CHAPTER 58

Large Intestine

STRUCTURE AND FUNCTION

Robert J. Washabau

The large intestine of the dog and cat has evolved to serve two major functions: extraction of water and electrolytes from the fluid contents of the lumen and control of defecation. The large intestine accomplishes these functions by regulating fluid transport, bacterial fermentation, motility, immune surveillance, and blood flow. Sodium and water absorption serve to dehydrate the feces prior to defecation; mucus glycoproteins serve to trap bacterial pathogens and prevent bacterial translocation; epithelial cells, lymphocytes, plasma cells, macrophages, and dendritic cells serve to regulate the bacterial flora and the immune response to microbes; and motility serves to facilitate storage or defecation of feces. Perturbations in any of these functions may result in the problems of diarrhea, constipation, or systemic inflammatory response syndrome.

Structure

Macroscopic Anatomy

The large intestine consists of the cecum, colon, rectum, and anal canal (Figure 58-1). In dogs and cats, the ileum communicates directly with the colon, and what is referred to as the cecum in the dog and cat is actually a diverticulum of the proximal colon. The colon is further compartmentalized into ascending, transverse, and descending portions, each segment having slightly different functions and properties. The right colic or hepatic flexure separates the ascending and transverse colon, and the left colic or splenic flexure separates the transverse and descending colon. In dogs and cats, the large intestine contributes 20% to 25% of the total (small and large) intestinal length.[1,2]

The arterial blood supply to the colon is provided by the cranial and caudal mesenteric arteries, and venous return from the colon is transmitted to the main portal vein via the cranial and caudal mesenteric veins. Lymph is circulated from the colon to the right, middle, and left colic lymph nodes, and eventually into the cisterna chyli and thoracic duct. Parasympathetic innervation arises from the vagus nerve in the proximal colon, and from the pelvic nerves in the distal colon. Sympathetic innervation arises from the paravertebral ganglia and follows the lumbar splanchnic nerves and mesenteric arteries to the colonic mucosa and muscularis. Parasympathetic preganglionic fibers and sympathetic postganglionic fibers synapse on cell bodies and neurons of the enteric nervous system, respectively.

Microscopic Anatomy

As with the small intestine, the cross-sectional structure of the large intestine consists of four distinct layers, that is, mucosa, submucosa, muscularis, and serosa (Figure 58-2). The large intestine differs from the small intestine in the following important ways: villi are absent in the large intestine; the microvilli of the large intestine epithelial cells are much less abundant; goblet cells are more prominent in the large intestine; endocrine cells are less prominent in the large intestine; and crypt-to-epithelial migration is a much slower process in the large intestine.

The mucosa of the large intestine is a flat absorptive surface area differing from the small intestine in that villi are not present. However, numerous straight tubular glands (400 to 600 μm) are present in parallel cylinders and they extend from the muscularis mucosa to the mucosal surface.[3] The glands are lined by a continuous sheet of columnar epithelial cells, which are separated from the mesenchymal tissue of the lamina propria by a well-defined basement membrane. The epithelium in the lower half of the crypts is composed of proliferating undifferentiated columnar cells, mucus-secreting goblet cells, and at least three types of endocrine epithelial cells.[4] Cellular proliferation is predominantly in the lower part of the crypts in both dogs and cats. The epithelium of the upper half of the crypts consists of differentiating columnar cells, goblet cells, and a few endocrine cells. The flat absorptive surface is lined by many columnar cells as well as a moderate number of goblet cells (10 to 25 goblet cells per 100 epithelial cells),[3,5] most of which are largely depleted of their mucous granules. Intraepithelial lymphocytes are relatively sparsely distributed throughout the epithelium (one to seven lymphocytes per 100 epithelial cells),[3,5] and as in the small intestine, the predominant T cell subset is the cytotoxic-suppressor (CD8+) type.[6,7] The cellular elements of the lamina propria of the large intestine resemble closely those found in the small intestine and include lymphocytes, many plasma cells, mast cells, macrophages, eosinophils, enteric neurons, and fibroblasts.

The innermost layer of the mucosa is separated from the submucosa by the muscularis mucosae, a layer of smooth muscle cells roughly eight to 10 cells (or 70 to 80 μm) thick. The submucosa of the colon resembles the submucosa of the other tubular digestive organs. It contains many blood and lymph vessels, dense connective tissue sparsely infiltrated by cells (fibroblasts, lymphocytes, plasma cells, mast cells, macrophages, and eosinophils), and the unmyelinated nerve fibers and ganglion cells that form the submucosal plexus.

The muscularis is composed of an inner circular muscular layer forming a tight spiral circumferentially along the course of the colon and an incomplete outer longitudinal muscle layer. The ganglion cells of the myenteric plexus of Auerbach are found between the

(Reprinted with permission from Washabau RJ: Diseases of the large intestine. In: Ettinger SJ, Feldman ED, editors: *Textbook of Veterinary Internal Medicine*, ed 6, Philadelphia, 2005, Saunders, p 1379.)

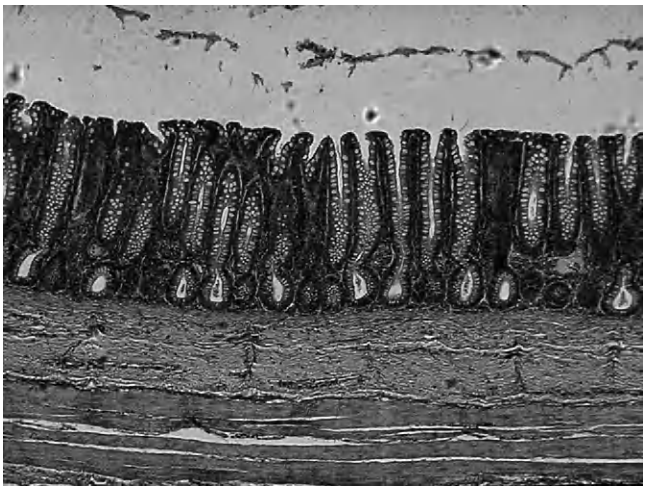

Figure 58-2 Microscopic anatomy of the canine colon. (Reprinted with permission from Washabau RJ: Diseases of the large intestine. In: Ettinger SJ, Feldman ED, editors: *Textbook of Veterinary Internal Medicine*, ed 6, Philadelphia, 2005, Saunders, p 1379.)

circular and longitudinal muscle layers. Unmyelinated postganglionic fibers are also found in the circular muscle layer and communicate with the submucosal (Meissner) plexus. The interstitial cells of Cajal, which are located on the submucosal surface of the circular smooth muscle, play a dual role as pacemaker cells and as mediators of neuromuscular transmission in the colon.[8-10]

The serosa is composed of mesothelial cells and covers only the portions of the large bowel that lay within the peritoneal cavity (cecum and colon).

Several classification systems for colonic mucosal architecture and cellularity have been proposed (see Chapter 29).[1,3,11] It should be emphasized that there are important age,[12] site,[1,3] diet,[13-16] and procedure-related[3] differences in the cellularity and architecture of the colonic mucosa, and these differences must be taken into account when interpreting colonic histology. For example, the protein and fiber content of the diet have significant effects on colonic mucosal morphology (e.g., crypt depth and cellularity).[14-16] The pathologist should always take these factors into account when interpreting colonic biopsy specimens. The method of biopsy also influences the architecture and cellularity of the mucosa. Compared to full-thickness biopsies, gland length is 25% to 30% shorter and goblet cell numbers are 70% to 75% less in endoscopic biopsies from the same animals. The shallow depth of the endoscopic biopsy apparently causes glandular collapse, and enema or cathartic preparative solutions are believed to cause discharge of mucous goblets.[3,11]

Function

Mucus Secretion

A lubricant layer of mucus forms a crucial physiologic barrier between the colonic mucosa and the luminal environment. Mucus is a constantly changing mix of secretions and exfoliated epithelial cells, the chief determinants of which are high-molecular-weight glycoproteins or mucins.[17] Gastrointestinal mucins are secreted from goblet cells as they ascend from their origin in the crypts up to the colonic epithelium. Mucin secretion is dependent upon the close integration of the cystic fibrosis transmembrane regulator (CFTR), chloride secretion, and granule exocytosis. In addition to their physiologic role as a mucosal barrier, mucins may also have a pathologic role in the metastases of epithelial tumors and enhanced susceptibility to infection.

Water Absorption

In health, approximately 2.7 L of fluid (oral intake, saliva, gastric fluid, bile, pancreatic fluid, and intestinal secretions) is presented each day to the small intestine of a 20-kg dog. Approximately 1.35 L

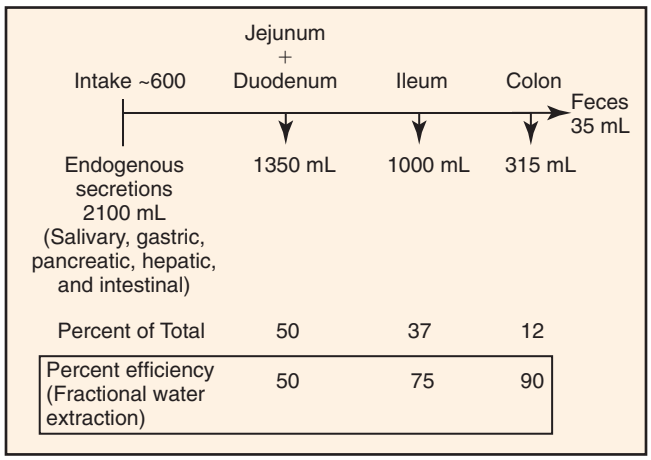

Figure 58-3 Regional daily net water turnover in the canine gastrointestinal tract. (Approximate figures: 20 kg dog, mL/24 h) (Reprinted with permission from Burrows CF: Chronic diarrhea in the dog. *Vet Clin North Am Small Anim Pract* 13:521, 1983.)

is absorbed in the jejunum, 1.0 L in the ileum, and 315 mL in the colon, leaving 35 mL in feces.[18] Thus, the jejunum absorbs 50%, the ileum 75%, and the colon 90% of fluid volume presented to it (Figure 58-3). This fluid absorptive capacity of the colon is largely determined by basal electrolyte (primarily sodium) transport and by the ability of several agonists (aldosterone and glucocorticoids) to augment electrogenic and electroneutral Na absorption. As long as ileocecal flow is less than the colonic absorptive capacity, significant alterations in small intestinal fluid movement may be present, but colonic absorption will prevent the development of diarrhea. On the other hand, when small intestinal absorption and ileocecal flow are normal, a relatively small decrease in colonic absorption (inflammatory bowel disease) will produce significant increases in fecal water output.

Electrolyte Transport

The large intestine regulates the electrolyte and water composition of the feces. There are distinct differences in the mechanisms of electrolyte transport between the ascending and descending colon,[19,20] but in general the canine and feline colon absorbs water, sodium, and chloride while secreting potassium and bicarbonate.

In many ways, the mechanisms of absorption and secretion in the large intestine are similar to those of the small intestine, but there are several important differences (Table 58-1). Active nutrient (glucose, amino acid, monoglyceride) transport is prominent in the small intestine, but there is no evidence of active glucose or amino acid absorption in the colon except during the early neonatal period. Sodium transport also differs in the colon. Glucose- and amino-acid–stimulated sodium transport is a well-established property of the small intestine, so much so that oral glucose-electrolyte solutions have been used to reduce the morbidity of cholera and other infectious diarrheal diseases of the small intestine. In contrast, glucose-coupled sodium transport does not take place in the colon and glucose-electrolyte solutions are of no benefit in diarrheal diseases of the large intestine. Sodium transport in the colon instead relies upon electrogenic transport.[20,21] The large intestine also differs in its response to mineralocorticoids. Aldosterone markedly increases sodium transport in the colon, but it has only a modest effect in the small intestine. Net sodium absorption ceases in the colon only when the luminal sodium concentration is reduced below 30 to 50 mEq/L, whereas net sodium absorption in the jejunum occurs only at luminal sodium concentrations above 130 mEq/L.[21]

Table 58-1 Special Features of Colonic Electrolyte Transport

	Small Intestine	Large Intestine
Water	Yes	Yes
Amino acid + glucose absorption	Yes	No
Lipid absorption	Yes	No
Glucose-stimulated Na absorption	Yes	No
Electrogenic Na absorption	No	Yes
Mineralocorticoid-stimulated Na absorption	Negligible	Significant

Chloride absorption in the colon has both passive and active properties. Passive chloride absorption primarily represents a potential–dependent process secondary to the electrical potential generated by electrogenic Na absorption.

Bicarbonate secretion is an important feature of colonic electrolyte function and helps to neutralize acids produced by bacterial fermentation. Chloride-bicarbonate ($Cl\text{-}HCO_3$) exchange is the primary cellular mechanism responsible for bicarbonate secretion.

The descending colon possesses both potassium absorptive and potassium secretory processes that are regulated by luminally and hormonally mediated mechanisms, and the overall net potassium movement represents the balance of these oppositely directed transport mechanisms.[20,21] The colon, therefore, has the potential to serve as an important regulatory system for the maintenance of overall potassium balance. Although renal potassium transport is critical in the overall control of potassium balance, the colon also contributes to the maintenance of potassium balance by modifying both potassium secretion and absorption, especially when kidney function is impaired.

Immune Surveillance

The colon contains a diverse array of immune cells, including T and B lymphocytes, plasma cells, macrophages, dendritic cells, antigen-presenting cells, mast cells, eosinophils, and neutrophils.[3,5-7,22-25] Immune cells are found in the epithelium, lamina propria, and submucosa of the colon. As in the small intestine, appropriate interactions between these different cell types are essential in generating either immune responsiveness or tolerance to the large array of luminal antigens.[26,27] Much less is known about colonic immunity, but some generalizations may be made. In the colon, CD8+ T cells are found primarily in the epithelium; very few CD8+ T cells are found in the lamina propria or submucosa. Most intraepithelial lymphocytes are CD3+/CD8+, a phenotype consistent with suppressor-cytotoxic functions. Lamina propria T cells on the other hand are predominantly of the CD4+ helper phenotype. Immunoglobulin (Ig) A-containing plasma cells are more prominent than IgG- or IgM-containing plasma cells in the lamina propria. Thus, in the normal colonic mucosa, a balance would appear to be maintained between helper and suppressor T-cell populations, which allows specific antigen responsiveness while avoiding hyperreactivity.[5,6,28] There are many similarities in the immune systems at both sites, but there are important differences in the immune response of the small and large intestine.

Motility

The colon has evolved to serve two important functions: extraction of water and electrolytes from the luminal contents in the ascending and transverse colon, and control of defecation in the descending colon. This specialization of function is attributed to regional differences in colonic motility patterns.[29-33] Electrical slow-wave frequency and rhythmic phasic contractions are slower in the proximal portion of the colon, thus facilitating extraction of water from the fecal mass by diffusion and active transport. Retrograde giant contractions (RGCs) and antiperistalsis further facilitate the mixing of contents in the proximal colon. In contrast to that of the proximal colon, motility of the distal colon is characterized primarily by migrating spike bursts and powerful giant migrating contractions (GMCs) that propagate the fecal mass toward the rectum.[4,33]

Colonic smooth muscle generates at least four different types of contractions to perform the complex motility functions of mixing and propulsion: (a) tone, (b) rhythmic phasic contractions (RPCs), (c) RGCs, and (d) GMCs. The time course, frequency, and force generated by each of these contractions are significantly different from each other.[30-33] The precise role of tone in circular muscle cells is not known, but the resulting decrease in the diameter of the colon may enhance the efficiency of the phasic contractions in mixing and propulsion. Tone is normally of small to moderate force and can last for prolonged periods of time (several minutes to hours). RPCs produce mixing and net slow distal propulsion of luminal contents in the postprandial and fasting state. Phasic contractions occur rhythmically at a few cycles per minute, last for approximately 3 to 5 seconds, and generate a moderate force (75 to 100 g). RGCs occur infrequently, last for approximately 20 seconds, generate a very strong force (>150 g), and are propagated from their point of origin into the ascending colon. RGCs facilitate mixing in the ascending colon. The GMCs are of a similar magnitude and frequency to the RGCs, but they generate mass movements from their point of origin to the anorectal junction. It has been suggested that different signal transduction pathways are used by smooth muscle cells to trigger different contractions.[34,35] It is remarkable that the same smooth muscle cells can generate so many different types of contractions using a limited number of second messengers.

