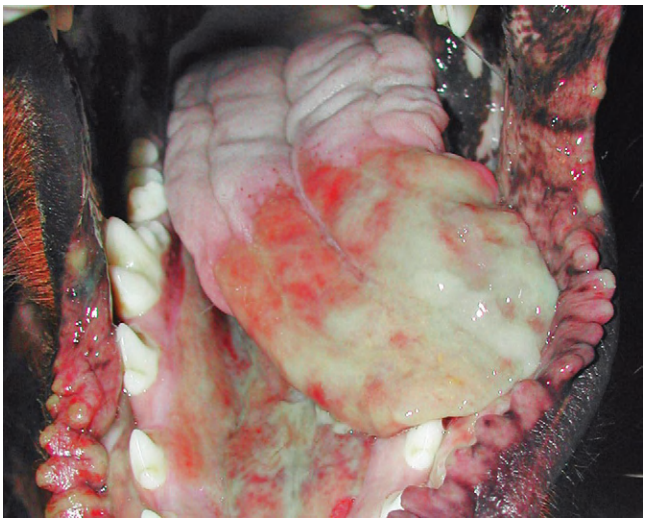

Figure 54-20 Alkaline chemical burn in the rostral oral cavity of a dog's mouth after chewing on a battery. Note the ulcerative buccal and lingual mucosa with sloughing of the epithelium. (Photograph courtesy of Gary Goldstein, DVM, FAVD, Dipl. AVDC, University of Minnesota.)

Figure 54-21 Chronic ulcerative paradental stomatitis (*white arrows*) where oral mucosa is ulcerated when contacting adjacent teeth. The plaque biofilm is the inciting cause.

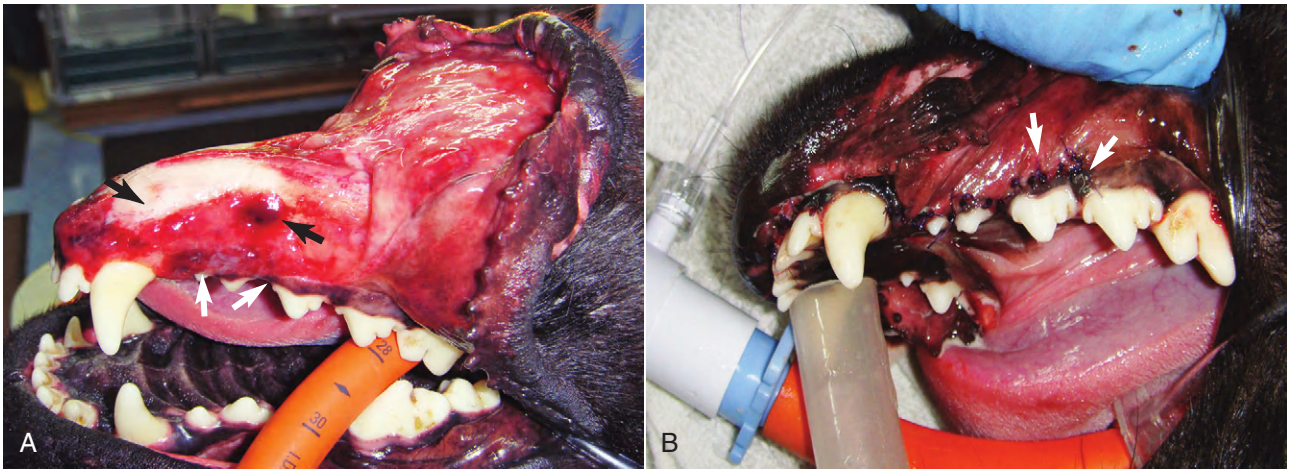

Figure 54-22 **A** and **B,** A mandibular lip avulsion injury in a dog after having its collar caught in a moving car tire. Mandibular mental foramen with avulsed neurovascular bundles are evident (*black arrows*). The tissue avulsed from the mucogingival junction. The mucosa was sutured to the gingiva at the mucogingival junction (*white arrows*).

Systemic chemotherapy and maxillofacial radiation damage soft and hard tissues. Mucositis, osteoradionecrosis, xerostomia, and radiation-induced caries result from oropharyngeal radiation damage. Unless the oral cavity is assessed as part of a comprehensive maxillofacial oncology plan, subsequent dental and oral surgery increases patient morbidity and regional sequelae.[13]

Mechanical and Electrical Trauma

Soft-tissue traumatic injuries (e.g., vehicular trauma, animal fights, and high-rise syndrome) are common and include avulsion of the oral mucosa/lips from the bone, the mucogingival junction, and associated teeth (Figure 54-22). Oral electrocution from chewing electrical cords can produce severe injury to the soft and hard tissues. Projectile ballistics (gunshot wounds) cause significant damage to soft and hard tissues. Thermal injuries from hot liquids and foods are much less common in animals than in humans. However, if food is warmed in a microwave to encourage pets to eat, uneven or over heating can result in thermal burns of the oral mucosa, only worsening the patient's anorexia.

Self-trauma ("gum chewer lesions") produces caudal oral buccal and sublingual granulomas. They are often incidental findings but may be problematic if they become large and secondarily infected. Separation anxiety and cage-biting patients self-inflict mucosal injury and gingival lacerations during behavioral episodes.[14]

Malocclusions[1] can lead to both soft-tissue and hard-tissue trauma. Linguoversed mandibular canine teeth damage the palatal mucosa leading to ulcerations, infections, pain, maxillofacial growth abnormalities, and behavioral changes such as head shyness and aggressive protection of the face and oral cavity (Figure 54-23). Alternatively, the patient may show no obvious clinical signs despite significant trauma. As the linguoversed teeth penetrate into the hard palate and nasal cavity, oronasal fistulation and rhinitis will result.

Brachycephalic cats have a shortened maxilla. Mandibular bowing during growth and development may occur in some cases. The maxillary fourth premolar cusps, occluding on the buccal aspects of the mandibular first molar, traumatize the gingiva and oral mucosa. Pain, infection, periodontal disease, inflammatory masses, and tooth loss result.

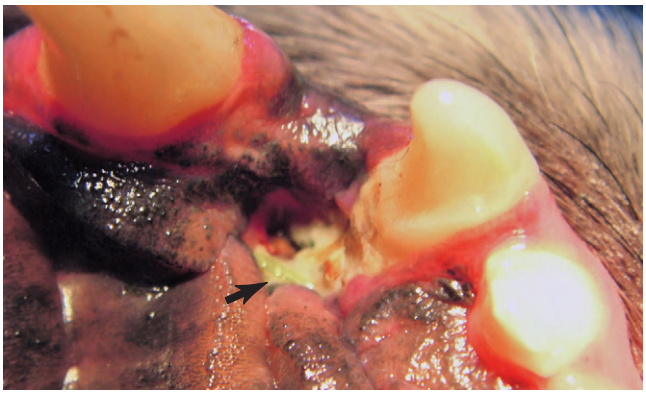

Figure 54-23 Palatal mucosal and bone trauma with a resulting oronasal fistula from a linguoversed mandibular canine tooth in a young standard poodle. The patient was head shy, aggressive, would not permit an oral examination, and was noncompliant with the owners and veterinarians. Following repair of the oronasal defect and crown reduction and direct pulp capping of the offending mandibular canine tooth, the patient's behavior dramatically improved.

Hard Tissue: Tooth Trauma

Dentition is often an overlooked aspect of the oropharyngeal cavity.[1] Approximately one in 10 cats and one in four dogs have dental fractures.[15,16] The most common injuries to the teeth are caused by hard objects (e.g., baseball bats, golf clubs, rocks), vehicles, falls, animal fights, and hard dental chews (e.g., cow hooves, bones, nylon bones). Physical forces from foreign objects can result in concussive pulpitis, dentin tubule exposure, fractured teeth with pulp exposure, and tooth luxation injuries (subluxated, luxated, and avulsed teeth). If a tooth fractures or luxates, endodontic inflammation, necrosis, and infection can result days, weeks, or months later as the patient suffers silently.

Abrasion of the teeth exposes porous dentin tubules and the pulp cavity. Trauma from tennis balls is frequent (Figure 54-24). Tennis balls, rocks, and other hard substances can quickly wear the teeth resulting in dentin tubule and pulp exposure and subsequent

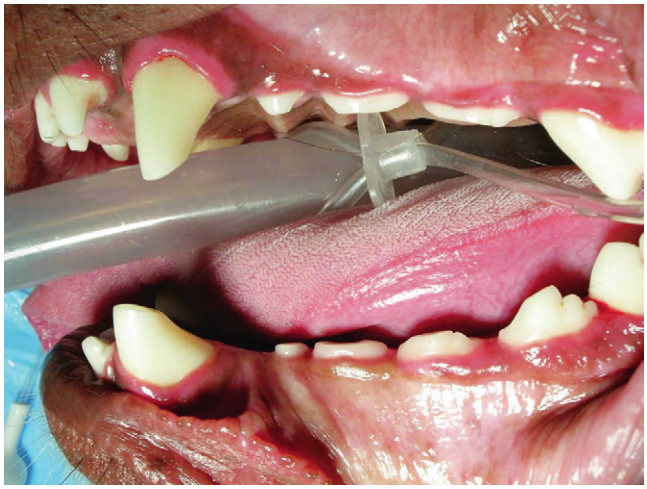

Figure 54-24 A young Labrador Retriever who routinely played with tennis balls. Maxillary and mandibular premolars have worn and the abrasion has resulted in pulp exposure in several of the teeth. Root canal therapy or surgical extraction is necessary to treat any tooth with pulp exposure.

infection. Similarly, separation anxiety and cage biting patients wear the distal aspects of the canine teeth and maxillary third and incisors.

Corrosive acid and alkalis can damage the teeth by dissolving the enamel and dentin mineral resulting in pulpal inflammation and infection. Iatrogenic thermal tooth trauma, from poorly performed ultrasonic dental cleanings, results in pulpitis, intrinsic staining (pulpal hemorrhage), and death of the tooth. Although uncommon, as compared with humans, dental caries do occur on the occlusal molar surfaces in dogs.[17]

Fibrous material such as string and dog hair can wrap around teeth and quickly induce gingival inflammation and periodontal disease. Small breeds with large and crowded teeth[18] and significant facial hair "beards" are overrepresented.

Hard Tissue: Skeletal Trauma

Significant force is required to fracture the maxillofacial skeletal (e.g., vehicular trauma, falls, baseball bats, golf clubs, and animal bites, and from poorly performed surgical extractions). If there is one mandibular or maxillary fracture following trauma, there are often more.[19,20] Trauma can cause a patient to have pain or difficulty opening or closing the mouth.

If the patient has difficulty closing the mouth, or pain in closing the mouth, the following pathologies should be considered: temporomandibular joint (TMJ) luxation with or without fracture, TMJ dysplasia with coronoid entrapment (open-mouth jaw locking),[21-24] zygomatic or coronoid neoplasia, mandibular neurapraxia, and masticatory muscle neurogenic atrophy.[25] If the patient has difficulty opening the mouth or pain in opening the mouth, other pathologies should be considered, including TMJ intracapsular or extracapsular ankylosis (previous trauma), zygomatic arch/coronoid fracture/healing, masticatory myositis, retrobulbar abscess/cellulitis, tetanus (*Clostridium tetani*), osteoarthritis of TMJ, craniomandibular osteopathy, severe otitis interna/media, and neoplasia.

Side effects of bisphosphonate therapy (bisphosphonate-related osteonecrosis of the jaws) are theoretically possible in veterinary patients. Although not yet documented in clinical canine patients, intravenous use of bisphosphonate compounds can lead to osteonecrosis of the jaws following dental extractions or trauma.[26,27] This may become a concern as bisphosphonate use in veterinary medicine increases over time.

Pathophysiology

Soft Tissue

Oropharyngeal Foreign Body

Foreign bodies lacerate, puncture, and penetrate oropharyngeal tissue resulting in hemorrhage, ulcers, and granulomas. Many cases of oropharyngeal cellulitis and retrobulbar abscesses are the result of foreign-body penetration.[28] Environmental pathogens may be easily inoculated into the soft tissue. *Actinomyces* and *Nocardia* cause chronic pyogranulomatous inflammation resulting in swellings and draining tracts of the head and neck.

Oral Mucosal Inflammation

Acute traumatic ulcerations are often associated with pain, have a yellow base and red halo, are associated with a traumatic event, and often in heal in 7 to 10 days after the inciting cause has been removed.[29] Chronic ulcers have little or no pain, are yellow-based with elevated and scarred margins, delayed healing, and may be easily confused with neoplastic conditions such as SCC.[29]

Mucositis may be secondary to periodontal disease, autoimmune conditions, or radiation therapy. Radiation induced mucositis results from damaged basal cell turnover of the oral mucosa and mucosal atrophy resulting in a thin, fetid, pseudomembrane that sloughs and leaves an ulcerated surface.[13] The flow, character, and protective properties of saliva are lost in these conditions.

Glossitis accounts for 33% of all lingual lesions in dogs.[30] The cause of glossitis includes plant material, suture, bone, hair, chemicals, medications, and electrical injuries, as well as systemic diseases such as uremia.[30] Trauma of the tongue and oral mucosa can result in amorphous, gritty, hard mineral deposits in the tissue (lingual calcinosis circumscripta).[4,30,31]

Ballistic characteristics, such as yaw, flight length, and blast effect, factor into the damage caused by gunshot wounds.[32] Ballistic projectiles cause laceration and crushing injuries of the soft tissues; fractured, thrombosed, and concussed teeth; and maxillofacial fractures. In addition to the direct effect of the ballistic, soft-tissue injuries secondary to the related shock wave and cavitation occur.[32]

Mechanical and Electrical Trauma

Obvious lacerations, crushing injuries, and avulsion injuries lead to major hemorrhage if the lingual, sublingual, maxillary, infraorbital, palatine, or mandibular vessels are damaged. Electrical trauma causes necrosis of tissue, fibrosis, and wound contracture that affect the function of the oral cavity. Developing tooth buds may be damaged. As pets chew on electrical cords, low-voltage (<1000 V) conduction and arcing currents, generating 2000°C to 4000°C, damage tissue and thrombose vessels.[6,33] The extent of injury to the lips, palate, gingival tissue, mucosa, tongue, and pharynx may take several weeks to demarcate; blanched, pale, gray, tan ulcerative mucosa with secondary infection results. Without corrective surgery the wounds contract and epithelialize from the margins. Oronasal fistulas, functional disfigurement, dysphagia, and severe morbidity result from electrocution injuries. Multiple organ failure is possible in severe cases.[33]

Hard Tissue: Tooth Trauma

Endodontic disease is a silent source of pain and infection in pets. Bacteria may enter the tooth via exposed pulp, exposed dentin

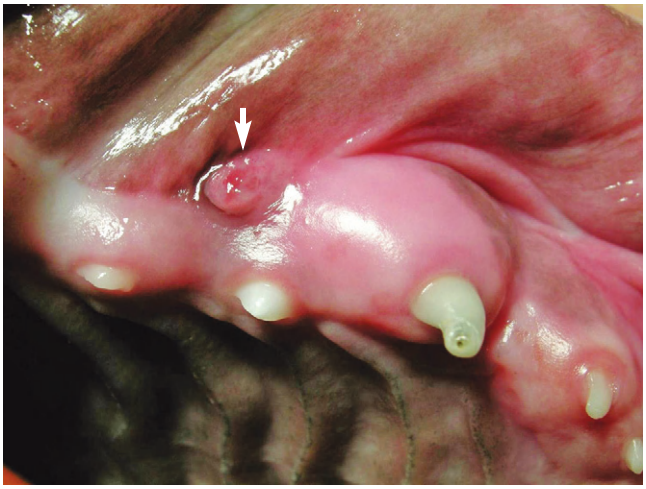

Figure 54-25 A complicated crown fracture (pulp exposure) in right maxillary deciduous canine tooth (note the black hole in the coronal aspect of the canine tooth). The patient is approximately 12 weeks old. The fracture likely occurred several weeks prior to the photograph. Note the sinus draining tract just apical to the mucogingival junction. The infection and inflammation is occurring in the region of the developing adult tooth buds of the canine and second premolar. The first premolar is erupted. Immediate extraction of the deciduous canine tooth is indicated.

tubules, or anachoresis (hematogenous distribution).[34] Complicated crown fractures result in irreversible pulpitis, pulp necrosis, and apical periodontitis that will not resolve unless the tooth is endodontically treated or surgically extracted. Complicated crown fractures[1] of deciduous teeth expose the pulp to bacteria (Figure 54-25). An apical infection results and the developing adult tooth bud can be damaged by the regional infection and inflammation. Malformed teeth, enamel defects, unerupted teeth, and associated dentigerous cysts can result.

Enamel fractures, uncomplicated crown fractures (no direct pulp exposure), and abrasions cause reversible and irreversible pulpitis from the concussive trauma and the ingress of bacteria through the porous dentin tubules. The odontoplastic process within the tubules transmit pain. If reversible pulpitis occurs, the odontoblasts will seal the dentin tubules by producing reparative dentin.

Concussive injuries to teeth lead to pulp hemorrhage and a pink-purple-gray intrinsic staining. It was reported that 92.2% of discolored dog teeth had partial or total pulp necrosis with 42.9% having no endodontic radiographic signs.[35] Thermal injury to the tooth results in pulp thrombosis and irreversible pulpitis. Lack of appropriate water coolant and/or prolonged periods of instrument to tooth contact while cleaning and polishing can overheat the pulp within the tooth.

Luxation injuries disrupt apical blood supply, the periodontal ligament, and alveolar bone resulting in a nonvital (endodontic) tooth and compromised periodontal tissues. Therefore, both the periodontal tissues and the endodontic system require treatment.[36,37]

Hard Tissue: Skeletal Trauma

Mandibular fractures are more common than maxillary fractures. However, without careful examination and the use of CT, maxillary fractures may be underrecognized and go unreported.[19] The mandibular molar region, particularly in the region of the first molar, and the maxillary bone are the most common regions for oral fractures in dogs.[38] Mandibular symphyseal separations are the most common maxillofacial fracture in the cat.

Feline high-rise syndrome is the result from falls higher than the second story.[39] The patients can fracture the hard palate and mandible, separate the mandibular symphysis, luxate the TMJ, avulse oropharyngeal soft tissue, and fracture teeth.[39,40] Concurrent injuries include skeletal fractures, pneumothorax, pulmonary contusions, hemothorax, urinary bladder ruptures, and diaphragmatic hernias.[39] Occasionally, the animal will show few clinical signs but may present with inability to open the mouth or eat several weeks after the injury.[39] The severity of the injuries increases linearly up to the height of the seventh floor, but the incidence of fractures decreases after the third floor as a consequence of the feline's vestibular mechanism and limb position.[39]

Bites to the face of the developing skeleton in dogs and cats may seem innocuous in some cases. However, damage to the growth plates and tooth buds may not manifest for several weeks or months. In such instances, there may be axillary–mandibular asymmetry malocclusions, unerupted teeth resulting in dentigerous cyst formation, malformed teeth, and malpositioned teeth.

Bisphosphonates target the osteoclasts and suppress osteoclast-mediated bone resorption.[41,42] The mandible and maxilla have increased skeletal remodeling rates and require proper functioning osteoclasts. Bisphosphonates accumulate in the bone and proper bone remodeling is impaired following tooth extraction and trauma.

Clinical Examination

Conscious Oropharyngeal Examination

Prior to oral examination, a complete history, including signalment, vaccination status, diet, previous dental and oral treatments, trauma, behavior, chew toys, infectious diseases, and oral home care, should be obtained. Dysphagia, anorexia, ptyalism, pawing at the face, chewing on one side, bruxism, and dropping food are indicators of oropharyngeal pain. However, many patients may not show any of these clinical signs.

The oral examination begins in the conscious patient. The oral examination should proceed slowly, methodically, and thoroughly so that subtle lesions are identified and patients remain compliant. Observations for facial symmetry, punctures, wounds, lacerations, masticatory muscle atrophy or swelling, alopecia, draining tracts, pyoderma, and moisture are noted.[43] Halitosis may be noted at this time. Halitosis may be the result of dental disease, oral ulcerations, respiratory disease, gastrointestinal disease, or dermatologic disease (e.g., lip-fold pyoderma).

The regional lymph nodes are palpated for size, symmetry, and mobility. The eyes are retropulsed for resistance. Resistance and pain suggests retrobulbar abscess or cellulitis, space-occupying lesions, or myositis. The maxillary and mandibular bones are palpated for irregularities, swellings, crepitation, and draining tracts. Each side of the mouth is separately evaluated by gently, and carefully, lifting the lips. Occlusion is evaluated to rule out traumatic occlusions as a cause of mucosal trauma. The oral examination should account for a complete dentition (42 and 30 teeth in an adult dog and cat, respectively). The distal dentition may be difficult to assess without opening the mouth. The mouth is opened and the TMJs are evaluated for pain, crepitation, and clicking. The mucosa of the hard palate and caudal oral pharynx is evaluated. However, patients with oropharyngeal trauma to the bones and soft tissue will resist opening or have pain upon opening the mouth. Mandibular fractures often are shifted toward the side of the

fracture whereas the mandible is more often shifted to the contralateral side of a luxated TMJ.

Lingual foreign bodies present with dysphagia and rapid tongue and jaw movements.[4] The base of the tongue should be closely evaluated for foreign bodies. This can be accomplished by pushing the tongue dorsally from the ventral aspect in the intermandibular space during examination. However, complete evaluation of the tongue requires general anesthesia.[44,45]

Anesthetized Oropharyngeal Examination

Physical forces that fracture the maxillofacial skeleton may cause trauma beyond the oral cavity. Therefore, the entire patient must be evaluated for pulmonary, neurologic, and systemic injuries prior to anesthesia. Anesthesia is required for a complete and thorough oral exam in addition to intraoral radiographs, biopsy, and advanced imaging techniques.

The oral mucosa of the tongue, palate, cheeks, and oropharynx are evaluated for ulcerations, erosions, lacerations, foreign bodies, sinus tracts, and vesicles. Sinus tracts apical to the mucogingival junction often indicate endodontic disease whereas those at, or coronal to, the mucogingival junction often indicates periodontal disease. Definitive diagnosis requires intraoral radiography. The sublingual and ventral regions of the tongue should be closely evaluated by moving the tongue laterally and dorsally. Sublingual edema needs to be differentiated from ranula.

Acute oropharyngeal penetrating injuries cause swelling, pain, and ptyalism with or without blood.[46,47] However, these signs are often missed and most cases present chronically with sinus tracts, swelling, dysphagia, and oral pain.[46,47] Oropharyngeal injuries resulting in retrobulbar cellulitis cause pain on opening the mouth, painful retropulsion of the eye, and possible swelling distal to the last maxillary molar. Exophthalmos, prolapse of the third eyelid, chemosis, and scleral injection may occur.[48-50]

The teeth are evaluated for fractures, mobility, gingival recession, and furcation exposure. The dental explorer will often stick in an exposed endodontic system whereas the explorer will slide across the smooth surface of worn teeth. If the dental explorer sticks to the tooth substance, endodontic disease should be thoroughly evaluated with intraoral radiography. Periodontal measurements with a dental probe should be made around each tooth (six surfaces of each tooth) and abnormal measurements recorded. The normal sulcus depth of the dog is 0 to 3 mm and of the cat 0 to 0.5 mm.[51]

Diagnosis

Diagnosis of oropharyngeal trauma requires history, clinical exam, an anesthetized oral exam, intraoral radiographs (when appropriate), and advanced imaging. Some dental pathology has sub-gingival manifestations therefore intraoral radiographs are *required* for complete assessment.[52,53] A complete blood count, chemistry panel, and urinalysis should be part of the systemic evaluation of the patient in preparation for anesthesia.

Skull and TMJ radiographs are reasonable screening tools. However, superimposition of maxillofacial skeletal anatomy, a requirement for heavy sedation or anesthesia to obtain diagnostically positioned films, and the related expense with a low diagnostic yield, make it less valuable compared with advanced imaging such as CT or MRI. CT improves both diagnosis and surgical planning for open-mouth mandibular and maxillofacial oropharyngeal trauma.[19,54,55]

Cytology from sinus tracts may aid in diagnosis but is often nonspecific. Cultures of oropharyngeal cavity and sinus tracts are also often unrewarding. The oral cavity contains hundreds of bacterial species in a mixed population. Additionally, it is difficult to culture anaerobic pathogens that are commonly involved in dental pathology. Special culture medium and consultation with the laboratory are necessary if trying to culture specific anaerobic pathogens.

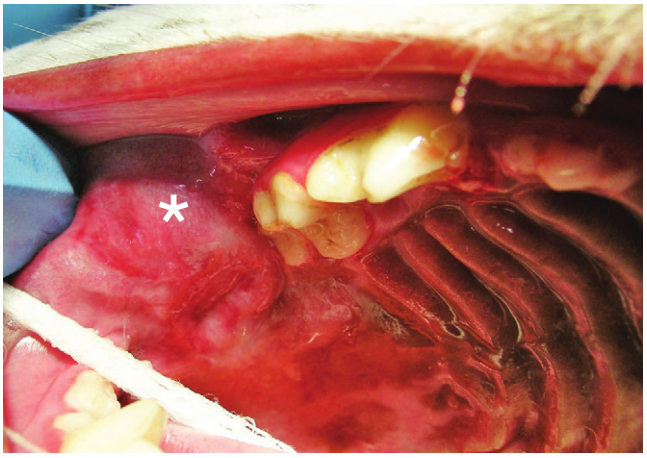

Figure 54-26 A caudal oropharyngeal puncture wound is present distal to the second right maxillary molar in the pterygopalatine fossa (*white asterisk*). The suborbital tissues and eye are present dorsal to the region. The patient was diagnosed with retrobulbar and caudal oropharyngeal cellulitis and responded well to treatment.

Exploration of the pterygopalatine fossa, retrobulbar tissue, and caudal oropharynx may be both diagnostic and therapeutic. The tissues are carefully explored to look for regions of abscess, sialocele, and cellulitis (Figure 54-26).[48] Vital maxillary arteries and their branches, maxillary and optic nerves, and the eye must be avoided.[56] Diagnosis of penetrating foreign bodies in the oropharyngeal regions includes CT, MRI, and ultrasound.[28,50,57]

Biopsies of oral mucosa are often nonspecific but are useful in the ruleout of autoimmune and neoplastic processes that may have clinical appearances similar to ulcers and granulomas. Experienced veterinary pathologists or human oral pathologists are necessary for challenging and atypical cases.

Additional testing, such as for type 2M antibody and muscle biopsies, are useful to rule out masticatory myositis as a cause of pain and difficulty in opening the mouth.[58] Proper diagnosis of oropharyngeal and retrobulbar infections is necessary as misdiagnosis and treatment may result in systemic and neurologic infection.[49]

Treatment

General Oropharyngeal Treatment

Treatment should be based on an accurate diagnosis. If antibiotics are necessary to treat oropharyngeal soft- and hard-tissue infections, the antibiotic spectrum should include drugs for anaerobic and facultative anaerobic infections (e.g., clindamycin, amoxicillin/clavulanic acid, tetracyclines, and metronidazole).[59,60]

Trauma often has an inflammatory component; therefore, nonsteroidal antiinflammatory drugs are needed to control inflammation and pain if there are no medical contraindications to their usage. Additional analgesia with regional nerve blocks, opioids, for example, for multimodal pain control, is always recommended.[61,62]

An often overlooked, but excellent treatment modality, is the use of an oral 0.12% chlorhexidine gluconate rinse.[63] The oral cavity can be rinsed every 8 to 12 hours to help control oral bacteria and secondary infection of oropharyngeal wounds, ulcers, and inflammation. Soft food (canned and/or moistened kibble) is necessary during the healing period of mucosal injuries, oral surgery, and skeletal repair.

Oropharyngeal Soft-Tissue Trauma Treatment

Ulcerative oropharyngeal trauma requires removal of the inciting cause and supportive analgesic, antibiotic, and nutritional care (e.g., feeding tubes if necessary) during the healing period. Retropharyngeal cellulitis and abscesses may be explored with blunt dissection. Whether or not a true pocket of purulent debris is found, the site is lavaged with sterile saline and surgically closed to prevent further bacterial contamination from the oral cavity. Deep and blind biopsy is contraindicated because of the vital regional anatomy.

Traumatic soft-tissue wounds can be treated intraorally with debridement, lavage, and surgical closure with poliglecaprone 25, chromic gut, or polyglactin 910 suture material. It may be difficult to identify a foreign body with penetrating injuries.[46] If cervical emphysema is present, exploration of the cervical region may be necessary.[47] If the presumptive diagnosis is *Actinomyces* or *Nocardia* infection, treatment involves surgical debridement and drainage, as indicated, and prolonged use of antibiotics. Removal of impaled oropharyngeal, cervical, and transoral foreign bodies should be done under general anesthesia as the removal of the object may unmask occluded major vessels that result in immediate and massive hemorrhage of the regional vasculature.

Soft-tissue avulsion injuries require the mucosa to be sutured back over the bone. It is crucial to return *gingiva* to surround each tooth, as it is required to protect the tooth and underlying periodontium. Small 5-0 suture should be used to suture the mucosa and gingiva (often at the mucogingival junction). Interdental sutures with 3-0 or 4-0 may be used to support the mucoperiosteal flap. Treatment of electrical wounds requires extensive client consultation and, potentially, multiple surgeries as the trauma demarcates over several weeks.

Soft-tissue and palatal trauma secondary to malocclusion dentition requires endodontic, orthodontic, and/or exodontic treatment.

Dental Trauma Treatment

Any tooth with pulp exposure *requires* endodontic treatment or surgical extraction. Endodontic treatment for a tooth fracture is not an emergency and the patient can be referred in a timely manner to veterinary dentists experienced in endodontic treatment. Even if the pulp is not exposed, sealing of the dentin tubules with a dental sealant or unfilled resin decreases tooth sensitivity and pain and stops the ingress of bacteria through the dentin tubules. Discolored teeth require endodontic treatment or surgical extraction as indicated. A root canal treatment involves accessing and mechanically and chemically cleaning and disinfecting the root canal(s), followed by obturation (sealing the root canal system), and, finally, restoring the tooth. The tooth is dead, but functional, and the periapical inflammation can heal. Freshly fractured immature adult teeth, without formed apices and minimal secondary dentin production, can often be treated with vital pulp procedures (partial coronal pulpectomy and direct pulp capping). Fractured deciduous teeth require careful and complete extraction at the time of diagnosis to prevent damage to the adult tooth buds.[64]

Tooth luxations are urgent and avulsion of the tooth is a true dental emergency. Tooth luxation injuries require gentle replacement *without* debridement of the microscopic periodontal ligament cells and cementum from the tooth surface. The tooth must be splinted in place with stainless steel wire and/or composite material and treated with a root canal therapy within a couple of weeks.[37,65,66] Avulsed teeth must be immediately placed in saliva or milk and a veterinary dentist should be contacted within the hour to reimplant the tooth, splint the tooth, and perform endodontic treatment.

Skeletal Trauma Treatment

Treatment of trauma patients includes stabilization of the patient, thoracic radiographs to evaluate for pneumothorax and pleural effusion, and treatment of concurrent injuries. Often maxillofacial repair can be delayed for 24 to 72 hours to allow the patient to be a more suitable anesthesia candidate. During that period, aggressive pain management protocols and nutritional support is provided. Placement of esophagostomy or gastrotomy tubes should be considered based on the extent of maxillofacial trauma and planned repair. Nasoesophageal tubes should perhaps be avoided as many of the patients have nasal fractures that may not be obvious. Placing a tube in the nasal cavity can be irritating and painful in these cases.

Noninvasive fracture repair with preservation of occlusion and rapid return to function is preferred.[67,68] During fracture repair it is crucial to not only focus on skeletal structures but the dentition as well. Repair with interdental wires and composite materials provide stabilization to achieve these goals.[20] The use of straight orthopedic plates on curved jaws often results in a traumatic malocclusion and damage to the tooth roots and neurovascular bundles. If external fixators or plates are used, tooth roots and neurovascular bundles must be avoided. Fractured teeth may require endodontic or exodontic treatment.

Treatment of Gunshot Wounds

Treatment for gunshot wounds includes patient stabilization, recognition of life-threatening injuries, clarifying the history (type and range of firearm), and performance of CT, intraoral radiographs, and other imaging modalities. Client preparation and meticulous medical record documentation, including photographs, is essential.[32] The client should be counseled that multiple surgeries may be necessary with both primary closure and delayed second intentional healing. Projectile ballistics can remain in the tissues if they are not threatening vital structures as retrieval may lead to excessive regional damage and increased morbidity. If they are removed, they should be saved for potential criminal investigations. Long-term followup and intraoral radiographs in 6 to 12 months is necessary to evaluate for hidden tooth damage.

Prognosis

With proper recognition, early diagnosis, and treatment many oropharyngeal injuries have a good to excellent prognosis. The oral mucosa has a tremendous capacity to heal after the inciting cause has been removed. The most frustrating condition, with a reasonably good prognosis if identified and treated correctly, is cervicofacial actinomycosis from a penetrating foreign body.

Dental injuries have a good to excellent prognosis if there is not a failure to recognize the injury or failure to evaluate the dentition with intraoral radiographs. Endodontic (root canal therapy) treatment for fractured teeth is 96% successful if carried out by a trained and experienced veterinary dentist.[69] Endodontic treatment is

preferred compared with surgical extraction of the tooth. Vital pulp procedures (e.g., partial coronal pulpectomy, direct pulp capping, and indirect pulp capping) can have a good prognosis that is dependent on the duration of injury and age of the patient.[70-72] There are increased morbidity and functional and cosmetic sequelae with the loss of some teeth. However, if the owner declines endodontic treatment each patient deserves the right to a comfortable and infection free oral cavity and affected teeth should be surgically extracted. Just because they are "eating" does not mean that there is not chronic inflammation, infection, dull pain, and possible systemic associations.

Maxillofacial fractures can have a good to excellent prognosis once the patient is systemically stabilized. Even when there appears to be a hopeless destruction of the oropharyngeal tissues and of the maxillofacial skeleton, the tissues can be rebuilt in skilled hands. Electrocution injuries are the most challenging and have a guarded to fair prognosis to return to normal. Scarring, oronasal fistulas, tooth injury, bone injury, and the need for multiple reconstructive surgeries makes these cases challenging surgically, and financially and emotionally challenging for the client.

CHAPTER 55

Esophagus

STRUCTURE AND FUNCTION

Anjop Venker-van-Haagen

The esophagus conveys food from the pharynx to the stomach. This relatively narrow tube begins dorsal to the cricoid cartilage of the larynx and accompanies the trachea, at first inclining to the left but regaining a median position above the trachea before or shortly after entering the thorax. Within the thorax it runs in the mediastinum and, continuing beyond the tracheal bifurcation, it passes over the heart before penetrating the esophageal hiatus of the diaphragm to join the stomach at the gastroesophageal junction (the cardia).[1] The cardia is pulled caudally and may be found in the abdomen, but this is not a consistent finding in all canine breeds.[2]

Structure of the Esophagus

Macroscopic Structure

The structure of the esophagus conforms to a pattern that is common to the alimentary canal (see Chapter 1). The outer coat of loose connective tissue, the adventitia, is present in the cervical part but is largely replaced by serosa in the thorax. In dogs, the muscle of the esophagus is striated from the cricopharyngeus muscle to the junction with the stomach. In cats, the striated muscle is replaced by smooth muscle within the thorax, such that roughly the proximal one-third is striated muscle and the remainder is smooth muscle. The muscular layer of the esophagus is composed of two strata, both of which are spiral, and they wind in opposite directions in the first part of the esophagus. Closer to the stomach the outer stratum becomes more longitudinal and the inner more circular.[1,3] Two sphincters are suggested on the basis of functional studies; a cranial (upper) and a caudal (lower) sphincter, but these are less convincingly demonstrated morphologically. The cranial sphincter is provided by fibers of the cricopharyngeal muscle. In the cat the cricopharyngeal muscle and the esophageal muscle are not morphologically separate.[3] A thickening of the esophageal muscle mass at the junction of the esophagus with the stomach suggests a sphincter, but food is impeded slightly more cranial to this—just cranial to the diaphragm.[1] In dogs, the thickness of the circular striated muscle layer increases from the distal esophagus to the gastroesophageal junction and cardia.[3]

The inner part of the wall of the esophagus consists of submucosa and mucosa, divided by the fenestrated muscularis mucosae, which is more prominent in the thoracic part of the esophagus. The submucosa loosely connects the mucosa and the muscularis. This structure allows the relatively inelastic mucosa to be thrown into longitudinal folds when the esophagus is contracted. The submucosa contains blood vessels, nerves, and glands. Glands are found over the entire length of the mucosa in dogs, but only in the cranial one-third of the esophagus in cats.[3] In both dogs and cats, the muscularis mucosae is more prominent in the thoracic esophagus. The mucosa is composed of keratinized, stratified squamous epithelium, which contains the openings, at about 1-mm intervals, of the ducts of the esophageal glands. The cat has transverse folds in the mucosa in the caudal half of the esophagus. These folds are permanent and independent of the state of contraction of the esophagus.[3]

Microscopic Structure

The outer coat of the esophagus, the adventitia, consists of connective tissue with elastic fibers. In dogs the muscularis of the esophagus is entirely striated muscle, whereas in cats the striated muscle is replaced by smooth muscle within the thorax. Fiber type composition has been studied by histology and immunohistochemistry, and myosin type has been studied by electrophoretic peptide mapping and two-dimensional gel electrophoresis, respectively.[4]

In both dogs and the cats, the striated esophageal muscle was composed of a small percentage of type I and IIC fibers, but the predominant type was very different histochemically and immunohistochemically from all fiber types (I, IIA, IIB, IIC) present in skeletal muscles. This esophageal fiber type (IIoes) had an acid- and alkaline-stable m-adenosine triphosphatase (ATPase) activity and a moderate histochemical Ca-Mg actomyosin ATPase activity, and it reacted weakly with anti-IIA and anti-IIB myosin sera. Although the light chains of the IIoes were the same as the light chains of a mixture of IIA and IIB myosin, their respective heavy chains gave different peptide maps. Greater differences were observed between the heavy chains of IIoes and other striated muscle myosins.[4] It was concluded that this predominant fiber type in the dog and cat striated muscle is of the "fast" type, and contains a distinct isoform of myosin similar, but not identical, to the other fast-type myosins. Histochemically and immunohistochemically, the muscle of the canine esophagus was similar to that of cats.[4]

The histologic characteristics of the lower or gastroesophageal sphincter (LES) were compared with those of the smooth muscle of the distal esophagus in three cats. Numerous thin, annulospiral elastic fibers were found in the circular layer of the LES and the distal esophagus. These fibers were not observed in other areas.[5]

In dogs the esophageal glands were found over the entire length of the esophagus, whereas in cats they were found only in the cranial one-third of the esophagus.[3] Scanning electron microscopy (SEM), light microscopy, and morphometric analyses were used to study the morphology of the mucosa and submucosa of the cervical, thoracic, and abdominal esophagus in the dog.[6] Apart from the absence of a lamina muscularis mucosae in the cervical part of the canine esophagus, little regional variation was detected. There was, however, morphologic variation associated with age. The number and complexity of microplicae on surface epithelial cells observed by SEM increased with age, particularly between 1 and 21 days of age. Although SEM revealed typical duct openings from submucosal glands in 1-day-old dogs, light microscopy revealed few functional glands at that age. However, there was a marked increase in the volume fraction occupied by glands between 1 and 161 days of age, followed by some decrease between 161 and 337 days of age.

Ciliated cells were observed in the esophagus of 1-day-old dogs, being most abundant in the abdominal part, but by 21 days of age, groups of ciliated cells were no longer observed in any part of the esophagus.[6]

Vessels of the Esophagus

The arterial blood supply to the cervical part of the esophagus in dogs and cats is supplied by the thyroid arteries and esophageal branches of the carotid arteries.[7,8] The esophageal portion of the bronchoesophageal artery is the main supply to the cranial two-thirds of the esophagus and the remaining part is supplied by esophageal branches of the aorta.[7]

Venous drainage is via the external jugular and azygos veins; adjacent veins anastomose with each other on the esophagus.[7,8] Lymph vessels from the esophagus drain into the medial retropharyngeal, deep cervical, cranial mediastinal, bronchial, portal, splenic, and gastric lymph nodes.[7]

Nerves of the Esophagus

Innervation of the striated muscle of the esophagus in dogs and cats is provided by special visceral efferent neurons from the bilateral nucleus ambiguus in the medulla oblongata. Axons are carried in the vagus nerves and distributed with the pharyngoesophageal nerves, the recurrent laryngeal nerves, and the vagal trunks. In cats the smooth muscle innervation, via general visceral efferents, arises from the rostral parts of the bilateral nucleus ambiguus and is also distributed via the branches of the bilateral vagus nerves. Three major regions of innervation can be recognized in the esophagus of dogs: a cervical region, supplied by paired pararecurrent laryngeal nerves; a cranial thoracic region, supplied mainly by the left pararecurrent laryngeal nerve; and a caudal thoracic and abdominal region, supplied by the vagal trunks.[7,9]

Function of the Esophagus

The function of the esophagus is to transport food and liquid from the pharynx to the stomach. The esophageal stage is the last stage of the swallowing action and although linked to the pharyngeal stage, is under distinct neuronal control. Swallowing is a physiologic phenomenon that occurs many times daily. Although it may be initiated consciously as a voluntary act during eating, most swallowing occurs subconsciously between meals, without apparent cerebral participation. Swallowing irrespective of eating occurs about once a minute in conscious individuals and is driven by salivation, which stimulates the sensory receptors in the mouth and pharynx.[10] Studies in humans show that both salivation and swallowing virtually cease during sleep.

Swallowing is a complex and complicated function that can be divided into four overlapping stages: oral preparatory, oral, pharyngeal, and esophageal. The first two are voluntary and the last two are involuntary. In the oral preparatory stage, food is chewed and prepared for the oral stage (see also Chapter 54). In the oral stage the food bolus is moved from the front of the oral cavity to the faucial arch, where the pharyngeal stage is initiated. The pharyngeal stage has four defined components: palatopharyngeal closure, peristalsis of the pharyngeal constrictor muscles, airway protection, and cricopharyngeal relaxation. The larynx is elevated and closed, protecting the airway. These reflex movements occur in sequence and overlap one another. They are mediated by the reticular formation in the brainstem and follow a fixed pattern. The interneuronal network involved in this pattern is termed the central pattern generator (CPG) for swallowing. Interconnections between the left and right CPGs coordinate their activity (Figure 55-1). There is coordination with the respiratory center as well.

In the final stage of swallowing, the bolus is moved through the esophagus by the peristaltic contractions of the esophageal

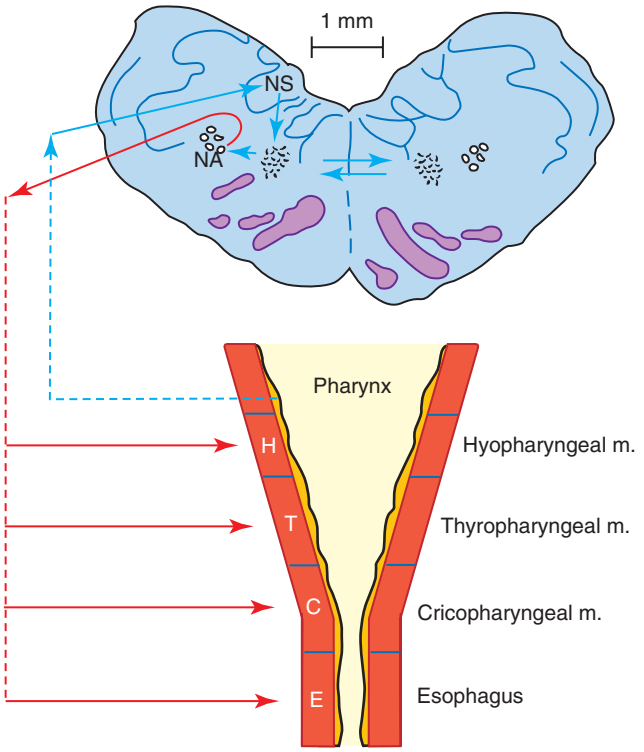

Figure 55-1 Swallowing occurs in sequential reflex of the pharyngeal and esophageal muscle contractions and in relation between these muscles and the brainstem. Afferent fibers in the glossopharyngeal nerve, the pharyngeal and esophageal branches of the vagus nerve and the cranial laryngeal nerve activate the solitary nucleus (NS). The sequential contractions are mediated by the reticular formation in the brainstem and follow a fixed pattern. The interneuronal network involved in this pattern is termed the *central pattern generator* (CPG) for swallowing. Via the CPG for swallowing the neurons in the nucleus ambiguus (NA), the motoneurons of the swallowing muscles, generate sequential swallowing activity. Interconnections between the left and right CPGs coordinate their activity. (From Venker-van Haagen AJ: Diseases of the throat. In Ettinger SJ, Feldman EC, editors: *Textbook of Veterinary Internal Medicine*, Philadelphia, 2000, Saunders.)

musculature.[11] The swallowing action during this stage is best illustrated by contrast videofluorography.[12] After the prehension of food by the stripping action of the tongue, a bolus is formed at the base of the tongue and is passed into the oropharynx. This is immediately followed by contractions of the pharyngeal muscles, lifting the food bolus up and passing it through the relaxed cranial esophageal (cricopharyngeal) sphincter into the cervical part of the esophagus. At the same time, the pharyngeal egresses (i.e., nasopharynx, oral cavity, and laryngeal opening) are closed, preventing regurgitation and leakage into the trachea. After entry of the bolus into the esophagus, the cranial esophageal sphincter immediately closes and the bolus is transported by one slow and regular peristaltic wave from the cervical region to the gastroesophageal junction, where it passed slowly through the relaxed sphincter into the stomach.

The passage of food through the cricopharyngeal sphincter is usually followed immediately by esophageal peristalsis. However, in some dogs, especially those that bolt their food, not every swallowed bolus is picked up immediately by esophageal peristalsis; sometimes, peristaltic activity starts only after a second or even a third bolus entered the esophagus. Another frequent phenomenon is the stopping of a bolus of food somewhere in the esophagus until it is carried along with the next bolus. Similarly, a bolus sometimes stops at the gastroesophageal sphincter and does not enter the stomach until it is carried in with the next bolus. Reflux of food from the stomach into the terminal portion of the esophagus occurs occasionally, but it is always followed by secondary peristalsis that clears the esophagus. The pharynx and esophagus are always completely cleared of food at the end of the meal.[12]

Neurophysiologic Control of the Esophageal Stage of Swallowing

Esophageal peristalsis initiated by the pharyngoesophageal action is termed *primary peristalsis*. Secondary peristalsis occurs when a bolus remains in the esophagus. It is initiated by receptive fields in the esophagus which are stimulated by the persistent bolus.[13]

The motor sequence of the esophageal stage depends, as does the pharyngeal stage, on the activity of medullary interneurons in the swallowing center. Through excitatory and inhibitory connections, these interneurons program the sequential excitation of motor neurons and vagal preganglionic neurons responsible for the entire motor sequence, in both striated and smooth muscles of the esophagus. The activity of the medullary swallowing neurons occurs without feedback phenomena, and is thus entirely dependent on a central network.[14]

Components of the Sensory Pathway in the Esophageal Stage of Swallowing

The esophageal stage of swallowing requires sensory feedback to control and modulate its function. The importance of sensory feedback is suggested by the finding that the peristaltic waves were slower, greater in amplitude, and longer in duration during swallowing of water than during dry swallowing.[14,15] The influence of stimulation of the afferent fibers of the esophagus was shown to increase the discharge of the vagal motor fibers supplying the esophagus.[15-17] The afferent fibers of the esophagus are in the glossopharyngeal and vagus nerves. The cell bodies of these cranial nerves lie in their associated sensory ganglia. Branches of these sensory nerves pass rostrally to innervate the nerve cells in the nucleus of the solitary tract in the medulla oblongata. The neurons of this nucleus connect with interneurons in the dorsal area around the nucleus tractus solitarius. This dorsal region contains the first synaptic sites for the sensory input that evokes swallowing and the interneurons that are excited switch on the specific timing during pharyngeal and esophageal swallowing. Once triggered, bursts of sequential activity in interneurons in the dorsal region may function without feedback. They are driven by central neurons, the "master" interneurons, which set up the sequential activation of specific motor neurons. These master neurons control in particular the pharyngeal swallowing pattern. They are linked to interneurons in the ventral region around the nucleus ambiguus, which control the esophageal stage of swallowing and activate the motor neurons in the nucleus ambiguus. The interneurons in the ventral region connect with the contralateral region involved in swallowing and thus unilateral activation of swallowing may activate nucleus ambiguus motor neurons bilaterally. It is not clear how the dorsal and ventral regions connect with the motor neurons of the dorsal motor nucleus of the vagus.[13]

Components of the Motor Pathway in the Esophageal Stage of Swallowing

The motor neurons for the esophageal stage of swallowing are in the left and right nucleus ambiguus in the brainstem. The motor neurons innervating both the striated and smooth muscles of the esophagus are located in the rostral part of the nucleus ambiguus. The dorsal motor nucleus of the vagus nerve, which would be expected to harbor preganglionic neurons innervating the smooth muscles of the distal esophagus, are apparently not of major importance to the swallowing action of the esophagus in the cat. The axons of the motor neurons in the nucleus ambiguus associated with esophageal swallowing proceed through the vagus nerve and directly innervate esophageal striated muscles, or they pass to ganglia near the esophagus from which postganglionic excitatory cells then innervate the smooth muscles.[13] As mentioned previously, the timing of esophageal swallowing is controlled by the CPG, a group of interneurons in the reticular formation and around the nucleus ambiguus, under influence of the sensory input that elicits swallowing.[13]

Peripheral Neural Control of Esophageal Peristalsis

Esophageal peristalsis is normally a smooth, uninterrupted contraction wave that traverses the esophagus. It consists of a rapid wave of relaxation followed by a slower wave of contraction. A rapidly descending wave of inhibition sequentially relaxes the upper esophageal sphincter, the body of the esophagus, and the LES, so that they are prepared for passage of an oncoming bolus. In recumbent subjects, transport of the bolus is exclusively the result of pharyngoesophageal peristalsis, while in upright subjects it is assisted by gravity.[10,18]

Neural control of esophageal peristalsis differs between dogs and cats in that the end organ in dogs is striated muscle and in cats it is both striated and smooth muscle. The striated muscle of the canine esophagus is a relatively slow-contracting muscle, as shown by direct electrical stimulation in vitro.[13,19] Electrical stimulation of the vagus nerve to the esophageal striated muscle caused contraction of the muscles,[13,20] and curare, which antagonizes the neurotransmitter acetylcholine, blocks the vagal excitation of the canine striated esophageal muscle. Curare blocks the peristaltic contractions of the entire esophagus in dogs.[13,21] Pharmacologic studies show that the striated esophageal muscle is under central neural control via motor fibers that release acetylcholine to stimulate nicotine receptors, the same receptors as in somatic muscles. In the same comparison with somatic muscles, inhibition of the striated esophageal muscles depends on a decrease in discharges from the vagal efferent fibers. No separate inhibitory mechanism for striated esophageal muscles

has been found.[13] Esophageal peristalsis in the dog is produced by a descending sequence of efferent neural discharges, generated by the central swallowing program.

In the cat, the esophageal striated muscles are innervated and function in the same way as in the dog. In the smooth muscles of the distal part of the esophagus in the cat, peristalsis can develop with or without central efferent signals via the vagus nerve.[13,22] As peristalsis reaches the distal part of the striated muscle segment, the central swallowing program stimulates the onset of peristalsis in the proximal part of the smooth muscle segment. Esophageal peristalsis is most likely initiated by neural excitation. This originates centrally in primary peristalsis and in cats it also does so in secondary peristalsis.[10] The organization of esophageal muscle peristalsis was shown to persist after experimental transection of the vagus, and the smooth muscle segment of the esophagus can also function without central control.

Acetylcholine is an important transmitter in the ganglia or at the neuromuscular junction of the esophageal smooth muscle.[13,23] It is postulated that the timing of sequential activation could depend on the amount and ratio of neural transmitters at each segmental level, the timing of their release, and the density of smooth muscle receptors.[13,24] It is probable that peristalsis in the smooth muscle segment of the esophagus in the cat functions via a neuronal network through the ganglia, with or without the smooth muscle providing control for a sequential contraction, and thus with or without sequential activity descending in the vagal efferent fibers.

Peripheral Neural Control of the Gastroesophageal Sphincter Function

During swallowing, the neural control of the LES in the dog and cat is similar to the neural control of peristalsis in the distal third of the esophagus. In dogs, relaxation and contraction of the LES follows the activity of the distal esophagus and is under control of the central pattern generator for primary peristalsis in the distal esophagus. Vagal nerve fibers directly innervate the striated muscle cells, their neurons being located in the nucleus ambiguus. In the cat, neural control of the sphincter is similar to control of peristalsis in the distal third of the esophagus and is under control of the central pattern generator. The smooth muscle of the sphincter is directly innervated by postganglionic cells and in part by mechanisms intrinsic to the esophagus itself.[10]

Other Influences on Gastroesophageal Sphincter Function

Also influencing LES function are the receptor responses to intrinsic or extrinsic pharmacologic agents. Most studies of these agents have been concerned with better understanding of the causes of reflux esophagitis in humans, but several of the studies have contributed to our understanding of the function of the LES in dogs and cats. In conscious dogs the LES response to a meal consists of tonic contractions of the sphincter. These appear to be mainly regulated by muscarinic receptors. Nitric oxide can inhibit postprandial contractions of the LES.[25]

In dogs, gastric distention induces transient relaxation of the LES. The basal LES pressure fell progressively during distention of the antrum but not during distention of the fundus alone. The antrum was considered to be primarily responsible for triggering transient relaxation of the LES induced by distention.[26] Radiofrequency energy applied to the LES in dogs inhibited the triggering of transient relaxations and this reduced the resulting gastroesophageal reflux. Basal LES pressure and LES relaxation during swallowing were unchanged.[27] In cats, swallowing and balloon distention of the esophagus both caused relaxation of the LES.[28] Microinjections of bicuculline (γ-aminobutyric acid [GABA] antagonist) in the dorsal motor nucleus of the vagus in the medulla oblongata in cats caused a decrease in the LES pressure. This effect was abolished by vagotomy. These results indicate that the dorsal motor nucleus of the vagus influences the functional regulation of the LES in cats.[29] It is to be expected that more detailed information about the function of the LES in relation to gastric motility will become available, since better understanding of the dysfunction of the LES in reflux disease is of high priority in human gastroenterology.

DIAGNOSTIC EVALUATION

Robert G. Sherding

Most esophageal diseases in dogs and cats are diagnosed by the signalment, history, physical examination, survey thoracic radiography, barium contrast esophagraphy ("barium swallow"), and esophagoscopy. Survey and static-image barium radiography and endoscopy are generally adequate for diagnosis of structural and intraluminal disorders of the esophagus; functional motility disorders are best evaluated by a dynamic contrast imaging procedure (three-phase barium videofluoroscopy). Ancillary laboratory tests are useful for identifying underlying causes of esophageal hypomotility and acquired megaesophagus. Specialized procedures for evaluating esophageal function include nuclear scintigraphy, manometry, pH monitoring, and electromyography, but these procedures have not been used routinely in dogs and cats because of limitations in availability and practicality.

History and Signalment

Clinical signs suggestive of esophageal disease include regurgitation, dysphagia, odynophagia, salivation, retching, gagging, and repeated swallowing. Other less-specific signs include weight loss, anorexia or ravenous appetite, and depression. Aspiration pneumonia, a frequent complication of esophageal disease, can cause fever, cough, tachypnea, and dyspnea.

Regurgitation

Regurgitation is the hallmark of esophageal disease and is defined as the passive evacuation of food or fluid from the esophagus into the environment. Regurgitation results primarily from local mechanical events within the esophagus and must be distinguished from *vomiting*, which is a centrally mediated reflex characterized by the active evacuation of gastroduodenal contents preceded by nausea, hypersalivation, retching, and abdominal contractions. The history should determine the age of onset of regurgitation, the duration of signs, the timing of regurgitation in relation to eating, and a description of the regurgitated material. Videorecordings of eating and drinking behavior are often very informative and may help to differentiate esophageal and upper airway signs. Chapter 21 has additional discussion of regurgitation and a diagnostic algorithm.

Breed predispositions for esophageal disease should be considered, especially in young puppies and kittens with persistent regurgitation of undigested food that begins shortly after weaning, which is suggestive of vascular ring anomaly, congenital idiopathic megaesophagus, or congenital esophageal stenosis.[1] The congenital form of megaesophagus is heritable in Wire-haired Fox Terriers and Miniature Schnauzers and an increased prevalence has been noted in Irish Setters, Great Danes, German Shepherds, Labrador Retrievers,

Newfoundlands, Chinese Shar-Peis, and Siamese cats.[2-4] In addition, acquired megaesophagus and oropharyngeal dysphagia may be associated with several types of myopathy (e.g., myasthenia gravis, muscular dystrophies, and polymyositis) that have increased incidence in many breeds of dogs and cats.[5,6] Vascular ring anomalies have been reported in many breeds of dogs and cats, but German Shepherds, Irish Setters, and Labrador Retrievers appear to be at increased risk.[7,8] Late-onset regurgitation can occasionally be seen with mildly obstructive vascular ring anomalies that have gone undetected until as old as 8 years of age.[9] Young Chinese Shar-Pei dogs are predisposed to congenital hiatal hernia resulting from malformation of the esophageal hiatus.[10,11] Bulldogs and other brachycephalic breeds with upper airway obstruction have a high prevalence of concurrent hiatal abnormalities, reflux esophagitis, esophageal deviation, gastroduodenal disease.[12]

An acute onset of signs of regurgitation, salivation, and dysphagia is suggestive of an esophageal foreign body, acute esophagitis, developing stricture, or gastroesophageal intussusception. A chronic history of regurgitation is more consistent with megaesophagus, vascular ring anomaly, diverticulum, hiatal hernia, chronic reflux esophagitis, mature stricture, or esophageal neoplasia. An intermittent pattern of regurgitation is most consistent with hiatal hernia and reflux esophagitis. Esophageal tumors usually develop in old-aged dogs and cats and the signs progressively worsen over time.

The timing of regurgitation in relation to feeding is determined by the location of the esophageal abnormality, the degree of luminal obstruction, and the reservoir effect of esophageal dilation. Regurgitation immediately after eating is most likely to occur with esophageal obstruction, especially involving the cranial esophagus, or gastroesophageal intussusception. Regurgitation may be delayed for minutes to hours with megaesophagus, diverticulum, and caudal obstructions because of the accommodation of the dilated esophagus.

The regurgitated material is usually composed of undigested food (often tubular in shape), water, and white to clear frothy liquid (mucus and saliva). In comparison, vomitus usually consists of partially digested food mixed with yellow bile-stained fluid. Dogs and cats with megaesophagus usually regurgitate both solids and liquids. Tolerance of liquids but not solid foods is more typical of obstructive esophageal diseases.[1] Fresh red blood is occasionally seen with severe mucosal trauma or erosions, especially from foreign bodies. Putrefaction of ingesta may occur after prolonged retention in a diverticulum or dilated esophagus, which can cause halitosis. Both regurgitation and vomiting can occur concurrently in animals with dysautonomia, hiatal hernia, gastroesophageal intussusception, or vomiting disorders complicated by secondary reflux esophagitis.

Dysphagia, Odynophagia, and Salivation

Dysphagia, or difficult swallowing, more often connotes oropharyngeal disease and cricopharyngeal dysfunction, but may be seen with cranial esophageal diseases such as foreign body, stricture, or esophagitis. Dysphagia is characterized by repeated, often unproductive attempts to swallow with extension of the head and neck during swallowing, and is often accompanied by gagging, retching, *odynophagia* (pain on swallowing), and *ptyalism* (excessive salivation). Anorexia and unexplained salivation may be the only clinical signs in some patients with painful esophageal disease, especially esophagitis. Esophageal dysphagia and salivation must be differentiated from oropharyngeal dysphagia and salivary gland diseases, such as sialadenitis and sialadenosis. Chapters 13 and 22 provide additional discussions of dysphagia and salivation, respectively, and diagnostic algorithms.

Historical Findings Indicative of Esophageal Injury

The history is important for identifying potential causes of esophageal injury that could culminate in severe esophagitis or esophageal stricture. These include esophageal foreign bodies, gastroesophageal reflux (secondary to general anesthesia, hiatal hernia, or malpositioned esophageal feeding tubes), acid or peptic injury from persistent vomiting, irritating oral medications (e.g., doxycycline, clindamycin), ingestion of corrosive chemicals, radiation injury, thermal injury from overheated (microwaved) food, and prior esophageal surgery.[1,13-17] Clinical signs of esophagitis usually develop within 1 to 3 days following injury and include regurgitation, dysphagia, salivation, odynophagia, retching, gagging, and repeated swallowing.[1,17] In mild esophagitis, clinical signs may be subtle or absent. Severe esophagitis or foreign-body impaction can lead to serious complications of esophageal necrosis, perforation, fibrosis, and stricture. The possibility of esophageal perforation may be suggested by a recent history of foreign body ingestion. Iatrogenic perforation can also occur after endoscopic removal of foreign bodies, dilation of esophageal strictures, laser ablation of tumors, and esophageal surgery. Penetrating injuries of the cervical esophagus can be caused by bite wounds or gunshot wounds.

Esophageal strictures result from deep circumferential injury of the esophagus that heals by intramural fibrosis, resulting in narrowing of the lumen and reduced distensibility.[1,14,17] Regurgitation (solids more than liquids) and other clinical signs attributable to esophageal obstruction usually begin within 1 to 4 weeks after the inciting esophageal injury.[14,18-22] Despite the severity of the inflammation, many animals will have preservation of appetite because of the caloric deprivation and worsening malnutrition.

Owners should be questioned about the likelihood of ingested foreign objects. Esophageal foreign bodies are common, especially in small dogs (weighing <10 kg), and include objects such as bones, chew toys, plastic, rubber, pins, needles, fishhooks, string, and trichobezoars. Trichobezoars are particularly important in cats.[23-29] In one report, 12% of dogs with moderate to severe foreign-body–induced esophagitis subsequently developed strictures.[25] Esophageal foreign-body obstruction caused by dental chew treats resulted in strictures in six of 25 dogs (24%) in another report.[24] Esophageal perforation and esophagobronchial fistula are also potential complications of foreign-body trauma.

Overall, 65% of esophageal strictures in dogs and cats occur following general anesthesia.[18-22,30,31] This is presumably a result of the reflux of gastric (H^+, pepsin) and/or intestinal (bicarbonate, bile salts, and pancreatic proteases) content associated with relaxation of the gastroesophageal sphincter (GES), and the delayed clearance of the refluxate from the esophagus in the anesthetized animal.[31,32] Clinical signs of esophagitis usually develop within 2 to 4 days of the anesthetic procedure, followed by progressive worsening of regurgitation if fibrosis takes place.

Hiatal hernia is a protrusion of a portion of the stomach through the esophageal hiatus of the diaphragm, which can be the result of congenital or acquired laxity in the hiatal opening.[1,13,33,34] Clinical signs in the acquired form are often intermittent and attributable to secondary reflux esophagitis caused by displacement of the GES into the thorax. Clinical signs in the congenital form are often more frequent and more severe due to extreme laxity at the esophageal hiatus. Reflux esophagitis can occur independently of hiatal hernia, is idiopathic in some dogs and cats, and presumably results from GES incompetence or dysmotility.

Corrosive injury to the esophagus can result from several oral medications and ingested chemicals. The severity of the injury depends on chemical concentration, pH, duration of contact with

the mucosa, and distribution of the lesion (e.g., focal vs. diffuse injury). Oral tablet and capsule medications with high acidity, especially doxycycline and clindamycin in cats, can cause severe focal esophagitis and strictures.[35-39] The corrosive effects of these medications are worse in cats because of the slower esophageal propagation velocity in this species (compared with the dog), and prolonged mucosal contact time when tablets or capsules are administered as a "dry swallow."[40,41] Ingested chemical irritants are usually concentrates that have highly acidic, alkaline, or oxidant properties. This should be suspected when esophagitis is accompanied by stomatitis and oropharyngeal ulcerations (mucositis). Examples include chlorine granules, button batteries, and undiluted quaternary ammonium disinfectants such as benzalkonium chloride that cats can lick from their paws and haircoat.[42,43]

Other Clinical Signs

Other clinical signs can be seen in dogs and cats with esophageal disease. Weight loss and poor body condition can occur secondary to persistent regurgitation and inability to retain ingested food. An otherwise healthy animal with persistent regurgitation may have a ravenous appetite. This is common in animals with megaesophagus, vascular ring anomaly, and some esophageal strictures. In contrast, anorexia can occur in animals that have painful and difficult swallowing associated with severe esophagitis, stricture, esophageal foreign body, or neoplasia. Anorexia can also occur in conjunction with cough, tachypnea, dyspnea, and fever in animals that have secondary aspiration pneumonia, esophageal perforation, mediastinitis, or bronchoesophageal fistula. The owner should also be questioned about signs of neurologic or neuromuscular dysfunction that could indicate an underlying cause of acquired megaesophagus.[1,2,4]

Laryngeal paralysis (stridor and change or loss of voice) can be associated with acquired megaesophagus in dogs.[4] Disorders of the esophageal hiatus (e.g., hiatal hernia, reflux esophagitis) can be associated with chronic obstructive airway conditions such as laryngeal paralysis and brachycephalic syndrome, presumably from enlargement of the esophageal hiatus and laxity of the surrounding support structures caused by abnormally high negative intrathoracic pressure.[12] Increased intraabdominal pressure associated with vomiting or blunt abdominal trauma can also cause hiatal hernia. Severe gastroesophageal reflux can cause signs of chronic laryngitis (stridor, change of bark) from exposure of the larynx to gastric refluxate. Mediastinal tumors (lymphoma, thymoma) that cause regurgitation from periesophageal compression of the esophagus can also cause dyspnea (pleural effusion) and Horner syndrome.

Geographic predispositions should always be considered, such as *Spirocerca lupi*–associated esophageal disease (granuloma or neoplasia) in dogs from the southern United States and many other endemic regions of the world, and *Pythium insidiosum*–induced necrotizing granulomatous esophagitis in the southeastern United States.

Physical Examination

When esophageal disease is suspected, the examination should include direct observation of the prehension and swallowing of food and water. A low body condition score is a frequent finding in animals that have lost weight from chronic regurgitation. Young dogs and cats with congenital megaesophagus or vascular ring anomaly may have poor weight gain and stunted growth.

The cervical esophagus should be palpated to detect masses, foreign bodies, or distention from mechanical obstruction or megaesophagus. Distention of the cervical esophagus can be accentuated in animals with megaesophagus by compressing the thorax while the nostrils are occluded. Perforation of the cervical esophagus can lead to local edema, cellulitis, abscess, or a draining fistula in the neck region. Enlargement of the mandibular salivary glands may indicate sialadenitis (see other sections in Chapter 55). A finding of oropharyngeal ulceration accompanied by signs of acute esophagitis may indicate ingestion of a corrosive substance.

Depression, fever, cough, tachypnea, dyspnea, mucopurulent nasal discharge, and abnormal pulmonary auscultation can indicate complicating aspiration pneumonia, or rarely, bronchoesophageal fistula. In animals with esophageal foreign body, a rigid stance with fever and depression can indicate mediastinitis secondary to esophageal perforation. Pleural effusion, Horner syndrome, and a noncompressible cranial thorax can be found in animals with periesophageal cranial mediastinal tumors (e.g., lymphoma or thymoma). Neurologic deficits or muscle weakness, atrophy, or pain may indicate an underlying neuromuscular disorder as a cause of esophageal hypomotility and secondary megaesophagus. A cranial nerve examination is also important in animals with abnormal oropharyngoesophageal motility. Dysautonomia, which is a generalized autonomic neuropathy that can cause megaesophagus, is suggested by mydriasis and loss of pupillary reflexes, decreased tear production, dry mucous membranes, bradycardia, dysuria, decreased anal tone, and diarrhea or constipation.[1,2]

Laboratory Evaluations

The results of routine laboratory evaluations are normal in most dogs and cats with esophageal disease. Nonetheless, a complete blood count (CBC) is indicated to detect neutrophilia and left shift that might suggest aspiration pneumonia or esophageal perforation, and a urinalysis and serum biochemical profile can help identify underlying disorders that have been associated with abnormal esophageal motility and megaesophagus. These include hyponatremia and hyperkalemia in hypoadrenocorticism; hypercholesterolemia in hypothyroidism; increased creatine kinase and aspartate aminotransferase in polymyositis. Fecal examination for *S. lupi* ova is indicated in endemic areas.

In dogs and cats with megaesophagus and motility dysfunction, additional laboratory evaluations should be considered to identify an underlying cause.[1-3,44] Primary megaesophagus can be either congenital or acquired. Acquired megaesophagus is often idiopathic, but this is a diagnosis of exclusion. Esophageal motility dysfunction and megaesophagus can also occur secondary to various underlying neuromuscular disorders that impair esophageal motility, including myasthenia gravis, polymyositis, muscular dystrophy, other polymyopathies, peripheral neuropathies, central nervous system disease, dysautonomia, botulism, tick paralysis, tetanus, anticholinesterase toxicity, lead toxicity, hypoadrenocorticism, and possibly hypothyroidism.[2-4,44] Measurement of serum acetylcholine receptor antibody for the diagnosis of acquired myasthenia gravis is especially important, even in the absence of generalized muscle weakness, because focal myasthenia can account for 25% of acquired canine megaesophagus cases.[5,45]

Radiography

Survey and contrast radiographic evaluations are useful for the diagnosis of many esophageal diseases (see Chapter 26 for techniques). Survey thoracic and cervical radiographs are obtained initially to evaluate the entire esophagus and to identify complications of esophageal disease, such as aspiration pneumonia (alveolar lung opacity) and esophageal perforation

(pneumothorax, pneumomediastinum, mediastinitis, pleural effusion). The esophagus is not normally visible unless it contains air, fluid, food, or foreign material, so survey radiographs can often identify radiopaque foreign bodies, megaesophagus, diverticula, esophageal masses, and esophageal dilation outlined by air, fluid, or ingesta cranial to an obstructive lesion.[46,47] A small amount of air in the esophagus from aerophagia can be an incidental finding caused by excitement, nausea, dyspnea, or anesthesia. Hiatal hernia and gastroesophageal intussusception are usually identified as a mass effect cranial to the hiatus in the dorsocaudal mediastinum if the stomach is displaced at the time of the radiograph.

Contrast radiography of the esophagus is indicated in animals with signs of esophageal disease that have normal or inconclusive survey radiographs.[46] Static image barium contrast radiography (i.e., without fluoroscopy) is useful for documenting radiolucent foreign bodies, megaesophagus, diverticula, and obstructive diseases (e.g., vascular ring anomalies, strictures, tumors, periesophageal masses). Hiatal hernia and gastroesophageal intussusception can be confirmed if the stomach is displaced at the time of the radiograph.

Potential complications of contrast esophagraphy are aspiration of contrast medium or leakage from an esophageal perforation. Perforation should be suspected when survey radiographs reveal cervical soft tissue emphysema, pneumomediastinum, pneumothorax, mediastinitis, or pleural effusion. In such cases a water-soluble, nonionic, iodinated contrast agent such as iohexol (Omnipaque; Amersham Health) is preferred over barium because it is less irritating to periesophageal tissues and more readily reabsorbed.[48] For demonstrating acquired esophagobronchial fistulas, which sometimes develop after foreign-body perforation of the caudal esophagus, a dilute barium mixture (20% to 30% w/v [weight per volume]) is preferred, as iohexol is hypertonic and can cause pulmonary edema if it enters the lung.[49]

Continuous videofluoroscopic recording of swallowing is required to characterize complex motility disorders of the esophagus, as exact timing of exposures is unlikely with static-image barium radiographs.[47,50] Contrast videofluoroscopy provides a dynamic evaluation of the oropharyngeal, esophageal (both primary and secondary peristalsis), and gastroesophageal phases of swallowing (see Chapter 26).[50] Sequential three-phase contrast videofluoroscopy can be performed in the unsedated animal using barium liquid, barium paste, and barium-soaked food (kibble, canned, or both).[51] Sternal positioning may be preferable to lateral positioning for videofluoroscopic evaluations of swallowing and esophageal transit.[52] Videofluoroscopy can be combined with esophageal manometry,[53] electromyography, and pH monitoring to provide additional information on pressure–time relationships, neuromuscular integrity, and gastroesophageal sphincter function, respectively (see "Esophageal Structure and Function" section).

Megaesophagus and Motility Disorders

Megaesophagus is characterized by severe diffuse esophageal hypomotility and flaccid dilation of the esophagus. Primary megaesophagus is usually idiopathic and can be either congenital or acquired.[2,3] Survey radiographs are usually diagnostic of a severely enlarged esophagus distended with air, fluid, or food.[2] If survey radiographs are inconclusive, a static-image barium contrast esophagram can be used to confirm esophageal dilation and reduced esophageal clearance. Contrast videofluoroscopy reveals aperistalsis and impaired esophageal transport of contrast medium in the absence of obstruction. Less severe esophageal motility dysfunction without overt megaesophagus usually requires barium swallow videofluoroscopy to assess the intensity and coordination of peristalsis and the coordinated functioning of the sphincters.[47,54] Diffuse or segmental esophageal hypomotility can also occur secondary to esophagitis, hiatal hernia, and obstructive esophageal lesions, such as strictures, vascular ring anomalies, and leiomyomas.[4,10,44]

Esophageal Diverticulum

Esophageal diverticula are large pouch-like sacculations of the esophageal wall that interfere with the orderly movement of ingesta through the esophagus. Diverticula can be identified by radiography or endoscopy.[55-57] Survey thoracic radiographs show an air-, fluid-, or food-filled esophageal sacculation or pouch, and contrast radiography demonstrates pooling of barium in the diverticulum. Most diverticula occur in the cranial mediastinal and epiphrenic regions of the esophagus.[55-57] Congenital diverticula are rare abnormalities of embryogenesis that permit herniation of the esophageal mucosa through a defect in the muscularis. Acquired diverticula can result from external traction and distortion of the esophagus caused by periesophageal inflammatory adhesions (traction diverticula), or most often from increased intraluminal pressure and food impaction (pulsion diverticula) associated with esophageal injury (esophagitis), hypomotility (megaesophagus), or obstruction (e.g., vascular ring anomaly, foreign body, stricture, and tumor). Radiographs should be evaluated carefully for underlying causes when an acquired diverticulum is identified. A redundant flexure or deviation of the esophagus at the thoracic inlet is a common incidental finding in clinically normal brachycephalic and Chinese Shar-Pei dogs and should not be mistaken for a diverticulum.[58] These false diverticula lack pooling of food and fluid and decrease or disappear with extension of the neck.

Vascular Ring Anomaly

Vascular ring anomalies are congenital malformations of the great vessels and their branches that entrap the intrathoracic esophagus and other intrathoracic structures, and cause clinical signs of esophageal obstruction.[1,7,59-62] Persistent right aortic arch accounts for 95% of vascular ring anomalies. In persistent right aortic arch, the ligamentum arteriosum continues to develop from the left side and forms a fibrous band that crosses over the esophagus to connect the main pulmonary artery and the anomalous aorta. The esophagus becomes entrapped and constricted circumferentially by the ligamentum, aorta, and base of the heart. Survey thoracic radiographs usually show a severe dilation of the esophagus with food and fluid cranial to the heart. A characteristic leftward deviation of the trachea near the cranial border of the heart is a consistent finding on ventrodorsal or dorsoventral views.[7] The normal shadow of the aortic arch to the left may be absent. Barium contrast esophagram will confirm obstruction of the esophagus at or just cranial to the base of the heart. Nonselective computed tomography (CT) angiography can be used to diagnose rare atypical vascular ring anomalies.[7,62]

Esophageal Foreign Body

Esophageal foreign bodies are common and lodge most often at the thoracic inlet, base of the heart, or gastroesophageal sphincter,[23-29] which are the least-distensible regions of the esophagus. Survey thoracic and cervical radiographs are usually diagnostic for radiopaque foreign bodies, such as bones or metal objects (pins, needles, fishhooks, etc.). Radiolucent objects can be identified if outlined by air, or they may require barium contrast radiography or esophagoscopy. Foreign bodies may injure the esophageal mucosa and cause complications such as esophagitis, perforation, or stricture. If

perforation is suspected, iohexol should be used as a contrast agent instead of barium.

Esophagitis and Stricture

Survey radiographs in esophagitis are usually unremarkable except for the occasional presence of small amounts of air in the esophagus. In some cases the underlying cause of esophagitis is identified (e.g., foreign body, hiatal hernia, or caudal esophageal mass with *S. lupi* infection). Contrast studies are normal in mild cases, but the mucosal surface may appear irregular with secondary hypomotility in severe cases. Segmental narrowing of the lumen can result from spasticity, intramural edema, and focal indistensibility caused by inflammation, which can be difficult to differentiate from a developing stricture. Contrast videofluoroscopy is helpful for identifying episodic gastroesophageal reflux or intermittent hiatal herniation that can cause esophagitis.

The diagnosis of esophageal stricture can be confirmed by barium contrast radiography of the esophagus or esophagoscopy. Survey radiographs are often normal unless the esophagus is distended cranial to the stricture with food, fluid, or air. Barium contrast radiography usually confirms the site of the stricture with dilation of the esophagus cranial to the stricture site. It is difficult to differentiate a fibrous stricture from severe inflammation or neoplasia radiographically, so endoscopic evaluation is usually needed. Moreover, the length of a stricture can be overestimated radiographically because of associated inflammation and esophageal spasm.

Hiatal Disorders

Hiatal hernia is a congenital or acquired protrusion of a portion of the stomach through the esophageal hiatus of the diaphragm.[1,10,11,13,33,34] In many cases the herniation and clinical signs are intermittent. A sliding hiatal hernia, which is most common, is a cranial displacement of the abdominal segment of the esophagus, gastroesophageal junction, and cardia region of the stomach through the esophageal hiatus of the diaphragm into the thorax. A paraesophageal hiatal hernia occurs when a portion of the stomach (usually the fundus) herniates through the hiatus into the caudal mediastinum alongside the caudal thoracic esophagus.[63]

Diseases of the hiatus can often be diagnosed radiographically, especially when the hernia is persistent. Survey thoracic radiographs may demonstrate a gas-filled soft-tissue mass (the stomach) in the dorsocaudal mediastinum. The normal gastric gas bubble that is usually seen in the cranial abdomen can be smaller and displaced. A contrast esophagram usually confirms the presence of hiatal hernia. The gastroesophageal junction and gastric rugae are visible cranial to the diaphragm, but the continuity of the esophagus and stomach is still obvious. Gastroesophageal reflux of barium is sometimes identified. Hiatal herniae that are small and reduce spontaneously are a diagnostic challenge because of their intermittent nature and unknown clinical significance. Applying pressure on the abdomen at the time of exposure may induce herniation at the hiatus. Fluoroscopy improves the chances of identifying an intermittent hernia and episodic reflux.

Gastroesophageal intussusception is an invagination of the stomach into the lumen of the caudal esophagus.[1,13,64-67] Gastroesophageal intussusception can be diagnosed by radiography or esophagoscopy. If needed to confirm the diagnosis, barium esophagram will identify gastric rugae within the lumen of the esophagus and severe esophageal obstruction. Like hiatal hernia, it can be a consequence of laxity of the esophageal hiatus and may occur intermittently. It is most often a complication of esophageal hypomotility or megaesophagus.[64,66,67]

Esophageal and Periesophageal Neoplasia

Primary esophageal tumors are rare.[1,13] Squamous cell carcinoma is the most common primary malignant tumor in cats.[68,69] In regions where *S. lupi* is an endemic parasite, dogs can develop fibrosarcomas and osteosarcomas from spirocercal granulomas.[70,71] Leiomyomas, which are the most common benign tumors of the esophagus, most often arise near the gastroesophageal junction of dogs and usually are incidental findings unless large enough to partially obstruct the lumen.[72] Leiomyosarcoma, lymphoma, and metastatic carcinoma are rare tumors of the esophagus. Survey thoracic radiography may be normal or may identify a soft-tissue mass in the region of the esophagus. The degree of luminal obstruction depends on the size and position of the mass, and the esophagus may be distended cranial to the tumor site. Barium esophagram may reveal stricture with irregular intraluminal filling defects, but endoscopic biopsy will be required for definitive diagnosis. Survey radiographs in dogs with *S. lupi*-induced sarcoma may reveal a dorsocaudal mediastinal mass, spondylitis of the caudal thoracic vertebrae, and hypertrophic osteopathy.[70,71]

Mass lesions arising from periesophageal tissues may cause extraluminal compression of the esophagus or may invade locally into the wall of the esophagus. Mediastinal lymphoma is most common, although any large tumor or abscess arising from cervical or mediastinal structures (e.g., thyroid, thymus, lymph node, lung, heart base) can cause secondary esophageal compression and occlusion. Survey thoracic radiography usually identifies an intrathoracic mass in the region of the esophagus. Barium esophagram, thoracic CT scan, or esophagoscopy can all be used to identify the location and extent of obstruction. Large mediastinal and pulmonary masses can be examined by ultrasound-guided fine-needle aspiration cytology. Thoracocentesis and cytology of pleural effusion may also be diagnostic.

Esophagoscopy

Esophagoscopy is indicated for the diagnostic evaluation of many dogs and cats with signs of esophageal disease, especially when radiography is inconclusive. Esophagoscopy enables thorough visual examination for diseases that disrupt the mucosa or obstruct the lumen, for example, foreign bodies, esophagitis, strictures, tumors, and gastroesophageal intussusception.[1,13,73] Esophagoscopy is less reliable for diagnosing megaesophagus and other functional motility disorders. Some diseases of the esophagus, stomach, and intestine cause overlapping signs or involve multiple regions of the digestive tract simultaneously; thus, most animals that undergo esophagoscopy should have a complete endoscopic examination of the entire upper gastrointestinal tract (*esophagogastroduodenoscopy*). It can be difficult to obtain good quality endoscopic biopsies of normal esophageal mucosa, but adequate biopsy specimens can usually be obtained from diseased mucosa with increased friability (esophagitis) and from neoplastic tissue. Endoscopic cytology specimens collected using a guarded (sheathed) cytology brush are sometimes useful for diagnosing esophageal neoplasia, unusual forms of esophagitis caused by infectious agents (pythiosis, candidiasis, and spirocercosis), and eosinophilic esophagitis. Esophagoscopy can also be used for therapeutic intervention to remove esophageal foreign bodies, guide balloon catheter placement with esophageal strictures, assist in the deployment of esophageal stents, place indwelling gastrostomy and esophagostomy feeding tubes, and ablate neoplastic tissue with lasers.[13,73] Chapter 27 describes the equipment and techniques for performing esophagoscopy.

Megaesophagus

Esophagoscopy is less reliable than radiography for confirming megaesophagus, but it can help rule out obstructive causes of esophageal dilation (GES abnormalities, vascular ring anomalies, strictures, tumors) and evaluate for the esophagitis that develops in many cases.[2,4] Esophageal motility and lumen size are difficult to assess with endoscopy because the normal esophagus becomes flaccid and dilated with general anesthesia and insufflation of air. The typical endoscopic appearance of megaesophagus is a markedly dilated, flaccid esophagus throughout its entire length, with variable amounts of saliva, fluid, and food residue in the lumen.[73] On initial insertion of the endoscope the normal esophagus in a fasted animal is usually empty, so a motility, hiatal, or obstructive disorder should be suspected when the esophagus contains a pool of fluid and ingesta. Megaesophagus must be differentiated from segmental dilations or sacculations that develop cranial to obstructions caused by vascular ring anomalies, strictures, tumors, or periesophageal masses. A diverticulum of the cranial thoracic esophagus sometimes develops as a complication of chronic megaesophagus.

Esophageal Diverticulum

In esophageal diverticulum, esophagoscopy reveals a saclike outpouching of the esophageal lumen, often with erosive esophagitis of the mucosa lining the diverticulum. Food, fluid, or hair may have to be removed from the diverticulum before it can be adequately visualized.[57] If a diverticulum is small, the only obvious finding may be a focal pooling of fluid. Because of the thin, weakened wall of the diverticular sac, caution must be used to avoid perforation.

Vascular Ring Anomaly

Esophagoscopy is useful for diagnosing vascular ring anomaly when radiography is inconclusive or unable to distinguish it from other causes of esophageal obstruction, such as stricture. Vascular ring anomaly causes entrapment and extraluminal compression of the esophagus, yielding a characteristic endoscopic appearance. Pulsations of the major vessels against the wall of the esophagus are seen at the level of the narrowed lumen, and the outline of the band-like ligamentum forms a distinct indentation that crosses over the left dorsolateral wall of the esophagus.[13,73] In some cases the obstructed lumen is only a tiny slit-like opening. The esophageal entrapment at the level of the heart base causes the cranial thoracic esophagus to be dilated, and often distended with ingesta and fluid at the time of endoscopy. In some cases vascular ring anomaly leads to sacculation of the cranial thoracic esophagus and secondary diverticulum formation.

Esophageal Foreign Body

Esophagoscopy is the definitive diagnostic procedure for esophageal foreign body. Most esophageal foreign bodies lodge at the thoracic inlet, base of the heart, or gastroesophageal sphincter, which are the least distensible regions of the esophagus. Depending on the type of object, its size and shape, and the length of time it is in contact with the mucosa, foreign bodies can injure the esophageal mucosa during passage or through impaction and pressure necrosis when they become entrapped.[23-29] Foreign bodies with sharp edges and points, especially bones, can become deeply embedded and lacerate or even perforate the esophagus, and with time tightly wedged objects can cause circumferential pressure necrosis.[23-25] In cats, large trichobezoars expelled from the stomach during vomiting may become lodged in the esophagus causing severe erosive esophagitis and stricture formation, presumably through the effects of pressure and prolonged mucosal contact with gastric acid and pepsin absorbed into the impacted hairball.[73] Chapter 27 describes techniques for the endoscopic retrieval of foreign bodies. After an esophageal foreign body has been removed, the mucosa should be examined for esophagitis, perforation, and esophagobronchial fistula.

Esophagitis

Esophagitis is an endoscopic diagnosis based on mucosal abnormalities that can include hyperemia, increased friability, ease of bleeding when rubbed by the endoscope tip, granular surface texture, accentuated folding, erosions, ulcers, focal necrosis, pseudomembranes, pale white areas of fibrosis with indistensibility, strictures, and GES abnormalities.[13-17,73] Inflammatory lesions in the caudal thoracic esophagus are indicative of reflux esophagitis, especially erythematous or erosive streaks radiating from the GES accompanied by a wide open sphincter and pooling of gastrointestinal contents (food, fluid, or bile) in the distal esophagus.[73] Reflux of gastric contents may be observed during endoscopy. In reflux esophagitis microscopic inflammation and epithelial changes may be evident before abnormalities can be seen with an endoscope, so if chronic reflux is suspected, mucosal biopsies should be taken adjacent to the GES for evaluation of hyperplastic, dysplastic, and metaplastic epithelial changes.[15,16,74]

Eosinophilic esophagitis is rare form of esophagitis diagnosed by endoscopic cytology and biopsy.[75] *P. insidiosum* is a waterborne fungus that can cause severe necrotizing pyogranulomatous esophagitis.[76] A presumptive diagnosis of pythiosis is based on finding characteristic broad, poorly septate hyphae with the Grocott methenamine silver stain in esophagoscopic biopsies. The diagnosis is supported by a positive serologic test for antibodies or by culture with polymerase chain reaction identification. *Candida albicans* causes white mucosal deposits of yeast, which develop secondary to retention of decomposing food residue in megaesophagus, diverticulum, or vascular ring anomaly. *S. lupi* is a nematode parasite that causes large granulomatous nodules in the caudal thoracic esophagus, which are transformed into fibrosarcoma or osteosarcoma.[70]

Esophageal Stricture

Esophagoscopy is the most reliable method for diagnosis of esophageal stricture and for determining the luminal diameter, stricture length, and presence of associated esophagitis. Diagnostic esophagoscopy is usually followed by endoscopic-guided mechanical dilation of the stricture using balloon catheter dilation or bougienage techniques. These procedures result in a favorable outcome in 70% to 88% of stricture patients.[18-22] Approximately 80% to 90% of strictures in dogs and cats are located in the intrathoracic esophagus, particularly between the heart base and gastroesophageal junction.[18-22] The degree of narrowing varies, but the luminal diameter averages 5 mm.[18,20,22] The stricture length averages 1 cm, but it can vary from a thin band, web, or ridge of fibrotic tissue to a segmental narrowing up to 10 to 15 cm in length.[18,20,31] In some cases diffuse esophagitis results in multiple strictures. Single strictures are found in 80% of cases and two or three strictures in the remaining 20%.[18-22]

Most strictures appear as focal circumferential narrowings formed by smooth, glistening-white, fibrotic rings or ridges.[18-22] Occasionally strictures form a web or imperforate membrane across the lumen. Concurrent esophagitis in 40% of cases causes the adjacent mucosa to be erythematous, hemorrhagic, friable, or ulcerated.[18-22] With chronicity, contraction of deep fibrotic tissue can distort the tubular axis of the esophagus so it appears to be angular or spiral shaped rather than straight. The degree of dilation of the esophagus cranial to the stricture depends on the duration and extent of obstruction. Benign strictures must be differentiated from other

causes of esophageal obstruction, such as neoplasia or extraluminal compression caused by a vascular ring anomaly or periesophageal mass. Mucosal biopsy is recommended to determine if an atypical appearing stricture is benign or malignant.

Esophageal Perforation and Fistula

Esophageal perforation is a rare complication of esophageal foreign bodies, especially objects with irregular or sharp edges such as bones, or chronically lodged foreign bodies that cause deep-pressure necrosis.[23,25,27-29] Iatrogenic esophageal perforation can also occur during endoscopic foreign-body extraction or stricture dilation, and as a complication of esophageal surgery or laser treatment. Esophageal perforation occurs in 4% to 9% of dogs and cats undergoing stricture ballooning or bougienage.[18-22] Penetrating injuries of the esophagus can result from bite wounds, gunshot injuries, and stick impalements. In general perforation of the intrathoracic esophagus has more serious consequences than perforation of the cervical esophagus because of the potential for tension pneumothorax and leakage of contaminated fluids into the thorax. During esophagoscopy, hemorrhagic fluid that bubbles from a deep defect in the thoracic esophagus in synchrony with respirations is indicative of acute perforation. If perforation occurs during endoscopic manipulation of a foreign body or stricture, life-threatening tension pneumothorax may occur that is accentuated by insufflation. This situation requires immediate thoracocentesis.

An esophageal fistula is a communication between the esophageal lumen and adjacent structures (e.g., mediastinum, trachea, bronchi). A fistula appears endoscopically as a small erythematous opening in the esophageal wall that drains purulent, bloody, or frothy fluid.[13,49] Esophagobronchial fistulas are the most common and often are accompanied by an esophageal diverticulum. Chronic perforations can also form fistulas that extend deep into the mediastinum.

Hiatal Disorders

Endoscopic findings consistent with hiatal hernia include pooling of fluid or ingesta in the caudal esophagus; enlargement of the esophageal hiatal opening; dilation and cranial displacement of the gastroesophageal sphincter into the thorax; rugal folds of the stomach protruding through the hiatus into the caudal thorax as viewed from the esophageal and gastric retroflex positions; and evidence of esophagitis in the caudal esophagus.[73] A pseudopouch can be seen if the stomach is herniated at the time of insertion of the endoscope.[73] This effect is created by narrowing of the lumen as the scope advances through the cranially displaced gastroesophageal junction followed by a dilated region of the lumen lined by rugal folds.

Gastroesophageal intussusception is diagnosed endoscopically when the rugal folds of the invaginated stomach form a bulging intraluminal mass that fills the caudal thoracic esophagus.[1,13,64-67] Concurrent findings can include esophagitis, esophageal obstruction, and megaesophagus. If intussusception is encountered, the endoscopist should maximally insufflate the esophagus and occlude it in the cervical region to retain the air. The combination of inflation pressure and advancement of the endoscope tip against the invaginated rugae may reduce small intussusceptions and allow entry into the repositioned stomach.

Esophageal and Periesophageal Neoplasia

Endoscopy and biopsy are indicated for the definitive diagnosis of esophageal neoplasia.[68,69,73] The intrathoracic esophagus is most often involved and the degree of luminal obstruction varies. Endoscopically, a carcinoma usually causes eccentric stenosis and appears as a proliferative mass with a friable, lobulated, or ulcerated surface. In dogs with *S. lupi*–associated esophageal granuloma or sarcoma, nematodes may be seen protruding from the nodular lesions and eggs may be identified by fecal examination.[70] Forceps biopsies should be obtained from all esophageal masses and proliferative lesions identified at endoscopy.

Endoscopy is useful for evaluating the extent of obstruction and determining whether masses are extramural or intramural. A stenotic region of esophagus with normal-appearing mucosa suggests extraluminal compression by a periesophageal mass rather than stricture or primary esophageal tumor.[73] Transmural endoscopic-guided fine-needle aspiration of periesophageal masses can be obtained for cytologic examination using a 21- to 23-gauge through-the-scope sclerotherapy needle.

Other Diagnostic Methods

Videofluoroscopy is the most clinically useful tool for evaluating all phases of swallowing in dogs and cats with esophageal motility dysfunction (see "Radiography" earlier in this chapter).[46,47] Other specialized procedures include nuclear scintigraphy, manometry, pH monitoring, and electromyography, but these studies are difficult and not routinely performed in dogs and cats.

Nuclear Scintigraphy

Scintigraphic evaluation of swallowing of a radioisotope such as technetium-99 m (^{99m}Tc) sulfur colloid or ^{99m}Tc-pertechnetate enables noninvasive quantitative assessment of esophageal transit time and clearance.[77] Nuclear scintigraphy can also be used to identify gastroesophageal reflux after intragastric instillation of the radioisotope via stomach tube. Scintigraphy can identify esophageal perforations and fistulas while avoiding the risks of extravasated contrast medium.

Esophageal Manometry

Continuous pull-through infusion manometry has been used extensively in people and research animals to record the pressure–time relationships during the cricopharyngeal, esophageal, and gastroesophageal phases of swallowing. Manometry techniques and normal values for dogs and cats have been described along with the effects of various drugs and neuroendocrine substances on gastroesophageal sphincter pressure.[78-84] Unfortunately, normal reference ranges in these studies have varied widely and individual dogs show considerable day-to-day variation, thus routine clinical application of manometry in animal patients has been limited. In addition manometry in dogs and cats may require anesthesia, which affects the measurements, except in some studies where research dogs have been trained to swallow manometric tubes while awake.[84,85] Esophageal manometry has been performed in dogs with idiopathic megaesophagus.[85] New high-resolution manometry catheters used in people have up to 128 circumferential pressure sensors that enable complex computer analysis of swallowing in new ways.

Esophageal pH Monitoring

Continuous ambulatory monitoring of the caudal esophageal pH and impedance with an intraluminal pH probe is the gold standard for verifying gastroesophageal reflux in people. Esophageal pH monitoring has not found clinical application yet in dogs and cats, but it has been used as a research tool to assess gastroesophageal reflux in anesthetized dogs.[86,87] A recent innovation in pH monitoring is a catheter-free pH sensor capsule (Bravo pH Monitoring System;

Medtronic) that is attached endoscopically to the esophageal mucosa where it transmits continuous pH data wirelessly (by telemetry) to a mobile receiver. The pH data are then downloaded to a computer for analysis. An esophageal acid clearance test was evaluated in healthy awake dogs using a pH probe in the caudal esophagus that recorded the number of swallows and time required for esophageal peristalsis to increase the pH to 4.0 following instillation of a 10-mL bolus of 0.1 N hydrochloric acid.[88] The mean clearance time was 5 minutes (range: 2.5 to 8) after eight swallows (range: 4 to 12).