Bacterial Fermentation

The colon contains the largest concentration of bacteria in the gastrointestinal tract, up to 10^{11} organisms per gram of feces. The colonic microflora play an important role in the nutrition of the animal primarily via the production of short-chain fatty acids (SCFAs).[36] Major fiber fermentation substrates include cellulose, hemicellulose, and pectin, substrates that typically are not digested by pancreatic or intestinal amylases. Acetate, propionate, and butyrate account for more than 85% of formed SCFAs, and they accumulate in concentrations up to 150 mmol/L in the colon of dogs.[37] SCFAs are rapidly absorbed by the colonic mucosa, are readily metabolized by colonic epithelial cells, and have various physiologic effects. Among their physiologic effects, SCFAs promote differentiation and proliferation of colonocytes,[38] stimulate absorption of water and electrolytes,[39] provide 7% to 10% of an animal's overall energy requirements,[37] and influence or modify motility of the gastrointestinal tract.[40]

The colonic flora is influenced by many factors, including host species, breed, developmental stage, dietary history, environmental conditions, geographic locale, colonic motility patterns, disease, and medication history.

In general, anaerobic bacteria (*Bacteroides* spp., *Bifidobacterium* spp., *Clostridium* spp., and *Lactobacillus* spp.) predominate in the canine colon, accounting for up to 90% of the colonic microflora. Most are facultative or aerotolerant anaerobes, not true obligate anaerobes.[41] Enterobacteria and streptococci are the predominant aerobic bacteria found in the canine colon. In the cat, approximately equal numbers of anaerobic and aerobic bacteria are found in the colonic lumen.[42]

The colonic flora changes significantly with developmental stages. The aging canine colon becomes more readily populated by *Clostridium perfringens* and other obligate anaerobes, and less populated by aerobes and aerotolerant anaerobes.[41,43] This change takes place in the ascending and descending colon, but is most significant in the descending colon where anaerobic conditions tend to predominate. Senescent changes in bacterial populations of the colon conform to the principles of successional ecology.[44] Over time, changes in pH, redox (oxidation-reduction) potential, bacterial competition, and nutrient availability facilitate the proliferation of anaerobic bacteria permitting them to eventually displace the aerotolerant forms.

The colonic flora may also be influenced by an animal's breeding and genetic background. For example, far fewer *Bifidobacterium* spp. are recovered from the feces of Beagle dogs than are recovered from other dog breeds.[43,45] This represents a problem for studies of colonic bacteriology because many of the reference studies have been generated from Beagle dogs.

Diet has a major impact on numbers and types of bacteria recovered from the colon. *Bacteroides* spp. appear to be particularly susceptible to changes in the diet.[45-47] The protein, carbohydrate, and fiber content of the diet all appear to influence the ability of bacteria to grow within the colon. Thus, dietary history should always be considered when interpreting results of fecal or colonic bacterial cultures.

Geographic locale and environmental conditions can also influence colonic bacteriology in the dog. *Bifidobacterium* spp. are readily isolated from dogs from Japan but they are inconsistently found in American dogs.[41,45] Housing conditions appear to be another confounding factor. Open housing environments[41] appear to facilitate colonization of a greater proportion of facultative anaerobic bacteria compared to closed facility conditions.[48]

Motility patterns of the colon influence the bacterial ecology of the colon. The antiperistaltic activity of the ascending and transverse colon particularly facilitates the mixing of fecal material with endogenous bacteria. Abnormalities in the motility patterns of this part of the colon lead to changes and proliferation of obligate anaerobes similar to that which is found in the descending colon.[29]

Disease and medical therapies, particularly antibiotics, alter the microbial characteristics of the colon. These changes are poorly understood in dogs and cats but they very likely contribute to clinical symptomatology (see Chapter 2).

DIAGNOSTIC EVALUATION

Robert J. Washabau

History and Physical Examination

Colitis

History

Inflammation is the most important pathophysiologic condition of the colon. Colitis is responsible for the major clinical signs of

Table 58-2 Clinical Signs Associated with Large Bowel Diarrhea

Signs	Small Bowel	Large Bowel
Weight loss	May be present	Uncommon
Vomiting	May be present	Uncommon
Flatulence	Present with malassimilation	Unusual
Defecation frequency	Normal to mild increase	Marked increased frequency
Fecal volume	Increased	Normal to mild increase
Urgency	Absent	Usually present
Tenesmus	Absent	Usually present
Mucous in feces	Usually absent	Frequently present
Hematochezia	Absent	Often present
Melena	Sometimes present	Absent
Steatorrhea	Present with malassimilation	Absent

hematochezia, mucus in the feces, dyschezia, abdominal discomfort, tenesmus, urgency, and increased frequency of defecation. The colon is an important target organ for inflammatory bowel disease (IBD) in the dog, whereas the upper gastrointestinal tract (stomach and small intestine) is more frequently involved in feline IBD. Clinical signs are useful in localizing the anatomic site of the diarrhea to the small or large bowel (Table 58-2), although some animals will have diffuse involvement of the small and large intestines.

The history should include specific questions about diet, parasite control, environment, travel history, concurrent medical disease, and drug history. Dietary sensitivity reactions[1] and parasitism are major causes of colitis in many pet populations. Dietary history should include information regarding type of diet, incidence of dietary indiscretion, supplements, snacks, and treats. Information concerning previous fecal examinations and anthelmintic usage may provide useful clues to the cause of the diarrhea. Environmental history should identify other pets in the household and the composition of their diets, and any behavioral interactions or hierarchies that might influence the development of clinical signs. The travel history may yield important information about exposure to histoplasmosis, pythiosis, and heterobilharziasis, all of which have regional distributions. Concurrent medical disease (e.g., Addison disease, IBD, pancreatitis) also helps to place the current episode of colitis in context. The drug history should include information about the use of alternative and complementary medicines that could contribute to clinical symptomatology.

Physical Examination

The physical examination may be normal in many cases of colitis. The most consistent physical examination findings are pain and irregularities of the colonic mucosa on digital rectal examination. The perineum should be examined carefully to exclude perineal diseases such as perineal hernia and perianal fistula. Physical examination may reveal other important findings, including *fever* (IBD, cecal or colonic perforation, fungal infection), *abdominal pain* (IBD, colonic neoplasia, cecal or colonic perforation), *abdominal mass* (colonic neoplasia, granulomatous colitis, intussusception), *small intestinal thickening* (concurrent small intestine IBD, small intestine lymphoma), *mesenteric lymphadenopathy* (small intestine IBD, small intestine lymphoma), *hepatosplenomegaly* (lymphoma, disseminated fungal infection), and *uveitis* (protothecosis, lymphoma). A scoring system has been developed to relate clinical signs with histologic findings in canine IBD.[2]

Constipation

History

Constipation is the second most important pathophysiologic condition of the colon. Clinical signs include reduced, absent, or painful defecation for a period of time ranging from days to weeks or months. Physical examination findings will depend on the severity and pathogenesis of constipation. Dehydration, weight loss, abdominal pain, and mild to moderate mesenteric lymphadenopathy are common findings in cats with idiopathic constipation.

Physical Examination

Physical examination might also reveal *abdominal mass* (cecal or colonic neoplasia, granulomatous colitis), *abdominal pain* (foreign bodies, colonic perforation), *autonomic neuropathy* (dysautonomia), *hind limb paresis* (lumbar spinal cord pathology), *pelvic fracture* (pelvic outflow obstruction), and *perineal hernia* (cause or complication of constipation).

For both inflammation (colitis) and constipation, the scope of the medical investigation is shaped by prior history, suspected etiology, chronicity, and signs of systemic illness (Figures 58-4 and 58-5).[3,4]

Laboratory Data

Complete blood count, serum chemistry, and urinalysis should be considered in animals with signs of colonic disease, particularly those with signs of systemic disease. These tests may provide evidence of *anemia* (chronic disease, GI blood loss), *leukocytosis* (IBD, neoplasia, cecal or colonic perforation), *eosinophilia* (parasitism, Addison disease, mast cell disease, hypereosinophilic syndrome), *thrombocytopenia* (concurrent immune thrombocytopenia), *hypoproteinemia* (protein-losing enteropathy), *hyperglobulinemia* (IBD, infection, neoplasia), *hypercalcemia* (neoplasia, fungal disease), *hypoglycemia* (leiomyosarcoma), and *hyponatremia/hyperkalemia* (Addison or pseudo-Addison disease). This minimum database is also useful to screen animals prior to anesthesia and colonoscopy. If fungal, oomycete, or algal infections are possible causes in the pet's geographic area, special serologic tests are available for the diagnosis of some of these diseases (Table 58-3). Feline leukemia virus (FeLV) and feline immunodeficiency virus (FIV) testing are warranted in cats with unexplained, chronic diarrhea.

Fecal Parasitic Evaluation

Direct fecal smears and fecal flotation studies should be performed to evaluate for helminth, protozoal, and some bacterial infections (see Table 58-3). Direct fecal smears may be useful in detecting *Giardia*, *Tritrichomonas*, and *Campylobacter* organisms. Zinc sulfate flotation is the most accurate and practical fecal flotation test available, and it may be more sensitive for the detection of *Giardia* and *Tritrichomonas* infections. Because some animals may have intermittent shedding of helminth ova and/or *Giardia* trophozoites and cysts, suspected infections should always be treated with anthelmintics or antiprotozoal agents before animals are subjected to colonoscopy.

Fecal Bacterial Culture

Fecal cultures should be considered in animals with suspected bacterial infections of the intestine and colon. Risk factors for bacterial

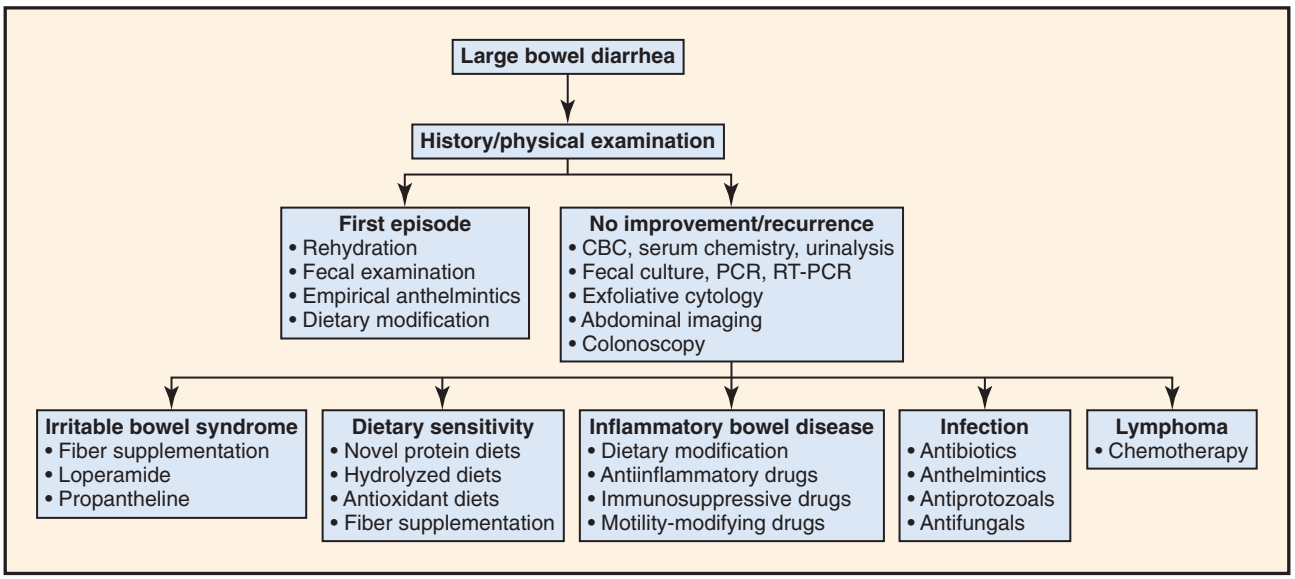

Figure 58-4 Diagnostic approach to large intestinal diarrhea. (Reprinted with permission from Washabau RJ: Diseases of the large intestine. In: Ettinger SJ, Feldman ED, editors: *Textbook of Veterinary Internal Medicine*, ed 6, Philadelphia, 2005, Saunders, p 1384.)

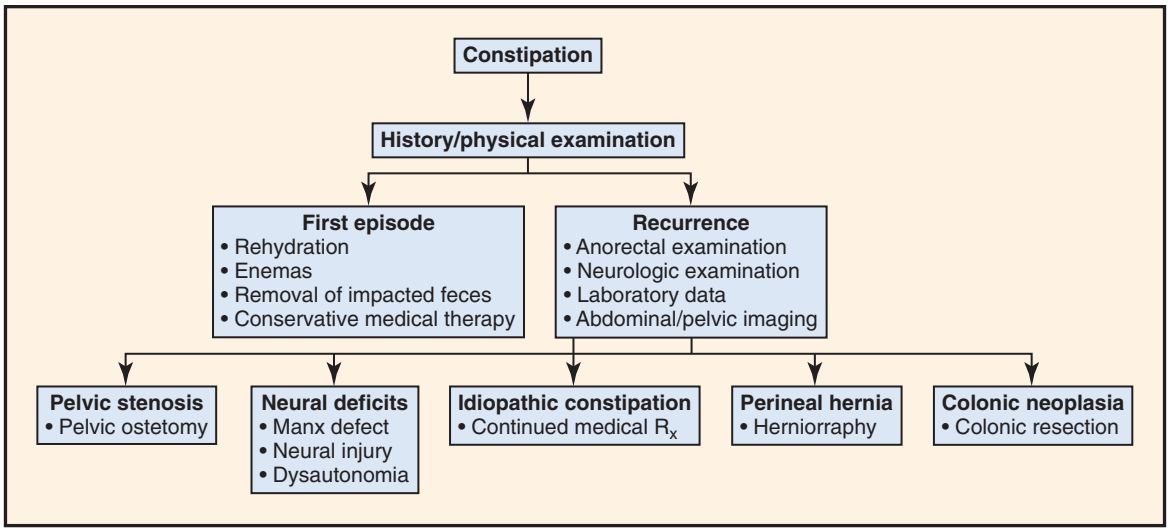

Figure 58-5 Diagnostic and therapeutic approach to constipation. (Reprinted with permission from Washabau RJ: Diseases of the large intestine. In: Ettinger SJ, Feldman ED, editors: *Textbook of Veterinary Internal Medicine*, ed 6, Philadelphia, 2005, Saunders, p 1384.)

colitis include young age, crowded or poor hygienic environmental conditions, coinfection with helminth or protozoal parasites, viral immunosuppression,[5] boarding or kenneling conditions, and multiple-pet households. Bacterial pathogens associated with colitis or enterocolitis lesions in dogs and cats have included *Brachyspira pilosicoli*, *Campylobacter* spp., *C. perfringens*, and *Clostridium difficile*, certain *Escherichia coli* (enterotoxigenic, enteroinvasive, enteropathogenic, enterohemorrhagic, enteroadherent), *Salmonella* spp., and perhaps *Yersinia enterocolitica* (see Table 58-3). The role of enteropathogenic bacteria in the pathogenesis of colitis-type diarrhea has been reviewed recently by Marks et al.[5a] Culture results should always be interpreted in light of clinical signs, other findings such as coinfections, and substantiating laboratory data such as serologies or polymerase chain reaction results. Fecal cultures should not be performed for the purpose of diagnosing small intestinal bacterial overgrowth.

Molecular Diagnosis

A number of polymerase chain reaction (PCR) and reverse transcriptase (RT)-PCR assays have been developed for gene amplification products and messenger RNAs of infectious organisms (see Table 58-3). Assays are now available for the molecular diagnosis of *Tritrichomonas foetus*, *Pythium insidiosum*, *Campylobacter jejuni*, *C. perfringens*, *C. difficile*, *E. coli*, *Salmonella* spp., and *B. pilosicoli*, and many more are likely forthcoming. Molecular detection is the standard for infectious disease diagnosis in many instances.[6]

Fecal Cytologic Examination

Exfoliative rectal or endoscopic cytology may be useful in identifying etiologic agents (e.g., fungal elements, neoplastic cells) and inflammatory cells (e.g., lymphocytes, eosinophils). Rectal smears

Table 58-3 Definitive, Suspected, and Unproved Pathogens of the Large Intestine of Dogs and Cats

Classification/Organism	Tissue Trophism	Evidence of Pathogenicity	Diagnosis
Helminths			
Trichuris vulpis–dogs	Colon	Good evidence	Fecal flotation
Trichuris serrata–cats	Colon	Weak evidence	Fecal flotation
Trichuris campanula–cats	Colon	Weak evidence	Fecal flotation
Ancylostoma caninum	Intestine, colon	Good evidence	Fecal flotation
Heterobilharzia americana	Colon	Good evidence	Fecal flotation, histology
Protozoa

Giardia canis	Intestine, colon	Moderate to good evidence	Fecal flotation, PCR, serology
Isospora canis–dogs	Colon	Weak evidence	Fecal flotation
Toxoplasma gondii	Intestine, colon	Good evidence	Fecal flotation, PCR, serology
Tritrichomonas foetus–cats	Ileum, cecum, colon	Moderate to good evidence	Fecal flotation, culture, PCR
Fungi			
Histoplasma capsulatum	Intestine, colon	Good evidence	Exfoliative cytology, histology
Oomycetes			
Pythium insidiosum	Stomach, intestine, colon	Good evidence	Histology, immunohistochemistry, ELISA, PCR
Algae			
Prototheca zopfii, P. wickerhamii	Colon	Good evidence	Exfoliative cytology, histology
Bacteria			
Brachyspira pilosicoli	Ileum, colon	Weak to moderate evidence	Fecal culture, PCR, histology
Campylobacter coli, C. jejuni	Intestine, colon	Moderate evidence	Fecal culture, PCR
Clostridium perfringens	Colon	Weak to moderate evidence	Fecal culture, enterotoxin, PCR
Clostridium difficile	Colon	Weak to moderate evidence	Fecal culture, enterotoxin, PCR
Escherichia coli (EPEC, EI, EH)	Intestine, colon	Good evidence	Fecal culture, serotyping, PCR
Salmonella typhimurium	Intestine, colon	Good evidence	Fecal culture, serotyping, PCR
Salmonella krefeld	Intestine, colon	Good evidence	Fecal culture, serotyping, PCR
Yersinia enterocolitica	Colon	Poor evidence	Fecal culture

EH, Enterohemorrhagic; EI, enteroinvasive; EPEC, enteropathogenic *E. coli*. ELISA, enzyme-linked immunosorbent assay; PCR, polymerase chain reaction.

may be obtained with a cotton-tipped applicator or conjunctival spatula during anorectal examination, or with a cytology brush at the time of endoscopy. A good correlation (specificity, 97%; sensitivity, 93%) was shown between exfoliative cytology and subsequent endoscopic or surgical biopsy in one study.[7] Additional studies are still needed to verify the diagnostic value of this test.

Imaging

Survey abdominal radiographs may occasionally document colonic foreign objects, mesenteric or sublumbar lymphadenopathy, intussusception, and extraluminal compression, but survey radiographs are generally nonspecific in the diagnosis of colonic disease. Contrast studies (e.g., barium enema) are performed infrequently because of their poor sensitivity and requirement for general anesthesia. Ultrasonographic imaging has proved more useful in documenting mass lesions, lymphadenopathy, intussusceptions, and bowel thickening. Abdominal ultrasound may also be used to facilitate percutaneous aspiration of luminal masses, mucosal thickenings, and lymph nodes.[8,9] Computed tomography (CT) colonography, also known as virtual colonoscopy, has been successfully implemented in human medicine, and has been studied experimentally in the dog.[10]

Colonoscopy

Colonoscopy is indicated for the diagnosis of colitis-type diarrhea unresponsive to dietary modification and medical therapy, suspected colorectal neoplasia, chronic constipation, unexplained stricture, and evaluation of prior surgical or medical treatment.[11] Colonoscopy is performed after other noninvasive diagnostic tests (e.g., fecal parasitologic examination, fecal bacteriologic examination, exfoliative cytology, abdominal ultrasonography, survey ± barium-contrast radiography) have failed to diagnose the disease.

Rigid or flexible endoscopy may be performed, but flexible endoscopy provides better visualization and examination of the entire colon. The normal colonic mucosa is pink in color, smooth in texture, and glistening in appearance (Figure 58-6). Unlike the esophageal, gastric, and duodenal mucosa, submucosal blood vessels are readily apparent. The mucosa should not hemorrhage when abraded by the endoscope; active hemorrhage usually implies an underlying disorder such as inflammation or infection. The colonoscopic procedure should include examination of the more proximal structures—for example, ascending colon, cecum, ileocecal sphincter, and distal ileum—whenever possible. The proximal colon is an important site of inflammation, parasitism, ileocolic intussusception, cecal inversion, and neoplasia.

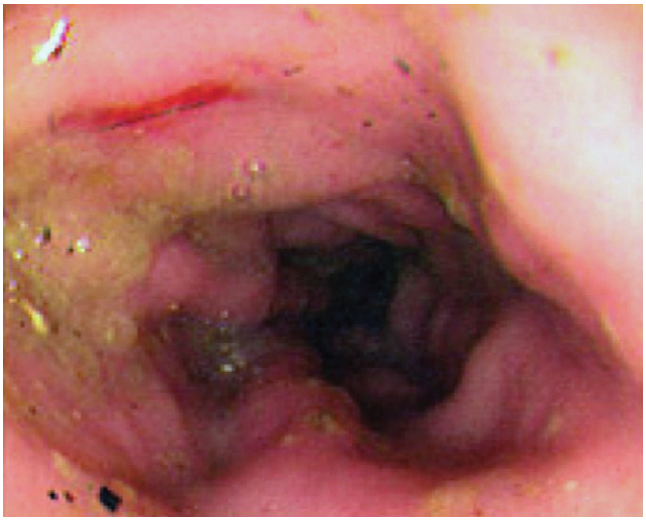

Figure 58-6 Endoscopic appearance of large intestinal inflammatory bowel disease. (Reprinted with permission from Washabau RJ: Diseases of the large intestine. In: Ettinger SJ, Feldman ED, editors: Textbook of Veterinary Internal Medicine, ed 6, Philadelphia, 2005, Saunders, p 1386.)

Box 58-1 Preparation and Patient Positioning for Colonoscopy

- Withhold food for 24 to 48 hours
- Lavage solutions → CoLyte, GoLYTELY
- 25 mL/kg, 24 and 12 hours before endoscopy
- Warm water enemas → 5 to 10 mL/kg,
- 24, 6, and 2 hours before endoscopy
- General anesthesia
- Left lateral recumbency

Fecal material must be completely evacuated before the colonic mucosa can be properly examined (Box 58-1). Incomplete bowel preparation is the major reason for an unsuccessful colonoscopic examination. Patient permitting, food should be withheld for 36 to 48 hours so that fecal material does not accumulate in the colon. The patient should also be given warm water enemas and/or gastrointestinal lavage solutions. Lavage solutions are preferable to warm water enemas,[12-14] but both may be given to facilitate successful colonoscopy. Polyethylene glycol solutions are isosmotic, are administered orally, and induce a diarrhea that rapidly removes fecal material from the bowel. Large volumes may be administered without inducing significant changes in water or electrolyte balance.[12] Electrolyte solutions should be given at a dose of 25 mL/kg at 24 and 12 hours prior to colonoscopy. Warm-water enemas should be performed gently, without irritating substances, at 24, 6, and 2 hours before colonoscopy. The combination of a 36- to 48-hour food fast, gastrointestinal lavage solution, and enemas usually results in a colon that is free of fecal fluids and solids.

Endoscopic examination of the colon has been described in detail.[11] General anesthesia is induced and the patient is placed in left lateral recumbency. The tip of the endoscope is introduced into the anorectal canal, and air is insufflated to dilate the anorectal and colonic lumen. As with upper gastrointestinal endoscopy, the tip of the endoscope should never be advanced unless the lumen is in full view. While inspecting the colonic mucosa, the endoscope is advanced through the descending colon to the splenic flexure. To facilitate passage of the endoscope through the splenic flexure, the tip of the endoscope is deflected slightly upward, and the endoscope is pushed into the transverse colon. The transverse colonic mucosa is now more visible as the endoscope enters the short, straight segment of the transverse colon. At the hepatic flexure, the tip of the endoscope is deflected caudally to enter the ascending colon. While keeping the tip of the endoscope in the center of the lumen, the endoscope is advanced the full length of the ascending colon into the cecum and ileocecal sphincter. The cecum is easily inspected, and the endoscope is then advanced through the ileocecal sphincter to evaluate the distal ileum. Endoscopic biopsies may be obtained at each sequential site or during withdrawal of the endoscope at the end of the study (see Chapter 27).

Diseased tissue, nondiseased tissue, and the transition zone between diseased and nondiseased tissue should be biopsied during colonoscopic procedures. This standard helps to verify the extent of the disease, ensures that disease in the submucosa has not been missed, and provides representative tissue samples to the pathologist to diagnose the disease.[15] In some cases of severe IBD or colonic neoplasia, advanced tissue necrosis may prevent the diagnosis of the disease process in the central part of the lesion. In the absence of gross mucosal abnormalities, three to five biopsy specimens should be obtained from each of the mid-ascending, mid-transverse, and mid-descending colonic regions (see Chapter 29).

INFLAMMATION

Frédéric P. Gaschen and Karin Allenspach

Inflammatory diseases of the colon are frequently encountered in dogs, but appear to be less common in cats. In many instances, acute nonspecific colitis may be self-limiting. However, chronic colitis is often associated with a long, sometimes waxing and waning clinical course and specific treatment is required to resolve clinical signs. Depending on patient signalment and history, dietary indiscretion, parasite infestation, and bacterial infection are common causes that need to be ruled out. The diseases discussed in this section are classically associated with noninfectious inflammation, although it appears that bacteria may play a role in multifactorial pathophysiology.

Acute Colitis

Acute colitis is characterized by a sudden onset of sometimes explosive watery diarrhea associated with the typical clinical signs of large bowel inflammation. Affected animals may also present with vomiting and lethargy. The disease often follows ingestion of toxins (e.g., spoiled food) as a component of "garbage can enterocolitis." However, intestinal parasites and bacterial infections must be ruled out systematically (or treated empirically) if deemed a likely cause based on signalment, history, and clinical signs. Acute nonspecific colitis is usually self-limiting and carries a good prognosis; most cases respond well to symptomatic treatment, which may include fluids, use of antimicrobials such as metronidazole, and a 24-hour fast followed by feeding an easily digestible, hypoallergenic diet over the following few days. Mild cases may be self-limiting. In the absence of exposure to toxins, hemorrhagic gastroenteritis should be considered as a possible differential diagnosis for dogs with bloody diarrhea of large bowel origin.

Inflammatory Bowel Disease

Definition

IBD is an idiopathic inflammatory disorder affecting the gastrointestinal (GI) tract of dogs and cats. Canine and feline IBD can be defined on the basis of clinical and histopathologic criteria. Clinically, IBD is diagnosed in animals with chronic (longer than 3 weeks' duration) GI signs such as anorexia, vomiting, diarrhea (small and/or large bowel in origin), and weight loss for which no other known cause of gastroenterocolitis can be documented. Therefore, affected animals fail to respond to symptomatic treatment, including parasiticides, antibiotics, and diet.[1] In addition, histopathologic evaluation reveals inflammatory infiltration of the colonic mucosa with predominantly round cells (lymphocytic plasmacytic colitis), eosinophils (eosinophilic colitis), neutrophils (suppurative or neutrophilic colitis), macrophages (granulomatous colitis), or a combination thereof. The inflammatory process can solely involve the colon (colitis) or affect the whole GI tract (enterocolitis).

Pathophysiology and Mechanism

Immunologic Basis of IBD

IBD is a complex disease that can affect any part of the GI tract in dogs and cats. Although the exact pathogenesis of IBD in small animals has not been elucidated, research on human and experimental IBD, as well as several studies performed recently in dogs and cats, has led to the formulation of current hypotheses.

In people, IBD encompasses two main disorders: Crohn's disease can occur anywhere in the GI tract and is characterized by a transmural inflammation, whereas ulcerative colitis is restricted to the colon and is characterized by a mucosal inflammation. IBD is clearly a multifactorial disease in which physiologic interactions of the innate and adaptive immune system with luminal microbial antigens are disrupted.[2,3] Overall, three factors are thought to be required for the development of IBD: (a) the presence of bacteria in the intestinal lumen with potential dysbiosis in the luminal microbiome; (b) defective mucosal barrier function that allows bacterial and/or food antigens to come in contact with the innate and adaptive immune cells in the lamina propria; and (c) an aberrant innate and adaptive mucosal immune response to bacterial antigens.[2,3]

In some human IBD patients, genetic alterations affecting the expression of important molecules of the innate immunity (e.g., polymorphisms in the gene encoding the nucleotide oligomerization domain 2 [NOD2]) are responsible for the abnormal recognition and response to luminal microbiota.[2] NOD2 is an intracellular pattern recognition receptor that binds to muramyl dipeptide derived from peptidoglycan common to both Gram-positive and Gram-negative bacteria.

Toll-like receptors (TLRs) are a family of transmembrane receptors with a ligand-binding extracellular domain that recognize microbe-associated molecular patterns. They are an important component of the innate immune system. In the GI tract, specific TLRs are found located on epithelial cells, macrophages, and dendritic cells. TLR2 recognizes bacterial lipopeptides, TLR4 is activated by lipopolysaccharides, and unmethylated cytosine-phosphate diester–guanine Cpg DNA found in prokaryotic genomes and DNA viruses act as ligand for the intracellular receptor, TLR9.[4,5] Once activated, TLRs elicit an intracellular signaling cascade leading to the production of proinflammatory cytokines. However, the physiologic function of TLRs in the GI tract includes maintaining hyporesponsiveness to innocuous luminal commensals, inhibition of allergic responses to food allergens and protection of mucosal barrier function.[4,5] Polymorphisms in the genes encoding TLR1, TLR2, TLR4, and TLR6 are associated with an increased risk for development of IBD in human patients and in murine animal models.[4,5]

NOD and TLRs are also a focus of attention in canine chronic enteropathies. Cultured primary canine colonocytes can express NOD2, TLR2, and TLR4 when stimulated by their respective ligands.[6] In a study investigating TLR expression profiles in endoscopic biopsies, it was found that dogs with chronic enteropathies that needed steroid treatment to keep their symptoms controlled had increased levels of TLR2, TLR4, and TLR9 messenger RNA (mRNA) expression compared with healthy dogs.[7] However, no difference in TLR expression was detected between biopsies sampled before and after clinically successful therapy, regardless of whether dogs had been treated with diet or steroids.[7,8] Another study identified a correlation between clinical severity of disease and expression of TLR mRNA. Duodenal mucosal mRNA expression of TLR2 was markedly increased in dogs with clinically severe IBD when compared with healthy controls, and TLR2 expression was correlated with clinical severity of diseases in a linear fashion.[8] Breed differences in TLR expression profiles have been reported in dogs with IBD. German Shepherd Dogs (GSD) with IBD have increased levels of TLR4 mRNA and decreased levels of TLR5 mRNA in the intestine compared to healthy greyhounds.[8a] Differences in TLR expression mimic those reported in people with Crohn's disease and have prompted genetic investigations into polymorphisms of pattern recognition receptors in dogs with IBD. In GSDs, single-nucleotide polymorphisms (SNPs) in TLR4 and TLR5 have been associated with an increased incidence of IBD.[8b] SNPs in TLR5 are associated with increased risk of development of IBD in 38 other breeds, and have been shown to be functionally hyper-responsive in GSD. This particular mutation may play a role in the pathogenesis of IBD in dogs in general.[8b] Finally, although it does not appear that food antigens play a direct role in the pathogenesis of human IBD, various dietary components can exert deleterious or beneficial effects on the intestinal microflora and on the intestinal mucosa, making it plausible that dietary changes could influence the inflammatory process in the mucosa of dogs with IBD.[9] To date, the effects of dietary antigens on canine and feline IBD have not been studied in detail. However, dietary treatment is viewed by most as an integral part of the therapeutic approach to chronic inflammatory GI diseases.

A number of studies have investigated the inflammatory process associated with canine and feline colitis. Immunohistochemical studies have shown T and B lymphocytes, as well as IgG-positive plasma cells to be increased in the colonic mucosa of dogs with IBD.[9-11] Semiquantitative RT-PCR has been used to evaluate cytokine mRNA expression in colonic mucosal biopsies. Human ulcerative colitis patients typically show a Th2 dominated inflammatory response.[2] In one study the prevailing cytokine mRNA expression pattern in dogs was that of a Th1 immune response.[12] Nevertheless, the accuracy of these results has since been questioned, at least in the duodenal mucosa, where the more reliable quantitative real-time RT-PCR showed a lack of difference in cytokine mRNA expression between healthy dogs and dogs with IBD.[13] However, colonic cytokine mRNA expression has not been investigated again using the more accurate amplification techniques, and it is prudent not to overinterpret the results from the initial study. To date there are no published data about cytokine expression in feline colitis, but duodenal mucosa of cats with IBD revealed a complex pattern of cytokine mRNA expression with a possible increase in Th1 cytokine mRNA expression.[14,15]

Table 58-4 Efficacy of Various Treatments for Chronic Colitis in Dogs and Cats Based on Published Case Series

Source	Number of Animals	Treatment Evaluated	Success Rate
Cats			
Nelson et al., 1984[29]	6 Cats	Homemade diet (boiled lamb and rice), then switched to highly digestible commercial diet. SS × 3 weeks in 1 cat with NR to commercial diet.	CR in 6 cats fed homemade diet. Rec in 2 cats when switched to highly digestible diet. Both controlled with homemade diets, 1 required SS for 3 wk.
Dennis et al., 1993[30]	13 Cats available for follow up	F (high F diet or addition of F to diet) in 8 of 10 cats with CR or PR, highly digestible diet in 2/7. CR cats received T and/or P initially, which was then d/c. All cats with CR maintained on diet alone. Cats with PR on P or SS as needed.	CR in 7 cats within 6 to 50 mo. PR in 3 cats. No change in one cat. Two cats with severe disease euthanized without treatment.
Dogs			
Nelson et al., 1988[39]	13 Dogs	Diet, initially homemade (cottage cheese and rice), followed by commercial novel antigen or low-residue diet. No medication.	CR to homemade diet in all dogs within 3 days to 6 wk. Rec in 2 of 13 after switch to commercial novel antigen or low-residue diet. Rec in 9 of 11 after exposure to pretreatment diet.
Simpson et al., 1994[40]	11 Dogs	Diet (commercial restricted antigen), initially SS in 9 dogs, d/c after resp of clinical signs. No F supplementation.	SS could be d/c after 1 mo in 3 of 9, 2 mo. in 8 of 9 but had to be resumed in 1 dog. Improvement in stool consistency, fecal mucus, and fecal blood, but not in frequency of defecation in all dogs.
Leib, 2000[31]	27 Dogs available for follow up	F (psyllium) added to various commercial or homemade (low-fat, low-residue or novel protein) diet.	Response excellent in 17, very good in 6, good in 3, and poor in 1 dog. Fiber could be d/c in 5 of 11 dogs, and special diet could be d/c in 5 of 7 dogs.
Allenspach et al., 2007[28]	30 Dogs	Diet (commercial novel antigen), P if NR to diet after 10 days.	CR in 28, NR or PR in 2. No data about resp to P in these 2 dogs.