Electromyography

Electromyography (EMG) can be used to evaluate striated muscle activity associated with swallowing, and it can be integrated with manometric and videoradiographic findings.[53] Abnormal EMG findings include fibrillation potentials, positive sharp waves, increased insertional activity, and complex repetitive discharges. In myopathic and neuropathic esophageal diseases, the EMG may reveal abnormalities in the muscles of the pharynx, cricopharyngeal sphincter, and cranial esophagus.[50,83] When esophageal disease is associated with polymyopathy, EMG of the masticatory and limb muscles may also be abnormal.[6]

INFLAMMATION

Robert J. Washabau

Esophagitis

Etiology

Esophagitis is an acute or chronic inflammatory disorder of the esophageal mucosa that occasionally involves the underlying submucosa and muscularis. It may result from ingestion of caustic or corrosive substances, injury from esophageal foreign bodies, gastroesophageal reflux, radiation injury, idiopathic generalized megaesophagus, and inflammation associated with malignancy.[1-5]

Pathophysiology

The esophageal mucosa has several important barrier properties to withstand caustic substances, including stratified squamous epithelium with tight intracellular junctions, mucus gel, and surface bicarbonate ions. Disruption of any of these barrier properties may result in inflammation, erosion, and/or ulceration of the underlying structures.[2,6-8] Clinical signs are related to the type of chemical injury, the severity of inflammation, and the involvement of structures underlying the esophageal mucosa, for example, the muscularis.[9] Although esophagitis may occur at any age, young animals with congenital esophageal hiatal hernia may be at increased risk for reflux esophagitis.[10,11] Cats appear to be particularly susceptible to doxycycline-associated esophagitis and esophageal stricture.[12-14] Anesthesia, poor patient preparation, and poor patient positioning during anesthesia places other animals at risk for gastroesophageal reflux and esophagitis.[15-19] Upper respiratory syndrome in brachycephalic breeds predisposes to reflux esophagitis.[20,21]

Esophagitis that is a consequence of gastroesophageal reflux may result from direct H^+ injury, or indirectly from inflammatory cytokines and chemokines (substance P [SP], interleukin-8 [IL-8], platelet-activating [PAF]) that induce neutrophil migration and activation (discussed in more detail in "Gastroesophageal Reflux" section).

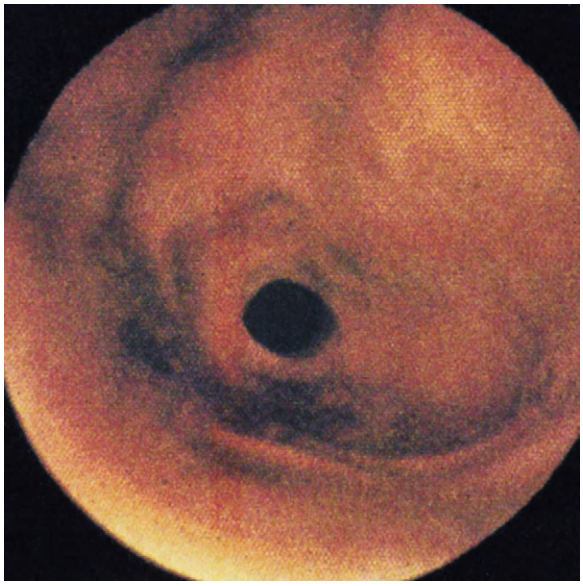

Figure 55-2 Endoscopic appearance of esophagitis and strieture in a 12-year old mixed breed dog.

Clinical Signs

Signs characteristic of esophagitis include regurgitation, salivation, odynophagia (inferred pain), extension of the head and neck during swallowing, and avoidance of food. Coughing may be observed in some animals with concurrent aspiration pneumonia. The physical examination is often nonremarkable in affected animals, although fever and salivation may be detected in animals affected with ulcerative esophagitis. Pulmonary wheezes and coughing occur with aspiration pneumonia.

Diagnosis

Leukocytosis and neutrophilia may be found in animals with severe esophagitis or aspiration pneumonia. Results of routine hematology, serum biochemistry, and urinalysis are otherwise nonremarkable. The esophagus often appears normal on survey thoracic radiographs unless there is some secondary dilation. Aspiration pneumonia may be evident in the dependent portions of the lung. Barium contrast radiographs include irregular mucosal surface, segmental narrowing, esophageal dilation, and/or diffuse esophageal hypomotility. Stricture formation may also be observed in chronic undiagnosed or untreated esophagitis. Endoscopy and biopsy are the most reliable means of diagnosing this disorder. In severe cases of esophagitis, the mucosa will appear hyperemic and edematous with areas of ulceration and active bleeding (Figure 55-2). Milder cases of esophagitis may appear endoscopically normal. Endoscopic biopsy of the esophageal mucosa is technically more difficult than other parts of the gastrointestinal tract,[22] but mucosal biopsy will be necessary to confirm the diagnosis in mild to moderate cases. Esophagitis will have several important differential diagnoses, including mechanical injury as a result of esophageal foreign body, esophageal stricture, hiatal hernia, megaesophagus, esophageal diverticulum, and vascular ring anomaly. Each of these disorders can be differentiated by survey or contrast radiography, or endoscopy.

Treatment

Animals with mild esophagitis may be managed on an outpatient basis. Oral food intake should be withheld for 2 to 3 days in cases of mild to moderate esophagitis. Animals with more severe esophagitis

Table 55-1 Components of Gastroesophageal Reflux and Therapy*

Pathogenesis	Components	Therapy
Esophagitis	Gastric acid	Acid suppression, e.g., H_2 histamine receptor antagonist; H^+,K^+-ATPase inhibitor
	Gastric pepsins	Chemical diffusion barrier, e.g., sucralfate
	Intestinal bicarbonate	Chemical diffusion barrier, e.g., sucralfate
	Pancreatic proteases	Chemical diffusion barrier, e.g., sucralfate
	Bile acids	Chemical diffusion barrier, e.g., sucralfate
Gastroesophageal reflux	Gastric secretions	Prokinetic agent, e.g., cisapride, metoclopramide, erythromycin
	Duodenal secretions	Prokinetic agent, e.g., cisapride, metoclopramide
Gastric secretion	Gastric acid	Acid suppression, e.g., H_2 histamine receptor antagonist; H^+,K^+-ATPase inhibitor
	Gastric pepsins	Chemical diffusion barrier, e.g., sucralfate
Delayed gastric emptying	Retention of gastric secretions	Prokinetic agent, e.g., cisapride, metoclopramide, erythromycin
Enterogastric reflux	Intestinal bicarbonate	Chemical diffusion barrier, e.g., sucralfate
	Pancreatic proteases	Chemical diffusion barrier, e.g., sucralfate
	Bile acids	Chemical diffusion barrier, e.g., sucralfate

*See also Figure 55-3.

may require hospitalization and enteral or total parenteral nutrition. Enteral feeding of half-solid nutrients (vs. liquids) reduces the frequency of gastroesophageal reflux in the dog.[23] Oral sucralfate suspensions (0.5 to 1.0 g PO, TID) are the most important and specific therapy for esophagitis.[24,25] Sucralfate suspensions are more therapeutic than intact sucralfate tablets because the liquid suspension will bind more readily to an erosive or ulcerative site. Gastric acid secretory inhibitors (e.g., cimetidine 5 to 10 mg/kg PO or IV, TID-QID; ranitidine 1 to 2 mg/kg PO or IV, BID-TID; famotidine 0.1 to 0.5 mg/kg PO or IV, BID; omeprazole 0.7 mg/kg PO, SID; esomeprazole, lansoprazole, or pantoprazole all at 1 mg/kg IV) should be useful in suspected cases of gastroesophageal reflux, but should be used in addition to, not in place of, sucralfate. Prokinetic agents should also be considered if there is concurrent gastroesophageal reflux (see "Gastroesophageal Reflux" later in this chapter). Broad-spectrum antibiotics may be needed in animals with aspiration pneumonia or severe esophagitis.

Prognosis

Animals with mild esophagitis generally have a favorable prognosis. Ulcerative esophagitis, on the other hand, warrants a more guarded prognosis. Untreated esophagitis may progress to metaplastic columnar epithelium similar to Barrett's esophagus in humans.[26] The most important complication of esophagitis in companion animals is progressive esophageal stricture.[17,18,27,28] Animals affected with esophageal stricture develop progressive regurgitation, weight loss, malnutrition, and aspiration pneumonia. A relationship between reflux esophagitis and idiopathic megaesophagus seems obvious,[4] but it is not yet clear whether this is cause or consequence (see Figure 55-11).

Gastroesophageal Reflux

Etiology

Gastroesophageal reflux is a disorder of the gastroesophageal sphincter permitting reflux of gastrointestinal fluids or ingesta into the esophagus. Varying degrees of esophagitis result from prolonged contact of gastric acid, pepsin, trypsin, bile salts, and duodenal bicarbonate with the esophageal mucosa.

Pathophysiology

The frequency of reflux and composition of the refluxed material determines the severity of the esophagitis.[29] Gastric acid alone produces a mild esophagitis, whereas combinations of acid and pepsin or trypsin, bicarbonate, and bile salts produce a severe esophagitis (Table 55-1 and Figure 55-3).[29] The risk of reflux esophagitis is also greater with multiple episodes than with a single long episode of acid exposure.[9] Gastroesophageal reflux has been poorly documented in dogs and cats, but it is undoubtedly more common than previously thought. Chronic vomiting, disorders of gastric emptying, hiatal hernia, upper airway obstruction, and anesthesia-induced reductions in gastroesophageal sphincter pressure have all been implicated in the pathogenesis of gastroesophageal reflux in dogs and cats.[2,15,16,19,21,30] Many of the preanesthetic agents currently in use are associated with reductions in gastroesophageal sphincter pressure as are all of the inhalant anesthetic agents.[15,19]

The pathophysiology of mucosal injury in gastroesophageal reflux remains to be completely elucidated, but prolonged contact of the mucosa with acid clearly contributes to the reflux injury. The central dogma has been that esophagitis develops from an acid (or other chemical) injury starting at the luminal surface of the squamous epithelium, progressing through the epithelium and lamina propria into the submucosa, and resulting in acid-induced necrosis of surface epithelial cells and stimulation of a proliferative response in the basal cells.[29] This dogma has been recently challenged by new experimental findings.[30] It has been proposed that refluxed gastric fluid does not directly damage the esophageal mucosa, but rather stimulates esophageal epithelial cells to secrete chemokines that attract and activate immune cells, causing damage to the esophageal squamous epithelial cells.[30] In this model, acid is believed to activate acid-sensitive transient receptor potential vanilloid 1 ($TRPV_1$) receptors, causing the production and release of PAF, SP, and IL-8, which attract and activate immune cells contributing to inflammation and injury of the esophageal mucosa (see Figure 55-4).[30] These data further suggest that inhibition of IL-8, SP, and PAF-induced neutrophil migration and activation may be the basis of future therapy in this disorder.[30]

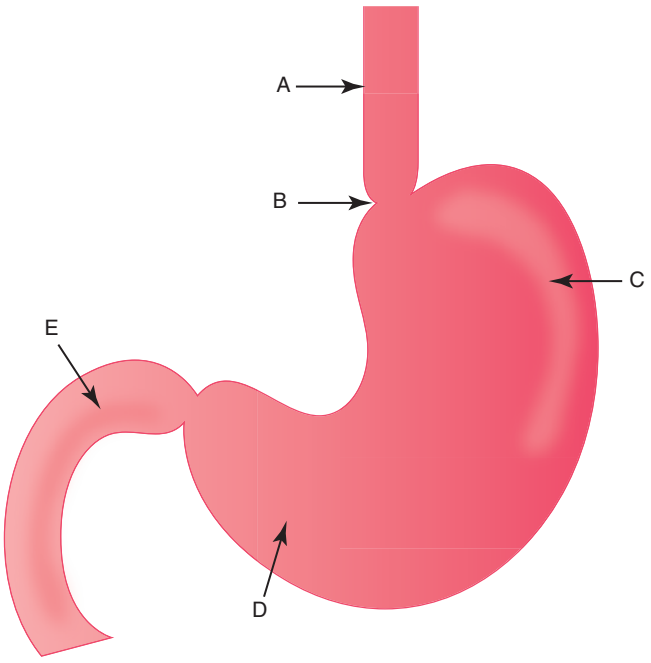

Figure 55-3 Mechanisms of esophageal inflammation with reflux esophagitis. Reflux esophagitis *(A)* results from gastroesophageal reflux *(B)*, continued gastric secretions *(C)*, delayed gastric emptying *(D)*, and enterogastric reflux *(E)*.

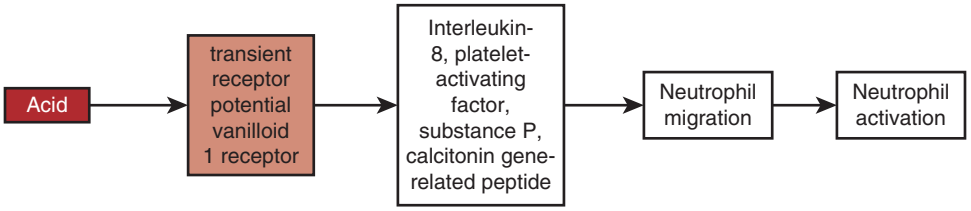

Figure 55-4 Activation of the inflammatory and immune response following acid injury in the esophageal mucosa.

Clinical Signs

The clinical signs of gastroesophageal reflux are similar to those of esophagitis. In severe cases, animals may develop regurgitation, salivation, odynophagia, extension of the head and neck during swallowing, and total avoidance of food. In milder cases, however, affected animals may have only an occasional episode of regurgitation, particularly in the early morning hours. The latter cases are physiologic and result from transient relaxations of the gastroesophageal sphincter during sleep.[31] The physical examination is usually unremarkable, but fever and excessive salivation may be detected in animals with severe concurrent esophagitis.

Diagnosis

The diagnosis of gastroesophageal reflux may be little more than clinical suspicion. Survey radiographs typically do not aid in the diagnosis. Videofluoroscopy may demonstrate intermittent gastroesophageal reflux, but this finding may also be observed in animals with normal esophageal function.[32,33] Endoscopy is the current best method for documenting mucosal inflammation consistent with reflux esophagitis (see Figure 55-2). Definitive diagnosis of gastroesophageal reflux requires continuous measurements of gastroesophageal sphincter pressure and 24-hour intraluminal pH, procedures for which most dogs and cats are not compliant. Hiatal hernia, esophagitis, and esophageal stricture are the most important differential diagnoses for gastroesophageal reflux.

Treatment

Because dietary fat delays gastric emptying and reduces gastroesophageal sphincter pressure, animals should be fed fat-restricted diets. Pet owners should also avoid late night feedings because this would tend to reduce gastroesophageal sphincter pressure during sleep. In addition to nutritional considerations, rational medical therapy for this disorder includes diffusion barriers (e.g., sucralfate), gastric acid secretory inhibitors (e.g., cimetidine, ranitidine, famotidine, or omeprazole), and prokinetic agents (e.g., cisapride or metoclopramide).[23-25] Diffusion barriers are perhaps the most important medical therapy in gastroesophageal reflux. Sucralfate (0.5 to 1.0 g PO, TID), for example, protects against mucosal damage from gastroesophageal reflux and promotes healing of existing esophagitis.[24,25] Refractory cases of gastroesophageal reflux should be concurrently medicated with acid secretory inhibitors and/or prokinetic agents. The H_2 histamine receptor antagonists, for example, cimetidine (5 to 10 mg/kg PO or IV, TID-QID), ranitidine (1 to 2 mg/kg PO or IV, BID-TID), and famotidine (0.1 to 0.5 mg/kg PO or IV, BID), inhibit gastric acid secretion and reduce the amount of

acid reflux. Omeprazole (0.7 mg/kg PO, SID); esomeprazole, lansoprazole, and pantoprazole (all 1.0 mg/kg IV, SID); and all H^+,K^+-ATPase inhibitors could be used to inhibit gastric acid secretion as an alternative to H_2 histamine receptor antagonism.[34] Metoclopramide (0.2 to 0.4 mg/kg PO, TID-QID)[35,36] and erythromycin (0.5-1.0 mg/kg PO, BID-TID)[37,38] may be useful in treating gastroesophageal reflux because they increase gastroesophageal sphincter pressure. 5-HT_4 agonists like cisapride and tegaserod also increase tone in the gastroesophageal sphincter,[39] and are likely superior to other prokinetic drug classifications. Both cisapride and tegaserod have been withdrawn from several international markets because of high-potency binding to ventricular 5-HT_4 receptors, inhibition of the delayed rectifying K^+ channel, delayed repolarization, and prolongation of the cardiac Q-T interval.[40] Cisapride has continued availability in many countries through compounding pharmacies. Recent studies show that GABA type B receptor agonists (e.g., baclofen),[41] cannabinoid receptor agonists (WIN 55,212-2),[42] and metabotropic glutamate (mGlu) receptor 5 antagonists (MPEP)[43] abolish transient gastroesophageal relaxations in the dog, and therefore may have future application in the treatment of gastroesophageal reflux.

Prognosis

The prognosis for most animals with gastroesophageal reflux is good with medical management. Anatomic correction of upper airway obstruction in brachycephalic breeds should ameliorate gastroesophageal reflux in affected patients.

Esophageal Fistula

Etiology

An esophageal fistula is an abnormal communication between the esophagus and adjacent structures. Most esophageal fistulae involve the lungs or airway structures, for example, esophagopulmonary, esophagobronchial, or esophagotracheal fistulae. Occasionally, esophageal fistulae expand into the pleural space or cervical tissues.

Pathophysiology

Both congenital and acquired fistulae have been described.[44] Congenital fistulae are rare and result from incomplete separation of the tracheobronchial tree from the digestive tract, from which it is formed embryologically. An increased incidence of congenital esophageal fistulae (and esophageal diverticula) has been reported in the Cairn Terrier.[1] Affected animals often have concurrent esophageal foreign bodies, presumably because of abnormalities in esophageal motility associated with the fistula.

Acquired esophageal fistulae typically result from foreign body ingestion, esophageal perforation, and extension of inflammation into adjacent tissues. Bones and grass awns are most commonly incriminated. A traction diverticulum often also develops because of the inflammatory reaction between the esophagus and bronchus. Secondary complications that may occur with esophagobronchial fistula are localized pneumonias, pulmonary abscessation, and pleuritis. The severity of the secondary complications usually depends on the duration and size of the fistula.

Clinical Signs

Animals with congenital esophageal fistula usually develop clinical signs shortly after weaning, whereas animals with acquired fistula develop signs much later in life. Clinical signs in nearly all cases are related to the respiratory system and include coughing and dyspnea. Other signs that may develop include regurgitation, lethargy, anorexia, fever, and weight loss. Regurgitation is usually reported in relation to an esophageal foreign body.

Diagnosis

The radiographic manifestations of esophagobronchial fistula consist of localized alveolar, bronchial, and/or interstitial lung patterns. The right caudal, right intermediate, and left caudal lung lobes are most often involved. The esophagus appears radiographically normal unless a radiopaque esophageal foreign body is observed. Definitive diagnosis of esophageal fistulae requires contrast radiography or endoscopy. An esophagram should be performed with a thin mixture of barium sulfate (30% w/v) to elucidate the fistula. Use of iodinated contrast agents should be avoided since they are hyperosmolar and chemically irritating to the lung. Endoscopy may also be useful in documenting an esophageal fistula although small fistulae are occasionally missed. Lobar pneumonia is the most important differential diagnosis for esophagobronchial fistula. Aspiration, bacterial, and foreign body pneumonias can all mimic esophagobronchial fistula.

Treatment

Surgical excision and repair provide the most successful outcomes in animals with esophagobronchial fistula.[45] The fistula is surgically excised, and the defect in the esophagus is closed. Resection of the affected lung lobe is also generally warranted. A postoperative course of broad spectrum antibiotics should be prescribed in all cases.

Prognosis

The prognosis is guarded if secondary complications, such as pneumonia, pulmonary abscesses, or large quantities of pleural fluid, are present. In the absence of such complications, the prognosis is generally good.

INFECTION

Remo Lobetti

The most important infection of the canine esophagus is by the helminth, *S. lupi*, with sporadic reports of bacterial, viral, and oomycetial infections in the dog. There are no documented reports of algal, protozoal, or fungal infections in either the dog or cat.

Spirocercosis

Spirocercosis is a disease caused by the nematode *S. lupi*, which has a variety of clinical presentations; is found worldwide, especially in tropical and subtropical regions; and affects mostly carnivores, especially canidae.[1-3] Clinical signs associated with spirocercosis are usually associated with larval migration and the persistence of adult worms within the host.

Distribution

S. lupi has a worldwide distribution with the majority of the clinical reports from Israel,[3] Greece,[4] India,[5] Pakistan,[6] southern United States,[7] Brazil,[8] Kenya,[9] and South Africa.[2] In Israel, spirocercosis is more prevalent in urban areas, whereas in the United States the disease is more common in rural areas.[3] In South Africa, there does not appear to be any obvious distinction in the distribution between urban and rural areas.[2] The most significant factor associated with

the prevalence of *S. lupi* infection is the proximity of dogs to the intermediate and paratenic (transport) hosts. There is no sex or age predilection for infection, although infected dogs younger than 6 months of age may not develop esophageal disease and the classic clinical signs.[10] There appears to be a breed predilection as there is a higher incidence of spirocercosis in Hound Dogs,[11] German Shepherds,[1,5] Poodles,[8] and Labrador Retrievers.[3] Spirocercosis has also been reported in the domestic cat[12] and wild felidae.[13]

Life Cycle

S. lupi eggs containing L1 larvae are passed from the esophagus through the gastrointestinal tract and into the feces but may also be shed in the vomitus. Eggs are then ingested by coprophagous beetles, the intermediate host, in which the larvae excyst and develop to L3 larvae within 2 months. The beetle is then ingested by either the final host or a paratenic host, which can be poultry, wild birds, lizards, rodents, hedgehogs, and rabbits. The L3 larvae form small nodules within the paratenic host.[10] The final host becomes infected by ingesting either the infected beetle or a paratenic host with the latter a more likely source of infection for carnivores.

In the final host, the L3 larvae excyst in the stomach, penetrate the gastric mucosa, and migrate within the walls of the gastric and gastroepiploic arteries, where hemorrhagic lesions are evident from the fourth day of infection. In the initial stages of infection, larval migration is nondirectional and thus they may be found within the veins and lymphatics of the gastric wall, which may result in aberrant migration to other organs. The stimulus for directional and aberrant migration is still not known. L3 larvae reach the caudal thoracic aorta via the celiac artery approximately 10 days after excysting and remain there from day 7 to day 109 where they mature to L4 larvae. After their final molt, which is approximately 3 months postinfection, they migrate as immature adults, from the caudal thoracic aorta to the caudal esophagus where they form nodules in the esophageal submucosa and adventitia. Mature adult worms develop by 3 to 9 months postinfection.[11] The adult is a large spiraled pink worm with males up to 54 mm, and females up to 80 mm in length. The adult worm can reside in the esophagus for up to 2 years, with the female producing up to 3 million eggs per day.[14]

Pathology

Adult worms form granulomatous nodules in the submucosa of the caudal esophagus, which vary from less than 1 to more than 4 cm in diameter. *Spirocerca* nodules bulge into the lumen of the esophagus and distort the esophageal wall while extending into the surrounding mediastinal tissue at the same time. The number of worms present in a nodule may vary from a few to more than 30, but typically there are between three and six worms.

Migrating larvae cause necrosis, hemorrhage, and neutrophil exudation within the blood vessel walls. Except for the thoracic aorta, most of these lesions usually completely heal. In the thoracic aorta the lesions form permanent intimal scars and aneurysms of varying size and number. Although spondylitis of the thoracic vertebrae is a common finding in spirocercosis, the exact pathogenesis has not been established,[5,11] but is likely associated with aberrant migration or severe periaortic inflammation secondary to aortic migration.

Aberrant migration of larvae is a fairly common occurrence in spirocercosis and may be responsible for some of the presenting clinical signs. Nodules containing worms have been found in the stomach and intestine, mediastinum, lumbar fascia, rectum, trachea, interdigital tissue, lung, thymus, diaphragm, heart, kidney, subcutis, urinary bladder, and spinal cord.

An important complication of chronic spirocercosis is esophageal neoplasia with osteosarcoma and fibrosarcoma commonly associated with *S. lupi* infection.[11] Fibrosarcoma generally develop in dogs younger than 2 years of age and osteosarcoma in dogs older than 5 years of age. In a recent study of 15 cases, nine were diagnosed with osteosarcoma, five with fibrosarcoma, and one with an undifferentiated sarcoma.[15]

Clinical Signs

The clinical signs of spirocercosis vary greatly, depending upon the stage of disease, presence of aberrant migrations, and clinical complications. A dog with uncomplicated infection may be subclinical, or show mild to moderate signs of vomiting, regurgitation, weight loss, polypnea, dysphagia, and head and neck extension.[3] Complicated cases more typically result from normal or aberrant nematode migration. The normal migration route along the gastroaortic arterial system may result in either rupture of the aorta, causing hemothorax and acute death, or of other major blood vessels, resulting in the development of large hematomas.[1,11] Migration through the wall of the aorta to the esophagus may result in mediastinitis, pneumomediastinum, pleuritis, or pyothorax.[1] Sialadenitis and hypertrophic osteopathy have also been reported in association with *S. lupi* nodules. Concurrent or secondary bacterial infection may lead to discospondylitis,[10,11] septic polyarthritis,[1] endocarditis, and interstitial nephritis.[16]

Other nonspecific clinical signs associated with *S. lupi* are fever and mild peripheral lymphadenopathy.[1,3] Aberrant migration may result in a spectrum of clinical signs but the most common presentations include respiratory, neurologic, and musculoskeletal signs.[1] Reported complications of spirocercosis include aortic thromboembolism, aberrant migration to the vertebral canal, secondary megaesophagus, hemopericardium, esophageal obstruction or perforation, and gastroesophageal intussusception.

Diagnosis

Diagnosis of spirocercosis is based on finding *Spirocerca* eggs on fecal flotation, and pertinent diagnostic imaging, esophageal endoscopic, and necropsy findings. One study showed a 100% sensitivity of endoscopy compared to 80% sensitivity for fecal flotation and 53% sensitivity of survey radiography in the diagnosis of spirocercosis.[3]

Fecal flotation

S. lupi eggs are small (35 × 15 μm), thick shelled, and larvated. There are several factors that can affect the results of fecal flotation, including egg passage occurs for a relatively short period in the lifespan of the worm and is thus unpredictable; eggs will be present in the feces only if the female has a patent passage to the esophageal lumen; and eggs are difficult to detect with routine flotation techniques using sugar and salt solutions. Results of fecal flotation can be improved by using either the modified Stoll or sugar flotation technique, and with sodium nitrate or zinc sulfate flotation solutions.[17] Diagnostic accuracy can also be improved with multiple fecal flotations.[3]

Diagnostic Imaging

Radiography should be the initial diagnostic test of choice and a caudal esophageal mass may be seen on survey thoracic radiographs.[1] *Spirocerca*-associated masses are best seen on ventrodorsal or dorsoventral views as a single midline soft-tissue opacity superimposed on the caudal cardiac border and diaphragmatic cupula. *Spirocerca*-associated masses are less frequently observed on lateral views where they are located dorsally to the caudal vena cava. A right lateral recumbent view is preferable as the normal esophagus is usually not

seen on this view.[18] Mineralized opacities within the mass are often an indication of neoplastic transformation.

On the lateral thoracic radiograph, spondylitis of the ventral borders of the caudal thoracic vertebra (T5 to T12) may be evident as a lamellar, thick, brush-like or solid periosteal reaction filling up the ventral surface of the vertebral body, giving it a rectangular or even bulging appearance. Aortic mineralization secondary to small aneurysms may occasionally be seen on the lateral view,[1,3] as mineralized streaks on the dorsal or ventral edge of the thoracic aorta.

The diagnostic accuracy of survey radiography can be improved by utilizing either positive contrast radiography or pneumoesophagography. Using barium contrast, a spirocercosis lesion appears as a dorsal esophageal mural filling defect. Disease complications detected on radiographs include tracheal or bronchial displacement or compression, pleural effusion, pulmonary metastases, mediastinitis, pneumothorax, pneumomediastinum, and hypertrophic osteopathy.[1]

Computed tomography may be helpful in delineating the esophageal mass; evaluating the extent of the lesion; identifying presence of vertebral, pleural, mediastinal and pulmonary pathology; and assessing lesions and aortic mineralization.

Esophageal Endoscopy

Endoscopic findings in *S. lupi* infection vary depending on the progression of the disease. In early infection, one or several smooth rounded nodules may be evident in the caudal esophagus. Over time, nodules become large and lobulated, cauliflower-like masses, which can obliterate the esophageal lumen. These masses are often ulcerated and friable and can bleed easily if traumatized by the endoscope. In advanced cases it is often difficult to determine the extent of the disease as the mass hampers complete visualization of the esophagus. In some cases the mass may be extraluminal (intramural or mediastinal) and the only abnormality visualized is a bulging from within the esophageal wall. In some cases, reflux esophagitis may be evident.

The results of endoscopically performed biopsies are usually unrewarding because either the intact stratified squamous epithelium of the esophageal mucosa resists biopsy efforts or with ulcerated lesions, the biopsy often does not often include diagnostic tissue.

Clinical Pathology

In early disease a normocytic normochromic anemia may be evident, whereas a microcytic hypochromic anemia is more likely in dogs with advanced disease and severe esophageal hemorrhage.[15] Mild anemia will be present in at least 50% of cases.[3,15] Leukocytosis and monocytosis are relatively common whereas eosinophilia is an uncommon finding.[3] There are no typical serum biochemical changes in dogs with early disease other than a mildly elevated serum creatine kinase. Increases in serum alkaline phosphatase, creatine kinase, amylase, and lactate dehydrogenase have been reported in cases with advanced disease.[15]

An immunofluorescence antibody test with 100% sensitivity and 80% specificity for *S. lupi* has been reported,[19] although further testing is needed.

Medical Therapy

Anthelmintic drugs that have been used for the treatment of spirocercosis include diethylcarbamazine, disophenol, ivermectin, and doramectin.

The only anthelmintic drug with proven efficacy against *S. lupi* is disophenol. The drug kills adult worms within the nodules but has no effect against juveniles. Unfortunately, the drug is no longer commercially unavailable. Diethylcarbamazine can be effective in ameliorating the clinical signs of vomiting and regurgitation in dogs with esophageal nodules. Although the drug results in a clinical improvement, it only suppresses egg shedding but has no effect on the adult worm.

A combination of nitroxynil (10 mg/kg) and ivermectin (1000 µg/kg) administered subcutaneously was reported to be successful in treating 81.6% infected dogs.[20] Mylonakis[21] reported that by using two doses of ivermectin at 600 µg/kg, administered subcutaneously, 2 weeks apart, in combination with oral prednisolone (0.5 mg/kg BID for 2 weeks followed by dose tapering) promoted nodular regression in five of eight animals with natural *S. lupi* infection.

Doramectin, a macrocyclic lactone, has good clinical efficacy against spirocercosis. Berry[22] reported that 200 µg/kg of doramectin injected subcutaneously at 14-day intervals for three treatments was effective in treating spirocercosis in five of seven infected animals. The two dogs with incomplete resolution were treated with doramectin at 500 µg/kg PO daily for an additional 6 weeks, which resulted in complete resolution. Lavy[23] reported a treatment protocol of 400 µg/kg of doramectin injected subcutaneously every 14 days for six treatments, followed by monthly dosing until resolution of the parasitic nodule. The author's current treatment regimen is 500 µg/kg doramectin given PO daily for 6 weeks and followed up with repeat esophagoscopy to ensure resolution of the nodules. Therapy is continued until there is endoscopic resolution of the nodules.

The use of doramectin to treat *S. lupi* in dogs is extralabel usage in most countries as it is only licensed for use in cattle, pigs, and sheep. However, in experimental studies, dogs given a daily dose of more than 500 µg/kg for 91 days showed only mild, transient, and reversible side effects. The drug is highly lipophilic with a half-life of approximately 3 days and a mean tissue residence time of approximately 5 days in the dog.[24] A breed-specific toxicity has been reported in certain Collies and other herding dog breeds following the use of both ivermectin and doramectin. Toxicities are likely a result of a mutation in the MDR1-1Δ gene and its ability to express the protective P-glycoprotein pump.

Surgical and Chemotherapeutic Therapy

Nonneoplastic nodules usually regress with medical treatment. Surgery is required only in cases of nodular neoplastic transformation. In a recent study,[15] 10 of 15 dogs with esophageal sarcomas underwent surgery, six of which had partial esophagectomies, two had esophageal resection, one had gastrostomy, and one had a lesion too extensive to for surgical resection. The survival times in the six dogs with the partial esophagectomy and medical treatment with doxorubicin and doramectin averaged 267 days. The outcome for the cases with resection was very poor with the dogs surviving only 3 and 4 days, respectively. Doxorubicin was used as adjuvant antineoplastic therapy in five cases, but conclusions could not be drawn regarding efficacy. Currently, there are no data available on the effectiveness of chemotherapy in the treatment of spirocercosis-associated esophageal sarcomas.

Prevention

Disease incidence can be reduced by disposal of feces, preventing dogs from hunting, scavenging and eating uncooked viscera, and decreasing egg shedding by infected animals. Control of intermediate and transport hosts is not a feasible form of control due to the variety and ubiquity of hosts in an endemic area. A study by Lavy[25]

to evaluate the prophylactic effect of doramectin showed that treatment with 400 µg/kg 30 days prior to exposure to infective larvae delayed the development of parasitic nodules in the esophagus, resulted in fewer nodules, and delayed egg shedding. Unfortunately this study did not address ongoing prophylaxis in endemic areas, as the dogs were not treated again during the trial period nor were they further exposed to infective larvae.

Oomycetes

P. insidiosum, a primary pathogen of plants and animals occurs in stagnant fresh water and dogs are infected when they come in contact with the zoospores. Chronic esophagitis caused by *P. insidiosum* has been reported in two dogs that showed clinical signs of hypersalivation, dysphagia, and weight loss.[26] Regional esophagitis was evident in both dogs on esophagoscopy but the diagnosis was only made on postmortem examination. *Lagenidium giganteum* has been reported to induce a hilar lymphadenitis with invasion of the distal esophagus in the dog.[27] The diagnosis was made on histopathology, with the lesions similar to those associated with pythiosis and zygomycosis. The organism was confirmed on both serology and culture.

Bacteria

Helicobacter pylori have been recovered from the esophagus of gnotobiotic Beagle pups that were infected with the bacteria. These Beagles developed gastritis and were positive for serum immunoglobulin G specific for *H. pylori*.[28] *Helicobacter*-induced gastritis is an established syndrome in dogs and cats (see Chapter 56), but esophagitis is probably subclinical.

Viral

Canine distemper virus inclusions can be identified in the cytoplasm of the esophageal epithelium,[29] which is part of the general systemic infection of the disease. Therefore, distemper can result in esophagitis following mucosal damage, which can contribute to the clinical signs of the disease.

Using immunofluorescence and histological techniques parvovirus inclusions have been found in the tunica muscularis of the esophagus with esophageal erosions and ulceration in both dogs and cats affected with the disease.[30] The esophagitis can thus contribute to the clinical signs of the disease.

OBSTRUCTION

Robert J. Washabau

Esophageal Stricture

Etiology

Esophageal stricture is a pathologic narrowing of the esophageal lumen. Congenital esophageal strictures have been reported,[1] but most strictures are acquired as a result of chemical injury from swallowed substances, traumatic injury from esophageal foreign bodies, gastroesophageal reflux and esophagitis following anesthetic procedures, complications of esophageal surgery, and intraluminal or extraluminal mass lesions (neoplasia or abscesses).[2]

Box 55-1 Poiseuille's Equation

$$\text{Flow} = \frac{\Delta P}{8} \cdot \frac{\pi}{\eta} \cdot \frac{r^4}{L}$$

ΔP = Change in pressure along the length of the tube; r = radius of the tube; η = viscosity of the fluid; L = length of the tube.

Pathophysiology

Anesthesia, poor patient preparation, and poor patient positioning during anesthesia place some animals at risk for gastroesophageal reflux, esophagitis, and subsequent stricture formation.[3-5] Cats appear to be particularly susceptible to doxycycline-associated esophagitis and esophageal stricture.[6-8] Fibrosis and mass compression are the most important pathogenetic mechanisms involved in stricture formation.

Laminar flow through a cylindrical tube, which is governed by the Poiseuille equation,[2] is directly related to the fourth power of the radius and the pressure change across the tube, and inversely related to the fluid viscosity and the length of the tube (Box 55-1). Because flow rates change exponentially with luminal radius, even small reductions in luminal diameter result in significant reductions in esophageal flow.

Clinical Signs

The clinical signs of progressive regurgitation and dysphagia are related to severity and extent of the stricture.[2,3] At the outset, the animal's appetite is unaffected. As the disease progresses, regurgitation occurs shortly after feeding, and the animal may attempt to reingest the regurgitated meal. An important clinical sign is that liquid meals are often better tolerated than solid meals. With progressive esophageal narrowing and inflammation, affected animals develop complete anorexia, weight loss, and malnutrition. Some animals also develop aspiration pneumonia. The physical examination is remarkable for salivation, cachexia, and malnutrition. Pulmonary signs (wheezes and cough) may be detected in animals affected with aspiration pneumonia.

Diagnosis

As with other esophageal disorders, the diagnosis is based on clinical history and radiographic and endoscopic findings (Figure 55-5). Intraluminal or extraluminal mass lesions may be evident on survey radiographs in animals with compressive esophageal stricture. Survey radiographs are usually unremarkable in animals with benign fibrosing strictures. Segmental or diffuse narrowing observed with barium contrast radiography is usually diagnostic of the disorder. There may also be some esophageal dilation proximal to the stricture site. Ultrasonography has not proved useful in diagnosing benign fibrosing strictures, but may be useful in diagnosing those caused by mass compression. Mediastinal and other periesophageal lesions have been successfully aspirated with ultrasound guidance. Endoscopy should be performed in all animals to confirm the site and severity of stricture, and to exclude the possibility of intraluminal malignancy and foreign body. Benign fibrosing strictures must be differentiated from vascular ring anomaly, esophagitis, intraluminal esophageal masses, and extraluminal periesophageal masses. These disorders can usually be differentiated with survey and contrast radiography, endoscopy, and/or thoracic ultrasonography.[9]

Treatment

Oral feedings should be withheld in cases of severe stricture. In such cases, a temporary gastrostomy tube may be placed at the time of esophageal dilation as a means of providing continuous nutritional support. Liquid meals should be used when reinstituting oral feedings. Animals may be discharged from the hospital after adequate rehydration, stabilization, dilation of the affected esophageal segment, nutritional intervention, and appropriate therapy for aspiration pneumonia. Esophageal strictures are best managed with mechanical dilation. Dilation may be achieved with balloon dilation catheters or bougienage tubes.[3,4,10,11] Esophageal tears have been reported with balloon dilation catheters, but the technology is still thought to be relatively safe in applying radial forces to the stricture site. A greater risk of perforation has been attributed to the use of bougienage tubes due to shearing forces applied by the instrument, although one report showed outcomes similar to those reported for balloon dilation.[12] Table 55-2 outlines the parameters needed for a successful balloon dilation. Multiple redilations at 1- to 2-week intervals may be necessary until the stricture is resolved.[3,4,13,14] Esophageal dilation is best performed with direct observation at the time of endoscopy, but it could be performed with videofluoroscopy.

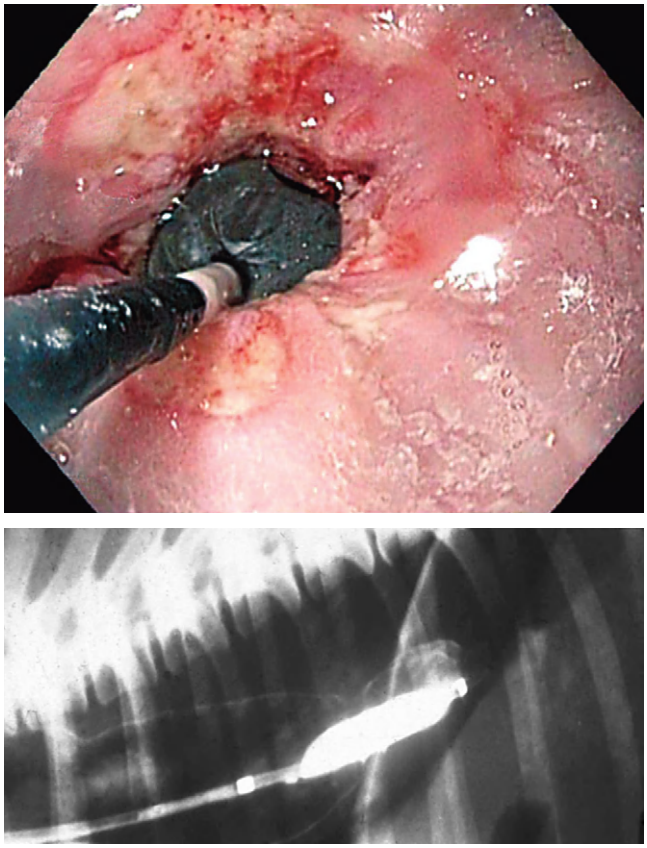

Figure 55-5 Inflammation, hemorrhage, and stricture of the esophagus in a 10-year-old dog undergoing balloon dilation.

Medical therapies aimed at treating the inflammatory component of this lesion are best used as adjunctive therapy to mechanical dilation.[2,9] Animals with concurrent esophagitis should be treated with oral sucralfate suspensions (0.5 to 1.0 g PO, TID) and gastric acid secretory inhibitors (cimetidine 5 to 10 mg/kg PO or IV, TID-QID; ranitidine 1 to 2 mg/kg PO or IV, BID-TID; famotidine 0.1 to 0.5 mg/kg PO or IV BID; or omeprazole 0.7 mg/kg PO, SID) or esomeprazole, lansoprazole, or pantoprazole at a dose of 1.0 mg/kg IV SID. Antiinflammatory doses of corticosteroids (e.g., prednisone 0.5 to 1.0 mg/kg PO or IM, BID) have been advocated to prevent fibrosis and restricture during the healing phase following esophageal dilation. It has been further suggested that intralesional steroid injections (e.g., 1 mg triamcinolone) administered at the time of stricture dilation may be beneficial in reducing the risk of recurrence.[4,15] Corticosteroid therapy should be used with caution if the esophageal mucosa is already ulcerative and/or devitalized as a consequence of the disease or of balloon dilation.

Surgical resection of esophageal stricture and reanastomosis has been reported, but resections may be complicated by inadequate surgical exposure, lengthy resections, tension on the anastomosis, and poor healing properties of the thoracic esophagus.[2] Omentopexy may improve vascularization and reduce stricture formation following esophageal anastomosis.[16] Surgical failures may subsequently be treated with intestinal interposition whereby a segment of the

Table 55-2 Strategies for Balloon Dilation Treatment of Esophageal Strictures

Intervention	Rationale	Implementation
Barium swallow	Determine location, length, and number of strictures	Barium suspension, 30% w/v
General anesthesia	High-pressure esophageal dilation stimulates visceral pain	Inhalant anesthesia, e.g., sevoflurane, isoflurane
Patient positioning	Inspection of esophagus and stomach poststricture dilation	Left lateral recumbency for maximal maneuverability
Endoscopes	Direct observation, balloon placement, postdilation trauma	7.5- to 8.5-mm insertion tube, 2.8-mm biopsy channel
Balloon dilation catheters	Multiple catheter lengths and balloon diameters	8 mm × 8 cm to 18 mm × 8 cm balloon catheters*
Procedure	Repeated balloon dilations to achieve increase in luminal diameter	1 to 3 cycles of balloon inflation and deflation/procedure
Manometry	Monitoring of inflation and deflation pressures	Vacuum to 160 psi pressure gauges
Gastrostomy tube placement	Nutritional maintenance during recovery phase with severe strictures	Low-profile gastrostomy tube systems
Recovery phase	Protect esophageal mucosa, inhibit acid secretion, promote healing	Sucralfate, H_2 histamine receptor antagonists
Recurrence/prevention	Most esophageal strictures require 2 to 4 successive balloon dilations	Repeat endoscopy at 13-day intervals as needed

*Sure-Flex esophageal balloon dilation catheters and Rigiflex esophageal balloon dilation catheters.

intestine is transposed to the esophageal body,[17] or by creation of a traction diverticulum.[18] Insufficient clinical experience with these techniques warrants caution before adopting them as best practice standards. Patients refractory or unresponsive to balloon dilation, may instead benefit from placement of a nitinol stent with or without drug elution (e.g., paclitaxel).[19,20] Although still relatively experimental, nitinol stents have been maintained for long periods of time with minimal tissue reactivity or worsening of esophageal compliance or biomechanics.[20] Future therapy may be based on principles of regenerative medicine[21-23] in which extracellular matrix scaffolds and autologous muscle tissue are used to prevent stricture recurrence.[21-23]

Prognosis

Strictures associated with foreign body ingestion or esophagitis have a fair to guarded prognosis. Multiple dilations are often required to achieve an adequate esophageal lumen (see Table 55-2).[14] Esophageal perforation is a potentially life-threatening complication of esophageal stricture dilation. Perforations usually occur at the time of esophageal dilation, although they have been observed several days to weeks afterward. Malignant strictures have a poor prognosis. Surgical resection is often the only possible recourse.

Hiatal Hernia

Etiology

Three types of hiatal hernia have been recognized in the dog and cat: (a) type I, which is the sliding hiatal hernia, in which the abdominal segment of the esophagus and parts of the stomach are displaced cranially through the esophageal hiatus, and (b) type II, which is the paraesophageal hiatal hernia, in which the abdominal segment of the esophagus and caudal esophageal sphincter remain in a fixed position but a portion of the stomach herniates into the mediastinum alongside the thoracic esophagus.[2,9,24] One case of a type IV esophageal hiatal hernia has been reported in which the liver, stomach, and small intestine were displaced into the thorax.[25]

Pathophysiology

Sliding hiatal hernia is the most common form and may occur as a congenital or acquired lesion in the dog and cat. Congenital sliding hiatal hernias have been reported in the Chinese Shar-Pei, Chow, English Bulldog, and French Bulldog breeds.[9] The hernia results from incomplete fusion of the diaphragm during early embryonic development. Affected animals develop clinical signs shortly after weaning.[24,26,27]

Acquired hiatal hernia may occur in any breed of dog or cat. The pathogenesis of acquired hiatal hernia is incompletely understood, but may result from chronic increases in intraabdominal pressure with chronic vomiting disorders, or from chronic increases in negative intrathoracic pressure in animals with intermittent airway obstruction.[2,28,29]

Clinical Signs

Regurgitation, vomiting, and hypersalivation are the most important clinical signs in congenital hiatal hernia. Regurgitation and hypersalivation result from the chemical effects of gastric fluid (e.g., H^+ and pepsins) on the esophageal mucosa, while vomiting may result from the obstructive effects of the hernia.[24] Dyspnea and coughing may also occur with severe obstruction and/or aspiration pneumonia. The physical examination findings are usually unremarkable but may include dehydration, pulmonary crackles or wheezes, and decreased body weight. Clinical findings are usually similar, but less severe, in animals with acquired hiatal hernia; these animals may have inspiratory stridor associated with laryngeal paralysis.

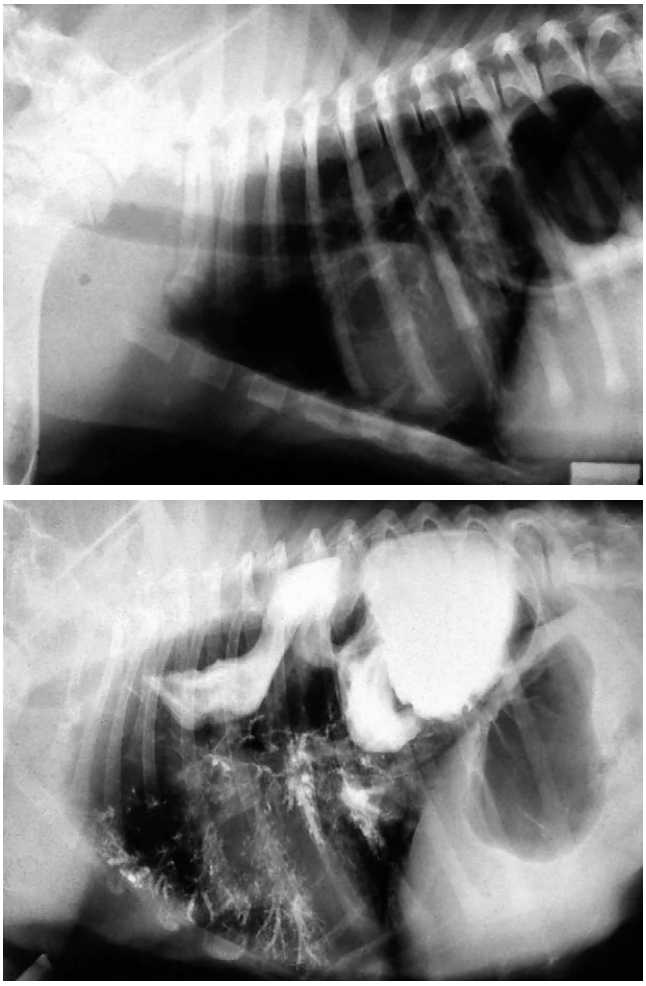

Figure 55-6 Congenital esophageal hiatal hernia in a 3-month-old Chinese Shar-Pei puppy.

Diagnosis

The survey radiographic finding of a caudodorsal gas-filled intrathoracic soft-tissue opacity is consistent with the diagnosis of hiatal hernia (Figure 55-6).[24] Affected animals may have concurrent esophageal dilation and dependent alveolar consolidation consistent with aspiration pneumonia. Barium contrast studies will confirm the diagnosis and further delineate esophageal dilation and hypomotility. Videofluoroscopy should always be performed if a hiatal hernia is suspected but not proved by survey radiographs. Endoscopic findings consistent with the diagnosis include cranial displacement of the caudal esophageal sphincter and a large esophageal hiatus. Because young animals with congenital hiatal hernia have varying degrees of esophageal dilation, a misdiagnosis of congenital idiopathic megaesophagus could be made if herniation at the hiatus is not readily apparent. Therefore, the finding of esophageal dilation in a young Shar-Pei or other breed should raise a high index of suspicion of an underlying hiatal hernia.[24,26] Gastroesophageal reflux, gastroesophageal intussusception, epiphrenic diverticulum, and diaphragmatic hernia are the other major differential diagnoses for hiatal hernia.

Treatment

A sliding hiatal hernia (type I) is not always associated with clinical signs, particularly the acquired form of the disease.[2,9] When animals develop clinical signs, medical therapy should be attempted first. Medical therapy is similar to that for gastroesophageal reflux and should be directed at reducing gastric acid secretion (e.g., H_2 receptor antagonism, H^+,K^+-ATPase inhibition), restoring the health of the esophageal mucosa (e.g., sucralfate), and increasing the tone of the gastroesophageal sphincter (e.g., metoclopramide, erythromycin, or cisapride). Many acquired sliding hiatal hernias will respond to conservative medical therapy alone,[27] although laryngeal surgery (e.g., partial laryngectomy or lateralization of the vocal folds) should be considered if laryngeal paralysis has contributed to the pathogenesis of the hernia. Congenital hiatal herniae often require surgical correction. Diaphragmatic crural apposition, esophagopexy, and gastropexy are usually sufficient to restore normal hiatus anatomy.[24,30] Fundoplication procedures may be performed but are generally not necessary.[24,30-32]

Prognosis

The prognosis for surgical correction is generally favorable. Animals have few if any clinical signs following restoration of the normal anatomy.

Esophageal Foreign Bodies

Etiology

Esophageal foreign bodies are a frequent clinical problem in dogs and cats. The most common esophageal foreign bodies found in dogs are bones, bone fragments, and coins, whereas play objects are more commonly found in cats.

Pathophysiology

Many foreign bodies are regurgitated or transported into the distal gastrointestinal tract, but others remain lodged in the esophageal body. Those that are too large to pass through the esophagus cause mechanical obstruction. The severity of esophageal damage is dependent upon foreign body size, angularity or sharp points, and the duration of obstruction.[2,33-36]

Clinical Signs

In many cases there is a history of foreign-body ingestion. Some cases go unnoticed, however, particularly those associated with garbage ingestion. The onset of clinical signs will depend upon the severity of esophageal obstruction. Animals with complete esophageal obstruction are often presented with acute signs, whereas animals with incomplete obstruction may be presented with clinical signs persisting for days or weeks. Relevant clinical signs include regurgitation, excessive salivation, odynophagia, anorexia, dysphagia, and retching. In severe cases, hematemesis and respiratory distress may predominate.

Diagnosis

Bone foreign bodies can occasionally be palpated if they become lodged in the cervical esophagus, but definitive diagnosis usually requires radiographic studies. Radiodense foreign bodies can be detected with survey radiography (Figure 55-7), but confirmation of radiolucent foreign bodies will require administration of contrast agents. Iodine contrast agents should be used instead of barium to avoid barium pleuritis if esophageal perforation is suspected. Foreign bodies may subsequently be confirmed and removed during endoscopy. A tentative diagnosis of esophageal foreign body may be made in animals presented with esophageal signs following a history of foreign-body ingestion. Without a compatible history, the most important differential diagnoses would include esophageal stricture, neoplasia, hiatal hernia, and gastroesophageal intussusception. Each of these conditions can be differentiated with radiography and/or endoscopy.

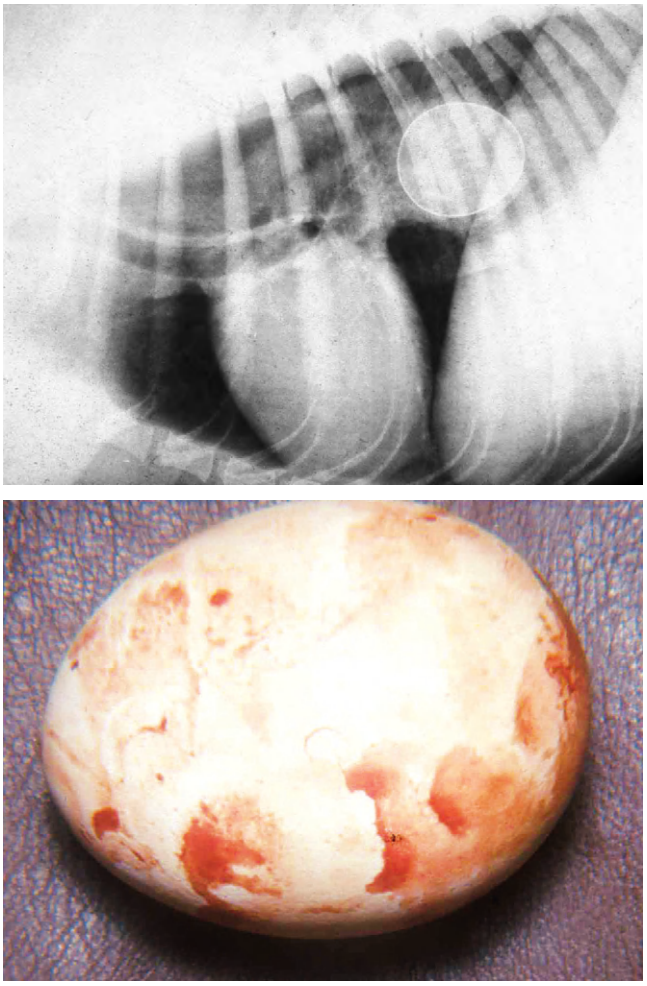

Figure 55-7 Esophageal foreign body in a 9-year-old dog.

Treatment

Esophageal foreign bodies should be removed promptly. Prolonged retention increases the likelihood of esophageal mucosal damage, ulceration, and perforation. Rigid or flexible fiberoptic endoscopic retrieval should be the initial approach to treating an esophageal foreign body although fluoroscopic-guided retrieval is also possible.[36] A rigid endoscope is most useful in retrieving large foreign bodies, particularly bones or bone fragments.[33] Large grasping forceps are passed through the rigid endoscope to retrieve the foreign body, and in many cases, the foreign body can be pulled into the endoscope for safe removal. Large foreign bodies that cannot be safely removed through the mouth can occasionally be pushed into the stomach and removed by gastrotomy. Smaller foreign bodies are best managed with a flexible fiberoptic endoscope and basket, tripod, or snare retrieval forceps.[34] Flexible endoscopes are particularly useful in retrieving fish hooks.[35]

Affected animals should be fasted for 24 to 48 hours after foreign-body removal. Longer periods of fasting may be required if the esophagus is necrotic or ulcerative. In the latter circumstance, animals may instead be fed through a gastrostomy tube placed at the time of endoscopy. Specific therapy for esophagitis should include oral sucralfate suspensions (0.5 to 1.0 g PO, TID).[37] Suspensions of sucralfate are more therapeutic than intact tablets. Antiinflammatory doses of glucocorticoids (e.g., prednisone 0.25 to 0.5 mg/kg PO, BID) should also be considered in those animals at risk for esophageal stricture. The risk of esophageal stricture is greatest in animals with 180-degree or greater transmucosal ulceration. Finally, broad-spectrum antibiotics should be considered in animals with severe ulceration and/or small perforations.

Surgery is indicated if endoscopy fails or if there is evidence of esophageal perforation. Gastrotomy is preferred to esophagotomy for distal esophageal foreign bodies because of the poorer healing properties of the esophagus and the potential for stricture formation. However, esophagotomy would certainly be indicated in those cases where the foreign body could not be removed through gastrotomy. Surgery is also indicated to repair esophageal perforation.

Prognosis

The prognosis for most esophageal foreign bodies is generally good, especially if they are removed immediately. A worse prognosis is associated with foreign bodies that are large, have sharp points, or are retained for a prolonged period of time. Immediate complications include complete obstruction or laceration, whereas late complications include perforation, hemothorax, fistulation, and diverticula or stricture formation.[9,38]

Vascular Ring Anomalies

Etiology

Vascular ring anomalies are congenital malformations of the major arteries of the heart that, because of altered anatomic relationships, entrap the esophagus and trachea. Persistent right aortic arch, persistent right or left subclavian arteries, persistent right dorsal aorta, double aortic arch, left aortic arch and right ligamentum arteriosum, and aberrant intercostal arteries have been described in both dogs and cats.[39,40]

Pathophysiology

Persistent right aortic arch is the most common vascular ring anomaly found in dogs and cats. Circular compression of the esophagus by the right fourth aortic arch results in physical obstruction of the esophagus and/or trachea. The anomaly is considered to be a familial disease with evidence of a hereditary basis in German Shepherds.[41] Aberrant subclavian arteries are the second most common vascular ring anomaly.[9] The latter anomalies result in significant esophageal compression from the left subclavian artery and brachycephalic artery.

Clinical Signs

Affected puppies and kittens are presented at a young age with the major complaints of regurgitation and failure to thrive. Animals usually do well until weaning. With the transition to solid food, progressive regurgitation ensues. Aspiration pneumonia develops in some animals as a result of constant regurgitation, but signs of tracheal compression are uncommon. Physical examination most often reveals a thin, stunted animal that is apparently malnourished but normal in other respects. Occasionally, a dilated esophagus can be observed or palpated in the cervical region.

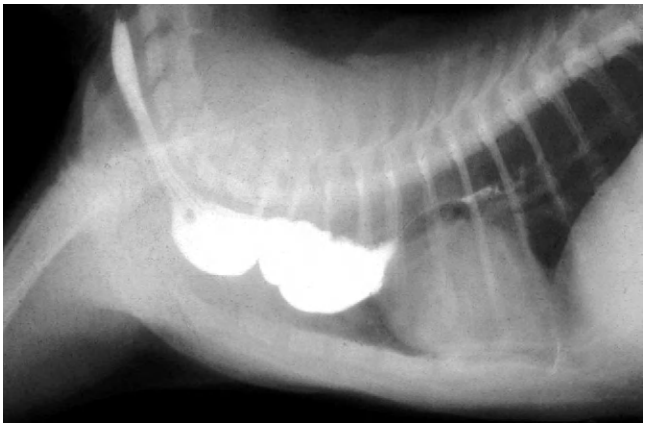

Figure 55-8 Persistent right aortic arch in a 3-month-old Persian kitten.

Diagnosis

Laboratory findings are usually normal. As with other esophageal disorders, regenerative neutrophilia may be associated with aspiration pneumonia, and hypoproteinemia may be associated with malnutrition. The diagnosis of a vascular ring anomaly is based upon a compatible history and the barium contrast radiographic finding of esophageal body dilation cranial to the base of the heart (Figure 55-8); a proximal diverticulum occasionally forms with longstanding untreated vascular ring anomalies. The caudal esophagus usually appears normal but there might be a mild dilation with reduced motility. Angiography is occasionally performed to clarify complex or atypical vascular ring anomalies, or to determine the best surgical approach. Endoscopy can be performed to differentiate intraluminal stricture from extraluminal compression. With vascular ring anomaly, pulsations of the major arteries can be observed in the region of esophageal narrowing. Furthermore, vascular ring anomalies occur at the base of the heart, whereas intraluminal strictures can occur in any segment of the esophageal body. The most important differential diagnosis for vascular ring anomaly is intraluminal stricture. Strictures resulting from ingestion of foreign bodies or chemical irritants, or from malignancy, are more common in adult animals.

Treatment

Vascular ring anomalies are best treated by conventional thoracotomy or interventional thoracoscopy.[42,43] Persistent right ductus arteriosus, aberrant right subclavian artery, and double aortic arch are all best managed by right intercostal approach, whereas persistent right aortic arch is best managed by a left intercostal approach. Ligation and division of the ligamentum arteriosum is the recommended therapy in cases of persistent right aortic arch.[42,43] If possible, periesophageal fibrosis should be reduced, and the stricture site should be dilated intraluminally with a balloon dilation catheter.[9] Other techniques to resect, reduce, or replace the redundant esophagus have not proven beneficial.

Some animals may have persistent esophageal hypomotility and clinical signs following corrective surgery. These animals may benefit from elevated feedings. Metoclopramide may be of some benefit in cats with esophageal motility disorders, but only those confined to the smooth muscle of the distal esophageal body.[9,44]

Prognosis

The best outcomes are obtained with early diagnosis and early surgical intervention. In undiagnosed cases, progressive esophageal

dilation causes irreversible myenteric nerve degeneration and esophageal hypomotility, but at least one study suggests that a 90% or greater recovery rate can be expected.[42] Clients should be informed that, although surgical correction is the preferred treatment, clinical signs may persist after surgery.

Gastroesophageal Intussusception

Etiology

Gastroesophageal intussusception is a rare condition of young dogs (most younger than 3 months of age) resulting from invagination of the stomach into the esophagus, with or without other abdominal organs, for example, spleen, duodenum, pancreas, and omentum.[45] The disorder is more common in males than in females, with a higher incidence reported in the German Shepherd breed.

Pathophysiology

Many affected animals have preexisting esophageal disease, most importantly idiopathic generalized megaesophagus. The role of idiopathic megaesophagus in the pathogenesis of gastroesophageal intussusception is incompletely understood, but it's likely that the greatly enlarged capacity of a dilated esophagus accommodates the invagination of the stomach through the diaphragmatic hiatus. Some gastroesophageal intussusceptions have been reported in association with hiatal hernia in young puppies.[46] Gastroesophageal intussusception is a true gastrointestinal emergency that may culminate in the death of the animal if untreated.

Clinical Signs

The initial clinical signs are vomiting or regurgitation, dyspnea, hematemesis, and abdominal discomfort. If diagnosis and therapy are delayed, these clinical signs are rapidly followed by marked deterioration in condition, shock, respiratory and cardiac arrest, and death.

Diagnosis

Survey radiographs will reveal proximal esophageal dilation, consolidation or mass effect between the cardiac silhouette and the diaphragm, and gastric rugal folds within the intrathoracic esophagus (Figure 55-9). Contrast radiographic studies usually reveal that the column of barium traverses the proximal esophageal body, but does not enter the distal esophagus or stomach. Endoscopy will confirm an intra-esophageal mass that completely obstructs the lumen of the esophagus. The major differential diagnoses are hiatal hernia, epiphrenic diverticulum, and diaphragmatic hernia. It is sometimes difficult to distinguish these entities from gastroesophageal intussusception. Because the defining characteristic of a gastroesophageal intussusception is the invagination of the stomach into the esophagus, gastric rugal folds are often readily identified within the lumen of the esophagus on survey or contrast radiographs.

Treatment

The recommended therapy is a brief period of stabilization followed by definitive endoscopic or surgical reduction.[45-47] After reduction of the intussusception, a gastropexy should be performed to prevent recurrence. If disease of the esophageal hiatus is involved in the pathogenesis of the intussusception, restorative surgery (e.g., diaphragmatic crural apposition) should also be performed.

Prognosis

The prognosis is poor unless the disorder is quickly recognized and treated. Mortality rates have been reported in excess of 95%.[45]

DYSMOTILITY

Robert J. Washabau

Esophageal dysmotility is a primary motility disorder of the esophagus characterized by reduced esophageal peristalsis, food retention, and regurgitation. It is not necessarily accompanied by esophageal dilation or permanent megaesophagus, and therefore is not referred to as idiopathic megaesophagus. Esophageal dysmotility has been reported in young dogs as a consequence of delayed maturation,[1-7] muscular dystrophy,[8,9] myasthenia gravis,[10] inflammatory myopathy,[11,12] transient dysfunction following anesthetic episodes,[13] and breed-specific abnormalities.[14]

Therapy is primarily supportive and follows therapy outlined for idiopathic megaesophagus (Table 55-3). The prognosis for esophageal dysmotility is generally more favorable than it is for idiopathic megaesophagus.

Idiopathic Megaesophagus

Etiology

The term idiopathic megaesophagus refers to concurrent esophageal dysmotility and dilation of unknown etiology, and is the most common cause of regurgitation in the dog.[15,16] Aside from

dysautonomia, megaesophagus is an uncommon finding in the cat. The canine disorder is characterized by progressive regurgitation, aspiration pneumonia, and loss of body condition. Several forms of the syndrome have been described, including congenital, acquired secondary, and acquired idiopathic megaesophagus (Table 55-4).[16]

Pathophysiology

Congenital idiopathic megaesophagus is a generalized hypomotility and dilation of the esophagus causing regurgitation and failure to thrive in puppies shortly after weaning. An increased breed incidence has been reported in the German Shepherd, Great Dane, Irish Setter, Labrador Retriever, Chinese Shar-Pei, and Newfoundland breeds, and autosomal dominant inheritance has been demonstrated in the Miniature Schnauzer and Fox Terrier breeds.[16] The pathogenesis of the congenital form is incompletely understood, although several studies have pointed to a defect in the vagal afferent innervation of the esophagus.[2-6,17] Primary, but not secondary, esophageal peristalsis appears to be intact in this disorder (Figure 55-10). Congenital idiopathic megaesophagus has been reported in several cats[18] and in one group of cats secondary to pyloric dysfunction.[19]

Acquired secondary megaesophagus may develop in association with a number of other conditions. Myasthenia gravis accounts for 25% to 30% of the secondary cases.[10,20,21] In some cases of myasthenia gravis, regurgitation and weight loss may be the only presenting signs of the disease, whereas in most other cases of acquired secondary megaesophagus regurgitation is but one of many clinical signs including peripheral muscle weakness. Acquired secondary megaesophagus has also been associated with hypoadrenocorticism, lead poisoning, lupus myositis, and severe forms of esophagitis.[16] Hypothyroidism has been suggested as a secondary cause of idiopathic megaesophagus but retrospective risk factor analysis has not identified it as an important cause.[15]

Acquired-idiopathic megaesophagus usually has no known underlying etiology and occurs spontaneously in adult dogs between 7 and 15 years of age with no sex or breed predilection. The disorder has been compared erroneously to gastroesophageal achalasia in humans. Achalasia is a hypertensive sphincteric disorder characterized by failure of relaxation of the LES and ineffective peristalsis of the esophageal body.[1] A similar disorder has never been rigorously documented in the dog although putative case reports are occasionally reported.[22] Several important differences between idiopathic megaesophagus in the dog and achalasia in humans have been documented.[1,2,17] Although the precise etiology has not yet been identified, some studies have suggested a defect in the afferent neural response to esophageal distention similar to what has been reported in congenital megaesophagus (see Figure 55-9).[23]

Clinical Examination

Regurgitation is the most frequent clinical sign associated with megaesophagus. The frequency of regurgitation varies from intermittent irregular episodes to multiple episodes per day. As with other esophageal disorders, affected animals suffer from malnutrition and aspiration pneumonia. Physical examination may reveal excessive salivation, mild to moderate cachexia, coughing, and pulmonary crackles or wheezes.

Table 55-3 Therapy for Canine Idiopathic Megaesophagus

Problem	Therapy
Regurgitation of food	Elevated feedings, liquid to semiliquid density
Malnutrition	High-biologic, high-energy feedings
Pulmonary infections	Broad-spectrum antibiotics
Esophageal dysmotility	Bethanechol
Esophagitis	Oral sucralfate (liquid suspension)

Table 55-4 Medical Investigation and Treatment of Canine Idiopathic Megaesophagus

Etiology	Medical Investigation	Treatment
Congenital Megaesophagus		
Myasthenia gravis	Edrophonium response ± electrophysiology	Pyridostigmine (1 to 3 mg/kg PO, BID)
Neuropathy	Esophageal manometry ± electrophysiology	Elevated, small frequent feedings; bethanechol (5 to 15 mg/dog PO TID)
Acquired Idiopathic Megaesophagus		
Neuropathy	Esophageal manometry ± electrophysiology	Elevated, small frequent feedings, bethanechol (5 to 15 mg/dog PO TID), sucralfate (0.5 to 1.0 g PO, TID), antibiotics as needed
Acquired Secondary Megaesophagus		
Myasthenia gravis	Nicotinic acetylcholine receptor antibody, edrophonium response, ± electrophysiology	Pyridostigmine (1 to 3 mg/kg PO, BID) ± prednisone (1 to 2 mg/kg PO or SC, BID)
Hypoadrenocorticism	Adrenocorticotropic hormone (ACTH) stimulation	Prednisone (0.1 mg/kg PO, BID)
Lead toxicity	Hematology, blood lead concentrations	Chelation with calcium ethylenediaminetetraacetic acid (EDTA)
Esophagitis	Esophageal endoscopy	Sucralfate (0.5 to 1.0 g PO, TID), cimetidine (5 to 10 mg/kg PO, TID), omeprazole (0.7 mg/kg PO, SID)
Hypothyroidism	Thyroid function tests	Levothyroxine (22 µg/kg PO, BID)
Dysautonomia	Clinical diagnosis	Supportive care
Polymyositis/polymyopathy	Serum creatine phosphokinase, muscle biopsy ± electrophysiology	Prednisone (1 to 2 mg/kg PO or SC, BID)
Systemic lupus erythematosus	Antinuclear antibody	Prednisone (1 to 2 mg/kg PO or SC, BID)

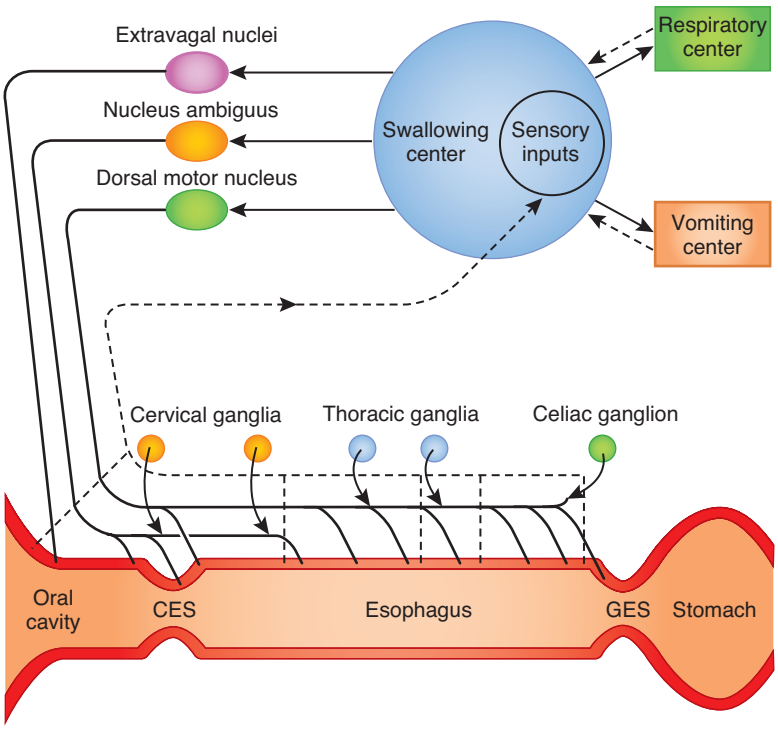

Figure 55-10 Neural regulation of swallowing in the dog and cat. Potential sites of esophageal hypomotility and megaesophagus: afferent sensory neurons, brainstem swallowing center, brainstem nuclei (dorsal motor nucleus of the vagus, nucleus ambiguus), efferent motor neurons, neuromuscular junction. The afferent neural pathway (from esophageal mucosa to brainstem) appears to be the site of involvement in both congenital and acquired idiopathic megaesophagus. *CES*, cricoesophageal sphincter; *GES*, gastroesophageal sphincter. (Reprinted with permission from Washabau RJ, Holt DE: Pathophysiology of gastrointestinal disease. In Slatter D, editor: *Textbook of Veterinary Surgery*, ed 3, Philadelphia, 2003, WB Saunders, p 532.)

Diagnosis

Routine hematology, serum biochemistry, and urinalysis should be performed in all cases to investigate possible secondary causes of megaesophagus. Survey radiographs will be diagnostic for most cases of megaesophagus (Figure 55-11), but generally do not differentiate one cause versus another.[24] Contrast radiographs may be necessary in some cases to confirm the diagnosis, evaluate motility, and exclude foreign bodies or obstruction as the cause of the megaesophagus. Endoscopy will confirm the diagnosis and may further reveal esophagitis, a frequent finding in canine idiopathic megaesophagus.[15,16] Risk factor analysis suggests that esophagitis markedly increases the risk for the development of megaesophagus.[15,16] Esophagitis could be cause or consequence of esophageal dysmotility and megaesophagus (Figure 55-12).

If acquired secondary megaesophagus is suspected (see Table 55-4), additional diagnostic tests should be considered, including serology for nicotinic acetylcholine receptor antibody, pre- and postadrenocorticotropic hormone (cortisol), serum creatine phosphokinase activity, electromyography and nerve conduction velocity, and muscle and nerve biopsy.[16] Additional medical investigation will be dependent upon the individual case presentation. Hypothyroidism has been cited as an important cause of idiopathic megaesophagus in the dog, although risk factor analysis has not revealed a clear association.[15] Thyroid function testing (e.g., thyroid-stimulating hormone [TSH] assay, TSH stimulation, free and total thyroid hormones) should be performed only in individual suspected cases.

Treatment

Table 55-4 provides an overview of therapy for canine idiopathic megaesophagus.

Animals with secondary acquired megaesophagus should be appropriately differentiated from other esophageal disorders (see Table 55-4). Dogs affected with myasthenia gravis should be treated with pyridostigmine (1 to 3 mg/kg PO BID), corticosteroids (prednisone 1 to 2 mg/kg PO or SC BID), or azathioprine (2 mg/kg PO SID initially, 0.5 to 1.0 mg/kg PO every other day). Mycophenolate has been recommended in the treatment of myasthenia gravis, but a recent report suggests that mycophenolate does not improve outcome over pyridostigmine alone.[25] Dogs affected with hypothyroidism should be treated with levothyroxine (22 μg/kg PO BID), and dogs affected with polymyositis should be treated with prednisone (1 to 2 mg/kg PO BID). If secondary disease can be excluded, therapy for the congenital or acquired idiopathic megaesophagus patient should be directed at nutritional management and treatment of aspiration pneumonia.

Affected animals should be fed a high-calorie diet, in small frequent feedings, from an elevated or upright position to take advantage of gravity drainage through a hypomotile esophagus. Dietary consistency should be formulated to produce the fewest clinical signs. Some animals handle liquid diets quite well, while others do better with solid meals. Animals that cannot maintain adequate nutritional balance with oral intake should be fed by temporary or permanent tube gastrostomy. Gastrostomy tubes can be placed surgically or percutaneously with endoscopic guidance.

Pulmonary infections should be identified by culture and sensitivity, and an appropriate antibiotic selected for the offending organism(s). This may be accomplished by trans- or endotracheal wash or by bronchoalveolar lavage at the time of endoscopy.

Smooth muscle prokinetic (e.g., metoclopramide or cisapride) therapy has been advocated for stimulating esophageal peristalsis in

affected animals, however metoclopramide and cisapride will not have much of an effect on the striated muscle of the canine esophageal body.[26-28] Esophageal 5-HT_4 receptors are present in many animal species, but are apparently absent in canine esophageal striated muscle.[26] Bethanechol (5 to 15 mg/dog PO TID) has been shown to stimulate esophageal propagating contractions in some affected dogs and is therefore a more appropriate prokinetic agent for the therapy of this disorder.[17] Because of the high incidence of esophagitis in canine idiopathic megaesophagus,[15] affected animals should also be medicated with oral sucralfate suspensions (1 g TID for large dogs, 0.5 g TID for smaller dogs, and 0.25 to 0.5 g BID-TID for cats).

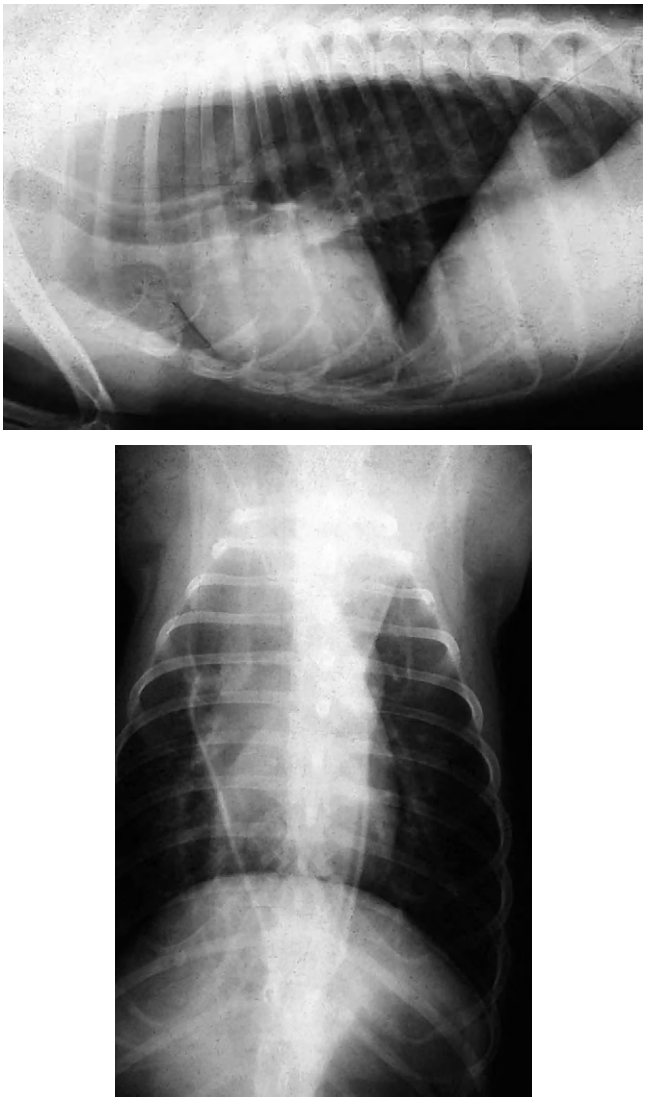

Figure 55-11 Idiopathic megaesophagus in an 8-year-old mixed-breed dog.

Surgical cardiomyotomy (myotomy of the gastroesophageal sphincter) has been recommended in the past as a therapeutic measure in the belief that canine megaesophagus is similar to human achalasia. Because most studies have reported normal gastroesophageal sphincter tone and appropriate relaxation with swallowing,[23] cardiomyotomy cannot be recommended for the treatment of this disorder. Indeed, animals treated with myotomy generally have had poorer outcomes than untreated animals.

Prognosis

Animals with *congenital* idiopathic megaesophagus have a fair prognosis. With adequate attention to caloric needs and recognition of episodes of aspiration pneumonia, many animals will develop improved esophageal motility over several months. Pet owners must be committed to months of physical therapy and nutritional support.

The morbidity and mortality of acquired idiopathic megaesophagus remain unacceptably high. Many animals eventually succumb to the effects of chronic malnutrition and repeated episodes of aspiration pneumonia. A poor prognosis must be given in such cases.

Animals with acquired secondary megaesophagus have a more favorable prognosis if the underlying disease can be promptly identified and successfully managed. Refractory cases result from chronic esophageal distention, myenteric nerve degeneration, and muscle atrophy.

Dysautonomia

Etiology

Dysautonomia is a generalized autonomic neuropathy that was originally reported in cats in the United Kingdom, but that has now been documented in dogs and cats throughout Western Europe and the United States.[29-35] The clinical signs reflect a generalized autonomic dysfunction but megaesophagus, esophageal hypomotility, and regurgitation are fairly consistent findings.[29,31]

Pathophysiology

Degenerative lesions are found in autonomic ganglia, intermediate gray columns of the spinal cord, and some sympathetic axons.[31,33,34] Despite an intensive search for genetic, toxic, nutritional, and infectious etiologic agents, no definitive etiology has ever been established.

Clinical Signs

The most frequently reported clinical signs are depression, anorexia, constipation, and regurgitation or vomiting. Fecal and urinary incontinence have been reported less commonly. Physical examination findings consistent with dysautonomia include dry mucous membranes, pupillary dilation, prolapsed nictitating membranes, reduced or absent pupillary light reflex, bradycardia, and areflexic anus. Paresis and conscious proprioceptive deficits have been reported in a small number of cases.[33]

Cause

Gastroesophageal reflux → Reflux esophagitis → Esophageal dysmotility → Idiopathic megaesophagus

Consequence

Esophageal dysmotility → Idiopathic megaesophagus → Gastroesophageal reflux → Reflux esophagitis

Figure 55-12 Interrelationships between gastroesophageal reflux, esophagitis, esophageal dysmotility, and idiopathic megaesophagus.

Diagnosis

A clinical diagnosis is made in most cases based on historical and physical examination findings. Additional findings consistent with the diagnosis would include (a) esophageal dilation and hypomotility on survey or barium-contrast radiographs; (b) delayed gastric emptying on barium-contrast radiographs; (c) reduced tear production in Schirmer tear tests; (d) atropine-insensitive bradycardia; and (e) bladder and colonic distention on survey radiographs. There are few differential diagnoses to consider in a dog or cat presenting with the myriad manifestations of the syndrome. Early in the course of the illness, however, other differential diagnoses to consider are colonic or intestinal obstruction, other causes of megaesophagus, and lower urinary tract disease.

Treatment

Supportive care (e.g., artificial tears, elevated feedings, expressing the urinary bladder, antibiotics, etc.) is still the basis of therapy in this disorder, although some dogs and cats are reported to show mild improvement with parasympathomimetic drugs (e.g., bethanechol or metoclopramide). Gastrostomy tube feedings or total parenteral nutrition may sustain some animals until they regain neurologic function.

Prognosis

In general, dysautonomia carries a guarded to poor prognosis for long-term survival in both the dog and the cat. Of affected cats, 20% to 40% are likely to recover, although cats may take 2 to 12 months to do so.[33-35] Recovery rates are lower still in the dog.[31,33] Complete recovery is uncommon and many cats and dogs are left with residual impairment, for example, intermittent regurgitation, dilated pupils, and fecal or urinary incontinence.

Esophageal Diverticula

Etiology

Esophageal diverticula are circumscribed sacculations in the wall of the esophagus that interfere with the normal esophageal motility patterns. Both congenital and acquired forms have been described.[36]

Pathophysiology

Congenital diverticula have been attributed to abnormalities in embryologic development that permit herniation of the mucosa through a defect in the muscularis. Acquired diverticula are subdivided into either traction or pulsion forms, depending upon the pathogenesis. Traction diverticula tend to develop in the cranial and midesophageal body and result from periesophageal inflammation and fibrosis. Adhesions to adjacent tissue (e.g., lung, bronchus, lymph node) distort the esophageal lumen and create sacculations. Abscess development from grass awn migration is a common cause of traction diverticula in the western United States. Pulsion diverticula develop in association with increases in intraluminal esophageal pressure, abnormal regional esophageal motility, or when normal peristalsis is obstructed by a stenotic lesion.[16] Pulsion diverticula may develop as a consequence of vascular ring anomalies in the cranial esophagus, or from foreign bodies that become lodged in the distal esophagus, in which case they are referred to as epiphrenic diverticula.

Clinical Signs

The clinical signs of esophageal diverticula are typical of many other esophageal disorders, and include regurgitation, odynophagia (painful swallowing), and retching. Signs usually result from impaction of food and/or fluid in the sacculated segment. On rare occasions, weakening of the muscularis results in perforation of the diverticulum, leakage of food and fluid into the mediastinum, and signs of sepsis.

Diagnosis

Survey radiographs may reveal an air-filled or tissue-density mass adjacent to or involving the esophagus. Contrast radiographs are necessary, however, because it may be impossible to differentiate an esophageal diverticulum from a periesophageal, mediastinal, or pulmonary mass. An epiphrenic diverticulum could also easily be confused with a hiatal hernia or gastroesophageal intussusception on survey radiographs. Contrast radiographs will demonstrate a focal dilated segment of esophageal lumen that fills partially or completely with contrast media. Videofluoroscopy might also demonstrate an underlying esophageal motility disorder associated with the diverticulum. Endoscopy will confirm the diagnosis, although it may be necessary to suction food and fluid to visualize the diverticulum. The differential diagnoses for cranial and mid-esophageal diverticula should include esophageal or periesophageal abscess, necrotic tumor, and pulmonary mass. Hiatal hernia and gastroesophageal intussusception are the major differential diagnoses for epiphrenic diverticula. The normal redundancy of the canine esophagus frequently seen in the brachycephalic breeds should not be confused with the sacculation of an esophageal diverticulum.

Treatment

Small diverticula may be managed by feeding liquid or semiliquid diets to minimize impaction of solid food in the diverticulum. Surgical excision and reconstruction of the esophageal wall are required for larger diverticula. Even small pulsion diverticula should probably be treated surgically as food impaction might cause them to enlarge.

Prognosis

Most cases warrant a guarded prognosis as segmental esophageal hypomotility may persist after surgery. Animals are also at some risk for esophageal stricture following corrective surgery. In cases of traction diverticula, the prognosis will also be somewhat dependent upon the pathogenesis and resolution of the periesophageal inflammation.

NEOPLASIA

Michael D. Willard

Etiology

Esophageal tumors are rare. Squamous cell carcinomas, fibrosarcomas, osteosarcomas, and leiomyomas are the more common types of primary esophageal tumor. Melanomas occasionally occur in dogs with black mucous membranes (e.g., Chows, Shar-Pei, Scottish Terrier), the same breeds that develop oral melanomas. Fibrosarcomas, osteosarcomas, and undifferentiated sarcomas are classically attributed to infection with *S. lupi*.[1] The cause of other esophageal tumors in dogs and cats is unknown. Gastric metaplasia caused by chronic gastroesophageal reflux (Barrett esophagus) is an important cause of human esophageal carcinoma, but it has only been reported in three cats,[2] none of which developed cancer. However, it is interesting to note that squamous cell carcinoma is the most common feline esophageal tumor.[3] Lymphoma, various carcinomas

(especially thyroid carcinomas[4]), and melanomas may secondarily invade the esophagus, which is probably as common as primary esophageal neoplasia.[5]

Pathophysiology

Esophageal tumors typically cause clinical signs as a result of mechanical obstruction. Poor esophageal motility might also occur in the region of the tumor, compounding the problem. Leiomyomas classically occur at or near the lower esophageal sphincter,[6] whereas most other esophageal malignancies more commonly occur in the caudal thoracic esophagus. Feline esophageal squamous cell carcinomas tend to occur in the middle third of the esophagus.[3,7] Esophageal tumors typically are locally invasive and occasionally metastasize to local lymph nodes.

Clinical Examination

Esophageal tumors tend to occur in older patients; breed-associations are largely unrecognized except for leiomyomas having a higher incidence in older Beagles.[6] *Spirocerca*-associated sarcomas are not as clearly age-associated since infection with the parasite is the initiating cause. Regurgitation is the "classic" clinical sign; however, this may occur late, not being seen until there is near complete esophageal obstruction (Figure 55-13). Odynophagia, excessive salivation, fever, anorexia, and lethargy[1,8] have been reported. Aspiration secondary to regurgitation may cause coughing, dyspnea, and/or fever. Hypertrophic osteodystrophy occasionally occurs (especially with *Spirocerca*-induced sarcomas), resulting in noticeably thickened extremities. In the later stages, patients may be lethargic, depressed, and/or emaciated.

Physical examination tends to be unrevealing unless there is evidence of aspiration pneumonia (e.g., pulmonary crackles, fever, dyspnea), a mass in the cervical esophagus, a dilated cervical esophagus (e.g., seen in the cervical region as an intermittent "puffing" out that coincides with respiration), or weight loss because of lack of nutrition (as a consequence of regurgitation) or cancer cachexia.

Sometimes a microcytic, hypochromic anemia and/or a neutrophilic leukocytosis may be found in dogs with *Spirocerca*-induced sarcomas, but these findings are nonspecific.[8]

Diagnosis

Diagnosis usually begins with thoracic radiographic findings. Esophageal masses produce soft-tissue densities that cannot always be distinguished from pulmonary or mediastinal masses unless they are partially surrounded by air, demonstrating that they are in the esophageal lumen. Sometimes these masses are noted fortuitously when thoracic radiographs are taken for other reasons (e.g., to evaluate the heart) (Figure 55-14). It may be necessary to perform a barium-contrast esophagram to distinguish pulmonary masses and esophageal masses. Dogs with *Spirocerca*-induced neoplasia often

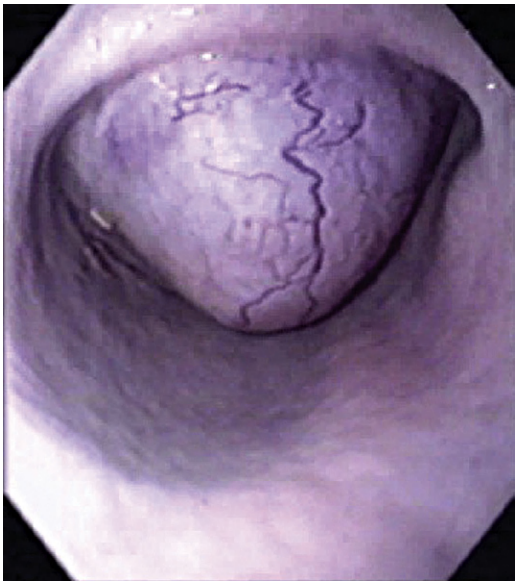

Figure 55-13 An endoscopic view of a large myxosarcoma occluding the distal lumen of the esophagus of a dog. Despite the large size of the mass, clinical signs were only reported 2 to 3 weeks before this image was taken.

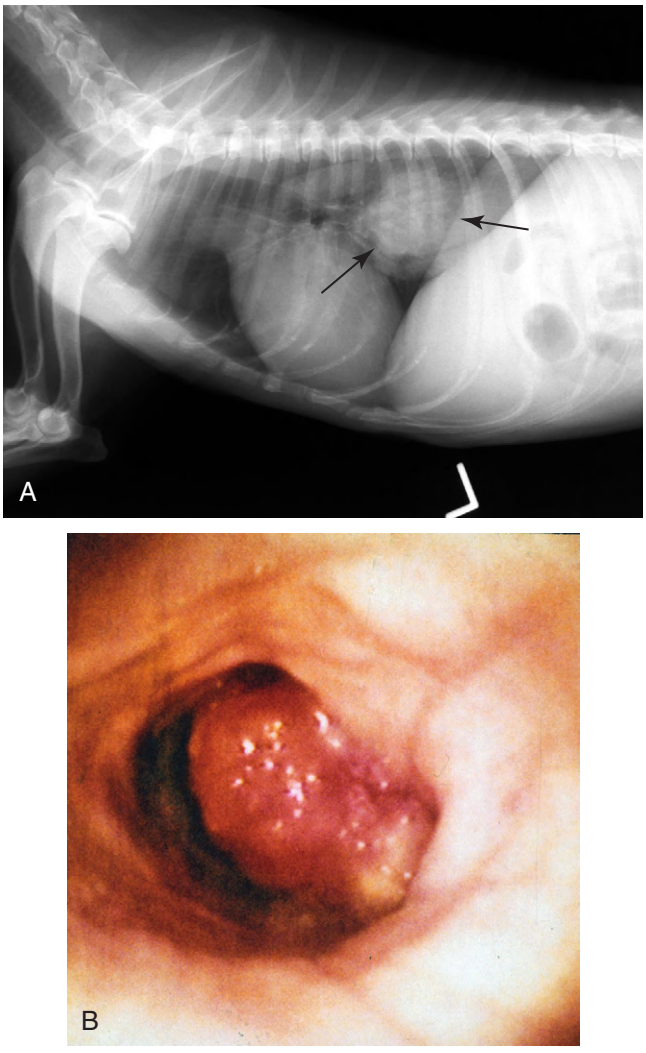

Figure 55-14 **A,** A radiograph of the chest of a Poodle with a heart murmur. There were no other clinical signs besides halitosis caused by dental disease. There is a mass in the caudal thorax (*arrows*), but it cannot be determined from this radiograph whether the mass is pulmonary, mediastinal, or esophageal. **B,** An endoscopic view of the esophagus of the dog in (**A**). There is a large carcinoma (*the red mass*) seen protruding into the esophageal lumen. (From Small Animal Surgery, ed 3, St. Louis, 2007, Mosby.)

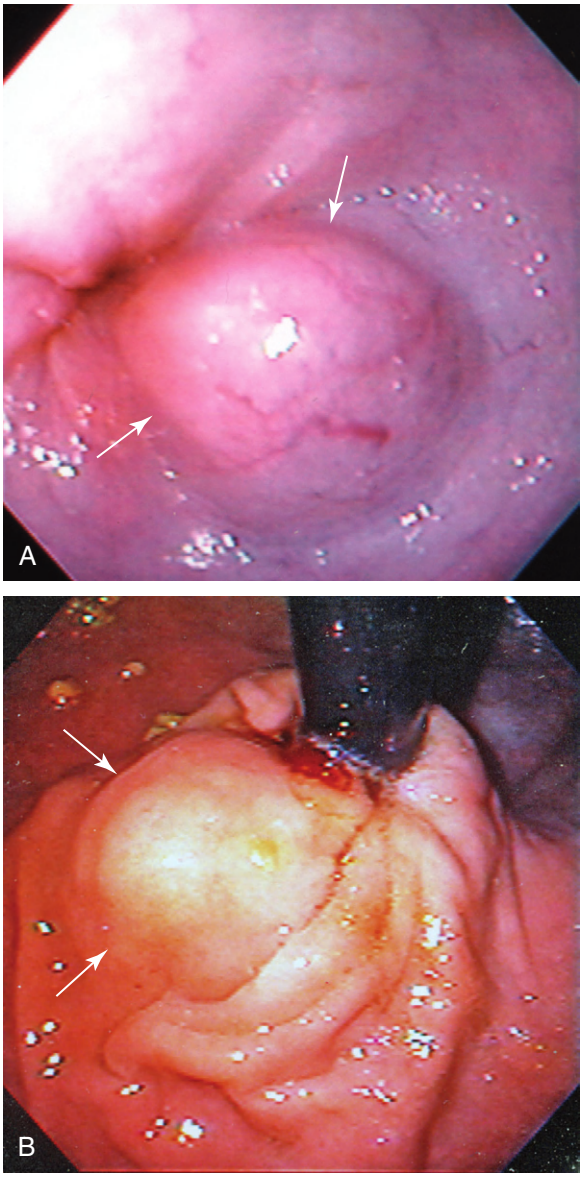

Figure 55-15 **A,** An endoscopic view of the lower esophageal sphincter of a dog, taken from inside the esophagus. There is a mass (*arrows*) seen near the sphincter. This is a submucosal leiomyosarcoma. **B,** An endoscopic view of the lower esophageal sphincter of a dog, taken from inside the stomach. The tip of the endoscope has been maximally retroflexed. A mass (*arrows*) is seen in the sphincter; this is a leiomyoma. The black tube is the insertion tube of the endoscope, entering the stomach.

have thoracic spondylosis.[5] Periosteal new bone proliferation of the limbs may be found in dogs with hypertrophic osteodystrophy secondary to esophageal neoplasms, but this is very nonspecific for esophageal disease.