CR, complete remission; D, diet; d/c, discontinued; F, fiber; NR, no response; P, prednisone; PR, partial remission; rec, recurrence; resp, response; SS, sulfasalazine; T, tylosin

Influence of Diet

A high proportion of dogs and cats with colitis respond to dietary therapy alone (Table 58-4); however, it is important to distinguish the various reasons for diet-responsive colitis. In humans, as well as in dogs and cats, adverse reactions to food can result from immunologic (food allergy) and nonimmunologic (food intolerance) mechanisms.[16] So far, in small animals, the clinical differentiation between food allergy and food intolerance relies heavily on restricted antigen dietary trials.[17,18] All dogs and cats with GI manifestations of adverse reaction to food get better when fed a novel diet, especially if it is designed to avoid antigens from their original diet. When challenged with their original food, they all show a relapse of GI signs. However, only food-allergic dogs and cats also relapse when their low-allergen diet is supplemented with proteins from a single source such as beef, chicken, milk, or any protein that was part of their original offending food.[17] Finally, a number of animals with colitis may simply benefit from being fed a highly digestible diet. These dogs and cats may have mild IBD that responds to the novel diet, which usually also offers additional benefits, such as an improved ratio of n6-to-n3 fatty acids or the presence of prebiotics. These animals usually do not experience a relapse when fed their original diet.

Effects of Inflammation on Colonic Function

The main functions of the colon include absorption of water and electrolytes (proximal colon) and storage of feces (distal colon). Colonic inflammation disrupts these normal events. It may decrease the total absorptive capacity of the mucosa through loss of functional colonocytes, increased epithelial permeability and disturbance of sodium and chloride transport.[19] Additionally, colitis has direct effects on colonic motility. The colon exhibits three types of contractions: While the individual phasic contractions and the migrating and nonmigrating motor complexes produce extensive mixing and kneading of fecal material and slow net distal propulsion, the giant motor complexes (GMCs) produce mass movements and expel feces during defecation.[20] In an experimental model, dogs with acute colitis had a decrease in nonpropulsive motility and an increase in GMCs, resulting in frequent defecation and tenesmus.[21] Decreased nonpropulsive motility may be explained by disturbances of the circular colonic smooth muscle cells associated with inflammation. These include impairment of calcium mobilization,[22-24] changes in expression of key signaling molecules for excitation–contraction coupling,[25] inhibition of muscarinic signaling,[26] and increased transcription of nuclear factor kappa B (NF-κB).[27] Finally, absorptive and motility disorders may change the composition of the luminal commensal flora, which plays an important role in the maintenance of colonic function, and therefore contribute to further deterioration.

Differential Diagnoses

Other colonic diseases that may lead to similar clinical signs include infectious diseases (e.g., parasite infestation with nematodes or

protozoa), infections with systemic fungi, oomycetes, algae, and bacteria. Histiocytic ulcerative colitis (HUC), another chronic inflammatory disease, can only be distinguished from lymphoplasmacytic IBD histologically. Moreover, lymphoma or other neoplasia can infiltrate the large intestine and cause identical clinical signs to those of inflammatory diseases. Finally, cecal intussusception, although rare, is another differential diagnosis of chronic noninfectious colitis. In cats with clinical signs of colitis, it is generally recommended to search for concomitant involvement of the small bowel as enterocolitis appears to occur more frequently than isolated colitis in that species.

Evaluation of the Patient

History

Dogs with IBD tend to be middle-aged (mean age: 6 to 6.5 years with a wide age range)[1,28] and older than those with diet-responsive enterocolitis (mean age: 3.5 years; range: 0.6 to 7.6).[28] In cats with lymphoplasmacytic colitis, the mean age of onset of clinical signs is similar (around 5.2 years; range: 0.5 to 10 years).[29,30] A predilection for purebred cats was noticed in one study,[30] but no canine breed appeared more frequently affected. There is no sex predilection. Signs of chronic colitis are characterized by large bowel diarrhea with frequent defecation of small volumes of soft to watery stool, often mixed with mucus and/or fresh blood (hematochezia). Urgency to defecate and tenesmus are often noticed by the owners, especially in dogs. Although occasional vomiting is often reported, abdominal pain, weight loss, anorexia, and/or lethargy are infrequently part of the history. They may occur during severe episodes, in severely affected animals, or in those with concurrent involvement of stomach and/or small intestine.[31] Clinical signs are often intermittent, although they may be continuous in some animals.[31] A gradual deterioration to more severe disease may be observed over weeks to months.

Physical Examination

Most dogs and cats with large intestinal IBD are in good general condition. Their nutritional status is unchanged by the disease. However, low body condition score and lethargy may be present in severe cases, or in animals with gastroenterocolitis. Without small intestinal involvement, abdominal palpation is often unrewarding, but may help ruling out space-occupying lesions affecting the colon (e.g., intussusception, neoplasia). Rectal palpation may be painful because of anal and rectal inflammation associated with colitis. The rectum may appear empty, or contain blood, mucus, and/or diarrheic stool. Abnormal surface of the rectal wall may be noticeable on rectal palpation.

Ancillary Tests and Laboratory Investigation

Generally, complete blood cell count, serum biochemistry, and urinalysis do not reveal significant abnormalities in dogs and cats with large intestinal IBD. This may be different in animals with generalized GI inflammation: leukocytosis with neutrophilia and left shift, hypoproteinemia with hypoalbuminemia and hypoglobulinemia, and mildly to moderately increased liver enzymes can all be present in such patients. Evaluation of acute phase reactants such as C-reactive protein in the serum has delivered mixed results,[1,28,32] and is not specific for GI inflammation. The precise clinical relevance of serum markers of autoimmunity such as perinuclear antineutrophil cytoplasmic antibodies still remains to be determined in dogs with IBD, but they may be suggestive of diet-responsive disease.[33] A parasitologic examination of one or several fecal samples is necessary to rule out parasite infestation. Alternatively, empirical treatment with broad-spectrum parasiticides such as fenbendazole (50 mg/kg PO daily for 3 days) will eliminate most GI nematodes and protozoa. Cytologic examination of rectal scrapings can reveal the presence of *Histoplasma capsulatum*, large numbers of neutrophils, a sign of inflammation, or increased numbers of Gram-positive rods (suggestive of overgrowth with *C. perfringens*).[34] Usually, diagnostic imaging (radiographs and ultrasonography) is not very helpful in cats and dogs with colitis. It may however yield useful information if the disease extends to the small intestine.

When the diagnostic elimination process confirms the possibility of large intestinal IBD, evaluation of the disease severity is desirable and best performed by colonoscopy (preceded by gastroduodenoscopy in cases with small and large bowel involvement). Full endoscopic examination of the colon requires general anesthesia but remains a safe diagnostic procedure.[35] Flexible colonoscopy allows full visualization of the rectum and descending and ascending colon, as well as cecum and ileocolic junction. Additionally, it is often possible to pass the endoscope into the ileum. Changes noticed during colonoscopy may include an increase in friability, granularity, or hyperemia; changes in the numbers of lymphoid follicles; decreased visualization of submucosal blood vessels; localized colonic spasms; and localized erosions.[31] Significant edema and inflammatory infiltrate may give the mucosa a honeycomb appearance (Figure 58-7); however, the colonic mucosa may also appear normal.[31] The endoscopic procedure also makes it possible to collect mucosal biopsies to evaluate the histopathologic appearance of the mucosa. As the colon can usually be easily distended, it is advisable to use an endoscope with a large-bore biopsy channel that makes the use of large biopsy forceps possible (≥2.8 mm diameter). Rigid proctoscopy/colonoscopy is an alternative method for procuring good size colonic mucosal samples.

Histopathology allows identification of neoplastic processes and differentiation between the various types of colonic inflammation. Recently, criteria for the scoring of colonic inflammation in dogs and cats have been proposed[36]; however, there is currently no universally approved grading system. Consequently, various pathologists may give different interpretations when evaluating the same mucosal sample.[37] Lymphoplasmacytic colitis is the most common form of chronic colitis. It may occur in young dogs (often associated with diet-responsive disease) as well as in older dogs (often associated with IBD). Eosinophilic inflammation may occur in association with IBD, or result from parasite infestation. Pyogranulomatous colitis is uncommon and associated with proliferative masses (millimeters to centimeters in diameter) visible during colonoscopy or palpable rectally. Affected dogs show severe clinical signs.[38] Suppurative colitis has been reported as a probable variant of IBD in cats and often responds to the empirical treatment of colitis.

Treatment and Management

In many instances, treatment of colonic IBD can be initiated after known causes of large intestinal disease have been ruled out. Empirical treatment should focus on a dietary approach and the use of several drugs with limited side effects. A precise assessment of the disease with colonoscopy and histopathologic evaluation of mucosal samples is required prior to using glucocorticoids or other immunosuppressive drugs. These drugs can have multiple side effects and may also hamper the success of further diagnostic efforts.

Several clinical reports describe the dietary approach to dogs and cats with histologically documented chronic colitis and large intestinal IBD (see Table 58-4).[28-31,39,40] Diets recommended for patients with chronic colitis include elimination diets (based on a novel

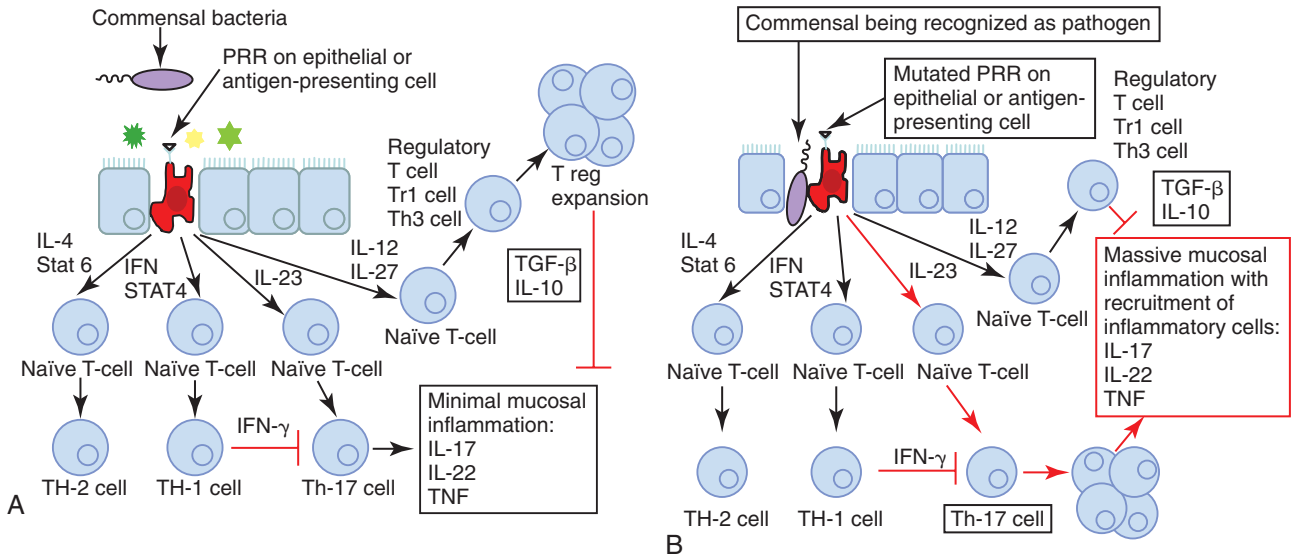

Figure 58-7 Proposed mechanism of oral tolerance against commensal organisms and pathogenesis of IBD. **A,** The pathogenesis of IBD involves three factors: the mucosal barrier, including an intact epithelial cell lining; the host immune system consisting of innate immunity and adaptive immunity; and microbes and food antigens in the intestinal lumen. The interplay of these three factors is important to maintain intestinal homeostasis. In the normal case scenario, antigen-presenting cells continuously sample antigens from the intestinal lumen through pattern recognition receptors (PRRs). Depending on the nature of these antigens, the signals elicited by the antigen-presenting cells drive the adaptive immune response in the appropriate direction to eradicate a pathogen. For example, in the case of a parasite, naive T cells are preferentially driven to differentiate into T-helper (Th) 2 cells that recruit eosinophils, basophils, and mast cells to kill the parasites. In the case of a pathogenic virus, the naive T cells preferentially differentiate into Th1 cells that produce cytokines such as interferon (IFN)-γ. These cytokines recruit macrophages that phagocytose and kill intracellular viruses. In the case of pathogenic bacteria being recognized, naive T cells preferentially differentiate into Th17 cells to produce proinflammatory cytokines such as interleukin (IL)-17 and IL-22. This recruits T cells and neutrophils to kill extracellular bacteria. In the case of commensal bacteria being recognized through PRRs, naive T cells preferentially differentiate into T-regulatory cells that counteract the effect of proinflammatory cytokines produced by Th17 cells. **B,** In the case of IBD, a primary defect in the recognition of commensals or certain pathogens by innate immune receptors may play a causative role. Mutations in PRRs lead to misrepresentation of commensals as pathogens, leading to the massive production of IL-23, driving naive T cells to differentiate into Th17 cells. These Th17 cells then produce large amounts of proinflammatory cytokines, such as IL-17, IL-22, and tumor necrosis factor (TNF). This leads to tissue destruction and epithelial cell injury, letting even more antigens pass through to the lamina propria. This inflammatory response cannot be counterregulated by regulatory T cells, leading to the characteristic inflammatory pattern seen in IBD.

protein or on hydrolyzed peptides),[28,40] and highly digestible, low-residue diets.[29,39] Most dogs and cats with colitis respond within 2 weeks to a diet change, some however may require up to 6 weeks. It is important to communicate the importance of exclusive feeding of the diet to the animal's owner, especially if an elimination diet is chosen. Recommendations regarding the required duration of dietary therapy after clinical remission diverge significantly. Although in one study most dogs relapsed after being fed their original pretreatment diet again,[39] many of the dogs could be switched again to their pretreatment diet after varying time periods in another study.[28] Consequently, it is important to discuss the risks and benefits of a reexposure to the regular diet with the patient's owners in each case to enable them to make an informed decision about their pet.

Dietary fiber consists of nondigestible complex carbohydrates. The addition of soluble fiber to the diet has provided additional benefits in clinical studies of canine and feline chronic colitis.[30,31] Fermentable fibers are metabolized to short-chain fatty acids by the large intestinal flora and provide a useful source of energy to the colonocytes. Overall, they enhance structure and function of the intestinal epithelium.[41] Examples of fermentable fibers include beet pulp, psyllium, and fructooligosaccharides. Fructooligosaccharides are oligosaccharides that resist digestion in the small intestine and are fermented by the colonic bacterial flora. Their beneficial effects on the large intestine include proliferation of colonocytes by increasing blood flow to the colonic mucosa and promotion of epithelial cell differentiation into fully functional colonocytes.[41] Additionally, fructooligosaccharides are prebiotics and therefore are able to influence the composition of the large bowel commensal flora. In cats, they were reported to increase colonic fecal concentrations of *Bacteroides* and *Lactobacillus* spp. and decrease those of *E. coli* and *C. perfringens*.[42] Finally, dietary fibers also have beneficial effects on colonic motility. As a tradeoff, addition of fiber to the diet may have a negative impact on nutrient digestibility, depending on the specific fiber type. Some fibers may also delay gastric emptying time and slow small intestinal transit time.[41] Psyllium is a soluble fiber derived from the seed of *Plantago ovata*. It has great water-holding capacities and forms gels in water, two properties that can contribute to improvement of fecal consistency. Psyllium was very efficient when added to a highly digestible diet in the treatment of chronic idiopathic colitis using the following initial daily dosage: 0.5 tablespoons (T) for toy breeds, 1 T for small dogs, 2 T for medium dogs, and 3 T for large dogs.[31] The fiber supplement should be administered with each meal, and the dose adapted to effect.

Probiotics are live microorganisms that may be beneficial to the host GI tract. Canine- and feline-specific probiotic cocktails are available commercially. However, the achievable benefits of modification of the large intestinal flora by administration of probiotics are subject to controversy. To date, no clinical study has been able to document positive effects of probiotics in dogs and cats with chronic GI diseases,[43] even though in vitro experiments yielded promising results.[44]

Table 58-5 Pharmaceutical Therapy of Large Bowel Inflammation

Drug Category and Name	Dosage Recommendation	Indication
Antimicrobials		
Enrofloxacin	5 mg/kg PO once daily (D)	HUC
Metronidazole	10 to 15 mg/kg PO BID (D, C) to TID (D) For metronidazole benzoate increase above dose by approximately 50%	Acute and chronic colitis
Antiinflammatory Drugs		
Sulfasalazine	10 to 30 mg/kg PO TID for 4 to 6 weeks, max 1 g total dose (D) 5 to 12.5 mg/kg PO TID for 2 to 4 weeks (C) Administer with food; slowly decrease in 10- to 14-day steps to BID, then half the dose BID, then once daily; regularly measure tear production	Colonic IBD refractory to diet and metronidazole
Immunosuppressive Drugs		
Prednisone	1 to 2mg/kg PO bid for 10 to 14 days, then slow tapering over several weeks	Colonic IBD refractory to diet and antibiotics
Azathioprine (D)	Starting dose 2 mg/kg PO once daily for 2 weeks, then 2 mg/kg every other day for 2 to 4 weeks, then 1 mg/kg PO every other day May take 2 to 4 weeks to take effect	Steroid-refractory colonic IBD
Chlorambucil (C)	Cats weighing >4 kg: 2 mg per cat PO every other day for 2 to 4 weeks then tapered to the lowest effective dose (2 mg/kg PO per cat every 3 to 4 days) Cats weighing <4 kg are started at 2 mg/kg per cat every third day	Refractory or severe feline IBD, combined with prednisolone
Cyclosporine (D)	5 mg/kg PO once daily for 10 weeks	Steroid-refractory chronic colonic IBD

C, cat; D, dog.

Pharmacologic intervention (Table 58-5) is required if dietary therapy fails to control clinical signs or may be initiated simultaneously to dietary changes in severe cases. Among antimicrobials, metronidazole is frequently used in the initial management of dogs and cats with colitis. Beside its antimicrobial effects against a variety of obligate anaerobic bacteria, metronidazole is also effective against *Giardia* spp. Furthermore, metronidazole has immunomodulatory effects.[45] It is used in dogs and cats with colitis to modify the intestinal flora (decrease in obligate anaerobes) and decrease inflammation. If a suspension is administered to a cat, metronidazole HCl is not a palatable formulation and may elicit ptyalism and anorexia. Metronidazole benzoate is the preferable formulation for feline patients, but it contains only 62% metronidazole and therefore requires a dose adjustment. Other side effects of metronidazole are rare, although cats may be more susceptible because of the probable increased half-life of the drug, and include vomiting and diarrhea. Hepatotoxicity and neurotoxicity have been reported at higher dosages.[45]

Sulfasalazine consists of 5-aminosalicylic acid (5-ASA; also called mesalamine [United States] or mesalazine [Europe]) linked by an azo bond to sulfapyridine, a sulfonamide compound.[46] Most of the orally administered sulfasalazine reaches the distal small intestine and colon unchanged. There, the microbial flora breaks the azo bond and liberates both molecules. Sulfapyridine is essentially a carrier molecule and is not thought to unfold any therapeutic effect. It is absorbed, metabolized in the liver, and filtered through the kidneys. The antiinflammatory effects of 5-ASA on the colonic mucosa are associated with inhibition of cyclooxygenase and a decrease in prostaglandin and leukotriene synthesis. Moreover, 5-ASA is an activator of peroxisome proliferator-activating receptor (PPAR)-γ.[46] In dogs, PPAR-γ are expressed at a high level in gastric, duodenal, and colonic mucosal epithelial cells.[47] They inhibit pathways leading to increased NF-κB transcription and hence to production of inflammatory cytokines and chemokines.[46] However, recent data do not support a decrease in PPAR in the colonic mucosa of dogs with colitis.[48] The main side effect of sulfasalazine is keratoconjunctivitis sicca (KCS). Although the exact mechanism of action is unknown, sulfapyridine is likely responsible for damaging lacrimal glands.[49] Early detection followed by treatment discontinuation is necessary to prevent the onset of irreversible KCS. Consequently, tear production must be measured at regular intervals in all dogs receiving sulfasalazine. Vomiting may also occur, and can be prevented if the drug is administered with food. Other drugs with the same mechanism of action are available and include olsalazine (two molecules of mesalamine linked by an azo bond) and other formulations of mesalamine coated with an acrylic resin that release the compound in the distal small bowel or colon. Although these drugs have not been extensively tested in small animals, KCS has been reported with their use in dogs.

Glucocorticoids are used as a second line of treatment in dogs with colonic IBD that are refractory to dietary modifications and treatment with metronidazole and sulfasalazine. Their antiinflammatory effects are partly a result of the lipocortin-mediated inhibition of phospholipase A that inhibits the cascade leading to formation of proinflammatory prostaglandin and leukotriene synthesis. Their therapeutic interest also relies on the multiple effects they have on both the innate and adaptive immune response.[50] However, because of their multiple side effects, immunosuppressive doses of prednisone should be reserved for dogs that have undergone colonoscopy, and for which a histologic diagnosis confirms the existence and type of the inflammatory infiltrate. Cats do not appear to develop as many side effects from glucocorticoid therapy as dogs. Additionally, cats may not tolerate TID medication with sulfasalazine, and are more susceptible to mesalamine toxicity. Moreover, many cats with colitis also have lesions in the small intestine (enterocolitis) on which sulfasalazine has no effect. This combination of facts makes glucocorticoids a treatment option that is often considered earlier in feline than in canine colitis patients.

In cases refractory to immunosuppressive doses of glucocorticoids, additional immunosuppressive drugs such as azathioprine (dogs only), chlorambucil (cats), and cyclosporine[51] may be helpful. Because of potential side effects and financial considerations, these drugs should be reserved for patients with well-documented colonic inflammatory disease that showed no response to any other treatment.

Prognosis

The prognosis for IBD is generally better when only the colon is affected. However, one retrospective study of dogs with IBD failed to find any association between localization of disease and outcome.[52] Nevertheless, the various clinical studies summarized in Table 58-4 demonstrate that a majority of dogs and cats with colitis will respond completely to dietary modification and/or to sulfasalazine treatment. If sulfasalazine is used, it can often be discontinued after a few weeks. However, there is a risk of recurrence when the animals are switched back to their original diet or a commercial diet. Therefore, the owners of dogs and cats with colitis should be prepared to feed their pets a special diet in the long-term, and consider the financial implications of the prolonged treatment. In a few cases, colitis may be refractory to treatment. This is probably most common in cats showing predominantly large bowel diarrhea, while in reality they have a general involvement of their GI tract (enterocolitis). In dogs with IBD, several negative prognostic factors have been identified that all reflect severe involvement of the small intestine, including hypoalbuminemia, hypocobalaminemia, severe duodenal lesions, and a high clinical disease score.[28,52] Therefore, they do not appear to apply to colonic IBD.

Histiocytic Ulcerative Colitis

Definition

HUC is a form of IBD that occurs most frequently in young Boxer dogs, also known as granulomatous colitis of Boxer dogs. It was first described 30 years ago[53] and has since been reported to occur in many countries, including the United States,[54-56] Australia,[57,58] Japan, and continental Europe and the United Kingdom.[59,60] HUC also occurs infrequently in other breeds, such as Mastiffs, Alaskan Malamutes,[61] French Bulldogs,[62] and English Bulldogs,[56] and has also been described in one cat.[63]

Pathophysiology and Mechanism

The mechanisms involved in the pathogenesis of HUC in dogs have been debated for decades. The recent success of antibiotic treatment raises the question of an infectious origin; however, this hypothesis has been investigated previously. The role played by macrophages containing cytoplasmic material stained by periodic acid-Schiff (PAS) is intriguing, and early electron microscopic studies have demonstrated so-called residual bodies, which resemble bacteria-like organisms in granules of PAS-positive macrophages.[64] These particles contained parallel pairs of membranes and electron-dense particles ranging in size from 100 to 500 nm, and may have represented bacterial cell membranes. Therefore, specific infectious agents, such as *Mycobacteria*, *Mycoplasma*, *Chlamydia*, and *Rickettsiales* ssp. have all been proposed to play a role in the pathogenesis of the disease.[55] However, attempts to reproduce the disease by infecting dogs with *Mycoplasma* spp. have failed.

Some reports have compared human Whipple disease with canine HUC. Whipple disease is caused by *Tropheryma whipplei* and mainly affects the small intestine. There is a striking histologic resemblance between both diseases involving severe granulomatous inflammation and distortion of the intestinal lamina propria. The causative organism in Whipple disease is susceptible to a variety of antibiotics, such as penicillin, chloramphenicol, and tetracycline, but seems to be resistant to fluoroquinolones. *T. whipplei* has not yet been identified in dogs with HUC, but the recent treatment success with enrofloxacin seems to make this organism less likely to be causally involved.

In a recent publication investigating the possibility of an infectious cause for canine HUC, large numbers of coccobacilli were found in the colonic mucosa by fluorescence in-situ hybridization (FISH) in Boxers affected with HUC but not in histologically normal tissues or in the mucosa of dogs with other types of colitis.[65] Further studies using culture, cloning, and sequencing of the colonic flora from Boxers with HUC identified the bacteria to be *E. coli*. Electron microscopy of HUC lesions allowed identification and localization of the bacteria to the intracellular compartment of PAS positive macrophages.[65] Additionally, the intracellular material found in PAS-positive macrophages from dogs with HUC was positively labeled with polyclonal antibodies against *E. coli*.[66] Further classification of the virulence genes and biologic behavior of these bacteria in coculture with epithelial cells and macrophages revealed specific adhesive and invasive properties.[65] The *E. coli* strains associated with HUC have a similar phenotype with adhesive and invasive behavior resembling *E. coli* isolates that were recently associated with Crohn's disease in people.[65] In several studies, a particular strain of *E. coli* (LF82) could be detected in biopsies of 20% to 35% of ileal lesions in Crohn's disease, but only in 6% of ileal samples from healthy controls or other colonic inflammatory diseases.[67] Crohn's disease affects primarily the mucosa and submucosa of the ileum and colon. It resembles canine HUC in its histologic appearance, as granulomas are the main feature of the disease. As in canine HUC, some cases of Crohn's disease are responsive to treatment with antibiotics. The *E. coli* strain LF82 that has increasingly been associated with Crohn's disease is unusual because it adheres to and invades intestinal epithelial cells in culture[68] and has been shown to replicate within the phagolysosomes of macrophages in the granulomatous lesions[69] instead of being cleared by the adaptive immune system. There is evidence that the adhesive and invasive *E. coli* associated with HUC are taken up by endosomes and persist in the macrophages instead of being cleared.[65] These findings support the hypothesis that genetics play a major role in the pathogenesis of Crohn's disease, and has led to recent genome-wide association studies in canine HUC. Certain defects in pattern-recognition receptors (PRRs) of the innate immune system have long been known to be associated with the development of Crohn's disease.[70] These receptors are important for the interaction of the mucosal innate immune system with the microflora of the intestinal lumen. The default response of the gut-associated lymphoid tissue is to clear offending pathogens, but to tolerate commensal organisms from the intestinal lumen.[71] Recent evidence confirms that polymorphisms in certain PRRs, such as NOD2, result in a disturbed response of human monocytes to *E. coli* LF82, linking genetics with functional disease for the first time.[72] Preliminary results from genetic studies in Boxers with HUC and healthy controls point to a defect in a protein in neutrophils that leads to defective clearance in *E. coli* in macrophages.

The inflammatory response normally only occurs as a reaction toward pathogenic bacteria breaching the intestinal barrier, and resembles the lesions observed in the mucosa of people affected with Crohn's disease and dogs with HUC. It is therefore possible that similar defects in PRRs occur in people with IBD and in dogs with HUC. A genetic predisposition for HUC is suspected due to the

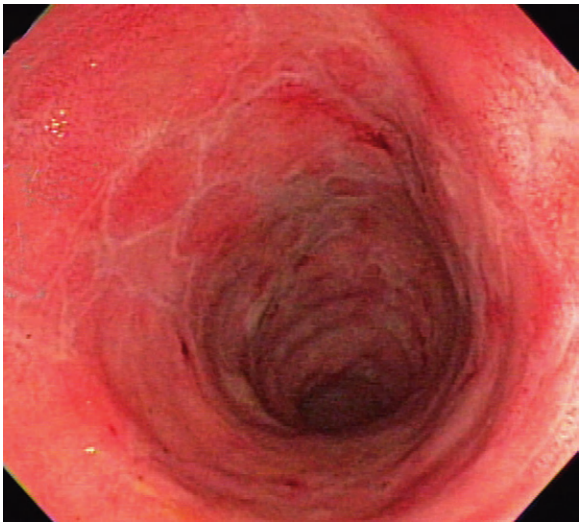

Figure 58-8 Endoscopic view of the descending colon from a dog with severe lymphoplasmacytic colitis. Note the honeycomb pattern that reflects mucosal edema and inflammation.

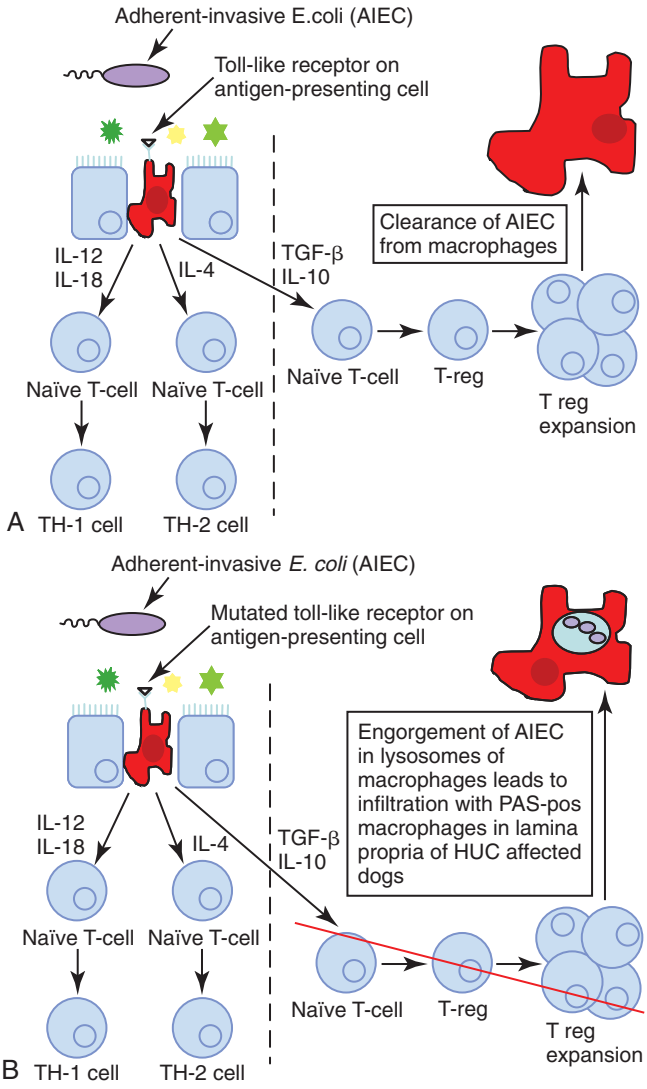

Figure 58-9 **A,** In the normal case scenario, various pathogens in the intestinal lumen, such as bacteria, viruses, and fungi, bind to PRRs on the surface of antigen-presenting cells, such as TLRs. To prevent infection, the innate immune system activates adaptive immune processes by promoting proinflammatory cytokine expression of T cells, such as tumor necrosis factor (TNF), interferon (IFN)-γ, and interleukin (IL)-17. This results in appropriate expansion of the relevant T cells to clear the infection, such as T-helper (Th) 1 cells for viruses and Th2 cells for parasites. In the case of normal commensals and adhesive–invasive *E. coli* (AIEC) in an animal not affected by HUC, T-regulatory cells will produce antiinflammatory cytokines such as IL-10 and transforming growth factor (TGF)-β, which leads to suppression of an inflammatory adaptive immune response and tolerance toward these bacteria. **B,** Hypothetical explanation for the pathogenesis of HUC. Mutations in pathogen recognition receptors, such as TLRs, lead to inappropriate activation of the adaptive immune system. In the case of AIEC, there is no expansion of T-regulatory cells, which results in engorgement of macrophages with AIEC within their lysosomes. The colonic lamina propria in dogs with HUC is filled with macrophages which stain positive for intracellular AIEC.

preponderance of cases in young boxer dogs. In the first report of the disease in 1965, most of the affected dogs could be traced to a single ancestor.[53] Confirmation and identification of mutations in PRRs such as TLRs or NODs in boxers with HUC is still lacking. However, it seems likely that a defect in innate immunity renders dogs with HUC more susceptible to infections with specific bacteria, such as the adhesive and invasive *E. coli* strains described previously (Figure 58-8).