Endoscopically, esophageal tumors can be seen as masses (Figure 55-15) or strictures (Figure 55-16).[5] Carcinomas and *Spirocerca*-induced sarcomas can typically be adequately sampled with flexible endoscopes; it helps to have an endoscope with a 2.8-mm biopsy channel as these biopsy forceps allow much larger tissues samples to be taken. Neoplastic and nonneoplastic lesions at the lower esophageal sphincter can resemble each other, making adequate biopsy of the lesion crucial (Figure 55-17). Leiomyomas usually

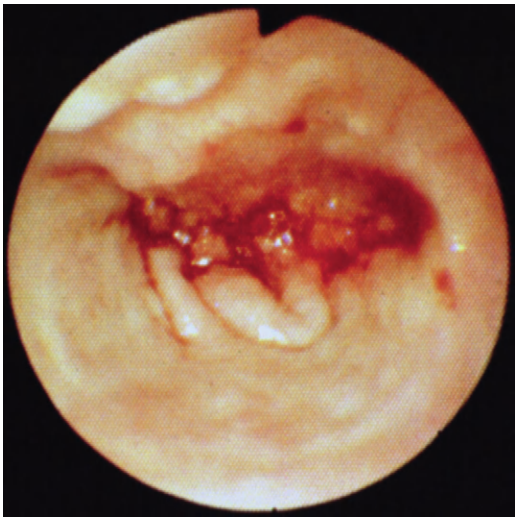

Figure 55-16 An endoscopic view of the esophagus of a cat. There is an irregular mass causing a stricture. This is a primary esophageal carcinoma.

occur close to the lower esophageal sphincter (see Figure 55-14, *A*)[6,9] and typically have a smooth appearance, covered by normal mucosa. If they are on the gastric side, one must maximally retroflex the endoscope tip after entering the stomach (see Figure 55-14, *B*). Their location and appearance are suggestive of the diagnosis. Leiomyomas typically cannot be successfully biopsied with flexible endoscopes because they are submucosal and covered with relatively normal esophageal mucosa (which is tough and cannot be readily penetrated by flexible biopsy forceps). Definitive diagnosis often requires surgical biopsy.

Malignancies that secondarily invade the esophagus (e.g., lymphoma, thyroid carcinoma) can be diagnosed by sampling the primary mass. Benign esophageal polyps are very rare in dogs and cats[5]; if a polypoid or adenomatous growth is diagnosed, an underlying carcinoma might be responsible for the overlying benign proliferation (Figure 55-18). Very rarely other causes of esophageal masses occur (e.g., pythiosis, ectopic esophageal tissue).

Spirocercosis before malignant transformation is typically seen as a large mass with a nodule or "nipple" (Figure 55-19). Occasionally, one may diagnose spirocercosis by fecal examination or by endoscopically seeing the parasite protruding from the esophageal granuloma, but these are not sensitive ways to diagnose this problem.[1,8]

Treatment

Surgery can cure benign masses (e.g., leiomyomas)[9,10]; however, it is extremely rare to cure esophageal malignancies with surgery. Tumors tend to be so locally invasive that complete resection is impossible by the time the patient shows clinical signs. If a patient is fortuitously diagnosed when the tumor is very small, cure might be possible, but even then a guarded to poor prognosis is appropriate. Aggressive resections can result in dehiscence as a result of excessive tension on the incision line. A surgical technique in which the esophagus is opened on the side opposite the mass has been reported.[11] This technique has the advantage of allowing the surgeon to determine more accurately the extent of the base of the tumor, aiding in deciding where to make the incision. Radiation, photodynamic therapy,[12] and chemotherapy[11] may be palliative in some

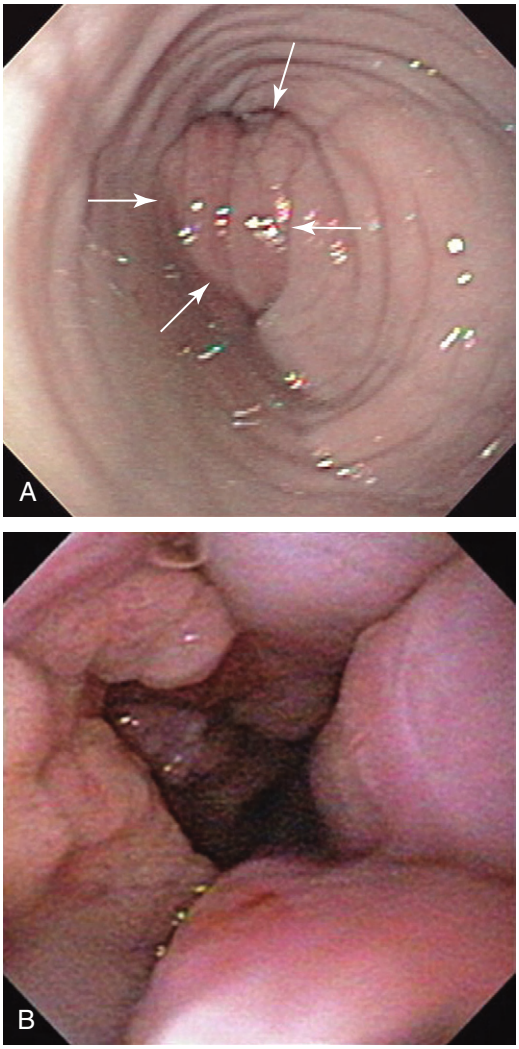

Figure 55-17 **A,** An endoscopic view of the lower esophageal sphincter of a dog. There is a mass of tissue protruding from the sphincter (*arrows*), which is nonneoplastic gastric mucosa that could be mistaken for a tumor. This must be biopsied because some carcinomas have a similar appearance. **B,** An endoscopic view of the lower esophageal sphincter of a Bulldog with a gastric carcinoma that has spread up through the lower esophageal sphincter and into the distal esophagus. The distal esophageal mucosa is irregular, especially from the 9 o'clock to the 12 o'clock position.

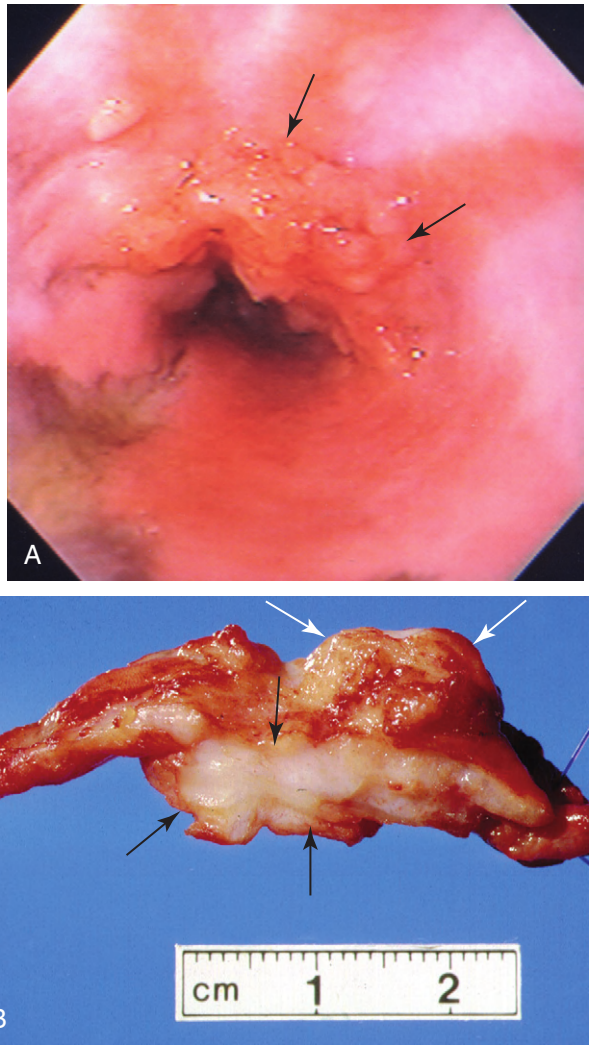

Figure 55-18 **A,** An endoscopic view of the esophagus of a dog showing an area in which the mucosa is roughened and irregular (*arrows*). Endoscopic biopsies revealed a benign, adenomatous growth. **B,** The same lesion seen in (**A**). Under the polypoid growth (*white arrows*) there is a thickening of the esophageal wall that is a carcinoma (*black arrows*).

cases; however, radiation-induced esophagitis and damage to surrounding structures is a significant concern. Spirocercosis can be treated successfully with doramectin (200 to 400 mg/kg given SC every 3 weeks for three treatments); however, resolving spirocercosis once malignant transformation has occurred will not resolve the malignancy.

Prognosis

The prognosis for patients with esophageal malignancies is poor with the exception of leiomyomas, which may be cured. One recent report gave survival times of 2 to 16 months in five dogs in which esophageal sarcomas, ostensibly caused by spirocercosis, were resected.[11]

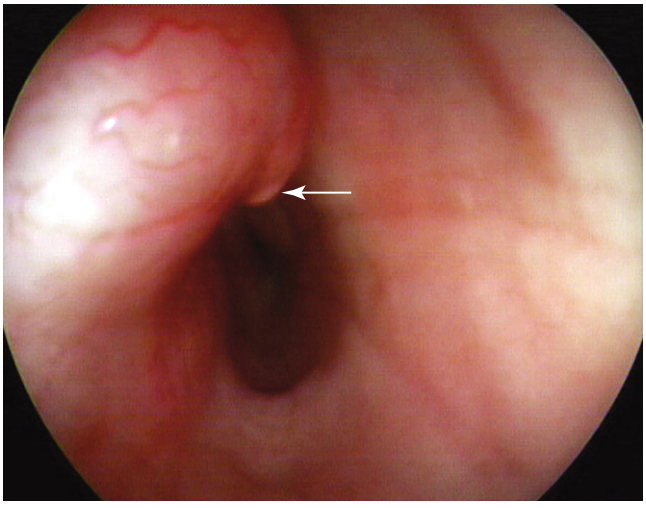

Figure 55-19 An endoscopic view of a canine esophagus with a mass caused by *Spirocerca lupi*. A small "nipple" is seen (*arrow*).

CHAPTER 56

Stomach

STRUCTURE AND FUNCTION

Kenneth W. Simpson

Functional Anatomy

The stomach acts as a reservoir to control the size and rate of passage of ingesta into the small intestine, to initiate the digestion of protein and fat, and to facilitate the absorption of vitamins and minerals (see Chapter 1)

The stomach is composed of five anatomic regions: cardia, fundus, corpus, antrum, and pylorus (Figure 56-1). The fundus and body expand greatly to accommodate ingesta and to regulate the emptying of liquids. The antrum grinds food into smaller particles (<2 mm) that are sieved into the duodenum. The gastroesophageal sphincter prevents reflux of gastric fluid into the esophagus, and the pyloric sphincter controls emptying into the small intestine.

The gastric wall contains a mucosa, submucosa, muscularis externa, and serosa (see Figures 56-2 and 1-3, *B*). The mucosa has a superficial epithelium, gastric glands, and an innermost layer of smooth muscle (the muscularis mucosa), with fine structure and function varying depending on the gastric region. The mucosa in the cardia and pylorus is thinner and less glandular than in the fundus and body. The mucosa of the body contains mucous neck cells (producing mucous, pepsinogen A, and gastric lipase), parietal cells (producing H^+, pepsinogen A, and intrinsic factor), and chief cells (producing pepsinogen A) (Figure 56-2).[1-4] A variety of neuroendocrine cells are involved in the regulation of acid secretion and are interspersed between the glands. The predominant cells are enterochromaffin-like and somatostatin-producing cells in the fundus, and gastrin and somatostatin-producing cells in the antrum (see Figure 56-2). Localized small aggregates of lymphoid tissues are frequently observed at the base of the gastric glands. A rich network of blood vessels, lymphatics, and nerves weaves between the gastric glands. Beneath the submucosa are two layers of smooth muscle (circular and longitudinal) that run perpendicular to one another. The serosa is the outermost layer.

Regulation of Acid Secretion

Physiologically, luminal peptides and gastric distention are the primary stimuli for H^+ secretion from parietal cells. Pharmacologically, parietal cell acid secretion is regulated by endocrine (gastrin), neurocrine (acetylcholine), and paracrine (histamine) mechanisms.[4,5] Somatostatin released in response to gastric pH levels below 3 provides negative feedback and decreases gastrin, histamine, and acid secretion.

Luminal peptides and gastric distention stimulate gastrin secretion from G cells and effect histamine release from enterochromaffin-like cells. Gastrin-releasing peptide and acetylcholine are the primary enteric neurotransmitters regulating gastrin release from antral G cells (Figure 56-3).

Unstimulated acid secretion in dogs and cats is minimal[6-8] (e.g., dogs <0.04 mmol/kg$^{0.75}$/h) and the unstimulated H^+/K^+-adenosine triphosphatase (ATPase), "the proton pump," is localized within tubulovesicles in the cytoplasm of parietal cells.[4,9] The stimulated H^+/K^+-ATPase and KCl transporters are incorporated into the parietal cell canalicular membrane and hydrogen ions (derived from the ionization of water within the parietal cells) are transported into the gastric lumen in exchange for K^+ by H^+/K^+-ATPase. Potassium and chloride transporters in the canalicular membrane enable luminal transfer of potassium (for recycling via H^+/K^+-ATPase) and chloride. Hydroxide combines with CO_2, catalyzed by carbonic anhydrase, to form HCO_3^-, which diffuses into the blood giving rise to the "alkaline tide" phenomenon. Recent studies have expanded our knowledge of ion transport in the parietal cell by identifying KCNQ1 as the primary channel responsible for K^+ recycling and establishing the contribution of CFTR (cystic fibrosis transmembrane regulator) and SLC26A9 to the process of chloride secretion.[5] Figure 56-4 shows a schematic of ion transport in the parietal cell incorporating these findings. Stimulation results in a rapid increase in fluid and hydrogen ion secretion, with pH rapidly declining to around pH 1. The concentrations of K^+ (10 to 20 mmol/L) and Cl^- (approximately 120 to 160 mmol/L) in gastric juice are higher than in plasma.

The stomach is protected from gastric acid injury by a functional unit known as the gastric mucosal barrier.[10,11] The gastric mucosal barrier comprises tightly opposed epithelial cells coated with a layer of bicarbonate-rich mucus and an abundant mucosal blood supply that delivers bicarbonate, oxygen, and nutrients. Local production of prostaglandin (PGE_2) is important in modulating blood flow, bicarbonate secretion, and epithelial cell renewal. When damage occurs, epithelial cells rapidly migrate over superficial mucosal defects aided by the local production of growth factors such as epidermal growth factor.

Evaluating Gastric Secretory Function

Gastric secretory testing is primarily performed in patients with esophagitis, gastrointestinal (GI) ulceration, mucosal hypertrophy, and in patients suspected of having acid hypersecretion.

As a starting point, fasting gastric pH and serum gastrin can be measured to determine if acid hypersecretion is likely. Ideally, antisecretory therapy should be discontinued for 7 days prior to testing,[12] and renal and hepatic function should be monitored as these may

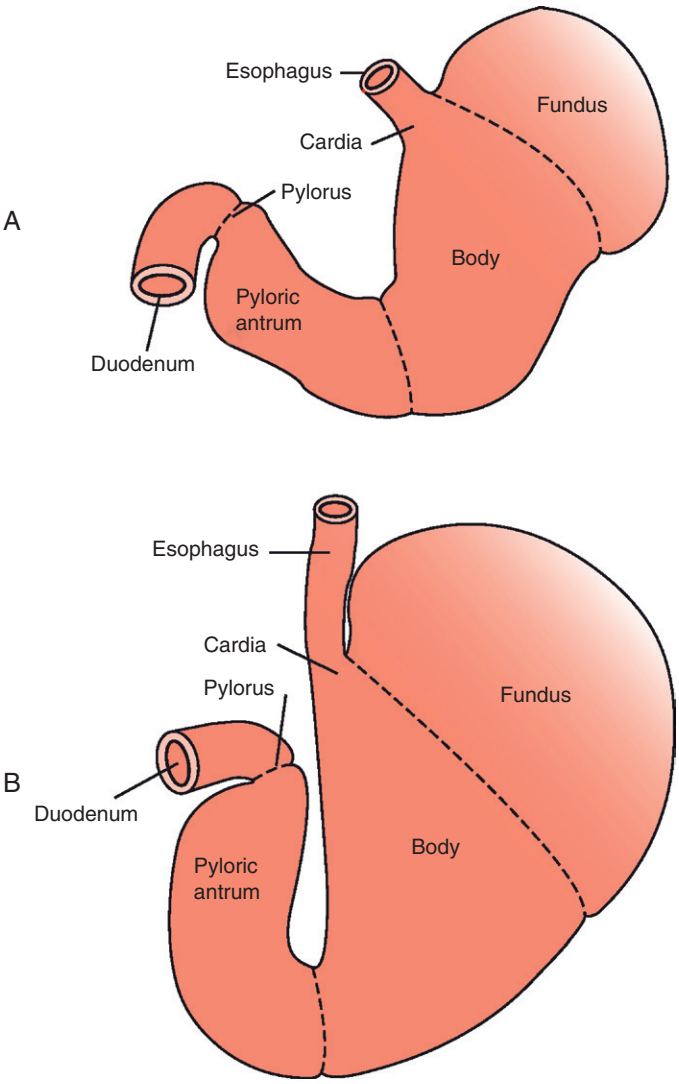

Figure 56-1 Gastric anatomy of the empty **(A)** and full **(B)** stomach. (From Guilford and Strombeck: *Strombeck's Small Animal Gastroenterology*, St. Louis, Saunders, 1996, p 239.)

be associated with decreased serum gastrin clearance and hypergastrinemia. The broad range of unstimulated (fasting) gastric pH in dogs and cats (from pH 1 to 8) makes definitive statements regarding basal acid production difficult. However, the presence of a gastric pH of less than 3 in the face of a high serum gastrin rules out the possibility of achlorhydria, or mast cell tumor, and raises the possibility of gastrinoma.[13,14] Dogs with mast cell tumors and hyperhistaminemia-induced acid hypersecretion have low serum gastrin concentrations,[15] whereas dogs with achlorhydria likely have a high gastrin, but a gastric pH greater than 3.

Measurement of serum gastrin following the intravenous infusion of secretin or calcium is used to further investigate the possibility of exogenous gastrin production by pancreatic gastrinomas (Zollinger-Ellison syndrome).[12-14] Basenji dogs with gastroenteropathy and diarrhea are reported to have elevated gastrin release in response to secretin stimulation, without evidence of gastrinoma.[16] Provocative testing of gastric acid secretion with pentagastrin or bombesin stimulation may be performed to detect achlorhydria in patients with atrophic gastritis, or elevated serum gastrin and gastric pH levels higher than 3, and in those with putative idiopathic small intestinal bacterial overgrowth to determine if achlorhydria is a contributing factor. Pentagastrin-stimulated acid secretion in dogs reaches a peak of 28 mL/kg$^{0.75}$/h, 4.1 mmol HCl/kg$^{0.75}$/h, 0.34 mmol K^+/kg$^{0.75}$/h, and 0.09 Na^+ mmol/kg$^{0.75}$/h.[6] Sedation with oxymorphone and acepromazine may be a suitable alternative to anesthesia for secretion studies in dogs.[16] In cats, acid output (mean ± standard deviation) in response to pentagastrin (8 µg/kg/h) ranges from pH 0.9 to 1.1, with secretion rates (median values) of 1.2 mmol/15 min to 1.4 ± 0.5 mmol/15 min in conscious cats and 1.2 (0.6 to 2.7) mmol/kg$^{0.75}$/h in anesthetized cats.[7]

Gastric Motility

Normal gastric motility is the result of the organized interaction of smooth muscle with neural and hormonal stimuli.[17,18] The rate of gastric emptying is directly proportional to the difference in pressure between the stomach and the duodenum, and inversely proportional to the resistance to flow across the pylorus. Liquids are emptied more rapidly than solids and the rate of emptying of liquids increases with volume. The emptying rate for digestible solids depends on caloric density. In dogs, digestible solids smaller than 2 mm are emptied into the duodenum, and gastric emptying is modulated via intestinal osmo-, chemo-, and tryptophan receptors. Lipids particularly retard gastric emptying. The release of cholecystokinin in response to fatty and amino acids such as tryptophan, is one factor that slows gastric emptying. Large, undigestible solids are expelled from the stomach in the fasted state by phase III of the migrating motility complex (MMC) in response to the release of motilin.

There is wide variation in the rate of gastric emptying reported in healthy dogs and cats that is largely a function of the method used to evaluate it (Table 56-1; see also Table 26-2),[19] and in clinical practice delayed gastric emptying is usually suspected when food is retained in the stomach for more than 8 hours. The advent of noninvasive, nonradioactive methods of measuring gastric emptying, such as telemetry capsules,[18,20,21] holds the promise of improving our basic understanding of gastric motility in health and disease.

Digestion and Assimilation of Nutrients

The stomach has a limited role in the digestion of proteins, fats, and micronutrients. Pepsin, which hydrolyzes peptide bonds, is secreted as pepsinogen in response to acetylcholine and histamine in parallel with gastric acid secretion. Dog gastric lipase, which digests fat, is secreted in response to gastrin, histamine, prostaglandin E_2, and secretin, and lipase secretion parallels the secretion of gastric mucus. Although pepsin is active only at acidic pH, dog gastric lipase remains active in the small intestine and constitutes up to 30% of total lipase secreted over a 3-hour period.[22] Although gastric lipase and pepsin are not essential for the assimilation of dietary fat and protein, the entry of peptides and fatty acids into the small intestine likely helps to coordinate gastric emptying and pancreatic secretion.

Intrinsic factor, which is necessary for cobalamin (vitamin B_{12}) absorption, is produced by parietal cells and cells at the base of antral glands in the dog but not the cat.[1,23] The importance of gastric intrinsic factor secretion in dogs is questionable as the pancreas is the major site of secretion in both dogs and cats. Gastric acidity may also have an effect on the availability of minerals such as iron and calcium.

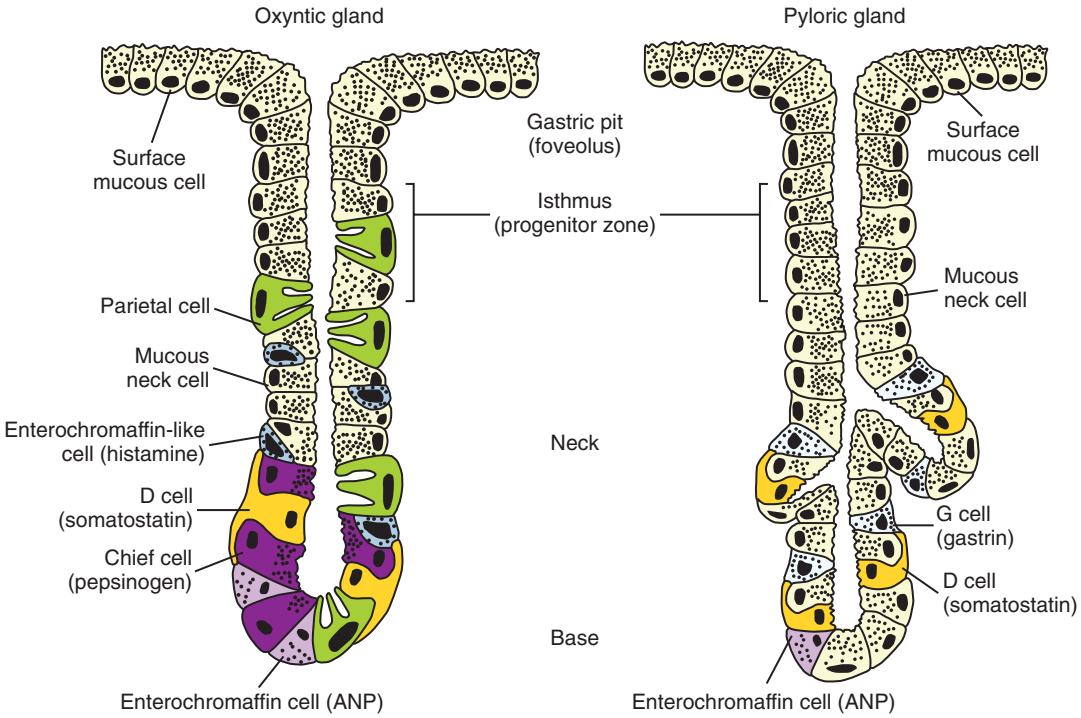

Figure 56-2 Functional mucosal anatomy. Somatostatin-containing D cells contain cytoplasmic processes that terminate in the vicinity of acid-secreting parietal and histamine-secreting enterochromaffin-like cells in the oxyntic gland area (fundus and corpus), and gastrin-secreting G cells in the pyloric gland area (antrum). The functional correlate of this anatomic coupling is a tonic paracrine restraint exerted by somatostatin on acid secretion that is exerted directly on the parietal cell as well as indirectly by inhibiting histamine and gastrin secretion. (From Schubert ML, Peura DA: Control of gastric acid secretion in health and disease. *Gastroenterology* 134:1842–1860, 2008.)

Gastric Flora and Immune Surveillance

The concept of the stomach as a sterile place was completely dispelled by the isolation of the gastric bacterium *Helicobacter pylori* from people in 1983.[24] A mixed flora of aerobes and anaerobes (approximately 10^6 to 10^7 cfu/mL) is rapidly established soon after birth in dogs,[25] and colonization with *Helicobacter* spp., which are likely acquired from the dam, has been documented as early as 6 weeks of age. The stomach of healthy dogs and cats harbors a diverse spectrum of large, spiral, acid-tolerant *Helicobacter* species[26] that stimulate local and systemic immune responses characterized by lymphoid follicular hyperplasia and seroconversion,[27-29] and may play a role in the development of gastritis[30,31] and cancer. These host–bacterial interactions are discussed further in Chapter 2 and in "Inflammation" section of Chapter 56. *Helicobacter* spp. are adapted to life in an acid environment and produce urease, which catalyzes the formation of ammonia from urea to buffer gastric acidity. Other bacterial species, such as *Proteus*, *Streptococcus*, and *Lactobacillus*, cultured from the canine stomach, may transiently increase after a meal or coprophagia. Acid secretion and gastric emptying likely regulate much of this transient flora and bacteria may proliferate in the event of gastric acid hyposecretion because of glandular atrophy or pharmacologic inhibition. From a diagnostic standpoint it is important to recognize that bacteria such as *Escherichia coli* and *Proteus* spp. produce urease that can lead to a false-positive test result for *Helicobacter* spp.

DIAGNOSTIC EVALUATION

Anette Spohr

Inflammation, ulceration, neoplasia, dysmotility, and obstruction are the primary gastric pathologies. The clinical signs of gastric disease range from mild anorexia and vomiting to hypersalivation, retching, weight loss, hematemesis, melena, abdominal distention, and abdominal pain. The clinical approach to these patients should

Table 56-1 Measurements of Gastric Emptying

Method	Species	Test Meal	Number (N)	Gastric Half-Emptying Time ($t_{1/2}$)
Radioscintigraphy	Dog	Eggs, starch + glucose	27	66 min (median); 45 to 227 min (95% CI)
		Beef baby food + kibble	6	4.9 ± 1.96 h (mean ± SD)
		Liver	4	Approximately 2 h
		Canned dog food + egg	6 (18 tests)	172 ± 17 min (mean ± SE)
		Canned dog food + egg	7 (14 tests)	285 ± 34 min (mean ± SD); 294 ± 39 min (mean ± SD)
		Canned dog food	6	77 min (mean)
	Cat	Dry cat food	10	2.47 ± 0.71 h (mean ± SD)
		Liver + cream	6 (15 tests)	163 ± 11 min (mean±se)
		Canned cat food	20	2.69 ± 0.25 h (mean ± SD)
		Dry cat food	20	3.86 ± 0.24 h (mean ± SD)
		Eggs	10	330 min (median); 210 to 769 min (range)
Radiography	Dog	Dry dog food + radiopaque solids	10	3.5 h (median); 1 to 6 h (range)
		Canned dog food + egg + BIPS	6 (18 tests)	Small BIPS = 416 ± 81 min (mean ± SE)
		Canned dog food + BIPS	20	Small BIPS = 6.05 ± 2.99 h (mean ± SD) Large BIPS = 7.11 ± 3.60 h (mean ± SD)
		Kibble + BIPS	8	Small BIPS = 8.29 ± 1.62 h (70% of dogs ± SE) Large BIPS = 29.21 ± 18.31 h (70% of dogs ± SE)
		Kibble + liquid barium	9 (27 tests)	Total gastric emptying time = 7 to 15 h (range)
		Kibble + liquid barium	4	Total gastric emptying time = 7.6 ± 1.98 h (mean ± SE)
	Cat	Canned cat food + BIPS	10	Small BIPS = 6.43 ± 2.59 h (mean ± SD) Large BIPS = 7.49 ± 4.09 h (mean ± SD)
		Canned cat food + BIPS	6	Small BIPS = 7.7 h (median), 3.5 to 10.9 h (range) Large BIPS = 8.1 h (median), 5 to 19.6 h (range)
		Canned cat food + BIPS	10	Small BIPS = 5.36 h (median) Large BIPS = 6.31 h (median)
		Cat food + liquid barium	8	Gastric emptying time = 11.6 ± 0.9 h (mean ± SD)
Gastric emptying breath test	Cat	Canned cat food	6	Peak ^{13}C excretion = 56.7 ± 9.8 min (mean ± SD)
	Dog	Bread, egg + margarine	6 (18 tests)	3.43 ± 0.50 h (mean ± SD)

BIPS, Barium-impregnated polyethylene spheres; CI, confidence interval; SD, standard deviation; SE, standard error. Small BIPS = 1.5 mm BIPS; Large BIPS = 5.0 mm BIPS.
From Wyse CA, McLellan J, Dickie AM, et al: A review of methods for assessment of the rate of gastric emptying in the dog and cat: 1898-2002. *J Vet Intern Med* 17:609-621, 2003.

be systematic as large numbers of nongastric diseases can demonstrate similar clinical signs.

History and Physical Examination

The diagnosis of diseases of the stomach starts with a thorough history and physical examination. The history should include consideration of signalment (age, gender, breed), description and duration of clinical signs, frequency and severity of vomiting, vaccination status, diet, past medical history, anthelmintic usage, travel history, and previous or current medications.

Special attention should be made if the vomiting animal has been treated with nonsteroidal antiinflammatory drugs (NSAIDs), as serious GI ulceration is a well-known side effect of this treatment.[1,2] Concurrent weight loss could indicate a low calorie intake, small intestinal involvement (e.g., inflammatory bowel disease [IBD]), or neoplasia. Access to garbage, plants, and cleaners all may be important causes of vomiting. The age and breed is important as young animals are more likely to ingest foreign bodies and older animals more frequently experience gastric cancer. Gastric cancer is more frequently seen in the Belgian Shepherd, Rough Collie, Staffordshire Bull Terrier, Beagle, and Lundehund breeds. The large and giant breeds with deep chest conformation, such as the Great Dane, are at increased risk for gastric dilation volvulus syndrome.

Vomiting is one of the major clinical signs of gastric disorders (see Chapter 23). Descriptions of the vomitus should include the amount, color, consistency, odor, and presence of bile or blood. The relationship of vomiting to food and water consumption should also be noted. Vomiting should also be differentiated from gagging, coughing, dysphagia, and regurgitation, all of which may appear the same for the pet owner, before beginning a medical workup for gastric disease. Nonproductive retching and vomiting in deep-chested dogs may require immediate medical attention for gastric dilation or gastric dilation and volvulus (GDV) syndrome. Persistent vomiting of large volumes of fluid is highly suggestive of GI obstruction, whereas vomiting of digested food 12 hours after feeding suggests delayed gastric emptying because of gastric outflow obstruction or a gastric motility disorder. Associated clinical signs, such as anorexia (nausea caused by gastritis), diarrhea (intestinal involvement), and melena (gastric bleeding), may occur in animals with gastric disease. Box 56-1 lists the most common causes of vomiting, and Table 56-2 lists the diagnostic procedures that are used in the differentiation of the vomiting disorders.

Complete physical examination is needed with special attention to abdominal palpation for distention and tympany (e.g., gastric dilation), masses or organomegaly (e.g., neoplasia, intussusception, and foreign body), pain (e.g., perforation, peritonitis, pancreatitis,

Box 56-1 Common Causes of Vomiting

Disorders of the Stomach
- Gastritis
- *Helicobacter* infection?
- Parasites
- Ulceration
- Neoplasia
- Foreign bodies
- Dilation and volvulus
- Hiatal hernia
- Obstruction
- Motility disorders

Disorders of the Small Intestine
- Inflammatory bowel diseases
- Neoplasia
- Foreign bodies
- Intussusception
- Infectious enteritis (viral, bacteria, parasites)
- Intestinal dysbiosis

Disorders of the Large Intestine
- Colitis
- Obstipation
- Parasites

Abdominal Disorders
- Pancreatitis
- Peritonitis
- Neoplasia
- Hepatobiliary diseases
- Urinary tract rupture

Metabolic/Endocrine Disorders
- Uremia
- Diabetes mellitus
- Hyperthyroidism
- Hypoadrenocorticism
- Endotoxemia/septicemia
- Hepatic encephalopathy
- Gastrinomas
- Hyper-/hypoparathyroidism

Drugs, Poisons, and Chemical Agents
- Nonsteroidal antiinflammatory drugs

- Xylazine
- Penicillamine
- Tetracycline
- Lead
- Ethylene glycol
- Strychnine

Dietary
- Indiscretion
- Intolerance
- Allergies

Miscellaneous
- Heartworm (*Angiostrongylus vasorum*)
- Motion sickness

Table 56-2 Diagnostic Procedures of Value for the Differential Diagnosis of Vomiting

Procedure	Advantage	Disadvantage
Survey abdominal radiographs	Foreign bodies, masses, ileus, intussusception, estimating size and position of abdominal organs and masses	Can overlook partial obstructions Ascites
Barium contrast radiographs	Motility disorders	Possibility of missing lesions
Barium-impregnated polyethylene spheres	Estimating gastric emptying Partial obstructions, e.g., pylorus or intestine	Full-study contrast takes 24 hours
Fluoroscopy	Motility disorders	
Ultrasonography	Mural thickening/infiltration Masses Metastatic neoplasia Enhanced by ascites	Compromised by aerophagia Expensive equipment Experience is needed
Endoscopy	Minimally invasive Inspection of the lumen and mucosa Mucosal biopsies Foreign-body retrieval	Expensive equipment Experience is needed General anesthesia Likely to miss nonmucosal lesions and motility disorders
Laparoscopy	Direct observation Full-thickness biopsy	General anesthesia Intermediately invasive Risk of peritonitis
Exploratory laparotomy	Full-thickness biopsies Mural diseases in GI tract Evaluation of abdominal organs Correction of gastric dilation and volvulus Removal of foreign body	General anesthesia Invasive Risk of peritonitis

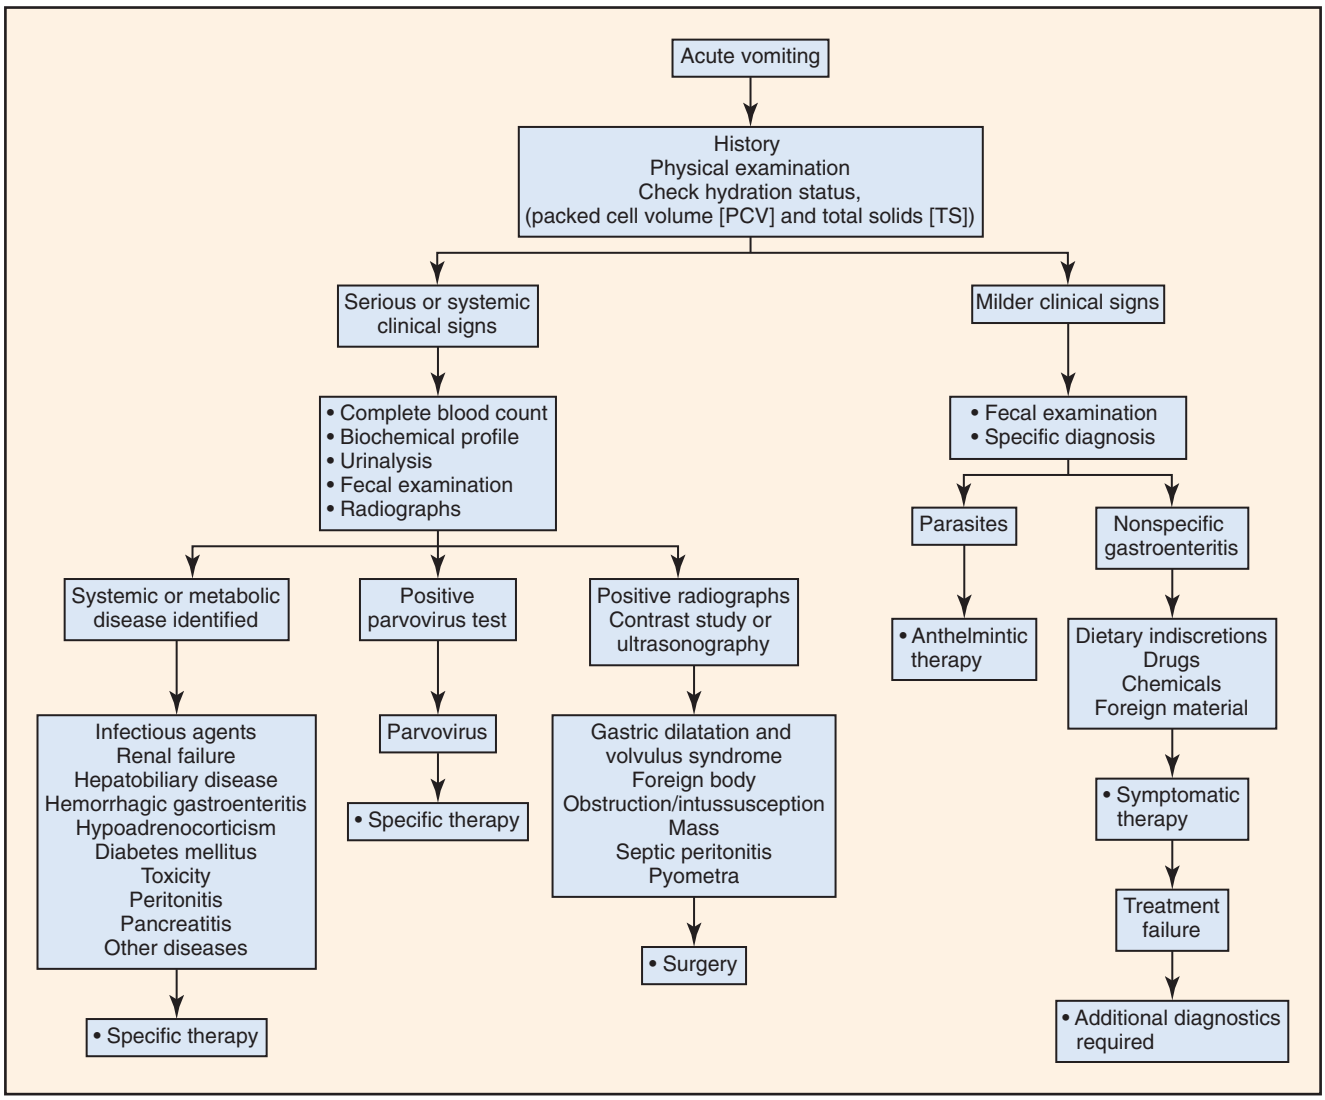

Figure 56-5 Diagnostic approach to the acute vomiting patient.

intestinal obstruction), and effusion (e.g., peritonitis). The occurrence of fever suggests infection or inflammation.

Based on the history and duration of clinical signs, the animal is classified as having either acute or chronic vomiting. The diagnostic approach depends on the duration of the clinical signs and whether the animal has other systemic signs (Figures 56-5 and 56-6). Chronic vomiting is often defined as vomiting that has persisted for 7 to 10 days or when there is no response to initial treatment.

Laboratory Data

Clinicopathologic testing is often warranted when differentiating primary gastric disorders from nongastric disorders. Complete blood cell count, serum chemistry, urinalysis, and fecal flotation should be considered when the patient is persistently vomiting or if there are signs of systemic diseases. Blood and urine samples should be obtained before treatment, which gives the clinician the chance to evaluate the metabolic consequences of the GI disease. Biochemical abnormalities in primary gastric diseases are usually consistent with mild to moderate loss of chloride, potassium, sodium, and bicarbonate. Prerenal azotemia is a result of dehydration. Elevated blood urea nitrogen without concurrently elevated serum creatinine may indicate gastric bleeding. Electrolytes and acid–base status are important parameters if symptomatic therapy is to be optimized in the vomiting animal.[3,4]

Laboratory data should be reviewed for evidence of systemic diseases; for example, kidney and liver insufficiency, toxemias (pyometra, peritonitis), anemia (chronic disease or GI bleeding), Addison disease, and diabetes mellitus. If the database suggests any of these disease entities, additional supportive evidence should be sought; for example, pre- and postadrenocorticotropic hormone (ACTH) cortisol, pre- and postprandial serum bile acids, pancreatic-specific lipase, and trypsin-like immunoreactivity. In cats with chronic vomiting, feline leukemia virus (FeLV) and feline immunodeficiency virus testing is warranted. In older cats, serum T_4 (thyroxine) should be measured as standard for the test for hyperthyroidism in which vomiting is a common clinical sign.

In patients with extensive GI bleeding (melena or hematemesis), an assessment of coagulation is essential. Severe GI bleeding as a consequence of coagulopathy caused by infection with *Angiostrongylus vasorum* has been reported in dogs. When gastric acid hypersecretion is suspected, as with gastrinoma, gastric secretory testing

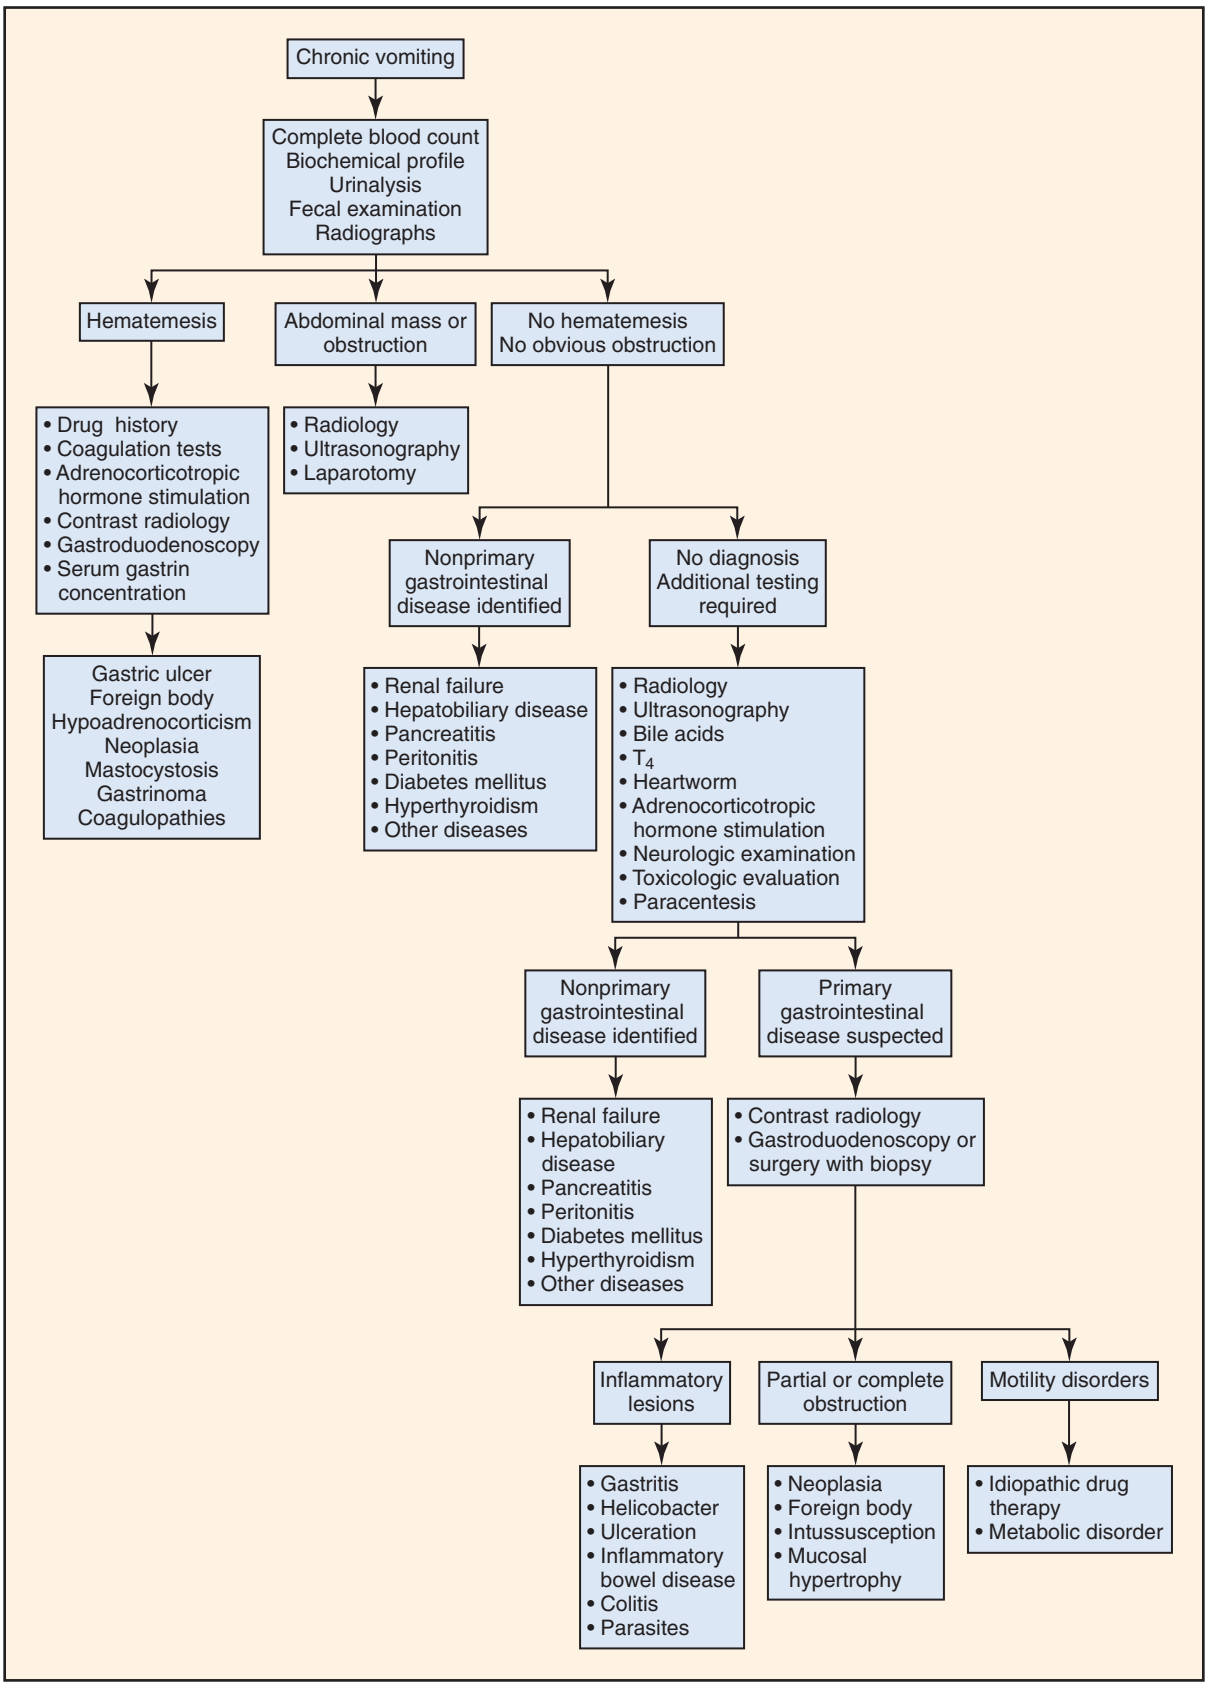

Figure 56-6 Diagnostic approach to the chronic vomiting patient.

(e.g., gastrin and fasting gastric pH measurement) should be performed.[5] The reader is referred to Chapter 25 for further detail.

Fecal examination is important in the detection of helminths, *Giardia* spp., *Salmonella* spp., *Campylobacter* spp., and parvovirus (as detected by enzyme-linked immunosorbent assay [ELISA]) as a cause of vomiting and diarrhea.

The pH of the vomitus can be used to differentiate vomiting from regurgitation. Additional laboratory evaluation for volume and content such as food, bile, foreign ingested material, digested or fresh blood, and parasites (ascarids, *Physaloptera* spp., cestodes, and *Capillaria* spp.) may be needed. Small clusters of fresh blood may be secondary to capillary microtrauma during the forceful vomiting process, but large amounts of digested blood usually indicate significant upper GI bleeding. Microscopic evaluations of the vomitus may sometimes reveal inflammatory or neoplastic cells, eggs of *Physaloptera* spp., and larvae or adult stages of *Ollulanus tricuspis*.

Gastric Imaging Techniques

Survey abdominal radiographs are often the initial diagnostic test when evaluating vomiting, abdominal pain, or abdominal distention. Radiographs provide information about gastric position, size, and content, which may help to diagnose GI obstruction, foreign bodies, gastric masses, ileus, intussusception, and gastric dilation or GDV. Survey radiographs are recommended in all animals in which GI foreign body such as carpet, socks, toys, bones, stones, or trash is suspected.

Contrast radiographs with barium sulfate liquid are also useful when inspecting size, shape, position, and motility of the stomach, as well as when nonradiographic foreign bodies, for example, socks, are missed on survey radiographs. Over time, the combination of ultrasonography and endoscopy have minimized the use of barium-contrast studies when evaluating mucosal conditions such as inflammation, neoplasia, and foreign bodies in the stomach.

When delayed gastric emptying is suspected, evaluation of gastric emptying is carried out using barium contrast (liquid or mixed with food), barium-impregnated polyethylene spheres, fluoroscopy, nuclear scintigraphy, or ^{13}C-octanoate breath test (see Chapter 26 and Table 56-1).[6-8]

The effects of sedation or other medications on gastric emptying times should always be taken into account when interpreting abdominal radiographs.

Ultrasonography is widely used when evaluating GI clinical signs. The gastric fundus is evaluated in left lateral recumbency, and the pylorus is evaluated in right lateral recumbency. Longitudinal and transversal views of stomach are required to measure the size of the organ and thickness of the gastric wall. Ultrasound may be used to assess wall thickness, wall layer identification, wall symmetry, extent of lesions, GI content, and motility. Diseases such as gastric cancer, chronic gastropathy, uremic gastritis, and delayed gastric emptying disorders have been diagnosed by ultrasonography in cats and dogs.[9-11] The test is noninvasive and requires little in the way of patient preparation. Ascites may enhance the image of abdominal organs in those patients with ascites. Aerophagia, on the other hand, may compromise identification of gastric or other organ pathology.

Endoscopy

Endoscopic evaluation and biopsy of the stomach is a commonly used procedure to evaluate the gastric mucosa in cats and dogs.[12] Endoscopy permits direct observation of the lumen and provides a noninvasive method of obtaining biopsy specimens for histopathologic evaluation. Brush cytology, fluid aspirations with culture, and foreign-body retrieval are all possible during routine endoscopy.

Endoscopy provides direct observation of the lumen and mucosa, but may miss extramural diseases. Endoscopy has the additional disadvantages of equipment expense, the need for general anaesthesia, and the inability to obtain full-thickness biopsies. Furthermore, the procedure does not permit the diagnosis of motility disorder or partial obstructions of the intestine. Endoscopy procedures are described in further details in Chapter 27.

Histopathologic Evaluation for Inflammation

Gastritis is a common finding in chronic vomiting dogs and cats. A diagnosis of gastritis requires histopathologic examination of gastric biopsy specimens. The histopathologic evaluation of the biopsy specimens includes cell types and number of infiltrating cells (lymphocytes, plasma cells, mononuclear cells, eosinophils, and neutrophils) and the presence of atrophy or hypertrophy, metaplasia, fibrosis, edema, or lymphoid follicles. Disagreements do exist among classification systems used by different pathologists when evaluating gastric biopsy specimens, making it important for the clinician, together with the pathologist, to define the criteria upon which the diagnosis is made. Figure 56-7 illustrates a visual scale grading system from 0 to 3 based on a photographic scale of cellular infiltrate, atrophy, and fibroses. Grade 0 is normal gastric mucosa and grade 3 is severe gastritis.[13] A standardized system of characterizing gastric cellularity and morphology has been developed by the World Small Animal Veterinary Association Gastrointestinal Standardization Group.[14]

There is an increasing interest in characterizing mucosal proinflammatory and immunomodulatory cytokines in cats and dogs with gastritis. Perhaps this will help the clinician's understanding of the immunologic response in the stomach and help the clinician's understanding of the mechanisms of gastritis.[13] Gastric biopsies can also reveal infections with parasites (*O. tricuspis*) or bacteria (*Helicobacter* spp.).[13,15,16] The reader is referred to other sections (Gastric Inflammation, Gastric Infection) in this chapter for more specific detail.

Evaluation for Gastric *Helicobacter* spp. Infection

Gastritis is often of unknown etiology in dogs and cats. *H. pylori* is accepted as an important pathogen in human gastroenterology and is believed to be the primary cause of chronic gastritis, gastric and duodenal ulceration, and even gastric carcinoma. For several years, interest in *Helicobacter* spp. infections as a cause of chronic gastritis in cats and dogs has been increasing. Several studies show that gastric infection with *Helicobacter* spp. is common in dogs, with a prevalence ranging from 67% to 100% in clinically healthy pet dogs, and 41% to 86% prevalence and in clinically healthy cats. Cats and dogs are infected with *Helicobacter felis*, *Helicobacter bizzozeronii*, *Helicobacter heilmannii*, *Helicobacter salomonis*, *Helicobacter bilis*, and *Flexispira rappini*.[17-22] The dilemma is that the pathogenicity of *Helicobacter* spp. is well described in several other species, such as ferrets, mice, and cheetahs, but is still evolving in cats and dogs. Investigations of the pathogenicity of *Helicobacter* spp. in dogs and cats with naturally acquired infections have so far been inclusive and indicate an overlap in the type and severity of gastric inflammation in infected and uninfected dogs and cats.

Several methods are available to diagnose *Helicobacter* infection in cats and dogs. Mucosal biopsies and histopathologic

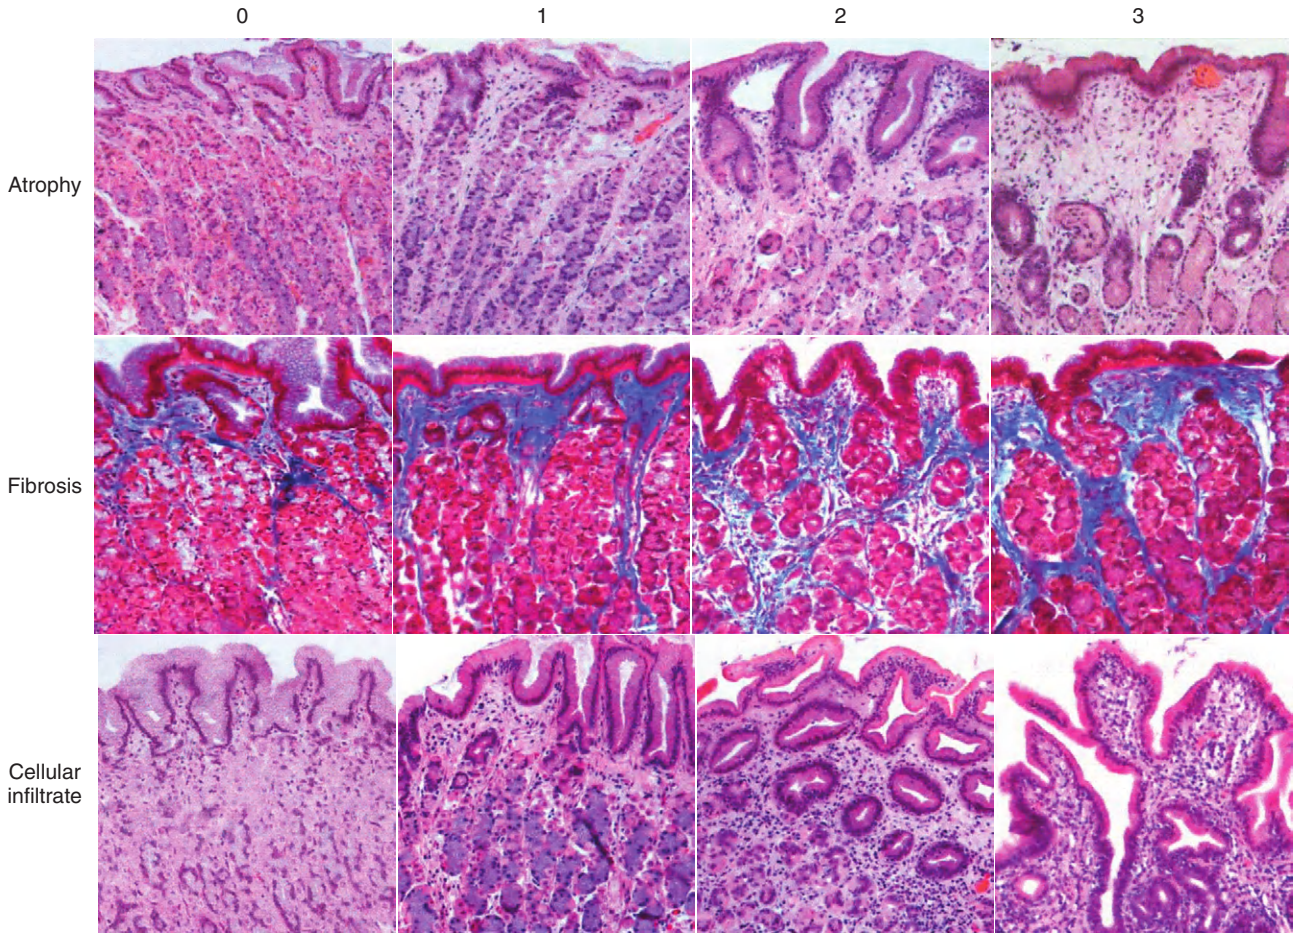

Figure 56-7 Photographic scale used to standardize the evaluation of atrophy, fibrosis, cellular infiltrate in fundic biopsies. A grade normal [0], mild gastritis [1], moderate gastritis [2], severe gastritis [3]. Magnification ×100; staining method: Masson trichrome (fibrosis) and hematoxylin and eosin (atrophy and cellular infiltrate). (From Wiinberg B, Spohr A, Dietz HH, et al: Quantitative analysis of inflammatory and immune response in dogs with gastritis and their relationship to *Helicobacter* spp. infection. *J Vet Intern Med* 19:4–14, 2005.)

evaluation have been used for many years. *Helicobacter* spp. can be recognized in a standard hematoxylin and eosin stain in the mucus and/or intracellularly in the epithelium. If *Helicobacter* spp. are present in very small numbers a Warthin-Starry silver stain may prove more useful.[13,15] *Helicobacter* spp. are a strong producer of urease and mucosal biopsies can be tested for urease activity with an "on site" rapid urease tests (e.g., CLO [*Campylobacter*-like organism] test). Urease breaks down urea and produces a high local concentration of ammonia, which makes it possible for *Helicobacter* spp. to survive the low pH of the gastric lumen. Rapid urease tests consist of a urea-rich medium with a pH sensitivity dye. Recent use of antibiotic, bismuth, or acid secretory inhibitors in the patient may interfere with the test and provide false-negative results. The ^{13}C breath test can be used to evaluate the effect of eradication.[23,24]

Polymerase chain reaction (PCR) techniques have proven very useful in the detection of *Helicobacter* spp. infections after DNA extraction of gastric biopsy specimens.[13] This method includes use of genus and species-specific primers to detect species verification. Brush cytology of the mucus are useful for detecting *Helicobacter* spp. in both cats and dogs.[25] The role of *Helicobacter* spp. in canine and feline gastritis is still unknown and much remains to be learned about the infection.

Exploratory Laparotomy

In some cases, exploratory laparotomy may be necessary to diagnose mural diseases of the GI tract that are beyond the reach of the endoscope, when perforation is suspected, or when multiorgan biopsy or full-thickness biopsy is required to obtain a definitive diagnose. At the time of exploratory laparotomy, full-thickness biopsy specimens of the stomach and intestine should always be considered, even with apparently normal macroscopic appearance. All abdominal organs must be examined and additional biopsies of the liver, lymph nodes, and masses should be obtained when indicated. If serum protein levels are low, this may influence tissue repair and increase the risk of biopsy-related complications. Fine-needle aspirates can be obtained from masses and lymph nodes when indicated. Cytology results may provide a preliminary result that will help the clinician initiate therapy before histopathology results are available. The complication rate following laparotomy is approximately 30% with 60% of the complications related to the primary disease and the rest related to surgical or anesthetic problems.[26]

INFLAMMATION

Kenneth W. Simpson

Gastric disease is typically the result of inflammation, ulceration, neoplasia, or obstruction. Clinical manifestations include vomiting, hematemesis, melena, retching, belching, hypersalivation, abdominal distention, abdominal pain, and weight loss. The clinical approach is guided by considering gastric disease as a group of clinical syndromes that segregate on the basis of etiology, pathology, and clinical presentation (Table 56-3).[1]

A large and varied group of gastric and nongastric disorders can cause similar clinical signs, so a systematic approach is essential to determine the cause. The diagnostic approach focuses initially on historical and physical findings, with clinicopathologic testing and diagnostic imaging used in patients with systemic involvement or chronic signs. This section focuses on etiopathogenesis, diagnosis, and treatment of acute and chronic gastritis.

Acute Gastritis

Etiology

Acute gastritis is the term applied to the syndrome of vomiting of sudden onset suspected to be associated with gastric mucosal insult or inflammation (Box 56-2). In most patients the cause is inferred from the history (e.g., dietary indiscretion), the diagnosis is rarely confirmed by biopsy, and treatment is more symptomatic and supportive than disease specific. Animals with acute gastritis associated with drug toxicity, foreign-body ingestion, or metabolic disorders frequently present with hematemesis, melena, concurrent diarrhea, or other signs of systemic illness and require a more thorough diagnostic approach to determine the cause and to provide optimal care. There is little evidence in the literature to suggest that viral infections such as parvovirus, distemper, or infectious canine hepatitis, have a role in acute gastritis.

Table 56-3 Diseases of the Stomach

Clinical Syndrome	Predominant Features
Acute gastritis	Sudden onset of vomiting
Ulceration or erosion	Vomiting, hematemesis, melena, ± anemia
Gastric dilation volvulus	Nonproductive retching, abdominal distention, tachycardia
Chronic gastritis	Chronic vomiting of food or bile
Delayed gastric emptying	Acute to chronic vomiting more than 8 to 10 hours after feeding
Neoplasia	Chronic vomiting, weight loss, ± anemia

Box 56-2 Causes of Acute Gastritis

- Dietary indiscretion or intolerance (nonallergic and allergic)
- Foreign bodies (e.g., bones, toys, hairballs)
- Drugs and toxins (e.g., antibiotics, digoxin, nonsteroidal antiinflammatory drugs, corticosteroids, heavy metals, plants, cleaners, bleach, dietary contaminants)
- Systemic disease (e.g., hypoadrenocorticism, uremia, liver disease)
- Parasites (e.g., *Ollulanus, Physaloptera* spp.)
- Bacteria (e.g., bacterial toxins, *Helicobacter*)
- Viruses

Clinical Examination

Vomiting of sudden onset is the principal clinical sign of acute gastritis. In some instances it is accompanied by hematemesis or melena and a variable degree of systemic involvement. The history may reveal access to garbage, toxins, medications, foreign bodies or ingestion of spoiled food. Signs of toxicity may be evident, such as jaundice and pallor with zinc ingestion, salivation or defecation with organophosphate toxicity or mushroom ingestion, and hypersalivation and oral ulceration with chemical ingestion.

Diagnosis

A diagnosis of acute gastritis is usually based on clinical findings and the response to symptomatic treatment. A specific diagnosis may be sought if the patient has access to foreign objects or toxins, is systemically ill, or has hematemesis, melena, and vomiting that fails to respond to symptomatic therapy, or other signs of more serious disease.

Laboratory testing in most animals with primary acute gastritis reflects mild dehydration and is often not performed in the absence of a suspicion of more serious disease. Abdominal radiographs can be taken to detect foreign objects or GI obstruction. Further diagnostics, such as ultrasonography and endoscopy, are rarely indicated, and most animals with simple gastritis respond to symptomatic therapy and "tincture of time."

Treatment

Therapy for uncomplicated acute gastritis is an empirical combination of symptomatic and supportive agents such as fluids, dietary restriction and modification, mucosal protectants or adsorbents, and possibly antacids.[2,3]

Fluid Therapy

Small amounts of oral fluids, little and often, can be given in the face of vomiting, with the volume increasing and frequency decreasing as vomiting subsides. Subcutaneous administration of an isotonic balanced electrolyte solution may be sufficient to correct mild fluid deficits (<5%), but is insufficient for patients with moderate to severe dehydration. Patients requiring intravenous fluids should undergo a more extensive diagnostic evaluation. Chapter 48 has more detailed information on fluid therapy.

Dietary Restriction and Modification

Where vomiting is acute, oral intake is typically discontinued for 24 hours. However, a liquid diet can be offered in the face of vomiting to maintain GI barrier function.[4] This can be transitioned to a homemade, nonspicy, fat-restricted, bland diet (e.g., boiled chicken and rice, low-fat cottage cheese and rice [1:3]) or a commercial fat-restricted, rice-based diet that is fed little and often. After a week or so, the normal diet can be reintroduced gradually.

Protectants and Adsorbents

Bismuth subsalicylate, kaolin-pectin, activated charcoal and magnesium, and aluminum- and barium-containing products are often administered in acute vomiting or diarrhea to bind bacteria and their toxins and to coat the GI mucosa. These agents are probably safer and more efficacious than antibiotics or motility modifiers in acute gastroenteritis. Pepto-Bismol (1 mL/5 kg PO TID), bismuth subcitrate, kaolin pectin (1 to 2 mL/kg PO TID), and sucralfate (0.25 to 1 g PO TID) are often employed although evidence-based

data in support of their usage is still incomplete. Acid-reducing drugs such as H_2-receptor antagonists can be administered, but are usually reserved for patients with signs of gastric erosion or ulceration (e.g., melena or hematemesis) or persistent gastritis as described below.

Antiemetic agents may be used in patients with acute gastritis but spontaneous resolution may take place without them. Chapters 23 and 35 provides more detailed information about the use of antiemetic agents.

Prognosis

The prognosis for complete recovery for uncomplicated acute gastritis is usually good to excellent.

Chronic Gastritis

Etiology

The diagnosis of chronic gastritis is currently based on the histologic examination of gastric biopsies and is subclassified according to histopathologic changes and etiology. Histopathologic evidence of gastritis is a common finding in dogs, with 35% of dogs investigated for chronic vomiting and 26% to 48% of asymptomatic dogs affected.[5,6] The prevalence in cats has not been determined.

Gastritis in dogs and cats is usually categorized according to the nature of the predominant cellular infiltrate (e.g., eosinophilic, lymphocytic, plasmacytic, granulomatous, lymphoid follicular), the presence of architectural abnormalities (e.g., atrophy, hypertrophy, fibrosis, edema, ulceration, metaplasia), and their subjective severity (e.g., mild, moderate, severe). A standardized visual grading scheme has been proposed by Happonen et al.[6] and has been adapted for pathologists.[7]

It should be noted that even with standardized grading schemes there is often poor agreement between pathologists.[7,8] Gastritis in dogs and cats is most commonly described as mild to moderate superficial lymphoplasmacytic gastritis, with or without concomitant lymphoid follicle hyperplasia. Eosinophilic, granulomatous, atrophic, and hyperplastic gastritis are less commonly reported.

Pathophysiology

Despite the high prevalence of gastritis in the companion animal population an underlying cause is rarely identified. In the absence of systemic disease, ulcerogenic or irritant drugs, gastric foreign objects, parasites (*Physaloptera* and *Ollulanus* spp.), and in rare instances fungal infections (*Pythium insidiosum*, *Histoplasma* spp.), chronic gastritis is usually attributed to dietary intolerance or allergy, occult parasitism, *Helicobacter* infection, or unknown pathogens. Treatment is often used to further define the cause of gastritis (e.g., diet responsive, antibiotic responsive, steroid responsive, or parasitic).

Although the basis of the immunologic response in canine and feline gastritis is unknown, recent studies have shed light on the immunologic environment in the GI tract and reveal a complex interplay between the microflora, epithelium, immune effector cells such as lymphocytes and macrophages, and soluble mediators such as chemokines and cytokines.[9-14] In health, this system avoids active inflammation by antigen exclusion and the induction of immune tolerance. The development of intestinal inflammation in mice lacking interleukin (IL)-10, transforming growth factor (TGF)-β, or IL-2 indicates the central importance of cytokines in damping-down mucosal inflammation. In many of these murine models, GI inflammation only develops in the presence of endogenous intestinal microflora, leading to the hypothesis that spontaneous mucosal inflammation may be the result of a loss of tolerance to this microflora. The role of these mechanisms in outbred species such as the dog and cat remains to be determined, but clearly loss of tolerance to bacterial or dietary antigens should be considered.

The epithelial cell is also emerging as a central coordinator in the inflammatory response. Epithelial cells are involved in sensing luminal constituents (e.g., bacteria) through pattern recognition receptors (also known as Toll-like receptors) and coordinating the inflammatory response. Gram-negative or pathogenic bacteria can induce proinflammatory cytokine secretion (e.g., IL-8, IL-1β) by epithelial cells, whereas "commensals" or bacteria such as *Streptococcus faecium* or *Lactobacillus* spp. induce the production of the immunomodulatory cytokines TGF-β or IL-10.[10] The proinflammatory cytokines produced by epithelial cells are modulated by the production of IL-10 from macrophages and potentially by the epithelial cells themselves.[15] In this context, dogs with lymphoplasmacytic gastritis of undetermined etiology show a correlation between the expression of the immunomodulatory cytokine IL-10 and proinflammatory cytokines (interferon [IFN]-γ, IL-1β, IL-8).[7] Mucosal pathology is related to cytokine messenger RNA (mRNA) expression (e.g., neutrophil infiltration in response to IL-8 and IFN-γ; macrophage and lymphocyte infiltration to IFN-γ; and fibrosis to IL-1β).

Histologic severity of lymphoplasmacytic gastritis in dogs correlates with atrophy, infiltration with lymphocytes and macrophages, and expression of IL-10 and IFN-γ.[7] Simultaneous expression of IL-10 and IFN-γ mRNA has also been observed in the intestines of Beagle dogs (lamina propria cells and the intestinal epithelium) in the face of a luminal bacterial flora that was more numerous than that of control dogs.[16] Thus it is tempting to visualize a "homeostatic loop" consisting of proinflammatory stimuli and responses, countered by immunomodulation and repair, with an imbalance in either of these arms manifest as gastritis.

Clinical Findings

The major clinical sign of chronic gastritis is vomiting of food or bile. Other clinical signs, like decreased appetite, weight loss, melena, and hematemesis, are variably encountered. The concurrent presence of dermatologic and GI signs raises the possibility of dietary intolerance.[17] Access to toxins, medications, foreign bodies, and dietary practices (including nutraceuticals) should be thoroughly reviewed. The signalment should not be overlooked as certain syndromes are breed restricted. Hypertrophy of the fundic mucosa is frequently associated with a severe enteropathy in basenjis[18] and stomatocytosis, hemolytic anemia, icterus, and polyneuropathy have not been noted in the Drentse Patrijshond.[19] Hypertrophy of the pyloric mucosa is observed in small brachycephalic dogs such as the Lhasa Apso and is associated with gastric outflow obstruction.[20,21] Atrophy of the gastric mucosa that may progress to adenocarcinoma has been reported in Lundehunds with protein-losing gastroenteropathy.[22,23]

Young, large-breed, male dogs in the Gulf States of the United States may have granulomatous gastritis caused by *Pythium* spp. with infection more prevalent in fall, winter, and spring.[24] Physical examination is often unremarkable. Abdominal distention may be related to delayed gastric emptying caused by obstruction or defective peristalsis. Abdominal masses, lymphadenopathy, or ocular changes may be encountered in dogs with gastric fungal or algae infections.

Diagnosis

A serum biochemical profile, complete blood count, urinalysis, and measurement of T_4 concentration (in cats >5 years old) should be performed as a basic screen for metabolic, endocrine, infectious, and other non-GI causes of vomiting, as well as the acid–base and

electrolyte changes associated with vomiting, outflow obstruction, or acid hypersecretion. Clinicopathologic tests are often normal in patients with chronic gastritis.

Eosinophilia may prompt the consideration of gastritis associated with dietary hypersensitivity, endoparasites, and mast cell tumors. Hyperglobulinemia and hypoalbuminemia may be present in basenjis with gastroenteropathy, or dogs with gastric pythiosis. Panhypoproteinemia is a feature of gastroenteropathy in the Lundehund breed, moderate to severe generalized IBD, GI lymphoma, and GI histoplasmosis. More specific testing, such as an ACTH stimulation test, or serology for *P. insidiosum*, is performed based on the results of these initial tests. Determination of serum food-specific immunoglobulin (Ig) E has not been proved useful in the diagnosis of dietary sensitivity in dogs or cats. The utility of non-invasive tests, such as serum pepsinogen and gastric permeability to sucrose, used to diagnose gastritis in people, has not been determined in dogs and cats.

Abdominal radiographs are frequently normal in dogs and cats with gastritis, but may show gastric distention or delayed gastric emptying (food retained for >12 hours after a meal). Contrast radiography may reveal ulcers or thickening of the gastric rugae or wall, but has largely been superseded by the combination of ultrasonography to detect mural abnormalities and endoscopy to observe and sample the gastric mucosa.

Endoscopic examination enables the visualization of foreign bodies, erosions, ulceration, hemorrhage, rugal thickening, lymphoid follicle hyperplasia (evident as mucosal pock marks), increased mucus or fluid (clear or bile stained), and increased or decreased mucosal friability. Discrete focal or multifocal mucosal nodules may be observed with *Ollulanus* spp. infection.

Gastric phycomycosis can be associated with irregular masses in the pyloric outflow tract and may prompt serologic testing by enzyme-linked immunosorbent assay (ELISA), western blotting, and culture of fresh gastric biopsies. Parasites such as *Physaloptera* spp. may be observed as 1- to 4-cm worms. Large amounts of bile-stained fluid are suggestive of duodenogastric reflux–associated gastritis, whereas abundant clear fluid may indicate hypersecretion of gastric acid. Gastric fluid can be aspirated for cytology (*Helicobacter* spp., parasite ova or larvae) and pH measurement. Impression smears of gastric biopsies are an effective way of looking for *Helicobacter* spp. and are more sensitive than the biopsy urease test (*Helicobacter* spp. produce urease). Serum gastrin should be measured in the face of unexplained gastric erosions, ulcers, fluid accumulation, or mucosal hypertrophy.[25-27]

The endoscopic procedure of dribbling dietary antigens onto the gastric mucosa to ascertain the presence of food allergy has not proved useful in dogs or cats. It is highly subjective, detects only immediate-type hypersensitivity reactions, and does not correlate very well with the results of dietary elimination trials. Biopsy samples should be taken from the gastric mucosa even when it looks grossly normal (usually three samples from each of the pylorus, fundus, and cardia). Thickened rugae may require multiple biopsies, and a full-thickness biopsy sample is often required to differentiate gastritis from neoplasia or fungal infection and to diagnose submucosal or muscular hypertrophy. The results of gastric ultrasonography can help to forewarn the clinician of these possibilities and to complement the endoscopic findings.[28]

Gastric sections should be stained with hematoxylin and eosin for the evaluation of cellularity and architecture, and a modified Steiner stain for gastric spiral bacteria. Fluorescence in-situ hybridization with oligonucleotide probes directed against bacterial 16S or 23S recombinant DNA can be used to document the presence of *Helicobacter* spp.[29] Special stains, such as Gomori methenamine silver, are indicated if pyogranulomatous inflammation is present to detect fungi. The Masson trichrome can be used to highlight gastric fibrosis, whereas Sirius red and toluidine blue help to reveal eosinophils and mast cells, respectively. Immunohistochemistry can be employed to help distinguish lymphoma from severe lymphocytic gastritis. Mucin staining has been performed in Lundehunds with gastric atrophy and reveals an abnormal presence of mucus neck cells and pseudopyloric metaplasia.[30]

The interpretation of gastric biopsy samples has important implications for patient care because biopsy findings are often used to guide treatment. For example, mild lymphoplasmacytic gastritis may be treated with a change in diet, whereas moderate lymphoplasmacytic gastritis without evidence of *Helicobacter* spp. infection or gastric parasites is often treated with corticosteroids. As the histopathologic evaluation of gastric biopsies is not uniform among pathologists, even when a standardized scoring scheme is used,[7,8] the prudent clinician should carefully review histologic sections to get a feel for the pathologist's interpretation. Even with optimum evaluation, similar histologic changes can be observed in patients with different underlying etiologies, so integrated evaluation of the clinical syndrome, presence or absence of concurrent intestinal disease, and well-structured treatment trials often form the basis of an etiologic diagnosis.

Treatment

Treatment of gastritis initially centers on the detection and treatment of underlying metabolic disorders and the removal of drugs, toxins, foreign bodies, parasites, and fungal infections.

Infection

Ollulanus tricuspis[31], *Physaloptera* spp, pythiosis[24], and *Helicobacter*–associated gastritis are discussed in the "Gastric Infection" section.

Chronic Gastritis of Unknown Cause

Lymphoplasmacytic gastritis of unknown cause is common in dogs and cats. It may be associated with similar infiltrates in the intestines, particularly in cats (that should also be evaluated for concurrent pancreatic and biliary disease). The cellular infiltrate varies widely in severity and it may be accompanied by mucosal atrophy or fibrosis, and less commonly hyperplasia.

Patients with mild, *Helicobacter*-negative, lymphoplasmacytic gastritis are initially treated with anthelminthics and dietary modification. The diet is frequently restricted in antigens to which the patient has been previously exposed, such as a lamb-based diet if the patient has previously been fed chicken and beef, or contains hydrolyzed proteins (usually chicken or soy) that may be less allergenic than intact proteins. Many of these diets are also high in carbohydrate and restricted in fat, which facilitates gastric emptying, and may contain other substances such as menhaden fish oil or antioxidants (vitamin C, vitamin E) that may ameliorate inflammation.

The test diet is fed exclusively for a period of about 2 weeks while vomiting is monitored.[17] If vomiting is improved a challenge with the original diet is required to confirm a diagnosis of food intolerance. The introduction of a specific dietary component to the test diet, such as beef, is required to confirm dietary sensitivity. If vomiting is unresponsive the patient may be placed on a different diet for another 2 weeks, usually the limit of client tolerance, or treated with prednisolone (1 to 2 mg/kg/day PO, tapered to every other day at the lowest dose that maintains remission over 8 to 12 weeks).

Patients with moderate to severe, *Helicobacter*-negative, lymphoplasmacytic gastritis are usually started on a combination of a test diet and prednisolone. If the patient goes into remission, it is maintained on the test diet while prednisolone is tapered and potentially discontinued. This regimen is typically supplemented with antacids and mucosal protectants if ulcers or erosion are detected at endoscopy or if hematemesis or melena is noted.

If gastritis is unresponsive to diet, prednisolone, and antacids, additional immunosuppression may be indicated. Gastric biopsies should be carefully reevaluated for evidence of lymphoma. In dogs, immunosuppression is usually increased with azathioprine (2 mg/kg PO SID for 5 days then every other day, on alternating days with prednisolone). Chlorambucil may be a safer alternative to azathioprine in cats and has been successfully employed in the management of IBD and small cell lymphoma. Prokinetic agents such as mosapride (Japan), prucalopride (Western Europe), cisapride, and erythromycin can be used as an adjunct where delayed gastric emptying is present and are discussed in more detail in Chapter 52.

Diffuse eosinophilic gastritis of undefined etiology is usually approached in a similar fashion to lymphoplasmacytic gastritis. The presence of eosinophilia, dermatologic changes, and eosinophilic infiltrates may be even more suggestive of dietary sensitivity or parasitic infection, or it may be a still ill-defined eosinophilic gastroenteropathy of the Rottweiler breed. In cats, it should be determined if these changes are part of a hypereosinophilic syndrome. Treatment for occult parasites, dietary trials, and immunosuppression can be carried out as described previously. Focal eosinophilic granulomas can be associated with parasites or fungal infection that should be excluded prior to immunosuppression with corticosteroids.

Atrophic Gastritis

Atrophic gastritis in dogs and cats is often associated with a marked cellular infiltrate. In people atrophy is associated with *Helicobacter* spp. infection and inflammation, and immune-mediated destruction.[32] Gastric disease is often not discovered until the patient presents with pernicious anemia secondary to cobalamin deficiency caused by a lack of gastric intrinsic factor. In people, atrophic gastritis, intestinal metaplasia of the gastric mucosa, hypergastrinemia and hypochlorhydria are thought to precede the development of gastric cancer.[33] The host inflammatory response is also thought to contribute to the development of atrophy and proinflammatory IL-1β and IL-10 gene polymorphisms in people are associated with increased inflammation, gastric atrophy, hypochlorhydria, and gastric cancer.[34-37]

Atrophic gastritis has been described infrequently in dogs and cats, but does share some similarities with people. Atrophic gastritis characterized by reduction in parietal cells and hyperplasia of neuroendocrine cells has been associated with gastric adenocarcinoma in Lundehunds.[38] Some of the adenocarcinomas displayed enterochromaffin-like cell differentiation, suggesting that hypergastrinemia secondary to fundic atrophy may be important in carcinogenesis. In murine models, the presence of concurrent gastric inflammation and hypergastrinemia is pivotal for the development of gastric cancer.[39] In dogs with lymphoplasmacytic gastritis of undetermined cause, gastric atrophy correlates with the expression of mRNA for IL-1β and IL-10 and the presence of neutrophils.[7] However, with the exception of the Lundehund, clear evidence that gastritis progresses to atrophy and gastric cancer in dogs or cats,[40] and the role of *Helicobacter* spp., regional or systemic neuroendocrine perturbations, and antigastric antibodies in the development of atrophy in dogs and cats remains to be determined.

In contrast to people, dogs and cats with atrophic gastritis have not been reported to develop cobalamin deficiency. This is probably because the pancreas, rather than the stomach, is the main source of intrinsic factor in these species.[41-43] Achlorhydria has been described in dogs and may enable the proliferation of bacteria in the stomach and upper small intestine, although this has not been proven. The treatment of atrophic gastritis has received limited attention, but *Helicobacter* spp. eradication and immunosuppression have been effective in people.

Hypertrophic Gastritis

Hypertrophy of the fundic mucosa is uncommon and is often part of the breed-specific gastropathies or gastroenteropathies mentioned previously. Measurement of gastric pH and serum gastrin can help to differentiate idiopathic hypertrophic pylorogastropathy from hypertrophy associated with hypergastrinemia.[25,26] Pancreatic polypeptide-producing tumors may also be associated with mucosal hypertrophy. Concurrent hypergastrinemia should prompt consideration of underlying hepatic or renal disease, achlorhydria, or gastrin-producing tumors, which should be pursued appropriately. Basenji gastroenteropathy is variably associated with fasting hypergastrinemia and exaggerated secretin-stimulated gastrin, and anecdotal reports suggest that affected Basenjis may respond to antimicrobial therapy. Brachycephalic, middle-aged, small-breed dogs such as Shih Tzus seem predisposed to the syndrome of hypertrophic pylorogastropathy, in which vomiting is secondary to pyloric outflow obstruction caused by hypertrophy of the pyloric mucosa and/or muscularis.[20,21] Antral hypertrophy of brachycephalic dogs causes outflow obstruction and is treated surgically.

When hypertrophic gastropathy, ulcers or erosions, or excessive gastric juice are encountered at endoscopy, intravenous H_2-antagonists or proton pump inhibitors can be given during the endoscopic procedure as prophylaxis for postoperative perforation or esophagitis.[2]

INFECTION

Kenneth W. Simpson and Robert J. Washabau

The stomach may be colonized by several types of infectious organisms (Table 56-4). The most important of these are the helminths (*Physaloptera* spp., *Ollulanus* spp., *Gnathostoma* spp., *Spirocerca* spp.), protozoa (*Cryptosporidium* spp.), fungi (*Histoplasma* spp.), oomycetes (*Pythium* spp.), and bacteria (*Helicobacter* spp.). The routine medical investigation of any dog or cat affected with chronic vomiting should include direct and indirect fecal examinations for helminth and protozoa, bacterial culture of feces, serologies, and molecular methodology. Some organisms appear to be of low pathogenicity, but it should be emphasized that even commensal organisms may become pathogens given the appropriate circumstance.

Helminth Infection

Physaloptera

Physaloptera spp. are approximately 2 to 6 cm long and may be detected sporadically in the stomachs of dogs and cats (Figure 56-8). *P. rara* are described most commonly and appear to be primarily a parasite of coyotes. Diagnosis is difficult as worm burden is often low and the eggs are transparent and difficult to see in sugar flotation.

Table 56-4 Etiology of Gastric Infection in the Dog and Cat

Infectious Agent	Geographic Distribution	Hosts	Location in the Host	Method of Infection
Helminths				
Physaloptera	Worldwide	Dogs	Stomach, intestine	Ingestion
Ollulanus	Worldwide	Cats	Stomach	Ingestion
Gnathostoma	Africa, Asia, Europe	Dogs, cats	Stomach, systemic migration	Ingestion
Spirocerca	Worldwide	Dogs	Stomach, esophagus	Ingestion
Protozoa				
Cryptosporidium	Worldwide	Dogs, cats	Stomach, small intestine	Ingestion
Fungi				
Histoplasma	Worldwide, temperate, subtropical	Dogs, cats	Stomach, intestine, colon	Ingestion
Oomycetes				
Pythium	Worldwide, tropical, subtropical	Dogs	Stomach, colon	Skin, GI tract
Bacteria				
Helicobacter	Worldwide	Dogs, cats	Stomach, colon	Ingestion

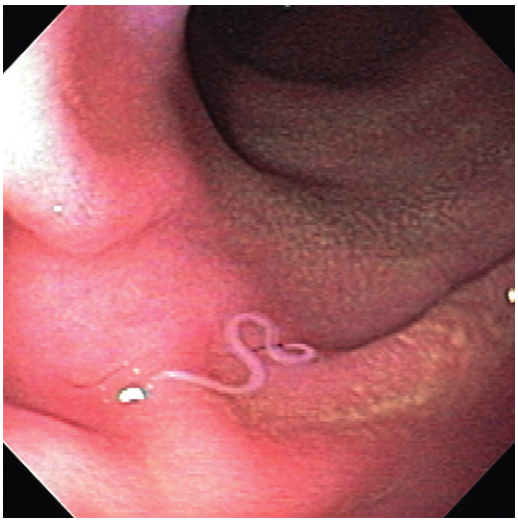

Figure 56-8 Endoscopic image of a mature *Physaloptera* worm in the gastric fundus of an 11-year-old mixed-breed dog. (Courtesy of Dr. Michael D. Willard of Texas A&M University.)

Treatment with pyrantel pamoate (5 mg/kg PO: dogs single dose; cats two doses 14 days apart) may be effective. Control of infection may be difficult because of the ingestion of intermediate hosts, such as cockroaches and beetles, and paratenic hosts, such as lizards and hedgehogs. Given the difficult diagnosis of *Ollulanus* and *Physaloptera* spp., empirical therapy with an anthelminthic such as fenbendazole (50 mg/kg PO daily for 5 days) may be warranted in dogs and cats with unexplained gastritis.[1]

Ollulanus

O. tricuspis is a microscopic worm (0.7 to 1 mm long, 0.04 mm wide) that infects the feline stomach. Its predominant cat-to-cat transmission is through ingestion of vomitus. It can also undergo internal autoinfection with worm burdens reaching up to 11,000 per stomach. Mucosal abnormalities range from none, to rugal hyperplasia, and nodular (2 to 3 mm) gastritis.

Histologic findings include lymphoplasmacytic infiltrates, lymphoid follicular hyperplasia, fibrosis, and up to 100 globular leukocytes per high-power field. *Ollulanus* spp. are not detected by fecal examination and require evaluation of gastric juice, vomitus, or histologic sections for the presence of larvae or worms. Gastric lavage and xylazine-induced emesis have been described to aid diagnosis. Treatment with fenbendazole (50 mg/kg PO daily for 5 days) may be effective.[2]

Gnathostoma

Gnathostomes (e.g., *Gnathostoma spinigerum*, *Gnathostoma binucleatum*) are parasitic nematodes of dogs and cats.[3] Any organ system may be involved, but the most common manifestations of infection are localized swelling of the skin and gastric mucosa. Following ingestion of infective larvae, the larvae excyst in the stomach, penetrate the gastric wall, and migrate through the liver to more distant connective tissue and muscle. After 4 weeks, they migrate once again to the gastric wall where they produce an inflammatory response, and mature into adults in 6 to 8 months. At 8 to 12 months after initial ingestion, the worms mate, and eggs are passed in the feces of the host.

Spirocerca

Spirocercosis affects primarily the dog and is caused by the nematode *S. lupi*.[4] Typical clinical signs are regurgitation, vomiting, and dyspnea. Ingested larvae follow a specific migratory route, penetrating the gastric mucosa of the host, migrating along arteries, maturing in the thoracic aorta before eventually migrating to the caudal esophagus (Figure 56-9). The worm lives in nodules provoking a severe mixed inflammatory/neoplastic-like response. Radiographic lesions regarded as diagnostic for spirocercosis are esophageal nodules, aortic aneurysms and mineralization, and caudal thoracic spondylitis. Doramectin is the current drug of choice, effectively killing adult worms and decreasing egg shedding. In endemic areas, monthly administration of a combination of imidacloprid 10%/moxidectin 2.5% in puppies starting at 2 to 4 months of age achieves effective and safe protection of canine spirocercosis.[5]

Protozoal Infection

Cryptosporidium

Cryptosporidium spp. are protozoan parasites of a large number of vertebrate species, including humans, cats, and dogs.[6]

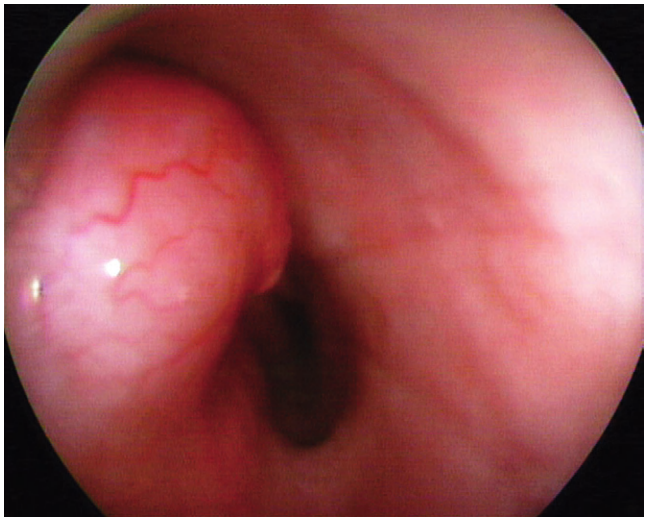

Figure 56-9 Endoscopic appearance of a *Spirocerca lupi*-induced fibrosarcoma of the gastroesophageal junction in an 8-year-old mixed-breed dog. (Courtesy of Dr. Michael D. Willard of Texas A&M University.)

Cryptosporidia have a worldwide distribution and are important pathogens of veterinary and public health concern because of their ability to produce debilitating GI disease. Cryptosporidia are obligate, intracellular parasites generally of the gastric and intestinal epithelium. Diarrhea is the most important clinical sign, but other clinical findings include nausea, vomiting, abdominal pain, lethargy, and malaise. Clinical signs are not always present, indeed some infections are discovered only through routine surveillance. Recent studies of *Cryptosporidium* infection rates in cats and dogs have reported prevalence rates in dogs ranging from 0.5% to 44.1%, and in cats from 0% to 29.4%, and, of course, cats and dogs may serve as an important source of human infection.[6] Cryptosporidial infections may not be associated with active shedding of oocysts; acid-fast staining, immunofluorescent antibody staining of a fecal smear, and fecal antigen ELISA may aid in the identification of cryptosporidial oocysts. No treatment is currently registered for *Cryptosporidium* infection in small animals. Tylosin has been used successfully in cats but requires a long course of therapy.[6]

Fungal Infection

Histoplasma

Etiology

Histoplasmosis is a systemic fungal disease of dogs and cats caused by *Histoplasma capsulatum*. In the environment, *Histoplasma capsulatum* organisms are mycelial, saprophytic soil fungi. In infected tissue or when cultured at 30°C (86°F) to 37°C (98.6°F), the organism is a yeast. The fungus is endemic throughout most of the temperate and subtropical regions of the world. Most cases of histoplasmosis in the United States occur in the central states, with the geographic distribution following the Mississippi, Ohio, and Missouri Rivers.[7,8]

Pathophysiology

Infection is probably via inhalation or ingestion of infective conidia from the environment. The respiratory system is thought to be the primary route of infection in cats and dogs, although the GI tract may also be an important route in the dog. After inhalation or ingestion, conidia transform from the mycelial phase and are phagocytized by macrophages, where they grow as facultative intracellular organisms. Hematogenous and lymphatic dissemination results in multisystemic disease. Organisms can be disseminated to any organ system, but the lungs, diffuse GI tract, lymph nodes, liver, spleen, bone marrow, eyes, and adrenal glands are the most common organs of dissemination in dogs; lungs, liver, lymph nodes, eyes, and bone marrow are most commonly affected in cats. Cell-mediated immunity induces a granulomatous inflammatory response in most infection.[9]

Clinical Examination

Dogs with GI histoplasmosis are typically presented with mild fever, anorexia, lethargy, weight loss, vomiting, diarrhea, hematochezia, and tenesmus. Cachexia is a common physical examination finding. Other historical and physical examination findings (dyspnea, cough, ascites, lameness, oropharyngeal ulcerations, chorioretinitis, neuropathy) depend upon organ and tissue involvement.