Differential Diagnoses

Typically, HUC is characterized by chronic large intestinal diarrhea in relatively young dogs. Differential diagnoses include parasitic diseases such as infestation with *Trichuris vulpis* or *Giardia* spp., bacterial infections with *Campylobacter* or *Clostridia*, infections with oomycetes (*Pythium* spp.) and fungal microorganisms (*H. capsulatum*), as well as diet-responsive diseases such as food intolerance or food allergy. Further differentials include IBD other than HUC, such as lymphoplasmacytic and eosinophilic colitis. Rectal and colonic polyps as well as neoplastic disorders, such as lymphoma or adenocarcinoma, are less likely to occur in younger animals.

Evaluation of the Patient

History

The onset of disease occurs predominantly before 2 years of age. The clinical signs are those of severe chronic large intestinal inflammation and comprise diarrhea, hematochezia, increased frequency of defecation, tenesmus, and presence of excessive mucus in the feces.

Physical Examination

Physical examination findings are normal in many cases of HUC. However, weight loss and inappetence can be seen in severe cases, and should prompt further more invasive investigations. Fresh blood and mucus can be seen upon rectal examination.

Diagnostic Investigation

The diagnostic approach to cases with HUC is as described for chronic colitis. Typically, colonoscopy reveals sites of severe colonic hemorrhage and ulceration interspersed with stretches of normal appearing mucosa (Figure 58-9). Ten to 15 biopsies should be taken for histopathological analysis. Early lesions can consist of a mixed inflammatory infiltrate in the lamina propria, subjacent to degenerative epithelium.[53,55,73,74] With more extensive lesions and chronic disease, the ulcers become more visible on histology with severe infiltration of the lamina propria and the submucosal regions with

neutrophils, macrophages, lymphocytes, plasma cells and mast cells. There is also usually marked loss of the epithelial surface in biopsies from lesions and loss of goblet cells in the entire colon. Accumulation of large PAS-positive macrophages is pathognomonic for HUC[54,73,75] and remains the best way to confirm the diagnosis (Figure 58-10). In immunohistochemical studies HUC lesions are characterized by an increased number of L1-positive cells (Figure 58-11), as well as major histocompatibility complex (MHC) class II-positive cells, CD3-positive cells, and IgG-positive plasma cells.[60] L1 is a cytosolic calcium-binding protein, the function of which has not been described in detail in the dog. In humans, it is expressed by macrophages and neutrophils at an early stage in their differentiation and is lost when macrophages migrate into tissues and mature. It is possible that in canine HUC recently emigrated blood monocytes progressively differentiate into tissue macrophages, and become eventually filled with PAS-positive material, while L1 expression is downregulated.[55] MHC class II molecules are normally present on macrophages. Therefore it is not surprising to find an increased MHC class II expression associated with PAS-positive macrophages in HUC. Increased T-cell numbers were observed in HUC and are reminiscent of increased numbers of CD3-positive cells seen in other forms of canine IBD, particularly lymphoplasmacytic IBD.[60] Confirmation of the presence of *E. coli* using FISH analysis on formalin-fixed biopsies is now recommended as part of the detailed diagnostic work-up for dogs with suspected HUC.[75a] Up to 43% of dogs with HUC develop enrofloxacin resistance early in the disease process and may be refractory to treatment if they are treated without taking bacterial culture results into account.[75b]

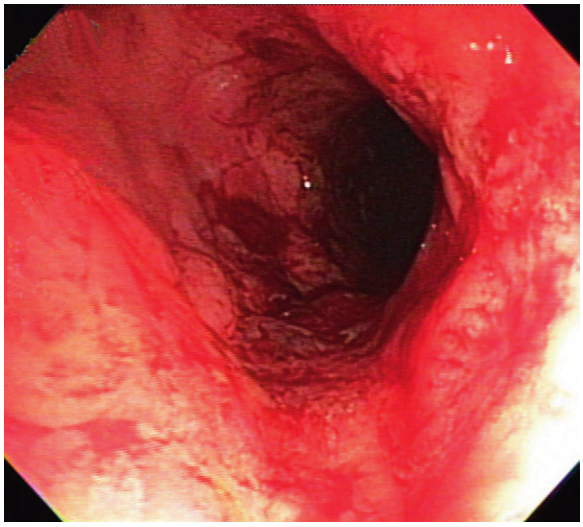

Figure 58-10 Endoscopic view of the descending colon in a young Boxer dog with histiocytic ulcerative colitis (HUC). The mucosa is very irregular, with discolored swollen areas interspersed with fistulae and spontaneous bleeding is observed. The final diagnosis was made after histopathologic evaluation of colonic mucosal biopsies.

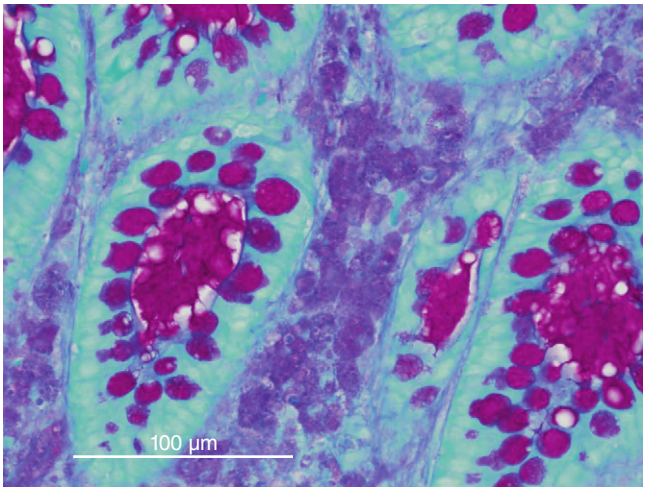

Figure 58-11 Photomicrograph of the colonic mucosa from a Boxer dog with HUC (PAS). The transversely cut colonic crypts have dark magenta-colored mucus in their goblet cells and lumen. There is an inflammatory infiltrate in between the crypts with large mononuclear cells with purple, heterogeneous material in their cytoplasm. This material represents in part phagocytosed *E. coli*. The granulomatous infiltrate and the PAS staining of infiltrating macrophages are diagnostic of HUC.

Treatment and Management

The prognosis for HUC was considered to be guarded to poor until recently. Management of HUC used to consist of various combinations of dietary modification (e.g., increasing fiber content and specific elimination diets), and antiinflammatory or immunosuppressive treatment with sulfasalazine, prednisone, and azathioprine, as described previously for the treatment of chronic colitis. Typically these strategies were not successful, and most cases had to be euthanized because of refractoriness to treatment. In recent years two reports have sparked hope for treatment of HUC: a total of 35 cases have been described and have shown a dramatic response to treatment with enrofloxacin (5 mg/kg PO once daily), or a combination protocol with enrofloxacin, amoxicillin (20 mg/kg PO twice daily), and metronidazole (10 to 15 mg/kg PO twice daily).[56] Reports of the disease almost 30 years ago also occasionally described a good response to treatment with antibiotics, namely chloramphenicol and tetracycline.[76] The response to treatment with enrofloxacin in the more recent reports was dramatic, with all dogs responding within 3 to 12 days of initiating therapy. It is particularly encouraging that several dogs were reportedly disease-free after the drug had been discontinued following a 4- to 6-week course of treatment.[56]

This implies that HUC can be cured in some cases. Five dogs were rebiopsied when they were in clinical remission after completion of the antibiotic treatment. A dramatic improvement in the histologic lesions was evident in all cases, with disappearance of PAS-positive macrophages in three dogs and marked reduction in the number of macrophages in the other two cases.[56]

However, care must be taken to treat dogs with HUC long enough to avoid relapse after discontinuation of treatment. In addition, it may be prudent to send intestinal biopsies for culture and sensitivity before starting treatment, so that the use of antibiotics can be tailored to the specific sensitivity profile of the cultured *E. coli*.[75a,77]

Colitis Associated with Anal Furunculosis

Anal furunculosis (AF) is a chronic and painful disease of the anorectum in dogs that preferentially affects German Shepherd dogs and is characterized by inflammation, ulceration, and sinus tract formation. Clinical signs include a painful ulcerated perineal region that may cause tenesmus, hematochezia, and even anorexia and weight loss. Histologic evidence of colitis has been documented in several cases of AF.[78,79] This association is interesting because

chronic fistulation is frequently observed in people with Crohn disease. Moreover, PRRs are thought to play an important role in the pathogenesis of IBD in people and dogs, and have been the object of recent research in dogs with AF. One study found dysfunctional NOD2 responses in German Shepherd dogs with AF.[80] Moreover, a restricted allelic variation in TLR1, TLR5, and TLR6 was found in German Shepherd dogs. However, there were no significant associations between these PRR polymorphisms and AF. Nevertheless, these polymorphisms may influence innate immune responses in German Shepherd dogs and may be an important predisposing factor for the development of AF in that breed.[81] In other studies, increased prevalence of a specific haplotype of alleles of genes encoding class II molecules of the canine MHC was shown in German Shepherd dogs with AF, suggesting a possible defect in antigen presentation associated with the disease.[82] Finally, it is noteworthy that feeding a restricted antigen diet maintained more than 80% of dogs with AF in complete remission after en bloc surgical excision and anal sacculectomy,[83] and that both AF and IBD respond to treatment of immunosuppressive drugs such as prednisone and cyclosporine.[84] These similarities underline the possibility of a comparable pathomechanism for both diseases.

Typhlitis

Definition

Typhlitis refers to inflammation of the cecum and is a rare condition in small animals.

Pathophysiology and Mechanism

There are few case reports that describe typhlitis in association with concurrent inflammation of the ileum and/or colon in dogs. The inflammation has been reported to be predominantly eosinophilic in one dog. Little is known about the pathomechanism of disease, but it is likely that the pathogenesis is similar to lymphoplasmacytic and/or eosinophilic IBD in the small and large intestine.

Differential Diagnoses

Typhlitis usually presents in combination with enteritis or colitis, and the clinical signs are associated with small and/or large intestinal chronic diarrhea. In addition, the anatomical location of the cecum makes it more likely that severe inflammation could result in signs of intestinal obstruction or pseudoobstruction. Consequently, differential diagnoses include infectious and inflammatory causes of enteritis and colitis such as *T. vulpis*, as well as causes for obstruction, such as foreign bodies, abscesses, inversion of the cecum into the colon, fecaliths, or neoplasia.

Evaluation of the Patient

History and physical examination in patients with typhlitis resemble those for chronic small intestinal and/or large intestinal diarrhea.[85] In some cases, ileus or pseudoileus can occur as a consequence of obstruction of the cecum, which results in acute or chronic vomiting.[86,87] Radiography may reveal signs of partial or complete ileus. Abdominal ultrasound may show thickening of the cecal mucosa or evidence of obstruction in the cecal lumen. Endoscopy is recommended in all cases of suspected nonobstructive typhlitis as it allows direct visualization of the mucosa and collection of multiple endoscopic biopsies.

Management

If typhlitis occurs secondary to enteritis or colitis, the management consists of treatment of these diseases. If chronic typhlitis has led to obstruction or abscessation, surgical typhlectomy is the treatment of choice and usually results in a favorable prognosis.[86,87]

INFECTION

Jody L. Gookin

Infectious diseases of the canine and feline gastrointestinal tract are numerous and commonly affect function of the small and large bowel. The infectious agents included in this section are those for which the colon is a primary target of injury or for which signs of large intestinal disease are a dominant clinical feature.

Helminths

Heterobilharzia americana

Etiology

Heterobilharzia americana, a fluke parasite, is the causative agent of canine schistosomiasis in North America.[1-5] Infection is enzootic in the Southeastern and Gulf Coast of the United States. Raccoons are considered the most important reservoir host of the parasite. Domestic and wild canid infections are uncommon, but clinically significant. The major intermediate hosts are the freshwater lymnaeid snails, *Lymnaea cubensis* and *Pseudosuccinea columella*.

Pathophysiology

Infection is acquired when free-swimming cercaria, released from the snail intermediate host, penetrate skin. The cercaria migrate through the lung and liver where they mature into adult flukes and then to the terminal mesenteric veins to reproduce. Ova are deposited in the terminal branches of the mesenteric veins and work their way through the intestinal mucosa to the bowel lumen by secretion of proteolytic enzymes. When ova are excreted in feces and come into contact with water, they give rise to miracidia that penetrate susceptible snails to reinitiate the cycle. The presence of ova in the submucosa of the small intestine and colon elicits an intense granulomatous tissue reaction.[2] Lesions are characterized by epithelioid macrophages, usually surrounding parasitic ova, admixed with varying amounts eosinophils, neutrophils, lymphocytes, and plasma cells.[1,2] Ova that do not make it to the intestinal lumen may be hematogenously disseminated to distant sites, particularly via the portal vein to hepatic venules where ova-induced chronic inflammation can lead to hepatic fibrosis and organ failure. Ova and associated granulomatous inflammation may also be found in the pancreas and lungs.

Clinical Examination

Clinical signs range from profuse acute to chronic mucoid diarrhea and tenesmus. Signs of inappetence, weight loss progressing to cachexia, and bloody diarrhea of small bowel (melena) or large bowel (hematochezia) origin are common. Physical examination findings may include thickened loops of intestine, abdominal effusion, peripheral edema, and mild generalized lymphadenopathy. Dermatitis caused by cercarial penetration of the skin or coughing because of lung migration are uncommonly reported. Clinicopathologic abnormalities include anemia, hyperglobulinemia, hypoalbuminemia, eosinophilia, and proteinuria. Dogs with *Heterobilharzia* infection may present with clinical signs arising from moderate to severe hypercalcemia.[1,6] In 2 dogs with *Heterobilharzia* infection, and lack of evidence for malignancy, hypercalcemia was attributed to elevated parathyroid hormone-related peptide concentrations.[6]

Diagnosis

Diagnosis of *H. americana* is made by performing saline sedimentation of feces to observe ova containing miracidia and by the observation of motile miracidia released from ova when exposed to water.[7] In cases where infection is suspected, but ova are not observed in feces, diagnosis may be attempted by detection of circulating anodic antigen in serum by enzyme-linked immunosorbent assay (ELISA).[2]

Treatment

Treatment with high-dose praziquantel (25 mg/kg per os BID-TID for 2 to 3 days)[2,6] or fenbendazole (40 mg/kg per os once a day for 10 days)[8] is reportedly effective is resolving ova shedding and clinical signs.

Prognosis

The prognosis for acute infection is good. Chronic infections may result in liver fibrosis and organ failure.

Strongyloides tumefaciens

Etiology

Strongyloides tumefaciens is a feline threadworm parasite. Infections are rare and observed primarily in temperate regions of the United States Gulf Coast. Infections are more common in tropical and semitropical climates wherein favorable conditions for the free-living stages of the lifecycle can be obtained.

Pathophysiology

Infective larvae penetrate oral-esophageal mucosa or skin and are carried in the circulation to the lungs. Larvae break into alveoli, migrate up the airways, and are subsequently swallowed. Adult parasites are comprised exclusively of parthenogenetic female worms that burrow into the submucosa of the large intestine. Worms, eggs, and larvae reside in submucosal, epithelial-lined cavities where they elicit adenomatous proliferation and infiltration of macrophages, neutrophils, lymphocytes, plasma cells, and connective tissue resulting in visible nodules on the mucosal surface of the colon.

Clinical Examination

Infection is usually asymptomatic, but in clinical cases the parasite causes intractable diarrhea, particularly in young cats and kittens.[9-12] Adult parasites residing in the submucosa are associated with formation of whitish-colored, raised nodules and mucus on the mucosal surface of the colon. Each nodule has a central depression corresponding to an epithelial-lined pore through which the cavities communicate with the lumen of the colon. Coalescence of nodules may give the appearance of adenomatous tumors.

Diagnosis

Embryonated ova are identified in fresh feces by fecal flotation. Larvae may be identified in feces by the Baermann technique and must not be confused with larvae of *Aelurostrongylus abstrusus*. Adult worms, eggs, and larvae may be observed in biopsy specimens of colonic mucosal nodules.