Diagnosis

Organism identification is required for definitive diagnosis. The most common means of organism identification is cytology. Cytology from affected tissue reveals pyogranulomatous inflammation, often with numerous small, round to oval intracellular yeast cells (2 to 4 μm in diameter) characterized by a basophilic center and a light halo. Exfoliative cytology during endoscopy is particularly useful in diagnosing the disease.[10] Histopathology is helpful if cytology is nondiagnostic or inconclusive. Multiple endoscopic biopsies are usually sufficient to diagnose the disease. The yeast form does not stain well with routine hematoxylin and eosin stains, so special stains such as periodic acid-Schiff and Gomori methenamine silver stain are often used to demonstrate organisms. Fungal culture from affected tissue can be used for diagnosis but is rarely needed in clinical cases. Currently available serologies have poor specificity and sensitivity.[9]

Treatment

Itraconazole (5 mg/kg PO BID for 2 to 4 months) is considered the treatment of choice for feline histoplasmosis. In one study, itraconazole therapy cured histoplasmosis infections in all eight study cats.[11] Ketoconazole and amphotericin B have been described as the treatments of choice for canine histoplasmosis (see Chapter 36). With gastric, intestinal, and colonic involvement, additional GI therapy may be useful in affected dogs, for example, dietary modification, treatment for small intestinal bacterial overgrowth, and direct antidiarrheal therapy. Corticosteroids may have been used successfully in the treatment of airway obstruction secondary to hilar lymphadenopathy in chronically infected dogs.[12]

Prognosis

There may be important species differences in prognosis although the paucity of reports, especially of prospective clinical trials, makes it difficult to generalize. It would seem that the prognosis is guarded in dogs, but fair to good in cats.

Oomycetes Infection

Pythium

Etiology

P. insidiosum is an aquatic oomycete that causes severe GI pathology in a range of hosts in the tropical and subtropical climates.[13] Based on ribosomal RNA gene sequence data, members of the Class *Oomycetes* are phylogenetically distinct from the Kingdom *Fungi*, and are

more closely related to algae than to fungi.[14] The oomycetes differ from fungi in two important properties: cell wall and cell membrane composition. Chitin is an essential component of the fungal cell wall, but it is generally lacking in the oomycete cell wall. Oomycetes also differ from fungi in that ergosterol is not a principal sterol in the oomycete cell membrane. This difference may explain why ergosterol-targeting drugs like itraconazole are less effective in the medical treatment of pythiosis.[14]

Pathophysiology

The infective state of *P. insidiosum* is thought to be the motile zoospore, which is released into stagnant water in warm environments, and likely causes infection either by encysting in the skin, or by being ingested into the GI tract. Ingested zoospores encyst and adhere to the gastric, jejunal, and colonic epithelium with a polarity oriented toward the submucosa for rapid tissue penetration following germ tube eruption. *Pythium* induces a chronic pyogranulomatous response in the GI tract and mesenteric lymph nodes. The gastric outflow tract and ileocolonic junction are the most frequently affected portions of the GI tract, and it is not uncommon to find two or more segmental lesions in the same patient.[15] Inflammation in affected regions is typically centered on the submucosa, with variable mucosal ulceration and occasional extension of disease through serosal surfaces, resulting in adhesion formation and peritonitis.

Clinical Examination

Weight loss, vomiting, diarrhea, and hematochezia are the most important clinical signs. Physical examination often reveals emaciated body condition and a palpable abdominal mass. Signs of systemic illness such as lethargy and depression are not typically present unless intestinal obstruction, infarction, or perforation occurs.

Diagnosis

Gastric outflow obstruction, ileocolonic wall thickening, obliteration of the normal layered appearance, and regional lymphadenopathy are common ultrasonographic features of canine intestinal pythiosis.[16] Of course, these findings cannot be readily differentiated from those associated with GI malignancy. Definitive diagnosis requires histologic demonstration or immunohistochemical staining of the organism and/or positive ELISA or PCR assays. The histologic findings associated with pythiosis generally are characterized by eosinophilic granulomatous to pyogranulomatous inflammation with fibrosis. Affected tissue typically contains multiple foci of necrosis surrounded and infiltrated by neutrophils, eosinophils, and macrophages. Discrete granulomas composed of epithelioid macrophages, plasma cells, multinucleate giant cells, and neutrophils and eosinophils may also be observed. *Pythium* zoospores may be cultured directly from affected tissue in antibiotic-containing (e.g., streptomycin and ampicillin) media. More recently, sensitive and specific ELISA and PCR assays have been developed for the accurate diagnosis of pythiosis in dogs.[17-19]

Treatment

Aggressive surgical resection remains the treatment of choice for pythiosis in dogs. Because it provides the best opportunity for long-term cure, complete resection of infected tissue should be pursued whenever possible. Segmental lesions of the GI tract should be resected with 3- to 4-cm margins whenever possible. Medical therapy for the oomycetes has not been very promising. This may relate to the absence of ergosterol (cell membrane target of most currently available antifungal drugs) in the oomycete cell membrane. Clinical and serologic cures have been obtained in a small number of dogs following therapy with amphotericin B lipid complex (2 to 4 mg/kg QOD administered to a cumulative dose of 24 to 27 mg/kg) or itraconazole (10 mg/kg q24h for 6 to 9 months).

Prognosis

Unfortunately, most dogs with GI pythiosis are not presented to the veterinarian until late in the course of the disease, when complete excision is not possible. The anatomic site of the lesion (e.g., pylorus or ileocolic sphincter) may also prevent complete excision. Consequently, the prognosis is usually grave in most animals.[14]

Bacterial Infection

Helicobacter

Etiology

The importance of bacteria and unrecognized pathogens (obligate or opportunistic) in the development of gastric inflammation is best demonstrated by the gastric bacterium *H. pylori*, a Gram-negative bacterium, that chronically infects more than half of all people worldwide.[20] Chronic infection of human adults with *H. pylori* is characterized by the infiltration of polymorphonuclear and mononuclear cells and the upregulation of proinflammatory cytokines and the chemokine IL-8. Mucosal T cells in infected individuals are polarized toward the production of IFN-γ, rather than IL-4 or IL-5, indicating a bias toward a T-helper (Th)1 response.[21,22] This sustained gastric inflammatory and immune response to infection appears to be pivotal for the development of peptic ulcers and gastric cancer in people.[23-25]

The prevalence of gastric *Helicobacter* spp. infection ranges from 67% to 100% of healthy pet dogs, 74% to 90% of vomiting dogs, 100% of laboratory Beagles and 40% to 100% of healthy and sick cats.[26,27-39] In contrast to people, in whom *H. pylori* infection predominates, dogs and cats are colonized by a variety of large spiral organisms (5 to 12 μm). In cats from Switzerland, the United States, and Germany, *H. heilmannii* is the predominant species, with *H. bizzozeronii* and *H. felis* much less frequent. In dogs from Finland, Switzerland, the United States, and Denmark, *H. bizzozeronii* and *H. salomonis* are most common, followed by *H. heilmannii* and *H. felis*; *H. bilis* and *F. rappini* have also been described. Cats can also be colonized by *H. pylori* (2 to 5 μm) but infection has been limited to a closed colony of laboratory cats.

Pathophysiology

The large *Helicobacter* spp. found in dogs and cats do not attach to the epithelium, but colonize the superficial mucus and gastric glands, particularly of the fundus and cardia, and may also be observed intracellularly.[27,28,35,36] Degeneration of gastric glands, with vacuolation, pyknosis, and necrosis of parietal cells is more common in infected than uninfected animals. Inflammation is generally mononuclear in nature and ranges from mild to moderate in severity. Gastric lymphoid hyperplasia is common and can be extensive in dogs and cats infected with *Helicobacter* spp. In addition to this local gastric immune response, a systemic response characterized by increased circulating anti-*Helicobacter* IgG has been detected in sera from naturally infected dogs and cats.[29,30] However, the gastritis observed in cats and dogs infected with large spiral bacteria is generally less severe than that observed in *H. pylori*–infected people (where neutrophilic aggregates, and moderate to severe gastritis, are commonly encountered), and GI ulcers, gastric neoplasia, or changes in serum gastrin or acid secretion have not been associated with *Helicobacter* spp. infection in dogs and cats.[27,28,37]

The effect of eradicating *Helicobacter* spp. on gastritis and clinical signs, the main form of evidence supporting the pathogenic role of *H. pylori* in human gastritis, has not been thoroughly investigated to date in dogs and cats. Antibiotic trials in dogs and cats with gastritis and *Helicobacter* spp. infection showed that vomiting improved in 90% of 63 dogs and cats, and 86% of 24 dogs.[38,39] In one trial, 14 of the 19 animals having repeat endoscopy had resolution of gastritis and no evidence of *Helicobacter* spp. in gastric biopsies.[38] Another study found that gastritis scores in dogs that were *Helicobacter*-negative at 6 months were decreased, whereas those in *Helicobacter*-positive dogs increased.[39] With such limited information from eradication trials, most current knowledge about the pathogenicity of *Helicobacter* spp. in dogs and cats comes from evaluation of animals with and without infections and clinical signs, and a small number of experimental infections.

Clinical Examination and Diagnosis

The interspecies differences in *Helicobacter*-associated gastritis in people, dogs, and cats may be attributed to differences in the virulence of the infecting *Helicobacter* spp., or the host response. Studies that address this issue indicate that *H. pylori* evokes a more severe proinflammatory cytokine and cellular response in dogs and cats than natural or experimental infection with large *Helicobacter* spp.[40,41] The limited mucosal inflammatory response and absence of clinical signs in the vast majority of dogs and cats infected with non–*H. pylori Helicobacter* spp., despite significant antigenic stimulation (evidenced by seroconversion and lymphoid follicle hyperplasia), suggest that large gastric *Helicobacter* spp. are commensal rather than pathogenic for the population in general. With this in mind, it is interesting to speculate that enhanced susceptibility to *Helicobacter* spp. conferred by differences in host genetics or an environmental trigger, rather than the innate pathogenicity of these bacteria, could explain the development of gastritis and clinical signs in some, but not all *Helicobacter*-infected dogs and cats. This is consistent with recent thinking on IBD[42] and much still remains to be learned about the role of *Helicobacter* spp. in canine and feline gastritis.

Ownership of dogs and cats has been correlated with an increased risk of infection of *H. heilmannii* in people.[43] Case reports have also suggested the transmission of *Helicobacter* spp. from pets to man.[44] Recent studies clearly confirm that dogs and cats harbor *H. heilmannii*, but the subtypes of *H. heilmannii* present in dogs and cats (types 2 and 4) are of minor importance (approximately 15% of cases) to people, who are predominantly colonized by *H. heilmannii* type 1 (the predominant *Helicobacter* sp. in pigs).[34]

The finding of *Helicobacter* DNA in the oral cavity of dogs raised potential for transmission through contact with oral secretions; however, it has been shown recently that *Wolinella* rather than *Helicobacter* spp. are the dominant *Helicobacteraceae* in the canine oral cavity.[45,46]

Treatment

The general lack of knowledge of the pathogenicity of gastric *Helicobacter* spp. has meant that veterinarians are faced with the dilemma of either treating or ignoring spiral bacteria observed in biopsy samples from patients with chronic vomiting and gastritis. In light of their pathogenicity in humans, ferrets, cheetahs, and mice, and results of recent antibiotic trials in dogs and cats, it would seem prudent to attempt to eradicate gastric *Helicobacter* spp. prior to initiating treatment with immunosuppressive agents to control gastritis. However, this must be decided on an individual basis. For example, in the patient with a lymphoplasmacytic infiltrate of the stomach and small intestine and concomitant gastric *Helicobacter* spp. infection, should one treat for IBD, *Helicobacter*, or both?

The authors recommend treating symptomatic patients that have biopsy-confirmed *Helicobacter* spp. infection together with gastritis (typically described as lymphoplasmacytic with lymphoid follicular hyperplasia). Current treatment protocols are based on those found to be effective in people infected with *H. pylori*. An uncontrolled treatment trial of dogs and cats with gastritis and *Helicobacter* spp. infection showed that clinical signs in 90% of 63 dogs and cats responded to treatment with a combination of metronidazole, amoxicillin, and famotidine, and that 14 (74%) of 19 animals subject to repeated endoscopic examination had no evidence of *Helicobacter* spp. in gastric biopsies.[38] A controlled trial of amoxicillin (15 mg/kg PO BID for 14 days), metronidazole (10 mg/kg PO BID for 14 days) and bismuth ± famotidine in 24 dogs found a similar decrease in vomiting (86.4%) and reduced gastritis scores in dogs that were *Helicobacter*-negative 6 months later.[39] The use of famotidine did not improve resolution of clinical signs or eradication of *Helicobacter*. Unfortunately, only 43% of dogs were free from *Helicobacter* at 6 months,[39] which echoes the results of controlled studies in asymptomatic *Helicobacter*-infected dogs and cats. Treatment combinations evaluated in these asymptomatic animals included (a) amoxicillin (20 mg/kg PO BID for 14 days), metronidazole (20 mg/kg PO BID for 14 days), and famotidine (0.5 mg/kg PO BID for 14 days) in dogs[37]; (b) clarithromycin (30 mg PO BID for 4 days), metronidazole (30 mg PO BID for 4 days), ranitidine (10 mg PO BID for 4 days), and bismuth (20 mg PO BID for 4 days) (CMRB) in *H. heilmannii*–infected cats[47]; and (c) azithromycin (30 mg PO SID for 4 days), tinidazole (100 mg PO SID for 4 days), ranitidine (20 mg PO SID for 4 days), and bismuth (40 mg PO SID for 4 days) (ATRB) in *H. heilmannii*–infected cats.[47] Reevaluation of infection status at 3 days (dogs) or 10 days (cats) after treatment revealed six of eight dogs and 11 of 11 CMRB- and four of six ATRB-treated cats to be free of *Helicobacter* spp. on the basis of histology and urease testing (dogs) or ^{13}C-urea breath test (dogs and cats).[47,48] However, at 28 days (dogs) or 42 days (cats) after completing antimicrobial therapy, eight of eight dogs, four of 11 cats that received CMRB, and five of six cats that received ATRB, were found to be reinfected. A transient effect of combination therapy (amoxicillin 20 mg/kg PO TID for 21 days, metronidazole 20 mg/kg PO TID for 21 days, and omeprazole 0.7 mg PO SID for 21 days) on bacterial colonization also has been observed in six cats with *H. pylori* infection.

Further analysis of gastric biopsies from infected dogs and *H. pylori*–infected cats using PCR and *Helicobacter*-specific primers revealed persistence of *Helicobacter* DNA in gastric biopsies that appeared negative on histology and urease testing. These studies suggest that antibiotic regimens that are effective against *H. pylori* in people may only cause transient suppression, rather than eradication, of gastric *Helicobacter* spp. in dogs and cats. The reason for the much higher apparent recrudescence or reinfection rate in dogs and cats than people (1% to 2% per year observed after treatment of *H. pylori*) could be a result of antimicrobial resistance of non–*H. pylori Helicobacter* spp. or the relatively high proportions of intracellular *Helicobacter* in dogs and cats.[35-37] Antibiotic sensitivity testing of cultivable *Helicobacter* spp. infecting dogs and cats indicates they are sensitive to most commonly selected antibiotics, but can harbor resistance against metronidazole.[49]

In a recent study, metronidazole (11 to 15 mg/kg PO BID), amoxicillin (22 mg/kg PO BID), and bismuth subsalicylate (0.22 mL/kg PO TID-QID) were administered to five *Helicobacter*-infected animals (three dogs and two cats) for 21 days, and there was resolution of vomiting and long-term eradication of *Helicobacter* (9 to

38 months) in all animals. The combination of amoxicillin (20 mg/kg PO BID), clarithromycin (7.5 mg/kg PO BID), and metronidazole (10 mg/kg PO BID) for 14 days has been used to successfully eradicate *H. pylori* infection in cats.

Prognosis

These studies suggest that a longer duration of treatment (21 days) or the use of antibiotics that can eradicate intracellular *Helicobacter* spp. (e.g., clarithromycin) may improve eradication, but further studies are required before clear guidelines regarding the treatment of gastric *Helicobacter* spp. in dogs and cats can be made.

Diffuse Gastrointestinal Infection

Some GI pathogens infect the entire span of the GI tract from stomach to anorectum. Infection with these pathogens (e.g., *Giardia, Campylobacter, Salmonella, Clostridium*) is more often associated with small and/or large intestinal pathology, but gastric pathology (inflammation, edema, necrosis) and clinical signs (anorexia, vomiting, hematemesis) may be evident concurrently. A recent study reported that for dogs in which intestinal biopsy specimens and gastric biopsy specimens were collected, concurrent pathologic changes were recorded in 72% of dogs. These data support the notion that GI pathology, including GI infection, may span the entire GI tract.[50]

OBSTRUCTION

Jean A. Hall

Gastric outlet obstruction refers to an inability of food and/or water to properly exit from the stomach because of mechanical blockage at or near the pylorus.[1] There are four main causes for this problem: (a) foreign objects and/or intraluminal masses, (b) mucosal or muscular proliferative and/or infiltrative disease, (c) compression of the outflow tract by masses and/or organs outside the stomach, or (d) malpositioning of the stomach. Diagnosis of mechanical obstruction is usually straightforward and can be made radiographically (e.g., failure of barium to leave the stomach, finding a mass or object in the pyloric antrum), endoscopically, ultrasonographically, or surgically. Surgical removal of the foreign object or the affected area is often the preferred therapy.

Gastric Dilation and Volvulus

Etiology

GDV is an acute life-threatening condition characterized by malposition of the stomach, rapid accumulation of air in the stomach, increased intragastric pressure, and shock. Although some progress has been made in determining risk factors, understanding the pathophysiology, and in developing new treatments, the cause is still speculative.[2] Overall mortality rate for GDV is 33%.[3] Early diagnosis and treatment have improved survival rate significantly, although mortality remains high at 15% even with current treatments.[4-6]

Risk factors for GDV include purebred status, large- or giant-breed conformation (especially breeds with a deep and narrow thorax such as the Great Dane, Weimaraner, St. Bernard, Gordon Setter, and Irish Setter), middle to older age (mean age approximately 7 years), and a first-degree relative that had GDV (see Chapter 62).[3,7-9] Controlled epidemiologic studies show that eating fewer meals per day and a rapid rate of eating increased susceptibility to GDV; dogs characterized by their owners as happy or easygoing were at lower risk than nervous or fearful dogs.[7,10] Dogs fed a larger volume of food per meal were at significantly increased risk of GDV, regardless of the number of meals fed daily.[11] The risk of GDV was highest for dogs fed a larger volume of food once daily.[11] Rapid eating and a raised feeding bowl were also associated with an increased risk of GDV.[12] The only breed-specific characteristic significantly associated with a decreased incidence of GDV was an owner-perceived personality trait of happiness.[13] Despite popular opinion, epidemiologic studies have not supported a causal relationship between feeding soy-based or cereal-based dry dog food and GDV.[14] There is no clinical evidence that fermentation is the cause of gastric gas production. In fact, dry foods containing fats or oils among the first four label ingredients predispose high-risk dogs to GDV, but soy- and cereal-based ingredients do not.[14] Scientific studies do not overwhelmingly support the role of previously proposed causes, including hypergastrinemia, exercise after ingestion of large meals of highly processed foods or water, and inflammatory bowel disease.[2,3,7,15-18] A seasonal increase in GDV incidence was noted in one population of military working dogs.[19]

It is well known by veterinarians that dogs can experience GDV when no food is in the stomach. Pathologists have performed necropsies on dogs with GDV that had only a small amount of fluid in the stomach, or had empty stomachs. Anesthesia, surgery, trauma, and parturition have all been observed to be associated with GDV.[20]

Certain anatomic considerations are important for the development of GDV. In healthy awake dogs, gastric distention with nitrogen consistently decreases lower esophageal sphincter pressure and is followed by eructation.[21] The same is true in GDV dogs.[21] The gastroesophageal sphincter pressure was not significantly increased compared with normal dogs in dogs tested more than 9 months after treatment for and recovery from GDV.[16] Thus, it is unlikely that elevated gastroesophageal sphincter pressure inhibits orad movement and relief of gastric distention in GDV dogs. The gastroesophageal sphincter is physiologically unable to retain gas within the stomach unless volvulus is present. During abdominal surgery, the stomach in normal dogs can be forcibly rotated into a volvulus position, but it immediately returns to a normal position when released because the pylorus is tightly fixed to the right side of the abdomen by the hepatoduodenal and hepatogastric ligaments. The stomach of a dog that has experienced GDV, however, can easily be placed in the volvulus position and remains in an abnormal position once released. With volvulus and twisting of the gastroesophageal sphincter, swallowed air cannot be easily eructated and gastric dilation persists. Therefore, volvulus must precede dilation for gastric distention from aerophagia to occur, which is contrary to the alternative premise that dilation precedes a volvulus. It is well known that chronic gastric volvulus exists, and malpositioning of the stomach may be constant or intermittent. It is also known that adaptive relaxation allows the proximal stomach to stretch and accommodate some degree of gastric distention without an increase in intraluminal pressure (see receptive relaxation and accommodation in Chapter 1). Gastric emptying of liquids can even be normal in dogs with chronic gastric volvulus.[22] Initially food, air, and saliva can enter the stomach in the presence of volvulus. At some point, however, perhaps related to the degree of rotation, volvulus prevents further air from entering or leaving the stomach. Up until that point, gas accumulation occurs. Rotation of the stomach is likely the factor that initiates aerophagia. Swallowing of air is accompanied by swallowing of saliva. A considerable amount of gas

accumulates because the volvulus prevents belching of air (and vomiting of ingesta) and inhibits pyloric emptying into the duodenum.

Delayed gastric emptying of solid particles fed with a meal has been documented in dogs with GDV following surgical treatment and recovery,[23,24] whereas the liquid phase of gastric emptying is not similarly affected.[22,25] Using radiopaque particles mixed with food, gastric emptying was assessed in healthy dogs not subjected to surgery, in healthy dogs 9 to 35 days after circumcostal gastropexy, and in dogs 1 to 54 months after surgical treatment and recovery from GDV. Circumcostal gastropexy surgery did not alter the 90% gastric emptying time for radiopaque particles in healthy dogs. However, 90% gastric emptying time was significantly increased after circumcostal gastropexy in dogs with GDV, compared with healthy dogs after the same surgical procedure and recovery period. These results suggest that dogs with GDV have delayed gastric emptying of solid particles, although it is still not clear whether delayed gastric emptying of markers in affected dogs after surgical treatment and recovery is the result or the cause of GDV. Other studies indicate that delayed gastric emptying in the GDV syndrome is associated with increased gastric slow wave propagation velocity in the fed state.[26] Atypical fasting state phase III activity suggests that gastric emptying may be impaired in the fasting state as well.[26] Recordings were not altered in healthy dogs after short-term experimental gastric dilation suggesting that altered electrical and contractile activities in GDV dogs are not likely to be secondary to the process of acute gastric dilation.[27] These results imply that electrophysiologic abnormalities in gastric smooth muscle cells may be associated with delayed gastric emptying. Because delayed gastric emptying predisposes to chronic gastric distention, which could stretch the gastrohepatic ligament and permit increased stomach mobility, it has been hypothesized that a primary disorder of gastric motility might precede and predispose the dog to GDV.[28] The length of hepatogastric ligaments in GDV-affected dogs is significantly longer than those of control dogs.[28] Others have also speculated that gastric dysrhythmias may predispose to GDV.[29,30]

Two dogs were reported to develop GDV 2 and 17 months after splenectomy for treatment of splenic torsion. Splenic displacement and torsion may stretch the gastric ligaments, allowing increased mobility of the stomach. After splenectomy, an anatomic void may be created in the cranioventral part of the abdomen, contributing to the mobility of the stomach.[31]

Acute GDV has been reported rarely in cats. Two of five cats reported on in one case series and three cats in another had concomitant diaphragmatic hernia.[32,33] Clinical signs and therapeutic management are similar in cats and dogs.

Pathophysiology

Gastric dilation refers to distention of the stomach, caused most often by swallowed air, fluid, and/or food. Gastric dilation implies an innocuous condition that can easily be corrected by passing a stomach tube to relieve the distention. GDV is different, however, from simple engorgement because of overeating (a syndrome that occurs most commonly in young animals) or gastric distention as a consequence of aerophagia. In GDV, the air-filled stomach becomes tympanic because of the large volume of air present.[34] Dogs experiencing gastric dilation almost invariably have gastric volvulus.[35] A fundamental abnormality associated with GDV is laxity of the hepatoduodenal and hepatogastric ligaments, leading to a high degree of mobility of the stomach within the abdomen.[35] This allows the stomach to twist on its longitudinal axis at the esophageal cardia and the pylorus. In normal dogs, the pylorus is tightly fixed to the cranial right quadrant of the abdomen by the hepatoduodenal ligament, lesser omentum, and common bile duct. Even though the pylorus in normal dogs can be forced to the left and placed in a volvulus position, it immediately returns to its normal position once released. The stomach of a dog that has experienced GDV, however, can easily be placed in the volvulus position and remains in the abnormal position once released. Thus, a predisposition for gastric volvulus must be present to produce the GDV syndrome.

Generally, the stomach rotates in a clockwise direction when viewed from the surgeon's perspective (with the dog on its back and the clinician standing at the dog's side, facing cranially). The rotation may be 90 to 360 degrees, but is usually 220 to 270 degrees.[36] When the stomach twists, the pylorus and duodenum move ventrally, passing under the stomach and to the left of midline, finally coming to rest dorsally above the cardia on the dog's left side. Because the spleen is attached to the greater curvature of the stomach via the gastrosplenic ligament, twisting of the stomach usually displaces the spleen to the right ventral side of the abdomen and causes congestion and splenomegaly.

GDV results in occlusion of the cardia and obstruction of the pylorus. This prevents belching of air or vomiting of ingesta, and inhibits pyloric emptying into the duodenum. It is postulated that after volvulus develops, swallowed air can pass the twisted gastroesophageal junction but cannot escape the stomach. Analysis of gastric gas supports aerophagia as the cause of gastric distention, with dilation explained by an inability to eructate or empty air into the intestines.[34] The bicarbonate in swallowed saliva reacts with hydrochloric acid in the stomach to produce carbon dioxide. This may be the reason why carbon dioxide concentrations in gastric gas of GDV dogs are higher than atmospheric carbon dioxide concentrations. Swallowed air is the only explanation for the presence of nitrogen and oxygen in relatively high concentrations in gastric gas of GDV dogs. Caywood's study[34] showed that neither hydrogen nor methane were present in sufficient quantities in the gastric gas samples from dogs with GDV to support fermentation as the source of gastric gas. Gastric dilation results in increased gastric wall tension, decreased blood flow, local ischemic injury, and gastric wall necrosis. Normal gastric secretion and transudation of fluids into the gastric lumen secondary to venous congestion contribute to fluid accumulation. The most commonly infarcted area is along the greater curvature in the area served by the short gastric vessels.[37] GDV also causes splenic engorgement and compression of major abdominal vessels returning blood to the heart.[38] Occlusion of the portal vein and posterior vena cava reduces venous return to the heart, which in turn dramatically decreases cardiac output and mean arterial pressure, leading to hypovolemic shock. Inadequate tissue perfusion affects multiple organs, including the heart (myocardial ischemia), kidney (acute renal failure), pancreas (myocardial depressant factor is an arrhythmia-inducing compound produced by the ischemic pancreas),[39,40] liver (depressed reticuloendothelial cell function prevents removal of endotoxin),[41] and small intestine (local acidosis, subepithelial hemorrhage and edema, followed by hemorrhagic enteritis). In addition, occlusion of the portal vein and caudal vena cava cause marked passive chronic congestion of the abdominal viscera. The organs suffer from ischemia as well as accumulation of endotoxin (from the GI tract), which, in turn, activates many inflammatory mediators (e.g., histamine, prostaglandins, leukotrienes, and cytokines). Endotoxemia and endothelial damage lead to coagulation cascade activation, and disseminated intravascular coagulation may result. The enlarged stomach also encroaches on the thoracic diaphragm, which decreases tidal volume of the

lungs and further impairs ventilation-perfusion matching. Ultimately, shock reaches a point of irreversibility (likely caused by endotoxemia), wherein death ensues regardless of therapy.[35]

Clinical Examination

Dogs with GDV may present with a history of an acute, progressively distending abdomen, nonproductive retching, hypersalivation, restlessness, depression, weakness, and abdominal pain.[1] Physical examination usually reveals abdominal distention with tympany, although it may be difficult to detect gastric distention in heavily muscled large-breed or very obese dogs. There is also evidence of poor tissue perfusion and/or shock, such as weak peripheral pulses, tachycardia, prolonged capillary refill time, pale mucous membranes, or dyspnea. Eventually, depression and a moribund state may occur.[42] Cardiac arrhythmias, such as ventricular premature beats or ventricular tachycardia, may be detected on initial examination or may develop up to 72 hours after presentation.[43]

Clinicopathologic findings often show an increased hematocrit, and a variety of acid–base and electrolyte abnormalities.[43] Metabolic acidosis and hypokalemia are the most common finding in about 25% of dogs. Metabolic acidosis is likely the result of tissue hypoperfusion, anaerobic metabolism, and lactic acid accumulation. However, metabolic alkalosis also may occur as a result of sequestration of gastric acid and vomiting. Acid–base abnormalities predispose to cardiac arrhythmias and muscle weakness. Coagulation abnormalities are most consistent with disseminated intravascular coagulation (DIC).

Diagnosis

Usually GDV is diagnosed in the examination room based on signalment, history, and physical examination findings, and therapy is begun immediately. It is impossible to differentiate between gastric dilation and GDV on the basis of ability or inability to pass an orogastric tube. If unsure, radiographic evaluation may be necessary, although caution should be exercised because positioning these dogs for radiographs may further impair cardiopulmonary function. Affected animals should be decompressed and rehydrated before radiographs are taken. Right lateral and dorsoventral radiographic views are preferred.[44] In a right lateral view of a dog with GDV the smaller, gas-filled pylorus lies dorsal and cranial to the larger, ventrally positioned fundus. The dorsally positioned pylorus is separated from the rest of the stomach below by a soft-tissue fold (antral wall folding back). On the dorsoventral view, the pylorus appears as a gas-filled structure to the left of midline. Free abdominal air suggests gastric rupture. Blood should be collected for a complete blood cell count, serum biochemistry profile, and blood gas analysis prior to treatment.

Treatment

Shock

One or more large-bore intravenous catheters are placed in jugular or cephalic veins. High-volume isotonic fluids (60 to 90 mL/kg/h), low-volume hypertonic saline (7% NaCl solution in 6% dextran, 4 to 5 mL/kg over 5 to 15 minutes), hetastarch (5 to 10 mL/kg over 10 to 15 minutes), or a mixture of 7.5% saline and hetastarch (dilute 23.4% saline with 6% hetastarch until a 7.5% solution is achieved; administer at 4 mL/kg over 5 minutes) are administered.[45,46] If hypertonic saline or hetastarch is given, the rate of subsequent crystalloid fluid administration must be adjusted accordingly. The animal should be monitored closely and fluid administration rate decreased if clinical improvement occurs. If clinical signs of shock persist, then fluid administration should continue at a high rate until a response is noted. The packed cell volume (PCV) and total protein should be monitored regularly during fluid therapy for shock. Whole blood or plasma should be administered if the PCV falls below 20% or total protein falls below 3.5 g/dL, respectively.[35] Although controversial, corticosteroids (dexamethasone sodium phosphate, 4 mg/kg, or prednisone sodium succinate, 20 mg/kg IV) may be administered for endotoxemia and to stabilize lysosomal membranes. Administration of systemic antibiotics is reasonable as mesenteric congestion caused by the enlarged stomach predisposes to infection and endotoxemia.[42] Bactericidal antibiotics should be administered intravenously (e.g., cefazolin or ampicillin plus enrofloxacin). Flunixin meglumine is sometimes recommended (0.5 to 1.1 mg/kg IV once) to decrease prostaglandin synthesis and attenuate the effects of endotoxemia, although it may place the patient at risk for severe GI ulceration.[47] Sodium bicarbonate is administered if indicated based on the blood gas analysis.[48] Sequestration of hydrogen ions in the gastric lumen can offset the lactic acidosis, causing the blood pH to be normal. Therefore, bicarbonate therapy should not be routinely administered.

Gastric Decompression

Gastric decompression should be performed at the same time as the other components of shock therapy.[49] Gastric decompression improves cardiac output and arterial blood pressure by relieving caudal vena cava and portal vein occlusion. An orogastric tube is premeasured from the point of the nose to the last rib, and a tape mark is made on the tube so that when it is passed it is not advanced too far. Placing the animal in different positions (sitting, on a tilt-table, or with front legs elevated on a table) may help to advance the tube by shifting the weight of the abdominal viscera. A well-lubricated tube is advanced with firm pressure and in a twisting motion. If an orogastric tube will not pass, then intragastric pressure should be reduced by gastrocentesis. Gastrocentesis is performed in an aseptically prepared area caudal to the costal arch on the right flank with several 16-gauge hypodermic needles. The region should be percussed to determine the location of the spleen. Relief of intragastric pressure by gastrocentesis will usually allow passage of an orogastric tube. Once positioned, the tube is used to remove as much gastric liquid and gas as possible. Gastric lavage using warm water may help to remove ingesta. One should note whether there is evidence of blood in the gastric contents.[1]

To facilitate intubation, the animal may be lightly sedated with diazepam (0.1 mg/kg IV) plus either butorphanol (0.5 mg/kg IV) or oxymorphone (0.1 mg/kg IV).[43] If the stomach tube still cannot be passed after gastrocentesis, temporary decompression may be achieved by performing a temporary gastrostomy. However, this procedure carries a high risk for peritoneal contamination and must be closed before the permanent gastropexy is performed.

Surgery

Several studies show no association between the time from admission to a clinic to the time of surgery and outcome.[4,5] The presence of gastric necrosis at surgery is, however, associated with a much higher risk of dying.[4-6] If there is no blood present in the gastric contents, it may be advantageous to stabilize the patient's condition for a few hours, or even overnight, before performing corrective surgery and gastropexy.[1] If the stomach is twisted, it will continue to have impaired mucosal perfusion even with de-rotation[50]; therefore, surgery should only be delayed as long as is necessary to make the patient the best anesthetic risk possible. The benefits of delaying surgery are that surgery can be performed at a convenient time, the dog can be safely transported to a referral center, and a full

preoperative diagnostic evaluation can be performed.[49] A pharyngostomy tube may be used to maintain gastric decompression. For example, if immediate surgery is not possible and the stomach dilates rapidly again after decompression, the stomach tube can be exteriorized through a pharyngostomy approach. The disadvantages of delaying surgery include failure to detect necrosis or leakage of gastric contents, emergence of more serious cardiac arrhythmias, and continued damage to the gastric mucosa. An electrocardiogram should be monitored to detect cardiac arrhythmias.

If blood is found in the gastric contents, surgery should be performed as soon as the patient is capable of withstanding anesthesia because of the danger of gastric wall devitalization and perforation because of devitalization. The stomach is repositioned and if necessary devitalized gastric wall tissue is resected, or preferably to prevent perforation and abdominal contamination, a partial gastric invagination technique may be performed.[51] If there is splenic necrosis or significant splenic infarction, partial or complete splenectomy should be performed. A permanent gastropexy is performed to prevent recurrence of GDV. Many surgical procedures have been developed to permanently attach the stomach to the body wall and prevent recurrence of GDV.[52,53] These include tube gastropexy,[54,55] circumcostal gastropexy,[56-60] muscular flap gastropexy,[61] belt-loop gastropexy,[62] and incisional gastropexy.[63,64] Randomized controlled trials comparing different types of gastropexy have not been conducted. The choice of a particular technique often depends on individual preference. Probably the most critical factors in success rate are the surgeon's familiarity with a technique and ability to perform it proficiently and in a timely manner.[2] Failure rates are in the range of 3% to 8%. Right-sided percutaneous gastrostomy is not recommended as a means of prophylactic gastropexy despite the use of that procedure for nutritional management in other situations.[65] Corrective pyloric surgery is no longer recommended.[52,66] Intermittent gastric dilation may occur after gastropexy.[64,67]

Ischemia–Reperfusion Injury

Restoration of tissue perfusion and oxygenation can initiate deleterious biochemical reactions that contribute to further tissue damage. This phenomenon is called ischemia–reperfusion injury.[68,69] During ischemia, conditions develop that predispose to the production of oxygen free radicals upon reperfusion. First, adenosine triphosphate undergoes degradation resulting in accumulation of hypoxanthine. Second, intracellular calcium increases and activates calpain, a protease which converts xanthine dehydrogenase to xanthine oxidase. Xanthine oxidase catalyzes the conversion of hypoxanthine into superoxide radicals in the presence of oxygen. Superoxide radicals are converted into hydrogen peroxide by superoxide dismutase. Superoxide radicals and hydrogen peroxide react, forming hydroxyl radicals. During reperfusion an overabundance of free radicals are generated, which overwhelms the normal antioxidant defense mechanisms (superoxide dismutase, catalase, glutathione peroxidase, α-tocopherol, ascorbate, beta-carotene). The hydroxyl radical is a potent oxidizing agent, which initiates cell membrane lipid peroxidation. This results in increased cell membrane permeability, increased microvascular permeability, tissue edema, inflammatory cell influx, hemorrhage, and mucosal necrosis. Neutrophils play a major role in the pathophysiology of reperfusion injury. Neutrophil activation and degranulation leads to synthesis and release of numerous enzymes (proteases) and oxygen-free radicals. Inhibition of neutrophil adhesion or neutrophil depletion has been shown to reduce or prevent GI tract injury. Intestinal mucosal injury can be attenuated by both protease inhibitors and scavengers of oxygen free radicals.

Lipid peroxidation activity in the duodenum, jejunum, colon, liver, and pancreas was significantly less during reperfusion in dogs with experimentally induced GDV treated with a lipid peroxidation inhibitor.[70,71] Free radical scavengers such as deferoxamine and allopurinol may also protect abdominal organs against reperfusion injury. These results suggest that use of drugs that prevent lipid peroxidation (e.g., lazaroids such as U74389G) may be useful for reducing the mortality associated with GDV. These agents work best if given before reperfusion occurs, that is, prior to untwisting a volvulus.

Cardiac Arrhythmias

Arrhythmias are a common sequela of GDV and usually begin 12 to 36 hours postoperatively.[72,73] Electrocardiographic monitoring should be performed in all GDV patients throughout hospitalization. Ventricular tachyarrhythmias (premature ventricular contractions, paroxysmal ventricular tachycardia, and multifocal ventricular tachycardia) are most frequently described.[72-74] They are generally self-limiting and resolve after 2 to 4 days.[35] The mechanisms that initiate and maintain these arrhythmias are varied and include acid–base abnormalities, electrolyte abnormalities, autonomic imbalances, myocardial depressant factors, and myocardial ischemia.[72] Cardiac damage is common as evidenced by increased serum concentrations of troponin.[75] They should be treated if they are severe enough to decrease cardiac output, that is, the origin is multifocal, ventricular rate exceeds 160 beats/min, pulses are weak, shock is present, or subsequent premature beats are inscribed on the wave of the previous complex (R on T phenomenon).[35,36] Intravenous lidocaine is the preferred antiarrhythmic drug. Lidocaine is administered in boluses of 2 mg/kg up to a total dose of 8 mg/kg IV; if this is successful then an IV drip at 50 to 75 μg/kg/min is used as a constant rate infusion. If lidocaine is ineffective, procainamide may be administered slowly IV as a bolus at 10 to 15 mg/kg or as a continuous IV infusion at 25 to 60 μg/kg/min. Contributing factors (to the arrhythmias) should be corrected. Hypokalemia, acidosis, and hypoxia promote arrhythmogenesis and the patient becomes resistant to antiarrhythmic therapy and, therefore, must be resolved with treatment.[1] The presence of cardiac arrhythmias may not be associated with an unfavorable outcome.[4,5] In contrast, others have reported mortality rates as high as 38% in dogs with preoperative cardiac arrhythmias.[6]

Postoperative Care

Fluid, electrolyte, and acid–base status should be monitored postoperatively. Fluid therapy is based on clinical findings. Shock that persists into the postoperative period must be treated vigorously with crystalloid fluids. Whole blood and plasma must be administered to maintain the PCV and total protein above critical levels. Intravenous fluid therapy is continued until hydration can be maintained by oral fluid intake. Hypokalemia is common and requires potassium supplementation. Sepsis and DIC are also potential complications.[76] Gastritis secondary to mucosal ischemia is also common and may result in gastric hemorrhage or vomiting. Antiemetic agents and histamine H_2-receptor blockers (e.g., cimetidine, ranitidine, or famotidine) may be beneficial to control vomiting and to decrease gastric acidity. Ranitidine may also promote gastric emptying.[77] Metoclopramide may be useful as an antiemetic agent, but would be unlikely to promote increased gastric emptying.[78] Cisapride is recommended as a prokinetic agent to improve gastric emptying in dogs with GDV but is available only through compounding pharmacies.[79,80] If mosapride and pruclaopride are available in regional practices, they are now considered superior to cisapride.

Prognosis

The prognosis for GDV in general is guarded, and dependent upon how quickly the condition is diagnosed and treated. Mortality rate for dogs receiving current treatment recommendations for GDV is approximately 15%.[43] Early therapy improves the prognosis, whereas a delay lasting more than 5 hours between onset of signs and presentation to the veterinarian's office worsens the prognosis. Hypothermia at admission, preoperative cardiac arrhythmias, increased preoperative blood lactate concentrations, gastric wall necrosis, severe DIC, partial gastrectomy, splenectomy, and postoperative development of acute renal failure seem to worsen the prognosis.[42] The presence of gastric necrosis can be predicted by measuring plasma lactate concentration, with a value greater than 6 mmol/L having a specificity of 88% and a sensitivity of 61% for necrosis.[81]

Several studies have been conducted to examine survival and recurrence data following acute GDV. Dogs depressed or comatose upon admission were three and 36 times, respectively, more likely to die than alert cases, whereas cases with gastric necrosis were 11 times more likely to die.[4] Recurrence rate ranges from 54.5% to 75.8% for those cases that do not have gastropexy and from 4.3% to 6.6% for those that do.[4,64,82,83] Thus, a gastropexy should be performed even when conservative management successfully alleviates the gastric malpositioning. In another prospective study, the recurrence rate of GDV was 9% after circumcostal gastropexy and 20% after gastrocolopexy (not significantly different between treatments).[84]

In dogs at high risk for GDV, it is prudent to consider gastropexy as an elective surgery to prevent GDV. Circumcostal gastropexy has not been shown to delay gastric emptying nor to alter gastric myoelectric activity.[23,85] Gastropexy would be effective in preventing a first episode of GDV in a genetically predisposed dog. Owners of high-risk breeds, for example, Bloodhounds and Great Danes, should be advised to consider prophylactic gastropexy at the time of elective surgical neutering.

Chronic Gastric Volvulus

Etiology

Chronic gastric volvulus[22,86,87] is less common and more difficult to recognize than acute GDV.[1] The causes for partial, intermittent, or chronic gastric volvulus may be the same as for acute GDV.[42]

Pathophysiology

Malpositioning of the stomach may be constant or intermittent. These dogs do not present with the life-threatening characteristics of acute GDV. Between bouts, dogs may appear normal. Some dogs are asymptomatic despite having chronic volvulus with gastric displacement.

Clinical Examination

Vomiting with or without abdominal distention and/or pain may be reported. The signs may be intermittent and mild so that the diagnosis of chronic gastric volvulus is not considered initially. Affected dogs may vomit food several hours after eating, but otherwise feel well. Anorexia and/or weight loss may occur.

Diagnosis

Multiple radiographs are needed over a period of days or weeks to confirm the diagnosis.[1] Contrast studies may also be helpful to confirm malpositioning of the stomach. Chronic volvulus is rarely diagnosed by endoscopy.[42]

Treatment

Surgical repositioning and gastropexy to adhere the stomach to the body wall to prevent subsequent gastric volvulus are required.

Prognosis

The prognosis is good once the problem is diagnosed and surgically corrected.

Gastric Foreign Bodies

Etiology

Simple Foreign Objects

Vomiting caused by foreign body ingestion is very common in dogs (especially puppies) and less so in cats because of their more discriminating eating habits. Many gastric foreign bodies are eliminated by vomiting, dissolved by gastric acid, or passed uneventfully through the GI tract. Approximately 50% of the objects retained in the stomach cause vomiting.[88] Unless an object obstructs the outflow or irritates the mucosa, it can remain in the stomach for months without clinical signs. Thus, not all vomiting animals in which a gastric foreign body is discovered are vomiting because of the foreign body.

Linear Foreign Objects

Linear foreign objects may have one end lodged in the pylorus with intestinal pleating at the leading edge of the foreign body.[89] Rapid diagnosis is preferred because of the potential for duodenal perforation and subsequent peritonitis.

Hairballs

Hairballs are common and form in cats of all ages. They are often recurring problems.

Pathophysiology

Vomiting may result from gastric outlet obstruction because of mechanical blockage at or near the pylorus.[1] Occasionally, a foreign body that obstructs the pylorus and causes severe clinical signs may be dislodged by vomiting, yet remain in the stomach. Cyclic signs may develop as the foreign body reobstructs the pylorus. Chronic pyloric obstruction can cause delayed gastric emptying with postprandial gastric distention and discomfort, vomiting of food more than 8 hours after a meal, and weight loss.[88] Some animals may be asymptomatic and/or anorexic without vomiting. Hair should empty from the stomach during the fasting state by a motility pattern similar to the MMC in dogs.[90] Gastric retention of hair, with subsequent formation of hairballs, may reflect abnormal gastric motility.

Clinical Examination

Acute onset of vomiting in an otherwise normal animal, especially a puppy, is typical. Cats with hairballs may vomit food many hours after eating.

Diagnosis

Diagnosis is based on history (seeing the animal eat something or have an acute onset of vomiting after a toy or object disappears), physical examination (palpation of the object), radiography (survey abdominal radiographs may demonstrate radiopaque objects whereas a barium contrast study may be needed to demonstrate a filling defect if the object cannot be visualized), and/or endoscopy. Clinical pathology sometimes reveals hypochloremic, hypokalemic

metabolic alkalosis as significant complications of gastric outlet obstruction.[1]

However, these changes may be absent in animals with gastric obstruction and present in animals without obstruction.[42]

Treatment

Foreign objects may be removed surgically, or endoscopically to avoid the morbidity and risks associated with surgery. Useful endoscopic retrieval forceps include rat-tooth, snare, and basket forceps. It is helpful to insufflate the stomach with air to dilate the gastroesophageal sphincter. Alternatively, some foreign objects may be allowed to pass through the alimentary tract back into the environment (e.g., even glass, needles, and fish hooks), or the animal may be given an emetic agent to stimulate vomiting if the object does not have sharp edges or points and is small enough to pass easily.[42] There are risks, however, that the object may cause obstruction or perforation of the small intestine if allowed to pass, or esophageal laceration if vomiting is induced. Common sense and good communication skills with the client are essential. It is often preferable to remove objects by surgery or endoscopy to avoid potential complications. If the foreign object is fixed at the base of the tongue and has been present for less than 2 to 3 days, and if the patient does not have evidence of peritonitis, it is reasonable to cut the object at its point of attachment to see if it will pass through the GI tract uneventfully.[91] However, the patient must be monitored for signs of abdominal pain or depression (indications for surgery). One may also attempt to remove the foreign object endoscopically if present for less than 2 to 3 days, especially if it is a thick mass of cloth or cotton. It is possible to rupture a previously intact intestine, however, if one applies traction to a linear foreign object that has already compromised the intestine. One should not hesitate to proceed to surgery if the risk of perforation seems significant.[1] Before the animal is anesthetized for surgery or endoscopy, it is best to evaluate the electrolyte and acid–base status because hypokalemia, for example, predisposes to cardiac arrhythmias and should be corrected before anesthesia is induced.[42] A final set of radiographs are always obtained before anesthesia to ensure that the object is still in the stomach.

Prognosis

The prognosis is generally good if the obstruction can be removed. The prognosis is more guarded if there is septic peritonitis secondary to gastric perforation. Hairballs are often recurring problems, and preventive measures (petroleum-based lubricants and frequent grooming) are important to avoid repeated problems.[88]

Congenital and Adult Forms of Antral Pyloric Hypertrophy

Etiology

Stenosis of the pyloric canal is one of the more common causes of gastric outlet obstruction.[92] The narrowing can be caused by hypertrophy of the circular muscle of the pylorus, by hyperplasia of the antropyloric mucosa, or by a combination of both muscular and mucosal thickening. Hypertrophy of the pyloric muscle exclusively is the least common form of the disease and usually is seen as a congenital disorder in Boxers, Bulldogs, and Boston Terriers (see Chapter 62).[93,94] This disorder is referred to as congenital pyloric stenosis, benign muscular hypertrophy, benign antral muscular hypertrophy, benign muscular pyloric hypertrophy, congenital hypertrophic stenosis, and congenital pyloric muscle hypertrophy.[95] Most adult dogs with stenosis of the pyloric canal are affected by either hypertrophy of the mucosa exclusively or by a combination of muscular and mucosal hypertrophy. The hypertrophic mucosa may be focal (a polyp or single mucosal fold), multifocal (multiple polyps or folds), or generalized (involving the entire pyloric antrum). Synonyms for the adult syndrome include acquired antral pyloric hypertrophy, chronic antral mucosal hypertrophy, chronic hypertrophic pyloric gastropathy, acquired pyloric stenosis, pyloric or gastric mucosal hypertrophy, chronic hypertrophic gastritis, multiple polyps of the gastric mucosa, and acquired hypertrophy.[95] For simplicity, it has been suggested that the disorder be referred to as congenital and adult forms of antral pyloric hypertrophy in recognition of the two ages of dogs affected, the involvement of the antrum in addition to the pylorus, the hypertrophic nature of the lesions, and the probability of nonspecific etiology.[93]

Adult forms of antral pyloric hypertrophy affect older, predominantly male dogs of the smaller breeds (e.g., Lhasa Apso, Pekingese, Maltese, Shih Tzu; see Chapter 62).[1,93,96-100] Histopathologic changes include hypertrophy of the mucosal or muscular layers of the pylorus, or both, with or without inflammation. Hyperplastic gastropathy has also been reported in the cat.[101]

Congenital antral pyloric hypertrophy is less common than acquired antral pyloric hypertrophy. The cause is unknown. Most affected dogs are male, young to middle-aged, brachycephalic or small breeds. The congenital form may also be seen in cats.[102]

Pathophysiology

The cause of muscular hypertrophy is unknown, although neuroendocrine (hypergastrinemia) and stress-related causes have been postulated, because many of the cases are observed in highly excitable and nervous small breeds.[103] Mild congenital pyloric stenosis or dysfunction could lead to gastric distention that in turn would stimulate gastrin secretion. Gastrin's trophic effects on pyloric musculature would eventually exacerbate the disease by encouraging pyloric muscular hypertrophy.[93] Neural dysfunction may be the underlying cause of abnormal antral motility. Acute stress, inflammatory disease, or trauma may stimulate the sympathetic innervation, reducing gastric motility and thereby causing retention. Distention associated with delayed gastric emptying may then lead to increased gastrin secretion and subsequent hypertrophy.[95]

The cause of acquired antral mucosal hypertrophy is also unknown. It may result from mucosal irritation because of chronic retention of indigestible material.

Clinical Examination

Vomiting with or without weight loss is the most common clinical sign. Dogs often have been vomiting intermittently for several months to years, and the frequency of vomiting increases as the obstruction worsens. The vomiting often occurs many hours after eating, usually contains food, and may be projectile.[93] Some cats may vomit so much that secondary esophagitis, megaesophagus, and regurgitation occur.[42,104] Clinical pathology sometimes reveals hypochloremic, hypokalemic metabolic alkalosis, but this is inconsistent and nonspecific for this disorder.[42]

Vomiting is usually first observed in animals with congenital pyloric stenosis shortly after weaning or at an early age. The animal is usually hungry but thin and often reingests the vomitus. Chronic intermittent vomiting usually becomes more severe with time.

Diagnosis

Positive-contrast radiographic studies are useful in documenting gastric outflow obstruction. Ultrasonography can help identify a thick hypoechoic layer of pyloric muscle and a thickened gastric wall.[105] The diagnosis is suggested by the endoscopic appearance of enlarged

mucosal fold(s) surrounding the pyloric orifice and by exclusion of other causes, for example, neoplasia, by mucosal biopsy.[106] Endoscopic biopsies are usually of sufficient quality to detect mucosal changes characteristic of the disease, but the changes are subtle.[106,107] At surgery, with congenital muscular hypertrophy, the serosa is grossly normal, but the pylorus feels thickened upon palpation. With acquired antral mucosal hypertrophy, there should be no evidence of submucosal infiltration (suggestive of neoplasia) or muscular thickening (suggestive of congenital muscular hypertrophy).

The radiographic features of pyloric stenosis include gastric distention, delayed gastric emptying time, pyloric filling defects, a narrow and blunted pyloric canal, or failure of contrast to fill the pyloric canal and empty into the duodenum. Stenosis may result in a "beak sign" when barium appears as a beak-like projection entering the pyloric canal. The canal may also appear elongated and narrow, with a string of contrast passing through. In some cases only barium mixed with food demonstrates an obstruction, whereas liquids pass through the pylorus uneventfully. Once gastric outlet obstruction has been documented, pyloric hypertrophy is diagnosed by finding muscular thickening (with perhaps redundant mucosal folds). Redundant mucosal folds may resemble a submucosal neoplasm, thus biopsy is necessary for a definitive diagnosis to rule out neoplasia.

Treatment

Surgery is the treatment of choice for these benign lesions. The goal is to remove the obstruction and reestablish normal gastric emptying.[95] A full-thickness biopsy must be taken to ensure that the thickening is benign. Redundant tissue is resected in combination with a pyloroplasty or a pyloric antral resection (e.g., Y-U pyloroplasty or Billroth I procedure).[95,96,108,109] Some clinicians prefer pyloromyotomy because it has fewer potential complications.[98] Pyloromyotomy is easier to perform than pyloroplasty, but does not seem as reliable in enlarging the pylorus, and is therefore not recommended.[95,98,110]

Prognosis

Surgery should be curative. The prognosis is excellent if there are no postoperative problems.[1,111,112] A poor outcome may result if there is dehiscence or leakage, or when an inappropriate surgical technique is performed.[95]

Gastric Neoplasia

The role of gastric neoplasia in gastric outflow obstruction is detailed in the "Neoplasia" section.

Gastric Phycomycosis

The role of gastric phycomycosis in gastric outflow obstruction[113-116] is detailed in the "Gastric Infection" section.

Miscellaneous Causes of Gastric Obstruction

Cryptococcosis resulting in a granulomatous gastritis mimicking carcinoma has been reported in a Doberman Pinscher as a cause of gastric outlet obstruction.[117] Granulomatous gastritis and severe eosinophilic gastritis can also cause pyloric obstruction. Duodenal–gastric intussusception is uncommon, but has been reported in the dog.[118] Hepatic or pancreatic abscesses may result in pyloric obstruction via external compression. Endoscopy or exploratory laparotomy and biopsy are required for definitive diagnosis. Treatment and prognosis depend upon the underlying cause. GI prokinetic agents are contraindicated in treating patients with mechanical obstruction of the pylorus.[119]

Iatrogenic gastric outflow obstruction in two dogs appeared to be caused by prior gastric surgery. This may be prevented by minimizing tissue inversion into the gastric lumen when surgery is performed near the pyloric outflow tract. It is important to preserve the continuity of the outflow tract when large lesions near the pylorus are resected surgically.[111]

DYSMOTILITY

Robert J. Washabau and Jean A. Hall

Gastric Physiology

Anatomically, the stomach is composed of five distinct anatomic components: cardia, fundus, corpus, antrum, and pylorus. Physiologically, the stomach can be thought of as a two-component model: a proximal stomach (cardia, fundus, first one-third of the corpus) characterized by slow tonic contractions, and a distal stomach (distal two-thirds of the corpus and antrum) characterized by phasic propagating contractions (Figure 56-10).[1] Slow waves without action potentials give rise to the sustained tonic contractions of the proximal stomach. During swallowing, gastroesophageal sphincter and intragastric pressure decrease to accommodate emptying of solids and liquids. This phenomenon, referred to as *receptive relaxation*, takes place with each swallow, and as a consequence, large volumes can be accommodated with minimal increases in intragastric pressure. The proximal stomach becomes much less compliant with fundic disease or fundectomy.

A pacemaker site in the proximal fundus of the greater curvature generates action potentials and phasic contractions that propagate from the site of origin circumferentially and distally to the pylorus.[2] During feeding, phasic contractions of the distal stomach trigger a repetitive cycle of propulsion, trituration, and retropulsion that progressively reduce the size of the ingesta. Thus, the peristaltic qualities of the distal stomach regulate the emptying of solid particles into the duodenum. Antral disease or antrectomy abolishes this physiologic effect resulting in a "dumping syndrome" because of accelerated gastric emptying, nutrient overload in the small intestine, and an osmotic type of diarrhea.

Gastric emptying is regulated by several physiologic parameters, including (a) pyloric resistance and pressure differential between the

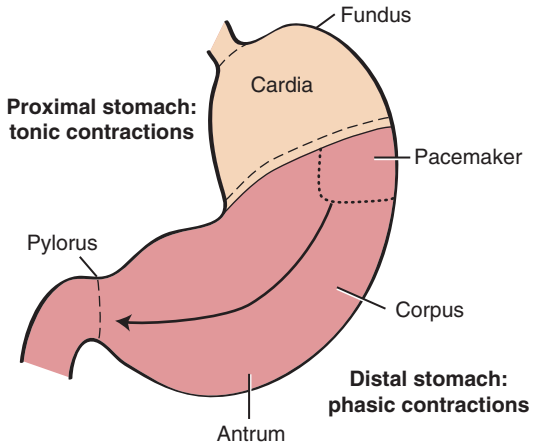

Figure 56-10 Functional model (proximal and distal) of the stomach.

stomach and duodenum; (s) water content—liquids are emptied more rapidly than solids; (c) nutrient composition—carbohydrates are emptied more rapidly than proteins, which, in turn, are emptied more rapidly than lipids; (d) nutrient acidity—delayed at acid or alkaline pH; (e) nutrient osmolality—delayed at high osmolality; and (f) hot or cold temperatures. Duodenal, jejunal, and ileal braking mechanisms also feedback inhibit gastric emptying through activation of mucosal sensory receptors for fatty acids, tryptophan, osmolality, and acid. Intestinal braking mechanisms serve to prolong transit time and nutrient contact time.[1]

During the fasting state the stomach is ordinarily empty, aside from swallowed saliva, a small amount of mucus, and cellular debris that collects in the gastric lumen. In addition, there may be particles of indigestible solids left over from the previous meal. A special mechanism exists to empty this fasting content called the MMC. The ability of the MMC to completely empty the stomach of its residue is so striking that it is sometimes referred to as the "interdigestive housekeeper" of the GI tract.[1] The GI hormone, motilin, is involved in the regulation of this MMC pattern. Cats and rabbits do not have a MMC, and instead have a less-vigorous emptying pattern known as the *migrating spike complex*.[3,4]

Clinical Signs of Disease

Delayed gastric emptying most often results in the clinical signs of gastric distention and retention of food and vomiting. A gastric motility disorder should be considered when there is a history of chronic vomiting. Vomiting may or may not be associated with feeding. Typically, vomiting of undigested or partially digested food is observed 8 to 10 hours after feeding, at a time when the stomach should be empty of ingested solids. The character of the vomitus is dependent on time lapse since the last meal, degree of gastric trituration, amount of gastric secretions, and extent of hydrolytic digestion. Other signs of a gastric motility disorder may include anorexia, belching, polydipsia, pica, and weight loss. Animals may occasionally assume a position of relief referred to as the "praying posture" to relieve gastric pain. The physical examination may be normal or may reveal findings associated with the underlying disease process. Abdominal distention may be present, increased bowel sounds may be noted with abdominal auscultation, and nonspecific pain may be evoked on abdominal palpation. Palpable abdominal masses are most consistent with intestinal or other visceral neoplasia, foreign bodies, and intussusceptions. Neuromuscular abnormalities may also be observed in dogs with severe electrolyte or metabolic derangements secondary to chronic vomiting.

Pathophysiology of Gastric Outflow Obstruction

Anatomic lesions of the pylorus and adjacent duodenal segment impede gastric emptying because of mechanical obstruction (Figure 56-11).[5,6] In general, diagnosis of mechanical obstruction is usually straightforward and involves survey and contrast radiography, ultrasonography, or gastroscopy. Mechanical or anatomic obstructions of the stomach are discussed in great detail in the "Gastric Obstruction" section.

Pathophysiology of Functional Gastric Motility Disorders

See Figure 56-11 for the management of gastric outflow obstructions and gastric emptying disorders.

Accelerated Gastric Emptying

The best example of an accelerated gastric emptying disorder is the vomiting associated with the hyperthyroxinemia of feline hyperthyroidism. Hyperthyroxinemia induces a tachygastria and accelerated

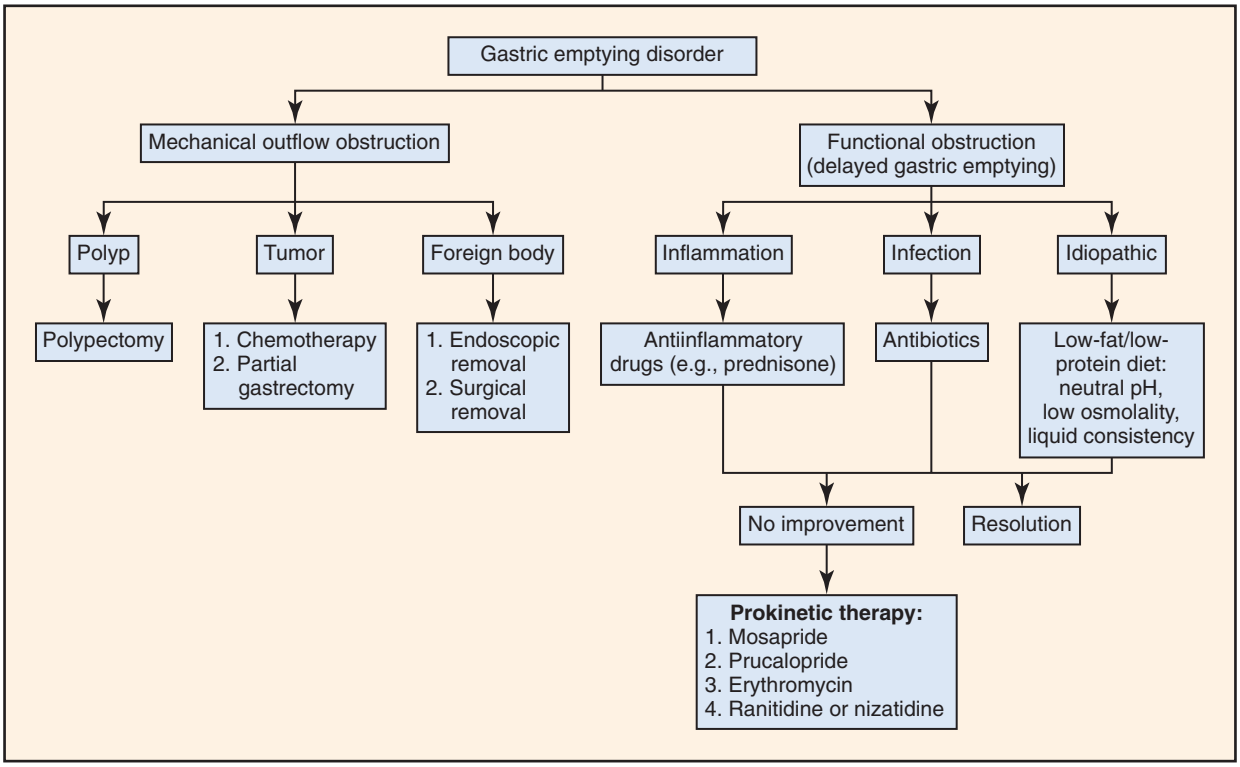

Figure 56-11 Management of gastric outflow obstruction and the delayed gastric emptying disorders.

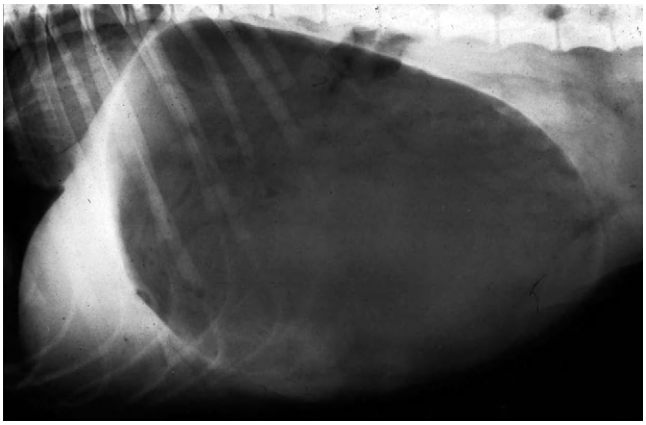

Figure 56-12 Severe gastric distention that persists following dilation and volvulus.

gastric emptying. Normal gastric emptying rhythm is restored following successful treatment of hyperthyroidism. Accelerated gastric emptying occasionally occurs in dogs following antral and/or pyloric resections for the treatment of gastric cancer. A postprandial "dumping syndrome" develops in these animals characterized by acute vomiting, abdominal pain, and diarrhea.

Retrograde Transit

Gastroesophageal reflux and duodenogastric reflux are the two best examples of retrograde transit disorders. Gastroesophageal reflux is an increasingly recognized clinical disorder in the dog, although clinical signs are more related to esophageal dysfunction.[7] Duodenogastric reflux may be the underlying pathogenesis of the so-called bilious vomiting syndrome in the dog. Affected animals tend to vomit small amounts of bile in the morning following an overnight fast.

Delayed Gastric Emptying

Delayed gastric emptying is now recognized as an important cause of upper GI tract signs.[8,9] Delayed gastric emptying has been reported in animals recovering from GDV (Figure 56-12), infectious and inflammatory gastric diseases, experimental gastric ulcer, and radiation gastritis. It has also been associated with several secondary conditions, including electrolyte disturbances (e.g., hypokalemia), metabolic disorders (e.g., hypoadrenocorticism, uremia, diabetes mellitus), concurrent drug usage (e.g., anticholinergics), and acute abdominal inflammation.[7-9]

Gastric Prokinetic Therapy

See Chapter 52 and Table 56-5 for a listing of mechanisms, sites of activity, indications, and doses of currently available GI prokinetic agents.

Dietary management should always be used as an adjunct to GI prokinetic therapy. Dietary management is based on the knowledge that liquids are emptied from the stomach more rapidly than solids, and that carbohydrates are emptied more rapidly than proteins, which, in turn, are emptied more rapidly than lipids. A low-fat, low-protein diet of liquid or semiliquid consistency should be fed at frequent intervals to facilitate gastric emptying. Diets should be selected for low acidity and low osmolality and should be fed at warm temperatures (22°C to 38°C [72°F to 100°F]). Gastric prokinetic agents should be considered in patients that fail to respond to dietary management alone.[10]

Dopaminergic Antagonistic Drugs

The dopaminergic antagonists are a group of drugs with GI prokinetic and antiemetic effects at peripheral (prokinetic) or central (antiemetic) dopamine D_2 receptors. The best representatives in this classification, metoclopramide and domperidone, reverse gastric relaxation induced by dopamine infusion in dogs, and they abolish vomiting associated with apomorphine therapy. Although the role of dopamine receptors in chemoreceptor trigger zone-induced vomiting is fairly well established, there is no definitive evidence that inhibitory dopaminergic neurons regulate GI motility. The prokinetic effects of metoclopramide and domperidone thus may not be readily or exclusively explained by dopamine receptor antagonism. Some dopaminergic antagonists (e.g., metoclopramide) have other pharmacologic properties, for example, 5-HT_3 receptor antagonism and 5-HT_4 receptor agonism. Domperidone also has α_2- and β_2-adrenergic receptor antagonistic effects. The characterization of these drugs as dopaminergic antagonists is convenient but may not properly describe their overall in vivo effects.

Serotonergic Drugs

Drugs acting on GI 5-hydroxytryptamine (5-HT or serotonin) receptors have potent motility effects. As prokinetic agents, the serotonergic drugs bind 5-HT_4 receptors on enteric cholinergic neurons inducing depolarization and contraction of GI smooth muscle. These drugs are not entirely selective for the 5-HT_4 receptor, however. Some of the putative 5-HT_4 receptor agonists also have 5-HT_1 and 5-HT_3 antagonistic effects on enteric cholinergic neurons, and direct noncholinergic (perhaps 5-HT_{2a}) effects on colonic smooth muscle. Cisapride and tegaserod were perhaps the best examples in this classification although they have been withdrawn from several markets, including the United States, Canada, and several Western European countries. Mosapride restores gastric motility in dogs with vincristine–induced gastric hypomotility, and therefore may be clinically useful in other gastric emptying disorders. Mosapride is marketed as Pronamid by DS Pharma Animal Health in Japan. Prucalopride also appears to stimulate gastric emptying in the dog. In lidamidine–induced delayed gastric emptying in dogs, prucalopride dose-dependently accelerates gastric emptying of dextrose solutions. Prucalopride is marketed as Resolor by Movetis in Europe.

The 5-HT_4 receptor appears to hold the most interest and promise for future drug development. 5-HT_4 receptor activation can cause relaxation or contraction depending on the region, cell type, and animal species. In the dog, the effects of selective 5-HT_4 receptor agonists suggest that these receptors are present on jejunal mucosa, ileal mucosa, gastric cholinergic neurons, and circular colonic smooth muscle cells. Increased motor activity following 5-HT_4 receptor activation results from increased release of acetylcholine from cholinergic neurons, and relaxation results from 5-HT_4 receptors on smooth muscle cells. Development of 5-HT_4 ligands is somewhat constrained by the effects these drugs have on cardiac 5-HT_4 receptors and the delayed rectifier potassium channel (I_{Kr}). Some, but not all, 5-HT_4 agonists prolong the Q-T interval and delay cardiac repolarization. Molecular biology experiments have revealed differences in the carboxyl terminus of smooth muscle and cardiac muscle 5-HT_4 receptors, but these amino acids differences are distant from the receptor binding site. Thus, receptor sub-types may exist but they may not be important from a functional or therapeutic standpoint.

Motilin-Like Drugs

The antibiotic properties of erythromycin and other macrolides were discovered in the early 1950s. Since then, erythromycin has been

Table 56-5 Mechanisms, Sites of Activity, Indications, and Doses of Currently Available Gastrointestinal Prokinetic Agents

Drug Classification/ Mechanism	Sites of Activity	Indications	Dose	Other Properties
Dopaminergic D_2 Antagonist Drugs				
Metoclopramide	GES, stomach, intestine, CRTZ	Vomiting disorders, gastroesophageal reflux, delayed gastric emptying, ileus/pseudoobstruction	0.2 to 0.5 mg/kg PO, IV TID; 0.01 to 0.02 mg/kg/h infusion	α_2-Adrenergic antagonist β_2-Adrenergic antagonist 5-HT_4 serotonergic agonist 5-HT_3 serotonergic antagonist
Domperidone	GES, CRTZ	Vomiting disorders, gastroesophageal reflux	0.05 to 0.10 mg/kg PO BID	α_2-Adrenergic antagonist β_2-Adrenergic antagonist
Serotonergic 5-HT_4 Agonist Drugs				
Cisapride	GES, stomach, intestine, colon, CRTZ	Gastroesophageal reflux, delayed gastric emptying, ileus/pseudoobstruction, constipation, chemotherapy-induced vomiting	0.1 to 0.5 mg/kg PO TID (doses as high as 0.5 to 1.0 mg/kg have been used in some dogs)	5-HT_3 serotonergic antagonist 5-HT_1 serotonergic antagonist 5-HT_2 serotonergic agonist
Mosapride	Stomach	Delayed gastric emptying	0.25 to 1.0 mg/kg PO BID	None
Prucalopride	Stomach, colon	Delayed gastric emptying, constipation	0.01 to 0.20 mg/kg PO BID	None
Tegaserod	Intestine, colon	Constipation, ileus/ pseudoobstruction	0.05 to 0.10 mg/kg PO or IV, BID	5-HT_1 serotonergic antagonist
Motilin-like Drugs				
Erythromycin	GES, stomach, intestine, colon	Gastroesophageal reflux, delayed gastric emptying, constipation (dogs)	0.5 to 1.0 mg/kg PO IV TID	5-HT_3 serotonergic antagonist
Acetylcholinesterase Inhibitors and Cholinomimetic Agents				
Ranitidine	Stomach, colon	Delayed gastric emptying, constipation	1.0 to 2.0 mg/kg PO BID-TID	H_2 histaminergic antagonist
Nizatidine	Stomach, colon	Delayed gastric emptying, constipation	2.5 to 5.0 mg/kg PO SID	H_2 histaminergic antagonist
Bethanechol	Esophagus	Canine idiopathic megaesophagus	Dog: 5 to 15 mg/dog PO TID	
Nitric Oxide Donors				
AMU-301	Stomach	Diabetic gastroparesis	Not yet established	
Prostanoids				
Misoprostol	Colon	Constipation	Dog: 2 to 5 µg/kg PO TID-QID	

CRTZ, chemoreceptor trigger zone; GES, gastroesophageal sphincter.

widely used in treating patients with Gram-positive and Gram-negative bacterial and mycoplasmal infections. Physicians and veterinarians noted that erythromycin therapy was accompanied by frequent GI side effects, including nausea and vomiting. This occurrence suggested to researchers that erythromycin might have effects on GI motility. It was subsequently demonstrated that microbially effective doses of erythromycin stimulate retrograde peristalsis and vomiting in dogs, and that lower microbially ineffective doses of erythromycin stimulate migrating motility complexes and antegrade peristalsis similar to that induced by the endogenous GI hormone, motilin.

Acetylcholinesterase Inhibitors and Cholinomimetic Agents

Ranitidine and nizatidine, classic histamine H_2 receptor antagonists, stimulate GI motility by inhibiting acetylcholinesterase activity. As parasympathetic potentiating agents, ranitidine and nizatidine stimulate gastric emptying and small intestinal and colonic motility. The prokinetic effects of ranitidine and nizatidine appear to be more prominent in the proximal GI tract (e.g., gastric emptying). Other members of this classification, for example, cimetidine and famotidine, apparently have no effect on GI motility. Bethanechol is a cholinomimetic agent that binds muscarinic cholinergic receptors and stimulates motility throughout the GI tract.

Nitric Oxide Donors

Diabetes mellitus is the most common endocrinopathy of the domestic dog.[11] Long-standing undiagnosed or untreated diabetes mellitus is associated with significant gastroparesis in the dog,[12,13] just as it in humans. The pathogenesis of gastroparesis in diabetes mellitus is complex and probably multifactorial, involving one or more of the cellular elements (neurons, smooth muscle cells, interstitial cells of Cajal) regulating gastric motility.[14] An important pathophysiologic mechanism appears to be the loss of neuronal nitric oxide synthase, the enzyme responsible for the production of

nitric oxide, an inhibitory neurotransmitter that is required for relaxation of smooth muscle and therefore a critical component of normal GI motility. In the absence of nitric oxide, the stomach cannot relax, resulting in bloating, satiety, nausea, and vomiting.[15]

Cisapride, metoclopramide, and erythromycin have all been used with variable effect in diabetic gastroparesis. Therapy aimed instead at restoring nitrergic neurotransmission could have intrinsic beneficial effects in canine diabetic gastroparesis. AMU-301, a nitric oxide donor, is recognized as an effective treatment for diabetic gastroparesis in streptozocin-induced diabetic rat models of delayed gastric emptying, and may eventually prove useful in spontaneous canine diabetes mellitus.[16]

NEOPLASIA

Takeo Minami

Etiology

Gastric tumors account for less than 1% of all malignancies in dogs. These tumors include gastric adenoma, adenocarcinoma,[1] leiomyoma,[2] leiomyosarcoma,[3] lymphoma,[4] carcinoid,[5] and GI stromal tumor (GIST).[6] One review of gastric tumors reported 61 cases in 10,179 dogs representing a prevalence in this population of 0.18%.[1] Although the etiology is not definitively known, long-term administration of nitrosamines may induce carcinomas in dogs.[7] A predisposition to gastric carcinoma was found in Rough Collies and Staffordshire Bull Terriers[8] and a familial occurrence of gastric carcinoma has been reported in Belgian Shepherd dogs.[9] Affected dogs range in age from 3 to 16 years (mean: 7.5 years).[10-12] One study reported a male-to-female ratio of 1:5 for adenomas and 17:7 for adenocarcinomas.[11] Males are more commonly affected with gastric lymphoma than females.[4] Leiomyomas tend to occur in very old dogs (mean age: 15 years).[13]

Pathophysiology

Most malignant gastric tumors in dogs are adenocarcinomas. The stomach is generally firm with thickened walls. Lesions can be focal or extend to involve the entire wall (Figure 56-13) and they are commonly found on the lesser curvature.[14] They tend to be polypoid and can ulcerate into the mucosa.[12] Metastases are frequently present. One report described metastasis in 14 (74%) of 19 dogs with gastric adenocarcinomas. Metastatic sites included gastric lymph nodes, the omentum, liver, duodenum, pancreas, spleen, esophagus, adrenal glands, and lungs.[14]

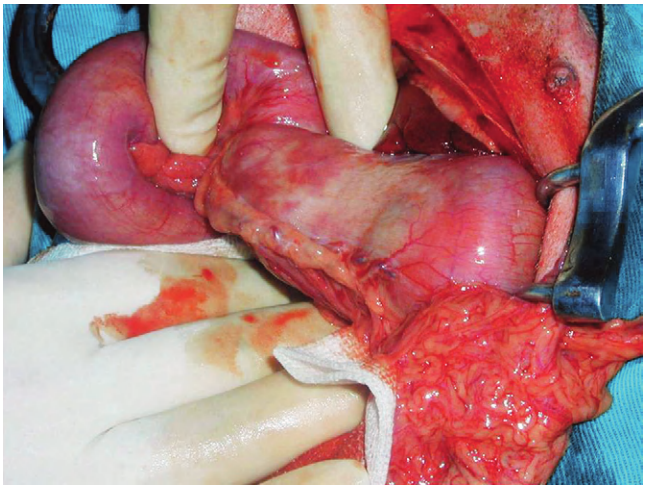

Figure 56-13 Canine gastric adenocarcinoma. The serosal surface is pale white and the gastric wall is firm and not expandable.

Other malignant gastric tumors include leiomyosarcoma, lymphoma, mast cell tumor, and fibrosarcoma. Leiomyosarcomas occur predominantly in males (82%) with a mean age of 11 years (range: 8 to 17 years). These tumors tend to metastasize and common sites include the stomach (76%), esophagus (4%), and intestine (10%). Median survival time in dogs with GI leiomyosarcoma is reported as 7.8 months.[6]

In human medicine, immunohistochemistry of GI tumors has led to reclassification of some tumor types. Some leiomyosarcomas have now been renamed as GISTs.[15] GISTs occur equally in males and females with a mean age of 11 years (range: 5 to 14 years). GISTs can occur throughout the intestine, but were located in the stomach in 19% of cases (four of 21) in one report. In that study, 52% of the tumors expressed CD117 (KIT) and 33% were positive for smooth muscle markers, but none expressed desmin or S-100 protein (Figure 56-14). In a further study, 28 (67%) of 42 leiomyosarcomas were reclassified as GISTs when new criteria were applied.[6] These GISTs were found more commonly in the cecum and large intestine. Only two of the 28 GISTs were located in stomach. With this tumor median survival time was 11.6 months in dogs without surgical intervention. Median survival for dogs with GIST was prolonged with surgery to 37.4 months.[6] One report described 29% of dogs with GIST as having metastasis to the liver or abdominal cavity at the time of diagnosis.[15]

Gastric lymphoma can be primary or represent GI involvement in the multicentric form of the disease. Gastric mast cell tumor is also documented.[16]

Lymphomas are the most common gastric tumors in cats. Most cats with gastric lymphoma are negative for FeLV.[17,18] It has been suggested that chronic *Helicobacter* infection raises the risk for gastric lymphoma in humans and ferrets. Only tentative evidence has been shown for this association in cats.

The benign proliferative lesions of the stomach include leiomyoma, hypertrophy of muscle, and adenoma.

Clinical Examination

The most common clinical sign of a gastric tumor is chronic progressive vomiting. Physical examination in patients with gastric tumor is nonspecific. Weight loss and lethargy may be due to reduced food intake, maldigestion, bleeding from mucosal ulcers or tumor cachexia. Hemorrhagic ulcers or hemorrhage from a gastric mass may lead to anemia and dark stool or melena can be present. Scleral icterus may occur if biliary drainage is obstructed. Dehydration and metabolic alkalosis may be present secondary to chronic vomiting.

Most animals with gastric tumors are relatively asymptomatic until the disease is advanced enough to disturb gastric or intestinal function (Figure 56-15). It may take several months for a small lesion to produce clinical signs and by the time of clinical presentation the tumor is often at an advanced stage.

Diagnosis

Laboratory Findings

Laboratory changes in dogs and cats with gastric tumors are usually nonspecific.

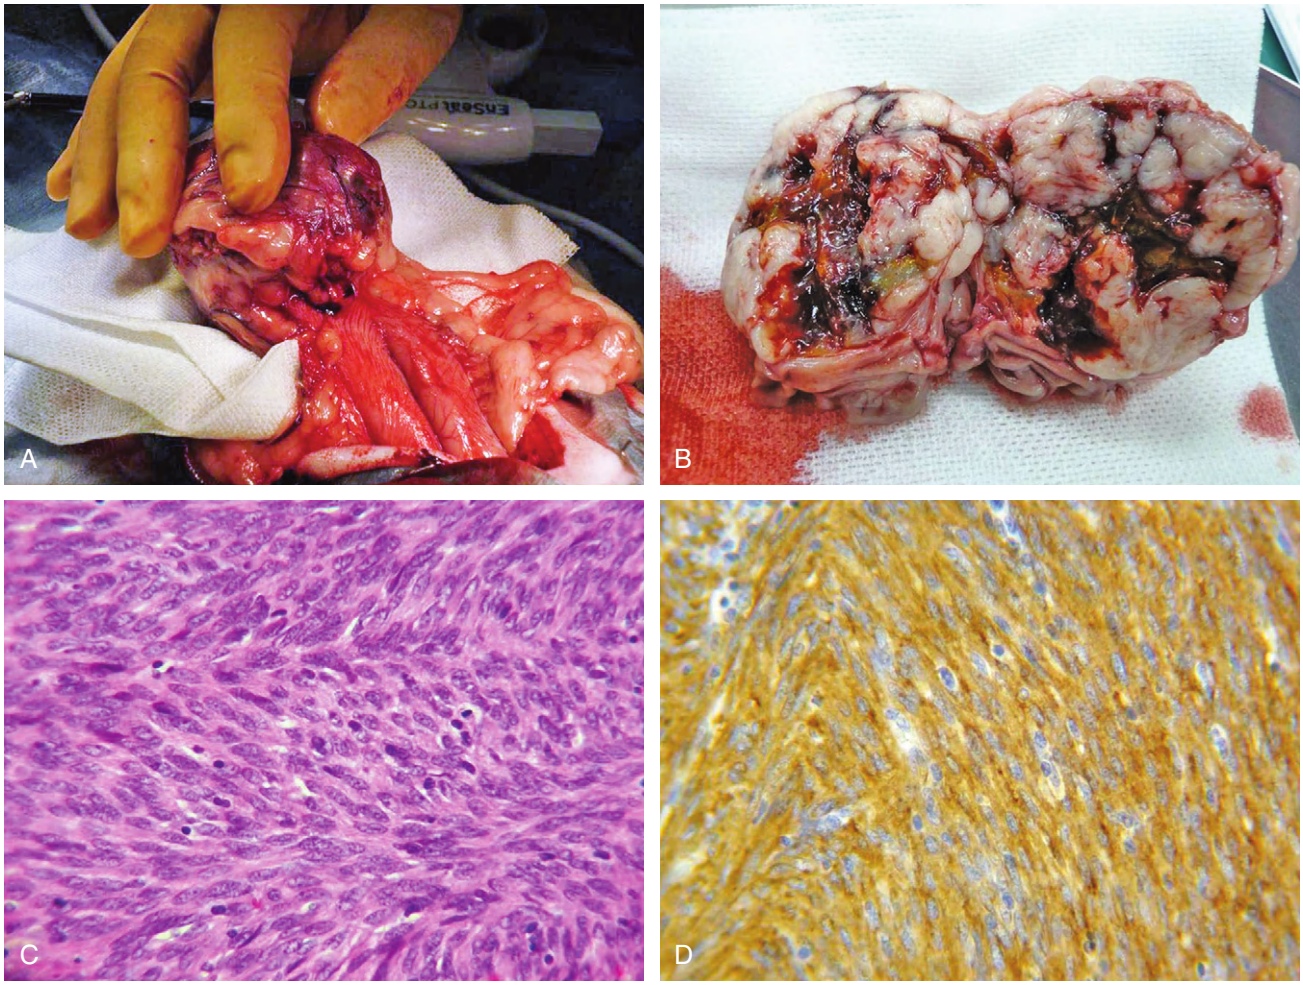

Figure 56-14 **A**, Canine gastric GI stromal tumor. The mass is pedunculated and well-circumscribed. **B**, The cut surface shows fibrous tissue and multifocal hemorrhage. **C**, The microscopic appearance is of interwoven bundles of spindle cells (hematoxylin and eosin stain). **D**, On immunohistochemistry, the cells are positive for c-kit.

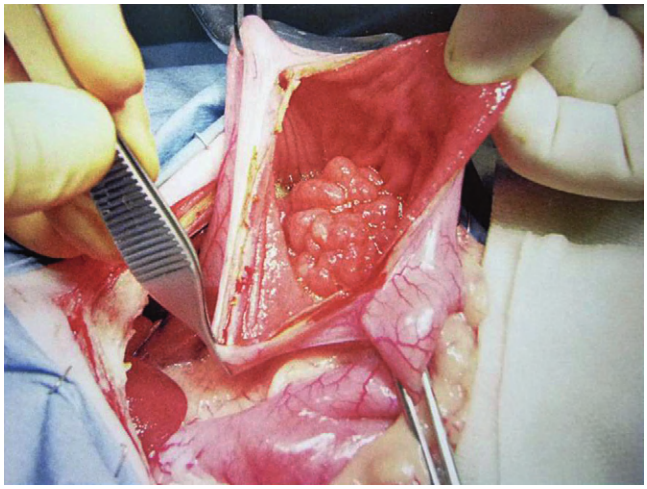

Figure 56-15 Canine gastric adenocarcinoma. This large mass occupies most of the stomach.

Diagnostic Imaging

Plain films and survey radiographs are generally nondiagnostic; however, thoracic radiographs can help rule out pulmonary metastasis. A variety of findings may be present with gastric tumors on barium studies. These include filling defects, delayed gastric emptying, ulcers, loss of normal rugal folds, mucosal thickening, or loss of gastric wall compliance. Contrast radiography is less frequently undertaken now because of the advantages that ultrasound and endoscopy have over such procedures.

Ultrasonographically, gastric neoplasia is associated with mural thickening with loss of normal wall echo texture and diminished to absent local motility. An ultrasound-guided fine-needle aspirate or needle core biopsy may provide a preoperative diagnosis in affected animals. Ultrasonography may also detect metastasis to the liver or regional lymph nodes and help to define the anatomy of gastric lesions.[19-21]

Endoscopy

Endoscopy is the preferred diagnostic test as it allows biopsy of the observed lesion. Some tumors may be difficult to sample if they are completely submucosal or if they are scirrhous. Even without a biopsy sample endoscopic evaluation of the gross appearance of the stomach can be very suggestive of neoplasia and this may help the

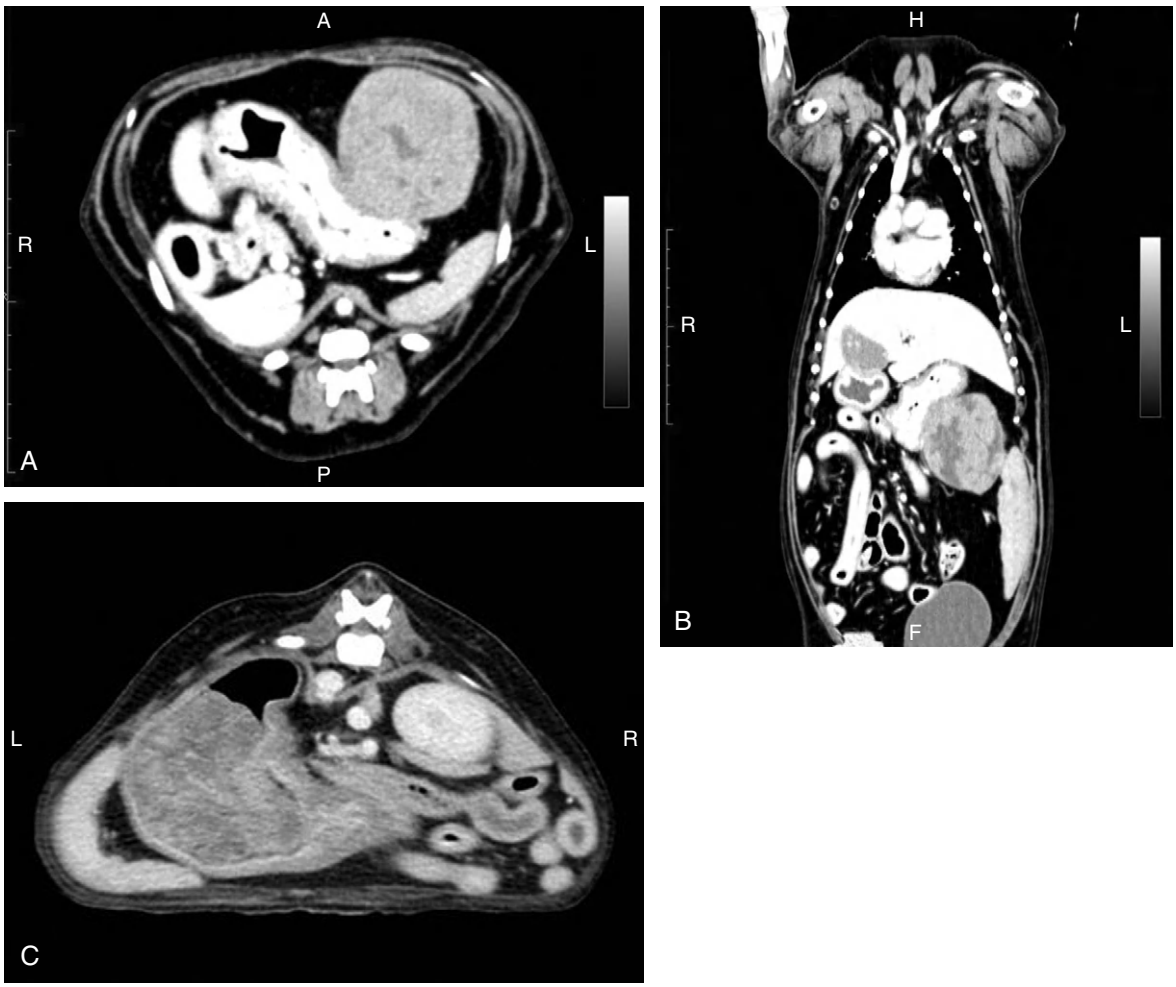

Figure 56-16 **A**, Axial CT image of canine gastric GI stromal tumor. The mass extends from the stomach and is pedunculated. **B**, Coronal CT image of canine gastric GIST. The mass is pushing against the abdominal wall, but there are no hepatic metastases. No areas of the mass are filled by contrast agent. **C**, Axial CT image of canine gastric adenocarcinoma. The mass fills the stomach cavity.

client decide if surgery is appropriate. Finding a deep ulcer with a firm, dense, necrotic base surrounded by raised or distorted mucosa is very suggestive of scirrhous carcinoma. Scirrhous tumors are very dense, and it may be impossible to sample the lesion. Because muscular tissue is located beneath the submucosa, leiomyomas and leiomyosarcomas are usually deep in location. They may or may not be associated with ulceration. These tumors are also hard to biopsy with flexible endoscopic forceps, but a diagnostic sample can usually be obtained if the sample is taken from deeper tissue.

Advanced Imaging

Computed tomography (CT) or magnetic resonance imaging allows visualization of the primary lesion, its extent, and the presence of synchronous lesions, and both local and distant metastases. The thickness of the gastric wall and the size of regional lymph nodes are seen with these techniques (Figure 56-16). Contrast enhancement can help to identify metastases as small as 1 mm in diameter in the liver, spleen, and thoracic cavity.

Treatment

Medical Management

Medical management depends on the severity of the clinical signs. If possible, electrolyte, acid–base, hydration, and coagulation abnormalities should be corrected before surgery. No effective chemotherapy is known for adenocarcinoma and sarcomas of the stomach.

Radiation therapy is rarely utilized because of the poor radiation tolerance of surrounding normal tissue (liver and intestine). Nonresectable lymphoma burden may be dramatically reduced with lower doses of radiation than required for other tumors.

In people and dogs, GISTs may be responsive to inhibitors of c-kit, and as these drugs have become available in veterinary medicine, they could theoretically have efficacy against this tumor.[16,22,23]

Surgical Treatment

Preoperative Management

Food should be withheld for 12 hours before surgery. Antibiotics may be given at the time of induction of anesthesia and continued for several days after surgery.

Surgical Technique

The patient must be under general anesthesia. An upper midline skin incision is performed to open the abdominal cavity. If there is ascites or visible metastatic lesions, cytology must be performed to look for neoplastic cells. If there are neoplastic cells, radical surgery is not optimal. At the time of surgery, the operator must search for metastatic lesions in abdominal organs, the peritoneal wall,

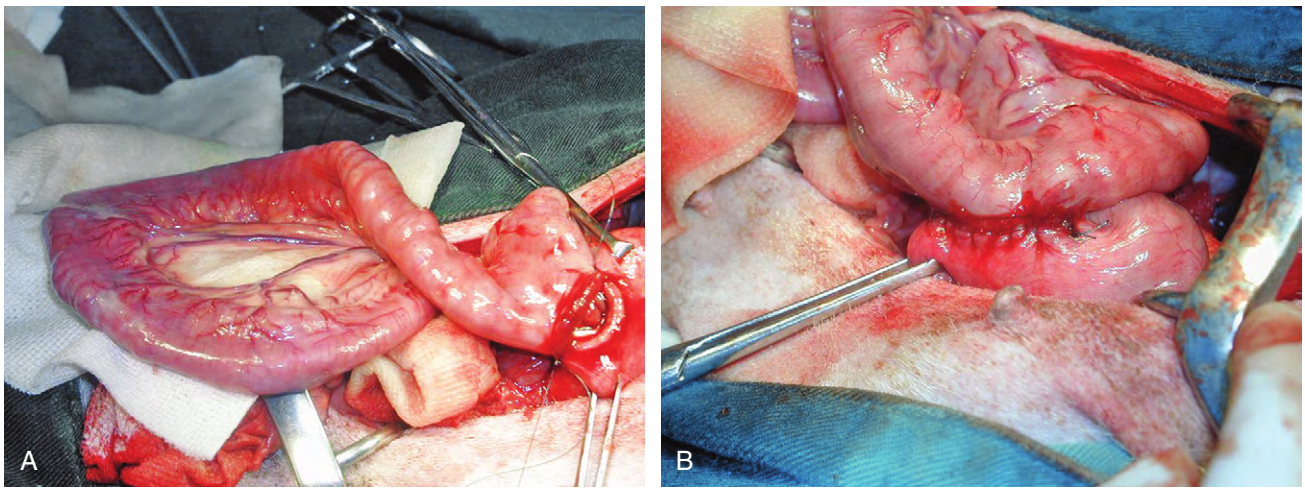

Figure 56-17 **A**, Surgical approach to gastrojejunostomy. Full-thickness incisions are made and both sides are ligated. A one-layer closure is made on both sides. **B**, The completed gastrojejunostomy.

omentum, mesentery, and lymph nodes. Excisional margins in the stomach are determined based upon the anatomy of the tumor. Stomach arteries and veins are ligated and regional lymph nodes are dissected. The stomach wall and tumor is excised (Figure 56-17). Resection strategies include a partial (proximal, body, and distal) gastrectomy and total gastrectomy. If there is a sufficient portion of the upper duodenum remaining, a Billroth 1 procedure is performed, where the remaining portion of stomach is anastomosed to the duodenum proximal to the bile duct and pancreatic duct. If the stomach cannot be anastomosed to the duodenum a Billroth 2 procedure is performed. In this procedure, the remaining portion of the duodenum is sealed off, an opening is cut into the jejunum and stomach is reattached at this point (Figure 56-17). If complete gastrectomy is needed, a Roux-en-Y method is performed. Abdominal lavage is performed and the abdominal cavity is closed.[2,24]

With the exception of lymphoma, surgery is the only potentially curative treatment for gastric tumors. Solitary gastric lymphoma is rarely cured by surgery alone, and chemotherapy is only palliative for diffuse lymphoma.

ULCER

Caroline S. Mansfield and Linda A. Abraham

Etiology

Gastric ulceration is defined as a defect in the gastric wall that extends through the muscularis mucosae into the deeper layers of the wall (submucosa or the muscularis propria). Erosion of blood vessels in this deeper tissue can lead to life-threatening hemorrhage.[1] In humans, defects are required to be greater than 0.3 cm in diameter with considerable depth to fulfill the true criteria of gastric ulceration.[2] When the disruption is confined to the mucosa and does not extend to the muscularis mucosae, it is defined as a gastric erosion.[2] Duodenal ulcers appear to be far less common in companion animals. With severe ulceration, perforation of the gastric wall may occur, leading to contamination of the peritoneal cavity.

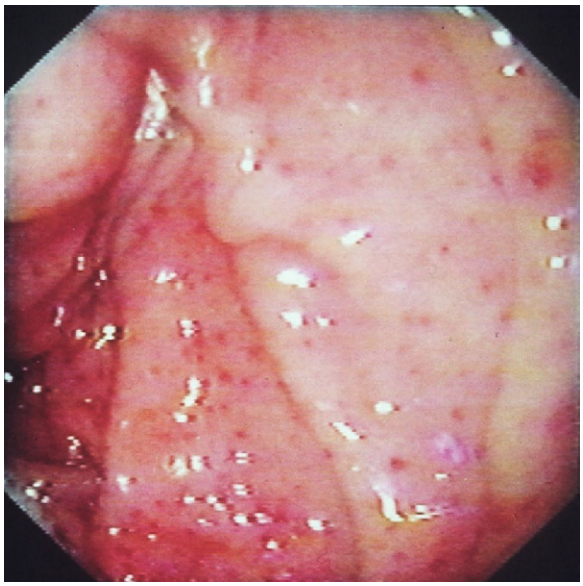

Figure 56-18 Shallow and small gastric erosions observed on endoscopy in a dog with atypical hypoadrenocorticism. They did not cause abdominal pain or noticeable blood loss.

Gastric ulceration is more commonly reported in dogs than in cats.[3-6] Many studies of gastric ulceration, particularly pharmacologic studies, define gastric ulceration as the presence of shallow erosions or ulcerations visible by endoscopy, such as is evident in Figure 56-18. These shallow erosions may not always be clinically significant, and may not truly fulfill the definition of gastric ulceration (Figure 56-19).

There are many different causes of gastric ulceration reported in dogs and cats. The most commonly reported causes in companion animals are drug-associated injury, mast cell tumors, and primary gastric tumors.[3,4,7]

Intravenous administration of high-dose corticosteroids, particularly in dogs with intervertebral disk disease, is associated with severe GI hemorrhage and ulceration.[8] NSAIDs, particularly aspirin, are also reported to cause substantial gastric ulceration.[4,7] This effect is enhanced when NSAIDs are given in conjunction with

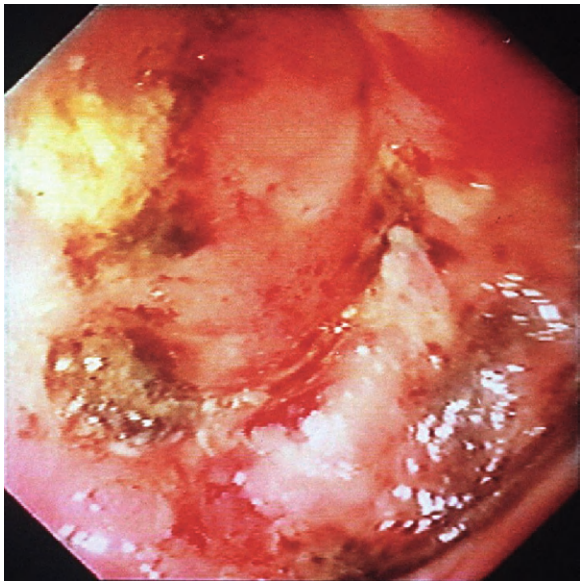

Figure 56-19 A deep and large gastric ulceration observed on endoscopy in a dog displaying signs of abdominal pain and melena. The final diagnosis was gastric adenocarcinoma.

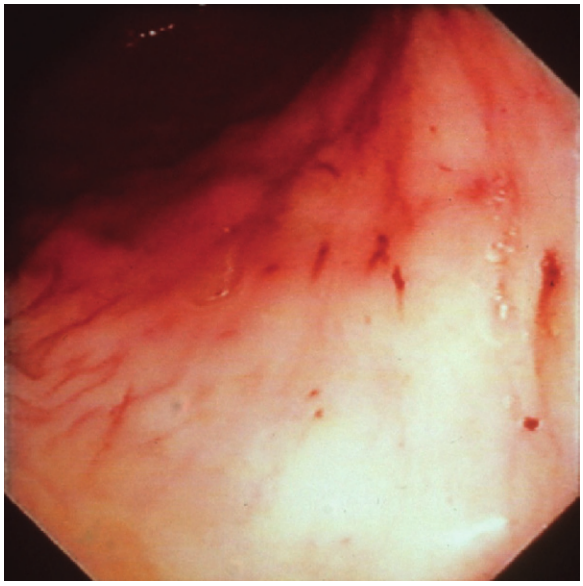

Figure 56-20 Linear gastric erosions secondary to severe vomiting in a dog. Garbage ingestion was the suspected underlying cause.

corticosteroids, and reduced when cyclooxygenase-2 selective NSAIDs are concurrently used.[2,9]

Excessive production of gastric acid (which overwhelms the protective mechanisms of the stomach) is infrequently reported in association with gastrinomas (Zollinger-Ellison syndrome), and mast cell tumors.[10-15] The resulting gastric ulceration can be quite severe. Zollinger-Ellison syndrome is characterized by gastric or duodenal ulceration, diarrhea, and gastric hyperacidity.[11-13] It is usually caused by a gastrin-producing tumor in the pancreas.

Conditions that directly disrupt the gastric mucosa can also cause significant ulceration. Gastric neoplasia is rare, accounting for less than 1% of all malignancies.[16] Primary gastric (adeno)carcinoma is the most commonly reported gastric malignancy in dogs, although leiomyomas/leiomyosarcomas, GISTs, and lymphoma have also been reported in the canine stomach. Lymphoma is more commonly reported in the feline stomach.[5,17-24] Belgian Shepherds, Rough Collies, and Staffordshire Bull Terriers are reported to be predisposed to developing malignant gastric (adeno)carcinomas, but not all studies support a breed predisposition.[20,21,24] There is a tendency for malignant gastric tumors to affect the lesser curvature (incisura angularis) or pyloric antrum. Leiomyomas or GISTs, on the other hand, tend to be found more commonly on incidental finding in older dogs.[16,18,24]

Other primary gastric diseases implicated in the pathogenesis of gastric ulceration include *Helicobacter*-associated inflammation and IBD.[6,9,17] The amount of gastric erosion caused by chronic vomiting is often self-limiting or mild in nature (Figure 56-20).

Systemic disease is also frequently cited as causing gastric ulceration, in particular pancreatitis, DIC, hypoadrenocorticism, liver disease, and uremia. Although the degree of gastric ulceration may be substantial in these conditions, often the other associated clinical signs are more clinically obvious. In one study, only dogs with severe uremia developed gastric ulceration, despite many of the dogs having GI signs.[25] The most common gastric histologic abnormality found in the study of uremic dogs was gastric mineralization.[25] The exact incidence of gastric ulceration in other systemic diseases has not been fully assessed.

Strenuous exercise, particularly in Alaskan sled dogs, is also associated with increased intestinal permeability and GI ulceration.[26,27] Other less-common conditions include parasitic disease, hypereosinophilic syndrome, and pyloric outflow obstruction.[3] GDV is also associated with gastric ulceration and necrosis.

Pathophysiology

The gastric mucosal barrier is one of the main mechanisms by which the stomach protects itself against acid injury (see Chapter 1). This barrier has low permeability for sodium and hydrogen ions.[28,29] The barrier is formed and supported by intact apical cell membranes with tight epithelial cell junctions; bicarbonate secretion; mucus production; a rich blood supply; active cell renewal; surface active phospholipids; and endogenous prostaglandins.

Mucus is produced by surface mucosal cells in the gastric glands. The surface mucosal cells also secrete bicarbonate across a concentration gradient into the surface mucus layer.[30,31] Bicarbonate secretion is dependent on blood flow to the mucosa, as well as serum bicarbonate concentrations and the acid productivity of oxyntic (or parietal) cells. Prostaglandins are responsible for stimulating the bicarbonate secretion from mucosal cells.[31] The bicarbonate-rich mucus layer neutralizes hydrogen ions and leads to the formation of carbonic acid, which is then converted by carbonic anhydrase to form carbon dioxide and water for excretion.[30]

If the bicarbonate-mucus layer is breached, intracellular bicarbonate is another mechanism that protects epithelial cells against acid backdiffusion.[32,33] Proton (H^+) pump exchanges on the basolateral membrane also protect against increasing intracellular acid. Epithelial cells undergo rapid replication and restitution, with surface mucous cells migrating from the gastric pit to the overlying epithelium in as little as 3 days. This rapid renewal is mediated by a number of factors, of which epidermal growth factor is the most prominent.[34] If there is excessive intraluminal acidity (pH < 3), gastric epithelial cell renewal is impaired, unless there is a sufficient compensatory increase in bicarbonate.[30,33] When the stomach is exposed to acidic stimulants, there is localized hyperemia caused by

increased mucosal blood flow. This, in turn, increases the bicarbonate-rich mucus secretion locally and protects against further damage.

It can thus be deduced that gastric ulceration can develop if there are perturbations in any of these protective mechanisms. The most commonly implicated pathophysiologic mechanisms for gastric ulceration in veterinary medicine are decreased mucosal blood flow, depletion of surface prostaglandins, increased gastric acid secretion, and loss of the epithelial cell tight junctions because of inflammatory or neoplastic infiltration.

NSAIDs, especially aspirin, are reported to exert their adverse effects by direct toxicity to the gastric mucosa as well as by inhibition of the cyclooxygenase-1 pathway, thereby decreasing gastric mucus and bicarbonate production.[35] The pathogenesis of corticosteroid-induced gastric ulceration is not yet fully elucidated, as it is not necessarily caused by depletion of prostaglandin synthesis. Other factors, including poor mucosal blood supply associated with the underlying condition necessitating glucocorticoid administration, may contribute as well. Similarly, the underlying pathophysiologic mechanism by which sled dogs develop gastric ulceration is not well understood, but they do respond to treatment with gastric cytoprotective agents (see Chapter 45).[36] Increased epithelial permeability, and potentially altered local mucosal blood flow as well, may play an important roles under these circusmtances.[27]

Systemic disease, such as uremia, more commonly causes mineralization, mucosal edema, and vasculopathy rather than gastric ulceration per se.[25] When gastric ulceration does develop in uremic animals, it may well be a result of reduced circulating blood volume and consequently altered gastric mucosal blood flow. Similarly, hypotension, liver disease, DIC, hypoadrenocorticism, and pancreatitis may all alter gastric mucosal blood flow by causing splanchnic hypoperfusion resulting from hypotension and hypovolemia.[33] Other potential contributing causes, such as proinflammatory cytokine production or changes in surface prostaglandins, have not been investigated in companion animals. In addition to the reduction in bicarbonate and mucus secretion secondary to poor gastric mucosal blood flow, GI motility is often reduced in these conditions, thereby increasing the exposure time to gastric acid and pepsin.[33] It is postulated that reperfusion injury may ensue following restoration of circulating blood volume, mediated by nitric oxide synthetase, further exacerbating gastric epithelial cell damage in critically ill humans.[33] It is unknown if this syndrome occurs in critically ill companion animals.

Mast cell degranulation releases histamine, which stimulates excessive gastric acid production via parietal H_2 histamine receptors. Malignant mast cells contain up to 50 times more histamine than nonmalignant mast cells.[37] Additionally, dogs with mast cell tumors have higher serum histamine concentrations and lower serum gastrin concentrations than normal dogs.[14] This low serum gastrin is postulated to be a result of negative feedback from gastric hyperacidity. The histamine concentration is not linearly related to the tumor burden.

Gastrinomas, tumors of the endocrine pancreas (δ cells) that produce gastrin, induce hypergastrinemia and gastric hyperacidity. Gastrin directly stimulates secretion of hydrochloric acid from the parietal cells, as well as indirectly stimulating acid production by releasing histamine from fundic enterochromaffin-like cells.[12] The amount of gastric acid stimulated overwhelms the protective mechanisms, and reduces the epithelial cell turnover because of the high acidity.

Theoretically inflammatory conditions of the stomach, such as chronic gastritis or *Helicobacter*-associated gastritis, can cause disruption of the tight junctions and gastric mucosal barrier. However, even though ulceration may be detected microscopically, it requires severe disease for overt gastric ulceration to develop. The true pathogenicity of *Helicobacter*-related disease in companion animals is still under debate, but may be less ulcerogenic than in humans.

Clinical Examination

A careful and thorough physical examination, including rectal examination, is very important in animals with gastric ulceration. Special attention should be made to gentle palpation of the cranial abdomen, as well as assessment of the skin for any ulcerated or newly identified masses that potentially could be mast cell tumors.

The findings on clinical examination are highly dependent on the underlying disease process. Animals with significant gastric ulceration often show signs of focal or diffuse abdominal pain. This may be manifested as a hunched appearance, groaning, or reluctance to get up from a recumbent position. This finding is not pathognomonic for gastric ulceration, however, and other conditions causing true or referred abdominal pain, such as pancreatitis or intervertebral disk disease, should be considered.

Melena is the presence of digested blood pigments in feces, causing a dark, tarry appearance and a foul odor as a consequence of oxidized iron derived from hemoglobin. This may not be reported by the pet owner, but should be apparent on examination of the feces. Experimentally, one study has shown that grossly detectable melena develops 12 to 36 hours after administration of 350 to 500 mg/kg of hemoglobin.[38] This equates roughly to sudden gastric hemorrhage of between 70 and 107 mL in a 30-kg dog. As such, the absence of gross melena does not rule out gastric ulceration.

In some animals, the volume and degree of blood lost into the stomach may cause significant hematemesis (vomiting of blood; Figure 56-21). Consequently, the animal may also show signs of anemia, with pale mucus membranes. If anemia is severe, profound weakness and lethargy may also be apparent. If gastric perforation develops, an inflammatory and septic peritonitis usually follows. Animals may have palpable free abdominal fluid, and show signs of shock and severe inflammatory disease.

Dependent on the underlying cause of gastric ulcer, weight loss resulting in poor body condition score may well be present. This is often associated with a decreased appetite because of the significant gastric pain, but may also be a consequence of cancer cachexia syndrome. Alternatively, the initial stages of gastric digestion may be impaired along with the perturbations in gastric emptying.[12]

Figure 56-21 Substantial hematemesis in an aged dog. (Courtesy of Peter Irwin, Murdoch University, Perth, Western Australia.)

Diagnosis

Historical information and physical examination may suggest predisposing causes, such as recent treatment with NSAIDs, or detection of dermal masses consistent with mast cell tumors. In animals with severe, acute illness, the associated history may be all that is necessary to reach a tentative diagnosis.

Clinical pathology testing may provide further evidence of diseases associated with gastric ulceration, and is also useful to determine the consequences of vomiting and severity of blood loss. Platelet counts and clotting times are helpful in the assessment of primary and secondary hemostasis when a coagulopathy is considered the likely cause of blood loss (see Chapter 9). Acute and chronic blood loss may be associated with anemia and chronic blood loss may exhibit features of iron deficiency (hypochromic, microcytic red cell indices, with associated thrombocytosis). Eosinophilia may be present if the underlying condition is associated with eosinophilic gastroenteritis, mastocytosis, hypoadrenocorticism, and hypereosinophilic syndrome.

Serum chemistry survey in conjunction with urinalysis may indicate pre-renal or renal azotemia, acute or chronic liver failure, and hypoproteinemia. Serum bile acid assays may be indicated to confirm liver dysfunction when the serum biochemistry is only weakly supportive of liver dysfunction. Serum bile acid determinations may also be used to determine the site of protein loss when there is hypoproteinemia.

Electrolyte and acid–base changes are helpful diagnostically and will influence the choice of intravenous fluid therapy. Electrolyte and acid–base abnormalities may reflect severe vomiting. Hyponatremia with a Na^+:K^+ ratio of less than 27:1, however, could suggest hypoadrenocorticism and other biochemical changes supportive of such a diagnosis include hypercalcemia, azotemia, hypoglycemia, hypoalbuminemia, hypocholesterolemia, and increased serum liver enzyme activities. ACTH stimulation test is indicated if the electrolyte changes and clinical presentation are consistent with a diagnosis of hypoadrenocorticism. Hyponatremia and a low Na^+:K^+ ratio can alternatively be caused by *Trichuris vulpis* or *Salmonella* infection (pseudohypoadrenocorticism)[39] and definitive diagnosis is typically made by finding ACTH normoreactivity and a positive fecal flotation. Hypokalemia, hypochloremia, and metabolic alkalosis in combination are suggestive of a proximal intestinal tract obstruction which should be considered and ruled out. Survey radiographs or ultrasound examination of the abdomen are often used for this purpose.

Fecal occult blood tests assist in confirming the site of blood loss although the test is limited in many situations by the requirement for dietary modification prior to the test.[40,41]

Dermal masses and enlarged lymph nodes should be cautiously aspirated to detect mast cell or lymphoma origin. Smears are routinely stained with Romanowsky-type stains although some mast cell granules may not stain strongly unless the slides are immersed in the alcohol fixative for several minutes when staining with rapid modified Romanowsky type such as Diff-Quik.[42]

Diagnostic imaging has limited value in the diagnosis of gastric ulceration per se, but is valuable for ruling out other causes of vomiting and may also detect early evidence of perforation.[43] Radiographic changes associated with GI perforation include lack of serosal detail, pneumoperitoneum, and leakage of positive contrast medium. Complementary use of abdominal ultrasound can assist in the localization of the abnormality and identification of the underlying cause of perforation.[43,44] Double-contrast radiologic techniques have been used to identify benign gastric ulceration, and demonstrate good agreement with endoscopic diagnosis.[45] In addition, radiographic features have been used to predict ulcers that may be refractory to treatment with H_2-histamine receptor antagonists.[46] Positive contrast studies are less useful in small animals, and have the associated risk of aspiration.

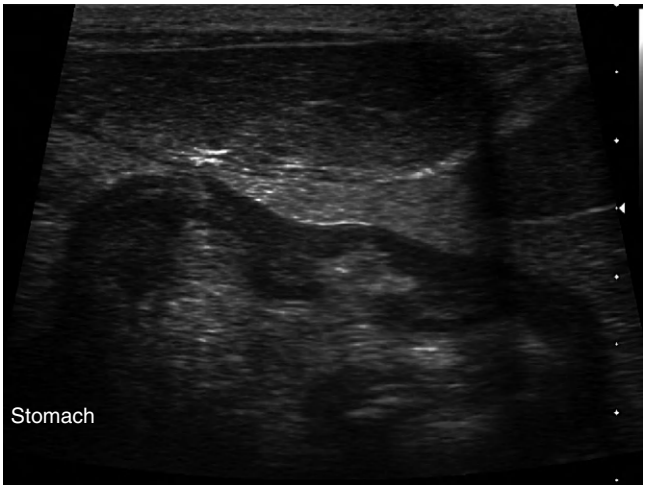

Figure 56-22 Ultrasound image of the stomach of a dog with severe gastric ulceration. There is loss of layering almost through the entire gastric wall (*arrowheads*), with the defect filled with ingesta. (Courtesy of Catherine Beck, University of Melbourne.)

Ultrasonography may be used to examine the stomach wall for changes in thickness, presence of a defect or crater, and loss of the normal layering patterns (Figure 56-22).[43,47] A small amount of orally administered water and positional changing may enable a more complete examination of the stomach. It should be noted that a normal study does not rule out the presence of ulceration, and that ultrasound does not readily distinguish between benign and malignant ulcers. Perforation of the GI tract is associated sonographically with bright mesenteric fat, peritoneal effusion, pneumoperitoneum, thickened GI wall with or without loss of layering, and dilated fluid filled stomach or intestines.[44] Evaluation of lymph nodes and other abdominal organs for the presence of metastasis is possible using ultrasound, and collection of fine-needle aspirates may assist in the definitive diagnosis of neoplasia such as systemic mastocytosis and lymphosarcoma.

CT virtual endoscopy has been proposed as a noninvasive screening test for gastric disease in humans.[48] The technique has yet to be developed adequately for dogs,[49] and until that time conventional endoscopy remains the preferred endoscopic technique. Endoscopy permits direct observation of the depth and diameter of the gastric ulcer, as well as enabling routine acquisition of tissue biopsies. During endoscopy the entire stomach should be examined. The use of a J or retroflex maneuver is recommended to allow complete inspection of the cardia. Malignancies tend to occur in the antrum and lesser curvature of the stomach, but theoretically could be present anywhere in the stomach. Erosions associated with NSAID use are located predominantly in the antrum, although there is no specific location for mast cell tumor–induced lesions.[3]

Biopsies of the ulcerated areas are obtained to rule out primary gastric infiltrative disease. Biopsies should be taken from the periphery of the ulcer to reduce the risk of perforation, and multiple biopsies should be taken from the abnormal region. Endoscopic biopsies, however, may not be adequate to diagnose gastric tumors and full-thickness biopsies taken at laparotomy may ultimately be required for a definitive diagnosis.

Measurement of gastric pH and serum histamine and gastrin concentrations may be useful in the diagnosis of hypersecretory states as a result of mast cell tumors or gastrinomas. Mast cell tumors are associated with acidic gastric pH, low plasma gastrin, and high plasma histamine concentrations, with the gastrin concentration being inversely related to the histamine concentration.[14] In contrast, a gastric pH lower than 3 and markedly high plasma gastrin concentration are typically associated with gastrinoma.[50] In cases where the plasma gastrin concentration is normal or only mildly increased, provocative testing, with feeding or secretin administration, can confirm the diagnosis of gastrinoma.[51-53] It should be recognized that treatment with proton pump inhibitors or H_2-histamine receptor antagonists will cause an increase in plasma gastrin concentration due to lack of negative feedback inhibition. In humans, it has been shown that gastrinomas cannot be diagnosed by means of a fasting plasma gastrin concentration in patients treated with proton pump inhibitors or H_2-receptor antagonists.[54] Plasma gastrin may also be increased in renal failure, hepatic disease, and enteropathies. These alternative conditions should be considered and ruled out, and the presence of a tumor confirmed by diagnostic imaging.

The diagnostic imaging modality of choice to localize gastrinomas in small animals is debatable given the small number of reports of this rare tumor. In humans, all forms of cross-sectional imaging may be unsuccessful at localizing these tumors.[55,56] CT, magnetic resonance imaging, and transabdominal ultrasound all have similar sensitivities for diagnosis (29%).[55] A combination of endoscopic ultrasound with somatostatin receptor scintigraphy, resulted in an improved detection rate of 93%.[56] CT imaging can be helpful in the diagnosis of insulinomas in dogs[57] and it may be a useful modality for detection of gastrinomas in dogs and cats, as well. Ultrasound examination of the abdomen and pentetreotide scintigraphy are typically indicated to confirm the presence of a gastrinoma.[58] In addition, positive somatostatin receptor scintigraphy may predict whether use of somatostatin analogues will be beneficial clinically. However, this has not been validated in small animals to date.

Treatment

Treatment aims are to treat the underlying disease process if possible; reverse fluid, electrolyte, and acid–base derangements; and restore the gastric mucosal barrier to limit further damage. Antiemetics may be required in the initial treatment regimen. The reader is directed to other sections in this chapter for details on treatment of gastric neoplasia and *Helicobacter* infection (see also Chapter 61 for details on liver failure.) When animals are painful, analgesia may be necessary as well. Opioid analgesics are best tolerated, although morphine should be avoided because of its emetic properties.

Surgery may be required for ulcers that are refractory to medical management, have perforated or are at risk of perforation, and to make a definitive diagnosis where there is no apparent cause for the ulceration.

Treatment of preexisting conditions is mandatory. NSAID and corticosteroid therapy should be discontinued as soon as possible. Hypoadrenocorticism is treated with lifelong supplementation of mineralocorticoid (e.g., desoxycorticosterone pivalate or fludrocortisone) and variable glucocorticoid replacement. The reader is directed to other sections in this chapter for discussion of the treatment used for gastric neoplasia, liver failure, and *Helicobacter* (see also Chapter 61).

Treatment of gastrinoma is aimed at surgical removal of the primary tumor, which is often small and often difficult to localize. Management is complicated by the frequent presence of metastases at the time of diagnosis.[53,58-64] Medical therapy may be adjunctive, or in many cases is the sole therapy for controlling clinical signs associated with acid hypersecretion. Long-term survival (2 years) has been reported with omeprazole monotherapy.[65] Combination therapy with antisecretory drugs, sucralfate, and octreotide has also been described.[58] The use of octreotide is thought to be dependent on positive somatostatin receptor scintigraphy, and has had variable success in the limited numbers of dogs treated.

Mast cell tumor treatment is dependent on the grade and stage of the tumor, neither of which correlate very well with the degree of hyperhistaminemia.[14] Treatment with histamine receptor (types 1 and 2) antagonists should reduce some of the effects of histamine. They may be helpful prior to surgery when degranulation of mast cells with histamine release is anticipated from tumor handling. Similarly, treatment with omeprazole will decrease the gastric acidity associated with hyperhistaminemia. Direct treatment of the tumor may consist of surgery, chemotherapy or radiation therapy, dependent on the location of the tumor as well as histologic grading.

Maintenance of normal hydration is an important component of treatment, and administration of fluid therapy will depend on the degree of dehydration or hypovolemia. The administration rate for crystalloids is calculated to restore losses and provide ongoing maintenance requirements over a 24-hour period. In animals that present with evidence of shock or poor peripheral perfusion, crystalloids should be given at an initial rate of 60 to 90 mL/kg/h for 1 to 2 hours before decreasing to a rate that maintains the circulation. Packed red blood cells or whole-blood transfusion is indicated in severe anemia, as is plasma or colloid support when there is severe hypoproteinemia. Treatment aimed at restoring the gastric mucosal barrier comprises administration of anti-secretory drugs together with mucosal protectants. This is required regardless of the underlying cause. Histamine receptor (type 2) antagonists and proton pump inhibitors are the two classes of drugs used to reduce acid secretion and are discussed in Chapter 45 together with mucosal protectants. Sucralfate is typically used in combination with antisecretory drugs, but its efficacy is unproven, especially when given in conjunction with a gastric acid suppressant.

Nutritional management is an important component of treatment and diets should be chosen to facilitate gastric emptying and enable healing. Diets with reduced fat and fiber contents will increase the rate of gastric emptying. High-quality, highly digestible proteins should be present and the diet should provide adequate amounts of protein to reverse catabolism when present. Dietary modification should also be aimed at management of the underlying disease process. Fat restriction and modification of dietary protein (elimination type diet or hydrolyzed protein) can assist in the management of inflammatory bowel disease. In cases of advanced renal insufficiency, dietary modification typically involves feeding a moderately restricted amount of a high quality protein together with restricted phosphate. Care must be taken to provide sufficient protein to avoid endogenous protein catabolism. In cases of liver dysfunction, the protein content only requires restriction when hepatic encephalopathy is present (see Chapter 17). In such cases, protein derived from milk, soy, egg, and cottage cheese may be better tolerated than protein of animal origin. In acute liver failure, it is important to supply adequate protein to prevent malnutrition, enable hepatic regeneration, and prevent catabolism of endogenous protein. For all forms of liver disease, inclusion of antioxidants such as vitamin E and *S*-adenosyl methionine can protect against oxidative injury.

Prognosis

The prognosis for gastric ulceration is highly dependent on the severity of signs at the time of presentation, whether perforation has occurred, and the underlying cause. Surgical intervention is associated with a good outcome in dogs when the predisposing factors are controlled or eliminated.[3] Approximately 10% of dogs treated surgically or medically died from their ulcer disease compared with 37.5% of those untreated.[3,5] Cats frequently present in a critical condition and prompt stabilization prior to surgery has been associated with a good outcome. Cats with intestinal and pancreatic neoplasia that is associated with gastric ulceration can be palliated for prolonged periods.[5]

Survival time in dogs with gastric carcinoma is dependent on the size and invasiveness of the tumor at diagnosis, with advanced cases being inoperable and carrying a grave prognosis. Less-advanced cases may be treated surgically (the treatment modality of choice) and are likely to have a more favorable long-term prognosis.[66] The prognosis for gastrinoma is typically considered poor to grave given the high likelihood of metastasis at the time of presentation. Survival times of 2 years have been reported when the gastric ulceration was controlled with omeprazole monotherapy.[65] Addition of somatostatin to omeprazole may further improve survival in dogs continuing treatment with omeprazole.[58,67] The prognosis for dogs presenting with mast cell tumors will depend on tumor location, stage, and grade, together with presence of systemic paraneoplastic signs. Dogs presented with high-grade tumors, evidence of metastasis, and systemic signs carry a poorer prognosis than those presented with a localized, low-grade tumor.

Prognosis in cases associated with nonneoplastic disease will be dependent on the control of the underlying disease process. Generally, progressive disease (such as chronic liver failure and renal insufficiency) will carry a guarded to grave prognosis dependent on the rate of progression and response to treatment.

STRUCTURE AND FUNCTION

Edward J. Hall

The small intestine (SI) is, in essence, an interface between the external environment and the body, and is both an absorptive surface and a barrier; it must digest and absorb nutrients while excluding antigens and microbes and eliminating fecal waste. It faces a frequently changing dietary and bacterial intake, and yet has to maintain a dynamic but balanced microflora within its lumen while being intermittently exposed to pathogens. All of its functions—mixing and propulsion, secretion, digestion, absorption, regulation of blood flow, immunologic reaction and tolerance, and elimination—are fully integrated through both local and remote neuroendocrine and immunologic mechanisms (see Chapter 1). It thus has a complex task and requires specialized anatomic arrangements to perform them.

Gross Structure

Anatomic Regions

The SI is basically a tube, beginning at the pylorus of the stomach and ending at the ileocolic valve. However, this tube is ultimately in continuity with the external environment, proximally from the mouth via the esophagus and stomach, and distally to the anus via the large intestine (Figure 57-1, *A*).[1-3] It is relatively short, reflecting the typical dietary intake of cats and dogs. It is approximately 1 to 1.5 meters long in adult cats and ranges from 1 to 5 meters in adult dogs, in proportion to the size of the individual. It is divided arbitrarily into three anatomic segments: the duodenum proximally, then the jejunum, and finally the ileum distally (see Figure 57-1, *A*).

Duodenum

The first part of the SI, the duodenum, comprises approximately 10% of its total length. It passes from the pylorus dorsally and to the right, at the level of the ninth intercostal space, and is immobilized by the hepatoduodenal ligament. It then turns caudally into the descending duodenum in contact with the right flank, turning again at the caudal flexure near the pelvic brim. It is in close association with the common bile duct and the head and right limb of the pancreas, which lie in its mesentery.

The common bile duct and one pancreatic duct enter the duodenum via the major papilla. In dogs an accessory pancreatic duct often enters at a minor papilla more distally and slightly more ventrally (Figure 57-2, *A*), but there is a range of variations in the actual number of ducts and their drainage pattern from the pancreas (see Chapter 60). The papillae are notable endoscopic landmarks in dogs, but may not be obvious in cats.

The distal duodenal flexure, where the duodenum courses to the left side of the abdomen (see Figure 57-2, *B*) is often at the limit of the reach of a standard 1-meter gastroscope, except in cats and small dogs. In dogs the antimesenteric side of the duodenum is marked by a line of whitish, mucosal depressions signifying the presence of specialized lymphoid areas, the Peyer patches (see Figure 57-2, *C*). Secretory Brunner glands and annular mucosal folds are features of the human proximal duodenum, but are not present in dogs and cats. After the distal duodenal flexure, the ascending limb of the duodenum crosses the midline and ends at the level of L6 close to the root of the mesentery near the left kidney, with a mesenteric attachment to the colon, the duodenocolic ligament.

Jejunum

The middle part of the SI, the jejunum, arises as an indistinct structural and functional transition from the duodenum and forms the majority of the SI. The jejunum is loosely suspended in the middle of the peritoneal cavity in a dorsal mesentery, forming mobile loops, and is potentially palpable throughout its length in cooperative and nonobese patients. The mesentery is normally a continuous sheet that is folded to allow the SI to loop within the peritoneal cavity, unlike in humans where segments of the duodenum (and colon) are retroperitoneal. The mesentery carries the vascular, lymphatic, and nervous connections between the SI and the rest of the body.

Defects in the mesentery, most often traumatic in origin, can allow internal hernia formation and small intestinal incarceration. An outpouching of the dorsal mesentery of the stomach forms the greater omentum. This structure functions as a protective, immunologic organ, having the ability to migrate to sites of intraperitoneal inflammation and potentially prevent leakage from an intestinal perforation and seal off pockets of infection.

Ileum

Approximately the last 30 cm of the SI comprises the ileum. The transition from jejunum to ileum in humans is based on changes in diameter, color, and the presence of Peyer patches; in dogs and cats the distinction has been arbitrarily based on the extent of attachment of the ileocolic ligament. In fact the basic structure of the ileum is no different from the rest of the SI and it is not clearly demarcated microscopically from the jejunum. However, it does have some unique functional characteristics, such as the absorption of bile salts and cobalamin. It is also a site of dense lymphoid follicle expression. Meckel diverticulum, a remnant of the embryonic omphalomesenteric duct, found in the ileum of approximately 2% of people and a potential source of bleeding, obstruction,

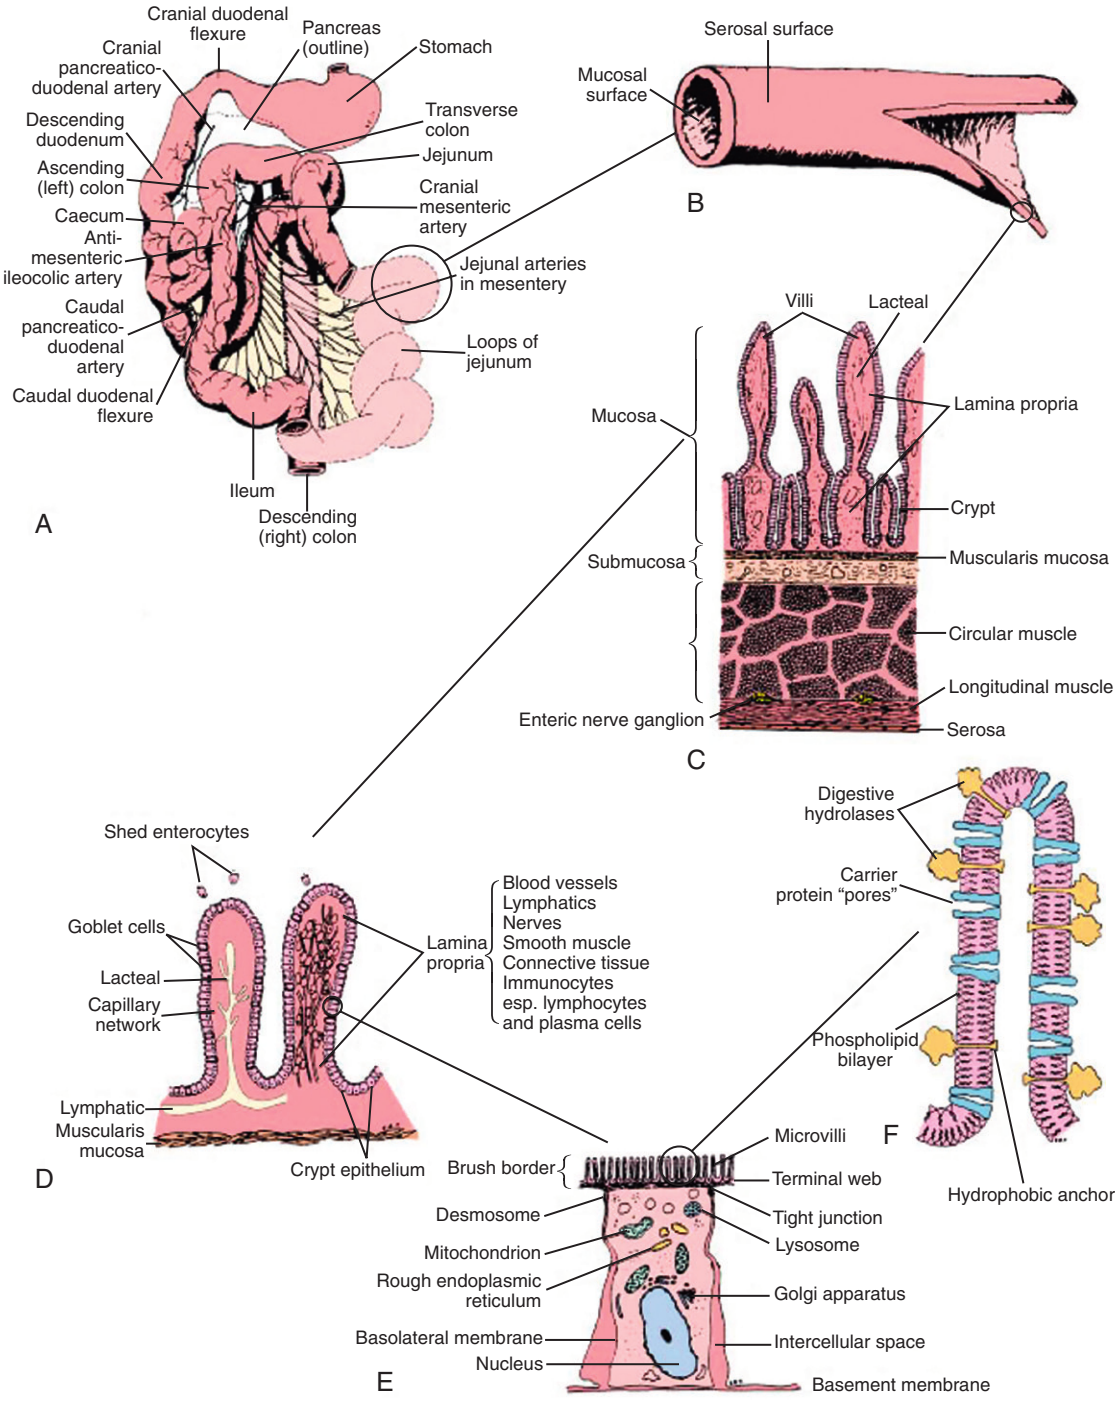

Figure 57-1 Functional anatomy of the small intestine. A, Anatomic arrangement of the small intestine. **B,** The small intestine is basically a tube with a serosal surface covered by visceral peritoneum and an inner absorptive and digestive surface, the mucosa. **C,** Beneath the outer serosa, longitudinal and circular muscle layers produce peristaltic and segmental contractions for propelling and mixing the luminal contents. The submucosa is rich in blood and lymphatic vessels. The mucosa comprises the thin muscularis mucosa, the lamina propria, and the columnar epithelium; it is thrown into folds and is covered by finger-like villi to increase the digestive and absorptive surface area. **D,** Enterocytes, which are shed from the villus tip but are continually replaced through division of crypt cells, are the site of nutrient digestion and absorption. Goblet cells secrete protective mucus. Water-soluble nutrients pass into the rich capillary network of the lamina propria, and fat is passed as chylomicrons into the lacteals. Immunocytes in the lamina propria are involved in maintaining tolerance to luminal antigens. **E,** The luminal membrane of the enterocyte is thrown into processes called *microvilli*, which increase the luminal surface area. Tight junctions between enterocytes maintain epithelial integrity. Absorbed nutrients are passed from the enterocyte into the intercellular space for distribution to the body. **F,** Schematic of a microvillus showing digestive hydrolases anchored in the phospholipid cell membrane and protruding into the intestinal lumen. Carrier proteins in the membrane are believed to act as "pores," shuttling nutrients across the membrane by means of conformational changes in their structure often induced by sodium influx at the expense of energy utilization through Na/K-adenosine triphosphatase (ATPase) on the basolateral membrane. (From Hall EJ: Small intestinal disease. In: Gorman NT, editor: *Canine Medicine and Therapeutics*, ed 4, Oxford, UK, 1998, Blackwell Science, p 488.)

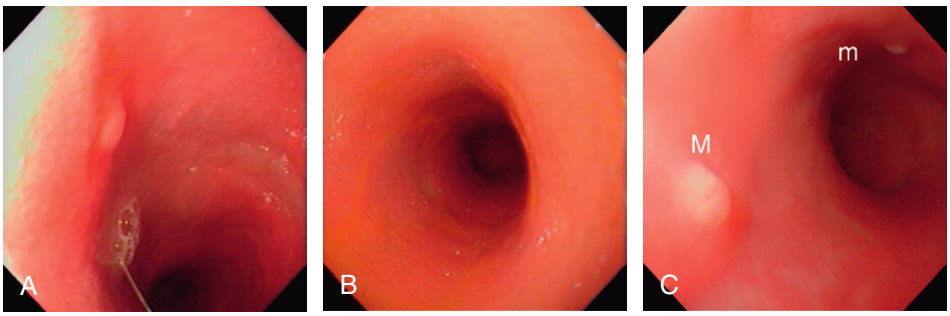

Figure 57-2 **Videoendoscopic appearance of the normal upper small intestine. A,** The major duodenal papilla (M) in the duodenum of the dog is the site of entry of the common bile duct and major pancreatic duct. The minor duodenal papilla (*m*) is seen in some but not all dogs distal to the major papilla and approximately 100 degrees clockwise from it. **B,** Normal descending duodenum in a dog; the distal flexure is visible in the distance. **C,** Peyer patches (lymphoid aggregates) in the duodenum appear as pale oval depressions along the antimesenteric border of the descending duodenum. intussusception, and volvulus, is not reported in dogs and cats. The ileum ends at the ileocolic valve in close association with the cecocolic junction.

Blood Supply, Lymphatic Drainage, and Innervation

The blood supply to the proximal duodenum is from the celiac artery. Its cranio-pancreatico-duodenal branch anastomoses with the caudo-pancreatico-duodenal branch of the cranial mesenteric artery. The latter is the major blood supply to the remainder of the SI and proximal colon, anastomosing distally with the caudal mesenteric artery. It forms an arcade along the mesenteric border of the jejunum and ileum, with a short antimesenteric ileal branch. Its branching nature is an important consideration when assessing the viability of lengths of SI during surgical resection and end-to-end anastomosis.

The venous drainage of the whole SI is ultimately to the liver via the hepatic portal vein. Multiple embryonic vessels linking portal venous drainage and the systemic venous system (i.e., via ovarian veins, caudal vena cava, and esophageal veins) exist but only become functional shunting vessels if there is chronic portal hypertension as a consequence of liver disease.

Lacteals in the villi drain via intestinal lymphatics in the mesentery to the mesenteric lymph nodes and then the cisterna chyli and on to the thoracic duct. Vagal and sympathetic innervation coordinate with the intrinsic enteric nervous system and enteric hormones to regulate SI motility and function.

Intestinal Compartments

Microflora

The microflora of the SI is an integral part of its structure and function. There is a gradual increase in bacterial numbers and a shift from aerobic to anaerobic organisms progressing distally down the SI. Chapter 2 provides a more detailed description of the composition of the microflora and its interaction with the mucosa.

Mucosa

The SI mucosa performs the intestinal barrier and absorptive functions, and is comprised of an intestinal epithelium covering the lamina propria that hosts the local mucosal immune system, and is surrounded by the submucosa and the outer muscle layers.

One of the most important structural modifications of the mucosa is a vast increase in its surface area relative to the size of the animal, with an almost 600-fold increase compared with the basic tubular structure of the intestine. The surface area of the human intestine has been estimated at 175 m^2, and although the adult human intestine is longer than in even the largest dog, the villi in cats and dogs are almost twice as long (approximately 1 mm) compared with those of humans. The increase in surface area is created by folds in the mucosal wall (tripling the surface area), villus projections into the intestinal lumen (providing an approximate 10-fold increase), and microvilli on the surface of each epithelial cell (providing a further 20-fold increase in area) (see Figure 57-1, C). Diseases causing villus atrophy or even just microvillus damage are likely to produce profound malabsorption and diarrhea.

Gut-Associated Lymphoid Tissue

The GI tract is the largest immunologic organ in the body, and the SI comprises a large component of the mucosal immune system. Within the SI, the Peyer patches (see Figure 57-2, C) act as inductive sites and are covered with a specialized epithelium containing microfold (M) cells, which sample luminal antigens. Activated lymphocytes migrate via mesenteric lymph nodes to the circulation, from where they home to their effector sites, the lamina propria and epithelium. Chapter 3 details the structure and role of the gut-associated lymphoid tissue.

Microstructure

An identical, basic, tubular, cross-sectional structure is present throughout the length of the SI (see Figure 57-1, C): the external serosa surrounds the muscularis, submucosal and mucosal layers which are present throughout, and can be detected ultrasonographically (Figure 57-3).[4-10] A very narrow hyperechoic interface between the lumen and mucosal surface is usually visible above the four true layers: (a) a slightly hypoechoic mucosa, (b) hyperechoic submucosa, (c) hypoechoic muscularis, and (d) brightly hyperechoic serosa.

Regional variations in the relative proportions of each layer reflect differences in the functions of the proximal, middle, and distal regions. The mucosa is thickest in the duodenum (normal dog ≤6 mm) and thinnest in the ileum (normal dog ≤4.7 mm). Variations in the microstructure also occur with species and age and within individual animals depending on their dietary intake, as well as disease. Submucosal Brunner glands are found in the human duodenum but not in dogs and cats. Loss of normal ultrasonographic layering is suggestive of neoplastic infiltration, and echogenic mucosal striations may indicate lymphatic dilation.

The mucosal layer is responsible for secretion and absorption as well as being a barrier to the luminal environment. The submucosa, between the muscularis mucosa and muscularis, provides

Figure 57-3 Ultrasound Image of the Small Intestine. Abdominal ultrasound image showing transverse image of three loops of bowel in a dog, with normal layering of the small intestinal wall. (From Ettinger SJ and Feldman EC, editors: *Textbook of Veterinary Internal Medicine*, ed 7, Philadelphia. 2010, Saunders, p 1541.)

connective tissue support and delivers blood vessels, nerves, and lymphatics. Within the muscularis, the outer longitudinal and inner circular muscular layers provide propulsive and segmental peristaltic contractions that mix chyme and ultimately propel it aborally. Neural plexuses are found between the muscle layers (the myenteric or Auerbach plexus) and in the submucosa (Meissner plexus), and communicate with all layers of the intestinal wall. They help coordinate intestinal motility and secretory activity, and even mucosal immune responses (see Chapters 1 and 3).

Mucosa

This is the most important layer of the intestine clinically. It is comprised of the epithelium and lamina propria overlying the muscularis mucosa, and is modified by gross folds and the villi (see Figure 57-1, C). The muscularis mucosa is a thin sheet of smooth muscle, from three to 10 cells thick, separating the mucosa from the submucosa. Smooth muscle branches within the villus lamina propria enable shortening and lengthening movements of the villi.

The lamina propria is a continuous connective tissue space bounded by the muscularis mucosa below and the epithelium above, and contains aggregates of lymphoid tissue, and nonaggregated immunocytes (see Chapter 3), enteric neurons, and blood and lymphatic vessels. A central lymphatic vessel (lacteal) within each villus drains chylomicrons into intestinal lymphatics and ultimately to the cisterna chyli.

Blood flow to a villus is provided by an arteriole that passes to the tip of the villus where it arborizes and forms a subepithelial capillary network that drains into veins. Crypts are supplied by separate arterioles and blood flow in the two regions can be controlled independently. Mucosal capillaries are fenestrated, and in conjunction with the lacteal, carry away protein-rich tissue fluid. Loss of epithelial integrity permits leakage of the protein-rich fluid and the development of a protein-losing enteropathy (PLE).

Crypt-Villus Unit

A group of crypts and their associated villus comprise the functional unit of the SI (see Figure 57-1, D).[11] Crypts are continually replenished by cell division, producing undifferentiated epithelial cells. It is estimated that there are between four and 40 stem cells per crypt in the adult intestine, with further division of daughter cells occurring as the cells pass up the crypt. As the crypt cells pass through a maturation zone they undergo a final division and differentiate into immature epithelial cells. The predominant epithelial cell type is the enterocyte, but as a number of crypts may supply the enterocytes to one villus, each villus epithelium may consequently represent a polyclonal cell population.

Mucosal Epithelium

The intestinal surface is covered by a monolayer of polarized epithelial cells; their luminal surface is structurally and functionally distinct from their basolateral membrane.[12-18] The epithelial basement membrane is readily permeable to nutrients, but has an important role as the structural matrix on which the epithelium grows. It expresses glycoproteins, called laminins, that interact with integrins, transmembrane recognition molecules expressed by epithelial cells. These interactions promote cell adhesion, growth, polarization, and differentiation. Enterocyte differentiation during migration up the villus may be programmed, but is likely also to be modulated by the expression of different integrins at different sites on the crypt–villus axis. Communication between epithelial cells is mediated by E-cadherin, a transmembrane molecule, linked to intracellular catenins, proteins that transmit signals to the actin cytoskeleton and to intracellular growth control pathways.

A mucosal barrier is formed by the intestinal epithelium (Box 57-1). This barrier depends on intercellular tight junctions between enterocytes, encircling their lateral aspects and excluding antigens and bacteria. Effete enterocytes are shed from the villus tip by a mechanism that maintains the mucosal barrier (see Figure 57-1, D). Studies in rodents suggest intercellular bridges develop between neighboring enterocytes below the effete cell before it is shed, thus maintaining mucosal integrity. However, epithelial integrity is likely to be altered in some intestinal diseases, and the integrity of the tight junctions is actually least in the crypts, where fluid secretion occurs. There is an association of cryptal lesions with the development of PLEs.

Crypt cells have a potent secretory capacity and the crypts are the site of most mucosal fluid secretion. As enterocytes migrate to the villus tip, maturation involves loss of secretory activity and the expression of digestive and absorptive molecules in the apical (luminal) cell membrane. Some enterocytes undergo stochastic (random) cell death, but the majority undergoes apoptosis via a caspase-dependent process, and exfoliates at the tips of the villi. The duration of migration from crypt to villus tip is believed to be 3 to 5 days in dogs and cats. More rapid transit may occur in diseases where cells are lost and compensatory crypt activity occurs, but the new enterocytes tend to be functionally immature.

Enterocytes predominate in the epithelium, representing approximately 80% of all cells, with interspersed mucus-secreting goblet

cells. Goblet cell density in the SI mucosa varies, being highest in the ileum. These cells secrete protective mucus and some novel clover leaf–shaped peptides (trefoil peptides) that act as growth factors. Paneth cells, a population of cells found in some species below the proliferation zone in crypts and that secrete antibacterial peptides, are not recognized in dogs or cats. Endocrine- and paracrine-secreting cells (*synonyms:* enteroendocrine, enterochromaffin, argentaffin, argyrophil cells) are also present in the mucosal surface layer, and have important trophic and functional activities.

In addition to locally produced growth factors, a variety of luminal and humoral factors act as physiologically active growth regulators. Receptors for epidermal growth factor (EGF) are found on the luminal and basolateral surfaces of enterocytes, suggesting that they may respond to bloodborne EGF and to EGF secreted into the lumen by salivary and pancreatic tissue or delivered in milk. Transforming growth factor (TGF)-α, a polypeptide related to EGF and expressed throughout the mucosa, has growth regulatory properties. However, EGF and TGF-α are also probably important in repair of damaged epithelium as they stimulate repair without fibroblast activity, unlike TGF-β, which inhibits epithelialization and stimulates fibroplasia, and is important in deeper wound repair.

In the Peyer patches, enterocytes overlying lymphoid aggregates are modified into follicle epithelium and M cells, probably in response to signals from underlying lymphoid cells. The M cells sample the luminal contents and help present antigen to the mucosal immune system (see Chapter 3).

Enterocytes

Enterocytes contain the intracellular organelles, such as mitochondria, lysosomes, and endoplasmic reticulum, common to all cells, and which support normal cellular functions. However, enterocytes also perform specific digestive and absorptive functions.[19,20] Enzymes expressed on the surface of enterocytes perform terminal digestion of polysaccharides and peptides in conjunction with luminal hydrolysis of food polymers by pancreatic enzymes. The enterocytes then absorb the simple nutrients. These functions depend on the polarity of the enterocyte, involving a specialized portion of the cell membrane on the luminal surface, the microvillar membrane (MVM). The microscopic appearance of the MVM is the basis of its alternative name, the "brush-border" (see Figure 57-1, *E* and *F*). It consists of thousands of parallel cylindrical processes (microvilli) bearing the digestive enzymes and specific carrier proteins.

The MVM is a phospholipid bilayer that has specific proteins inserted into it. Enzymes responsible for the terminal stages of carbohydrate and protein digestion are usually anchored in the MVM by a small hydrophobic terminal and have an active site exposed to the intestinal lumen (see Figure 57-1, *F*). Specific carrier proteins traverse the MVM or basolateral membrane and, through conformational changes, shuttle nutrients into and out of the enterocyte across the cell membrane. The maximal brush-border enzyme and transport activities are expressed in the mid-villus region. Diseases damaging enterocytes often accelerate cell production and the more immature enterocytes are not as effective functionally.

Brush-border enzyme activities are highest in the proximal SI and decline in an aborad gradient. Digestive enzymes, especially disaccharidases and transport proteins, may be inducible in response to changes in the composition of the diet. This has been shown in dogs but not in cats, perhaps reflecting the obligate carnivore status of cats. Indeed dogs, which are omnivorous, show increased sucrase and maltase in response to increased dietary carbohydrate and, conversely, when fed a cereal-free diet develop reduced activities of brush-border sucrase and maltase but not lactase. Thus a sudden change in diet in dogs may cause diarrhea through transient intolerance until either existing enterocytes upregulate expression of specific enzymes and carriers, or new enterocytes expressing induced proteins differentiate, thus rendering the diarrhea self-limiting.

Enterocyte metabolism is geared toward the production of brush-border proteins and the transfer of nutrients and water from the lumen to the blood. Basolateral cell membranes export sodium from the cell via an energy-dependent N^+-K^+-ATPase. Water can follow osmotically, or compensatory sodium influx at the luminal surface can drive carrier-mediated nutrient absorption. Natural inhibition of glycolysis through expression of an alternate phosphofructokinase isoenzyme in enterocytes facilitates the transfer of glucose from the lumen to the blood. Gluconeogenesis is also inhibited, and so enterocytes can utilize ketone bodies. However their major energy source is actually glutamine (Figure 57-4). A surge in enterocyte glutamine metabolism during digestion is probably partly responsible for the postprandial rise in blood ammonia seen in some patients with hepatic dysfunction.

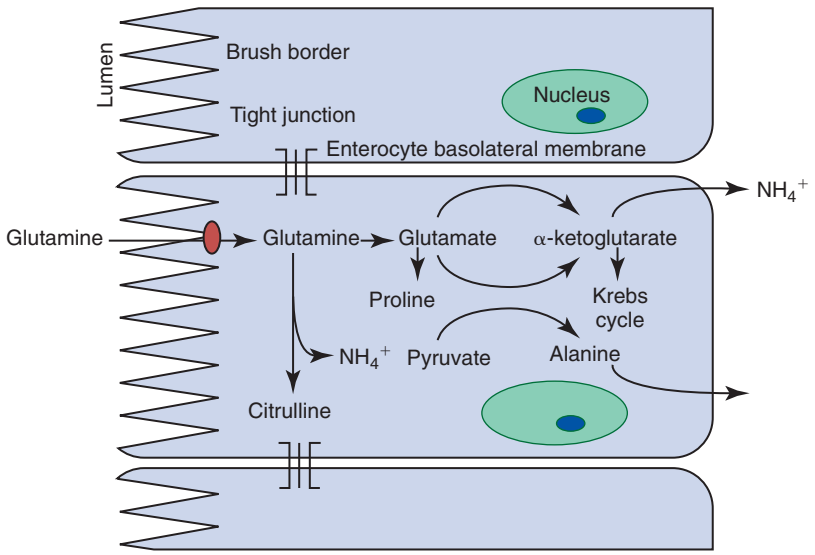

Figure 57-4 Metabolism of glutamine by enterocytes, and one potential mechanism for postprandial increases in endogenous ammonia.

Both major nutrients for enterocytes (glutamine and ketone bodies) are largely derived from the lumen, which helps explain the decline in villus structure, epithelial integrity, immune function, and absorptive function in starvation and anorexia. Consequently, attempting to maintain enteral nutrition, often by using glutamine-containing products, may be of clinical benefit.

Digestive and carrier proteins are synthesized by enterocytes and inserted in the MVM. This mechanism has been demonstrated for the synthesis of the enzyme complex of sucrase–isomaltase in pigs, but a similar process is likely to occur for this and other enzymes in dogs and cats. The sucrase–isomaltase complex is synthesized as a single polypeptide by ribosomal translation of its messenger RNA (mRNA). A terminal signal peptide extension that is ultimately cleaved, directs the intracellular trafficking of the protein from the ribosome to the endoplasmic reticulum and Golgi apparatus, where glycosylation of the protein backbone occurs. The glycosylated polypeptide is directed to the brush-border where it is inserted. It then "flips" across the apical membrane so that the active sites are on the luminal surface, and the polypeptide is anchored in the membrane by an N-terminal hydrophobic chain. The parts of the exteriorized polypeptide containing the sucrase and isomaltase activity are cleaved by pancreatic proteases but remain in close association, and form a dimer with another sucrose–isomaltase molecule.

As enterocytes migrate to the villus tip, enzymes are cleaved from the brush-border by bacterial and pancreatic proteases and are released into the lumen where they comprise solubilized enzyme activities, commonly called *digestive juice*. However, this liquid, the succus entericus, is not a true intestinal secretion.

Submucosa

Beneath the muscularis mucosa, the submucosa contains a heterogeneous population of cells: lymphocytes, plasma cells, macrophages, eosinophils, fibroblasts, and mast cells within a connective tissue matrix. An intricate network of blood vessels, nerve fibers, ganglia and interstitial cells of Cajal (Meissner plexus), and lymphatics supply the mucosa and muscularis.

Muscularis

Two muscle layers, the outer longitudinal and inner circular layers, encircle the submucosa. The intermuscular plane is a connective tissue layer bearing the myenteric (Auerbach) neural plexus. Ring contractions by the circular muscle and sleeve contractions by the longitudinal muscle may be tonic or rhythmic, and intestinal movements may be standing or migrating, allowing mixing and propulsion. Contraction of the muscle layers is coordinated by the enteric nervous system to produce peristaltic and segmental movements, with interstitial cells of Cajal acting as pacemakers. Chapter 1 details how intestinal motility is integrated with other functions of the SI.

Serosa

This is a single layer of mesothelial cells surrounding the intestine, and forms the visceral peritoneum.

Small Intestinal Function

The basic functions of the SI, that is digestion, absorption, and elimination, occur as a result of complex intercellular interactions between epithelial cells, immune cells, mesenchymal and neuronal cells and with luminal nutrients and microbes.[21] The SI is also the largest immunologic organ in the body, interacting with the intestinal microbial flora and a diverse range of food antigens (see Chapters 2 and 3, respectively).

Digestion

To be transported across the MVM, major dietary constituents must be hydrolyzed from their initial polymeric structure into monomers. This digestive process is achieved within the SI lumen by mechanical disruption (in conjunction with bile salt emulsification of fats) that allows enzymatic hydrolysis of polysaccharides, proteins, and triglycerides.[22]

The SI provides the optimum environment in terms of solute, temperature, pH, and mixing for the actions of bile salts and digestive enzymes, but most enzymes are secreted by the pancreas, and exocrine pancreatic insufficiency (EPI) is a major cause of malabsorption. The brush-border peptidase enterokinase (enteropeptidase) is important in the initial activation of pancreatic trypsin from trypsinogen by cleaving a terminal octapeptide, trypsinogen activation peptide, from the native protein.

Only terminal digestion of oligomers need normally be performed by brush-border enzymes. However, brush-border activities can partially compensate for the lack of secreted proteases and amylase in EPI, with at least 40% of dietary protein still being hydrolyzed, although severe fat maldigestion persists. Even with significant diffuse SI mucosal disease there is usually sufficient reserve capacity to enable adequate digestion of starch. However, early estimates of a 10-fold reserve capacity of digestive and absorptive activity have been refuted. The "reserve capacity" that is called into action after intestinal resection probably represents not only increases of brush-border protein expression, but also compensatory hypertrophy of the remaining tissue, as it is known to take months to reach maximal effect (see "Short Bowel Syndrome" section). Capacity appears to be regulated according to physiologic demand, and probably does not normally exceed twofold, but it is relevant that it can be modified in response to dietary change.

Carbohydrate

Starch and glycogen are the major carbohydrates in the diet and must be hydrolyzed completely to glucose for absorption (Figure 57-5, *A*). There is no salivary amylase activity in dogs and cats, and these complex carbohydrates are hydrolyzed by pancreatic α-amylase. Straight-chain starch molecules (amylose) are split to maltose, maltotriose, and some glucose. Branched-chain starch molecules (amylopectin) and glycogen are also hydrolyzed to the same products, except that the branched parts of their molecules remain as α-limit dextrins as their 1,6-glycosidic bond cannot be hydrolyzed by α-amylase. The digestion products of α-amylase are subsequently hydrolyzed, particularly by brush-border maltase (glucoamylase) and isomaltase (α-dextrinase). The brush-border enzyme trehalase hydrolyzes the 1,1 link in the fungal sugar trehalose, but is not expressed in cats.

Sucrose is an unusual constituent of canine and feline diets unless semimoist pet foods or human foods are fed. It is hydrolyzed directly at the brush-border to glucose by sucrase, part of the sucrase–isomaltase brush-border enzyme complex. Congenital sucrase–isomaltase deficiency is a rare genetic defect of man, but has not been recorded in small animals. Sucrase activity in cats is lower than dogs (Table 57-1), probably reflecting the average composition of their diets.

Lactose is found almost exclusively in dairy products and its hydrolysis to glucose and galactose by brush-border lactase is nutritionally most important in the nursing animal. At weaning, activities of lactase begin to decline, especially in cats, and adult animals may exhibit lactose intolerance if fed excess milk. This mirrors the age-related downregulation of lactase expression seen in certain human races. If animals have underlying SI disease, dairy products

should be avoided as marginal lactase activities will be reduced even further. Absolute congenital lactase deficiency, as seen rarely in humans, has not been demonstrated in cats or dogs.

Protein

Digestion of proteins follows a similar overall pattern to carbohydrate digestion (see Figure 57-5, *B*), and the amounts of pancreatic enzyme secreted and mucosal peptidases expressed are influenced by the protein content of the diet. Digestion is initiated by acidic denaturation and the proteolytic activity of pepsin in the stomach. Luminal digestion under a more neutral pH is continued in the SI by pancreatic proteases (trypsin, chymotrypsin, elastase, and carboxypeptidase), which are initially secreted as inactive proforms, and are subsequently activated by enterokinase and trypsin. Luminal proteolysis results in a mixture of oligo-, tri-, and dipeptides as well as free amino acids. Oligopeptides are subsequently hydrolyzed by brush-border peptidases, which have some selectivity for particular amino acid residues. However, there is considerable overlap in specificity, and a selective deficiency of aminopeptidase N reported in dogs is of no clinical consequence. Furthermore, any tri- and dipeptides can still be absorbed on a brush-border carrier. Theoretically a deficiency of enterokinase could cause protein malabsorption through failure of trypsin activation, but this has never been documented in dogs and cats, and trypsin autoactivation would probably still occur.

Lipid

Fat digestion is completed entirely within the GI lumen by secreted enzymes and bile salts. Partial digestion is begun in the stomach by the action of gastric lipase secreted by gastric epithelial mucus cells. Subsequent mixing of the fat emulsifies it into small droplets. Further mixing with bile and pancreatic juice results in the formation of mixed micelles, which are approximately $1/100$ the size of the smallest fat droplet and solubilize approximately 1000 times more fatty acids. At the surface of mixed micelles, triglyceride is hydrolyzed by pancreatic lipase to di- and monoglycerides and free fatty acids (Figure 57-6). Maximal lipase activity in the gut lumen is dependent on a protein cofactor, colipase, which is secreted by the pancreas as inactive procolipase. There is some reserve capacity for fat digestion if pancreatic function is normal, and a fat-rich diet, especially one rich in unsaturated fatty acids, also stimulates increased pancreatic lipase secretion. However, neuroendocrine mechanisms initiated by the presence of fat in the duodenum and ileum, control the rate of gastric emptying and hence the rate of fat delivery. Thus a fat-rich diet or intestinal fat malabsorption delays gastric emptying.

Pancreatic phospholipase A_2 is secreted in an inactive form, and once activated in the intestinal lumen hydrolyzes phospholipid to lysophospholipids. Finally, pancreatic cholesterol esterase deesterifies cholesterol. After fat absorption, the bile salts may form further mixed micelles, but ultimately are reabsorbed by a specific

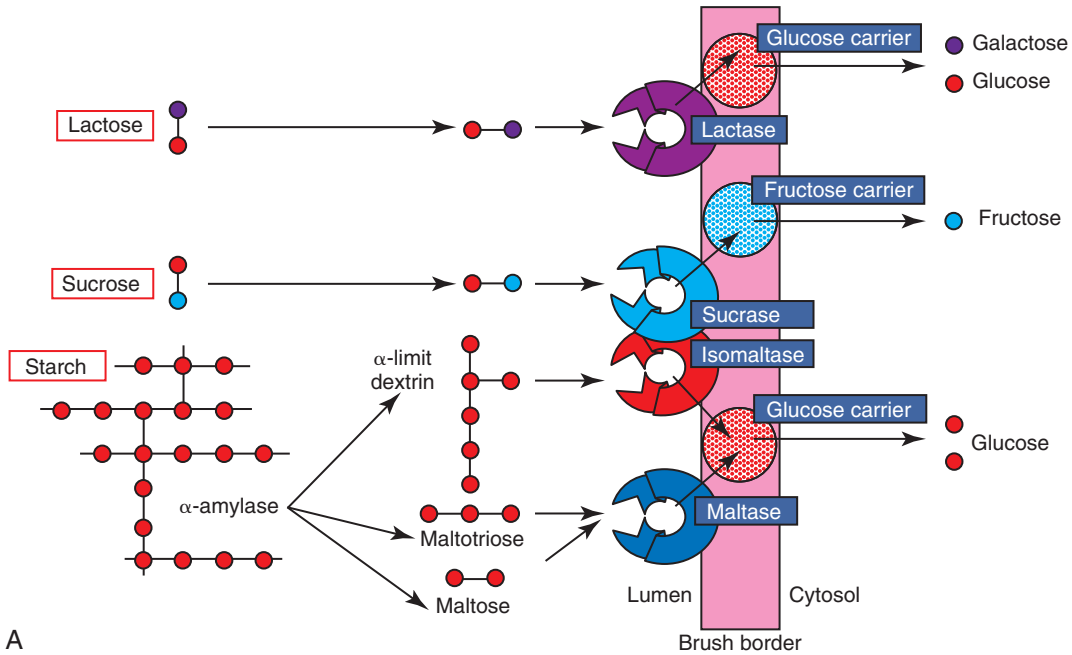

Figure 57-5 Diagram of the digestion and absorption of (**A**) carbohydrate, (**B**) protein, and (**C**) fat. (Adapted from Batt RM: The molecular basis of malabsorption. *J Small Anim Pract* 21:555, 1980.)

sodium-linked cotransporter in the ileum and recycled from the portal blood back into bile.

Nucleotides

Little is known of the digestion of dietary nucleotides and hydrolysis of nucleic acids released from exfoliated enterocytes. Ribonuclease and deoxyribonuclease are present in pancreatic secretions, and there is a common sodium-dependent brush-border carrier for the uptake of purines and pyrimidines.

Absorption

Digested Nutrients

Simple sugars, amino acids and oligopeptides, and fatty acids and other lipids are delivered to the body across the mucosal barrier and

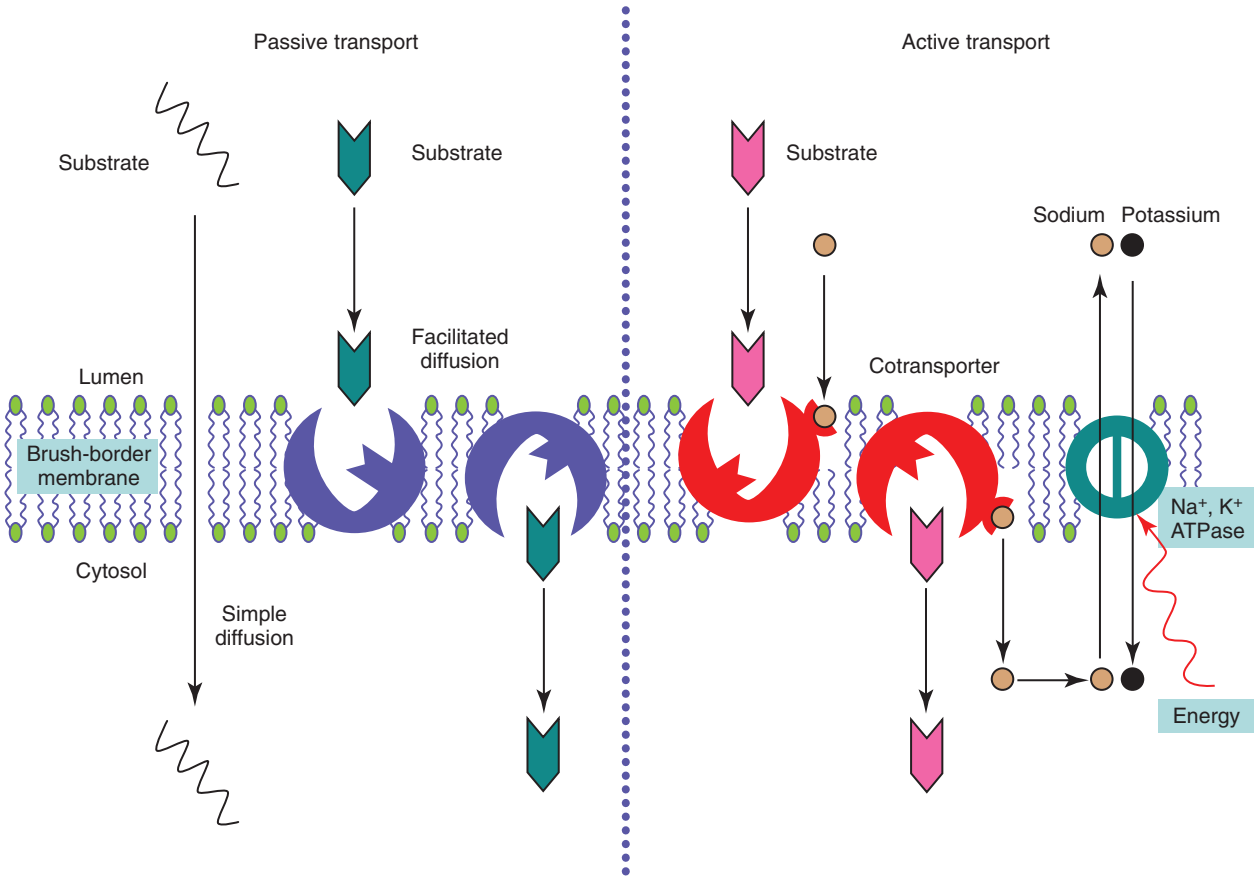

Figure 57-6 Mechanisms of diffusion.

then via the lymphatics or bloodstream.[23,24] Uptake occurs by passive diffusion or by active or facilitated carrier-mediated transport mechanisms (see Figure 57-6). Endocytosis of small, antigenic peptides is of no nutritional significance, but is involved in the neonatal absorption of colostral antibodies, and is crucial to the mucosal immune response.

The products of fat digestion are absorbed by passive diffusion from mixed micelles across the MVM and ultimately lipoproteins are passed into lacteals. The limiting factors, assuming normal pancreatic function, are the intestinal surface area and lymphatic functionality, and so villus atrophy and lymphangiectasia are likely to cause malabsorption of fat.

Mechanisms of Absorption

Passive Diffusion

Lipid-soluble products of digestion do not need a specific carrier mechanism to be absorbed across the mucosal barrier, and can bypass passive diffusion by "dissolving" in the brush-border membrane. This absorptive process obeys the Graham Law of Diffusion, being proportional to the concentration gradient across the membrane, nonsaturable, and limited only by the surface area of the membrane. Diffusion back across the brush-border is prevented by reesterification of free fatty acids within the enterocyte.

Carrier-Mediated Transport

Some small, nonpolar, water-soluble molecules (and perhaps water molecules) also appear to be absorbed by passive diffusion through "pores" in the mucosal membrane. The structure of these hypothetical pores is likened to that of ion channels in other membranes (i.e., small fixed channels through the membrane that function without a conformational change). Molecules with a molecular radius greater than 0.4 nm appear to be excluded, but larger, although numerically fewer pores may traverse tight junctions. Debate remains as to whether the predominant route is via an intracellular or paracellular route through tight junctions.

Water-soluble nutrient molecules that are too large to diffuse via the "pore route" and are insoluble in the lipid MVM must cross the brush-border on specific carrier proteins that bridge the membrane. Conformational changes in the carriers are thought to shuttle the substrate molecule across. The products of carbohydrate and protein digestion enter by this process. Transport proteins are usually highly specific and may only carry the L or D isomer of a molecule, but competitive inhibition with related solutes may occur. The number of carrier molecules in the mucosa is finite, so that the process is saturable, and although the expression of the carriers may be inducible, dietary overload is likely to cause transient intolerance and diarrhea.

Active transport of substrates across the MVM into the enterocyte is usually against a concentration gradient and energy must be expended to drive the process (see Figure 57-6). Usually the uptake of the nutrient is linked to the entry of sodium down its electrochemical gradient, with energy expenditure by a N^+-K^+-ATPase on the basolateral membrane of the enterocyte pumping sodium back out of the cell.

Facilitated transport is the carriage of substrates by a transport protein across the MVM, down a concentration gradient without energy expenditure (see Figure 57-6). Some sugars, oligopeptides,

and folate are absorbed by this process. The number of carriers is finite, and the process saturable and subject to competitive inhibition.

Endocytosis

Small antigenic peptides may be engulfed nonspecifically within endocytotic vesicles of epithelial cells. The amounts absorbed by this route are negligible from a nutritional standpoint, but this sampling of luminal contents is crucial to the mucosal immune response (see Chapter 3). Receptor-mediated endocytosis enables the uptake of small amounts of a specific intact nutrient and is the mechanism of cobalamin absorption.

Nutrient Absorption

Carbohydrate

The main product of carbohydrate digestion, glucose, is absorbed by active transport on a stereo-specific carrier that recognizes a D-pyranose structure with a C-2 hydroxyl group. Glucose is cotransported with sodium; the energy required for the coupling is provided through the entry of sodium down a concentration gradient but with the basolateral N^+-K^+-ATPase reexporting sodium against the concentration gradient. The carrier molecule in the brush-border has been identified in many species, including dogs and cats, as the sodium-glucose cotransporter protein (SGLT1; Figure 57-7). This molecule has the highest affinity for glucose, but it is also the carrier for galactose. Indirect evidence for this is shown by the inability to absorb either sugar in people with glucose–galactose malabsorption in whom a single amino acid mutation ($Asp_{28} \rightarrow Asn_{28}$) in the SGLT1 protein has been identified. Glucose and galactose thus may exhibit competitive inhibition, but glucose is the major substrate. There is circumstantial evidence for another aldohexose carrier in cats.

Facilitated transport of glucose across mammalian cell membranes is performed by a family of facilitated glucose transporters (GLUTs) with different isoforms found in different tissues. One member of this family, GLUT2, is found on the basolateral membrane of enterocytes, where it shuttles glucose, galactose, and fructose out of the enterocyte by facilitated diffusion (see Figure 57-7). GLUT2 is absent from the brush-border, and so a mechanism exists for active transport of glucose across the MVM into the enterocyte by SGLT1 and facilitated transport into the body by GLUT2. Most of the glucose is not used within the enterocyte, because of expression of a phosphofructokinase isomer that directs metabolism away from glycolysis.

Another member of the facilitated glucose transporter family, GLUT5, is found on the brush-border. It shares homology with other family members but actually allows facilitated diffusion of fructose; it is not even competitively inhibited by glucose. In humans, GLUT5 is also probably the site of D-xylose absorption, as both fructose and xylose absorption are unaffected in glucose–galactose malabsorption. However, the mechanism of D-xylose uptake is species dependent, and evidence for facilitated diffusion in dogs and cats has largely been extrapolated from humans. Nevertheless, fructose uptake in cats is low, and D-xylose absorption is equally low. This may be one reason why the xylose absorption test is unhelpful in cats. However, potential fructose malabsorption has little clinical relevance in cats as the feline diet likely contains little fructose.

Although dietary carbohydrates must be hydrolyzed to monosaccharides to be absorbed and be nutritionally useful, a small but measurable amount of disaccharide can cross the brush-border, probably through leaky tight junctions. This is of no nutritional significance, but increased uptake and subsequent urinary excretion of disaccharides can be a marker of increased intestinal permeability when damaged.

Protein

The products of protein digestion are absorbed on carriers that are stereo-specific for L-amino acids (Figure 57-8; also see Figure 57-5, *B*).[25] Sodium-linked active transport is responsible for free amino acid uptake via one of four different carriers that have a variable degree of selectivity for neutral (Gly, Ala), acidic (Asp, Glu), basic (Arg, Lys), and imino (Pro, HO-Pro) amino acids. The cat has the highest rate of uptake of basic amino acids perhaps because it has an essential requirement for arginine.

Traditionally, peptide uptake has been considered to be facilitated diffusion, with the concentration gradient being maintained by intracellular peptide hydrolysis, and only free amino acids being exported from enterocytes into the portal blood (see Figure 57-8). A single carrier for di- and tripeptides with no selectivity for their amino acid content has been demonstrated. However, in people this

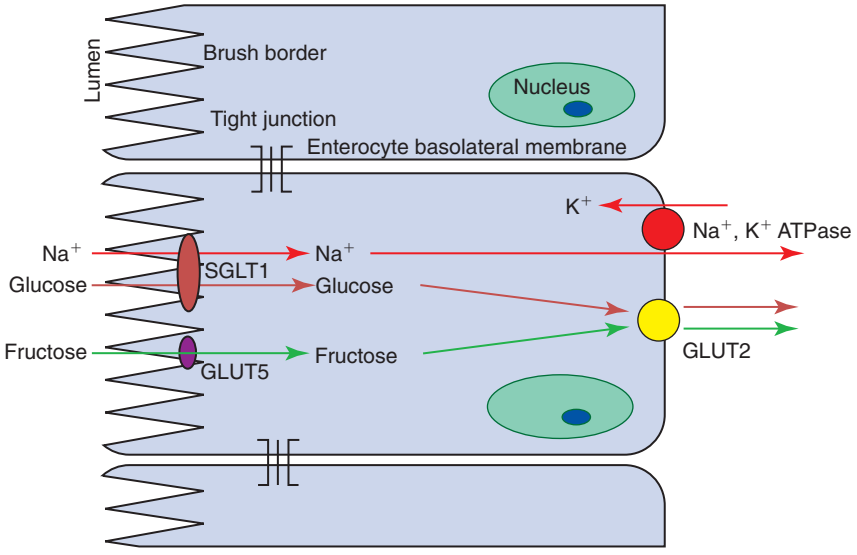

Figure 57-7 Diagram of the absorption of monosaccharides by enterocytes. GLUT, Glucose transporter; SGLT, sodium-glucose co-transporter protein.

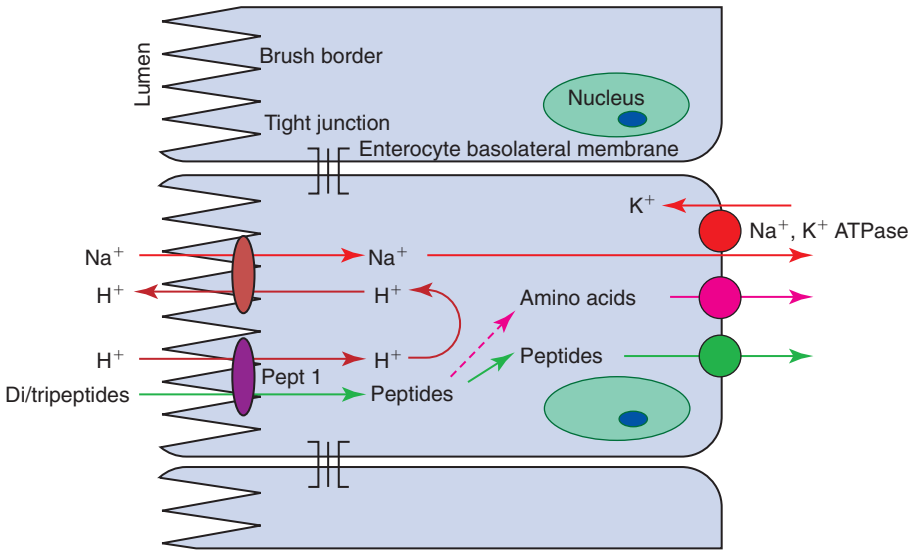

Figure 57-8 Diagram of the absorption of di- and tripeptides by enterocytes. Pept 1, a peptide carrier.

peptide carrier, Pept-1, is involved in the active influx of peptides, being linked to the influx of H^+ down an electrochemical gradient. The protons are exchanged across the MVM with sodium, which is pumped out by the basolateral N^+, K^+ ATPase. A mixture of peptides and free amino acids is exported to the blood, but it appears that peptides are absorbed more readily than free amino acids. This has clinical significance as the inclusion of dipeptides in elemental diets has a theoretical advantage over simple amino acid solutions. This transport protein is also the carrier for peptidomimetic drugs such as β-lactams and angiotensin-converting enzyme inhibitors.

Lipid

The products of fat digestion are absorbed by passive diffusion from mixed micelles into lacteals (see Figure 57-5, C). The limiting factors, assuming normal pancreatic function, are the intestinal surface area and lymphatic functionality, and so villus atrophy and lymphangiectasia are likely to cause malabsorption of fat.

Generally, the products of fat digestion are reassembled within enterocytes to prevent rediffusion back out of the enterocyte. They are combined with synthesized lipoproteins for passage into the lymphatics as chylomicrons. However, medium-chain triglycerides (length = 8-12 carbon atoms) can be absorbed directly into the portal blood, and provide an alternative route for fat uptake when lymphatic flow is impaired, as in lymphangiectasia. However, evidence exists that a proportion of medium-chain triglycerides are absorbed into the lacteals as they can be found within the thoracic duct.

Fat-Soluble Vitamins

Dietary fat-soluble vitamins A, D, E, and K are solubilized in mixed micelles before passive diffusion across the brush-border. Fat malabsorption associated with inadequate amounts of bile salts (e.g., bile duct obstruction), lymphangiectasia, or severe villus atrophy is also likely to result in vitamin deficiency. This is clinically most relevant for vitamin K as its body stores are not large and, particularly in cats, can lead to vitamin K–dependent coagulation factor deficiencies.

Vitamin A (retinol) is ingested either as a dimer (beta-carotene) or as an ester that must be hydrolyzed by pancreatic esterases. Beta-carotene is absorbed directly from micelles, but retinol is insoluble and must be anchored by a binding protein before absorption. Subnormal serum vitamin A concentrations have been observed in dogs with EPI but no associated signs of deficiency have been reported. However, vitamin A supplementation has been recommended following surgery in animals subsequently treated with corticosteroids to aid wound healing, and would be particularly relevant in animals that have had surgical intestinal biopsies.

Vitamin D is absorbed from mixed micelles. It is important for calcium homeostasis, controlling calcium absorption from the gut, as well as renal excretion. Vitamin D malabsorption may be (partly) responsible for the reductions in serum ionized calcium and magnesium that are reported in protein-losing enteropathies, which cannot be due to reduced protein binding because of hypoalbuminemia.

Vitamin E (α-tocopherol) is absorbed from mixed micelles by passive diffusion, and passes into the lymphatics unchanged. Vitamin E deficiency has been reported in Beagles with severe malabsorption, and is associated with EPI and bacterial overgrowth in German Shepherd dogs.

Vitamin K is derived from dietary sources (K_1) and synthesis by the enteric flora (K_2). Vitamin K_2 is probably absorbed in the ileum and colon. As well as bile salt deficiency, prolonged antibiotic usage may result in vitamin K deficiency.

Water-Soluble Vitamins

Water-soluble vitamins B and C are absorbed by a mixture of passive diffusion (e.g., pyridoxine [B_6] and C), saturable facilitated transport (e.g., riboflavin [B_2]), or active and facilitated transport (e.g., thiamine [B_1]) in other species, but the mechanisms in cats and dogs are uncertain. The absorptive mechanisms for folic acid and vitamin B_{12} are more complex and important clinically as they may be helpful in determining the site and nature of intestinal disease.

Folic acid is present in adequate amounts in most commercial foods, but is also produced by the enteric flora. It is usually conjugated in a poorly absorbable polyglutamate form and must be hydrolyzed by folate deconjugase, a brush-border enzyme, before absorption. Folate (pteroyl monoglutamate) is absorbed by a carrier-mediated process at low luminal concentrations and by passive diffusion at high concentrations (Figure 57-9). After absorption folate is methylated in the cell to form methyltetrahydrofolate.

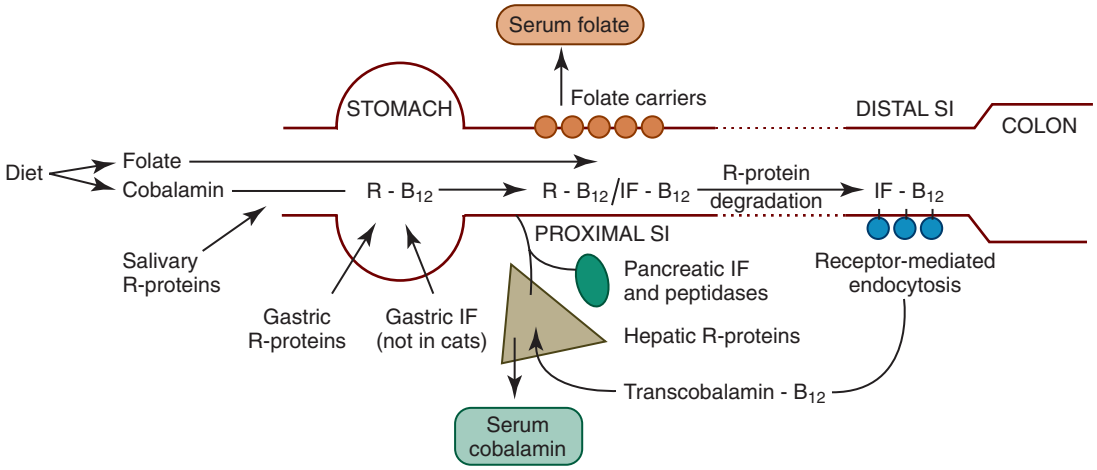

Figure 57-9 Diagram of the absorption of folate and cobalamin. Folate is absorbed in the proximal SI by means of carrier-mediated diffusion. Dietary cobalamin is initially protected from digestion by R proteins, and is then absorbed in the ileum through receptor-mediated endocytosis bound to intrinsic factor (IF). (From Ettinger SJ, Feldman EC, editors: *Textbook of Veterinary Internal Medicine*, ed 7, Philadelphia, 2010, Saunders, p 1528, Figure 270-1A.)

Vitamin B_{12} (cobalamin) is absorbed by receptor-mediated endocytosis in the ileum (see Figure 57-9), but the process is complex so that intact cobalamin is absorbed and potentially harmful analogues are excluded. Following ingestion, cobalamin is released from food in the stomach and then bound by R proteins (haptocorrins), which are nonspecific binding proteins of salivary and gastric origin. At acidic pH, cobalamin has high affinity for R proteins, but on entering the more alkaline environment of the SI, R proteins bind cobalamin less avidly and undergo proteolysis. Thus cobalamin is transferred to another binding protein, intrinsic factor, which promotes cobalamin absorption in the ileum. The source of intrinsic factor is the stomach and pancreas in dogs and solely the pancreas in cats. Intrinsic factor–bound cobalamin complexes pass to the ileum until they bind specific receptors and are endocytosed. Cobalamin is passed into the portal blood where it is bound to a protein, transcobalamin 2, enabling it to enter tissues and to be reexcreted in bile. Inherited abnormalities of the cobalamin–intrinsic factor receptor in breeds such as the Giant Schnauzer and Border Collie cause selective cobalamin deficiency.

Minerals

Zinc and copper are absorbed via divalent cation transporters. There is competition for binding, while intracellular binding of copper by metallothionein is also part of the normal homeostatic mechanism, as the copper is trapped within effete enterocytes and shed.

Iron is absorbed by the duodenum and proximal jejunum both as heme and nonheme iron. Heme, found largely in meat, is better absorbed as it is unaffected by other dietary constituents or intraluminal factors. Gastric acid and chelation with mucopolysaccharide, ascorbate, and citrate help maintain iron in solution for absorption, and ferrous forms of nonheme iron are better absorbed than ferric forms. Ferrous iron is absorbed by an energy-dependent carrier mechanism, and is carried out of the enterocyte bound to transferrin. However, absorption is regulated, and if the body is iron-replete, crypt cells synthesize apoferritin, which traps iron in enterocytes as ferritin. When the enterocyte is exfoliated at the villus tip, the trapped iron is excreted back into the lumen.

Calcium absorption is complex and is modulated by systemic control mechanisms. In particular, vitamin D stimulates the activity of calcium-binding protein within enterocytes. However, uptake of calcium at the brush-border is an active process and is markedly influenced by the intraluminal pH and other substances such as organic and inorganic phosphates.

Motility

Slow wave, segmental, and peristaltic contractions of the SI are generated by the coordinated contraction of smooth muscle in response to spontaneous electrical activity.[26-34] Interstitial cells of Cajal are considered coordinating/pacemaker cells and smooth muscle contraction is also modulated by coordinated neurohumoral and neurochemical molecule release. Many of these molecules are also involved in the regulation of intestinal secretion and absorption and the mucosal immune response, producing a complex coordinated process for the digestion of food.

Intestinal motility in the fasted state in dogs is characterized by three phases. A cycle comprising a quiescent phase (lasting approximately 1 hour), phase two comprising minor contractile activity (15 to 40 minutes), and then migrating myoelectric (motor) complexes (MMCs) (4 to 8 minutes), and is repeated approximately every 3 hours. The short MMC phase is a period of intense contractile activity that sweeps undigested food, secretions, desquamated cells, and bacteria down the intestine. This process is known as the *intestinal housekeeper* wave and is induced by motilin secretion. Erythromycin can stimulate motilin receptors and at low doses it can be prokinetic mimicking the MMC; higher doses overstimulate and may cause emesis. The pattern of intestinal motility in cats is somewhat different, but a migrating spike complex correlates with the MMC.

In the fed state, the pattern of motility is most similar to phase two fasting motility. Its duration is determined by the nature of the diet, with fats and fiber prolonging it. The presence of unabsorbed fat in the distal SI reflexly inhibits gastric emptying by neurohormonal mechanisms. This "ileal brake" mechanism may be the cause of the delayed gastric emptying that is typically seen in malabsorption. Feeding a patient with SI disease more than four times a day is unlikely to be helpful as the stomach will be trickle-feeding it anyway.

Segmental contractions slow intestinal transit and ensure mixing and digestion of nutrients, until peristalsis propels the ingesta onwards. Reduced segmental motility may lead to rapid transit, and decreased peristalsis delays transit, conditions manifesting clinically as diarrhea and ileus, respectively.

Secretion and Absorption of Water and Electrolytes

Intestinal secretion, a function of villus crypt cells, is believed to occur by passive flux of water osmotically following active transcellular chloride secretion into the intestinal lumen. Bacterial toxins can cause hypersecretion.

The ability of the intestine to absorb fluid and electrolytes varies according to the site, with water absorption becoming increasingly efficient distally. The net amount of fluid and electrolytes in the GI tract reflects a balance between absorption and secretion, with net absorption in health. However the daily fluxes are massive (approximately 2.7 L/day in a 20-kg dog) and the consequences of net loss is not only diarrhea but also rapid dehydration.

The absorption of water is passive and follows transport of solutes across the GI epithelium by one of three processes: passive absorption, active absorption, or solvent drag. The jejunum absorbs approximately 50%, the ileum approximately 75%, and the colon approximately 90% of the fluid volume presented to it, leaving approximately 2% in feces. This gradient in absorptive ability is a function of enterocyte pore size, membrane potential difference, and the type of transport processes associated with each intestinal segment. The site of the enterocyte on the villus is also important; villus enterocytes absorb, whereas crypt cells secrete.

Colonic absorption is important in SI disease because it helps to compensate for fluid losses and diarrhea will only occur if the colonic reserve capacity is overwhelmed. SI dysfunction may then present with signs of dysfunction of the large intestine because products from the SI, such as hydroxylated fatty acids and deconjugated bile acids, stimulate colonic secretion.

Control of Fluid Balance

Intestinal fluid balance is regulated by the neurocrine systems in the submucosal plexus as a largely autonomous process.[35,36] Acetylcholine and vasoactive intestinal polypeptide are major mediators of secretion, increasing intracellular calcium and cyclic adenosine monophosphate (cAMP), inhibiting neutral sodium and chloride absorption, and facilitating transcellular chloride efflux. Many bacterial agents exert their diarrheagenic effects by increasing cAMP in enterocytes. The principal regulators of absorption—noradrenaline, somatostatin, and opioids—lower intracellular cAMP and calcium concentrations and stimulate neutral NaCl absorption and thereby can have therapeutic antidiarrheal effects.

Mucosal Immunity

The mucosal immune system is a large and complex organ and is critical to the health of not only the intestine but the whole animal. Chapter 3 describes its structure and function in detail.

DIAGNOSTIC EVALUATION

Edward J. Hall

General Approach

As most cases of small intestinal disease are acute, self-limiting, and nonfatal, they require only symptomatic support and not necessarily a definitive diagnosis. Medical investigation is more necessary if acute diarrhea is hemorrhagic, accompanied by systemic signs, and unresponsive to symptomatic treatment, although the extent of the medical workup may still be a balance between the severity of the illness and the cost of investigation. By definition, chronic diarrhea is not self-limiting, and an etiologic or histopathologic diagnosis is usually required to allow specific treatment.