Treatment

Fenbendazole 50 mg/kg once a day for 5 days.

Prognosis

Good.

Trichuris spp.

Etiology

T. vulpis, the parasite responsible for whipworm infection, is likely one of the most common causes of chronic large bowel diarrhea in dogs. In cats, infections are rare and caused by *Trichuris campanula* and *Trichuris serrata*.

Pathophysiology

Worms of the genus Trichuris are parasites of large intestinal mucosa. Infection is transmitted by the fecal–oral route. Eggs are ingested and develop into larvae that hatch in the small intestine where they burrow into the epithelial crypts. Larvae subsequently migrate to the cecum and colon where they develop into adults. Adult worms tunnel their thread-like anterior body into the mucosa and use a mouth spear to puncture and shred tissue, blood vessels, and epithelial cells upon which they feed.[12,13] Heavy infections may produce severe typhlitis and colitis. Cecal inversion is uncommonly reported. Factors contributing to pathogenicity and clinical severity include the number and location of adult worms, degree of mucosal inflammation, severity of anemia or hypoproteinemia, nutritional status of the host, and presence of other GI parasites and microorganisms.[14]

Clinical Examination

Trichuris spp. can infect dogs of all ages. Many, if not most, infections are asymptomatic. Characteristic clinical signs are those of mucoid large bowel diarrhea with tenesmus and hematochezia. Signs may be acute, chronic, or intermittent. Severe infections may be accompanied by eosinophilia, anemia, and hypoproteinemia. Rarely, infected dogs have serum electrolyte abnormalities consistent with hypoadrenocorticism (hyponatremia and hyperkalemia). When tested, these dogs are normoresponsive to adrenocorticotropic hormone stimulation.[15]

Diagnosis

Characteristic bipolar operculated, thick-walled, unembryonated ova are identified by routine fecal flotation. Immature adults can cause severe disease and adults are sporadic egg producers. Accordingly, repeated fecal examination may be necessary to identify ova and negative fecal examinations do not rule out infection. Empirical treatment for occult *Trichuris* infection should always be performed before moving on to a more detailed, costly, and unnecessary medical investigation. Ova of the feline trichurids, *T. campanula* and *T. serrata*, may be easily confused with pseudoparasites, for example, ova of *Trichuris* or *Capillaria* spp. that parasitize feline prey and pass unaltered into feline feces.

Treatment

Drugs effective for treatment of *Trichuris* spp. infections include fenbendazole and febantel. The latter drug is partially metabolized to fenbendazole and oxibendazole. Regular use of milbemycin oxime for heartworm prevention is also effective for treatment and prevention of *T. vulpis* infection.[16] Immature worms are less susceptible to drug treatment and it takes approximately 3 months for larval stages to mature to egg-laying adults. Therefore, treatment should be repeated in 3 weeks and again in 3 months. Whipworm ova survive for prolonged periods of time in the environment and dogs housed in areas that are difficult to decontaminate (e.g., on dirt) may need to be retreated every 2 to 3 months. When possible, feces should be collected and removed.

Prognosis

Excellent.

Protozoa

Balantidium coli

Balantidium coli is a ciliated protozoan that primarily infects swine and nonhuman primates.[17] The infection is rare in dogs[18-22] and is frequently associated with exposure to swine. Trophozoites reside in the colon and result in ulcerative colitis.[19] Dogs are frequently coinfected with *T. vulpis*.[18,20] Clinical signs consist of chronic hemorrhagic colitis. Diagnosis is based on demonstration of large ciliated protozoa with prominent macronuclei in fresh saline smears of diarrheic feces or cysts in feces following zinc sulfate flotation. The distinctive macronuclei of the trophozoite and cyst can only be seen after staining. Treatment for any concurrent helminth infection may alone be curative in some cases.[20] Because of their effectiveness in people, specific therapy for *B. coli* is likely to be attained with tetracycline or metronidazole.

Entamoeba histolytica

Entamoeba histolytica is the causative agent of human amebic dysentery. Infection in dogs[23,24] and cats is rare and acquired by ingestion of food or water contaminated by human or nonhuman primate feces containing infective cysts. Trophozoites dwell in the lumen of the colon and invade the submucosa by secreting lytic factors that allow them to undermine and ulcerate the mucosa. These pathogenic effects result in ulcerative to necrotic colitis and bloody, mucoid large bowel diarrhea. Rarely, trophozoites disseminate to other organs.[24] Diagnosis is made by finding ameboid trophozoites in wet-mount preparations of fresh diarrheic feces, quadrinucleated cysts in feces following zinc sulfate flotation, or trophozoites in colonic biopsy specimens. Treatment with metronidazole alleviates clinical signs of colitis, but dogs may continue to shed trophozoites.[25]

Tritrichomonas foetus

Etiology

T. foetus is a flagellated protozoan characterized by three anterior flagella and an undulating membrane. Trichomonads are obligate parasites of warm, moist and anaerobic sites within the gastrointestinal or genitourinary tract of their hosts. Trichomonads do not form cysts, reproduce by binary fission, and are transmitted directly from host to host in the form of trophozoites. *T. foetus* was first identified as a cause of chronic large bowel diarrhea in cats in 2003 and the duration of its existence in cats prior to that time is unknown.[26] The prevalence of *T. foetus* infection is high among densely housed cats (31% of 117 cats from 89 catteries sampled at an international cat show).[27]

Pathophysiology

In cats, *T. foetus* colonizes the distal ileum and colon where trophozoites can be found in close proximity to the surface of the mucosa or in the lumen of colonic crypts.[28] Less commonly, subepithelial invasion of trichomonads may also be observed. Inflammatory infiltrates consist of plasma cells, lymphocytes, and neutrophils.[29]

Clinical Examination

Cats with symptomatic *T. foetus* infection are generally young. Asymptomatic infection in older cats may be common. Cats originating from a cattery (e.g., purebred) or shelter appear to be at increased risk for infection because of a history of dense housing. A true breed predisposition has not been shown.[27] Clinical signs are characterized by a waxing and waning large bowel diarrhea with occasional fresh blood and mucus. Diarrhea is semiformed to cow pie in consistency and malodorous. The anus may appear inflamed and painful; involuntary dribbling of feces or rectal prolapse may be present. Despite these clinical signs, most cats maintain good health, and normal appetite and body condition.

Diagnosis

Feline *T. foetus* infection may be diagnosed by identifying the organism in feces by direct saline smear examination, selective protozoal culture, PCR using species-specific primers, or by observation of trichomonads in colonic mucosal biopsy specimens. The sensitivity of direct fecal smear examination for diagnosis of *T. foetus* is low (2% in cats with experimentally induced infection and 14% in cats with spontaneous disease). *T. foetus* trophozoites are often misdiagnosed as *Giardia* and can be difficult to distinguish from nonpathogenic trichomonads such as *Pentatrichomonas hominis*. If repeated direct microscopic examination results are negative for *T. foetus*, feces may be cultured in commercially available pouches marketed for diagnosis of *T. foetus* infection in cattle (In Pouch TF, Biomed Diagnostics, White City, OR). Neither *Giardia* spp. nor *P. hominis* organisms survived in In Pouch TF for longer than 24 hours in one study; consequently, positive cultures are strongly suggestive of *T. foetus* infection.[30] A sensitive and specific single-tube nested PCR based on amplification of a conserved portion of the *T. foetus* ribosomal RNA (rRNA) gene unit from feline feces is commercially available (http://www.JodyGookin.com). Nested PCR assays are believed to be superior to fecal culture for diagnosis of infected cats.[31] Histopathology should not be relied upon to make a diagnosis of *T. foetus* infection, although a diagnosis can be attained if organisms are identified.[29]

Treatment

Ronidazole has been demonstrated to be effective at killing feline isolates of *T. foetus* in vitro and eradicated *T. foetus* from experimentally infected cats (on the basis of PCR).[32] The recommended dose is 30 mg/kg q24h PO for 14 days. Ronidazole is not registered for human or veterinary use in the United States and is currently banned for use in food-producing animals because of human hazards. Neurotoxicosis may be a common and serious side effect. Therefore, treatment with ronidazole should only be considered in cases of confirmed *T. foetus* infection where informed consent has been obtained. Follow-up testing by PCR is recommended if diarrhea persists longer than 2 weeks post treatment. Importantly, negative results should be interpreted with caution as PCR cannot prove the absence of infection and prolonged asymptomatic carriage of the organism after antimicrobial therapy may be common.

Prognosis

For single-cat households where reinfection is improbable, the prognosis for eradication of *T. foetus* infection with ronidazole is generally good. When left untreated, 88% of cats with *T. foetus* infection had spontaneous resolution of diarrhea within 2 years (median: 9 months; range: 5 months to 2 years). Time to resolution of diarrhea was significantly longer for cats from multiple-cat households, and those receiving a variety of different diets and antimicrobial drugs in an attempt to treat the condition. Importantly, spontaneous resolution of diarrhea does not imply recovery from infection, as 57% of these cats remain infected with *T. foetus* as determined by PCR when performed 2 to 5 years after diagnosis.[33]

Fungi

Histoplasma capsulatum

Etiology

H. capsulatum is a dimorphic fungus whose free-living mycelial stage flourishes in warm, moist, and nitrogen-rich (contaminated with bird or bat excrement) soil. Although sporadic cases may occur throughout the United States, most infections are diagnosed in animals living or traveling in the Ohio, Missouri, and Mississippi River valleys.

Pathophysiology

Fungal spores (macro- and microconidia) are inhaled and develop into yeast in the lung parenchyma. The yeast are ingested by macrophages wherein they reproduce by budding and may be disseminated via the blood and lymphatics to organs rich in mononuclear phagocytes including the GI tract, lymph nodes, liver, spleen, and bone marrow. Intestinal involvement in the absence of lung disease in many cases suggests that ingestion may also be a route of infection, however experimental studies have failed to produce GI disease reliably after oral administration of *H. capsulatum* spores.[34] Intestinal infection results in a granulomatous inflammatory response, mucosal ulceration, and blood loss.

Clinical Examination

Dogs with intestinal histoplasmosis are typically young, large breed, and have chronic diarrhea, inappetence, weight loss, pale mucous membranes, and fever that is unresponsive to antibiotics.[35] Although signs of large bowel diarrhea (tenesmus, mucus, and fresh blood in the feces) predominate, the small bowel is invariably involved and may result in a voluminous, watery stool, melena, and accompanying protein-losing enteropathy. Clinical signs of intestinal involvement are identified less commonly in cats.[36] Other historical and physical examination findings will depend on organ and tissue involvement.

Diagnosis

Definitive diagnosis of intestinal histoplasmosis is made by demonstrating *Histoplasma* organisms within mononuclear phagocytes by exfoliative cytology, intestinal biopsy, or tissue aspirates. Rectal mucosal scrapings, imprints of colonic biopsy specimens, and aspirates of liver, lung, spleen, and bone marrow are most productive in the dog.[34] For formalin-fixed, paraffin-embedded biopsy specimens, special staining (PAS, Gomori methenamine silver) is needed to demonstrate the organisms. Fungal culture is not recommended as this fosters growth of the mycelial phase, thereby increasing the risk of human inhalation of infective microconidia. Serologic and intradermal skin tests to diagnose histoplasmosis currently lack suitable sensitivity and specificity for clinical use.

Treatment

Itraconazole (10 mg/kg PO q12-24h) is the drug of choice for treatment of systemic histoplasmosis.[34,37] Amphotericin B may be combined with itraconazole in cases of severe or fulminating infection. In general, treatment is continued for 2 to 3 months beyond remission of clinical signs and for a minimum of 4 to 6 months. Symptomatic treatment may alleviate clinical signs of intestinal disease. Recommended therapies have included dietary modification (highly digestible diet for small intestinal disease, increased fiber diet for large intestinal disease), antibiotics for control of intestinal bacterial overgrowth, direct antidiarrheal drugs, and antiinflammatory drugs such as the 5-aminosalicylates.[38,39]

Prognosis

Depending on severity of clinical signs and systemic involvement, prognosis can vary from guarded to good.

Oomycetes

Pythium insidiosum

Etiology

P. insidiosum is an aquatic oomycete.

Pathophysiology

In an aquatic environment, *P. insidiosum* releases motile biflagellate zoospores that cause infection by penetrating and encysting in damaged skin and gastrointestinal mucosa. Gastrointestinal pythiosis is characterized by eosinophilic and pyogranulomatous inflammation and necrosis that localizes predominantly in the submucosal and muscular layers of the intestine[40] resulting in severe, segmental thickening that most frequently involves the gastroduodenal and ileocolic sections of the GI tract. However, multisegmental lesions and diffuse involvement of the GI tract have been described.[40-43] Infection may extend directly to adjacent tissues including the mesenteric lymph nodes, blood vessels, pancreas, uterus, and prostate.[40,41,44]

Clinical Examination

Pythium is identified most often in young, male, large breed dogs with recurrent exposure to warm freshwater habitats.[40,45] Gastrointestinal or cutaneous disease may be present, but are rarely found together in the same patient.[45] Gastrointestinal pythiosis in cats appears to be rare.[45] In dogs, GI pythiosis typically results in clinical signs of weight loss, vomiting, diarrhea, and hematochezia in association with a palpable abdominal mass on physical examination.[45] Hematologic and serum biochemistry abnormalities may include anemia, eosinophilia, hyperglobulinemia, and hypoalbuminemia. Cutaneous lesions consist of nonhealing wounds and invasive masses that contain ulcerated nodules and draining tracts.[45]

Diagnosis

A tentative diagnosis of gastrointestinal pythiosis is made by deep wedge biopsy of affected segments of intestine wherein broad, sparsely septate, and occasionally branching hyphae are demonstrated after staining with Gomori methenamine silver or anti–*P. insidiosum* antibodies.[45] Definitive diagnosis of *P. insidiosum* can be made using a species-specific nested PCR assay applied to DNA extracted from cultured isolates, appropriately preserved tissue samples (frozen at −70°C (−94°F) and stored in 95% ethanol at room temperature), or paraffin-embedded specimens.[45-47] Alternatively, a soluble mycelial antigen-based ELISA or Western analysis may be used to detect anti–*P. insidiosum* antibodies in the serum.[48]

Treatment

The treatment of choice for *P. insidiosum* infection is aggressive surgical resection. In the GI tract, 3- to 4-cm surgical margins (beyond tissue pathology) are recommended.[45] Because of frequent postoperative recurrence, postsurgical medical therapy with itraconazole (10 mg/kg PO q24h) and terbinafine (5 to 10 mg/kg PO q24h) is recommended.[45] Medication should be continued for 2 to 3 months at which time ELISA serology should be performed and compared with presurgical values. Medical therapy should be continued until serologic results (checked at 2- to 3-month intervals) are negative for *P. insidiosum* antibodies.[45] Medical therapy alone for treatment of pythiosis is unrewarding; this may be attributed to the

absence of cell membrane ergosterol (the target of most available antifungal drugs) in oomycetes.

Prognosis

Most dogs with GI pythiosis are presented late in the course of infection when complete excision is not possible. The anatomic site of the lesion may also preclude complete resection. Accordingly, the prognosis in most patients is guarded to grave.

Algae

Prototheca zopfii

Etiology

P. zopfii and *P. wickerhamii* are achlorophyllous algae that are ubiquitous to raw and treated sewage, slime flux of trees, and animal wastes with secondary contamination of the environment. *P. zopfii* is responsible for disseminated infections in dogs, whereas *P. wickerhamii* is responsible for cutaneous infections. Only the cutaneous form of infection has been described in cats.

Pathophysiology

It is presumed that *P. zopfii* is ingested by susceptible hosts, passes through the GI tract, replicates by endosporulation in the colon, and is subsequently disseminated to other organ systems via the blood and lymph. The kidney, liver, heart, brain, and eye are the most common sites of systemic dissemination. Inflammatory infiltrates are minimal in active lesions. Less commonly, however, pronounced granulomatous or pyogranulomatous inflammation may be observed.

Clinical Examination

Prototheca infection is predominantly identified in immunocompromised hosts. The most frequently reported clinical sign is intermittent and protracted bloody large bowel diarrhea. Other clinical signs depend on the organ systems involved and include acute renal failure, central vestibular disease, and posterior granulomatous uveitis.

Diagnosis

Diagnosis of protothecosis requires identification of the organisms by cytology, histopathology, or culture for *Prototheca* spp. High-yield, minimally invasive samples for diagnosis of disseminated disease include rectal scrapings, and urine for sediment examination and standard aerobic culture.[49] More invasive samples obtained by vitreocentesis, cerebrospinal fluid tap, or biopsy may be required as indicated by the existence of disseminated disease.

Treatment

Based on previous reports, and in the absence of susceptibility data, *P. zopfii* infection in dogs should be treated with amphotericin B alone or in combination with itraconazole. Aminoglycosides or tetracyclines should also be considered.[50]

Prognosis

The prognosis for disseminated *P. zopfii* infection is guarded to grave. Treatment may prolong the course of infection, but the outcome is uniformly fatal.