The history and physical examination are crucial steps toward reaching a diagnosis and in some cases may be all that is required. Preliminary laboratory investigation may include collection of baseline data (e.g., hematology, serum biochemistry, urinalysis, and fecal examination), and are performed before more specific laboratory tests, imaging, and biopsy with histopathologic investigations are undertaken.

History

Background

Information about the recent activity of a patient is helpful in acute small intestinal disease as it may follow an episode of dietary indiscretion, particularly if the animal is allowed to roam or has contact with other animals with infectious gastroenteritis. A full dietary history is helpful when investigating chronic disease, especially when trying to formulate an exclusion diet. Travel information is important as regional infectious diseases, such as histoplasmosis, may move from one geographic site to another.

Clinical Signs

The presence of dehydration should be ascertained by clinical signs (e.g., skin tenting, tachycardia, dry mucous membranes, and depression) and addressed therapeutically, as dehydration can rapidly become life-threatening through profuse diarrhea. Metabolic acidosis and hypokalemia are common acid–base and electrolyte abnormalities, and a balanced electrolyte solution containing potassium can be administered while the medical investigation is being pursued.

The cardinal sign of small intestinal disease is diarrhea, but other signs (Box 57-2) may occur in the absence of diarrhea. Vomiting may be stimulated by intestinal distention or inflammation, and, indeed, vomiting is the most common manifestation of inflammatory bowel

Box 57-2 Clinical Signs of Small Intestinal Disease

Cardinal sign
- Diarrhea
- Increase in frequency, volume, and consistency of stool

Other signs
- Vomiting
- Weight loss and/or failure to thrive
- Hematemesis
- Melena
- Altered appetite
- Inappetence/dysorexia
- Anorexia
- Polyphagia
- Coprophagia
- Pica
- Abdominal discomfort, pain
- Abdominal distention
- Borborygmi and flatus
- Halitosis
- Dehydration
- Polydipsia (compensatory)
- Ascites and edema
- Shock

disease (IBD) in cats. Vomiting of blood may indicate gastric and/or upper GI bleeding, and copious volumes of bilious vomit are suggestive of upper GI obstruction. More distal obstructions of the SI may cause infrequent vomiting of a fecal-like material.

Anorexia can be a feature of intestinal disease, especially if there is sepsis, severe inflammatory, or extensive neoplastic disease. Some weight loss is expected in anorexic patients, but losses in the face of an increased appetite (or very rapid losses) are often an indication of malabsorption, and/or PLE. Severe SI disease is sometimes observed despite the absence of any diarrhea, which is testament to the colon's reserve capacity for the absorption of water (see Chapter 1).

Diarrhea caused by SI disease is usually of large volume and watery, but passed only a few times each day. Urgency and tenesmus are rare findings unless there is colonic involvement in a more diffuse disease process, or if colitis has developed secondary to the chronic passage of undigested food. Diarrhea associated with SI disease may contain undigested food, especially fat (steatorrhea), and may be malodorous; patient breath may have a characteristic odor, as well. The diarrhea can be a bizarre color, such as yellow or green, indicative of incomplete intestinal bacterial metabolism of excreted bile pigments that normally impart a brown color to the feces.

If there is bleeding, the blood is usually partially digested, and if in sufficient volume, will be recognized as melena; at least 1 mL blood/kg/day must be lost before it becomes grossly visible.

Physical Examination

Nonspecific signs of SI disease, such as dehydration and weight loss, are readily apparent, and fever is sometimes present with infectious enteritis. Weight and body condition score should be recorded in all patients.

Direct, noninvasive examination of the SI is impossible, but examination of the mouth for a linear foreign body and rectal examination should be performed. Abdominal palpation is best performed with gradual, gentle, manual pressure on the abdomen. In larger dogs pressure is applied between the hands placed on either flank, but in cats and small dogs the thumb and fingers of one hand may be used. Elevating the cranial abdomen may allow masses normally within the rib cage to fall back to where they can be detected. Masses, foreign bodies, or distended or thickened loops of bowel may be readily palpated. However, the success of palpation depends not only on the skill and patience of the examiner, but also on the body condition and patient compliance. Abdominal palpation should be repeated at least daily in hospitalized patients, and the opportunity should be taken to repeat palpation if the patient is sedated or anesthetized when the abdominal wall will be relaxed.

Free fluid within the peritoneal cavity should be detected by ballottement; tapping on one side of the abdomen allows detection of a fluid wave on the opposite flank. Detection of abdominal pain may be more difficult, depending on how the patient responds. Specific localization is rarely possible as abdominal visceral sensory output is not segmental and decussates within the spinal cord. Localized peritonitis may be detected as the parietal peritoneal sensory output is segmental.

Minimum Database

Results of the hemogram, serum biochemistry, and urinalysis are rarely diagnostic of any specific SI disease. Indeed they are often more reflective of hydration status, and are largely undertaken to rule out diseases in other organ systems that may manifest with SI signs. Some changes can help assess dehydration (e.g., packed cell volume, total solids/proteins, azotemia) and secondary electrolyte abnormalities, but changes seen in SI disease are often quite nonspecific.

Hemogram

Elevation of the packed cell volume can be indicative of dehydration, whereas extreme erythrocytosis is a hallmark of hemorrhagic gastroenteritis or paraneoplastic syndrome. Paraneoplastic production of erythropoietin by intestinal stromal cell tumors causing erythrocytosis has been reported in rare cases.

Anemia can reflect chronic illness or intestinal blood loss. Mild normocytic normochromic anemia is the most common abnormality, but a regenerative anemia may be seen if there is blood loss. Hypochromic, microcytic anemia (and thrombocytosis) is indicative of iron deficiency, which can occur through chronic SI blood loss.

A stress leukogram is often associated with significant SI disease, but an inflammatory leukogram is unusual, even in the presence of marked intestinal inflammation. Neutrophilia, left shift, and sometimes toxic neutrophils can indicate incipient sepsis or SI perforation and peritonitis. Eosinophilia can be a result of parasitism, but is an unreliable marker of intestinal parasites and eosinophilic enteritis. Marked eosinophilia may be seen as a paraneoplastic effect in lymphoma and mastocytosis.

Serum Biochemistry

Total serum proteins will be increased if there is dehydration and decreased by chronic blood loss. If a PLE exists, panhypoproteinemia typically develops, as both albumin and globulin are lost through the leaky gut wall. This can usually be differentiated from protein-losing nephropathy (low albumin, normal globulin, proteinuria) and hepatic failure (low albumin, raised globulin, and hyperbilirubinemia). Occasionally hyperglobulinemia is found in severe IBD, and a monoclonal gammopathy is seen rarely in alimentary lymphoma and plasmacytoma.

Liver enzymes may be elevated secondarily in SI disease because of portal venous transport of toxins and/or bacteria from a compromised SI, but overall liver function (as assessed by serum bile acids) will usually be normal. Hypocholesterolemia is a crude indicator of malabsorption.

Hypoglycemia is a complication found in perinatal patients that have reduced nutritional intake during SI disease. Paraneoplastic hypoglycemia is occasionally found with SI stromal cell tumors that produce insulin-like factors.

Prerenal azotemia (i.e., increased urea and creatinine) will develop if the patient is dehydrated, but an increased urea-to-creatinine ratio in a fasted animal is suggestive of GI bleeding, with conversion of blood proteins to ammonia by intestinal bacteria, and hence urea formation by the liver.

Hypokalemia is common in SI disease as a result of decreased intake and intestinal losses. The finding of an abnormal sodium-to-potassium ratio may identify cases of hypoadrenocorticism, but is sometimes seen in primary SI disease, notably salmonellosis and whipworm infection,[1] or if ascites and third-space effects are associated with PLE.

Fecal Examination

Fecal examinations[2] are an important component in the investigation of SI disease. Tests such as quantification of fecal fat excretion are unsuitable for most practice settings, and bacteriologic culture

is sometimes of questionable value, but identification of endoparasites is important.

Direct Smear

Fecal smears can be stained for undigested starch granules (Lugol iodine solution), fat globules (Sudan stain), and muscle fibers (Wright or Diff-Quik stain). Positive findings may indicate maldigestion and malabsorption but are generally unreliable and completely nonspecific. The presence of fungal elements is of uncertain significance, but rectal cytology may be useful, with fecal leukocytes being suggestive of intestinal inflammation.

Unstained wet mounts may be used to identify protozoal trophozoites of *Giardia* (dogs and cats) or *Tritrichomonas* (cats). Clostridial endospores and fungal elements (*Histoplasma*, *Aspergillus*, *Pythium*, and *Candida* spp.) may be identified. Enterotoxin production by *Clostridium perfringens* is a potential cause of diarrhea. The presence of a large number of clostridial endospores (more than 5 per oil field) on Diff-Quik–stained smears may be significant, but a positive fecal enterotoxin assay (enzyme-linked immunosorbent assay [ELISA] or reverse passive latex agglutination) is likely more significant. However the correlation of sporulation, toxin production, and diarrhea is unclear.[3]

Rectal Cytology

Although probably more relevant for large intestinal disease, the rectal wall can be very mildly abraded at the end of a rectal examination, and the gloved finger rolled on a microscope slide for special staining. Cytologic examination is often negative, showing only bacteria and fecal debris, but when positive it can provide some useful information. Although the test is fast and simple, in all cases confirmatory tests are indicated. An increased number of neutrophils may be suggestive of a bacterial problem, indicating the need for fecal culture, and malignant lymphocytes may exfoliate if lymphoma is present. *Histoplasma* and *Prototheca* organisms may be visualized.

Fecal Concentration Techniques

For detection of most parasites, fecal concentration techniques are more rewarding. Examination of three fecal samples by zinc sulfate flotation is recommended to detect *Giardia* oocysts. A direct smear, sedimentation, or the Baermann technique can identify larvae of *Strongyloides* spp.

Bacteriologic Examination

Routine Culture

The culture of all bacteria from a fecal sample in vitro is of little value, but targeted evaluation for potential pathogens may be helpful, although molecular techniques may be needed to identify pathogenic strains. For example *Escherichia coli* can be cultured from most fecal samples, but only certain strains are pathogenic, and polymerase chain reaction (PCR) probes are needed to detect genetic pathogenicity markers.

Culture of feces is indicated in animals with acute hemorrhagic diarrhea, with fever, and an inflammatory leukogram, and/or with neutrophils on rectal cytology. Identification of *Salmonella* spp., *Campylobacter jejuni*, and *Clostridium difficile* may be helpful, although the significance of a positive isolate should be interpreted in the light of the clinical history, because these organisms can be present in the feces of clinically healthy animals. Furthermore, the fecal flora does not necessarily reflect the SI flora and cannot be used to diagnose small intestinal bacterial overgrowth, but may be representative of colonic bacterial populations.

The significance of a positive result needs further evaluation, because potential pathogens can be isolated from feces from both healthy and ill dogs. Failure to speciate *Campylobacter* isolates may lead to erroneous conclusions, as the relatively nonpathogenic, and potentially commensal, *Campylobacter upsaliensis* is a more common isolate from dog feces than the pathogenic *C. jejuni*. Testing by PCR may aid speciation, but still does not overcome the fact that isolation does not necessarily indicate the cause of the diarrhea. Feces can be cultured for fungi, such as *Histoplasma capsulatum*, but isolation is difficult and slow.

Molecular Fingerprinting[4]

Many intestinal bacteria cannot be cultured in vitro. Identification can be performed by comparative gene sequencing of the bacterial 16S ribosomal RNA (rRNA) derived from mucosal brushings or fecal samples. This method can be used to identify a single species using degrading gradient gel electrophoresis or to look at the pattern of the flora in both mucosal brushings and feces by the high-throughput pyrosequencing metagenomic approach (see Chapters 2 and "Infection" section in this chapter).

Virologic Examination[5]

Viral diarrhea is usually acute and self-limiting and does not require a positive diagnosis. Electron microscopy can be used to identify the characteristic viral particles of rotavirus, coronavirus, and parvovirus. Fecal ELISA tests for parvovirus are also available.

Examination for Protozoa

Coccidia

Oocysts are best detected by fecal flotation methods.

Giardia

Zinc sulfate flotation in the hands of an experienced technician remains the diagnostic method of choice. A commercially available ELISA can be used to detect *Giardia* antigen in feces and may be more sensitive. PCR is also likely to be more sensitive.

Tritrichomonas fetus[6]

Infection with this organism, which can be an important pathogen in young cats,[6] and may complicate canine diarrhea, can be diagnosed by direct evaluation of a fresh fecal smear, although experience is needed to distinguish it from *Giardia*. In vitro culture in pouches, developed to identify cattle infections, can be used but needs to be examined every 2 days for the presence of the organism. A fecal PCR is available, but can be problematic because of inhibitors of the PCR reaction in feces, and the intermittent excretion of the organism; false negatives are less likely if diarrheic feces or colonic washings are used.

Occult Blood

At least 1 mL of blood per kilogram of patient body weight is needed to recognize overt melena.[7] The occult blood test is used to test for intestinal bleeding from ulcerated mucosa and benign or malignant tumors before melena is observed grossly. Unfortunately, it is very sensitive and tests nonspecifically for hemoglobin from any mammalian species, thus reacting with any dietary meat as well as patient blood. Consequently the patient must be fed a meat-free diet for at least 72 hours for a positive result to have any significance.

α_1-Protease Inhibitor[8]

α_1-Protease inhibitor (α_1-PI; synonym: α_1-antitrypsin) is a naturally occurring endogenous serum antiprotease. If lost into the intestinal

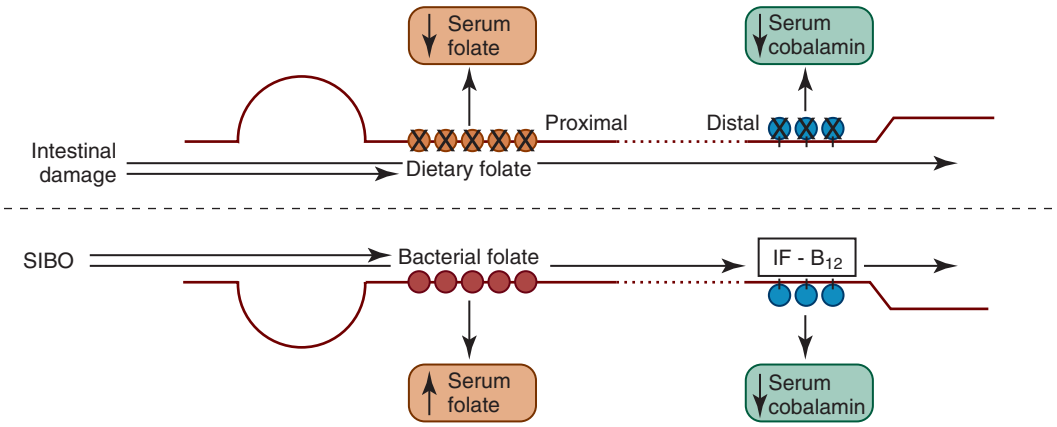

Figure 57-10 Diagram of the absorption of folate and cobalamin. In diseased intestine, proximal and distal mucosal damage causes folate and cobalamin malabsorption, respectively. Reduced serum folate and/or cobalamin are markers for proximal and/or distal SI damage. Classically, small intestinal bacterial overgrowth (SIBO) causes increased folate uptake because of bacterial folate synthesis and decreased cobalamin uptake because of bacterial incorporation. However, these changes are poorly sensitive, and cannot be used to reliably diagnose SIBO: they do not correlate with antibiotic responsiveness. IF, Intrinsic factor. (From Ettinger SJ, Feldman EC, editors: *Textbook of Veterinary Internal Medicine*, ed 7, Philadelphia, 2010, Saunders, p 1528.)

lumen because of PLE, it can be found in feces as it resists bacterial degradation. The α_1-PI test originally assayed the presence of α_1-PI in feces by ELISA, but has been replaced by a validated radioimmunoassay.

To improve the diagnostic accuracy of the test, three fresh fecal samples should be sampled. The assay is only valid when used on fecal samples collected following spontaneous defecation, as abrasion of the colonic wall during digital evacuation is enough to elevate α_1-PI concentrations. The test is less useful in patients with GI blood loss. The test appears to be of value for the diagnosis of PLE, correlating well with historical testing by fecal radioactive ^{51}chromium-labeled albumin excretion. Fecal α_1-PI may prove to be more sensitive than the finding of reduced serum albumin for the detection of early disease.

Fecal Calprotectin

Calprotectin has been characterized as a marker of neutrophil elastase activity.[9] Assay of fecal calprotectin is a useful marker of inflammation in human IBD, and a dog-specific assay has been developed, but the clinical utility, sensitivity, and specificity are unknown.

Special Tests

In cases of malabsorption, intestinal biopsy is usually necessary to obtain a definitive diagnosis. However, exocrine pancreatic insufficiency should be ruled out before biopsy, because signs of malabsorption are nonspecific and not easily differentiated from maldigestive disorders.[10,11] Thus serum trypsin-like immunoreactivity (TLI) measurement must be performed in all cases (see Chapters 25 and 60). It is also well-recognized that biopsies from up to 50% of malabsorption patients are considered normal by light microscopy. Therefore before biopsy, a number of indirect tests are performed to assess for intestinal damage, altered permeability, and dysfunction. Indeed, empirical treatments, such as administration of fenbendazole or an exclusion diet trial, may be indicated before biopsy.

Serum Folate and Cobalamin Concentrations

The assay of serum folate and cobalamin concentrations[12] can be performed on the same serum sample taken for the TLI test (see Chapter 25). This assay has limited value in the diagnosis of specific SI diseases and is not recommended for the diagnosis of canine small intestinal bacterial overgrowth (SIBO). However, subnormal folate and cobalamin concentrations are markers of GI disease as well as indicators for the need for vitamin supplementation (see Figures 57-9 and 57-10).

Tests of Intestinal Absorption

Attempts to assess intestinal function by measuring the absorption of numerous substrates (e.g., lactose, glucose, starch, triglyceride, and vitamin A) are no longer performed because of a lack of sensitivity and specificity. Even the D-xylose test has been abandoned because it is insensitive in dogs and nondiscriminatory in cats. GLUT5 on the MVM allows facilitated diffusion of both fructose and D-xylose, and as fructose uptake in cats is low, the xylose absorption test is particularly unhelpful in this species. The differential absorption of two sugars (xylose and 3-*O*-methyl-D-glucose) eliminates the nonmucosal effects that blight the xylose test, and initial results suggest that the test may be of more value in dogs and cats.[13]

Intestinal Permeability

Intestinal permeability[13-15] is an index of mucosal integrity and is assessed by measuring noncarrier mediated uptake of nondigestible probe markers. These tests use a nonmetabolizable probe that is measurable in plasma and/or excreted in the urine. The permeability probe ^{51}chromium-labeled ethylenediaminetetraacetic acid (^{51}Cr-EDTA) was used in original studies, but the need for a γ-emitter limited its safe use.

Errors related to nonmucosal factors (including the gastric emptying rate, intestinal transit time, and completeness of urine collection) can be eliminated by concurrently measuring the absorption of two probes with different pathways of absorption (Figure 57-11). Calculation of their excretion ratio eliminates errors from extramucosal factors because both probes should be affected equally. The ratio, which is altered by villus atrophy or epithelial damage or both, offers a simple, sensitive diagnostic test.

A 5-hour urine collection is performed after oral administration of two sugars. A number of candidates can be used for the probe molecules, and a mixture of one large simple sugar (e.g., lactulose, cellobiose, raffinose) and one small one (e.g., rhamnose, arabinose,

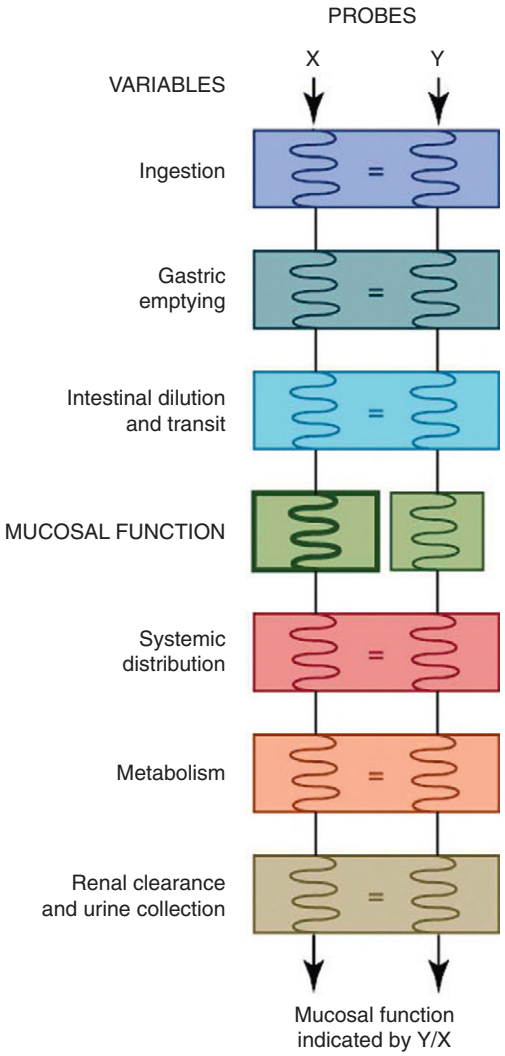

Figure 57-11 Principle of differential permeability testing. Simultaneous administration of two probes selected to respond identically to each variable except mucosal permeability. The Y-to-X ratio provides a specific index of mucosal permeability. (From Hall EJ: Small intestinal disease: is endoscopic biopsy the answer? *J Small Anim Pract* 35:408, 1994.)

mannitol) can be chosen. The cellobiose-to-mannitol excretion ratio and lactulose/mannitol ratio have been used in companion animals, but with advances in the high-performance liquid chromatography assay of these sugars in blood and urine, the lactulose/rhamnose ratio test has become the standard test of SI permeability.

Tests for Protein-Losing Enteropathy

Historically, intestinal protein loss has been detected by measuring the fecal loss of radiolabeled molecules such as ^{51}Cr-labeled albumin and ^{67}Cu-labeled ceruloplasmin. These tests are difficult to perform, potentially hazardous, and have largely been discarded, although they remain the standard by which other tests, such as the assay of fecal α_1-PI (see previous), are judged.

Breath Tests

Breath tests[12,16] have been used to assess bacterial metabolism in the GI tract. Intestinal bacteria synthesize hydrogen and volatile gases (e.g., methane), which are partially absorbed and excreted in breath where they can be measured. Breath hydrogen tests have been used most extensively because mammalian cells cannot produce hydrogen, and therefore any H_2 gas that is measured must be of bacterial origin. Such tests can assess carbohydrate malabsorption and orocecal transit time, when most of the hydrogen is produced by colonic bacteria. Theoretically breath hydrogen can detect increased bacterial colonization of the SI, that is, bacterial overgrowth, but as colonic bacterial numbers are massive, the test is unlikely to be discriminatory.

A variety of protocols has been used, including giving xylose to assess malabsorption, lactulose to assess orocecal transit, and a test meal to assess SI bacterial fermentation. A number of studies have attempted to standardize the techniques for companion animals, and use of substrates labeled with stable isotopes has increased. However, these techniques are not widely used, even in referral centers, because of technical difficulties, and lack of specificity.

Unconjugated Bile Salts

The hypothesis behind the test to measure serum unconjugated bile acids (SUBAs) is that conjugated bile acids are excreted into the intestine via the biliary tract where some SI bacterial species carry out deconjugation reactions.[17] Unconjugated bile acids are then absorbed passively by the SI, poorly cleared from portal blood, and measured in peripheral blood. Therefore, in theory, increases in SI bacterial numbers might result in an increase in SUBAs. Preliminary work suggesting that the test was sensitive and specific for canine SIBO has since been contradicted. Its utility has been questioned as there is a marked postprandial rise in healthy animals, deconjugation is partly a function of *Lactobacillus* activity, and results do not correlate with the diagnosis.

Miscellaneous Tests

A number of tests for intestinal bacterial metabolites have been devised to detect bacterial metabolic activity or SIBO, or to assess orocecal transit time. These include the nitrosonaphthol test, urinary indican excretion, bacterial release of sulfapyridine from sulfasalazine, and bacterial release of paraaminobenzoic acid (PABA) from a bile salt conjugate (PABA-UDCA [ursodeoxycholic acid]).[18] However, none of these tests are widely used in companion animals. Evaluation of the volatile gases emitted by feces can give a profile that is characteristic of specific infections, but has not been evaluated in small animals.

Assessment of Intestinal Motility

Methods to measure intestinal transit time include barium studies with and without food, ultrasonography (including pulsed Doppler measurements), breath hydrogen following carbohydrate administration, and using visual (e.g., carmine red dye, chromic oxide) or chemical markers that are excreted in the urine after absorption (e.g., sulfasalazine, acetaminophen, nitrofurantoin, PABA-UDCA).[19] Results are quite variable and often the methodologies do not correlate well as results are variable with both the composition of the test diet and stress affecting transit rates as much as disease. Intestinal transit is best studied with wireless motility capsule system and scintigraphy, but again the diet composition and stress affect the result. Measurement of myoelectrical activity either in vivo or in vitro is impractical in clinical practice.

Imaging

With the development of ultrasound, advanced imaging techniques, and endoscopy, imaging of the intestinal tract is no longer limited

Box 57-3 Differential Diagnosis of Ileus

  - Intussusception or other mechanical obstruction, e.g., incarceration

to plain and contrast radiography. Scintigraphy, computed tomography (CT), and magnetic resonance imaging are now being adopted, and "virtual endoscopy" by helical CT is becoming available.

Plain Radiography

Survey, plain radiographs[20] are most useful in the investigation of diarrhea associated with vomiting, abdominal pain, and palpable abnormalities. The diagnostic yield is enhanced if orthogonal views are taken, although a single lateral radiograph may be adequate if combined with ultrasonography. The utility of plain radiographs in malabsorption is minimal, especially if ascites is present, as detail is obscured by fluid and lack of fat contrast, respectively. Generally the aim of plain, survey radiographs is the detection of (acute) surgical disease (e.g., foreign bodies, free gas, displacement, masses, obstructions), decreased serosal detail suggestive of effusion, and ileus, an abnormal dilation of an immotile segment of intestine. The differential diagnosis of ileus depends on whether it is localized or generalized and whether an accumulation of gas or fluid is present (Box 57-3). Interpretation should be cautious if the patient has been treated with drugs that affect the GI tract.

Contrast Radiography

Since the introduction of alternative imaging techniques, especially endoscopy, contrast radiographic studies are of limited value in the assessment of SI disease.

Follow-through Examinations

Studies using microfine barium suspensions can identify ulcers and irregular mucosal detail. Although they may confirm the presence of radiolucent foreign bodies, they are of limited use in identifying mural masses and partial obstructions, and rarely provide more information than good quality survey radiographs.

Although contrast studies theoretically can be used to assess the rate of intestinal transit, results do not correlate closely to movement of ingesta as assessed by scintigraphy. Furthermore, dysmotility may occur secondary to other causes and studies provide limited etiologic information. Administration of barium may delay endoscopy for at least 24 hours. If perforation is suspected an iodine-based contrast is used if confirmation is required, although the presence of free abdominal gas on survey films is adequate for a diagnosis in most cases.

Barium-Impregnated Polyethylene Spheres

These are solid-phase radiopaque markers that provide information on gastric emptying, intestinal transit, and obstructive disorders. Given that the transit time of barium-impregnated polyethylene spheres (BIPS)[21] is highly variable, their use for transit studies is limited. They may be most helpful in the detection of partial obstructions, as the larger BIPS are held up by partial obstructions that are seen clinically significant, but may not be identified by barium suspension transit.

Ultrasonography

Transabdominal ultrasound examination is now a routine part of the investigation of SI disease.[22,23] In the future, endoscopic ultrasound will allow the mucosal wall and adjacent viscera (e.g., pancreas) to be examined in more detail.

A conventional examination can detect layering of the wall, peristalsis, ileus, and luminal contents, and can measure SI wall thickness. It has excellent sensitivity for the detection of lesions such as intussusceptions, masses, radiolucent foreign bodies, and intestinal wall thickening and lymphadenopathy in chronic inflammatory, lymphatic, and neoplastic enteropathies. Intussusceptions are usually recognized in the transverse plane as multiple concentric rings and longitudinally as a thick, multilayered segment.

Values for normal SI wall thickness have been reported for dogs and cats; thickness decreases from proximal (5 to 6 mm) to distal (4 to 5 mm), but depends on body size, with the thickest seen in the large- and giant-breed dogs. Disruption of the normal five-layered sonographic appearance (mucosal surface–mucosa–submucosa–muscularis–serosa) is typical of neoplasia, whereas wall thickening can result from other infiltrative disorders and edema, as well as neoplasia. Ultrasound-guided fine-needle aspiration for cytologic examination is possible.

Duodenal Fluid Examination

Duodenal fluid[17,24-26] can be collected either by needle aspiration through the intestinal wall at laparotomy, or during duodenoscopy through a sterile polyethylene tube passed down the biopsy channel. Collection of sufficient sample without blood and tissue contamination can be difficult.

The sample can be examined for motile *Giardia* trophozoites, although this has not proved reliable for diagnosis. Quantitative and qualitative aerobic and anaerobic cultures can be performed. This is considered the gold standard for diagnosis of SIBO, although there are major problems in interpretation and routine diagnostic use of duodenal fluid bacterial culture is not recommended.

Intestinal Biopsy

In most cases of acute diarrhea, a histologic diagnosis is not needed, and intestinal biopsy is very rarely performed. However, in chronic diarrhea a definitive diagnosis often depends on histologic examination of intestinal tissue, although this has major limitations. Biopsy specimens are collected either endoscopically or surgically.

Best practice is to perform endoscopic biopsy first unless there is evidence that the disease is beyond the reach of the endoscopy; the surgical option is preferred if there is any possibility of extraintestinal disease or focal intestinal pathology, or if endoscopic biopsy has

failed to reveal a diagnosis. Thus the client should always be made aware that surgical biopsies may ultimately be required.

Endoscopic biopsies should always be taken, even in the absence of gross abnormalities, because microscopic changes may be present but only the duodenum (and proximal jejunum, if accessible) are biopsied routinely via gastroscopy, while ileal biopsies may be obtained via colonoscopy. Multiple specimens (a minimum of six from each area) should be collected, because small size, artifacts, and fragmentation can make interpretation difficult. The size and quality of endoscopic biopsies depends not just on the equipment available, but also on the pressure exerted by the forceps, which is in part dependent on the operator's experience. At laparotomy, full-thickness biopsies are usually taken from at least three sites, the duodenum, the jejunum, and the ileum. Intestinal biopsies can also be obtained laparoscopically, but evidence of a greater diagnostic utility than endoscopy or greater safety than surgery has yet to be proven.

Tissue handling and processing also affect the diagnostic quality of the sample. Careful orientation of the sample so that the tissue is flattened with the mucosa uppermost theoretically improves the likelihood of optimal sectioning, but must be weighed against the increased time needed to lay out the tissue and the attendant development of artifacts through handling and delayed fixation.

Examination of Biopsies

Histopathology

Although histopathologic assessment of intestinal biopsies remains the gold standard for diagnosis of intestinal disease, it too has limitations.[27-33] Biopsies may be normal by light microscopy, which suggests that many diseases have a functional rather than a morphologic abnormality or that sampling or interpretation problems have occurred. Histopathology may be satisfactory when there are pathognomonic changes, for example, neoplasia, but it has become evident that it may be difficult to diagnose intestinal inflammatory diseases reliably because of a lack of standardized sample preparation and staining practices and agreed upon histologic criteria.

Agreement between histopathologists often is poor, especially when examining endoscopic biopsies and a standardized approach is required. Histopathologic scoring schemes and standardized criteria have been suggested by the World Small Animal Veterinary Association (WSAVA) GI Standardization Group as a means of improving agreement. However, Group members also have shown that the experience of the endoscopist, as well as simply the quality and numbers of biopsies, can influence the reliability of the histologic interpretation. Furthermore there is emerging evidence that ileal biopsies are more likely to be diagnostic than duodenal. As expected, fewer biopsies are needed to reliably detect architectural changes the better their quality (i.e., better size, depth, and integrity) and more specimens are needed the deeper the lesion. Therefore the clinician should always interpret endoscopic biopsy results cautiously; results should be questioned if the tissue diagnosis does not fit the clinical picture, or if the response to apparently appropriate therapy is poor. In some cases, repeat biopsy (e.g., by exploratory laparotomy) may be required. Cytologic examination of endoscopic biopsy squash preparations or mucosal brushings are only an adjunct to histopathologic examination.

Even if intestinal inflammation can be diagnosed reliably, there remains the difficulty that the histologic pattern in intestinal inflammation seen is likely a common final pathway caused by a number of potential causes. Thus unless an etiologic agent is evident on microscopic (e.g., visible protozoa) biopsy alone, it may not be possible to determine the cause of any intestinal inflammation. Although different histologic patterns, for example, eosinophilic and lymphoplasmacytic, are recognized, their specificity in indicating the etiology is poor.

Box 57-4 Research Methods beyond Routine Histopathology Used for Examining Intestinal Biopsies

- Electron microscopy
- Biochemical assay of brush-border enzymes
- Immunocytochemical characterization of B cells, T cells, and their subsets (e.g., CD4 and CD8 cells) and major histocompatibility complex expression by immunohistochemistry and flow cytometry
- PCR for cytokine and receptor (nucleotide-binding oligomerization domain, Toll-like receptors) mRNA expression
- Assessment of T-cell clonality—PCR for antigen receptor rearrangement (PARR)
- Fluorescence in-situ hybridization to demonstrate bacteria in biopsies

Alternative Examinations

A number of research tools have been applied to the investigation of intestinal biopsies. However they are largely research tools, limited by availability and/or cost.[34-36] Box 57-4 outlines more specific examinations.

Empirical Treatment

If a specific diagnosis is made, specific treatment(s) can be given. Yet often the diagnosis is not obvious, usually because of a lack of specific or marked histopathologic changes, and it may be appropriate to perform empirical treatment(s). It is logical and safest to do this sequentially, starting with the treatment least likely to do harm. Therefore parasiticides, followed by an exclusion diet trial, and then an antibacterial trial should be considered before finally attempting immunosuppression. This empirical approach may identify occult parasitism, diet-responsive conditions, and antibiotic-responsive diarrhea, respectively. However, because treatments lack specificity, caution should be exercised in using such trials to make a diagnosis without investigation.

INFLAMMATION

Alexander J. German

In companion animal gastroenterology, IBD is the term used to describe patients affected by persistent or recurrent GI signs, and that have histopathologic evidence of inflammation in intestinal tissues.[1] It is only appropriate to use the term *idiopathic* IBD if no underlying cause for the inflammation can be found. Although there are recent studies into pathogenesis, diagnosis, and treatment, much controversy remains. To make a diagnosis of IBD, detailed investigations must be undertaken to exclude other potential causes of intestinal inflammation; nevertheless, the likelihood is that IBD represents a syndrome comprising a group of disorders with similar characteristics, rather than a single disease entity. It should be noted that canine and feline IBD bear little resemblance histologically or

Table 57-2 Histopathologic Classification of Idiopathic Inflammatory Bowel Disease

Histopathologic Description	Comment
Lymphocytic-plasmacytic enteritis (LPE)	Most common
Basenji enteropathy	A variant of LPE?
Familial PLE and protein-losing nephropathy in soft-coated Wheaten Terriers	A variant of LPE?
Eosinophilic enteritis	Second most common form; marked increase in eosinophils
Granulomatous enteritis	Rare; due to feline infectious peritonitis in cats
Regional enteritis	Rare, a variant of granulomatous enteritis?
Neutrophilic enteritis	Rare in dogs, uncommon in cats

clinically to either of the main IBD variants in humans (i.e., Crohn disease and ulcerative colitis).

Companion animal IBD is further subdivided based on the predominant inflammatory cell type present as judged by histopathologic examination of intestinal biopsy samples (Table 57-2). However, such classification is often arbitrary, and depends upon the opinion of the pathologist concerned. Indeed, many cases have a generalized increase in several cell subsets and cannot easily be classified. The WSAVA GI Standardization Group has undertaken the task of reviewing both collection of biopsy material (endoscopy) and subsequent histopathologic interpretation.[2] It is hoped that such standardization will improve the reliability and diagnostic yield from this procedure.

Types of Small Intestinal Inflammatory Bowel Disease

Forms of small intestinal IBD include lymphocytic-plasmacytic enteritis (LPE), eosinophilic enteritis (EE), granulomatous enteritis, regional enteritis, and neutrophilic enteritis (see Table 57-2). Furthermore, certain breed-specific patterns of disease are recognized, including Basenji enteropathy and the PLE/protein-losing nephropathy (PLN) syndrome of soft-coated Wheaten Terriers. Although the histopathologic findings of these disorders may differ, the etiopathogenesis is thought to be broadly similar.

Lymphocytic-Plasmacytic Enteritis

LPE is the most common histopathological form of SI IBD, and is characterized by mucosal infiltration of lymphocytes and plasma cells (Figure 57-12). LPE can be associated with lymphocytic-plasmacytic inflammation in other regions of the GI tract (e.g., lymphocytic-plasmacytic gastritis [see Chapter 56] and lymphocytic-plasmacytic colitis [see Chapter 58]). LPE in cats can be associated with inflammatory disease in the pancreas (see Chapter 10) and/or liver (see Chapter 61) as part of the "triaditis" syndrome.

Clinical signs of LPE are similar to other forms of IBD and are not pathognomonic. Severe LPE is reportedly prevalent in German Shepherd dogs, Shar-Peis, and pure-bred cats. The approach to diagnosing LPE is the same as for any other form of IBD. However, in both cats and dogs, it can be difficult to differentiate severe LPE from alimentary lymphoma. Exploratory celiotomy may be a preferable means of collecting biopsy material in cats, given both concerns over differentiation of LPE from GI lymphoma on endoscopic biopsy, and the concurrence of pathologic change in other organs. Given these diagnostic dilemmas, clonality studies assessing T-cell receptor rearrangements may assist in identifying low-grade lymphoma.[3]

Eosinophilic Enteritis

EE is reportedly the second most common form of IBD and can be associated with disease elsewhere in the GI tract. On histopathologic examination, mucosal architectural disturbances (e.g., villus atrophy) are present in conjunction with a mixed infiltrate of inflammatory cells with eosinophils predominating (Figure 57-13). The diagnosis has been problematic in the past because diagnostic criteria (e.g., degree of eosinophil infiltration) varied amongst pathologists. However, the WSAVA standards suggest clear diagnostic criteria (e.g., mild 5 to 10 eosinophils per ×40 field; moderate 10 to 20 per ×40 field; marked eosinophils dominate the tissue population).[2] A diagnosis of EE should only be made once other causes of eosinophilic infiltration (e.g., endoparasitism and hypersensitivity disorders) have been eliminated. EE also may be associated with systemic eosinophilic disorders (e.g., hypereosinophilic syndrome) in both cats and dogs.

The condition can be seen in dogs and cats of any breed and age, although it is more common in younger adult animals. Boxers, German Shepherds, and Dobermans may be predisposed. The clinical signs reported are similar to other forms of IBD, although mucosal erosion and/or ulceration may occur more frequently and lead to hematemesis and melena. Concurrent PLE is also recognized, and severe eosinophilic gastroenteritis is also associated with spontaneous perforation of the GI tract.[4]

Basenji Enteropathy

Basenji enteropathy is a severe, hereditary form of LPE that has been well characterized in Basenjis, although the mode of inheritance remains unclear. Vomiting and small intestinal diarrhea are the main clinical signs. A progressive PLE is often noted, and some severe cases develop spontaneous intestinal perforation. Intestinal lesions in Basenjis are characterized by increases in $CD4^+$ and $CD8^+$ T cells.[5,6] In addition to lymphocytic-plasmacytic gastritis, mucosal hyperplasia occur, and this is thought to be secondary to hypergastrinemia. Treatment is usually unrewarding, with progressive clinical signs and dogs dying within months of diagnosis. However, early aggressive combination treatment with glucocorticoids, antibacterials, and dietary modification may achieve remission in some cases.

Familial Protein-Losing Enteropathy and Protein-Losing Nephropathy In Soft-Coated Wheaten Terriers

A unique clinical syndrome has been reported in soft-coated Wheaten Terriers.[7] Affected dogs may present with signs of PLE, PLN, or both. A genetic basis is likely and, although the mode of inheritance is not yet clear, a common male ancestor has been identified. An immune-mediated pathogenesis is likely and dietary hypersensitivity might be involved, as suggested by alterations in antigen-specific fecal immunoglobulin (Ig) E concentrations.[8,9] Signs of PLE tend to develop at a younger age than PLN, and clinical signs include vomiting, diarrhea, weight loss, and pleural and peritoneal effusions. Affected dogs are at risk of thromboembolic disease.[10] Treatment is similar to that described for general IBD.

Hematoxylin and eosin stain, original magnifications ×40.

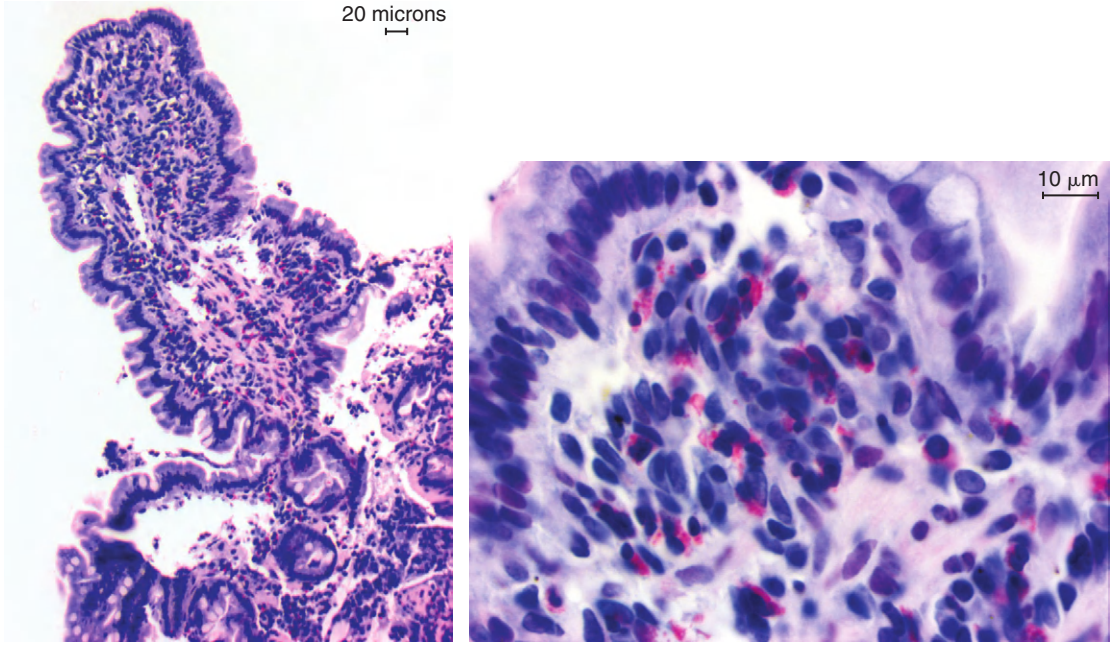

Figure 57-13 Histologic appearance of duodenal biopsy specimens taken from a dog with eosinophilic enteritis. Sirius red stain.

Granulomatous Enteritis

This rare form of IBD is characterized by the development of granulomas and mucosal infiltration with macrophages. This condition is likely to be the same as regional enteritis where ileal granulomas are reported.[11,12] Potential causes of granulomatous inflammation include *Yersinia* and mycobacterial infections, foreign-body reactions, and fungal diseases. In cats a pyogranulomatous transmural inflammation has been associated with feline infectious peritonitis (FIP) virus infection. Although there are similarities between this condition and human Crohn disease, intestinal obstruction and fistula formation are not observed. Conventional therapy for IBD is usually not effective and the prognosis is guarded, although a combination of surgical resection and antiinflammatory treatment was reported to be successful in one case.

Neutrophilic Enteritis

Some inflammatory diseases may be characterized by infiltrates of neutrophils or by granulomatous inflammation, although these patterns are rare. If neutrophils are evident, an underlying bacterial infection should be considered. Alternatively, the neutrophilic infiltrate may have arisen from bacterial invasion secondary to mucosal barrier disruption from erosive or ulcerative lesions. Glucocorticoids are generally not recommended for such cases, unless they fail to respond to all other therapeutic modalities.

Proliferative Enteritis

Proliferative enteritis is characterized by segmental mucosal hypertrophy of the intestine. It is most common in pigs, but a similar although very rare condition has been reported in dogs.[13] There may be an underlying infectious etiology and *Lawsonia intracellularis* infection has been implicated but not yet been proven. Other potential infectious causes include *Campylobacter* spp. and *Chlamydia*.

Etiology and Pathogenesis

Reportedly, IBD has an immune-mediated etiology and thus the GI associated lymphoid tissue likely plays a critical part in pathogenesis.[14] Full details of the mucosal immune system are found in Chapter 3, while intestinal inflammation is reviewed in Chapter 4. Briefly, the intestinal mucosa has a barrier function ("immune exclusion"), and controls exposure of antigens to the gut-associated lymphoid tissue, which must generate protective immune responses against pathogens while remaining "tolerant" of harmless environmental antigens such as commensal bacteria and food. IBD develops when the normal decision-making process breaks down, leading to inappropriate immune responses and uncontrolled inflammation. Critical to the development of inflammation is a breakdown in tolerance to normal luminal antigens (particularly endogenous bacterial species). This loss of tolerance may result from disruption of the mucosal barrier leading to excessive antigen exposure to the underlying immune system, from dysregulation of normal mucosal immune system function, or from a combination of these processes. The end effect is uncontrolled inflammation, which is the result of activation of the many effector pathways. The inflammation can then lead to architectural disruption, resulting in adverse effects on function, which depend upon the part of the bowel affected.

Unfortunately, data that directly assess the pathogenesis of canine small intestinal IBD are limited, and many gaps in our understanding remain. Many studies have used histochemical and immunohistochemical techniques to quantify immune cell populations within the intestinal mucosa with variable results.[14] For canine IBD, recent studies have suggested an increase in cells expressing Toll-like receptors-2, -4, and -9.[15] Other studies have shown a decrease in certain lymphocyte populations (total T cells and IgG^+ plasma cells), while others have shown increases ($\alpha\beta$ T cells, $CD4^+$ T cells, IgG^+ plasma cells) as well as increased macrophage and granulocyte numbers.[14] The confusion is compounded by the fact that in feline IBD, a disease with similar histopathologic changes to the canine form, the only reported difference from control samples was an increase in cells expressing major histocompatibility complex class II.[16]

Inconsistent results have also been seen with the studies conducted to date on soluble immunologic factors. Increased concentrations of acute phase proteins (e.g., C-reactive protein) have been documented in canine IBD in some,[17] but not all studies.[18,19] Recent studies suggest decreased acute-phase proteins in feline IBD.[20] Initial semiquantitative reverse transcriptase PCR (RT-PCR) studies suggested increased cytokine gene expression in canine chronic enteropathies,[21] and this has been confirmed in one,[22] but not all,[23] more recent studies that have used real-time PCR methodology. Again, these results differ from feline studies, where histopathologic evidence on mucosal inflammation correlated with increases in a range of cytokines.[24] Unfortunately, in all of these studies, gene expression alone was assessed, and not the functional protein. However, in a recent study, tumor necrosis factor (TNF)-γ protein was not detected in the serum of 15 dogs with IBD.[16]

The reasons for such discrepancies are not known but may relate to the fact that the chosen gold standard throughout was histopathology, which itself is variable and lacks consensus among pathologists.[2] An alternative possibility is that the many studies have assessed patients in various stages of disease, and it may be that immunologic responses differ, and this lead some researchers to suggest the alternate name of "chronic enteropathy."[18]

Clinical Presentation

Historical Findings

Many clinicians consider small intestinal IBD to be the most common cause of chronic vomiting and diarrhea in dogs and cats; however, given that large scale epidemiologic studies have hitherto not been conducted, the true prevalence of the condition is unknown. In reality, the condition may be overdiagnosed as a result of the ease with which endoscopic biopsy samples of the intestine can be collected, the current difficulties in interpretation of histopathologic specimens, and because alternative reasons for the clinical signs are inadequately eliminated during the diagnostic workup.

The studies that have been published to date suggest that canine SI IBD is most common in middle-aged animals and is uncommon in dogs younger than 12 months of age. Young and growing animals are most likely to suffer from either infectious causes of chronic diarrhea or adverse reactions to food components. No apparent gender predisposition has been reported. IBD can potentially occur in any breed of dog, although predispositions are reported for certain breeds (discussed previously). IBD can affect cats of any age or gender, although middle-aged animals are most commonly affected. Some pure breeds (e.g., Siamese) are said to be predisposed to IBD; the pattern of disease also differs in that concurrent histopathologic changes can be seen the intestine, pancreas, and liver (often termed *triaditis*) (Figure 57-14). For instance, there may be concurrent LPE, lymphocytic cholangitis, and chronic lymphocytic pancreatitis.[2] Interestingly, concurrence of IBD and pancreatitis has been reported in dogs,[25] suggesting that the distinction between species may be less clear than previously thought.

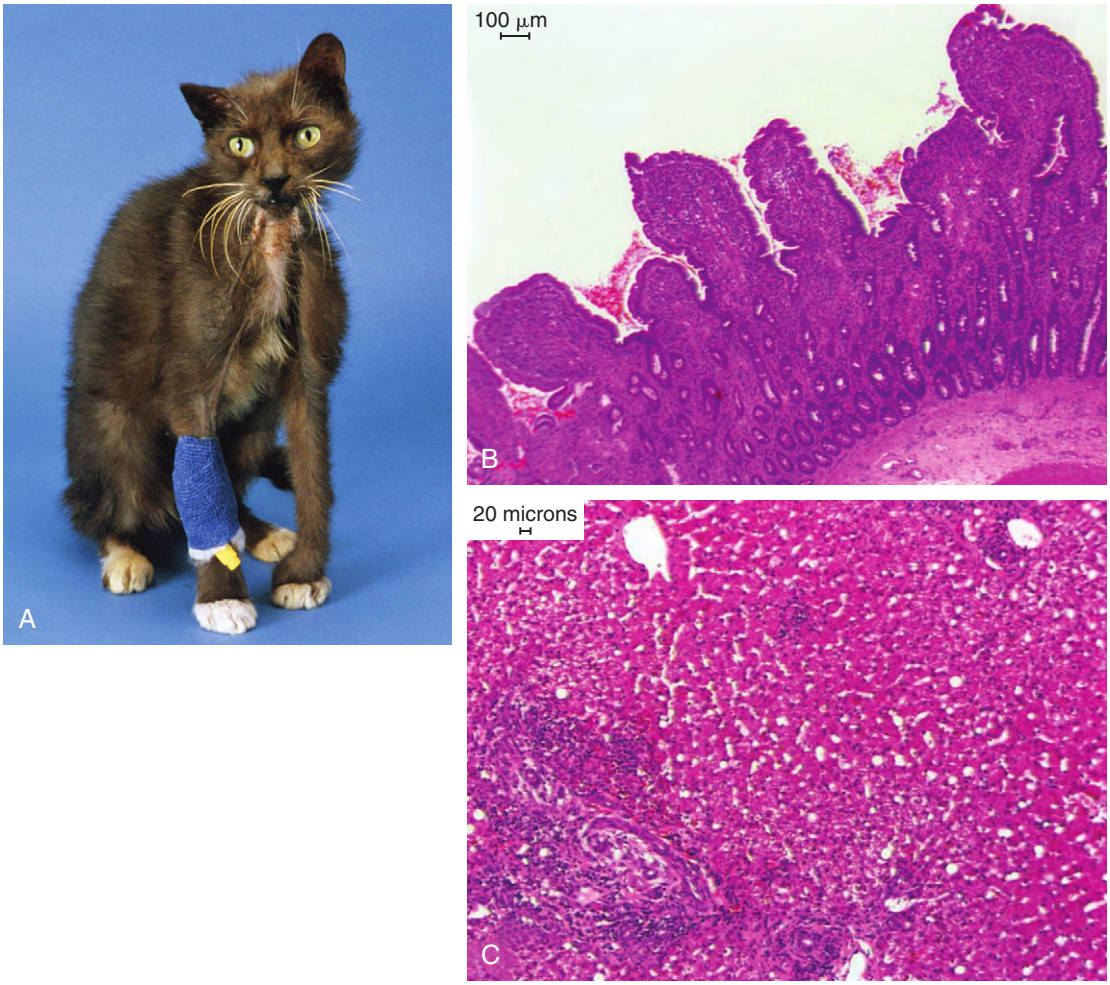

Figure 57-14 **A,** Eight-year-old, neutered female, domestic shorthair cat with severe cachexia, diarrhea, and *Malassezia* dermatitis. **B,** Histologic appearance of a jejunal biopsy specimen taken from the cat in **(A)**, showing evidence of LPE. Hematoxylin and eosin stain; bar, 100 µm. **C,** Histologic appearance of a liver biopsy specimen taken from the cat in (A), showing evidence of mild lymphocytic-cholangitis. Hematoxylin and eosin stain; bar, 20 µm.

A range of possible clinical signs is associated with both canine and feline SI IBD, but none are pathognomonic for the condition. Not surprisingly, a "small intestinal pattern" diarrhea is most commonly seen (e.g., increased volume, watery, altered color). However, mixed-pattern diarrhea can be seen if the IBD also involves the large intestine and, in occasional cases, a large intestinal pattern diarrhea occurs, most likely the result of prolonged SI diarrhea or the presence of agents that stimulate colonic secretion (e.g., bacteria, bacterial toxins, deconjugated bile acids, or hydroxylated fatty acids).

In cats, vomiting is often the predominant clinical sign of small intestinal IBD, and diarrhea may be only occasional or absent. This may, in part, be related to the fact that some cats do not use a litter tray and thus owners may be unaware of toileting habits. Vomiting is also seen in canine SI IBD although, in the author's experience, almost invariably accompanies, and is less severe than, diarrhea. Hematemesis or melena is usually associated with more severe disease, which has caused mucosal ulceration or erosion; although it can occur in any form of IBD, it appears to occur more often with EE.

Appetite changes can be variable in SI with some cases demonstrating polyphagia, others show differing severities of anorexia, or there may be no appetite change observed. If marked inflammation is present within the SI, significant malabsorption may result, and this can lead to weight loss. Such cases may also develop panhypoproteinemia, and two studies demonstrated that hypoalbuminemia is a poor prognostic indicator in IBD.[18,26] If marked hypoalbuminemia is present (e.g., serum albumin concentrations below approximately 1.5 g/dL), associated signs such as ascites and subcutaneous edema may develop. Thromboembolism and remote organ failure is seen in some patients with PLE. Other systemic consequences of IBD include thrombocytopenia and arthropathies and typical signs may be noted. However, such reports are rare,[27] and in my opinion these are uncommon findings in both canine and feline IBD. Progression of disease is variable and, in some cases, signs may wax and wane.

Physical Examination

General physical examination findings may include dehydration, alterations in demeanor, poor body condition, and signs of anemia if associated blood loss is severe. Abdominal palpation is an important component of the examination, and associated findings include (mild) abdominal discomfort, thickened intestines, turgid or thickened intestinal loops, and ascites (fluid thrill). Although rectal examination does not directly investigate the SI, it may reveal evidence of changes in fecal characteristics (e.g., melena).

Determining Clinical Severity

In humans, activity indices are used to quantify disease severity in IBD, aiding the assessment of the response to treatment and allowing comparisons between published studies in the literature. Recently, an activity index was suggested for canine IBD (canine IBD activity index [CIBDAI]; Table 57-3),[17] and its use in the clinical setting provides a more objective measure of therapeutic response.[18,28] In one study, CIBDAI correlated with serum acute phase protein concentrations,[17] although this was not confirmed by recent work.[19] Clinicians must understand that increases in CIBDAI simply suggest an increase in severity of GI signs, and that high values do not confirm the diagnosis of IBD. For example, increased CIBDAI has been seen in dogs with food-responsive conditions, and values decreased on successful treatment.[29] More recently, a variation of CIBDAI, the canine chronic enteropathy activity index (CCEAI; see Table 57-3) was proposed.[18] All of the same signs are scored as for the CIBDAI, but additional characteristics are also assessed (e.g., presence of ascites and/or peripheral edema, pruritus, and serum protein concentrations). A recent study shows that this correlates better with prognosis than the CIBDAI[18]; however, the advantage of improved performance may be offset by the requirement for blood sampling and serum albumin measurement. Time will tell which system is preferred by clinicians and researchers. Finally, an activity index for feline IBD (FIBDAI) was proposed, which makes use of histology, GI signs, serum total protein and phosphorous concentrations, serum alkaline phosphatase concentration, and endoscopic lesions.[30]

Approach to Diagnosis

Given that none of the clinical signs and physical examination findings that are seen with IBD are pathognomonic, further investigations are essential in order to make a diagnosis. Because the term *idiopathic IBD* should be restricted to use in cases in which intestinal inflammation is found without an obvious underlying cause, all other etiologies must first be excluded. Therefore detailed preliminary diagnostic investigations must be performed, prior to acquisition of GI biopsy samples, to ensure that other etiologies are

Table 57-3 Criteria for Assessment of Severity of Canine Inflammatory Bowel Disease

Characteristic	CIBDAI	CCEAI
Attitude/activity	0. Normal 1. Slight decrease 2. Moderate decrease 3. Severe decrease	0. Normal 1. Slight decrease 2. Moderate decrease 3. Severe decrease
Appetite	0. Normal 1. Slight decrease 2. Moderate decrease 3. Severe decrease	0. Normal 1. Slight decrease 2. Moderate decrease 3. Severe decrease
Vomiting	0. None 1. Mild (once/wk) 2. Moderate (2 to 3/wk) 3. Severe (>3/wk)	0. None 1. Mild (once/wk) 2. Moderate (2 to 3/wk) 3. Severe (>3/wk)
Stool consistency	0. Normal 1. Slightly soft feces, fecal blood mucus, or both 2. Very soft feces 3. Watery diarrhea	0. Normal 1. Slightly soft feces, fecal blood mucus, or both 2. Very soft feces 3. Watery diarrhea
Stool frequency	0. Normal 1. Mild increase (2 to 3/day) 2. Moderate increase (4 to 5/day) 3. Severe increase (>5/day)	0. Normal 1. Mild increase (2 to 3/day) 2. Moderate increase (4 to 5/day) 3. Severe increase (>5/day)
Weight loss	0. None 1. Mild (<5%) 2. Moderate (5% to 10%) 3. Severe (>10%)	0. None 1. Mild (<5%) 2. Moderate (5% to 10%) 3. Severe (>10%)
Serum albumin		0. Albumin >2.0 g/dL 1. Albumin 1.5 to 1.99 g/dL 2. Albumin 1.2 to 1.49 g/dL 3. Albumin <1.2 g/dL
Ascites and peripheral edema		0. None 1. Mild ascites or peripheral edema 2. Moderate ascites/peripheral edema 3. Severe ascites/pleural effusion and peripheral edema
Pruritus		0. No pruritus 1. Occasional episodes of itching 2. Regular episodes, but stops when asleep 3. Dog regularly wakes up due to itching
Final score	0 to 3. Clinically insignificant disease 4 to 5. Mild IBD 6 to 8. Moderate IBD ≥9. Severe IBD	0 to 3. Clinically insignificant disease 4 to 5. Mild IBD 6 to 8. Moderate IBD ≥9. Severe IBD

CIBDAI, Canine inflammatory bowel disease activity index; CCEAI, canine chronic enteropathy activity index.

excluded. Investigations include fecal analyses, routine hematologic analysis, clinical chemistry, urinalysis, assay of serum TLI, pancreatic lipase immunoreactivity, and diagnostic imaging. Although none of these tests is diagnostic for IBD, they help to eliminate the possibility of extraintestinal disease (e.g., pancreatitis, hypoadrenocorticism, renal failure, and hepatic failure), anatomic intestinal disease (e.g., tumor or intussusception), and other known causes of intestinal inflammation. Diagnostic imaging in particular allows the clinician to determine whether focal or diffuse intestinal disease is present, allowing selection of the most appropriate method of intestinal biopsy. In many cases, standardized therapeutic trials can help to confirm the diagnosis, by eliminating other possible causes of intestinal inflammation.

Hematology

In companion animals with SI IBD, hematologic examination is frequently unremarkable. Changes in white blood cells that are occasionally observed include mature neutrophilia, neutrophilia and left shift, and eosinophilia, but none are pathognomonic. Reactive "atypical" lymphocytes may be seen in patients with LPE, and lymphopenia can occur if lymphangiectasia is present. If anemia is present, it may be a reflection of either chronic inflammation or chronic blood loss. Iron-deficiency anemia, with a microcytic hypochromic pattern, also has been reported in IBD,[31] and thrombocytosis also may be seen.[31]

Clinical Biochemistry

In many patients with SI IBD, clinical biochemistry is unremarkable. If PLE is present, serum concentrations of both albumin and globulin can be decreased. Confirmation of PLE requires the absence of significant liver changes (e.g., marked enzyme elevations, low urea, low glucose) on clinical chemistry, or the absence of anemia on complete blood cell count, and of proteinuria on urinalysis. However, fecal α_1-PI measurement may help. Hypocholesterolemia may suggest malabsorption, but this finding is not pathognomonic. Ionized hypocalcemia and hypomagnesemia are also reported.[32,33] Intestinal inflammation in dogs may cause a reactive hepatopathy with mild to moderate (two- to fourfold increases) in liver enzyme (i.e., alanine transaminase [ALT] and alkaline phosphatase) activities. In contrast, as a consequence of their shorter half-lives, liver enzyme increases are less common in feline IBD, and marked elevations in ALT more commonly occur secondary to alimentary lymphoma than feline IBD.[34]

Fecal Examination

Fecal flotation is very important in eliminating parasitic causes of mucosal inflammation. In most cases of SI IBD, these tests yield negative results. When occasional positives do occur, determining the significance can be problematic, as these organisms can be found in the stool of healthy animals. Although trial therapy may be considered, clinicians should exercise caution given concerns over the development of therapeutic resistance.

Serum Folate and Cobalamin

Measurement of serum folate and cobalamin is available for both dogs and cats, and deficiency of these substances is associated with IBD. Recent work has highlighted the importance of hypocobalaminemia in cats,[35] and hypocobalaminemia is also a negative prognostic indicator in chronic enteropathy in dogs[18] as well as other alimentary tract diseases such as EPI.[36] Although such alterations are not pathognomonic, deficiencies in IBD suggest the need for more aggressive therapy against the primary disease, and also the need for parenteral supplementation. This is particularly important, because cobalamin deficiency may itself have systemic metabolic consequences and cause intestinal dysfunction,[37] and anecdotal evidence suggests that the response to immunosuppressive therapy for IBD may be suboptimal until cobalamin deficiency is resolved.

Diagnostic Imaging

Radiographic and ultrasonographic studies are most commonly used to eliminate other possible diseases rather than to make a diagnosis of SI IBD. However, when used in conjunction with specific clinical signs and laboratory testing, the information from imaging studies enables an appropriate choice of a biopsy method (e.g., upper or lower GI endoscopy, or exploratory celiotomy). Ultrasonography in IBD patients can help to document mesenteric lymphadenopathy.[38,39] Although intestinal wall thickness can be measured, one study suggests that this measure is of limited value in the diagnosis of SI IBD.[40] In fact, the only occasions when the bowel wall was notably thickened was when edema was present secondary to marked hypoproteinemia. A recent study suggests that different ultrasonographic patterns can help to differentiate chronic enteropathies with different etiologies.[41] Loss of normal intestinal layering is more commonly seen with neoplasia than IBD.

Intestinal Biopsy

Intestinal biopsy is essential to prove the presence of intestinal inflammation and confirm a diagnosis of SI IBD; either endoscopy or exploratory celiotomy can be used. During endoscopy, the gross appearance of the intestinal mucosa can also be observed. Intestinal inflammation may be indicated by findings such as increased granularity, irregularity, and friability with the presence of erosions, ulceration, and spontaneous hemorrhage. However, these findings are not pathognomonic, and correlation between gross inspection and histopathology is poor.[18,28] Limitations of endoscopy include small sample size, superficial and often fragmented samples, and the fact that tissue can only be collected from proximal regions and (occasionally) the distal ileum. Exploratory celiotomy and full-thickness biopsy may be necessary, although this is more invasive and wound healing can be problematic if severe hypoproteinemia is present.[42] Nonetheless, the approach may be more suitable for cats, given the tendency for concurrent hepatic and pancreatic involvement,[43] the difficulties in differentiating IBD from small-cell lymphoma in endoscopic duodenal biopsies,[34] and the reliability of the small size of endoscopic biopsies that are often collected in this species.

Histopathologic Assessment of Biopsy Samples

The pattern of histopathologic changes in biopsy specimens depends upon the type of IBD. Histopathologic assessment of intestinal biopsies remains the gold standard for diagnosis of many intestinal diseases, but has marked limitations, most notably variable quality of tissue specimens obtained endoscopically[44] and poor agreement between histopathologists.[45] The latter may be a result of the subjective nature of interpretation of the degree of inflammation, the patchiness of inflammation, or the presence of edema (caused by hypoproteinemia) leading to difficulties in assessing cell density.

It can be difficult to distinguish severe LPE from lymphoma, particularly when endoscopic biopsy samples are examined. This may be a result of the fact that infiltration of malignant lymphocytes is patchy, that inflammatory change may accompany alimentary lymphoma (and predominate in some areas), or that lymphocytic infiltration is deep to the area sampled. Cases of feline alimentary lymphoma can be missed if duodenal endoscopic biopsy samples are used in histopathologic assessment, rather than full-thickness

specimens.[34] Hence, it may be preferable to collect surgical specimens in this species, and this approach gives the added advantage that other organs can be sampled (e.g., liver and pancreas) when checking for "triaditis."

The standards published by the WSAVA GI Standardization Group[2] hopefully will improve the reliability of IBD diagnosis.[18,28] Ultimately, the primary clinician should interpret histopathology results cautiously and try to relate them to the clinical presentation. Results should be questioned if the histopathologic diagnosis does not fit the clinical picture or the response to apparently appropriate therapy is poor. In some cases repeat biopsy (e.g., by exploratory celiotomy) may be required.

Diagnostic Horizons

Many research techniques have been developed to assess alterations of the immune system that occur in IBD. Examples include immunohistochemical characterization of immune cell populations,[46-49] measurement of gene expression for cytokines by RT-PCR,[21-23] assessment of T-cell clonality,[3] measurement of mucosal perinuclear antineutrophilic antibody (pANCA),[50] and measurement of mucosal P-selectin expression.[51] Although these techniques have not been widely adopted for clinical diagnosis, there may be potential for future application. In particular, assessment of T-cell clonality may prove to be a useful tool to differentiate LPE from low-grade lymphoma.[3] In addition, there may be benefit in development of mucosal pANCA and P-glycoprotein expression for helping to predict response to therapy.[50,51]

Treatment as a Diagnostic Tool

In many cases, clinicians can use an organized therapeutic plan to help confirm the diagnosis, and determine the optimal therapy for a particular case. Unless the animal is debilitated, single therapeutic modalities are instigated sequentially, and the owner is asked to record precisely in an event diary the frequency and nature of clinical signs. The clinician can then review the diary and calculate disease severity using one of the recognized scoring schemes (see Table 57-3). Although response to treatment can inevitably be judged more objectively, clinicians should still be cautious that therapy might have only invoked a placebo effect. My favored order of treatment trials is anthelmintic/antiparasitic medication, dietary modification, antibacterial trials, and, finally, trial immunosuppressive therapy.

Approach to Therapy

Regardless of the histologic type of IBD, treatment usually involves a combination of dietary modification, antibacterials, and immunosuppressive therapy. Most recommendations are based upon individual experience because objective information of efficacy is generally lacking, and no randomized controlled clinical trials have been conducted. A staged approach to therapy is recommended whenever possible, but may not be appropriate in seriously ill patients (e.g., those with severe hypoproteinemia) where immediate intervention with combination therapy may be essential. Where sequential therapeutic trials are used, initial treatment should be with antiparasitic agents to eliminate occult endoparasite infection. I most commonly use fenbendazole at 50 mg/kg q24h PO for 3 to 5 days. However, not all parasites are sensitive to this drug (e.g., *Trichomonas* in cats) and resistance may be present in other organisms (e.g., *Giardia*). Subsequently, an exclusion diet and antibacterials should also be employed, before the use of immunosuppressive medication is considered. Some authors no longer bother with antibacterial medication, as one study suggested that it is not beneficial in canine IBD.[52]

As mentioned above, a diary record can be maintained by the owner, and used to determine success of each therapy. Where partial responses are noted to single agents, multimodality therapy can be justified. The treatment trial approach is labor intensive, but is the best way of achieving successful resolution of the clinical signs. Clients appreciate the interest shown by the clinician, and are more accepting of the advice, than when communication is poor subsequent to diagnosis.

Therapeutic Options

Intravenous Fluid Therapy

Crystalloid therapy is usually only necessary if the patient is dehydrated, but is not required for most patients. If hypoproteinemia is present, intravenous colloid therapy may be required, and options include synthetic colloids (e.g., hydroxyl-ethyl starch), and plasma transfusion. Infusions of human albumin can be considered, but this approach is controversial. First, the half-life is shorter than for synthetic colloids such as hydroxyl-ethyl starch so that any benefit may be short-lived; second, recent work has demonstrated rapid development of immune responses to the human albumin molecule, which can lead to anaphylactic reactions[53]; importantly, some dogs developed anaphylaxis even on first administration of albumin, perhaps because prior exposure had occurred (e.g., during vaccination or intradermal skin testing). Finally, because the human albumin molecule will crossreact in the serum albumin assay, this parameter cannot be used as a means of monitoring response to therapy.

Dietary Management

Most clinicians agree that dietary management is a key component in the successful treatment of IBD, and in support of this, dietary modification was recently shown to play a critical part in long-term therapy for cats with chronic GI disease,[54] and dogs with chronic enteropathy.[50] Two main approaches exist for dietary management of SI IBD: switching to a highly digestible diet or to an exclusion diet. In reality, these strategies need not be mutually exclusive because most commercial exclusion diets are also formulated to be highly digestible.

High digestibility ensures that components can be readily assimilated in the face of suboptimal digestive function. Protein should be of high biologic value. Gluten is perceived to be a common food allergen, largely because of its known association with gluten-sensitive enteropathy in Irish Setters.[55,56] As a result, most formulated diets avoid the use of gluten. However, although undoubtedly responsible for some adverse reactions to food, there is no evidence that gluten is any more antigenic to other commonly fed proteins. Fat restriction was traditionally recommended because of concerns over malabsorption, meaning that unassimilated fatty acids could be available for hydroxylation, thus stimulating electrolyte secretion. However, the need for fat restriction has recently been challenged as most cases can tolerate a higher dietary fat content, and fat restriction may exacerbate existing weight loss. Modification of the n3:n6 fatty acid ratio may also modulate the inflammatory response and have some benefit in treatment and maintenance of remission.[57,58] However, there have been no studies done to prove a benefit of such modification in canine IBD.

An exclusion diet trial should be considered in all cases of unexplained intestinal inflammation to exclude the possibility of an adverse food reaction. Most clients are willing to try this first, given concerns over the side effects of immunosuppressive drugs, but this may not be feasible in severely ill animals. The choice of diet

depends upon prior dietary exposure, and the preference of both owner and clinician, and options include home-prepared recipes or commercial single-source protein diets. Although, no GI-specific data exist to recommend one approach over the other, recent work in canine atopic dermatitis demonstrates improved efficacy of commercial rations over home-cooked rations.[59]

The main recent advance in this field has been the availability of hydrolyzed protein diets, where a native chicken or soy protein has undergone chemical or enzymatic treatment, producing low-molecular-weight protein derivatives. In theory, such diets should be less antigenic; this supposition is supported by recent work, in an experimental model of canine food-allergic skin disease, demonstrating reduced in vitro antigenicity compared with the native molecule.[59] The other major advantage of utilizing protein hydrolysates is the improved digestibility of the protein components, which may be superior to traditional single-source protein exclusion diets. Thus they are now the exclusion diet of choice for many clinicians, and a recent clinical trial was encouraging.[60]

Whichever type of diet is chosen, it must be palatable and should be introduced in gradually increasing amounts over 4 to 7 days. It is best to feed the chosen diet exclusively, and in small, frequent meals (e.g., 4 to 5 per day). Finally, parenteral nutrition is occasionally required for cases of severe, debilitating IBD.

Vitamin Supplementation

Cobalamin malabsorption is relatively common in SI IBD, especially if distal regions are involved, and this can have significant metabolic consequences, including ill-thrift and poor appetite. As mentioned previously, cobalamin deficiency is a negative prognostic sign in canine chronic enteropathy[18] and is associated with more severe feline alimentary tract disorders.[35] When hypocobalaminemia is identified, therapy is recommended. Oral administration of cobalamin is ineffective and it must be given by subcutaneous injection (e.g., 20 μg/kg q7days for 4 weeks and then the same dose q28days for a further 3 months). Serum cobalamin concentration should be rechecked a month after the last dose and should be supranormal at that time, indicating that cobalamin supplementation can be discontinued. Less commonly, folate malabsorption may accompany severe and prolonged SI IBD, and oral supplementation is easily achieved with administration of approximately 1 mg of folic acid per day. Although such therapy is well-tolerated, no published studies are available to support the therapeutic benefit of such an approach.

Antibacterial Therapy

The use of antimicrobials in IBD can partly be justified by the potential to treat any undiagnosed enteropathogens, and partly by the fact that it is bacterial antigens which are thought to drive the pathogenetic pathways. However, this approach is not universally accepted and a recent study suggests that antibacterial therapy is of limited benefit in canine IBD.[52] Metronidazole remains the preferred antibacterial for SI IBD, and it has long been suggested to have immunomodulatory properties in addition to an antimicrobial action. Tylosin also may have immunomodulatory effects and may have some efficacy in canine IBD. Although there are few studies demonstrating the efficacy of these drugs in companion animal IBD, a recent study in a rat model of IBD (colitis induced by 2,4,6-trinitrobenzene sulfonic acid) suggests that tylosin is effective at decreasing inflammation.[61] This work is particularly interesting in light of the recent report of a series of dogs with diarrhea that responded to tylosin therapy.[62] However, the relationship between this condition and the IBD syndrome is not well understood.

Immunosuppressive Drugs

Undoubtedly, the most important therapy for idiopathic IBD is immunosuppression, although this should only be considered a last resort. In human IBD, glucocorticoids and thiopurines (e.g., azathioprine, 6-mercaptopurine) are the most widely used.[63]

In dogs and cats, glucocorticoids are most frequently used for immunosuppressive therapy in SI IBD, and prednisolone (or prednisone) is the drug of choice. The standard initial dosage in dogs is 1 mg/kg PO q12h, given for 2 to 4 weeks, and then tapered slowly over the subsequent weeks to months. In most cases therapy can be only be reduced to a low maintenance dose given q48h, and in the minority of cases can be completely withdrawn. Cats are usually treated with higher doses, typically twice those of dogs (2 mg/kg q12h PO initially, then tapering).

If severe malabsorption is present, prednisolone can be administered parenterally and oral therapy instigated once signs have improved. In some cases an initial response to steroids is followed by a relapse and lack of further response even when dosages are increased. This may be either a result of transformation to lymphoma or an incorrect initial diagnosis. However, it is feasible that resistance to steroids may have developed, because of induction of the multiple-drug resistance gene and expression of P-glycoprotein.[51] Despite the widespread use of these drugs in companion animal gastroenterology, controlled clinical trials demonstrating efficacy are lacking. A recent study in dogs suggests that CIBDAI decreases upon successful treatment with steroids,[29] although neither mucosal permeability nor histopathologic abnormalities change significantly. This further supports the supposition that the condition is controlled rather than cured with such therapy.

In some dogs, high doses of conventional glucocorticoid therapy are poorly tolerated. In this circumstance, options include adding a drug to provide a "steroid-sparing" effect, or using a novel steroid with fewer side effects. Budesonide is a glucocorticoid with high first-pass metabolism, and an enteric-coated formulation of this drug has been successful in maintaining remission in human IBD. The use of this drug has been reported for canine IBD,[13] although there is no evidence to suggest it is more efficacious than prednisolone. Interestingly, both suppression of the hypothalamic–pituitary–adrenal axis and development of glucocorticoid hepatopathy have been demonstrated in dogs, but minimal systemic effects are noted.[13,64] The optimal dose has not yet been determined, although, anecdotally, a dose of 1 to 3 mg/m^2 q24h PO has been used. A delayed-release formulation is most often used, but the main concern in SI IBD is that the drug may not become active until after it reaches the large intestine. Further work is required before clinicians can be confident in the use of this drug.

Azathioprine at 2 mg/kg PO q24h is commonly used in dogs in combination with prednisolone/prednisone when the initial response to steroid therapy is poor or side effects are marked. However, its activity may show a delayed onset (up to 3 weeks) and, given its myelosuppressive potential, regular hematologic monitoring is necessary. Azathioprine is not recommended for cats, largely because cats have very low activities of thiopurine methyltransferase (TPMT), the major enzyme involved in the degradation of 6-mercaptopurine (6-MP), the active metabolite of azathioprine. Chlorambucil (2 to 6 mg/m^2 PO q24h until remission, then tapering) is a better choice of a cytotoxic immunosuppressive agent in cats. A combination of prednisolone and chlorambucil can also be effective for alimentary lymphoma in cats, and is particularly suitable for use when differentiation of severe IBD from lymphoma has been problematic.

Cyclosporine binds to the cytosolic protein cyclophilin (immunophilin) of immunocompetent lymphocytes (especially T

lymphocytes); the resulting complex then inhibits calcineurin, which itself is responsible for activating interleukin-2 transcription, thereby leading to a reduced function of effector T cells. As a result, it has been proven to be useful as an immunomodulator in human gastroenterology.[65] Efficacy has been demonstrated in immune-mediated conditions such as anal furunculosis and atopic dermatitis. A recent uncontrolled study also shows that cyclosporine (5 mg/kg q24h PO) may be effective in IBD, which is refractory to steroid therapy.[66] Most dogs achieved either complete or partial remission, and response correlated with reductions in both CIBDAI and mucosal T-lymphocyte numbers; however, no change in histopathology score was noted. The favorable response came at a cost, with side effects (including vomiting, gingival ulceration, alopecia) occurring in almost half of the dogs.

This drug is most commonly used in refractory cases of IBD, when other immunosuppressive therapy has failed, but widespread use may be limited by cost of therapy. Furthermore, given the marked immunosuppressive effect, it is vital that all possible infectious etiologies have first been eliminated; thus the drug should be used with caution in areas where fungal infections are endemic, and it may be prudent to screen for occult infectious diseases (e.g., *Toxoplasma*, feline leukemia virus [FeLV], and feline immunodeficiency virus in cats), prior to instigating therapy.

Other immunosuppressive cytotoxic drugs include methotrexate and cyclophosphamide. Methotrexate is effective in the treatment of human Crohn disease,[67] but it is not widely used in companion animals. A single case report has reported a response of severe IBD, with concurrent hypoproteinemia and lymphangiectasia, to methotrexate after a combination of prednisolone and cyclosporine were ineffective.[68] This observation should be confirmed with larger case series and, preferably, evidence-based medicine before the routine use of this drug is recommended. Cyclophosphamide has few advantages over azathioprine and is rarely used.

Mycophenolate mofetil has been used to treat human IBD, although its efficacy is variable.[69] Its use is reported for the treatment of canine myasthenia gravis,[70] but to my knowledge there are no published studies on its use for SI IBD in dogs or cats. Drugs that target TNF-α (e.g., thalidomide, oxpentifylline) are used in human IBD, but have not been used in dogs. Anti–TNF-α monoclonal antibody therapy is also beneficial in human IBD, but will only be suitable for canine and feline IBD if species-specific monoclonal antibodies are developed for therapeutic use.[71-73]

Prebiotics and Probiotics

Modulation of the enteric flora with probiotics or prebiotics included in the food may have benefits in IBD. Nondigestible carbohydrates, such as lactulose, inulin, fructooligosaccharides, and mannanoligosaccharides are the most frequently used prebiotics. However, there is little evidence that they modify the bacterial flora of the SI.[73] These agents are frequently incorporated in diets formulated for therapy of SI IBD. Probiotics can directly antagonize pathogenic bacteria, but they also modulate mucosal immune responses. Probiotics are suggested to be beneficial for human IBD,[74] although no truly objective data (e.g., double-blind placebo-controlled trials) exist, despite promising initial reports. More work is required before probiotic use becomes commonplace in companion animal IBD therapy.

Miscellaneous Therapies

Diuretics may reduce ascites: spironolactone at 1 to 2 mg/kg PO BID may be more effective than furosemide for treating ascites. Thromboembolism is a feature of some patients with PLE, and prophylactic low-dose aspirin at 0.5 mg/kg BID has been advocated in PLE. Some dogs with SI IBD present with severe microcytic anemia[31] and these may require intravenous blood replacement (whole blood or packed red cells). Furthermore, oral ferrous sulfate (at 200 mg/dog) may be required for a prolonged period (often months).

Predicting Response to Therapy

Some studies have examined ways of predicting response to future therapy. For example, high mucosal pANCA expression prior to treatment correlates with response to dietary therapy, while those that did not respond (and required glucocorticoids) had lower levels of expression.[50] P-glycoprotein is a transmembrane protein that functions as a drug-efflux pump in the intestinal epithelium. In human IBD, high lymphocyte P-glycoprotein expression is seen in patients who fail to respond to treatment with steroids. Recent work in canine IBD demonstrates that low pretreatment mucosal lymphocyte P-glycoprotein expression correlates with a favorable response to treatment.[51] The lowest levels of expression were found in dogs that responded to a dietary trial, moderate levels in steroid-responders, and the highest levels in those that responded neither to steroid nor diet. However, the main limitation of this assay is the necessity for repeat endoscopy to monitor cases, given that many owners may be reluctant to allow their pet to undergo such procedures.

Prognosis and Prognostic Indicators

A recent study examining prognosis in canine IBD suggests that success of therapy is variable.[26] Although many cases initially responded, only a quarter achieved complete remission; intermittent signs remained in a further half of the dogs, while response was poor in the remaining cases and many were euthanized. One negative prognostic indicator was hypoalbuminemia, a finding recently confirmed in another study, which also identified hypocobalaminemia as a negative risk factor.[18] A high disease activity index (e.g., CIBDAI, CCEAI) and a high endoscopic score were also identified as risk factors for a poor outcome in this study.

Other potential markers for IBD prognosis include serum acute-phase proteins, such as C-reactive protein; in one study, C-reactive protein was found to decline upon successful therapy[17]; however, this acute-phase protein did not correlate with outcome in two more recent studies.[18,19] Furthermore, histopathologic scoring of biopsies, prior to and after therapy, does not correlate with outcome,[18,28] although this study was conducted prior to the release of the histologic scoring scheme.[2] Mucosal pANCA expression recently was shown to be increased (prior to therapy) in cases that ultimately respond to dietary management, and expression of this marker increases posttherapy in steroid-responsive cases. Finally, low pretreatment mucosal lymphocyte P-glycoprotein expression was recently shown to predict a favorable response to therapy, and could also be of use in determining which treatments (diet or steroids were most suitable).[51]

MALABSORPTION

Michael D. Willard

Etiology

Malabsorption

Malabsorption generally connotes chronic small intestinal disease that may have one or more underlying pathophysiologic

mechanisms.[1] Malabsorption is usually, but not always, associated with diarrhea. Common causes of malabsorption include dietary-responsive disease (e.g., allergy and intolerance; see Chapter 31), antibiotic-responsive diarrhea (also referred to as SIBO and "dysbiosis"; see other sections in this chapter, Infection, Neoplasia, and IBD).

Protein-Losing Enteropathy

PLE is associated most importantly with lymphangiectasia (dogs only), lymphoma, parasites, fungal infections, ulceration/erosion, intussusception, and IBD,[2] but dietary-responsive disease and antibiotic-responsive disease may also be responsible.

Short Bowel Syndrome

Short bowel syndrome (SBS) occurs when a patient has a large resection of the SI.[3] It is almost always an iatrogenic phenomenon, and is typically caused by overly aggressive small intestinal resection as a result of diffuse malignancy, linear foreign bodies, multiple perforations, and adhesions caused by peritonitis.

Pathophysiology

Malabsorption

Malabsorption may result from reductions in absorptive surface area (e.g., villus atrophy and villus fusion), damage to enterocytes (e.g., bacterial infection), and intestinal mucosal infiltration (e.g., inflammatory or neoplastic cells).[1] Multiple pathophysiologic mechanisms may be operative in an individual patient. Villus atrophy is caused by loss of enterocytes, decreased precursors in intestinal crypts, infiltrative disease causing villus fusion, and mechanical destruction of the absorptive surface area (e.g., massive gastric acid emptying into the intestine with gastrinoma). Enterocytes can be damaged by bacteria (e.g., damage to the microvillar membrane) or can be immature and poorly functional as a result of accelerated turnover. Infiltrates of the mucosa can affect mucosal permeability, villus structure and function, and lymphatic flow; therefore the host's immune system may be integral to the ultimate severity of the intestinal lesion. Intestinal pathology from any number of causes might allow otherwise normal luminal bacteria to proliferate or persist, in turn causing worsening of enterocyte damage and/or more mucosal inflammation. Finally, animals severely malnourished and protein-deficient from the intestinal disease may have a more difficult time repairing intestinal damage. In this way malabsorptive disease may become self-perpetuating.

Dietary antigens can cause immune (types I and IV hypersensitivity) as well as non–immune-mediated (i.e., intolerance) reactions in the intestinal mucosa (see Chapter 31).

Intraluminal bacteria (discussed in more detail in Chapters 2 and in other sections of this chapter, e.g., "Infection") can elicit inflammatory responses in the intestinal mucosa, and bacterial toxins and metabolic by-products can damage enterocytes through various mechanisms such as deconjugated bile acids, alcohols, and hydroxylated fatty acids. Antibiotic-responsive disease is generally caused by nonpathogenic bacteria, hence specific toxins (as are seen with certain *E. coli* or *Campylobacter* infection) are not usually considered important.

Parasites (e.g., *Giardia*) can have direct cidal effects on enterocytes.

IBD is a syndrome in which intestinal mucosal inflammation becomes self-sustaining and recurrent (see Chapters 3, 56, and 59). Dietary and bacterial antigens play an important role in disease pathogenesis. The mechanisms are speculative, but it is believed that these antigens gain access to the mucosa, perhaps as a result of increased mucosal permeability, and then either an aberrant immune response or a constant ingress of antigens maintains the inflammatory response. Cats might have a greater incidence of IBD, which might be partially explained by their strong inflammatory response to exogenous antigens.

Protein-Losing Enteropathy

PLE occurs when serum proteins are lost into the GI tract. There are three basic mechanisms for protein loss: lymphatic obstruction or rupture, increased mucosal permeability because of mucosal infiltrates (e.g., inflammatory and neoplastic), and mechanical causes (e.g., ulcers, erosions, and congestion).[2,4]

Lymphangiectasia affects dogs only and is usually caused by lymphatic obstruction, either anatomic or physiologic.[5] Lacteals in the villi dilate as they absorb lipid and lipoprotein until they finally rupture, releasing protein and lipid back into the intestinal lumen. The severity of PLE depends mostly upon the distribution of this lesion. If only a small portion of the intestine is affected, protein loss may be offset by the ability of the healthy intestine to digest and absorb proteins and lipids, as well as the liver's ability to produce more albumin. Some PLE patients may have normal serum albumin concentrations if the obstructive process is of short duration and limited distribution but, PLE is seldom diagnosed until the discovery of hypoalbuminemia causes the clinician to look for a reason.

Lipogranulomas in the intestinal wall or mesentery (Figure 57-15) develop as a consequence of lymphatic leakage and further complicate the disorder. As lipogranulomas enlarge and coalesce, they alter tissue compliance and contribute to the obstructive lymphatic process. Some dogs with lymphangiectasia and severe hypoalbuminemia have minimal mucosal inflammation except perhaps for a few inflammatory cells around areas of lymphatic leakage or some macrophages attempting to eliminate the chyle.[2]

Inflammatory conditions (e.g., IBD, histoplasmosis) and some neoplasia (e.g., lymphoma) seemingly cause PLE because inflammatory and neoplastic cell infiltrates alter vascular and mucosal permeability, thereby permitting serum proteins and red blood cells to leak from the mucosa. *Parasites* (hookworms, whipworms) and ulcers/erosions cause mucosal bleeding that produces the PLE. Congestion in the tip of an intussusceptum can cause serum exudation and hypoalbuminemia.

Short Bowel Syndrome

Massive small bowel resection, nutrient malabsorption, and protein-calorie malnutrition define SBS.[3] There is no precision in the amount of small bowel resection that must take place before the development of SBS. Some patients tolerate large resections with minimal complication, whereas others have significant complications following lesser amounts of resection.[6] Development of SBS is influenced by the patient's preoperative nutritional status as well as postoperative pathophysiology. For example, following resection, gastric acid may cause chemical injury to the remaining unbuffered SI. Moreover, the remaining small bowel often assumes a bacterial flora more typical of the large bowel. This problem is further exacerbated with resections of the ileocolic sphincter.

Clinical Examination

Malabsorption

Weight loss or loss of body condition, small bowel-type diarrhea, and polyphagia are the primary clinical signs of malabsorptive

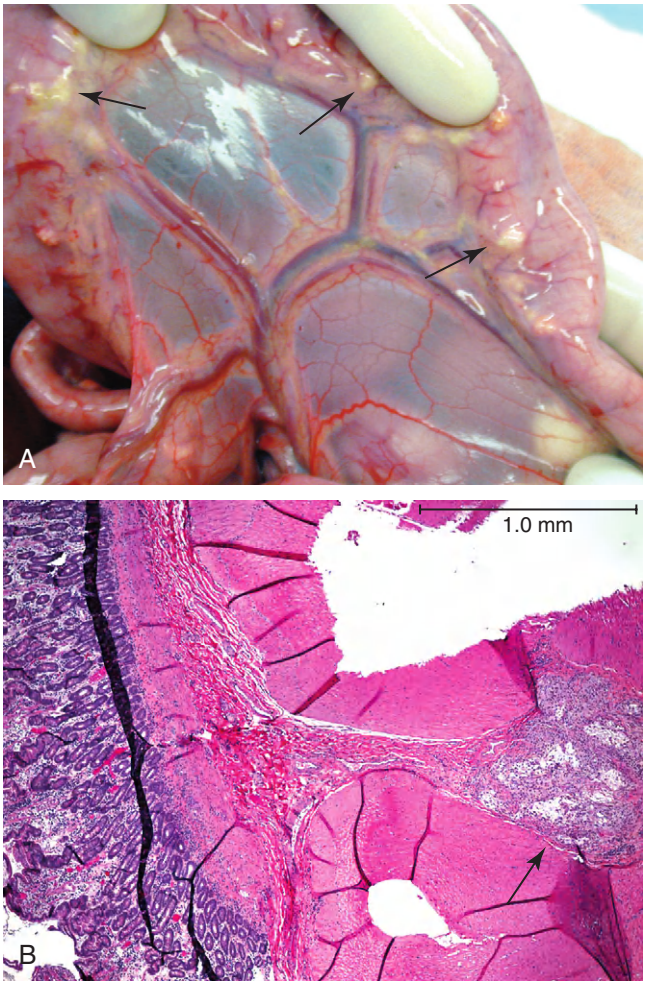

Figure 57-15 **A,** A gross picture taken at surgery of a dog with lymphangiectasia that had severe lipogranulomas (*arrows*) at the mesenteric border. **B,** A photomicrograph of an intestinal biopsy from the tissues seen in **(A).** Note the large lipogranuloma in the tunica muscularis (*arrow*).

disease, although this triad is not uniformly present in all SBS patients. Diarrhea is defined as an increase in the liquidity, frequency, or volume of feces. The colon has an abundant reserve capacity to absorb water (see Chapter 1); therefore the feces may appear "normal" to the pet owner despite severe small bowel disease. Instead these patients will have a voluminous fecal output as a result of intestinal malabsorption. If accelerated transit and hypersecretion make the patient nauseous, it may have a poor appetite instead of polyphagia.[1] The vestigial SI may seem normal or thickened on abdominal palpation. Some patients with dietary allergies also will have cutaneous manifestations consistent with allergy.

Clinical pathology testing is often not very informative, except for hypoalbuminemia, hypocholesterolemia, and hypocobalaminemia. Changes in cobalamin (vitamin B_{12}) metabolism are very specific for distal small intestinal disease, but it is a fairly insensitive biomarker; many animals with severe small intestinal disease have normal serum cobalamin concentrations.[7] Imaging of the gut is also insensitive. Ultrasonographic determination of small intestinal thickness has not been shown to clearly correlate with disease[8]; however, changes in small intestinal layering may reflect infiltrative disease. Mild to moderate mesenteric lymphadenopathy may be seen in patients with nonneoplastic disease.

Protein-Losing Enteropathy

Diarrhea as a clinical sign is inconsistently reported in many PLE patients. Intestinal lymphangiectasia patients in particular often have normal-appearing feces.[2] Ascites (low-protein transudate) and/or peripheral edema may be the only historic or physical examination findings, especially in lymphangiectasia patients. Weight loss is common but may be "hidden" by the ascites, unappreciated until palpation reveals boney prominences across the body. Two breeds at risk for PLE are the soft-coated Wheaton Terrier[9] (Wheaton Terriers may have concurrent PLN) and the Norwegian Lundehund.[10] Yorkshire Terriers have an increased risk for PLE, based upon data reported from one institution.[11,12] Chinese Shar-Pei and Basenji dogs are prone to severe IBD with concurrent PLE.[2]

Hypoalbuminemia is the key clinicopathologic finding in PLE. Panhypoproteinemia is "classic" but not invariable.[2] Patients who hyperglobulinemic prior to developing PLE (e.g., chronic inflammation caused by rickettsial, fungal, cutaneous, or heartworm infection) may lose most of their serum proteins but still have normal serum globulin concentrations. Lymphopenia sometimes occurs if the intestinal lymphatics are involved in the disease process. Hypocholesterolemia is common and expected, but is also seen in hepatic insufficiency. Hypocholesterolemia is not typically seen in PLNs (which sometimes helps distinguish between these causes). Hypocalcemia is common finding,[5] and would appear to be secondary to hypoalbuminemia in many patients, but suppression of parathyroid function[11,12] and/or decreased vitamin D[13] may be responsible in others. The hypocalcemia is seldom associated with tetany. It is more clinically useful to measure ionized serum calcium as opposed to total serum calcium. Hypomagnesemia often occurs in severe PLE and may contribute to hypocalcemia by affecting parathyroid function.[11,12] Fecal α_1-PI concentrations are generally increased in this patient population.[14] Ultrasound sometimes reveals "streaking" within the mucosa, presumably associated with the dilated lymphatics in lymphangiectasia.[15]

A thickened segment of bowel is palpated in many patients with GI intussusception, although this can be easily missed if the intussusception takes place at the root of the mesentery. Young dogs with a recent history of enteritis (e.g., parvoviral, parasitic) from which they should have recovered, but which continue to have diarrhea, is suggestive of the disorder. Finding hypoalbuminemia in these same patients strongly suggests parasites or intussusception. Abdominal ultrasound is the best way to noninvasively detect intussusceptions.

Short Bowel Syndrome

These patients have had a recent, massive, intestinal resection and are typically losing weight (or are already emaciated) with severe, profuse diarrhea.[3]

Diagnosis

Malabsorption

Malabsorptive disease is presumptively diagnosed from history, physical examination findings, clinical pathology data, and by eliminating other causes of disease (e.g., feline hyperthyroidism, hepatic insufficiency).[1] Finding small intestinal histopathology with an appropriate history and physical examination findings is confirmatory, but not all small intestinal malabsorptive diseases have concurrent histologic changes. In particular, dogs with antibiotic-responsive enteropathy or dietary-responsive disease may have minimal to no discernible histologic change in the SI. Therapeutic trials are often

the best way to diagnose these last two diseases. For most other disorders (e.g., IBD, intestinal lymphoma), biopsy is necessary.

Protein-Losing Enteropathy

PLE is often a diagnosis of exclusion.[2] Patients typically have serum albumin ≤2.0 g/dL, and other causes of hypoalbuminemia must be eliminated. PLN and hepatic insufficiency are the two major differentials for this finding. Anorexia and weight loss are inadequate explanations for a serum albumin this low. Urinalysis/urine protein-to-creatinine ratio and hepatic function tests (e.g., serum bile acid concentrations) are typically needed to eliminate these syndrome. Serum blood urea nitrogen and creatinine concentrations, ALT activity, and bilirubin concentrations will be inadequate for this purpose. It should be reemphasized that some dogs with PLE will not have diarrhea, at least as defined by an increase in the liquidity of feces.

It should also be recognized that patients with PLN or hepatic insufficiency can have concurrent PLE. If a patient with modest urinary protein loss has concurrent diarrhea and a serum albumin of 1.5 g/dL, the urinary protein is likely inadequate to explain the magnitude of the hypoalbuminemia. Such patients may require measurement of fecal α_1-PI concentrations for a definitive diagnosis.[14] This test is available through the GI laboratory at Texas A&M University. The test has many difficulties in the collection and storage of feces, making it critical to consult the laboratory before beginning the study.

In parasite-rich environments, one cannot eliminate parasitism because of one negative fecal examination. Adult animals can die of prepatent hookworm infections, and whipworm ova are often difficult to detect. Ultrasonographic imaging may be indispensable in the detection of neoplastic masses, inflammatory infiltrates (which might permit diagnosis by fine-needle aspiration), and intussusceptions. Ultrasound findings also may aid the clinician in deciding whether to do endoscopic or full-thickness intestinal biopsies. Intestinal biopsy is often crucial because there are numerous causes of PLE, and histopathology is often the only way to distinguish between the various causes.

There is considerable debate about endoscopic versus full-thickness biopsy (see Chapter 27). Advantages of endoscopy include its ease, noninvasive nature, ability to detect mucosal lesions allowing one to direct the biopsy to those areas, and ability to take multiple samples from one area.[16] The major disadvantages of endoscopy are that it does not allow access to the mid-jejunum, and nondiagnostic tissue samples may be obtained if the operator was not trained properly. Superficial samples (e.g., villus tips only) or compressed lacteals (Figure 57-16) may be obtained with all too vigorous handling of the endoscopic biopsy forceps. Surgery and laparoscopy provide ready access to the mid-jejunum (which endoscopy seldom can reach) and facilitate tissue sampling that will detect submucosal lesions. Surgery also permits biopsy of mesenteric lymph nodes. Surgical and laparoscopic biopsy are more invasive, have greater risk for morbidity and mortality from dehiscence,[17] are more expensive, do not reliably detect mucosal lesions (which means you may have biopsied the wrong site), do not guarantee a diagnosis, and generally require removal of ascites. The latter intervention has the possibility of lowering body albumin content further still, making it all the easier for ascites to quickly reform. Furthermore, untrained individuals can easily take nondiagnostic full-thickness biopsies.

It is important to be able to reliably diagnose lymphangiectasia. It may be more common than generally realized and yet can be particularly difficult to diagnose. Endoscopy allows strong presumptive diagnosis when erratic, grossly enlarged lacteals are observed (Figure 57-17).[2,4] I typically feed a small amount of a very-high-fat diet to the patient the night before the procedure to help ensure that lacteals will be filled, hopefully augmenting diagnosis.[18] Lymphangiectasia can affect the entirety of the GI tract, but more often than not is localized to one segment of the SI (which can

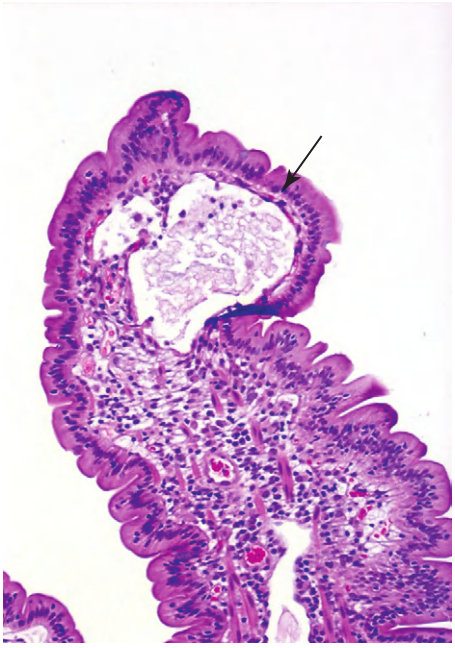

Figure 57-16 A photomicrograph of a villi with lymphangiectasia. Note how the lacteal has engorged so much that now only the epithelium (*arrow*) is holding the chyle in the lacteal. This lacteal is about to rupture and release its contents into the intestinal lumen. It would be very easy to rupture this relatively fragile "balloon" if it were compressed, as might likely happen when using endoscopic biopsy forceps.

Figure 57-17 An endoscopic view of the duodenum of a dog with lymphangiectasia. The large, white spots are dilated lacteals. This dog has lymphangiectasia. Note that if a full-thickness biopsy was obtained, the likelihood of diagnosis could depend upon where the biopsy was performed, as the lesions are not uniform throughout the mucosa.

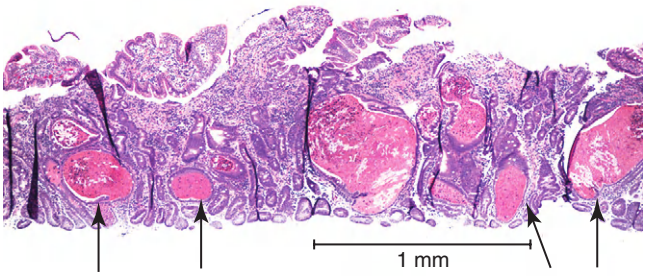

Figure 57-18 A photomicrograph of intestines from a dog with PLE. Note the crypts that are engorged and dilated with pink, proteinaceous material (*arrows*).

sometimes be ascertained by ultrasound). Sometimes an obvious white fluid is released as biopsies are taken, which is chyle being released from lacteals that are ruptured during the biopsy process.[2] There are at least two significant problems with histologic diagnosis of lymphangiectasia. First, the lesions may be localized to one section of the gut (e.g., lymphangiectasia is found in the ileum but not the duodenum). Second, lesions may be relatively localized to the deeper layers of the intestine (e.g., the border between the mucosa and the submucosa) and can only be found with full-thickness biopsies. The extent of these problems is unknown.

Intestinal crypt lesions have been reported in association with PLE (Figure 57-18).[19,20] It is not known whether this lesion is disease specific or associated with several disease entities. The need to identify lesions such as these illustrates the importance of obtaining the entire thickness of intestinal mucosa and not just the villus tips.

Some patients with severe PLE do not have discernible histologic lesions nor do they have strongly suggestive ultrasonographic or endoscopic abnormalities. In these situations, there appear to be at least two main possibilities. First, the patient may have lymphangiectasia at a site not biopsied or observed. Second, the patient may have PLE as a consequence of a disease that does not always cause severe histologic mucosal changes, such as antibiotic-responsive enteropathy or food-responsive diarrhea.

In certain cases (e.g., client monetary constraints, inability to find a histologic lesion), a rapid increase in the serum albumin concentration after the initiation of an ultralow-fat diet is suggestive of lymphangiectasia. Likewise, an increase in serum albumin after initiating antibiotic therapy or dietary therapy suggests antibiotic-responsive disease or dietary-responsive disease, respectively. It is generally preferable to do intestinal biopsy in patients with severe PLE as opposed to observing the response to therapeutic trial; however therapeutic trials are clearly necessary in some patients.

Extra-GI disease (e.g., hypoadrenocorticism, cardiac disease,[21] pulmonary disease[22]) may be associated with PLE. Hypoadrenocorticism may be suspected because of the classic electrolyte changes or lack of a stress leukogram, or because all other causes have seemingly been eliminated.

Short Bowel Syndrome

SBS is diagnosed based upon history and physical examination, as defined for example.

Treatment

Malabsorption

Successful treatment of malabsorptive disease requires that the underlying cause be determined. The reader is referred to other sections of this chapter, e.g., "Antibiotic-Responsive Diarrhea," "Dietary Responsive Disease," "IBD," "Parasitism," and "Neoplasia."

Protein-Losing Enteropathy

Treatment of PLE requires that the underlying cause (see appropriate sections in this chapter, e.g., "IBD," "Lymphoma," "Parasites," "Ulcers," "Fungal Infections," "Antibiotic Responsive Enteritis," and "Dietary Responsive Diarrhea") be resolved. Intussusception is treated by resection and anastomosis.

In general, patients with PLE do not benefit substantially from IV administration of plasma unless very large amounts are given. Even then, the subsequent rise in serum albumin tends to be transient because the administered albumin is all too quickly lost from the body. Generally ascites should not be removed unless it is causing a substantial problem (e.g., diaphragmatic compression and dyspnea). Removing ascites removes albumin as well as fluid, which ultimately lowers the total body albumin concentration, making it easier for ascites to reform. To lessen ascites, one may administer hetastarch IV (10 to 20 mL/kg), which hopefully stays in the intravascular compartment longer than albumin because of its size, thereby drawing third space fluid into the intravascular compartment. Although one may administer furosemide (2 to 4 mg/kg BID-TID) to lessen ascites, it is best to administer moderate doses. Massive doses of diuretics can deplete the intravascular compartment and cause hypovolemia. In emergency situations (e.g., severe dyspnea as a consequence of pressure on the diaphragm), an abdominocentesis can be performed but only to remove sufficient fluid to alleviate the dyspnea. Patients should be monitored for hypomagnesemia, which can complicate cases and worsen hypocalcemia. If magnesium supplementation is necessary, a continuous rate infusion of $MgSO_4$ in 5% dextrose in water (35 to 50 mg/kg/day) is preferred. Orally administered magnesium tends to act as a laxative.

Lymphangiectasia is primarily treated by feeding an ultra-low-fat diet to minimize lacteal dilation and rupture.[2] Historically, medium-chain triglyceride oil was supplemented to the diet to provide calories without causing lacteal dilation. Most ultra-low-fat diets were high in fiber and lacking in calories; hence, the supplementation. High fiber concentrations are not optimal because the patient often needs caloric support. If an ultra-low-fat diet without a lot of fiber is fed, medium-chain triglyceride oil is unnecessary (which is fortunate because the oils are expensive and not very palatable).

Antiinflammatory and/or cytotoxic drugs help some patients, possibly because they minimize or eliminate intestinal and mesenteric lipogranulomas. Glucocorticoids (at a dose of 1 to 2 mg prednisolone/kg/day) can help but have several important side effects, including fluid retention. Azathioprine (2.2 mg/kg once daily or every other day) or cyclosporine (3 to 5 mg/kg BID; adjust dose based upon therapeutic drug monitoring) appears to be useful in some cases. Monitoring the serum albumin concentration and body weight are probably the best way to monitoring the patient's response to therapy. Substantial improvement of the serum albumin concentration implies that therapeutic progress is occurring, even if diarrhea persists.

Short Bowel Syndrome

SBS is best treated by preventing it. Aggressive intestinal resections should be avoided, even if it requires second exploratory

laparotomies a few days later to ensure that additional resection is unnecessary. Many intestinal resections resulting in SBS are unnecessarily aggressive. Once SBS has occurred, it is important to aggressively treat the animal with total parenteral and enteral nutrition (e.g., elemental diets). Decreasing gastric hyperacidity with H_2-receptor antagonists (famotidine 0.5 mg/kg) or proton pump inhibitors (omeprazole 0.7 to 1.5 mg/kg daily) and suppressing the proliferation of the intestinal microflora (oral broad-spectrum antibiotics) are important components of therapy.[3] The patient should receive parenteral nutrition until it is able to maintain itself on oral nutrition, which usually means multiple, small feedings of highly digestible diets, sometimes including monomeric or polymeric elemental diets. Some SBS patients may need supplementation with vitamin B_{12} (cobalamin) and the fat-soluble vitamins (A, D, E, and K). Treatment with ursodeoxycholate improves the nutritional status of dogs with experimentally induced SBS.[23]

Prognosis

The prognosis for the various nonneoplastic causes of malabsorption and PLE is usually good, assuming that the underlying cause is accurately diagnosed, the patient is seen before the disease is too far advanced, and the client can afford treatment. There are some exceptions. Intestinal lymphangiectasia that has marked lipogranuloma development within the walls of the intestines appears to be more difficult to treat. Pythiosis has a very poor prognosis if it cannot be surgically excised. Histoplasmosis usually responds to antifungal therapy, but very advanced cases may be difficult to salvage because of the marked fungal burden in the body. Diffuse intestinal lymphoma in dogs is more difficult to manage than multicentric lymphoma. Feline intestinal lymphoma may respond well to treatment, if it is well differentiated.

INFECTION

Michael R. Lappin

Helminths

Hookworms

Etiology

Ancylostoma caninum, *Ancylostoma braziliense*, and *Uncinaria stenocephala* are common hookworm infections in dogs. Cats are commonly infected by *Ancylostoma tubaeforme* and *A. braziliense*, but rarely by *U. stenocephala*. *A. caninum* and *A. tubaeforme* are found most frequently in tropical and subtropical areas; *A. braziliense* in warm coastal areas, Central and South America; and *U. stenocephala* in cooler areas like the northern United States, Canada, and Europe. Prevalence rates of hookworm infection have changed over the years.[1-5] In one large study of 1,213,061 dogs examined at 547 private veterinary hospitals in 44 states of the United States, 4.5% of samples contained eggs of *Ancylostoma* spp.[1] In high-risk areas and animals, infection rates can be much higher. For example, in one study in Florida *A. tubaeforme* and *A. braziliense* were found in feces of 75% and 33% of tested cats, respectively.[5]

Pathophysiology

Adult hookworms live in the SI and discharge eggs into the environment in the feces. The eggs develop into infective third-stage larvae in approximately 2 to 9 days depending upon environmental conditions. Dogs are infected by ingestion of larvae in the environment, skin penetration, ingestion of larvae during nursing, or ingestion of infected paratenic hosts (usually rodents). Cats are infected similarly but do not have transmammary infection. After transmammary infection in dogs, cutaneous infection, and ingestion of larvae, some larvae migrate to the lungs via the systemic circulation and molt to fourth-stage larvae in the bronchi and trachea. The larvae are then coughed up, swallowed, and develop into adults in the SI. Some larvae invade muscle tissue where they undergo arrested development (hypobiosis) and can be maintained for months to years. Upon reactivation, during stressful events like pregnancy, these larvae resume migration and reenter the intestine or concentrate in the mammary tissues of dogs and infect subsequent litters. Ingestion of infected paratenic hosts leads only to intestinal infections in dogs or cats. Puppies infected with *A. caninum* by nursing can shed eggs as soon as 10 days after birth. The prepatent periods for *A. braziliense*, and *U. stenocephala* are 13 to 27 days. The prepatent period for *A. tubaeforme* is approximately 3 weeks after ingestion and 3 to 4 weeks after transcutaneous infection.

The primary pathogenic mechanism of disease associated with hookworms is blood loss, which can start approximately 8 days postinfection, prior to shedding of eggs. To potentiate blood ingestion, hookworms release enzymes that cause local tissue necrosis as well as anticoagulants and hookworm platelet inhibitor.[6] Hookworm feeding and reattachment causes small ulcerative areas in the intestine. Blunting of the microvillar membrane and eosinophilic infiltrates may result in malabsorption and diarrhea. Heavily infected dogs and cats can develop cough and pneumonia from lung migration, and transcutaneous infection can result in local skin disease.

Clinical Examination

Heavy infections can result in life-threatening blood loss with the clinical findings of pale mucous membranes, weakness, lethargy, and elevated heart and respiratory rates, particularly if concurrent *Ctenocephalides* spp. infestation is present. Chronic infection can lead to iron-deficiency anemia in puppies. Other clinical signs observed in young animals include small bowel diarrhea with melena and failure to thrive. Hookworm infections may induce weight loss, poor hair coat, loss of appetite, and pica. Adult dogs and cats are less likely to have clinical signs of disease; however, hookworm infection may result in eosinophilic IBD or potentiate other intestinal diseases. Cough and dyspnea can occur from heavy pulmonary infections. When skin lesions occur, they are most common in the interdigital spaces of affected animals and are characterized by pruritus, erythema, and papules.

Diagnosis

The diagnosis of hookworm infection is confirmed by microscopic visualization of eggs in feces after fecal flotation. Centrifugation techniques are more sensitive than passive flotation.[7] Hookworms can produce significant intestinal pathology prior to the shedding of eggs and so fecal flotation can be falsely negative. Adult worms can be visualized in feces and in the intestinal lumen.

Treatment

Anthelmintic drugs to treat the intestinal stages and supportive care as needed are used in the management of hookworm infected dogs or cats (Table 57-4; see Chapter 37). There are no drugs available that can eliminate larvae from the tissues however. Some heavily infected dogs and cats may require blood transfusion and iron

Table 57-4 Drugs Approved for the Treatment of Hookworm Infections of Dogs and Cats

Animal	Approved Drugs
Dogs	
Adult *Ancylostoma caninum*	Fenbendazole, milbemycin oxime, moxidectin, pyrantel pamoate
Adult *Uncinaria stenocephala*	Fenbendazole, pyrantel pamoate, moxidectin
Adult *Ancylostoma braziliense*	Pyrantel pamoate
Fourth-stage and young adult *A. caninum* and *U. stenocephala*	Moxidectin
Cats	
Adult Ancylostoma tubaeforme	Emodepside, ivermectin, milbemycin oxime, moxidectin, pyrantel, selamectin
Fourth-stage and immature adult *A. tubaeforme*	Emodepside, moxidectin

supplementation is needed in some cases with chronic iron deficiency.

Prevention

If the risk of hookworm infection is high, all puppies and kittens (and their mothers) should be treated with appropriate anthelmintics at 2, 4, 6, and 8 weeks of age (see Chapter 37). In addition, the Companion Animal Parasite Council (CAPC) recommends that all puppies and kittens should be prescribed monthly preventives as soon as label recommendations allow and that administration be continued year round (www.capcvet.org). If puppies and kittens are not evaluated until 6 to 8 weeks of age or later, CAPC recommends the administration of a monthly preventive according to label recommendations from that point forward with administration of an anthelmintic 2 weeks later. If heavy hookworm infections have occurred in dogs, fenbendazole can be administered to pregnant bitches from the fortieth day of gestation through the fourteenth day of lactation. Kennel floors and runs should consist of tarmac or concrete, be free of crevices, and be kept as clean and dry as possible. Bedding in kennels and free feces in the environment should be removed daily to lessen larval contamination. CAPC recommends fecal examinations two to four times in the first year and one to two times per year thereafter, depending on the age of the animal and its prior history of infection to assess efficacy of the initial treatments, efficacy of the monthly control product, and client compliance.

Public Health Considerations

Cutaneous larva migrans is the most common syndrome in people associated with dog and cat hookworms.[8] This syndrome results when hookworm larvae penetrate human skin at the point of contact and migrate just beneath the skin. Self-limited, serpentine lesions that are very pruritic can occur; these lesions are usually more severe following infection by *A. braziliense*. Deeper tissue penetration can occur in some people leading to muscle pain, lung disease, abdominal pain syndrome, and eosinophilic enteritis.[9,10]

Prognosis

The prognosis for hookworm infections in dogs and cats is good to excellent.

Roundworms

Etiology

The significant roundworms (ascarids) of dogs or cats include *Baylisascaris procyonis* (raccoons and occasionally dogs), *Toxascaris leonina* (dogs or cats), *Toxocara canis* (dogs), and *Toxocara cati*. *B. procyonis* resides in the SI of the raccoon in North America and Europe, with higher prevalence in northeast, midwest, and west coast U.S. states. Prevalence of *B. procyonis* can be very high; the organism was detected in 12.7% of 188 raccoons in a recent study in Tennessee.[11] Dogs occasionally are infected by *B. procyonis* and the life cycle can be completed in the canine host. *Toxocara* spp. and *T. leonina* have worldwide distribution. Prevalence rates vary by the study, region, and age of animals tested with puppies and kittens more likely to have patent infections. For example, the overall prevalence rate for ascarid infections in cats was 2.92% in one study.[2] In other studies, *T. cati* was detected in 33% of kittens,[12] 21% of feral cats, and 18% of pet cats.[13] In one large study of 1,213,061 dogs examined at 547 private veterinary hospitals in 44 states of the United States, 5.04% of samples contained eggs of *T. canis*.[1]

Pathophysiology

B. procyonis, *Toxocara* spp., and *T. leonina* eggs are passed in feces. Infective larvae then develop in the environment after varying time periods (*B. procyonis*, 2 to 4 weeks; *T. leonina*, 1 week; *Toxocara* spp., 2 to 4 weeks) and can survive in the environment for months to years depending upon environmental conditions. Once larvation has occurred, *B. procyonis*, *T. leonina*, and *Toxocara* spp. eggs are infectious for a variety of hosts, including people (*B. procyonis* and *Toxocara* spp.). All three genera are transmitted by ingestion of embryonated eggs or by ingestion of tissues from other infected vertebrate hosts. Embryonated *Toxocara* spp. eggs have been transmitted by earthworms, flies, and cockroaches, and have been found on the fur of pets.[14,15] Raccoons tend to use favored defecation sites called latrines that often include rooftops, woodpiles, decks, base of trees, barns, and outbuildings, and these sites can become heavily infected by *B. procyonis*. After ingestion of larvated eggs, the prepatent periods for *B. procyonis*, *T. leonina*, *T. canis*, and *T. cati* are 7 to 10 weeks, 8 to 10 weeks, 4 weeks, and 8 weeks, respectively. The prepatent period for *T. canis* can be as short as 2 weeks if infection is acquired by ingestion of another infected vertebrate host.

In the definitive host, *T. leonina* remains in the intestinal tract. After ingestion of infective *Toxocara* spp. eggs, the larvae are released, penetrate the bowel wall, migrate to the liver via the systemic circulation, and then migrate to the lungs of infected dogs and cats. The migrating larvae induce inflammation while migrating through the liver and lungs of puppies and kittens. Hepatic migration rarely results in measureable clinical disease, but pulmonary migration can cause extensive damage, resulting in clinical signs of disease and occasionally death. After reaching the lungs, *Toxocara* spp. larvae either undergo tracheal or somatic migration. After somatic migration, the larvae encyst in tissues. For *T. canis* and possibly *B. procyonis*, the larvae can be reactivated by a triggering mechanism like pregnancy and migrate to the placenta, resulting in infection of the puppies. Transmammary transmission of *T. canis* can occur but is not as important for ascarids as for the hookworms. In young puppies or kittens, tracheal migration is more likely to occur leading to patent infections intestinal infections. As the puppies or kittens become adults, somatic migration is more likely, which explains the lower prevalence of infections in older animals. *Toxocara* spp. infections acquired by ingestion of infected vertebrate hosts result only in intestinal infections.

Table 57-5 Drugs Approved for the Treatment of Roundworm Infections in Dogs and Cats

Animal	Approved Drugs
Dogs	
Toxocara canis, Toxascaris leonina	Fenbendazole, milbemycin oxime, moxidectin, pyrantel pamoate, piperazine
T. canis, T. leonina	Pyrantel with ivermectin or pyrantel with ivermectin and praziquantel
T. canis, T. leonina	Febantel with pyrantel and praziquantel
Cats	
Toxocara cati, T. leonina	Fenbendazole, milbemycin oxime, moxidectin, pyrantel pamoate, selamectin, piperazine
T. cati	Pyrantel, febantel, emodepside

Clinical Examination

In puppies and kittens, intestinal ascarids infection is often associated with vomiting, small bowel diarrhea, potbellied appearance, and general ill-thrift. Heavy infections can induce coughing, increased respiratory rate, and death during pulmonary migration. Animals with large ascarid worm burdens have developed intestinal obstruction, intussusceptions, and intestinal rupture. Neurologic disease has been recognized in some dogs infected with *B. procyonis*. In adult dogs and cats, ascarid infections are often subclinical.

Diagnosis

The diagnosis of ascarid infection is confirmed by microscopic visualization of eggs in feces after fecal flotation. Centrifugation techniques are more sensitive than passive flotation.[7] Adult worms can sometimes be found in the vomitus of infected animals.

Treatment

Anthelmintic drugs to treat the intestinal stages and supportive care as needed are used in the management of ascarid infected dogs or cats (Table 57-5; see Chapter 37). There are no drugs available that can eliminate larvae from tissues.

Prevention

In people, prevention of infection revolves around avoiding the ingestion of embryonated eggs in the environment, particularly those frequented by dogs, cats, or raccoons. In pets, hunting should be discouraged and areas frequented by large numbers of untreated dogs and cats should be avoided. Feces should be removed from the yard and litterboxes with some regularity. All puppies and kittens should be dewormed; if the potential for concurrent hookworm infection exists, deworming can begin at 2 weeks of age. CAPC recommends that all puppies and kittens should be prescribed monthly preventives that control ascarids as soon as label recommendations allow and that administration be continued year round (www.capcvet.org). Raccoons should not be kept as pets and should be discouraged from defecating in areas frequented by people or dogs. Transplacental transmission by infected pregnant bitches can be lessened by administering fenbendazole as described for hookworms. CAPC recommends performing a fecal examination two to four times in the first year and one to two times per year thereafter, depending on the age of the animal and its prior history of infection to assess efficacy of the initial treatments, the efficacy of the monthly control product, and client compliance.

Public Health Considerations

T. leonina has no known public health risks. *Toxocara* spp. infections of people are associated with visceral larva migrans (pulmonary disease, hepatomegaly, and eosinophilia), ocular larva migrans (unilateral granulomatous retinitis), neural larva migrans, and nonspecific clinical signs including abdominal pain. Although these syndromes are relatively rare, many people are infected by *Toxocara* spp. Sera collected between 1988 and 1994 from 30,930 people 6 years of age or older in the United States had an age adjusted *Toxocara* seroprevalence rate of 13.9%.[16] In general, prevalence rates are greater in children because of potential for geophagia and otherwise poor hygienic practices. *B. procyonis*–associated neural larva migrans can be severe as the larvae grow and migrate through the tissues of the body, reaching sizes up to 1500 to 2000 µm. Because of this large size, as few as one to three larvae in the brain can be fatal. The severity of clinical disease depends on the number of eggs ingested, the number of larvae entering the brain, and the location and extent of migration damage. Because no effective treatment exists for larva migrans, prevention of these infections is paramount.

Prognosis

The prognosis for ascarid infections in dogs and cats is generally excellent.

Cestodes

The most common tapeworms infecting the SI of dogs or cats are *Dipylidium caninum*, *Taenia* spp., *Echinococcus multilocularis*, and *Echinococcus granulosa*. Cats or dogs are infected with *D. caninum* by ingesting infected *Ctenocephalides felis*. Dogs or cats are infected with *Taenia* spp. or *Echinococcus* spp. by ingesting other infected vertebrate hosts. The adult tapeworms live within the SI but usually are not associated with clinical signs of disease. Proglottids of *Taenia* spp. or *D. caninum* are often noted around the perineal area of infected animals. Eggs (*Taenia* spp. or *Echinococcus* spp.) or egg packets (*D. caninum*) can be detected on microscopic examination of feces after flotation procedures. Praziquantel (all three genera), epiquantel (*Taenia* spp. and *D. caninum*), and fenbendazole (*Taenia* spp.) are commonly prescribed drugs (see Chapter 37). Infections are prevented by controlling fleas (*D. caninum*) and preventing dogs or cats from hunting or scavenging (*Taenia* spp. and *Echinococcus*). *Echinococcus* spp. (ingestion of eggs) and *D. caninum* (ingestion of infected fleas) are zoonotic to people. The prognosis for these tapeworm infections in dogs and cats is generally excellent.

Protozoans

Cryptosporidium Spp.

Etiology

Cryptosporidium spp. are coccidians that reside in the SI and are occasionally associated with disease in some, but not all, infected hosts. In the past, most of the cases of mammalian cryptosporidiosis were attributed to infection with *Cryptosporidium parvum*. However, molecular studies demonstrate that cats are usually infected with the host-specific *C. felis* and dogs are usually infected with *Cryptosporidium canis*.[17-21] Infections of dogs and cats can be quite common with prevalence rates of 2% to 5% of animals with or without diarrhea, depending on the method of diagnostic testing.[12,13,21-25] In one study of samples collected from centers around the United States,

Cryptosporidium spp. DNA was amplified from feces of 29.4% of cats and 16.1% of dogs with diarrhea.[22]

Pathophysiology

C. felis and *C. canis* are transmitted among cats and dogs and by the ingestion of oocysts in feces from mutual grooming, shared litter-boxes, ingestion of contaminated food or water, and ingestion of infected prey species. Approximately 20% of the oocysts produced in the intestine are "thin-walled" oocysts that fail to form an oocyst wall. These oocysts rupture within the intestines and when the sporozoites are released, autoinfection occurs, which allows for rapid amplification of infection. In one study of cats inoculated with *C. parvum*, *C. parvum* DNA was detected by day 2 after inoculation, but oocysts weren't detected until day 7.[26] Thick-walled oocysts are passed in the feces, are environmentally resistant, are infective when passed, and are the likely source of new infections.

Although infection of dogs and cats with these agents is common, most infected animals do have clinical signs. Diarrhea is generally more common in young animals.[27-41] Coinfection with other protozoans like *Giardia* spp. (dogs and cats) or *Tritrichomonas foetus* (cats) may be associated with more significant illness than with single infections.[42,43] The presence of immunosuppressive disorders like lymphoma, feline leukemia virus infection, and canine distemper virus can potentiate the development of clinical signs of disease. When it occurs, *Cryptosporidium* spp. diarrhea is associated with impaired intestinal absorption and enhanced secretion. Histopathologically, infected animals show loss of intestinal microvilli, degeneration of host epithelial cells, villus atrophy, and lymphocytic-plasmacytic infiltration.[37,44] It is possible that susceptibility to cryptosporidiosis in animals could have a genetic component as suggested for humans.[45,46]

Clinical Examination

Most dogs or cats with *Cryptosporidium* spp. infection are clinically normal. When diarrhea occurs, it is usually watery, without mucous, blood, melena, or straining, and therefore is classified as small bowel-type diarrhea. On abdominal palpation, the SI may feel slightly thickened. Some of the infected dogs or cats with *Cryptosporidium* spp. infection and diarrhea have had underlying diseases like IBD, lymphoma, *T. foetus*, canine distemper virus, and/or feline leukemia virus, and so may have physical examination findings consistent with these conditions. Clinical signs of disease appear to be more likely in cats infected with *C. felis* than dogs infected with *C. canis*.

Diagnosis

Infectious causes of small diarrhea are common in dogs and cats and so the combination of wet mount examination and fecal flotation are usually performed as part of the initial diagnostic workup.[47] However, *Cryptosporidium* spp. oocysts are frequently missed because of the small size (approximately 4×6 μm) and low numbers in infected dog or cat feces (often <500 oocysts/g feces). Modified acid-fast staining of a thin fecal smear can be performed to aid in the diagnosis of cryptosporidiosis. *Cryptosporidium* spp. are generally the only enteric organism of the appropriate size that stains pink to red with acid-fast stain. However, acid-fast staining only detects approximately 70% of *Cryptosporidium* spp.–infected animals when a single sample is tested.[48] Fecal antigen tests for *Cryptosporidium* spp. are available for use with human feces, but results of these assays have been variable when applied to feces from infected animals.[48-50] Fecal antigen assays are based on antibodies against *C. parvum* and high false-negative rates may reflect antigenic differences between *C. parvum*, *C. felis*, and *C. canis*. Fluorescein-labeled monoclonal antibodies react with *Cryptosporidium* spp. oocysts and *Giardia* spp. cysts (Merifluor IFA, Meridian Biosciences, Cincinnati, OH). In limited studies, this assay appears to detect both *Giardia* spp. and *Cryptosporidium* spp. isolates from dogs and cats.[22,26,48] PCR is currently available to detect *Cryptosporidium* spp. DNA in canine or feline feces and is more sensitive than immunofluorescence assay (IFA) in feline studies.[22,26,51] PCR products can be evaluated by genetic sequencing to further determine what *Cryptosporidium* spp. is associated with the infection (Veterinary Diagnostic Laboratory, Colorado State University, Ft. Collins; http://dlab.colostate.edu/). *Cryptosporidium* spp. oocysts or DNA can be detected in normal dogs and cats, consequently positive test results do not prove a disease association.

Treatment

Highly digestible diets used for small bowel diarrhea might resolve some of the clinical signs. More than 100 compounds have been used in attempts to treat *Cryptosporidium* spp. infections in mammals and no compound is consistently effective.[52-54] There have been essentially no controlled treatment studies in dogs or cats and all protocols should be considered empirical. *Cryptosporidium* spp.–associated diarrhea in pets sometimes resolves after administration of tylosin (10 to 15 mg/kg PO q12h), azithromycin (10 mg/kg PO daily), paromomycin (150 mg/kg PO q12-24h), or nitazoxanide (25 mg/kg PO q12-24h). It is unlikely that tylosin has anti-*Cryptosporidium* effects and so cases with apparent responses may relate to the antibiotic or antiinflammatory effects of the drug. Tylosin and nitazoxanide are GI irritants. Paromomycin can be nephrotoxic in cats if absorbed and has had variable results in humans with cryptosporidiosis.[55-57] If the cat or dog shows clinical improvement within the first 7 days of therapy and toxicity has not been noted, treatment should be continued for 1 week past clinical resolution of diarrhea. Some cats with *Cryptosporidium* spp. infection, with or without *Giardia* coinfection, have required several weeks of treatment prior to resolution of diarrhea. The role of fiber, silymarin, or probiotics in addition to antimicrobial therapy is unknown at this time. Some cats and dogs with resistant cryptosporidiosis have underlying diseases (e.g., IBD, *T. foetus*, and immunodeficiency syndromes) and the diagnostic workup should be continued if therapeutic failures occur. No drug treatment has been shown to consistently eliminate *Cryptosporidium* spp. infections. Thus the primary goal for the treatment of dogs or cats with cryptosporidiosis is to eliminate diarrhea. As infection is unlikely to be eliminated, following results of *Cryptosporidium* spp. diagnostic tests in normal animals seems to have little clinical utility.

Prevention

Cryptosporidium oocysts are environmentally resistant but can be ruptured by steam cleaning. Avoidance of contaminated food and water or potential paratenic hosts is the primary means of prevention.

Public Health Considerations

DNA of *C. felis* or *C. canis* have been amplified from the feces of some immunosuppressed people suggesting that zoonotic transfer of these agents can occur.[19] However, the number of proven cross-infections is small and it appears unlikely that healthy or immunocompromised people acquire *Cryptosporidium* spp. infection from healthy cats or dogs.[58] Thus healthy pets are not considered significant human health risks for HIV-infected people by the Centers for Disease Control and Prevention (www.cdc.gov/hiv/pubs/brochure/oi_pets.htm).

Prognosis

Cryptosporidium spp. diarrhea can be difficult to treat in dogs or cats with concurrent diseases. However, in normal animals, diarrhea generally resolves with or without treatment.

Giardia Spp.

Etiology

The genus *Giardia* contains multiple species of flagellated protozoans that are indistinguishable morphologically. Host specificity was thought to be minimal for *Giardia* spp., but not all small animal isolates cause disease in human beings. There have been varying results concerning cross-infection potential of *Giardia* spp. Recent genetic analysis has revealed two major genotype assemblages in people.[18-20] Assemblage A (*Giardia duodenalis*) has been found in infected humans and many other mammals including dogs and cats. Assemblage B (*Giardia enterica*) has been found in infected humans and dogs, but not cats. There are specific genotypes of *Giardia* that commonly infect dogs (*Giardia canis*; Assemblages C and D) and cats (*Giardia felis*; Assemblage F) but are uncommonly identified in people. Prevalence rates for *Giardia* infection vary depending on the area studied, the diagnostic method used, and the health status of the animal, however, prevalence rates are commonly 5% to 10% in healthy or clinically ill dogs or cats.[3,12,13,15,24,25,59]

Pathophysiology

Giardia spp. are found on the surface of enterocytes, with the highest concentrations of the organisms being found in the duodenum of dogs and the ileum in cats. As the organisms are on the surface, pathogenesis is unlikely to be secondary to direct cell damage. Some of the pathogenic mechanisms proposed for *Giardia* spp. infections include production of toxins, disruption of normal flora, induction of IBD, inhibition of normal enterocyte enzymatic function, blunting of microvilli, and dysmotility.[60] There are many subclinically infected dogs and cats, and so *Giardia* is not always an effective primary pathogen. It has proven difficult to induce clinical signs of diseases in otherwise normal experimentally infected animals. For example, in one study, administration of 10^5 cysts induced infection in only 17 of 26 kittens of which diarrhea was only detected in 1 kitten for 1 day.[61] There may be strains than vary in their pathogenicity or other host factors may play an important role in determining whether disease will develop. The presence of immunosuppressive diseases or coinfections may potentiate the development of clinical signs of disease as discussed for cryptosporidiosis.[43,62]

Clinical Findings

Many dogs and cats have subclinical infection. When clinical disease occurs, the diarrhea is soft to watery and frequently has adherent mucus. Chronic malabsorption occurs in some animals and weight loss may be readily detected. On physical examination the SI may be slightly thickened and the animal can appear unthrifty. There may also be physical examination findings of coexisting syndromes that may potentiate giardiasis.

Diagnosis

The primary diagnostic tests for *Giardia* spp. infections are examination of direct fecal smear, direct saline preparation, passive fecal flotation, centrifugal fecal flotation (zinc sulfate and sugar are used most frequently), fecal IFA, fecal antigen ELISA, and fecal PCR assay. These tests can be used alone or in combination.

The direct smear and direct saline preparations can be used in the clinic for the presence of trophozoites of *Giardia* spp. (small bowel diarrhea), *T. foetus* (large bowel diarrhea), and *Pentatrichomonas hominis* (large bowel diarrhea). For the direct saline preparation, a 2-mm × 2-mm × 2-mm quantity of fresh feces is mixed thoroughly with 1 drop of body temperature 0.9% NaCl or water. The surface of the feces or mucus coating the feces should be used as the trophozoites are most common in these areas. After application of a coverslip, the smear is evaluated for motile organisms by examining it under ×100 magnification. Culture (*T. foetus*), antigen testing (*Giardia*), or PCR (*T. foetus* or *Giardia*) can be used to distinguish between specific organisms if the morphology is unclear.

Fecal flotation with the zinc sulfate or the sugar centrifugation technique (specific gravity 1.18 to 1.20) is optimal for the demonstration of *Giardia* spp. cysts and is more sensitive for detection of *Giardia* spp. cysts than passive flotation (www.capcvet.org).[7,63] Although sensitivity is less than 100% when a single sample is evaluated, fecal flotation remains the primary *Giardia* diagnostic test because of the ability of these assays to identify many other potential coinfections. Cysts are shed intermittently and their presence does not correlate very well with clinical signs of disease. Combination of fecal flotation with wet mount examination in cases with diarrhea or with a fecal antigen assay will increase sensitivity. In addition, sensitivity of fecal flotation increases to greater than 90% if at least three stool specimens are examined within 5 days.

Multiple ELISAs for detection of *Giardia* antigens in feces are available. In experiments performed in my laboratory, one assay labeled for veterinary use (SNAP Giardia, IDEXX Laboratories, Portland, ME) detected *G. canis* and *G. felis*.[64] False-positive and false-negative rates are estimated to be approximately 2% to 5%. Although it is unknown why false-positive reactions occur, it is likely that other fecal antigens are nonspecifically binding to the reagents. False-negative results likely relate to the sensitivity cutoffs of the individual assays. In one study, combination of fecal flotation with one commercially available *Giardia* spp. antigen assay had a combined sensitivity of 97.8%.[50]

Fluorescein-labeled monoclonal antibodies that react with *Cryptosporidium* spp. oocysts and *Giardia* spp. cysts (Merifluor IFA, Meridian Biosciences, Cincinnati, OH) are available in most veterinary diagnostic laboratories. In limited studies, this assay appears to detect both *Giardia* spp. and *Cryptosporidium* spp. isolates from dogs and cats.[65-67] Compared to *Giardia* antigen assays, this assay has the advantage of detecting a common coinfection and as the feces are examined microscopically, false-positive reactions are uncommon as the organism morphology can be assessed. The primary disadvantages include the need for a fluorescence microscope and additional technician time when compared with *Giardia* antigen assays.

A number of genes have been assessed for the amplification of *Giardia* DNA by PCR.[68] Results for assemblage determination can vary based on the gene chosen and it is possible that some dog or cat isolates could be genotyped as "potentially zoonotic" by one gene but as "host specific with another."[30] In experiments in our laboratory, *Giardia* PCR fails to amplify DNA from approximately 20% of samples that are positive for *Giardia* cysts or antigens. At this time, PCR testing is only recommended for assessment of the *G. duodenalis* assemblage in cats and dogs, and the use of multilocus genotyping is recommended.[69] This service is available at the Veterinary Diagnostic Laboratory at Colorado State University (http://dlab.colostate.edu/).

Treatment

Use of many drugs for the treatment of canine or feline giardiasis was extrapolated from use in humans.[70] Because dog and cat *Giardia* spp. have been difficult to grow in culture, there are minimal data

Table 57-6 Drugs Used for the Treatment of *Giardia* Spp. Infections

Drug	Species	Dose
Metronidazole	B	15 to 25 mg/kg PO q12-24h for 5 to 7 days
Ronidazole	F	20 mg/kg, PO q12h for 14 days (primarily used for *T. foetus*; neurotoxicity common)
Tinidazole	C	44 mg/kg PO q24h for 3 days
Ipronidazole	C	126 mg/L of water PO ad libitum for 7 days
Fenbendazole	B	50 mg/kg PO daily for 3 to 5 days
	B	15 mg/kg PO q12h for 2 days (less commonly used because of bone marrow toxicity)
Pyrantel, praziquantel, febantel	C	Label dose for 3 days
	F	Feline dose: 56 mg/kg (based on the febantel component) PO daily for 5 days
Quinacrine	C	9 mg/kg PO q24h for 6 days
	F	11 mg/kg PO q24h for 12 days
Furazolidone	F	4 mg/kg PO q12h for 7 to 10 days

B, Canine and feline; C, canine; F, feline.

on antimicrobial sensitivities. It is likely that sensitivities vary amongst different isolates and it is currently impossible to predict which anti-*Giardia* drug will be effective in an individual case. Although there have been multiple drugs used for the treatment of giardiasis in dogs and cats, there are few studies that utilized dose titrations and evaluation of drugs in experimentally infected animals. In most studies, fecal samples were only assessed for short periods of time after treatment and neither was immune suppression induced nor necropsy performed to evaluate whether infection was eliminated or merely suppressed. Infection with *Giardia* does not appear to cause permanent immunity and so reinfection can occur, a finding that also hampers assessment of treatment studies.

The primary goal of *Giardia* treatment is to stop diarrhea. Because healthy pets are not considered significant health risks to immunocompetent people, elimination of infection (which is difficult) is a secondary goal. Treatment options currently available or used historically include metronidazole, tinidazole, ipronidazole, ronidazole, fenbendazole, albendazole, pyrantel/praziquantel/febantel, quinacrine, furazolidone, and nitazoxanide (Table 57-6).[70-83]

Care should be taken when using metronidazole or ronidazole as central nervous system (CNS) toxicity can occur.[84-86] Because albendazole is associated with bone marrow suppression, many clinicians use fenbendazole or febantel when that class of drugs is chosen.[87]

If clinical findings suggest concurrent *C. perfringens* overgrowth, use of metronidazole may be indicated as this drug is an antibiotic with activity against *Clostridium* spp. If there are clinical findings that suggest concurrent infection with a nematode, fenbendazole or febantel are indicated. Many clinicians currently use fenbendazole once daily for 3 to 5 days as initial therapy. Some clinicians currently recommend the combination of metronidazole and fenbendazole (www.capcvet.org). Others only resort to combination therapy if there is evidence of a persistent infection that is not cleared by monotherapy. If the first drug fails to control diarrhea and the organism is still detected in feces, a second drug from an alternate class is indicated. The addition of fiber to the diet may help control clinical signs of giardiasis in some animals by helping to suppress bacterial overgrowth or by inhibiting organismal attachment to intestinal microvilli. Immunotherapy with the *Giardia* vaccine has aided in eliminating cyst shedding and diarrhea in some infected dogs.[88] However, in a controlled study in 16 experimentally infected cats, vaccination as immunotherapy was ineffective with one strain of *Giardia*.[89] In addition, both commercial products have been discontinued. Probiotic administration has been promoted as potentially beneficial in the control of giardiasis. In one study, dogs treated with silymarin and metronidazole had superior clinical responses to dogs treated with metronidazole alone.[90] However, in another study, administration of a commercially available probiotic (FortaFlora, Nestle Purina PetCare, St. Louis, MO) did not affect the outcome of *Giardia* infection.[91] In one study, bathing the dog on the last day of treatment was a beneficial adjunct therapy.[77] In dogs and cats with persistent diarrhea and *Giardia* spp. infection, a more extensive workup to attempt to diagnose other underlying diseases is indicated if several therapeutic trials fail. Common underlying disorders include cryptosporidiosis, *T. foetus* in cats, IBD, bacterial overgrowth, exocrine pancreatic insufficiency, and immunodeficiencies.

Public Health Considerations

Healthy pets are not considered significant human health risks by the Centers for Disease Control (www.cdc.gov/hiv/pubs/brochure/oi_pets.htm) and there is no current recommendation to test healthy dogs or cats for *Giardia* spp. infection. However, some dogs and cats are infected with the zoonotic assemblages and the same assemblage has been detected in dogs and people in the same family.[92-95] All healthy dogs and cats should be screened for hookworm and roundworm infection once or twice yearly as previously discussed. Thus healthy dogs and cats that are harboring *Giardia* cysts will be detected. As some *Giardia* spp. may be zoonotic, treatment of healthy infected animals should be considered with each owner. Treatment of healthy animals is controversial because all of the drugs can potentially cause side effects, animals with normal stools are not considered human health risks, treatment is unlikely to eliminate infection, and reinfection can occur within days. For example, in a study of naturally infected dogs, approximately 15% of treated dogs were still *Giardia* infected when rechecked 9 or 16 days after treatment.[76] In another study, 50% of the healthy, *Giardia*-positive dogs had adverse reactions to fenbendazole or nitazoxanide and 62.5% of those that successfully completed therapy were positive for *Giardia* cyst or antigen on day 34.[64] It is unknown whether these infections were not eliminated or if the dogs were reinfected. If treatment is deemed appropriate by the clinician and pet owner, many clinicians currently recommend administration of a 5-day course of fenbendazole in apparently healthy dogs and cats that test positive for *Giardia*. The American Association of Feline Practitioners (AAFP) Advisory Panel on Zoonoses recommends attempting to remove the source of infection during the treatment period and performing a fecal centrifugal flotation after *Giardia* treatment one

time, within 2 to 4 weeks after the end of the treatment period (www.aafponline.org). If the animal is healthy and negative for cysts, retesting is not indicated again until the next scheduled fecal flotation. Currently it is not recommended that the IFA or fecal PCR assays be used as a recheck test for any of the *Giardia* antigen assays. It is currently unknown how long *Giardia* antigens will persist in feces after successful treatment.

Occasionally, animals will be *Giardia* cyst-negative but *Giardia* antigen-positive. These animals either have a low-grade infection or a low percentage of animals (approximately 2% to 5%) have false-positive antigen test results. To further evaluate for cyst shedding, the veterinarian can perform an IFA test or two additional fecal flotations (three negative centrifugal flotation assays run within 5 days is considered adequate to ruleout a *Giardia* infection in both animals and humans); if these other test results are negative, the antigen test was likely falsely positive.

Prevention

Prevention of giardiasis involves boiling or filtering of water collected from the environment prior to drinking and disinfection of premises contaminated with infected feces with steam cleaning or quaternary ammonium compounds (1 minute contact time). Paratenic hosts should be controlled and treatment and bathing of all animals in the environment should be considered. Feces from infected animals should be removed from the environment promptly. The previously licensed *Giardia* spp. vaccines for dogs and cats were classified by American Animal Hospital Association (AAHA) and AAFP as generally not recommended as preventatives. Both products have been discontinued by their manufacturers.

Prognosis

Most dogs and cats with clinical giardiasis ultimately will have clinical signs of disease resolve with treatment and so the prognosis in otherwise healthy animals is good.

Isospora Spp.

Etiology

Dogs are the definitive hosts for *Isospora canis*, *Isospora ohioensis*, *Isospora neorivolta, and Isospora burrowsi* and cats are the definitive hosts for *Isospora felis* and *Isospora rivolta*.[96] These protozoans are host specific, have worldwide distribution, and infections are very common, particularly in young animals. In one Austrian study, 8.7% of dogs younger than 2 years of age were infected; 78% of the positive samples were in puppies younger than 4 months of age.[97] In the United States, CAPC reports prevalence rates for *Isospora* spp. infection from 3% to greater than 30% (www.capcvet.org).

Pathophysiology

Infection by *Isospora* spp. in dogs or cats is initiated by ingestion of sporulated oocysts in the environment or by ingesting tissues of other infected vertebrate intermediate hosts.[96-98] Infection may also occur if dogs or cats ingests sporulated oocysts carried by paratenic hosts like flies, cockroaches, or dung beetles.[99] The enteroepithelial phase occurs in the SI of infected animals which culminates in the passage of unsporulated oocysts in feces. The prepatent and patent periods vary slightly by species. In one study of dogs experimentally infected with *I. canis*, the mean prepatent period was 9.8 days (range: 9 to 11 days, n = 22 dogs), the patent period was 8.9 days (range: 7 to 18 days, n = 20 dogs), and all of the puppies developed diarrhea, suggesting the organism can be a primary pathogen.[98] In contrast, the prepatent period for *I. ohioensis* in one study was 6 to 7 days and diarrhea was variable.[97] Numbers of oocysts shed in infected animals can vary dramatically.[97,98] Depending on the environmental conditions, sporulation can occur in as little as 12 hours. Clinical disease is most common in young, debilitated, and immunocompromised animals. All of the *Isospora* spp. replicate in the SI but the regions with the heaviest infection varies by the species. Microscopic lesions observed in some infected animals includes villus atrophy, dilation of lacteals, and hyperplasia of lymph nodes in Peyer patches.

Clinical Findings

Isospora spp. infections are generally only associated with disease in puppies and kittens. Clinically ill puppies and kittens can exhibit vomiting, abdominal discomfort, inappetence, and watery diarrhea that sometime contains blood. Depending on the age of the animal and the parasite burden, severe dehydration and death can occur. Puppies and kittens with subclinical infection can repeat shedding and clinical signs of disease during stressful periods.

Diagnosis

Isospora spp. oocysts are large, occur in large numbers, and are generally easy to identify on microscopic examination of feces after fecal flotation. However, normal animals also pass *Isospora* spp. oocysts and so positive test results do not always prove a disease association. False-negative fecal flotation results are uncommon in clinically infected animals but occasionally clinical signs precede oocyst shedding and a second fecal flotation may be needed to prove infection in some cases.

Treatment

Coccidiosis is generally self-limited and most healthy puppies and kittens will resolve clinically without therapy. However, administration of treatment can speed resolution of disease and may lessen environmental contamination and the potential for infecting other in contact animals. The only approved treatment for coccidiosis in the United States is sulfadimethoxine administered at a dose of 50 to 60 mg/kg daily for 5 to 20 days (dogs and cats). Other drug regimens have been used with some success, including trimethoprim-sulfa (30 to 60 mg/kg of trimethoprim daily for 6 days in animals weighing more than 4 kg or 15 to 30 mg/kg trimethoprim daily for 6 days in animals weighing less than 4 kg) and a variety of protocols using amprolium alone or in combination with sulfadimethoxine. However, ponazuril and toltrazuril are coccidioidal and therefore are superior for the treatment for coccidiosis.[100,101] Ponazuril has been used most frequently in the United States. The drug can be administered off label at 20 mg/kg PO twice, 1 to 7 days apart or at 50 mg/kg PO once. Many compounding pharmacies in the United States will appropriately formulate the drug by prescription.

Prognosis

Most *Isospora* spp.–infected puppies and kittens will survive infection making the prognosis good to excellent.

Prevention and Public Health Considerations

Isospora spp. oocysts are very resistant to environmental conditions and disinfectants. The key to control is to provide good sanitation including prompt removal of feces prior to oocyst sporulation. Steam cleaning can be used to destroy oocysts that contaminate surfaces. Treatment of dams and queens with anticoccidial agents prior to parturition can lessen the occurrence of coccidiosis in young animals. In environments with heavy infections, treatment of all in contact animals, particularly puppies and kittens, could be

considered. *Isospora* spp. of dogs and cats do not infect people. Ponazuril administered to all at-risk puppies and kittens on intake to shelters may aid in the control of coccidiosis.[101]

Other Protozoans

While *Sarcocystis* spp., *Besnoitia* spp., *Hammondia* spp., *Toxoplasma gondii*, and *Neospora caninum* complete the sexual phase of the life cycle in the intestinal tract of dogs or cats, this phase of replication is rarely linked to GI clinical signs of disease. Clinical illness associated with *T. gondii*, *N. caninum*, and *Sarcocystis neurona* generally results from the tissue phase of the infections. However, IBD was linked to *T. gondii* infection in two cats.[102]

Fungal, Oomycetes, and Algae Infection

The fungal, oomycetes, and algae infections may diffusely involve the whole GI tract, and are discussed in detail in "Infection of the Large Intestine" in Chapter 58.

Bacteria

A number of bacteria are associated with GI signs of disease and may colonize or infect the SI. *Campylobacter* spp., *Clostridium* spp., *E. coli*, and *Salmonella* spp. are discussed in this chapter. *Yersinia* spp., and other mixed enterocolitic infections are discussed in Chapter 58 The syndrome of small intestinal bacterial overgrowth (or dysbiosis) is discussed in another section of this chapter.

Campylobacter Spp.

Etiology

C. jejuni, *Campylobacter coli*, *C. upsaliensis*, and *Campylobacter helveticus* are commensal organisms found in the GI tract of healthy dogs and cats throughout the world.[103-105] The high prevalence of these organisms in healthy nondiarrheic dogs (*C. jejuni*, 49%; *C. coli*, 5%; *C. upsaliensis*, 19%) and cats (*C. jejuni*, 46%; *C. coli*, 1%; *C. upsaliensis*, 5%; *C. helveticus*, 22%) complicates diagnosis.[106-109] Under certain conditions, however, *Campylobacter* can induce significant GI tract pathology. Young age, immunoincompetence, concurrent GI infections, prior therapeutic interventions (e.g., antibiotics), and poor hygienic conditions appear to be the greatest risk factors for the development of infection.[110]

Pathophysiology

At some point, *Campylobacter* organisms become enteroinvasive and induce the host inflammatory response. *C. jejuni* localizes in mucus-filled crypts of the intestine and colon where it induces a superficial erosive enterocolitis.[110,111] Colonic epithelial glands undergo hyperplasia and thickening with exfoliation of the brush-border and goblet cells. The colonic epithelium becomes cuboidal, crypt height is reduced, and crypt abscess are present. Shallow crypts and blunt irregular villi are features of the ileum response to infection.

Clinical Examination

Clinical signs are watery diarrhea, often containing mucous and blood pigments, tenesmus, anorexia, fever, and vomiting.[111,112] Concurrent infections with *Salmonella*, *Giardia*, or parvovirus cause more severe disease.

Diagnosis

Direct examination of a fresh fecal sample is the method of diagnosis in many instances. Large numbers of curved, highly motile bacteria along with increased numbers of leukocytes is presumptive evidence of *Campylobacter* infection. With Gram staining, large numbers of faintly staining Gram-negative, slender, curved (gull-wing shaped) rods are evident. Fecal cultures or PCR are the most conclusive ways to determine the presence of *Campylobacter*.[106-108] *C. jejuni* is best cultured microaerophilically at 42°C (107.6°F) for 48 hours on special *Campylobacter* blood agar plates.

Treatment

Erythromycin is the treatment of choice, although tetracyclines, aminoglycosides, clindamycin, and quinolones are also effective. Posttreatment cultures should be performed to confirm eradication. Pet owners should be advised about the importance of proper hygiene.

Prognosis

The prognosis for recovery and cure are generally excellent unless an underlying immunosuppressive condition has increased the susceptibility to infection.

Clostridium Perfringens

Etiology

C. perfringens is a Gram-positive, spore-forming, obligate anaerobic rod-shaped bacterium that contributes to the microbial ecology and nutrition of the colon in healthy dogs and cats.[113] Under certain conditions, proliferation and sporulation of *C. perfringens* permits enterotoxin A (or CPE) production, which may then induce mucosal damage, fluid secretion, and large bowel-type diarrhea. Evidence for and against a role for *C. perfringens* in the pathogenesis of large bowel diarrhea has been put forward. Enterotoxigenic *C. perfringens* is associated with canine nosocomial diarrhea,[114] hemorrhagic enteritis,[103] and acute and chronic large bowel diarrhea.[115,116] On the other hand, many dogs harbor *C. perfringens* and CPE in the GI tract without developing clinical signs.[104,105,110] Until more definitive evidence is obtained, including the fulfillment of the Koch postulates, *C. perfringens* should probably be considered as a suspected pathogen in large bowel diarrhea.

Pathophysiology

The presumed pathogenicity of *C. perfringens* requires an anaerobic environment, sporulation, and enterotoxin production. There are problems with this hypothesis however; enterotoxin may be demonstrated in the feces without sporulation, and enterotoxin may be found in the feces of healthy dogs. *C. perfringens* isolates are classified as one of five toxigenic types (A to E) based on the production of one or more of four major (α, β, ε, ι) and seven minor (δ, θ, κ, λ, μ, ν, and sialidase) toxins.[117] Although all five types of *C. perfringens* are capable of producing CPE, the majority is produced by type A strains. As with enterotoxigenic *E. coli* (ETEC) strains, CPE is believed to induce crypt epithelial cell secretion.

Clinical Examination

C. perfringens–associated colitis is believed to be a major cause of acute, nosocomial, as well as chronic, large bowel diarrhea. Acute nosocomial diarrhea often begins within 1 to 5 days of boarding or kenneling. Affected dogs develop diarrhea, often with blood pigments, mucous, and tenesmus. These diarrheas are usually self-limiting and may resolve with supportive care alone. Chronic large bowel diarrheas associated with *C. perfringens* are similar to other large bowel-type diarrheas, that is, chronic, intermittent, and recurring signs of colitis.

Diagnosis

There is no gold standard for the diagnosis of *C. perfringens*–associated diarrhea. Ideally, the diagnosis would be made on the basis of positive test results with Gram staining, fecal culture, ELISA enterotoxin (CPE) assay, PCR enterotoxin (*cpe*) genotyping, and ruleout of other colonic diseases on colonoscopy and biopsy.[118-121] Compared to normal dogs (without diarrhea), diarrheic dogs are more often CPE ELISA- and *cpe* PCR-positive, but many normal dogs are positive on both assays.

Treatment

Recent in vitro antimicrobial susceptibility testing suggests that *C. perfringens* should be susceptible to ampicillin, erythromycin, metronidazole, and tylosin.[122] These antibiotics have also been used in vivo with good success. It should be emphasized that many of the same patients respond to supportive care, including intravenous fluids, intestinal protectants, and bland or fiber-supplemented diets.

Prognosis

Affected animals usually respond to appropriate therapy within a matter of days. The prognosis for recovery is excellent.

Clostridium Difficile

C. difficile is believed to share many ecological factors with *C. perfringens*,[123,124] but the role of this organism as a pathogen in dogs and cats has not been firmly established. Compared with normal dogs (without diarrhea), diarrheic dogs are more often toxin A ELISA-positive even though they may be *toxin A* PCR-negative.[121] As with *C. perfringens*, many healthy dogs and cats carry *C. difficile* without developing clinical signs. In one recent study it was difficult to experimentally infect dogs with this organism, and those that were infected did not develop clinical signs.[125] Antibiotic-associated diarrheas develop in dogs and cats but they may have a pathogenesis other than *C. difficile*.

Escherichia Coli

Etiology

Most strains of *E. coli* are true commensal organisms that are not associated with clinical signs. Strains of *E. coli* that cause diarrhea in animals can be grouped into five main categories: ETEC, enteroinvasive (EIEC), enteropathogenic (EPEC), enterohemorrhagic (EHEC), and enteroadherent (EAEC) organisms.[126] Identification of pathogenic strains requires modern molecular technology such as bioassays, DNA hybridization, and PCR amplification.

Pathophysiology

Infection may result in enteritis, colitis, or both.[127] ETEC strains adhere to the surface of epithelial cells and produce heat-labile and/or heat-stable toxins that induce crypt epithelial cell secretion. EIEC strains invade, replicate in, and destroy epithelial cells. EPEC strains are neither enterotoxigenic nor enteroinvasive, but they do attach to and efface the brush-border of the enterocytes. EHEC strains produce verocytotoxins that induce hemorrhagic ileitis and colitis. EAEC strains also induce enterocyte pathology, but their mechanism of action is poorly understood. ETEC, EPEC, and EHEC have all been isolated from dogs and cats with diarrhea. *E. coli* endotoxin colonic absorption of water and sodium and contributes to the diarrhea seen during and after episodes of sepsis.[128]

Clinical Examination

Affected animals typically have diarrhea and hematochezia with clinical signs relevant to the SI, colon, or both.

Diagnosis

E. coli can be grown from the feces of healthy dogs and cats, so a positive culture does not necessarily reveal the identity of an underlying pathogen. In addition to positive culture, diagnosis may require enterotoxin assays, and DNA hybridization and PCR amplification.[129-133]

Treatment

Antibiotics should be used only in those cases in which there is firm evidence of bacterial infection. Fluoroquinolones appear to be a very effective classification for the treatment of enteric *E. coli* infections.

Prognosis

The prognosis is generally good for recovery and cure if infection is recognized early in the clinical course.

Salmonella

Etiology

Salmonella spp. are predominantly motile, Gram-negative facultative anaerobic rod-shaped bacteria found in the feces of normal and diarrheic animals.[104,105] As with many other commensal organisms of the GI tract, the high prevalence of these organisms complicates diagnosis. From 1% to 30% of the fecal samples or rectal swabs taken from healthy domestic pet dogs, 16.7% of dogs boarded in kennels, and 21.5% of hospitalized dogs were found to be positive on bacteriologic culture for *Salmonella*. From 1% to 18% of healthy cats and 10.6% of random source research colony cats were also culture-positive for *Salmonella* (summarized in reference 122). Despite these findings, several species of *Salmonella* have been impugned in the pathogenesis of acute enterocolitis in dogs and cats. *Salmonella typhimurium* is the species most commonly isolated from diarrheic feces of dogs and cats, although other species have been identified.[134-136]

Pathophysiology

Those most at risk for *Salmonella* infection are young and immunoincompetent animals, those with concurrent GI infections (e.g., parvoviral or parasitic infections), and those animals who have had prior therapeutic interventions (e.g., antibiotics or glucocorticoids).[110] *Salmonella* is an enteroinvasive organism that induces an acute inflammatory response resulting in enterocolitis, mucosal sloughing, and secretory diarrhea. Most *Salmonella* infections are resolved via the local immune response, but bacterial translocation and septicemia may evolve into systemic inflammatory response and multiple organ dysfunction syndromes in some patients. Early recognition is important in preventing this sequela.

Clinical Examination

The main clinical signs of *Salmonella* enterocolitis are anorexia, lethargy, fever, vomiting, diarrhea with mucous and blood pigments, dehydration, abdominal pain, and tenesmus. With bacterial translocation and septicemia, affected animals may have evidence of pale mucous membranes, weakness, tachycardia, tachypnea, and vascular collapse.

Diagnosis

Culture, serotyping, and PCR are the best methods of diagnosing *Salmonella* infections.[134]

Treatment

Treatment varies according to the severity of the clinical signs. Mild, self-limiting forms of enterocolitis may in fact resolve with little more

than supportive therapy. Antibiotic therapy in such cases may prolong fecal shedding and encourage development of the carrier state. In animals with severe hemorrhagic diarrhea, history of immunosuppression, suspected or documented septicemia, and/or evidence of systemic inflammatory response syndrome, parenteral antibiotics should definitely be used. If culture results are unavailable, therapy should include enrofloxacin, amoxicillin, or trimethoprim-sulfa, all of which are effective against *Salmonella*. Posttreatment cultures should be performed to confirm eradication, and pet owners should be advised of the public health importance of the disease.

Prognosis

The prognosis for recovery in nonsepticemic patients is generally good, although some animals may remain chronic carriers with recrudescence during periods of stress or unrelated disease. The prognosis for the septicemic patient is more guarded.

Rickettsia

Neorickettsia Helminthoeca

Etiology

Neorickettsia helminthoeca is a gram-negative organism in the family Anaplasmataceae that induces a clinical syndrome called *salmon poisoning disease* in dogs.[137] The syndrome is currently recognized in the Pacific Northwest of the United States, British Columbia in Canada, and an area in southern Brazil.[137-140] A similar clinical syndrome in dogs was called *Elokomin fluke fever* in Washington but now appears likely to have been caused by a strain of *N. helminthoeca*.

Pathophysiology

Nanophyetus salmincola is the trematode vector of *N. helminthoeca* and requires three hosts for the completion of its lifecycle.[137] A river snail, *Oxytrema silicula*, is the first intermediate host and is infected by rediae and cercariae of *N. salmincola*. The snail releases free-living cercariae that penetrate the skin of salmon, lose their tails, and become metacercariae that develop in a number of tissues of the salmon with heavy concentrations in the kidneys, liver, heart, and tail. The life cycle is completed when the adult trematode develops in the intestine of mammals or birds that eat fish. The syndrome has also been induced in dogs that have been fed infected snails. *N. helminthoeca* survives through all stages of the trematode. The adult flukes develop deep within the intestinal tissues causing local edema and inflammation in 5 to 6 days. The fluke releases *N. helminthoeca*, which infects intestinal histiocytes and disseminates in blood and lymph to lymphoid tissues. Mesenteric lymph nodes enlarge greatly from edema and an influx of inflammatory cells. Diarrhea results from the inflammation of intestinal lymphoid tissues and can be hemorrhagic. The typical incubation period is 5 to 7 days.

Clinical Examination

Clinical signs of disease in dogs starts with fever, anorexia, and vomiting. Affected dogs can also develop periocular swelling, ocular discharge and nasal discharge which have been confused with canine distemper virus infection. Local and generalized lymphadenopathy can be detected in most cases when clinical signs are first recognized. Diarrhea is generally small bowel-type in character, but can become bloody and be confused with canine parvovirus infection. Rapid, marked weight loss, and extreme polydipsia have been reported in some dogs and death is common.

Diagnosis

History, clinical signs, detection of *N. salmincola* eggs after microscopic examination of feces after fecal sedimentation, and response to therapy can be used to make a presumptive diagnosis. Clinical pathology abnormalities can include thrombocytopenia, lymphopenia, eosinophilia, increased alkaline phosphatase activity, and marked hypoalbuminemia.[137] Cytologic examination of enlarged lymph nodes after staining with Giemsa can reveal intracytoplasmic neorickettsial bodies within reticuloendothelial cells and lead to a definitive diagnosis. Current infection can be documented by demonstrating rising antibody titers, culture, immunohistochemical staining of tissues, or PCR assay.[137]

Treatment

Supportive care for dehydration is key to the management of dogs with salmon poisoning disease. *N. helminthoeca* is susceptible to tetracycline, doxycycline, and oxytetracycline. Parenteral treatment is indicated in dogs with concurrent vomiting. *N. salmincola* is susceptible to praziquantel.[141]

Prognosis

Without treatment, up to 90% of clinically affected dogs die within 6 to 10 days of developing clinical signs. Permanent immunity occurs in dogs that survive infection.

Prevention and Public Health Considerations

Dogs should not be allowed to feed on raw, uncooked, or smoked salmon in endemic areas. Freezing fish at −20°C (−4°F) for at least 24 hours or thoroughly cooking the tissues kills both the fluke and *N. helminthoeca*. *N. salmincola* infection can result in GI disease in people,[142] but it is unclear whether *N. helminthoeca* is pathogenic in people.[137]

Viral

Canine Enteric Coronavirus

Etiology

Canine enteric coronavirus (CCV) is a single-stranded enveloped RNA virus that replicates in the cytoplasm of small intestinal epithelial cells.[143] There are several genetic variants that occur in different parts of the world and prevalence varies by genotype and country.[144-148] CCV RNA has been amplified from the feces of more than 40% of dogs with gastroenteritis in some countries,[145] but CCV RNA can also be amplified from the feces of normal dogs. Canine respiratory coronavirus is genetically distinct from canine enteric coronavirus.[149]

Pathophysiology

CCV is transmitted by fecal–oral route via a contaminated environment and is highly contagious especially in neonatal puppies. Older dogs can be infected but seem to be less likely to develop clinical signs of disease. The inoculation period is approximately 1 to 4 days. CCV replicates intracellularly in the intestinal microvilli which become short and blunted. Necrosis and hemorrhage are rare in contrast to canine parvovirus infections. There are CCV variants that are more pathogenic than others and disease appears to be unusual in puppies greater than 6 weeks of age in the United States.[150,151] Co-infection with other infectious agents like canine parvovirus was thought to potentiate CCV-associated illness in some studies.[152]

Clinical Examination

Susceptibility to CCV associated gastroenteritis does appear to be overrepresented in any individual breed or sex. The primary clinical sign is small bowel–type diarrhea that may be preceded by vomiting. Secondary findings include fever, lethargy, anorexia, dehydration, and death in some affected puppies.

Diagnosis

Amplification of CCV RNA from feces by RT-PCR assay is currently the most frequently used diagnostic procedure in the United States. However, as normal dogs can be positive for CCV RNA, the positive predictive value of these assays is less than 100%.[148] Depending on the timing of tested, assay results can be falsely negative.

Treatment

Fluid therapy and other supportive care is used for the treatment of CCV-associated GI disease in puppies.

Prognosis

With appropriate supportive care, the prognosis for puppies with CCV infection is generally good.

Prevention and Public Health Considerations

CCV is rapidly inactivated by many detergents and disinfectants. Multiple CCV-containing vaccines are available in the United States. However, as clinical illness is usually only detected in very young dogs in this country, the AAHA Vaccine Panel does not generally recommend this vaccine antigen.[153] There are no proven human health risks with CCV.

Feline Coronaviruses

Etiology

Feline enteric coronavirus (FECV) and feline infectious peritonitis virus (FIPV) infections can cause GI disease in some cats.[154,155] Although enteric infection generally results in mild GI signs, systemic infection can induce a clinical syndrome with diverse manifestations commonly referred to as FIP.[155] There are multiple field strains of FECV and FIPV with varying degrees of virulence. FIPV capable of inducing FIP develop in the GI tract of some infected cats as mutations or recombinant strains of endemic FECV. FECV are commonly shed in feces, rarely in saliva, and are very contagious but minimally pathogenic.[156]

Pathophysiology

Coronaviruses can be detected in feces by use of RT-PCR as early as 3 days postinfection.[156] In studies of FECV-infected, closed cat colonies, almost every cat becomes infected, with some cats shedding continuously. Viral RNA has been detected in the ileum, colon, and rectum of cats with persistent shedding. FIPV-infected monocytes can disseminate throughout the body, potentially resulting in FIP, which has diverse manifestations related to the development of vasculitis or pyogranulomatous disease of multiple organs.[155] GI disease associated with FIP can result from focal obstruction.[157]

Clinical Examination

Enteric replication of feline coronaviruses commonly results in fever, vomiting, and mucoid diarrhea. GI disease from FECV is most common in kittens and is generally self-limiting or responsive to supportive care within days. Fever and weight loss are common with both the effusive and noneffusive forms of FIP, and small bowel diarrhea can occur chronically in some cats. A solitary ileocecocolic or colonic mass resulting in obstruction with vomiting and diarrhea occurs in some cats.[157] The other polysystemic manifestations of FIP are reviewed elsewhere.[154,155]

Diagnosis

There are no specific clinical or routine laboratory findings leading to a definitive diagnosis of FECV- or FIPV-associated GI tract disease. Because virus isolation and electron microscopy are not practical clinically, RT-PCR is used most frequently to amplify coronavirus RNA in feces. However, positive test results do not prove that diarrhea is caused by a coronavirus as normal cats can also be positive. Definitive diagnosis of FIP-associated GI obstruction is based on detection of characteristic histopathologic findings, virus isolation, demonstration of the virus in tissue by use of immunocytochemical or immunohistochemical staining, or by RT-PCR demonstration of viral RNA in tissues.

Therapy

FECV-associated GI signs of disease are treated with supportive care and are generally self-limiting. GI obstruction from focal FIP is generally treated surgically.

Prognosis

Most kittens with FECV-associated GI disease respond rapidly to therapy. Cats with focal GI obstruction from FIP may progress to systemic disease, which has a grave prognosis.

Prevention and Public Health Considerations

Prevention of coronavirus infection is best accomplished by avoiding viral exposure. Although viral particles of FECV and FIPV can survive in dried secretions for up to 7 weeks, routine disinfectants inactivate the virus. An intranasally administered, mutant strain of coronavirus that induces mucosal immune response but minimal systemic immune response is available (Primucell FIP, Pfizer Animal Health, Exton, PA). Whether the vaccine protects against FECV or all field strains, mutations, or recombinants of FIPV is unknown. It is unlikely the vaccine is effective in cats that have previously been infected by a coronavirus and is considered generally not recommended by the AAFP.[158] There is no known zoonotic transfer of FIP coronavirus or enteric coronavirus to humans.

Canine Distemper Virus

Etiology

Canine distemper virus (CDV) induces disease predominantly in terrestrial carnivores, but many other species, including seals, ferrets, skunks, badgers, porpoises, and exotic Felidae, have been infected by either CDV or related viruses.[154,159]

Pathophysiology

CDV replicates in lymphoid, nervous, and epithelial tissues and is shed in respiratory exudates, feces, saliva, urine, and conjunctival exudates for up to 90 days after natural infection. Replication in small intestinal epithelial cells results in the GI signs seen in acute CDV infection. Clinical signs of disease generally develop approximately 8 to 9 days after infection, with the severity of illness dependent on the strain of CDV and the immune status of the host when primary infection occurs.[154,155] If poor immune response exists, massive replication of the virus in the epithelial cells of the respiratory tract, GI system, and genitourinary system usually results in death from polysystemic disease. Dogs with moderate immune responses by days 9 to 14 postinfection, usually only have mild

respiratory or GI clinical signs related to replication in epithelial tissues. Dogs with good cell-mediated responses and virus-neutralizing antibody titers by day 14 postinfection clear the virus from most tissues and may not be clinically affected. Most infected dogs develop CNS infection, but clinical signs of CNS disease occur only in dogs with low or no antibody response.

Clinical Examination

Many clinically affected dogs are unvaccinated, inappropriately vaccinated, failed to receive colostrum from an immune bitch, or are otherwise immunosuppressed. Dogs with vomiting or small bowel–type diarrhea from CDV infection generally also have evidence of depression, malaise, oculonasal discharge, or cough. CNS signs may or may not be present. Tonsillar enlargement, fever, and mucopurulent ocular discharge are common physical examination findings. Increased bronchial sounds, crackles, and wheezes are usually auscultated in dogs with bronchopneumonia. When CNS disease occurs, it is usually characterized by hyperesthesia, seizures, cerebellar or vestibular disease, paresis, and chorea myoclonus that generally develop within 21 days of recovery from systemic disease. Ocular abnormalities associated with CDV infection include anterior uveitis, optic neuritis with resultant blindness and dilated pupils, keratoconjunctivitis sicca, and retinochoroiditis (medallion lesions).

Diagnosis

Lymphopenia and mild thrombocytopenia are consistent hematologic abnormalities in dogs with GI signs of CDV infection. Interstitial and alveolar pulmonary infiltrates are common radiographic findings in dogs with concurrent respiratory disease. Documentation of a fourfold increase in the CDV serum IgG titer over a 2- to 3-week period or detection of IgM antibodies in serum is consistent with recent infection or recent vaccination, but does not prove clinical disease. Definitive diagnosis of CDV infection requires demonstration of viral inclusions by cytologic examination, direct fluorescent antibody staining of cytologic or histopathologic specimens, histopathologic evaluation, virus isolation, or RT-PCR documentation of CDV RNA in peripheral blood, cerebrospinal fluid, urine, or conjunctival scrapings.[154,159-163] Viral inclusions can rarely be found in erythrocytes, leukocytes, and leukocyte precursors of infected dogs. Inclusions are generally present for only 2 to 9 days following infection and therefore often are not present when clinical signs occur. Recent administration of modified live CDV-containing vaccines can lead to positive results in direct fluorescent antibody assays and RT-PCR assays, making the positive predictive value of these tests less than 100% in recently vaccinated puppies. False-positive results have been detected occasionally in direct fluorescent antibody assays performed on conjunctival cells from specific pathogen-free puppies and results of these tests should be interpreted cautiously.[162]

Treatment

Therapy for the GI signs of CDV infection is nonspecific and supportive. Secondary bacterial infections of the GI tract are common and, if indicated, should be treated appropriately.

Prognosis

The prognosis for dogs with GI signs of CDV infection is generally good. However, in dogs with poor immune responses during primary infection, signs of CNS disease may develop several weeks after resolution of the GI tract signs. The prognosis for dogs with CNS disease resulting from CDV infection is poor.

Prevention and Public Health Considerations

CDV survives in exudates only for hours at room temperature and is susceptible to most routine hospital disinfectants. Dogs with GI or respiratory signs of disease should be housed in isolation so as to avoid aerosolization to susceptible populations and care should be taken to avoid transmission by contaminated fomites. Multiple effective CDV vaccines are available and when administered appropriately to immunocompetent puppies, can result in a sterilizing immunity that persists for years.[153,164] There is no proven public health risk associated with CDV.

Canine Parvoviruses

Etiology

Canine parvoviruses (CPVs) are nonenveloped DNA viruses that replicate in rapidly dividing cells.[143] These viruses emerged in the late 1970s, arose from the feline panleukopenia virus, and now have worldwide distribution. Currently, CPV-2b and CPV-2c are the predominant genotypes in most countries studied, including the United States.[165-168]

Pathophysiology

After a susceptible dog has oronasal exposure to secretions containing a CPV-2 virus, the organism infects lymphoid tissue and induces viremia for 1 to 5 days. CPV-2 preferentially infects rapidly dividing cells of multiple tissues, including the crypt epithelial cells of the intestine. Villus blunting, decreased absorption, inflammation, and necrosis are responsible for the classic signs of vomiting and diarrhea, the latter of which frequently contains blood. The severe inflammation and necrosis allow translocation of enteric flora that is commonly associated with sepsis. CPV-2 are shed for approximately 3 to 14 days after infection and shedding can begin prior to clinical signs. CPV-2 are environmentally resistant.

Clinical Examination

Dogs with partial or sterilizing immunity to CPV-2 frequently develop subclinical infection. Clinical signs are most likely to develop in puppies younger than 12 weeks of age that have no prior immunity. Inappetence is often the first clinical manifestation and most clinically affected puppies develop foul-smelling bloody diarrhea. Concurrent problems frequently include vomiting, leukopenia, fever, and secondary bacteremia, sepsis, and disseminated intravascular coagulation. Other clinical findings associated with CNS or cardiac inflammation may occur in some puppies.

Diagnosis

Presence of characteristic clinical and laboratory findings frequently lead to a presumptive diagnosis of CPV-2–associated disease. Infection can be documented by demonstrating the viruses in feces by electron microscopy, virus isolation, fecal antigen tests, or PCR assay of feces or blood.[143,169,170] Fecal antigen assays and PCR assays are used most frequently in clinical practice. Recent administration of modified live vaccines containing CPV-2 can lead to transient positive results in both types of assays.[169] Severe necrosis can lead to false-negative results in fecal antigen tests. Whether this occurs with PCR assay results has not been proven. It was recently shown that one currently available fecal antigen ELISA detects both CPV-2b and CPV-2c.[170]

Treatment

Clinical disease for CPV-2 infection is primarily supportive with administration of replacement fluids and electrolytes being paramount. Antiemetics are often indicated and antibiotics with a

Gram-negative and anaerobic spectrum are usually administered to puppies with clinical evidence of bacteremia or sepsis. Other therapies, like interferons, passive immunotherapy, colony-stimulating factors, and oseltamivir, are administered by some clinicians and in some small studies with inconclusive results.[171,172] Other GI supportive therapies, like bland diets and probiotics, are often prescribed during the recovery period.

Prognosis

The prognosis with CPV-2–associated GI disease can be poor. However, with rapid and appropriate supportive care many puppies will survive.

Prevention and Public Health Considerations

Avoiding exposure to CPV-2 is the best form of prevention until puppies have been fully vaccinated. However, the organisms are ubiquitous in areas frequented by dogs and exposure is common. Inactivated and attenuated live CPV-2 containing vaccines are available and appropriate vaccination results in sterilizing immunity in normal dogs and may be persistent for life. The AAHA supports the use of attenuated live, high-antigen mass vaccines in most situations.[153] There has been concern that the CPV-2b–containing vaccines do not cross protect against the more newly emergent CPV-2c.[173] However, recent studies show that cross protection induced by CPV-2b–containing vaccines is likely.[174,175] To date, there is no evidence of zoonotic transmission of CPVs to humans.

Feline Panleukopenia Virus

Etiology

Feline panleukopenia virus (FPV) is a nonenveloped DNA virus with worldwide distribution that potentially induces severe clinical signs of GI disease in susceptible cats.[176] Recently, it was shown that cats also can be infected with CPV-2b and CPV-2c.[177,178] Although many veterinarians in developed countries rarely diagnose FPV infection in client-owned cats, infection is still widespread in feral cats. In one study 33% of feral cats that presumably had not been vaccinated had FPV antibody titers.[179]

Pathophysiology

Previously exposed or vaccinated cats generally limit FPV replication and remain clinically normal. After a susceptible cat has oronasal exposure to secretions containing FPV, viremia occurs with an incubation period of approximately 2 to 7 days prior to development of clinical signs of disease. As for CPV in dogs, FPV invades and destroys actively dividing cells including those of the bone marrow, lymphoid tissues, intestinal epithelium, cerebellum of young animals, retina, embryonic, and fetal cells. In the GI tract, the resultant cellular destruction results in dilated intestinal crypts, degeneration of villi, edema, and necrosis, which are responsible for the clinical signs of disease. High numbers of viral particles are shed during the acute phase of infection and may be detected in feces for weeks following clinical recovery. FPV can survive for longer than a year in a suitable external environment.

Clinical Examination

The primary clinical signs of FPV infection include fever, depression, anorexia, vomiting, diarrhea, and acute death. Some cats with FPV have vomiting without diarrhea. On physical examination, dehydration, abdominal discomfort, thickened SI, and enlarged mesenteric lymph nodes may be detected. Less information is available concerning clinical signs in cats infected with CPVs, but these infections seem to be less severe than FPV infections.

Diagnosis

Presence of appropriate clinical signs and the presence of panleukopenia in a kitten that is FeLV antigen-negative strongly suggests FPV infection. As with dogs, feline parvovirus infections can be documented by demonstrating the agents in feces by electron microscopy, virus isolation, fecal antigen tests, or PCR assay of feces or blood.[176,180-182] Antigen assays developed for CPV-2 also detect FPV.[180,181] Recent administration of modified live vaccines containing FPV can give transient positive results in both canine antigen assays and parvovirus PCR assays so vaccination history should be considered in the interpretation of parvovirus test results in cats.[181,182]

Treatment

Clinical illness from parvovirus infections in cats is primarily supportive with administration of replacement fluids and electrolytes. Antiemetics are often used for persistent vomiting and antibiotic therapy for secondary bacteremia or sepsis may be indicated. Other therapies, like interferons, passive immunotherapy, and antiviral drugs, have been attempted by some but controlled data supporting use of these treatments is not available. GI supportive therapies like bland diets and probiotics are often prescribed during the recovery period.

Prognosis

Mortality rates for FPV infection in susceptible kittens can be very high even with administration of appropriate supportive care.[176] Clinical illness associated with CPV-2 infections in cats appears to be less severe and may have a better prognosis.

Prevention and Public Health Considerations

Immunization with FPV-containing inactivated or attenuated live vaccinations provides long-lasting sterilizing immunity. It is possible that some FPV-containing vaccines induce protection against canine parvovirus strains that may result in clinical illness.[183] The AAFP recommends use of attenuated live vaccines in high-risk kittens in an attempt to rapidly induce primary immune responses in the presence of potential maternal immunity.[158] There are no proven public health risk associated with parvovirus infections of cats.

Other Viruses

There are other viral infections of dogs and cats that may occasionally result in GI signs of disease in dogs or cats. For example, rotaviruses (dogs and cats), reoviruses (cats), and astroviruses (dogs and cats) have been detected in the feces of some animals with diarrhea.[143,184] FeLV infection is associated with a panleukopenia-like syndrome.[185] Both FeLV and feline immunodeficiency virus infections are associated with intestinal lymphoma and both organisms can induce immune deficiency during the late stages of infection, which can promote GI disease induced by opportunistic infections. Lastly, feline immunodeficiency virus infection can induce a distinct enteropathy that is associated with diarrhea.[154]

BACTERIAL OVERGROWTH (INTESTINAL DYSBIOSIS)

Alexander J. German

Bacterial Flora

The normal small intestinal flora is a diverse mixture of aerobic, anaerobic, and facultative anaerobic bacteria, full details of which

are covered in Chapter 2. The size of the bacterial microflora increases from the duodenum to the colon, and is regulated by various factors, including intestinal motility, substrate availability, cidal/bacteriostatic secretions (e.g., gastric, biliary, and pancreatic), and the presence of a functional ileocolic sphincter. Disruption of any of these factors may lead to qualitative or quantitative bacterial flora abnormalities.

There is much debate about what constitutes a normal bacterial population in dogs and cats. When luminal contents are sampled and conventional bacterial culture techniques are used, common species include *Staphylococcus* sp., *Streptococcus* sp., Enterobacteriaceae, *E. coli*, *Clostridium* sp., and *Bacteroides* sp., with a greater proportion of obligate anaerobic bacteria being reported in cats than in dogs. However, greater diversity can be seen when mucosal populations are assessed in addition to luminal contents.[1] Recent studies employing newer techniques (e.g., sequencing of the 16S rRNA gene, fluorescence in-situ hybridization), demonstrate that conventional techniques underestimate the true complexity of the bacterial flora because a significant number of bacterial species do not grow.[2,3] By conventional techniques, the total upper small intestinal bacterial counts of healthy cats range from 10^2 to 10^8 colony-forming units (CFU)/mL, and are higher than those reported in humans ($<10^{3-5}$ CFU/mL).[4] However, there is no clear consensus as to what constitutes a "normal" SI population in healthy dogs, and some studies suggest that healthy dogs can harbor up to 10^9 CFU/mL bacteria in the proximal SI.[5,6] Therefore, when using conventional culture techniques, the "cutoff" for normal flora in dogs and cats cannot be extrapolated from humans. Furthermore, clinicians must realize that numbers are likely to be greater, when taking into account the species that cannot be cultured by conventional means. The SI flora is relatively resistant to dietary changes; studies using different diets, or the addition of fructooligosaccharides to the diet have failed to demonstrate significant effects on the number or type of bacteria in the proximal SI of dogs and cat,[7,8] although some effects have been demonstrated on the colonic flora in cats.[9]

The resident bacterial flora is an integral part of the healthy SI; organisms are broadly divided into those with health positive effects, those that are health neutral, and, finally, those species that may have health-negative effects (Table 57-7; Figure 57-19). Beneficial effects include inhibition of the growth of bacterial pathogens (by producing antimicrobial factors, occupying receptor sites, and competing for nutrients), facilitating digestion and absorption of various nutrients, synthesizing vitamins, and stimulating immune function.[10] Health-negative effects include intestinal putrefaction, production of carcinogens, hepatic damage, and clinical signs such as diarrhea and constipation. In addition, studies implicate the intestinal flora in the development of obesity in humans.[11] Finally, loss of immunologic tolerance to the normal bacterial flora has been implicated in the development of chronic intestinal inflammation, abnormal intestinal function, and perhaps even neoplasia. An inability to tolerate a normal bacterial flora may explain the antibiotic-responsive enteropathy in German Shepherd dogs.[12]

Table 57-7 Comparison of Enteric Flora and Effects on Health in Various Species

	Humans	Dogs	Cats
Health positive	Bifidobacteria Lactobacilli	Bifidobacteria Lactobacilli	Lactobacilli
Health neutral	Enterococci *E. coli* Streptococci Bacteroides	Enterococci Eubacteria Streptococci Fusobacteria Bacteroides	Corynebacteria Enterobacteria Streptococci Clostridia Lc –ve Bacteroides
Health negative	*Pseudomonas aeruginosa* *Proteus* sp. Staphylococci Clostridia *Veillonella*	Clostridia	Clostridia Lc +ve

LC +ve: expresses the zinc-dependent proteolytic light chain (LC) portion of the clostridial enterotoxin. LC -ve: does not express the zinc-dependent proteolytic light chain (LC) portion of the clostridial enterotoxin.

Clinical Syndromes

Small Intestinal Bacterial Overgrowth (Or Intestinal Dysbiosis)

Genuine bacterial overgrowth is defined by an increase in the absolute number of bacteria in the upper SI during the fasting state (i.e., the number of "colony-forming units" cultured per milliliter of duodenal juice [CFU/mL]). In humans, SIBO arises secondary to a number of underlying disorders that interfere with the control mechanisms (as described previously). Although the existence of this condition in humans is not disputed, its existence in canine patients has been a subject of much controversy. By conventional methods of microbial culture in humans, SIBO is diagnosed when upper small intestinal bacterial numbers exceed 10^5 or 10^4 CFU/mL of intestinal juice for total bacteria and obligate anaerobes, respectively. Although these values were initially adopted for dogs, a number of studies suggest a larger microbial population (e.g., 10^7 CFU/mL or greater) in asymptomatic dogs.[6] Small intestinal bacterial numbers are also greater in cats. Therefore the current diagnostic criteria for SIBO in companion animals are inappropriate, and may lead to misdiagnosis in many cases. Nonetheless, a genuine bacterial overgrowth may exist in conditions equivalent to those in humans, and it is appropriate to use the term SIBO in such circumstances.

Box 57-5 Diseases Causing Secondary Small Intestinal Bacterial Overgrowth (Intestinal Dysbiosis)

Decreased gastric acid production (achlorhydria)
- Spontaneous (e.g., atrophic gastritis)
- Iatrogenic (e.g., acid-blocking drugs, surgical resection)

Increased small intestinal substrates
- Exocrine pancreatic insufficiency
- Malabsorptive disorders?

Partial obstructive disorders
- Chronic intussusceptions
- Stricture
- Neoplasia

Anatomic disorders
- Surgical resection of ileocolic valve
- Blind loop ("self-filling type")

Motility disorders
- Primary/idiopathic
- Secondary

Hypothyroidism
Electrolyte disorders
Intestinal surgery
Sepsis
Peritonitis

Potential associations have been reported for SIBO (Box 57-5). In all such conditions it is logical to assume that a genuine increase in bacterial numbers occurs, although few studies have documented its magnitude or whether the overgrowth is actually responsible for the clinical signs. Furthermore, although diagnostic investigations may identify the presence of secondary SIBO, in practice it is better to concentrate the diagnostic effort on identifying the underlying process. As in humans, therefore, canine SIBO is best viewed as a clinical sign or pathogenetic mechanism rather than a diagnosis in its own right. The consequences of a secondary SIBO include interference with absorption of nutrients (including cobalamin and possibly taurine) and fluid, because of microvillar enzyme dysfunction, altered mucosal permeability, deconjugation of bile acids, and stimulation of colonocyte secretion.[13,14]

Idiopathic Antibiotic-Responsive Diarrhea

Historically, the term *idiopathic SIBO* was used to describe an antibiotic-responsive condition of large-breed (especially German Shepherd) dogs,[13] in which no underlying cause could be recognized. In fact the most consistent sign, as suggested by the name, is a predictable response to and remission with antibacterial therapy. Given that recent studies question whether a genuine increase in bacterial numbers occurs, these cases have been renamed idiopathic antibiotic-responsive diarrhea (ARD).[12] Although cats might feasibly suffer from secondary SIBO, an idiopathic antibiotic-responsive condition similar to that in German Shepherd dogs has not been documented in this species.[15]

Most cases of idiopathic ARD have been seen in young German Shepherd dogs, although other breeds may be affected. There may also be similarities with the recently reported "tylosin-responsive diarrhea" (see later).[16] Recent hypotheses on pathogenesis suggest that host–bacterial interactions may be important. In this respect, ARD may develop secondary to defects in the mucosal barrier, aberrant mucosal immune responses, qualitative changes in the enteric bacterial flora, or a triangulation of these mechanisms. Defects in the mucosal barrier are supported by studies documenting abnormal permeability and the presence of brush-border enzyme defects.[13,14] A further extension of the hypothesis of defective mucosal barrier is the suggested association with IgA deficiency or dysregulation.[17] Some, but not all, reports suggest that German Shepherd dogs with intestinal disease may have defective small intestinal IgA production, although mucosal IgA^+ plasma cell numbers in affected dogs are either normal or increased.[18] However, IgA deficiency has not consistently been identified in German Shepherd dogs,[19,20] and the pathogenesis may be more complex. Recent studies suggest differences in relative expression of allelic variants of the IgA heavy gene in various dog breeds including German Shepherd dogs.[21,22] However, there is no clear association between the different allelic variants and the manifestation of GI disease.[23]

A further suggestion is that ARD arises secondary to a loss of tolerance toward endogenous bacterial antigen. Indirect evidence for this hypothesis comes from the findings that dogs with ARD have increased lamina propria $CD4^+$ T cells and increased expression of certain cytokines.[18,24] Such a hypothesis is supported by the fact that antibacterial agents lead to resolution of clinical signs, and decreased cytokine expression, but not a decline in bacterial numbers.[24] That the most effective antibacterials are those with immune-modulating properties (e.g., oxytetracycline, metronidazole, tylosin) may support this hypothesis. A final possibility is that the condition arises from defective acquired immune responses to an occult infectious agent (e.g., enteropathogenic *E. coli* or *Clostridium* species). Therefore the predisposition of German Shepherd dogs to this syndrome could be explained by genetic susceptibility to infection as a result of major histocompatibility complex class II antigen expression. In this respect, there could be similarities in pathogenesis with histiocytic ulcerative colitis in Boxer dogs.[25]

At the current time, there are many suggestions as to the pathogenesis of idiopathic ARD. Unfortunately, there is currently no direct evidence to support any particular hypothesis and further work is required.

Tylosin-Responsive Diarrhea

A condition has been described in dogs from Finland that has many similarities with idiopathic ARD.[16] Detailed investigations suggest that no underlying cause for signs could be determined; furthermore, bacterial numbers were normal, there were no characteristic changes on folate or cobalamin assay, and serum unconjugated bile acid concentrations were unhelpful. In addition, there was complete resolution of signs while on tylosin and, in many cases, relapse occurred upon discontinuation of therapy. The main difference from the classical description of idiopathic ARD was that a range of ages of dog was represented, and a mixed-pattern diarrhea noted. However, its true idiopathic nature was not demonstrated, as detailed diagnostics were lacking in many cases. Despite this limitation, the similarities with idiopathic ARD are striking; although the authors of the paper favored the term *tylosin-responsive diarrhea*, the likelihood is that this is a form of idiopathic ARD.

Clinical Findings

The most common signs for secondary SIBO and idiopathic ARD are chronic small intestinal diarrhea and weight loss or failure to thrive. Other signs include vomiting, appetite alterations (anorexia, polyphagia, scavenging, and coprophagia), excessive borborygmi, and abdominal discomfort. In addition, signs of large bowel diarrhea are sometimes noted. Signs are similar for tylosin-responsive diarrhea aside from the fact that a mixed-pattern diarrhea is seen.[16]

A thorough history is important, as this may demonstrate an underlying cause (e.g., previous GI surgery) in cases of secondary SIBO. If a partial obstruction is the cause of a secondary SIBO, the history often involves relapsing small intestinal diarrhea, weight loss, and a favorable response to antibacterial therapy; the intermittent clinical signs in such cases are thought to be the result of the recurrent diarrhea temporarily flushing out the overgrowth. For cases of idiopathic ARD, deterioration on glucocorticoid therapy may sometimes be noted in the history. Abdominal palpation may demonstrate a structural cause of secondary SIBO, for example, partial intestinal obstruction, although it is unremarkable in cases of idiopathic ARD.

Diagnosis

Secondary SIBO can be detected by a number of tests, but it is essential to detect the underlying cause. A complete investigation is recommended, for example, routine hematology, serum biochemical analysis, urinalysis, fecal bacteriology and parasitology, diagnostic imaging, and gastroduodenoscopy. EPI can be diagnosed by measuring serum TLI concentration, partial obstructions can be detected with diagnostic imaging, and an enteric pathogen might be detected on fecal analysis. However, findings are usually unremarkable or nonspecific in cases with idiopathic ARD. At this stage, a treatment trial with antibacterial agents (see Chapter 39) should be contemplated, because *response to empirical therapy* is currently the best means of diagnosing idiopathic ARD. True idiopathic ARD can be diagnosed if the following criteria are established:

- No other etiologic cause is identified with detailed preliminary testing and/or histopathologic assessment of small intestinal biopsies.
- There is a positive response to an antibiotic trial (e.g., resolution of clinical signs including weight gain).
- Relapse of clinical signs occurs upon withdrawal of treatment, and remission is achieved when antibiotic therapy is recommenced.

However, although response to antibacterials is critical for the diagnosis, a thorough diagnostic evaluation should ideally be performed to make certain that other reasons for a response to antibacterials (especially the causes of SIBO) have first been eliminated. Given current concerns over the development of antibiotic resistance by various bacterial flora, indiscriminate use of antibiotics in dogs and cats with diarrhea or gastroenteritis is ill-advised. Although the consequences of inappropriate antibiotic therapy are often mild and self-limiting, postantibiotic salmonellosis has had fatal consequences in cats.[26]

Diagnostic Tests for Small Intestinal Bacterial Overgrowth

Both direct and indirect tests are available, but none have been properly validated for companion animals, and widely accepted reference ranges have not been properly established. Therefore the results of these tests must be interpreted with caution. The main direct test is quantitative bacterial culture of duodenal juice. Indirect tests include hydrogen breath tests and serum biochemical analyses.

The current diagnostic gold standard for SIBO is *duodenal juice culture*, and the most commonly quoted figure for the upper limit for small intestinal bacterial numbers is 10^5 CFU/mL. However, the validity of this cutoff is questionable because quantitatively larger numbers (approximately 10^7 CFU/mL in some studies) have been documented in healthy dogs, while numbers as high as 10^9 CFU/mL have been found occasionally in cats and asymptomatic dogs.[4,5,8,9] Some of the discrepancies may reflect difficulties and differences in the methodology, as numbers vary widely when individual animals are repeatedly sampled.[1]

Use of an inappropriately low cutoff value will lead to the overdiagnosis of SIBO, probably explaining why it has been reported to be present in 50% of dogs with chronic intestinal disease.[27] In reality true secondary SIBO is rare, with the exception of SIBO secondary to EPI. An increase in small intestinal bacterial numbers has been documented in experimentally induced EPI, although bacterial numbers decrease upon treatment of the EPI with enzyme replacement.[28] Therefore in many cases the SIBO itself is of no significance. However, a proportion of naturally occurring EPI cases respond suboptimally to pancreatic enzyme supplementation alone, and may require concurrent antibiotic therapy. Given that the majority of dogs affected with EPI are German Shepherd dogs, it is not clear whether this is the result of secondary SIBO, or of a concurrent idiopathic ARD. Furthermore, duodenal juice collection is technically demanding, expensive, and rarely performed routinely. Attempts at improving diagnostic accuracy have included measuring bacteria in mucosal biopsies samples, but this has not been shown to be of added benefit.[1] Finally, quantitative PCR techniques may result in improved reliability by producing a more reliable bacterial yield[2,3]; however, they have not yet been used as a means of attempting to diagnose possible SIBO.

Given the limitations of the diagnostic gold standard, indirect tests have been adapted from human methodology for use in the clinical setting. The most commonly used diagnostic tests in dogs are the measurement of *serum folate and cobalamin concentrations*. The utility of these assays is based on the theory that many bacterial species synthesize folate, while others can bind cobalamin; therefore increased numbers of small intestinal bacteria may elevate serum folate concentrations, decrease serum cobalamin concentrations, or both. However, measurements of these parameters have poor sensitivity and specificity for canine SIBO, and cannot differentiate dogs with ARD from those with other etiologies.[12] Consequently the use of folate and cobalamin measurements for the diagnosis of SIBO, and especially ARD, is questionable. However, they may still be of value in detecting vitamin malabsorption (see following discussion).

An alternative indirect means of detecting SIBO was the *measurement of hydrogen concentrations in exhaled breath*, either in a fasted state or after administration of a test meal.[29-32] However, protocols have not been universally accepted and this remains a research technique. Canine assays for *SUBA* were also recommended at one time.[33] These tests relied on the principle that conjugated bile acids that are secreted into the intestines can be deconjugated by some bacterial species (e.g., *Clostridia*, *Bacteroides*), the so-called unconjugated bile acids, which then are absorbed passively and can be measured in blood. Although early work suggested that these assays might be promising,[33] more recent work suggests that they are of limited use in the diagnosis of idiopathic ARD.[12] To my knowledge, these assays are no longer available.

In summary, none of the diagnostic tests currently available are recommended for diagnosis of either secondary SIBO or idiopathic ARD. Where secondary SIBO is suspected, it is preferable to look for the underlying cause. Given that neither quantitative bacterial culture nor indirect tests reliably identify cases that respond to antibacterials, and given that correlation between all methods is poor, their use in the diagnosis of idiopathic ARD is not recommended.

Treatment

Secondary Small Intestinal Bacterial Overgrowth

Although antibacterial therapy will improve clinical signs, appropriate treatment for the underlying condition is preferable. For EPI, pancreatic enzyme supplementation can reduce bacterial numbers because exogenous proteases have antibacterial properties. Experimental studies show that bacterial numbers in dogs with EPI decline with pancreatic enzyme supplementation alone (probably because enzymes are bactericidal and available substrate is reduced), suggesting that the problem will resolve of its own accord. However, in some clinical cases concurrent antibacterial therapy is necessary.

Idiopathic Antibiotic-Responsive Diarrhea and Tylosin-Responsive Diarrhea

For idiopathic ARD, an appropriate antibacterial should be administered for an initial period of 4 weeks. If signs relapse, a longer course may be required, and many cases require long-term (or lifelong) therapy to maintain remission of signs. The choice of antibacterial is controversial; most cases of idiopathic ARD respond well to oxytetracycline at 10 to 20 mg/kg TID PO and for long-term therapy, low doses can often maintain clinical remission (10 mg/kg SID PO). However, it should not be used before permanent tooth eruption because of staining of tooth enamel. Other suitable drugs include tylosin at 10 to 15 mg/kg BID, which, unsurprisingly, is the drug most commonly used for tylosin-responsive diarrhea in Finland. A final option is metronidazole, given at 10 mg/kg TID PO.

The mechanism of action is not currently known. Interestingly, when oxytetracycline is administered bacterial numbers do not decline significantly and resistance soon develops, despite resolution of clinical signs. Hypotheses include the possibility that these drugs are exerting a selection pressure on the intestinal microflora in the same way as a prebiotic. Alternatively, immunomodulatory effects, as reported for some of the tetracyclines, are possible.

Currently, oxytetracycline remains the first choice for idiopathic ARD in the United Kingdom, but its use for secondary SIBO is controversial and other drugs may be more appropriate, for example, tylosin or metronidazole, as their spectrum of activity is better for the organisms that are likely to be present in secondary SIBO. Furthermore, some authors question whether oxytetracycline should be used at all because it is associated with rapid development of plasmid-mediated antibiotic resistance.[34] However, given that long-term efficacy is maintained in most cases, oxytetracycline may not be acting through its antibacterial properties as it does not significantly reduce SI bacterial numbers.[24] Instead, it may either provide a selective pressure on the intestinal flora encouraging the establishment of less harmful bacteria or utilize immunomodulatory effects, which this antibiotic group possesses. Immunomodulatory activities also have been suggested for other antibacterials, namely metronidazole and tylosin, that are commonly used to treat ARD. Finally, the drug is well-tolerated and there is no evidence that adverse effects (e.g., antibacterial-associated diarrhea) are a common effect of long-term oxytetracycline use.

Whichever antibacterial is chosen, a 4- to 6-week course is appropriate initially, although the antibiotic should be changed after 2 weeks if response has been suboptimal. In some cases, premature cessation of treatment can lead to relapse and prolonged therapy is often necessary. In some animals, a delayed relapse occurs several months after cessation of antibiotics, and such cases either require repeated courses or indefinite therapy. Efficacy is often maintained despite reducing the dosage from thrice to even once daily. Dogs may also "outgrow" the problem with age, either as a result of a decrease in caloric intake, or because of developing maturity to the mucosal immune system. It also has been suggested that idiopathic ARD in German Shepherd dogs may predispose individuals to IBD in later life, but there is currently no direct evidence to support this supposition.

Adjunctive therapy may be helpful in cases of both secondary SIBO and idiopathic ARD. This involves the feeding of a highly digestible diet. The need for fat restriction is logical for secondary SIBO, given that hydroxylation of fatty acids is implicated in the disease pathogenesis. However, whether this mechanism is involved in the pathogenesis of idiopathic ARD (and tylosin-responsive diarrhea) is not currently known. In addition, restricting fat may make it difficult for a cachectic patient to gain body weight and condition. Other suggestions include adding prebiotics (e.g., fructooligosaccharides) to the diet. Although these can modulate colonic microflora,[9] the effect on small intestinal bacteria is questionable[8] and there is limited current evidence for efficacy in clinical cases. Similarly, there is no published evidence supporting the use of probiotics for either secondary SIBO or idiopathic ARD. Finally, if low cobalamin concentrations are documented, parenteral cobalamin therapy is warranted.

Prognosis

The prognosis for secondary SIBO depends upon the nature of the underlying cause, and success of therapy for the particular condition. The prognosis for idiopathic ARD is guarded; many cases relapse after therapy is discontinued, and then require prolonged or even lifelong treatment. Other cases, however, require only occasional short courses of antibacterials to maintain clinical remission. Some cases may improve spontaneously as the animal enters adulthood.

OBSTRUCTION

Nick Cave

Definition

Obstruction of the SI is a common problem in companion animal practice. Severity of intestinal obstruction is classified according to a number of parameters including clinical signs, site, and patency. If ingested nutrients are unable to pass beyond the point of obstruction, it is termed *complete obstruction*. If some nutrients pass through the point of obstruction, even if only the liquid phase, it is termed *partial obstruction*. Physical or mechanical obstructions can result from intraluminal foreign bodies, intramural masses, and extramural compression. Functional obstructions result from generalized hypomotility or spasticity of a bowel segment. Functional obstructions are discussed in the "Dysmotility" section, and the mechanical obstructions of the intestine are discussed in this section.

Foreign Bodies

Luminal foreign bodies are the most common cause of acute intestinal obstruction. In a series of 174 cases in dogs in the United Kingdom, latex nipples were the most common foreign bodies, followed by plastic or rubber balls, stones, and strings.[1] In the same study, linear foreign bodies accounted for 44% of feline cases. In a survey of working farm dogs in New Zealand, plastic ear tags and bones constituted 66% of the intestinal foreign bodies.[2] Thus the

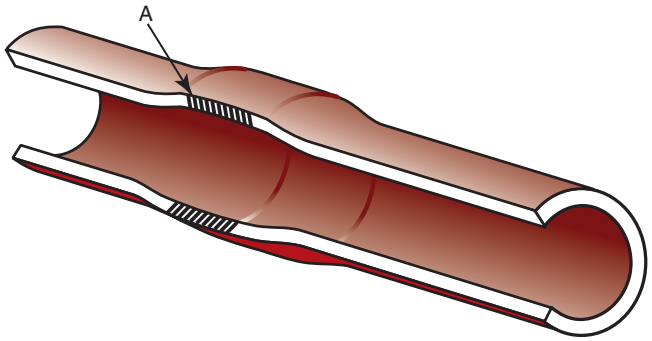

Figure 57-20 An annular bowel lesion or region of hypomotility (*shaded area*) can lead to intussusception when the adjacent contracted segment produces a kink at the border between normal and abnormal tissue (labeled A). The advancing wave of peristalsis drives the proximal segment into the lesional area creating an intussusception.

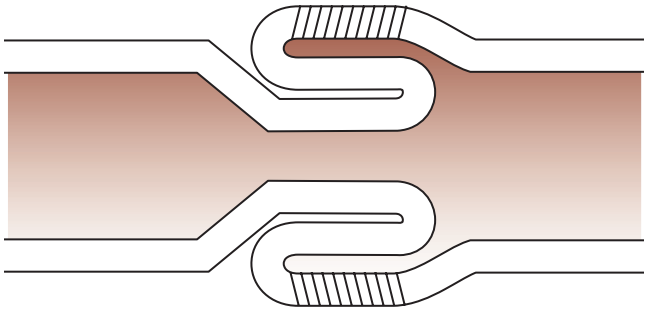

Figure 57-21 An aborad or direct intussusception is the most common form seen in dogs and cats. The internal section is termed the *intussuscipiens*, and the external (*shaded*) section is termed the *intussusceptum*.

nature of intestinal foreign bodies tends to reflect local practices and customs. In cats, trichobezoars (hairball obstructions) can cause partial or complete intestinal obstruction, often at a site of preexisting infiltrative intestinal disease.[3] Obstructive trichobezoars are rarely diagnosed in dogs and when they are seen, it is usually at a site of preexisting intestinal narrowing.[4] Foreign bodies can lodge anywhere along the small and large intestine, and there does not appear to be a predilection site, except that the jejunum, because of its length, is the most commonly affected region.[1,5] Linear foreign bodies may anchor around the base of the tongue, pylorus, or at more distal sites.[1,6] Most linear foreign bodies do not themselves obstruct the intestine, but gathering and pleating of the intestine around the foreign object causes partial to complete obstruction.

Intussusception

Intussusception represents an uncommon form of bowel obstruction, defined as the telescoping of a (usually) proximal segment of the GI tract, called the *intussusceptum*, into the lumen of the adjacent distal segment of the GI tract, called *intussuscipiens*. The most common sites in the dog are the ileocolic junction or jejunojejunum, whereas in cats, jejunojejunal is the most common type.[7-9] In general, an intussusception occurs when a migrating peristaltic wave reaches a fixed or noncontractile segment (labeled A in Figure 57-20). If the fixed or noncontractile segment is of sufficient diameter, and of sufficient length, then the proximal contracted segment will fold into the outer intussuscipiens (Figure 57-21). The majority of intussusceptions develops aborally in the direction of normal

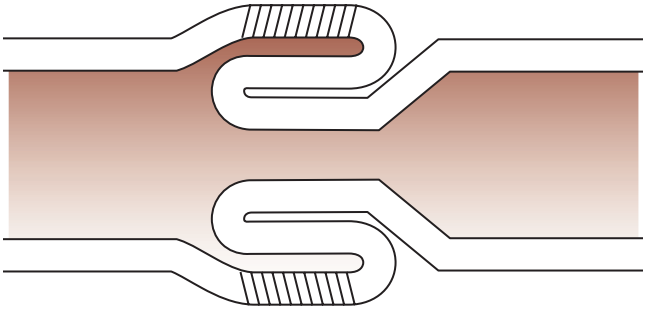

Figure 57-22 An orad or retrograde intussusception.

peristalsis, but can develop in an orad, or retrograde, direction (Figure 57-22). Alternatively, an intraluminal, or extraluminal linear fixed linkage such as a short linear foreign body, can result in formation of a kink in the wall, which progresses to a fold and then intussusception.[10]

Intussusceptions are generally more common in younger animals, many younger than 1 year of age, although the age distribution in cats appears to be bimodal.[7,8,11] Intussusception in young cats is most likely to be idiopathic, whereas in older cats it is more likely to be secondary to infiltrative disease such as lymphosarcoma or IBD. Intussusception has also been recorded in queens during the immediate postpartum period.[12] Most intussusceptions in dogs are idiopathic, although any disease that can disturb intestinal motility, such as viral enteritis, neoplasia, foreign bodies, and prior abdominal surgery, can lead to intussusception.[8,9,11,13,14] In dogs treated for severe viral enteritis (e.g., parvoviral or coronavirus), intussusception should be suspected if a sudden unexplained deterioration occurs.[13,15] Likewise, a newly diagnosed intussusception should not be assumed to be of idiopathic origin. Diagnosis always requires consideration and appropriate testing for an underlying condition.

Pathophysiology

Motility

Motility at the site of the obstruction is altered through the multiple pathogenetic effects of ischemia, inflammation, bacterial toxin absorption, and direct mechanical stimulation. In acute experimental jejunal occlusion, intestinal motor activity is almost immediately altered.[16] Initially, there is increased motor activity proximal to the obstruction, and reduced motor activity distal to it (the intestinointestinal reflex, see Chapter 1). Within 2 to 3 hours, however, hypermotility extends proximally to the duodenum, and hypomotility extends distally from the obstruction to the terminal ileum. Following occlusion of the small intestinal lumen, continued peristaltic activity proximally leads to transient increases in intraluminal pressure. Normal intraluminal pressure rarely exceeds 4 mm Hg, whereas after experimental occlusion in dogs or cats, proximal intraluminal pressure is sustained between 5 and 10 mm Hg, and peaks at 20 mm Hg during intense contractions.[17,18]

In chronic partial obstructions, there is an extensive remodeling of the muscularis layer proximal to the obstruction leading to smooth muscle hyperplasia and hypertrophy, neuronal degeneration, neoangiogenesis, and fibrosis.[19-21] (Muscularis remodeling does not occur distally despite the local mucosal atrophy that develops acutely.) The net effect of these changes is an increase in wall stiffness, loss of slow-wave activity, reduced neural responses, and reduced contractile capacity. In chronic partial obstruction, wall stress and strain rise significantly proximal to the obstruction as a

bolus is advanced by peristalsis. Mechanoreceptor stimulation triggers further increases in pressure to force the chyme through the obstruction. This may lead to localized luminal bulging. Most of this remodeling and degeneration is reversible over time once the obstruction has been removed, although neuronal degeneration may be irreversible and hypomotility may persist in some patients, particularly in more chronic cases.[22]

Mucosa

The mucosa proximal to the occlusion is stimulated to secrete water and electrolytes into the intestinal lumen. Distal to the obstruction, villus atrophy of the mucosa and reduced brush-border enzyme expression develop rapidly.[18] Although physical disruption to local vascular supply occurs, increased vascular pressure is not the mechanism for fluid hypersecretion. When the jejunum is experimentally occluded surgically in gnotobiotic dogs, proximal segment hypersecretion does not take place,[23] illustrating the role of the enteric microflora in the pathogenesis of the continued fluid secretion proximal to the obstruction. Vomiting of this hypersecreted fluid contributes to the dehydration, acid–base, and electrolyte disturbances of the disorder. Although there is a relative hypersecretion, the actual volume of fluid that accumulates proximal to the acute obstruction is surprisingly small and of low protein content.[24]

Intussusceptions commonly lead to more significant vascular compromise, and both lymphatic and venous vessels are occluded resulting in edema and hemorrhage, both intramurally, and into the intestinal lumen. Intramural and serosal hemorrhage can lead to fibrinous adhesions that prevent manual reduction of the intussusception.

Bacteria

Experimental occlusion of the SI leads to rapid death in conventional raised dogs. However, gnotobiotic dogs can survive for prolonged periods despite complete intestinal obstruction.[25,26] When a mixed intestinal microflora is reintroduced into an occluded intestine, it too leads to rapid death. However, common intestinal bacteria vary greatly in their pathogenicity after intestinal obstruction. *C. perfringens* mono-inoculation results in rapid death, *Bacteroides fragilis* mono-inoculation results in death after several days, whereas *E. coli* mono-inoculation inconsistently results in death. This emphasizes the importance of treating cases of intestinal obstruction with anaerobicidal antimicrobial agents.

The clearing function of the peristaltic waves is perhaps the most important factor that limits microbial numbers in the SI. It has long been known that a reduction in MMC activity leads to an increase in intraluminal bacteria, and a qualitative shift in the population distribution toward Gram-negative and anaerobic bacterial species.[27] In the segment proximal to an acute intestinal obstruction, there is a marked proliferation of both aerobic and anaerobic enteric microflora, but most markedly anaerobic and Gram-negative facultative aerobes.[28,29] Overgrowth of bacteria is required for induction of proximal enteritis and disturbance in mucosal secretory function. At the same time, bacterial translocation into the systemic and portal circulation is dramatically increased and leads to colonization of the hepatic parenchyma.[28] In experimental jejunal obstruction in rats, technetium-labeled *E. coli* readily translocate within 4 hours of the obstructing event.[30] Bacteria migrate from the strangulated segment into the peritoneal cavity, and are then disseminated systemically. Significant translocation of bacteria is observed in the heart, liver, and kidney. Higher numbers of bacteria migrate from the strangulated section, consistent with the importance of vascular integrity for maintaining normal barrier function.

Pain

Intestinal obstruction is a painful condition, although some affected animals do not demonstrate much discomfort. Several factors contribute to pain generation, including intestinal dilation, mechanical trauma, ischemia, and bacterial toxin absorption. Sensory nerve fibers innervating the mucosa, submucosa, muscle, myenteric plexus, and serosa, respond to mechanical distortion of the gut wall, particularly distention, but also contraction of smooth muscle, and changes in the chemical environment of the intestinal lumen.[31] Distention triggers release of substance P, which stimulates the secretomotor neurones via neurokinin $(NK)_1$ and NK_3 receptors, resulting in chloride and water secretion.[32] Through mediators such as substance P, nitric oxide, and neurokinin A, motor activity can be stimulated or inhibited, and alterations in electrolyte, mucus and fluid secretion, arteriolar dilation, vascular permeability, mast cell degranulation, and activation of immune cells can be induced.[31] Thus there is a bidirectional interaction in pain sensation and neurogenic inflammation during intestinal obstruction.

Intestinal Wall Integrity

As pressure at the site of obstruction progressively increases, lymphatic and then venous drainage is impaired while arterial perfusion is maintained, resulting in intestinal wall edema. Local endothelial barrier leakage and arteriovenous shunting causes intestinal ischemia and reperfusion injury with concomitant barrier dysfunction. Full-thickness wall necrosis may occur, leading to gross contamination of the peritoneum and septic peritonitis.

Differential Diagnoses

Patients with intestinal obstruction can present with acute clinical signs, as is often the case with complete obstruction, or with chronic clinical signs, which is more consistent with a partial obstruction. The differentials for patients with an acute onset of signs are those common to any patient with acute-onset vomiting, although acute intestinal obstruction is usually distinguished from self-limiting causes on the basis of the severity, history, and physical exam findings. The key differential diagnoses for acute onset of vomiting are discussed more fully in Chapter 23. Key differentials for abdominal pain are discussed in Chapter 6. Chronic partial intestinal obstruction should be considered for any patient with chronic vomiting, small intestinal-type diarrhea (Chapter 11), weight loss (Chapter 24), and evidence of PLE.

Evaluation of the Patient

History

Although any dog or cat of any age or breed can present with an intestinal foreign-body obstruction, young dogs and cats, especially large-breed dog conformations, are overrepresented in most case series.[1,33] Intussusceptions are more common in young dogs and cats, although they may be secondary to underlying disease (e.g., lymphoma) in older animals. The clinical signs of intestinal obstruction vary with the site and completeness of obstruction, degree of distention, presence of peritonitis, and whether there is concurrent systemic sepsis. The most obvious clinical signs are anorexia, abdominal pain, depression, and vomiting. In experimental intestinal obstruction, these signs are followed by profound dehydration, shivering and ataxia, and eventually collapse, coma, and death.[34] Chronic partial foreign-body obstructions and chronic patent intussusceptions are generally less severe in their clinical signs, for example,

vomiting and abdominal pain, and consequently nonspecific lethargy, inappetence, intermittent vomiting, and weight loss may be the only presenting clinical complaints. In acute cases, owners will frequently be aware of the possibility of foreign-body ingestion, and they should be questioned closely to ascertain the possibility.

In experimental complete occlusion of the duodenum, vomiting occurs within hours, and in almost all cases.[34] In surgically induced distal jejunal occlusion in dogs, only four of 38 dogs vomited during a 4-day postoperation period, and the volume of vomitus was small.[24] Thus the frequency and severity of vomiting may more importantly reflect the site of occlusion and factors other than simple mechanical occlusion. Nonetheless, vomiting is the most common presenting sign in both dogs and cats. When absorptive capacity is preserved oral to the site of the obstruction, fluid losses in vomitus may not be as severe. In general, it appears that more distal obstructions (e.g., jejunal) are associated with a lower frequency of vomiting than are seen with proximal obstructions (e.g., duodenal).[24] Proximal obstructions generally result in the loss of large amounts of ingested and secreted intestinal fluid. The duration of vomiting prior to presentation for a complete obstruction is usually 2 to 3 days, but partial obstructions can cause chronic intermittent vomiting for many weeks or months.[1,33,35] Thus intestinal foreign bodies are an important differential for patients presenting with a history of acute or chronic vomiting.

Diarrhea is less frequently reported in patients with acute complete intestinal obstruction, but it may be an important clinical sign with chronic partial obstruction. Patency of the lumen of an intussusceptum is often maintained with partial obstruction, such that intermittent vomiting and chronic diarrhea are frequently reported. Diarrhea associated with chronic partial obstruction is usually described as small bowel in character, and can be hemorrhagic in acute cases.[1] Ileocolic intussusceptions particularly are associated with hematochezia. Chronic weight loss and evidence of PLE are also seen in partial obstructions, especially intussusceptions.[36]

Physical Examination

Thorough physical examination is imperative for the differentiation of self-limiting causes of acute vomiting from intestinal obstruction and other life-threatening conditions. A diagnosis of intestinal foreign-body obstruction or intussusception can frequently be made on the basis of history and physical examination alone. Animals will be variably dehydrated, and in severe cases, physical parameters indicative of poor perfusion and shock may be present. Normothermia, fever, and occasionally hypothermia may be present according to disease duration, severity of necrosis and inflammation, presence of systemic sepsis, and cardiovascular status. Abdominal pain may be manifested by hunched stance, praying position, or a reluctance to stand and move.

Abdominal palpation may permit localization of pain to a specific region of intestine, or it may be more generalized, especially when peritonitis is present. Contraction of the abdominal musculature, vocalization, and aggression may indicate abdominal pain. Cats will frequently slump into lateral recumbency when abdominal pain is elicited. In many cases, a foreign body can be directly palpated.[1] Plication or bunching of the intestines may be suggestive of a linear foreign body. Gas-filled loops of bowel often are painful on palpation though minimally dilated. Intussusceptions frequently can be palpated as a firm, often painful tubular structure that is well demarcated, and cannot be indented with digital pressure, thus differentiating it from feces. The most common location for an intussusception is the cranioventral region. In some cases with severe abdominal pain, palpation may not be possible until heavy sedation or anesthesia is induced. If sedation is required for further investigation, careful palpation should be repeated.

Linear foreign bodies can have a proximal anchor point anywhere along the intestinal tract. Anchoring around the base of the tongue is sufficiently common as to make careful examination of that area imperative in a vomiting patient.[1,33]

Laboratory Evaluation

The severity of hematologic and serum biochemical changes depends upon the severity and duration of the obstruction, and presence of complicating factors such as peritonitis, systemic inflammatory response, and hypovolemia. In experimental mechanical occlusion of the jejunum, hemoconcentration, leukocytosis, mature neutrophilia, and progressive hypoglycemia are common.[34] A degenerative left shift in the white blood cell count is more likely when concurrent peritonitis is present.[37,38] Extravasation and hemorrhage may lead to hypoproteinemia, and variable degrees of azotemia may be seen consistent with reduced renal perfusion and/or blood loss.[34] Although important in the staging of disease, it is important to note that the degree of abdominal cytopathology, hematology, and serum biochemical changes does not predict survival following surgery for septic peritonitis.[37,38]

Patients with intestinal obstruction develop progressive dehydration, electrolyte imbalance, and acid–base disturbances. In a study of 138 dogs with intestinal foreign bodies, the most common electrolyte and acid–base abnormalities were hypochloremia (51.2%), metabolic alkalosis (45.2%), hyperlactatemia (40.5%), hypokalemia (25%), and hyponatremia (20.5%).[33]

It has been previously suggested that obstructions of the proximal SI are more likely to result in the loss of gastric chloride in excess of sodium. This would lead to an increased strong ion difference and a metabolic alkalosis, whereas more distal small intestinal obstructions would more likely result in metabolic acidosis.[39] Evidence-based data studies by Boag et al. have instead shown that there is no association between the site of obstruction (proximal vs. distal) and biochemical abnormalities including venous pH, serum lactate, potassium, and chloride.[33] Hypochloremic, hypokalemic metabolic alkalosis was reported in 12% and 13% of dogs with proximal and distal obstructions, respectively.

Chronic intussusception in dogs is commonly associated with hypoproteinemia, and varying degrees of hyponatremia, hypokalemia, and hypochloremia.[36] Because of the strong association between preexisting enteric disease and the development of intussusception, it is likely that biochemical abnormalities are influenced by the underlying disease, rather than the effect of the intussusception.

Diagnostic Imaging

History and physical examination findings, including direct palpation of a foreign body or intussusception, are often sufficient to justify preparation for exploratory laparotomy, but direct imaging should be performed to confirm the diagnosis prior to laparotomy. Chapter 26 discusses diagnostic imaging of the intestinal tract more fully.

Plain Radiography

Radiopaque foreign bodies are easily identifiable on plain radiography (Figure 57-23), but even when present, it is imperative to determine whether there is evidence of obstruction that would warrant immediate surgical intervention, or if it is reasonable to delay surgery to determine whether the object will pass from the GI tract. In other cases where there is intussusception or a radiolucent

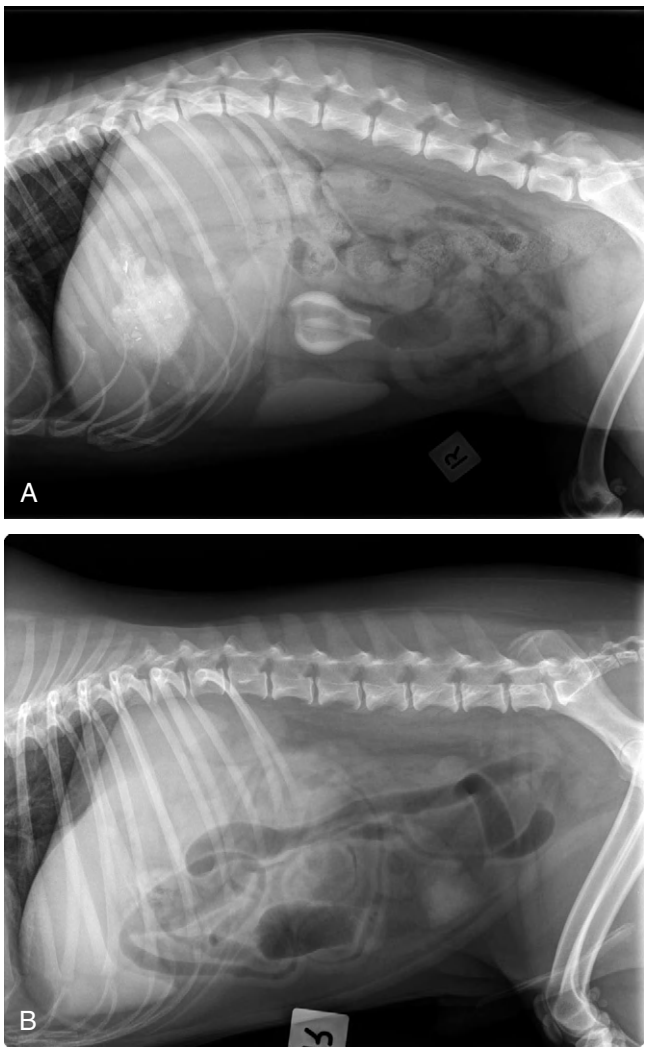

Figure 57-23 **A,** Lateral abdominal radiograph of a dog with a radiopaque foreign body. Notice the fluid-distended loop of small intestine cranial to the object. Radiopaque sand-like material can be seen in the stomach. **B,** Ventrodorsal radiograph of the same dog. In the left caudal abdomen there is a focal region of increased soft tissue/mild mineral opacity within the intestinal lumen associated with fluid distention on one side, and gas distention (with fluid bubbles) on the other side.

foreign body, the radiographic evaluation is focused on the detection of dilated intestinal loops, "gravel" appearance of intestinal contents, free abdominal gas and loss of abdominal detail, and intestinal mass effect.

Dilated Intestinal Loops. Intestinal obstruction leads to the accumulation of variable amounts of gas and/or fluid in the proximal segment. Several different parameters for assessing intestinal width have been suggested, but the best validated parameter is serosal-to-serosal width exceeding 1.6 times the height of the fifth lumbar vertebral body at its narrowest point.[40] Other suggested parameters include serosal-to-serosal width less than 1.2 cm in the cat, and less than twice the width of the twelfth rib.[41] With changes in patient positioning, gas and fluid will redistribute along the normal intestine, thus orthogonal views are important to increase sensitivity and specificity. Complete obstruction will usually lead to dilation of more than one loop proximally, and chronic obstruction can lead to extensive dilation. As the bowel becomes progressively distended, affected loops may lie closely adjacent to one another, creating a "stacked" appearance effect. In contrast, partial or very acute obstructions may not be associated with significant dilation at all. Thus the absence of intestinal dilation should not be used to exclude the possibility of intestinal obstruction.

Linear foreign bodies characteristically produce a bunched or pleated appearance on plain or contrast radiography.[41] In addition to intestinal pleating, tapering, enteric gas bubbles, intestinal needles, and evidence of bowel obstruction are common.[6] Linear foreign bodies are more likely to be associated with peritonitis from perforation of affected loops, which can produce a "ground-glass" appearance and loss of serosal detail, as well as potentially leading to the accumulation of free abdominal gas.

"Graveling" of Intestinal Contents Proximally. Chronic partial obstructions cause sedimentation and accumulation of insoluble, granular, slightly opaque material proximal to the site of obstruction. The appearance of this material has been described as "graveling" and "fecal-like," and its presence in the SI, rather than colon, is indicative of obstruction.

Free Abdominal Gas and Loss of Serosal Detail. The presence of free abdominal gas and loss of serosal detail on plain radiography is strongly associated with GI perforation and peritonitis, and is an indicator for rapid surgical intervention. Peritoneal gas frequently accumulates dorsally on the lateral radiograph and can be seen delineating the diaphragm dorsally and cranially to the liver margin. On the ventrodorsal image, gas may again be seen between the diaphragm and liver margins.

Intestinal Mass Effect. The differentiation between radiolucent foreign body and intussusception on plain radiography is often difficult, and a simple characterization of ileus with suspicion of obstruction may be the limit of confidence. In some cases, an intussusception may create a soft-tissue density or mass effect. Ileocolic intussusceptions are characteristically apparent in the ventrodorsal view caudal to the stomach, causing displacement of the unaffected SI caudally and to the right.

Contrast Radiography

Barium-contrast radiography is indicated if the history and physical examination is equivocal, plain radiography is nondiagnostic, and ultrasonography is not available. The recommended dose is 10 to 15 mL/kg of a 30% wet weight suspension of barium sulfate. Films should be taken at 0, 15, 30, and 60 minutes following barium administration and hourly thereafter until a diagnosis is made or the barium has been transported to the colon. In health, the barium should arrive in the ileum within 60 minutes and the ileocecal sphincter after 2 hours. Filling defects and transit time are the key radiographic features for obstruction. The pattern of barium at the site of obstruction varies greatly. Contrast may accumulate proximal to the obstruction, precisely delineating the shape of the foreign body, or revealing luminal filling defects. In the case of intussusception, patency of the lumen of the intussuscepted segment determines if barium will pass, which can be seen as a thin stream of barium within the narrowed lumen. In some cases, barium will flow into the surrounding enveloping intussuscipiens producing a tube-within-a-tube effect.

Contrast radiography can also be performed utilizing BIPSs. BIPSs are a convenient method to detect partial intestinal obstructions.[42] The principal advantage of BIPS over liquid barium is the ease of interpretation, especially in cases where a partial obstruction

can be excluded by unimpeded transit into the colon. BIPSs are administered as capsules or mixed with food, thus avoiding the difficulties of administration of liquid barium. Unlike liquid barium, BIPS transit more closely approximates the transit of food in the GI tract. In cats and dogs that present for chronic vomiting or diarrhea, one protocol is to (a) administer the BIPS with food, (b) take radiographs 2 hours later to rule out gastric dumping, and (c) take radiographs at 8 hours to detect delayed gastric emptying. If the radiographs taken at 8 hours do not reveal some large spheres in the colon, a third set of radiographs later that same day or early the next morning should be taken to rule out partial bowel obstructions. Persistent bunching of the spheres in the SI is highly suggestive of physical obstruction of the small bowel, particularly if the markers have bunched in a dilated loop of SI or if "graveling" is apparent. If the small bowel loop in which the bunching occurs is not dilated or graveling is not apparent, a repeat radiograph should be taken 1 or 2 hours later to ensure persistence of the bunching.

Fasting and enema administration improve the diagnostic accuracy of liquid contrast techniques, and a full study may require 12 to 24 hours to definitively establish transit into the colon. In acute presentations, and especially when the patient is compromised or septic, these require a delay in intervention that may not be optimal. For these reasons, and for reasons of diagnostic accuracy, contrast radiography has largely been supplanted by ultrasonography as a means of detecting mechanical intestinal obstruction.

Ultrasonography

Intestinal dilation caused by mechanical obstruction is readily detected with ultrasonography. In addition, intestinal motility can be subjectively assessed in the proximal and distal segments. It has been reported that in chronic obstruction, generalized decreased intestinal motility is seen, whereas increased motility is more commonly associated with acute obstruction.[43] Such a description is consistent with changes reported with experimental obstruction.[16]

The ultrasonographic appearance of intussusception is best characterized by a transverse view of the lesion, depicting the wall layers as a multilayered series of concentric rings, or a target-like lesion (Figure 57-24).[9,14,44] The rings have a hyperechoic or anechoic center surrounded by multiple hyperechoic and hypoechoic concentric rings. When viewed in a longitudinal direction, the intestinal layers appear as multiple hyperechoic and hypoechoic parallel lines. Other possible findings include invagination with mesenteric fat, concurrent inflammatory pseudocysts, mesenteric lymphadenopathy, and mass-like, or even a kidney-like appearing soft tissue.[9,14,44]

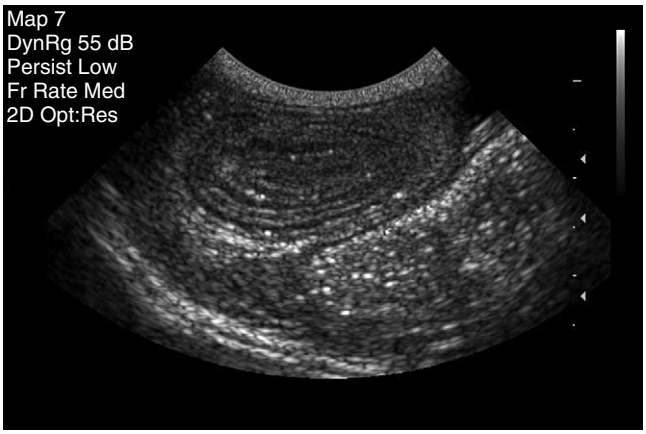

Figure 57-24 Ultrasonogram of an intussusception in transverse section showing the multilayered appearance.

Ultrasonographic evaluation has the added benefit of enabling guided fine-needle aspiration of abnormal bowel at the site of obstruction or intussusception. This would be indicated when an underlying intestinal mass, or diffuse loss of layering consistent with lymphosarcoma is suspected. A cytologic diagnosis prior to laparotomy may be invaluable for treatment planning, or even in a decision not to treat.

Treatment and Management

General Principles

Some intestinal foreign bodies will successfully pass into the colon despite clinical signs consistent with complete obstruction. In a patient with mild acute clinical signs, repeated imaging with careful monitoring is appropriate and necessary. Failure of movement of a foreign body within 8 hours, or failure of the object to pass into the colon within 36 hours, are indications for surgery.[45] It should also be noted that spontaneous resolution of an intussusception has been reported in the dog.[46] Therefore any delay between diagnosis and intervention should be followed by palpation and/or repeated imaging to confirm the persistence of the obstruction immediately prior to laparotomy.

Medical Preoperative Management

The primary therapeutic aim is to surgically relieve the intestinal obstruction. Rapid intervention improves the prognosis, although many patients do require preoperative stabilization. Establishment of adequate tissue perfusion by correcting dehydration is essential and of paramount concern. Volume resuscitation should continue until there is evidence of normal tissue perfusion, stabilization of central venous and arterial blood pressure, and urine production. In most cases, this can be adequately achieved using routine crystalloid replacement principles and therapy. Normal saline (0.9%) is reserved for cases of known hypochloridemic alkalemia because of its acidifying effects when administered in large volumes. The value of colloid solutions is still unsettled. In an experimental model of acute intestinal obstruction in dogs, the administration of synthetic colloid reduced loss of fluid into the intestinal lumen when compared with crystalloids.[47] This effect was consistent with a transient increase in plasma oncotic pressure. Nonetheless, evidence of improved outcome has not yet been provided in clinical patients, and the choice of crystalloids or colloids should be individualized according to evidence of low oncotic pressure and cost. A suggested approach is to start with crystalloid therapy, and administer a colloid solution if adequate perfusion and normotension cannot be achieved or maintained. In the face of severe hypotension (e.g., <60 mm Hg) or hypoalbuminemia, crystalloids, colloids, and plasma, may have to be administered concurrently.

Electrolyte derangements should be managed according to proven severity because predictions cannot be made as to the direction or severity of electrolyte and acid–base derangements in intestinal obstruction. Hypokalemia is especially problematic because of its deleterious effect on intestinal motility and systemic arterial pressure.[48,49] Thus a full preoperative evaluation would include a minimum database of packed cell volume, total plasma solids, serum electrolytes, and arterial or otherwise venous pH. If this information is not available, a conservative and sensible empirical fluid choice for rehydration and support is a high, strong ion gap electrolyte solution such as lactated Ringer solution, with potassium added to approximately 24 mmol/L.[39] Care should be taken not to exceed a

potassium infusion rate of 0.5 mmol/kg body weight/h during initial resuscitation.

Antibiotic therapy is essential because of the likelihood of systemic sepsis, and the risk of contamination during surgery. Antibiotic therapy should be commenced preoperatively, and the duration of antibiosis should be determined following surgical correction. The vast spectrum of potential pathogens dictates broad-spectrum antibiotic coverage for Gram-negative and Gram-positive aerobes and anaerobes. Gram-positive efficacy can be achieved with a β-lactam such as amoxicillin with or without a β-lactamase inhibitor, or a first-generation cephalosporin. Efficacy against Gram-negative bacteria can be achieved with an aminoglycoside, providing renal perfusion is adequate, or a fluoroquinolone, if azotemia is present. Anaerobic coverage may be adequate with the β-lactam alone, but the addition of metronidazole or clindamycin is warranted. Administration should be parenteral during the perioperative period. It is not known whether changing to oral administration postoperatively yields any added benefit. The disturbance in the microflora that ensues could contribute to delayed recovery. In the absence of evidence, continued parenteral administration is recommended as long as is practical.

Surgical Management

Although endoscopic retrieval may be successful in some cases of gastric foreign bodies, it is impossible to ascertain foreign material in the more distal GI tract. Small intestinal obstructions are best removed via laparotomy and enterotomy. Following careful inspection for integrity and adequate perfusion, intussusception should be reduced with or without resection. Chronic or nonreducible intussusceptions should be resected. The involved segment should always be carefully inspected for the possibility of local underlying disease such as neoplasia, and intestinal histopathology is indicated if any suspicious lesions or irregularities on palpation are detected. In all cases of intestinal obstruction, devitalized intestine should be resected, and appropriate decontamination of the peritoneal cavity through copious warmed sterile lavage.

Postoperative Care

Intravenous fluid therapy should be continued as required, and electrolyte and acid–base status should be monitored as needed. Empirical analgesia is indicated, regardless of the appearance of pain preoperatively. Reduced intestinal motility or complete paralytic ileus can complicate and prolong recovery. Neuronal pathology, enteritis, surgical manipulation, and persistent electrolyte derangements may all contribute to postoperative intestinal dysmotility. Insufficient evidence is available for firm recommendations in dogs and cats, but human experience suggests analgesia is important.[50]

Experimental studies show that early postoperative enteral feeding after intestinal anastomosis reduces intestinal inflammation, and increases the strength of the anastomotic site when compared with oral fasting for 48 hours.[51] Furthermore, the wound strength of the abdominal incision is increased when complex diets are fed enterally, compared with oral dextrose solution for 72 hours.[52] In a randomized trial of human patients treated surgically for intestinal perforation, early enteric feeding accelerates the recovery of normal intestinal motility, improves nitrogen balance, reduces weight loss, and reduces the risk of sepsis.[53,54] Interestingly, the risk of dehiscence is not necessarily reduced with the early introduction of enteral nutrition in clinical cases either in humans or in dogs.[54,55] The optimal nutritional formulas following enterotomy have not yet been established.

Regardless of the etiology, there is decreased motility with delayed gastric emptying and reduced segmental contractions in almost all cases.[56,57] Feeding decreases the development and duration of ileus in most intestinal pathologies. A recent metaanalysis on the recovery of human patients following a wide spectrum of abdominal surgical procedures demonstrated that early introduction of feeding resulted in shorter time to the presence of bowel sound and a trend toward shorter hospital stays.[58] At worst, continuing oral feeding will have no detrimental effect on motility, and at best it will promote normal motility and prevent ileus.

Multiple factors, including luminal nutrients, pancreaticobiliary secretions, and humoral agents are implicated in controlling the intestinal adaptive response after intestinal injury. Despite the multifactorial regulation of intestinal adaptation, luminal nutrients are fundamental to the adaptive response such that recovery is minimized or prevented in the absence of luminal nutrients. This conclusion is largely based on studies that show significant adaptive intestinal regrowth in rats and dogs fed orally compared with those fed parenterally following an intestinal resection. Indeed even in the absence of intestinal injury, total parenteral nutrition causes dramatic intestinal atrophy in dogs, cats, rats, and humans.[59-61] This fasting-induced atrophy is accompanied by inflammatory cell infiltrates in the lamina propria, increased intestinal permeability, and increased bacterial translocation.

Consequently, the early implementation of enteral nutrition with a complex diet is recommended in all patients following enterotomy or anastomosis unless there are specific contraindications. However, it is unlikely that attempting to feed the daily maintenance energy requirements is a sensible approach in the short-term postoperative period, and certainly not in cases of continued vomiting. Therefore it is recommended that only 25% of the animals resting energy requirements be fed as a highly digestible, low-fat diet, whereby intestinal recovery may be optimized, and exacerbation of diarrhea and vomiting is minimized. This can be offered orally, syringe fed, or administered as a liquid enteral diet via nasoesophageal tube or other feeding tube.

Relief of an intestinal obstruction does not result in immediate normalization of intestinal motility, and the persistence of hypomotility or ileus is more likely the longer the obstruction is present.[22] It is unknown if prokinetic drug therapy following relief of acute or chronic obstructions is helpful in dogs or cats. However, treatment with metoclopramide is effective in reducing the postoperative ileus in dogs that is experimentally induced by abrasion of the intestinal serosa.[62]

The prognosis for survival following enterotomy is generally very good, with reported survival rates of between 83% and 99%.[15,33] Studies to date have not specifically evaluated different preoperative, surgical, or postoperative protocols to establish best practice standards; however the prognosis for recovery from acute obstruction is improved with prompt treatment, which emphasizes the need for rapid diagnosis. The presence of intestinal perforation or leakage and septic peritonitis is proposed to be a negative prognostic indicator, but that has not been conclusively proved. Dehiscence of enterotomy sites is a major postoperative complication, and is more common following foreign-body removal than other reasons for enterotomy.[55] Reported dehiscence rates following foreign-body surgery range from 2.9% to 27.7%.[5,33,55,63] The risk of dehiscence following enterotomy is significantly increased if there is preoperative peritonitis, more than 15% loss of body weight prior to surgery, hypoalbuminemia, and leukocyte left shift.[55,63]

It is unknown whether the biomechanical remodeling that occurs proximal to a chronic partial obstruction could influence

tissue healing and risk of dehiscence following enterotomy. Future research is likely to elucidate if surgical margins that are extend beyond the simple points of adequate blood supply to regions devoid of architectural change, might improve the prognosis.[64-80]

DYSMOTILITY

Robert J. Washabau

Intestinal Motility Patterns

Contractions in the SI serve three general functions: mixing of the ingesta with digestive enzymes and other secretions, circulation of the intestinal contents to facilitate contact with the intestinal mucosa, and net propulsion of the intestinal contents in an aborad direction. Intestinal contractions are governed by four motility patterns: segmentation, peristalsis, intestinointestinal inhibition, and the migrating motility complex (see Chapter 1).[1]

Segmentation

If a contraction is not coordinated with activity above and below, intestinal contents are displaced both proximally and distally during the contraction and may, in fact, propagate orad during the period of relaxation. Such contractions appear to divide the bowel into segments, which accounts for the term *segmentation* given to the process. Segmentation serves to mix and locally circulate the intestinal contents. Segmentation primarily involves circular smooth muscle contraction (Figure 57-25).

Peristalsis

The SI is capable of eliciting a highly coordinated contractile response that is propulsive in nature. When the bowel is distended by a bolus of food the bowel responds with contraction orad and relaxation aborad to the point of distention. The neurotransmitters involved in the orad contraction are acetylcholine and substance P, and the neurotransmitters involved in the caudad relaxation are vasoactive intestinal peptide and nitric oxide. These events tend to move the material in an aborad direction. Short-segment peristalsis of the bowel is the norm in dogs and cats (see Figure 57-27). If short-segment peristalses occur sequentially they can propel a bolus the entire length of the gut in a short period of time. This peristaltic response, first characterized by Bayliss and Starling, is referred to as the "Law of the Intestine," and is less frequent than short-segment peristalses.

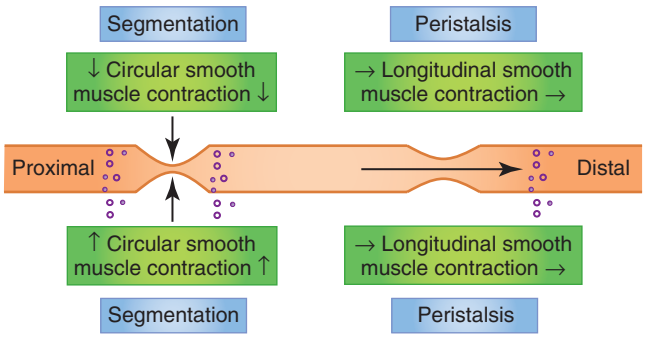

Figure 57-25 Segmentation- and peristaltic-type contractions in the small intestine.

Intestinointestinal Inhibition

If an area of the bowel is grossly distended, contractile activity in the rest of the bowel is inhibited. This reflex prevents the movement of ingesta into more distal segments of intestine that have been severely distended or obstructed. This reflex is mediated by the extrinsic (autonomic) nervous system.[2]

Migrating Motility Complex

The migrating motor complex propagates indigestible materials, mucus, and secretions from the stomach to the colon during the fasting state. The enteric nervous system regulates the periodicity and migration of the migrating motility complex, but the GI hormone motilin reinforces the migrating motility complex activity. Cats do not have migrating motility complexes, and instead have a migrating spike complex that is less vigorous than the canine migrating motility complex.[2,3]

Breed Differences in Gastrointestinal Transit Time

Significant differences in physiology and pharmacology have been found in dog breeds. There are more than 400 breeds of dogs recognized worldwide and 156 breeds recognized by the American Kennel Club. Among these various dog breeds, several important differences in metabolism have been noted, for example, P-glycoprotein–mediated metabolism, copper storage, and growth rates.[4,5] Differences in GI transit characteristics have also been noted. The GI tract of large-breed dogs (e.g., those weighing 60 kg) comprises 2.8% of their total body weight. In contrast, it comprises 7% of the total body weight of small-breed dogs (e.g., those weighing 5 kg). Breed-related differences in fecal water content could reflect differences in GI transit time, intestinal fermentation, diet, metabolism, and drug absorption. Using radiopaque markers (1.5-mm diameter administered in food), 12-week-old large-breed puppies (e.g., Great Danes) exhibited a significantly longer orocecal transit time (3.4 hours) as compared with small-breed puppies (e.g., Miniature Poodle, 2.5 hours). The longer transit time appears to reflect both a longer gastric emptying time and a longer small intestinal transit time among breeds. There also appear to be differences in intestinal permeability between dog breeds. The lactulose/rhamnose ratio reflects the relative absorption across the intestinal tight junction (transcellular absorption) versus the intestinal surface area (paracellular absorption, which occurs across the cell membrane of the enterocyte). The lactulose/rhamnose ratio is substantially greater in the Greyhound breed than in the Golden Retriever breed. Breed and age characteristics must be taken into account when differentiating normal and abnormal transit times. Chapter 26 outlines transit study techniques and times in more detail.

Definition of Ileus

Ileus has been defined as the functional inhibition of propulsive bowel activity, irrespective of pathogenetic mechanism.[6,7] There are several underlying causes of ileus, including dysautonomia, postoperative ileus, opioid-induced bowel dysfunction, muscular dystrophy,

visceral myopathy, viral enteritis, radiation enteritis, idiopathic pseudoobstruction, and hypothyroidism. Some ileus disorders are more readily treated than others.

Dysautonomia

Etiology

Dysautonomia is a generalized autonomic neuropathy that was originally reported in cats in the United Kingdom, but that has now been documented in dogs and cats throughout Western Europe and the United States.[8-16] The clinical signs reflect a generalized autonomic dysfunction but megaesophagus, esophageal hypomotility, gastric and small bowel distention and hypomotility, and urinary bladder distention are fairly consistent findings.[8,10,16] Aspiration pneumonia and megacolon are seen less frequently.

Pathophysiology

Degenerative lesions are found in autonomic ganglia, intermediate gray columns of the spinal cord, and some sympathetic axons.[10,12,13] Despite an intensive search for genetic, toxic, nutritional, and infectious etiologic agents, no definitive etiology has ever been established.

Clinical Signs

Vomiting, diarrhea, anorexia, lethargy, weight loss, dysuria, and inspiratory dyspnea are the most frequent clinical signs reported in dogs. In cats, dilated pupils, esophageal dysfunction, dry nose, reduced lacrimal secretions, prolapse of the third eyelid, regurgitation, and constipation are the most frequent clinical signs.[12]

Diagnosis

A clinical diagnosis is made in most cases based on historical and physical examination findings. Additional findings consistent with the diagnosis include (a) esophageal dilation and hypomotility on survey or barium contrast radiographs; (b) delayed gastric emptying on barium-contrast radiographs; (c) reduced tear production in Schirmer tear tests; (d) atropine-insensitive bradycardia; and (e) bladder and colonic distention on survey radiographs. There are few differential diagnoses to consider in a dog or cat presenting with the myriad manifestations of the syndrome. Early in the course of the illness, however, other differential diagnoses to consider are colonic or intestinal obstruction, other causes of megaesophagus, and lower urinary tract disease.

Treatment

Supportive care (e.g., artificial tears, elevated feedings, expressing the urinary bladder, antibiotics, etc.) is still the basis of therapy in this disorder, although some dogs and cats are reported to show mild improvement with parasympathomimetic drugs (e.g., bethanechol or metoclopramide). Gastrostomy tube feedings or total parenteral nutrition may sustain some animals until they regain neurologic function.

Prognosis

In general, dysautonomia carries a guarded to poor prognosis for long-term survival in both the dog and the cat. Twenty percent to 40% of affected cats are likely to recover, although cats may take 2 to 12 months to do so.[12-16] Recovery rates are lower still in the dog.[10,12] Complete recovery is uncommon and many cats and dogs are left with residual impairment, for example, intermittent regurgitation, dilated pupils, and fecal or urinary incontinence.

Postoperative Ileus

Etiology

Postoperative ileus has been defined as "ileus that develops following abdominal surgery, resolving spontaneously with 2 to 3 days."[17] It may be exacerbated by opioid administration during and following surgery. Multiple mechanisms have been proposed for the etiopathogenesis of postoperative ileus.[17]

Postoperative ileus is a significant problem in human medicine and constitutes the most important reason for delayed discharge from the hospital after abdominal surgery. The economic impact of postoperative ileus has been estimated to be $750 million to $1 billion in the United States. Similar data are not yet available in veterinary medicine.

Pathophysiology

Laparotomy and manipulation of the viscera are the main mechanisms underlying postoperative ileus, but other factors such as anesthetic agents and postoperative pain medication contribute to the delay in recovery of normal transit. The effect of general anesthetic agents is short lasting and therefore of only minor importance. The use of opioids to control postoperative pain has a much greater impact on postoperative motility. Postoperative opioids have significantly improved patient comfort in the early postoperative phase, but these drugs potently inhibit GI transit. Efforts to reduce the dose of opioids or to antagonize their effects with peripherally acting opioid μ-antagonists such as methylnaltrexone or alvimopan are important to minimize the detrimental effect of opioids on GI motility.

The main cause of postoperative ileus relates to the surgical procedure itself.[17,18] The first (or neurogenic) phase is neurally mediated and involves neural reflexes activated during and immediately following surgery. The second (or inflammatory) phase is triggered by the influx of leukocytes in manipulated intestinal segments and is responsible for the sustained inhibition of GI motility (Figure 57-26).[17]

Figure 57-26 Schematic of the two phases involved in postoperative ileus. The first phase starts during abdominal surgery and ends soon after it. The second inflammatory phase starts approximately 3 to 4 hours after surgery, lasts much longer, and is therefore clinically more relevant. (Reproduced with permission from Boeckxstaens GE, de Jonge WJ: Neuroimmune mechanisms in postoperative ileus. *Gut* 58:1300, 2009.)

Box 57-6 Causes of Intestinal Dysmotility in Dogs and Cats

- Dysautonomia
- Postoperative ileus
- Opioid-induced bowel dysfunction
- Muscular dystrophy
- Visceral myopathy
- Viral enteritis
- Radiation enteritis
- Idiopathic pseudoobstruction
- Hypothyroidism

Clinical Examination

Nausea, vomiting, intestinal distention, and abdominal pain are the most important clinical signs of postoperative ileus in dogs and cats. Fever and leukocytosis also may be found depending upon the type and severity of abdominal surgery.

Diagnosis

The diagnosis of postoperative ileus is usually straightforward, and an exclusion of other known causes of ileus (see Box 57-6). Laboratory testing (complete blood count, serum chemistry, urinalysis) are sometimes performed to rule out metabolic disorders such as liver disease and renal failure. Abdominal imaging (e.g., survey radiography and ultrasonography) should be performed to exclude other causes of ileus and their complications, for example, mechanical obstruction, peritoneal free air or fluid accumulation, and pancreatitis.

Treatment

Orogastric Intubation

Intermittent orogastric or nasogastric intubation may be of benefit particularly in those patients with gaseous GI distention.

Early Postoperative Feeding

Early postoperative feeding has been recommended as a means of decreasing the duration of postoperative ileus. Feeding may stimulate a reflex that coordinates propulsive activity and elicits the secretion of GI hormones, causing an overall positive effect on bowel motility.

Laparoscopic Procedures

Laparoscopic procedures offer the theoretical advantage of decreased tissue trauma compared with open abdominal procedures. This decrease in tissue trauma may lead to faster recovery of postoperative bowel function. Animal studies have found significant decreases in the duration of postoperative ileus after laparoscopic versus open abdominal procedures.[18]

Prokinetic Agents

GI prokinetic agents have a clear place in the management of postoperative ileus. Chapter 52 discusses these drugs and their clinical usage in greater detail.

Cyclooxygenase-2 Inhibitors

Mechanical stretch in intestinal obstruction induces marked expression of cyclooxygenase (COX)-2 in intestinal smooth muscle cells, and stretch-induced COX-2 plays a critical role in the suppression of smooth muscle contractility in bowel obstruction.[19] Therefore COX-2 inhibitors may have therapeutic potential in stretch-related disorders of the gut.

Opioid μ-Antagonists

Opioid μ-antagonists like alvimopan and methylnaltrexone may be useful in antagonizing the effects of morphine-like opioid agonists if that is part of the underlying pathogenesis of postoperative ileus.[20,21]

Electrical Stimulation

Although not yet clinically applicable, GI pacing is achievable in the canine stomach and SI (but not the colon).[22-26] The maximal entrainable frequency of the gastric and small intestinal slow waves is approximately 20% higher than the intrinsic frequency. In the future, stimulation parameters may be identified that will entrain slow waves, thereby normalizing gastric and intestinal dysrhythmias.[22-26]

Prognosis

The prognosis for short-term postoperative ileus is generally good to excellent. In animals with complicated, refractory postoperative ileus, the prognosis is less clear. More aggressive therapies may be needed in this patient population. In such cases, intestinal failure may result culminating in intestinal transplantation as a last resort.[27-29]

Opioid-Induced Bowel Dysfunction

Etiology

Opioid-induced bowel dysfunction may be part of a postoperative ileus syndrome, or it may relate solely to the use of opioid μ,δ-agonists as part of an analgesic therapeutic regimen. Opioids are a mainstay in the treatment of acute and chronic pain. Although opioids are very effective for pain relief from cancer and other nonmalignant diseases, their use is often limited by side effects. The most common adverse side effects are constipation and vomiting, but they also alter small bowel function causing opioid-induced bowel dysfunction. Opioid-induced bowel dysfunction can occur immediately after the first dose and persist for the duration of therapy. The peripherally acting μ-receptor antagonists methylnaltrexone and alvimopan are a new class of agents designed to reverse opioid-induced side effects on the GI tract without compromising pain relief.[30-36]

Pathophysiology

Endogenous opioids include endorphins, enkephalins, and dynorphins. They act selectively at opioid receptors composed of the μ, δ, and κ subtypes. Opioid μ receptors are present in the central and peripheral nervous system, as well as the GI tract. There are many species and site differences, but μ receptors have been reported on the interstitial cells of Cajal, smooth muscle, and epithelial cells. The predominant opioid effect appears to be at the local level and includes stimulation of absorption (villus epithelial cells), inhibition of secretion (crypt epithelial cells), increased segmentation (circular smooth muscle), and reduced peristalsis (longitudinal smooth muscle; reviewed in Chapter 1 in greater detail). Exogenously administered opioids have the same overall effect of opioid inhibition of peristalsis and secretion leading to the syndrome of opioid-induced bowel dysfunction.[31,32]

Clinical Examination

Constipation and vomiting are the primary clinical signs of opioid-induced bowel dysfunction. Left untreated, constipation can progress to fecal impaction and mechanical obstruction.

Diagnosis

The patient usually has a well-documented history of opioid μ-agonist therapy, for example, morphine, in the management of a pain syndrome. Still, it would be important to rule out other causes

of ileus, metabolic disorders, and mechanical obstruction. Therefore the minimum database should include laboratory data (complete blood count, serum chemistry, urinalysis) and imaging (survey abdominal radiography or ultrasonography).

Treatment

In most instances, discontinuation of the opioid μ-agonist is sufficient to ameliorate clinical signs. With persistence of clinical signs after drug withdrawal, laxative (reviewed in Chapter 50) and other therapies may be used to treat constipation, although it should be emphasized that a definitive role in the treatment of opioid-induced bowel dysfunction has not yet been proven. Any of the laxative agents (bulk, lubricant, osmotic, stimulant, emollient; see Chapter 50) could be used to attenuate the constipating effect of the opioid μ-agonist. Misoprostol, a synthetic prostaglandin E analogue also could be used to improve intestinal and colonic transit times.[36]

If the central analgesic effect of the opioid μ-agonist is paramount, the patient could be treated concurrently with an opioid μ-antagonist, methylnaltrexone or alvimopan, both of which will improve GI transit without inhibiting the central analgesic effect of the opioid μ-agonist. In dogs, methylnaltrexone at a dose range of 1 to 5 mg/kg subcutaneously abolishes the effect of morphine on GI transit without interfering with the central analgesic effect.[32] Safe and effective doses of alvimopan have not yet been reported in the dog.

If morphine must be used preoperatively, the epidural route (vs. continuous low-dose infusion) facilitates the time of appearance of the first gastric interdigestive migrating complex (the migrating motility complex) in dogs with paralytic ileus after open abdominal surgery.[37]

Prognosis

The prognosis for acute opioid-induced bowel dysfunction is generally good to excellent. Because chronic opioid-induced bowel dysfunction may persist it has a more guarded prognosis.

Muscular Dystrophy

Etiology

Duchenne-type muscular dystrophy in the Golden Retriever dog is an X-linked genetic disorder that is characterized primarily by progressive muscular weakness. Involvement of the GI tract is frequent and may occur at any level from stomach to intestine and colon.[38] The disorder is caused by mutations in the dystrophin gene responsible for production of the dystrophin membrane protein.[39] The absence of dystrophin is accompanied by alteration of the dystrophin–glycoprotein complex and results in progressive degeneration of the heart, skeletal, and smooth muscle with subsequent replacement by fibrosis and fatty infiltration.

Pathophysiology

The gastroenterologic clinical signs have been attributed to motility disorders caused by smooth muscle damage, but histologic evidence of alterations has not been a consistent finding. In a more recent report, Golden Retriever dogs affected with Duchenne-type muscular dystrophy had marked degenerative lesions in the smooth musculature of the GI tract, urinary, and reproductive systems. GI smooth muscle lesions were associated with the clinical findings of gastroparesis, gastric dilation, and intestinal pseudoobstruction.[38]

Clinical Signs

Dysphagia, regurgitation, gastroparesis, abdominal pain, and intestinal distention have been reported in affected animals. Gastroenterologic clinical signs may be the first sign of dystrophic disease and may precede the appendicular musculoskeletal features. The impairment of GI function may be gradual and undetected by the pet owner, breeder, or veterinarian.[38]

Diagnosis

Definitive diagnosis may be confirmed on the basis of history and physical examination findings, serum creatine kinase activity, genomic DNA analysis, muscle electrophysiology, gross morphology, and histologic features.[39] Ileus may be difficult to detect in the whole animal and may require the use of endoscopy, ultrasonography, and scintigraphy.

Treatment

Despite major advances in our understanding of the pathophysiology of the disease, therapy is still largely supportive and symptomatic. Gene replacement therapy has not yet succeeded in restoring muscle function or in prolonging life.

Prognosis

At the present time, the prognosis for cure is poor. With supportive and symptomatic therapy, some affected animals have survived for as long as 51 months.[38]

Visceral Myopathy

One case of visceral myopathy in a 6-month-old domestic short-hair cat has been reported in the veterinary literature.[40] The kitten had a 6-day history of anorexia, intermittent vomiting, and diarrhea, and severely dilated loops of hypomotile intestine were found on survey abdominal radiography and ultrasonography. Intestinal dilation was confirmed at the time of surgery, and a 20-cm section of jejunum was resected. In the proximal jejunum, there was marked atrophy of the longitudinal muscle of the muscularis externa layer and diffuse severe degenerative vacuolar change within the myocytes and endomysial cells. The circular muscle layer was of normal thickness and morphology. Villus stunting and fusion were evident in the mucosa. In the distal jejunum, the mucosa and submucosa were normal, but the longitudinal muscle layer was markedly atrophic with focal degeneration, calcification, loss of myocytes, and replacement by proliferating fibroblasts. Based upon descriptions of human visceral myopathy, the findings were thought to be consistent with a diagnosis of visceral myopathy causing chronic intestinal pseudoobstruction.[40] The cat was alive and doing well 20 months after surgery.

Parvoviral Enteritis

Ileus is a frequent finding in puppies affected with parvoviral enteritis.[41] The ultrasonographic appearance of the GI tract was characterized in 40 puppies with confirmed canine parvoviral enteritis.[41] Sonographic findings included fluid-filled SIs in 92.5% of the cases (Figure 57-27), and of the stomach and colon in 80% and 62.5% of the cases, respectively. Generalized atony was present in 75% of the cases, and weak peristaltic contractions indicative of functional ileus were observed in the remaining 25% of cases. The duodenal and jejunal mucosal layer thicknesses were significantly reduced when compared with normal puppies with mean duodenal mucosal layer measuring 1.7 mm and jejunal mucosal layer 1.0 mm. A mucosal layer with diffuse hyperechoic speckles was seen in the duodenum (15%) and the jejunum (50%). The luminal surface of the duodenal mucosa was irregular in 22.5% and the jejunal mucosa in 42.5%.

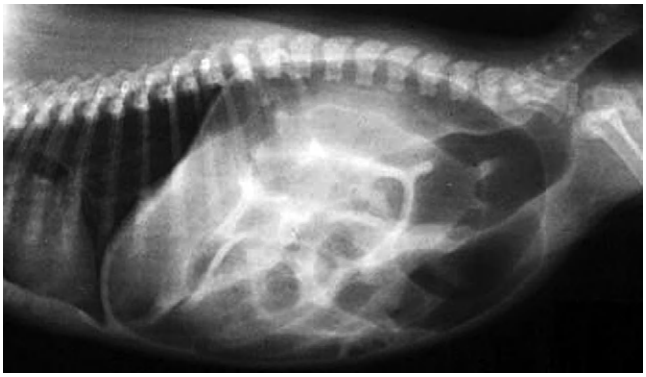

Figure 57-27 Survey lateral radiograph of a 4-month-old mixed-breed puppy with severe intestinal distention and chronic intestinal pseudoobstruction.

Changes were accompanied by generalized indistinct wall layering in all animals. A mortality rate of 30% was found in this patient population.[41]

Radiation Enteritis

Radiation produces a variety of changes in GI tract motility and ileus is a common clinical finding.[42] Most of the changes observed with radiation enteritis occur in other pathologic states. These include delayed gastric emptying, retrograde giant contractions and vomiting, giant migrating contractions, and abdominal cramping and diarrhea.[43] The threshold for these contractile events to occur and their control mechanisms are incompletely understood. Many studies suggest that treatment (i.e., 5-HT_3 antagonists) prior to exposure may be the best method to prevent the contractions from occurring. The role of dose rate is unclear. Within hours of a significant exposure to radiation, these contractions begin to occur and contribute significantly to the early stages of radiation illness.

Idiopathic Intestinal Pseudoobstruction

Etiology

Chronic intestinal pseudoobstruction is defined by the presence of chronic intestinal dilation and dysmotility in the absence of mechanical obstruction.[44] In humans, chronic intestinal pseudoobstruction has many causes that have been simplified into abnormalities of enteric smooth muscle (myopathies) and the enteric nervous system (neuropathies).[40] Such visceral myopathies and neuropathies are primary causes of chronic intestinal pseudoobstruction, and myopathies are either familial, or sporadic and idiopathic. Pseudoobstruction can also arise secondary to other underlying disorders, such as progressive systemic sclerosis, amyloidosis, muscular dystrophy, generalized neuromuscular diseases, endocrinopathies, infectious disease, and drug toxicity.[40]

Pathophysiology

Only 11 cases of chronic intestinal pseudoobstruction have been reported in companion animals (nine dogs and two cats).[44-49] Four dogs had atrophy, fibrosis, and mononuclear cell infiltration of the muscularis externa similar to what is observed in progressive systemic sclerosis in humans. Two dogs had atrophy of the muscularis externa but not fibrosis, either with or without mononuclear cell infiltration, whereas one dog had hyperplasia of the circular muscle without atrophy, fibrosis, or inflammation. In only two reported dogs with pseudoobstruction was the pathology described as primarily affecting the circular or longitudinal smooth muscle. Only two reports mention myocyte vacuolar degeneration, but it was not a prominent feature and marked myenteric plexus vacuolar degeneration was present, suggesting an underlying primary neuropathy. One of the cats reported with pseudoobstruction actually had diffuse intestinal lymphosarcoma with no additional histopathologic details.

Clinical Signs

As with visceral myopathy, the primary clinical signs seen with chronic intestinal pseudoobstruction are anorexia, intermittent vomiting, and diarrhea. Signs may be referable to one segment of the gut, but the disease is usually diffuse.

Diagnosis

Abdominal imaging showing intestinal dilation with no evidence of mechanical obstruction is the hallmark of the pseudoobstruction. Full-thickness intestinal histology is required to identify underlying causes of chronic intestinal pseudoobstruction.

Treatment

Because of the diffuse nature of the disease, surgical resection of diseased intestine is not generally recommended. Resection only benefits selected patients with localized disease. Medical therapy should otherwise be aimed at correcting electrolyte and acid–base disturbances, treating infection or sepsis, supporting nutritional needs, suppressing the inflammatory or immune response, and instituting prokinetic therapy (see Chapter 52).[44-49]

Prognosis

Aside from the apparent recovery reported in one cat with visceral myopathy, most of the cases of chronic intestinal pseudoobstruction had a poor outcome.

Hypothyroidism

Untreated or poorly regulated hypothyroidism is associated with important changes in GI motility. Compared with euthyroid dogs, thyroidectomized dogs have decreased frequency of electrical control activity of the stomach and jejunum, decreased occurrence of electrical response activity (spike potentials) following stimulation, and decreased mechanical response to feeding.[50]

NEOPLASIA

Philip J. Bergman

Incidence and Risk Factors

The first publication of a canine intestinal tumor was by Schlotthauer and Grindlay in 1951.[1] Since then a variety of investigations have increased our understanding of the biology of intestinal tumors. In most studies the incidence of intestinal tumors is reported to be less than 10% of all tumors,[2-7] and intestinal tumors represent approximately one-fifth (dogs) to one-third (cats) of all alimentary tumors.[8] The most common intestinal tumor in most studies is lymphoma, comprising one-third of all feline tumors compared with approximately 6% in dogs.[2,4]

Small intestinal neoplasia occurs typically in older dogs (mean age: 6 to 10 years) and cats (mean age: 10 to 13 years).[2,9-17] The mean age for feline alimentary lymphoma was younger when FeLV was more prevalent.[18-20] Although not significant, there is a slight male predisposition for canine intestinal tumors,[13,15] but this is less clear in cats.[9,21-23] Approximately 90% of dogs with GI lymphoma and 80% with leiomyoma/leiomyosarcoma are male.[16,24,25]

Large breeds of dogs (e.g., German Shepherds, Collies) appear to be most at risk for small intestinal neoplasia, specifically adenocarcinoma,[14,26] but leiomyosarcomas were reported to be rare in working military German Shepherd and Belgian Malinois dogs.[27] Siamese cats are consistently reported to be predisposed to intestinal lymphoma and adenocarcinoma, with one study suggesting an eightfold increased risk.[2,9,21,28]

There are no known chemical agents or microorganisms that are reliably associated with increased risk for intestinal neoplasia in dogs. The same is true for cats except for the clear associations with FeLV and feline immunodeficiency virus.[29-32] Most cats with intestinal lymphoma are older and FeLV-negative by serology, but a significant portion of these cats are positive for FeLV by immunohistochemistry or PCR studies of the tumor tissue.[33] Of further note is the change in presentation of feline lymphoma that occurred in recent decades. When the prevalence of FeLV was high, the most common presentation of feline lymphoma was of cranial mediastinal and multicentric disease in young, FeLV-positive cats, whereas now the most common presentation is of an older, serologically FeLV-negative cat with alimentary lymphoma.[18,34]

The risk of gastric cancer is greatly increased in people with *Helicobacter pylori* infection,[35,36] but this association has not been confirmed in dogs or cats to date. One domestic cat and a cougar were found to have concurrent *Helicobacter* infection and intestinal neoplasia (lymphoma in the domestic cat and intestinal adenocarcinoma in the cougar), but these studies do not allow for delineation of causation.[37,38] Based on the lack of a large number of reported concurrent cases of *Helicobacter* and intestinal neoplasia in cats, in addition to the fact that some cats normally shed *Helicobacter* sp., this agent at present appears to play minimal to no role in the induction of feline intestinal neoplasia and may be part of the normal feline GI flora.[39,40]

Pathology and Biologic Behavior

A large number of different types of neoplasia can be found in the intestine, including epithelial (e.g., carcinoma or adenocarcinoma), neuroendocrine, mesenchymal (e.g., sarcoma) or discrete/round cell neoplasia.[17] Most small intestinal neoplasia in dogs and cats is malignant, whereas more distal areas of the GI tract tend to have more benign disease. Lymphoma is the most common intestinal tumor with a variety of reported subtypes including lymphoblastic, epitheliotropic, lymphocytic, and large granular lymphocytic (also called granulated cell tumor or globule leukocyte lymphoma).[14,20,23,24,41-49] The predominant immunophenotype in feline intestinal lymphoma has historically been considered to be tumors of B-cell origin arising from germinal centers and Peyer patches; however, more recent literature suggests that B-cell predominance is no longer the case.[23,50,51] The presence of FeLV in the tumor is not now associated with immunophenotype, contrary to previous reports of younger, serologically positive cats with primarily T-cell immunophenotypes.[18,50] Approximately 80% of cats and 25% of dogs will have distant spread of alimentary lymphoma at presentation or surgery.[21,24] Although lymphoma is often thought to be a systemic disease in dogs, additional study is necessary to better delineate the metastatic propensity of solitary canine GI lymphoma, and therefore the potential need for chemotherapy in addition to local treatment options.

Most cats with epitheliotropic or large granular lymphocytic intestinal lymphoma are serologically FeLV-negative. Large granular lymphocytic intestinal lymphomas are generally very aggressive tumors, typically have heterochromatic granules, and are perforin-positive on immunohistochemistry.[46,52-54]

The second most common intestinal tumors are those of epithelial origin including adenocarcinoma (glandular), solid or undifferentiated carcinoma (no glandular formation), mucinous carcinoma (>50% mucinous), and signet ring carcinoma (>50% of the cells producing copious mucin which thereby gives a signet ring cytologic phenotype).[2,9,14] The most common sites of metastasis of an intestinal carcinoma are the lymph node, liver, lung, omentum, mesentery, spleen, bone, kidney, peritoneum (e.g., carcinomatosis), skin, and testes.[12,55-58]

The third most commonly reported intestinal neoplasm in dogs is of smooth muscle lineage (leiomyoma and leiomyosarcoma).[15-17,59-61] A more recently reported variant of leiomyosarcoma and occasionally leiomyoma in dogs is the GI stromal tumor (GIST).[25,62,63] GISTs are generally more commonly noted in the large intestine, but are reported arising in the SI and stomach. On immunohistochemistry, GISTs are typically vimentin-positive, cytokeratin-negative, and CD117 (c-kit, a transmembrane tyrosine kinase)-positive, and have minimal expression of smooth muscle actin. CD117-positive tumors (e.g., GISTs) may have a lower metastatic rate than CD117-negative leiomyosarcomas.[25,64]

Less common tumors of the canine SI are carcinoid, mast cell tumor (the third most common intestinal tumor in the cat), extraskeletal osteosarcoma, ganglioneuroma, hemangiosarcoma, and extramedullary plasmacytoma. Carcinoids are of neuroendocrine origin and contain secretory granules comprising a variety of substances including gastrin, secretin, serotonin, and somatostatin.[10,17,65] Primary intestinal carcinoids are locally aggressive and commonly metastasize to the liver.[10,66] Primary intestinal mast cell tumors are relatively common in cats, but rare in dogs.[67-71]

History and Clinical Signs

Clinical signs in dogs and cats with SI neoplasia include diarrhea, vomiting, weight loss, anorexia, melena, and possibly signs associated with nephrogenic diabetes insipidus (associated with smooth muscle tumors) or anemia. Clinical signs associated with obstruction, perforation, and/or peritonitis also are possible in severe cases. Clinical signs associated with paraneoplastic syndromes from small intestinal neoplasia include cutaneous, hyperviscosity, biochemical, and hematologic syndromes.[72-74] GI leiomyosarcoma is reported to be associated with nephrogenic diabetes insipidus.[75] The duration of clinical signs prior to presentation can be variable and range from 1 to 2 days to months, with an average of 4 to 8 weeks.[12,24,75]

Diagnosis

Physical Examination

Small intestinal neoplastic masses may be palpable in approximately 20% to 50% of dogs and 50% to 85% of cats.[9,12,13,23,24,45,55,76] Additional physical examination findings reported in dogs and cats with small intestinal neoplasia include dehydration, pain, and/or fever.[9,24,55]

Clinical Pathology

The most common finding on clinical pathology screening is anemia. This may reflect anemia of chronic disease, but is more commonly due to blood loss into the GI tract, which may then cause melena and possibly elevation in blood urea nitrogen.[12,13,15,16,23,45,55] Other changes include leukocytosis, monocytosis, and/or a left shift.[9,12,15,23,55] Serum biochemical changes include hypoproteinemia consistent with blood loss, elevations in alkaline phosphatase, and hypercalcemia (most common with lymphoma but reported across a variety of tumor types).

Diagnostic Imaging

Plain abdominal radiographs are reported to be diagnostic for an abdominal mass in approximately 40% to 50% of dogs and cats with small intestinal neoplasia.[9,12,15,24,45,55] Although difficult to offer precision across studies because of variability, a theme emerges whereby the percentage of cases with an abdominal mass on plain films is higher in dogs and cats with solid intestinal neoplasia and lower with lymphoma. This reduced ability to delineate an abdominal mass on plain films in patients with lymphoma is likely caused by numerous factors including the potential for diffuse lesions and/or the presence of peritoneal effusion and/or other organ involvement. The frequency of obstructive patterns noted on plain films in dogs and cats with intestinal neoplasia varies between studies. Because of the advent of, and widespread use of, abdominal ultrasound, use of contrast radiography has waned in the last 5 to 10 years, but this technique will find filling defects in approximately 50% to 90% of dogs or cats with intestinal neoplasia.[9,24] Three-view thoracic radiographs should be performed as part of routine staging in any case with an abdominal mass or strong suspicion of an abdominal mass. As many intestinal tumors often do not metastasize to the lungs, this is typically a low-yield procedure when staging for small intestinal neoplasia. Nevertheless it should be performed as the presence of metastasis would signal a very significant change in prognosis and therapy.

The use of abdominal ultrasound has revolutionized the diagnosis of intestinal neoplasia. Abdominal ultrasound is a much more sensitive diagnostic tool than radiography for the identification of an intestinal mass[12,13,16,26,77]; however, abdominal ultrasound alone is not diagnostic. The most frequent abdominal ultrasound changes noted in dogs and cats with intestinal neoplasia are loss of normal bowel wall layering and increased bowel wall thickness. Ninety-nine percent of dogs with intestinal neoplasia have loss of bowel wall layering, while 88% of dogs without intestinal neoplasia retain normal bowel wall layering. In addition, dogs with focal abdominal ultrasound lesions are approximately 20 times more likely to have neoplasia, and dogs with bowel thickness greater than 1 cm are at four times greater risk of neoplasia.[78] The advantages of abdominal ultrasound over plain and/or contrast radiography include (a) evaluation of other sites within the abdomen, (b) delineation of the presence or absence of carcinomatosis, (c) less time-consuming than contrast radiography, and (d) additional diagnostic utility gained through abdominal ultrasound-guided fine-needle aspirate or needle-core biopsy.[13,26,79] Other findings commonly reported with abdominal ultrasound in patients with small intestinal neoplasia include mixed echogenicity asymmetric lesions, diffusely thickened bowel loops, anechoic to hypoechoic mass lesions, and in patients with carcinomatosis, the presence of masses in the "double-sheet" region of the peritoneum where the parietal and visceral portions meet, and the presence of free fluid.[79]

Endoscopy

The use of endoscopy for the diagnosis of small intestinal neoplasia has become more commonplace over the last 10 to 20 years. Unfortunately, endoscopy has potentially significant limitations depending on the anatomic site of the tumor and the ability of the endoscope to reach the affected area. The gross appearance of neoplasia on endoscopy can range from a mass effect, to reduced dispensability of an otherwise phenotypically normal area, to a "cobblestone" and/or focal erythremic effect.[76] An additional limitation to endoscopy is the size of the biopsy sample obtained, which can lead to significant interobserver variation in histopathologic interpretation.[80] One study of feline lymphoma compared endoscopic samples with full-thickness biopsy samples collected at laparotomy. In that investigation, lymphoma was diagnosed in 10 cats from full-thickness samples, but in only three cats with endoscopic samples.[81] For those cats with gastric lymphoma, endoscopic sampling diagnosed three of four cases, whereas in cats with intestinal lymphoma none of the six cats were diagnosed by endoscopic sampling. A similar study in dogs comparing endoscopic versus full-thickness sampling had comparable outcome.[24]

Laparoscopy

The use of laparoscopy to diagnose and/or treat intestinal neoplasia has increased in the last 5 years because of increased operator proficiency and more widespread availability of the equipment.[82,83] The morbidity and surgical procedure time are greatly reduced when using laparoscopy compared to laparotomy; however, the lack of intraluminal viewing can be a significant limitation of the technique when the lesions are not producing a mass and/or full-thickness effect.

Laparotomy

Exploratory laparotomy is considered the gold standard when minimally invasive techniques are unable to provide a diagnosis of intestinal neoplasia in patients with signs of persistent and/or resistant intestinal disease. There are numerous advantages to laparotomy compared with other techniques including the ability to take full-thickness biopsies, the direct visualization of the entire abdomen, and the ability to perform therapeutic resection and anastomosis and/or placement of feeding tubes.

Treatment

Surgery

The gold standard of treatment for most intestinal neoplasia, except for lymphoma, is surgical excision. This means of gross local tumor control is possible when there is no evidence of lymph node metastasis, carcinomatosis, other distant metastasis and/or adhesions or serosal-specific abnormalities that would prevent full extirpation. In patients with lymphoma causing intestinal obstruction and/or perforation, or when diagnosis is not possible through other less-invasive means, surgery may be used for diagnosis and/or treatment.

Perioperative mortality rates are high and average 30% to 50% in patients undergoing surgery for intestinal neoplasia. The causes of such mortality include peritonitis, sepsis, and euthanasia as a consequence of the presence of gross metastasis and/or lack of resectability.[12,16]

Chemotherapy

The use of adjuvant chemotherapy after surgical resection of an intestinal epithelial tumor is relatively controversial because of the

paucity of publications. Survival greater than 1.5 years was reported in two dogs with intestinal adenocarcinoma after surgery and adjuvant chemotherapy.[13] A retrospective evaluation of adjuvant doxorubicin in cats with colonic adenocarcinoma reported a median survival time of approximately 9 months with doxorubicin versus 2 months without it.[11] It is unknown if similar results would be afforded in larger scale prospective trials of dogs or cats with small intestinal epithelial malignancies. Another study reported the use of chemotherapy in dogs with leiomyosarcoma to have variable outcome, with some dogs having long survival without chemotherapy after surgery.[16] Additional research is required to determine the usefulness of adjuvant chemotherapy in small intestinal nonlymphoid malignancies.

The use of chemotherapy in the treatment of intestinal lymphoma is less controversial; however, outcomes can be variable depending on species, anatomic site, histopathologic subtype, etc.[20,45,84,85] For example, in cats with a diagnosis of intestinal IBD or low-grade lymphocytic lymphoma (which can be difficult to distinguish histopathologically), cats treated with pulse-dose Leukeran and corticosteroid had a median survival approaching 2 years, whereas cats with intestinal lymphoblastic lymphoma treated with the same protocol had a median survival of only 3 months.[85] Few publications report outcomes of chemotherapy in dogs with intestinal lymphoma. In one case series, all eight dogs with intestinal lymphoma treated with chemotherapy were euthanized within 14 weeks.[24] Anecdotally, I believe that dogs with intestinal lymphoma often have very short survival.[14]

Radiation Therapy

Radiation therapy is rarely used in the treatment of intestinal neoplasia. There are significant toxicity concerns with the use of radiation therapy on the intestine and surrounding viscera, and it would be difficult to localize the same area of treatment for daily fractions in typical radiation therapy prescriptions because of intestinal motility.

Prognosis and Prognostic Factors

Canine Carcinoma and Adenocarcinoma

The prognosis for dogs with intestinal carcinoma or adenocarcinoma is guarded to poor. Investigators have found a 12-day survival time in dogs not treated with surgery compared with survival ranging from 4 to 10 months (40% 1-year survival) when treated surgically.[12,13,55] Unfortunately, these poor survival times are most likely a result of a high metastatic rate. In dogs with intestinal epithelial malignancies, 40% to 50% metastasize to local lymph nodes, 30% to 40% metastasize to the liver, and approximately 10% to 20% metastasize to distant sites.[10,12,55] The importance of the presence of lymph node metastasis is further highlighted by a report documenting a median survival time of dogs treated with surgery of 15 months (67% survival at 1 year) compared with only 3 months (20% survival at 1 year) when lymph node metastases were present.[12] Similarly, male dogs with intestinal epithelial malignancies were reported to have prolonged survival time compared with females.[13]

Differential expression levels of tenascin-C and vesicant are reported to occur between benign and malignant lesions in dogs, but these studies have not documented prognostic import within malignancies.[86,87] p53 is the most commonly mutated tumor-suppressor gene in human oncology and overexpression is commonly associated with immunohistochemical overexpression. Overexpression of p53 is uncommon in canine small intestinal epithelial malignancies with 15% to 23% expression noted across two studies.[88,89] In addition, p53 expression did not appear to correlate with the degree of malignancy of the tumors. COX-2 is commonly overexpressed in canine and feline small intestinal epithelial tumors and therefore the use of nonsteroidal antiinflammatory agents may represent a rational treatment approach in the primary setting with nonresectable disease or alternatively in an adjuvant setting.[90,91] To date, the only nonsteroidal antiinflammatory drug (NSAID) with a documented in vivo antitumor effect is piroxicam.[92,93] I believe that from an evidence-based medicine perspective the lead NSAID for antitumor use should continue to be piroxicam until further in vivo studies with NSAIDs of improved safety profile become available.

Canine Lymphoma

There are few publications examining outcomes for dogs with intestinal lymphoma, but as discussed previously all eight dogs with intestinal lymphoma treated with chemotherapy were euthanized within 14 weeks.[24]

Other Canine Tumors

The prognosis for dogs with leiomyosarcoma remains guarded with median survival times after surgery of 7.5 to 24 months.[15,16,64] Dogs with visceral metastasis from a leiomyosarcoma that underwent surgical removal of the primary tumor had a median survival time of almost 2 years, suggesting that metastasis may not be a strong prognostic factor.[16] When dogs with a GIST had surgical removal of the lesion, their overall median survival time was only 1 year, whereas if the large percentage of dogs with perioperative deaths were censored, the median survival time increased to approximately 3 years.[64] Maas and colleagues reported 62.6% and 52.3% 1- and 2-year survival rates, respectively, for dogs with intestinal GIST undergoing surgery.[63] Intestinal perforation was not a negative prognostic factor.[16]

Feline Carcinoma and Adenocarcinoma

The prognosis for cats with intestinal epithelial malignancies is guarded to poor. The median survival time of cats with intestinal epithelial malignancies not treated with surgery is only approximately 2 weeks,[9,55] whereas those cats taken to surgery can have high perioperative mortality rates.[56] For cats surviving the perioperative period, the median survival times are 5 to 15 months.[9,28] This prognosis is likely a result of the increased metastatic rate of epithelial malignancies in this anatomic location as approximately 50% metastasize to local lymph nodes, approximately 30% cause carcinomatosis, and approximately 20% have distant metastasis.[2,55,56] Cats with carcinomatosis may benefit from removal of the primary tumor, but this likely requires additional study because of the very small number of cats reported (n = 2).[9] The use of intracavitary chemotherapy for carcinomatosis in cats has not been examined to date; however, promising preliminary results have been noted in dogs.[94]

Feline Lymphoma

The prognosis for cats with intestinal lymphoma is variable because of a wide variety of factors. The combination of surgery and chemotherapy has no benefit over chemotherapy alone,[51] but there were only 21 cats in this study and it was not a randomized trial. I believe that for cats with a solitary intestinal lymphoma lesion, surgery should be seriously contemplated as it is one of the quickest and least-expensive mechanisms of tumor cytoreduction, especially in light of the relative chemotherapy resistance of feline lymphoma. FeLV status was highly prognostic for feline intestinal lymphoma

with FeLV-positive cats treated with chemotherapy having a median survival time of 3 months versus 17 months if the cats were FeLV-negative (but this was only true in cats with early stage lymphoma and not significant in cats with later-stage neoplasia).[19] Another study reported the primary prognostic factors to be FeLV status, substage, and response to therapy,[34] but in other studies FeLV status was not prognostic.[51,84] Immunophenotype is not of prognostic benefit in dogs or cats with intestinal lymphoma, but this may be a result of poor statistical power from small numbers of cases reported to date.[51] Labeling of argyrophilic nucleolar organizer regions is negatively correlated to clinical outcome in a variety of malignancies across species, but for feline alimentary lymphoma argyrophilic nucleolar organizer regions were not associated with duration of remission, percentage of remission, or survival time.[95] Median remission for cats with intestinal large-cell lymphoma is 5 to 7 months, but subsets that are poorly understood to date can have extended survival times.[45,84,85]

Other Feline Tumors

Cats with duodenal polyps have an excellent prognosis. One previous investigation determined that cats with surgically removed duodenal polyps were cured of their disease.[22]

Comparative Features

Small intestinal neoplasia is uncommon in humans, where there is a much higher incidence of large intestinal cancer. The reverse holds in small animal medicine where small intestinal tumors are much more common than those of the large intestine. The reasons for this difference are unknown but likely to involve differences across the species related to diet, genetics, toxin exposures, and/or physiology. Risk factors noted to date for small intestinal epithelial neoplasia in humans includes increased intake of fatty foods, red meats, high-temperature grilled meats, and salt-cured food products.[96] Risk factors noted to date for small intestinal lymphoma include celiac disease which may progress from IBD to overt lymphoma.[97]

Chronic use of COX-2 inhibitors reduces intestinal neoplasia in a variety of studies by approximately 50%.[98] Significant similarities across species are likely to exist in the potential use of COX-2 inhibitors for small intestinal epithelial tumors. Similarly, the use of tyrosine kinase inhibitors for GISTs across species is likely a result of the aforementioned commonly noted mutations in c-kit.[99]

The principles of diagnosis and treatment are similar across species. Minor differences exist in the more common use of CT scanning for the diagnosis of small intestinal neoplasia in people compared with its current use in veterinary medicine.[100] The use of tyrosine kinase inhibitors in unresectable and/or metastatic GISTs in people is commonplace, suggesting that the use of tyrosine kinase inhibitors in the same setting in dogs or cats may have potential utility.[99] There is a similar dearth of literature concerning the effectiveness of chemotherapy in the adjuvant treatment setting for people with small intestinal epithelial malignancies.[101]