Bacteria

Bacterial causes of large intestinal disease in dogs are numerous and increasingly recognized with the advent of molecular diagnostics. Problematic to diagnosis of disease causation is the high prevalence of many of these "pathogens" in healthy animals. Table 58-6 summarizes the bacterial agents to which large intestinal disease have been attributed, their prevalence in normal dogs, clinical signs in symptomatic dogs, diagnostic approaches to their recognition, and efficacy of available tests for determining disease causation.

Anaerobiospirillum

Anaerobiospirillum spp. are small, Gram-negative, spiral bacteria that can be isolated from the throat and feces of normal dogs and cats. In a small number of cats, infection is associated with subacute to acute ulcerative or necrotizing ileocolitis with secondary sepsis. In histologic sections of intestine, *Anaerobiospirillum* were observed in intestinal crypts after staining with Giemsa or Steiner stains, and identified by 16S rRNA gene PCR.[51] Treatment in cats has not been described.

Brachyspira pilosicoli

Etiology

Infection of the mammalian large intestine by diverse populations of spirochetes has been recognized for many decades. Their role in causation of disease is still poorly understood. In dogs, three major groups of spirochetes have been identified in feces on the basis of selective culture, multilocus enzyme electrophoresis, and 16S rRNA gene sequence data: *B. pilosicoli*, *Brachyspira canis*, and *Brachyspira alvinipulli*.[52,53]

Pathophysiology

Pathogenic spirochetes intimately attach to the apical membrane of cecal and colonic epithelial cells. The mechanism(s) by which their cellular interaction results in diarrhea remains unclear. Spirochetes can be found in large numbers in the colonic crypts of normal dogs. In dogs with diarrhea, spirochetes can appear in the feces in large numbers. Whether the spirochetes are causal to the diarrhea or alternatively, mechanically dislodged from the crypts by diarrhea induced by other etiologic factors, remains an area of active debate. In a small number of cases, it has been observed that *B. pilosicoli* can be isolated from dogs with diarrhea and intestinal spirochetosis, whereas *B. canis* were commonly isolated from healthy dogs.[53,54] Furthermore, *B. pilosicoli* will attach to cecal epithelial cells from chicks, whereas *B. canis* will not.[55] Accordingly, the current presumption is that *B. pilosicoli* may be pathogenic and *B. canis* commensal. A characteristic, but not invariable feature of *B. pilosicoli* infection is the attachment of one pole of the spirochete to the intestinal epithelium, resulting in a dense "false brush-border."[53,56] Other pathologic changes include colonic inflammation, thickening of the colonic mucosa, and enlarged Peyer patches and lymphoid follicles.

Clinical Examination

Limited descriptions of diarrhea attributed to *B. pilosicoli* have been reported in dogs housed in pet shops and research colonies.[54,57] Diarrhea has been variably characterized as mucohemorrhagic, watery, or mucoid.[58] Diarrhea appears to be more common in puppies or when intestinal function is compromised by concurrent disease.

Diagnosis

A diagnosis of *B. pilosicoli* infection can be based on anaerobic culture of feces in selective media for isolation of spirochetes and multilocus enzyme electrophoresis, or demonstration of *B. pilosicoli* 16S rRNA genes in fecal samples or cultures by means of PCR.

Table 58-6 Bacterial Causes of Large Intestinal Disease in Dogs, Prevalence of Isolation From Feces of Normal Animals, Clinical Signs of Symptomatic Infection, and Diagnostic Approaches to Infection and Their Efficacy for Determining Disease Causation

Bacterial Agent	Prevalence in Normal Dogs	Clinical Signs	Diagnostic Tests	Utility for Diagnosis of Disease Causation
Brachyspira pilosicoli	6% to 66%	Watery, mucoid, or mucohemorrhagic large bowel diarrhea	Fecal culture in selective media and multilocus enzyme electrophoresis for identification of *B. pilosicoli*	Disease causation of *B. pilosicoli* unclear
			Polymerase chain reaction (PCR) identification of *B. pilosicoli* 16S rRNA in feces	
Campylobacter jejuni	≤90%	Watery, mucoid to bloody diarrhea	Characteristic darting motility observed in fecal wet mounts	None
			Fecal culture in selective media for *Campylobacter*	
			PCR-restriction fragment length polymorphism demonstration of *Campylobacter* genes in feces	
Clostridium perfringens	≥80%	Acute, nosocomial large bowel diarrhea	Fecal culture for *C. perfringens*	None
			Fecal cytology ≥3 endospores per high-power field	Poor
			PCR identification of *cpe* gene	Fair to good (in combination)
			Immunodetection of *C. perfringens* enterotoxin (CPE) in feces	
Clostridium difficile	≤40%	Mixed small and large bowel diarrhea ± acute hemorrhagic gastroenteritis	Fecal culture for *C. difficile*	None
			PCR identification of toxin A or B genes	None
			Immunodetection of toxin A ± toxin B in feces	Fair
			Immunodetection of toxin A ± toxin B in culture isolate of *C. difficile*	Good
Enteropathogenic *Escherichia coli* (EPEC)	≤7%	Acute-to-chronic, watery, sometimes hemorrhagic, diarrhea	Demonstration of attaching and effacing intestinal lesions by electron microscopy or immunofluorescence and absence of *Shiga*-like toxins	Good
			Demonstration of locus of enterocyte effacement (LEE)-associated genes (e.g., *eae*) in fecal extracts or bacterial cultures by PCR or DNA hybridization	Fair
Enterotoxigenic *Escherichia coli* (ETEC)	<3%	Nonbloody, watery, small bowel diarrhea	Demonstration of enterotoxin in fecal extracts or bacterial cultures by (a) Y-1 cell cytotoxicity assay or (b) enzyme-linked immunosorbent assay (ELISA)	Good (in combination)
			Demonstration of enterotoxin genes in fecal cultures by PCR and Southern blot hybridization	
Enterohemorrhagic *Escherichia coli* (EHEC)	≤5% (25% Greyhounds)	Watery or mucoid to hemorrhagic diarrhea	Demonstration of *Shiga*-like toxin in fecal extracts or bacterial cultures by (a) Vero cell cytotoxicity assay or (b) ELISA	Good (in combination)
			Demonstration of *Shiga*-like toxin encoding genes in fecal extracts or bacterial cultures by (a) PCR or (b) in-situ hybridization	
Salmonella	1% to 36%	Watery or mucoid to hemorrhagic diarrhea	Culture or PCR identification of *Salmonella* in feces	Poor
			Culture or PCR identification of *Salmonella* in sterile body fluids	Good

Treatment
The best treatment for *Brachyspira* spp. infection has not been identified.

Prognosis
Likely good, although specific treatment outcomes in dogs with confirmed infection have not been reported.

Campylobacter

Etiology
Campylobacter spp. (*C. jejuni*, *Campylobacter coli*, *Campylobacter helveticus*, and *Campylobacter upsaliensis*) are Gram-negative, microaerophilic, gullwing-shaped and motile, bacterial rods. *Campylobacter* can be cultured from the feces of up to 90% of normal dogs and cats, especially in young animals housed in dense populations such as breeding facilities and shelters.

Pathophysiology
Campylobacter is acquired from contaminated food and water sources and transmitted in contaminated facilities by a fecal–oral route. *Campylobacter* replicate in the lumen of the GI tract, penetrate the mucus lining of the intestine, adhere to the intestinal epithelium, and are variably internalized into the host epithelial cells. Virulence factors are expressed by different *Campylobacter* isolates and include enterotoxins, cytotoxins (e.g., cytolethal distending toxin), and adherence/invasion proteins. Lesions induced by *Campylobacter* infection include typhlitis and colitis characterized by epithelial cell death and attenuation, loss of the microvillus brush-border, depletion of goblet cells, and infiltration of colonic crypts by neutrophils culminating in the formation of microabscesses. The factors responsible for inciting resident *Campylobacter* to become invasive have yet to be determined, although changes in intestinal microflora, the presence of concurrent enteric pathogens, immunoincompetence, and poor environmental hygiene likely play contributory roles.

Clinical Examination
Dogs and cats with *Campylobacter*-associated diarrhea are typically young puppies or kittens, stressed by hospitalization, travel, concurrent disease, or dense housing conditions. Diarrhea ranges from mild loose feces, to watery diarrhea, to bloody mucoid diarrhea. Inappetence, vomiting, fever, and leukocytosis may also be present. Concurrent infections with other enteric pathogens, such as parvovirus, *Giardia*, and *Salmonella*, may play a synergistic role and worsen clinical signs.

Diagnosis
As a result of the high prevalence of *Campylobacter* in normal and diarrheic dogs and cats, demonstration of the organisms in feces is not indicative of disease causation. Methods used to demonstrate *Campylobacter* include (a) phase-contrast or darkfield examination of fresh wet mount preparations of feces for characteristic darting motility; (b) bacterial culture of feces in selective media; or (c) molecular identification of *Campylobacter* in feces on the basis of PCR and restriction fragment length polymorphism of specific genes. The morphologic appearance of *Campylobacter* cannot be adequately differentiated from *Helicobacter* spp. on the basis of Gram staining.

Treatment
Erythromycin is the drug of choice for treatment of *C. jejuni* infections in people and has been shown to decrease fecal shedding within 24 to 48 hours when administered to dogs.[59] Dogs and cats are an important reservoir for *Campylobacter* infection in people, where the infectious dose can be as low as a few hundred organisms. Veterinarians should alert owners of the zoonotic risk of *Campylobacter* infection and stress the importance of appropriate hygienic measures, particularly when pets have diarrhea.

Prognosis
Generally good.

Clostridium difficile

Etiology
Clostridium difficile is a Gram-positive, anaerobic, spore-forming bacillus. These bacteria are the most common cause of nosocomial and antibiotic-associated diarrhea in people. *C. difficile* can be cultured from the feces of up to 40% of normal dogs and cats, with most of these isolates being toxigenic (containing toxin genes).[60-64]

Pathophysiology
Diarrhea is mediated by toxigenic strains of *C. difficile*; that is, those that produce cytotoxic proteins of which toxin A (an enterotoxin) and toxin B (a cytotoxin) are best characterized. Both toxins mediate glycosylation and inactivation of Rho-GTPases (guanosine triphosphatases), resulting in depolymerization of F-actin, loss of epithelial integrity, and cell death. In the lamina propria, toxin A stimulates the synthesis of prostaglandins by macrophages, release of substance P, and degranulation of mast cells. Collectively these effects promote intestinal fluid loss and inflammation. There have been no studies to date evaluating the sensitivity of canine intestinal epithelia to either toxin A or B.

Clinical Examination
Reports clearly attributing diarrhea to *C. difficile* infection are uncommon and experimental infections have not produced diarrhea to date. Although antibiotic administration is a predisposing factor for *C. difficile*–associated disease in humans and horses, this does not appear to be a predisposing factor for dogs, although carriage of *C. difficile* may be more common in a hospital setting.[62,65,66] Dogs with suspected *C. difficile*–associated diarrhea commonly have signs consistent with concurrent involvement of the small and large intestine and occasionally, hemorrhagic gastroenteritis.[65]

Diagnosis
In dogs, there has been no significant association between isolation of *C. difficile* (toxigenic or nontoxigenic) and the presence of diarrhea.[62,64,66,67] Toxigenic *C. difficile* can be isolated from up to 94% of neonatal dogs in the absence of clinical signs of disease.[68] An association has been documented between immunodetection of toxin A in feces and clinical signs of diarrhea in the dog,[66,67] although toxin A was also detected in some dogs without diarrhea. In general, a diagnosis of *C. difficile*–associated diarrhea is supported by laboratory detection of toxin A or B by ELISA. Commercially available assays for detection of toxin A and B have unacceptably low sensitivity when applied to feces, but have reasonably good sensitivity and specificity when applied to culture isolates.[64]

Treatment
Metronidazole is the drug of choice for treatment of dogs and cats with *C. difficile*–associated diarrhea.[69,70] Metronidazole resistance among canine isolates appears to be absent or low.[71]

Clostridium perfringens

Etiology

C. *perfringens* is a Gram-positive, anaerobic, spore-forming bacillus. These bacteria also are members of the normal intestinal flora and can be cultured from 80% or greater normal and diarrheic dogs.[66,67] Most isolates obtained from dogs are biotype A, approximately 15% of which carry the gene encoding C. *perfringens* enterotoxin (CPE).[72]

Pathophysiology

The pathophysiology of C. *perfringens* infection remains poorly understood. It is speculated that in response to changes in diet, antibiotic administration, or coinfection with other intestinal pathogens, commensal enterotoxigenic strains are somehow triggered to undergo massive sporulation and synthesis of CPE. CPE binds to intestinal epithelial cells, forming pores in the plasma membrane that initiate cell death signaling pathways. Subsequent access of CPE to the basolateral epithelium induces structural damage to intercellular tight junctions resulting in increased epithelial permeability.[73] When administered orally or directly into the intestinal lumen of dogs, CPE induces fluid secretion and diarrhea.[74] CPE is one of numerous polypeptide enterotoxins that may be produced by C. *perfringens*. CPE-negative strains of C. *perfringens* may mediate diarrhea by virtue of other virulence factors (e.g., β_2 toxin).

Clinical Examination

The clinical spectrum of GI disease attributed to C. *perfringens* varies considerably and ranges from mild self-limiting diarrhea to fatal acute hemorrhagic gastroenteritis. C. *perfringens* is believed to be a major cause of acute, nosocomial large bowel diarrhea that begins with 1 to 5 days of boarding or kenneling. Clinical signs of large intestinal diarrhea including mucus, increased frequency, tenesmus and hematochezia are most often attributed to C. *perfringens*. However, acute and chronic diarrhea of both large and small bowel origin have been described.

Diagnosis

Diagnosis of C. *perfringens* as a causative agent of diarrhea remains highly problematic. At present, the optimum diagnostic approach is demonstration of CPE (protein) in feces by ELISA (C. *perfringens* Enterotoxin Test, TECHLAB, Blacksburg, VA) in conjunction with PCR, performed on culture isolates, for the presence of the *cpe* gene. Although immunodetection of CPE has been significantly associated with diarrhea in dogs, CPE is also detected in dogs without diarrhea,[66,67] and available methods for immunodetection of CPE have poor sensitivity and specificity. Fecal culture or endospore enumeration are unreliable tests for establishing C. *perfringens* infection in the dog because the bacteria are commensal and there appears to be no association between fecal endospore numbers and presence of diarrhea or between spore counts and detection of CPE.[66,67,75]

Treatment

Drugs commonly used for treatment of C. *perfringens* diarrhea include ampicillin, erythromycin, metronidazole, and tylosin. Because of a high incidence of resistance, the use of tetracyclines is discouraged.[71]

Prognosis

The prognosis for recovery is excellent.

Enterohemorrhagic *Escherichia coli*

Etiology

Enterohemorrhagic *E. coli* (EHEC) mediate disease by production of *Shiga*-like toxins (Stx). These toxins are uniquely characterized by cytotoxic effects on cultured Vero (African green monkey kidney) cells and are therefore also referred to as *Verotoxins*. *E. coli* of a broad range of O:H serotypes are capable of producing Stx, of which *E. coli* O157:H7 is but one member. Verotoxigenic *E. coli* may be isolated from 2% to 13.8% and 0% to 4.8% of healthy cats and dogs, respectively.[76-80] Carriage of EHEC may be greater in Greyhound dogs, where 25% of normal animals in one study were found to be infected. A higher prevalence of EHEC in Greyhounds may be attributed to the common practice of feeding raw meat.[81] Most EHEC recovered from dogs and cats are *not* serotype O157:H7.

Pathophysiology

EHEC colonize the colon and produce Stx, which is translocated from the lumen of the intestine, across the intestinal epithelial cells, and into the bloodstream. The bacteria do not invade the intestinal epithelium, nor are they suspected to directly mediate toxic effects on the intestine. Rather, Stx is disseminated in the bloodstream and binds to glycolipid receptors that are expressed in abundance by the kidney and intestine. At these sites, Stx interacts with endothelial cells to disable 28S rRNA, inhibit protein translation, and thereby mediate cell death. When experimentally injected into the bloodstream of Greyhound dogs, *Shiga* toxins mediate severe bloody diarrhea and hemolytic uremic syndrome within 48 to 52 hours.[82]

Clinical Examination

Intestinal manifestations of EHEC infection range from asymptomatic disease, to watery or mucoid diarrhea with slight blood,[83] to anorexia, vomiting, and hemorrhagic diarrhea.[84-86] Extraintestinal sequelae of EHEC infection in dogs are reported rarely[84-86] and have not been reported in the cat. In these cases, hemorrhagic diarrhea is followed by a hemolytic uremic syndrome characterized by a triad of acute renal failure, microangiopathic hemolytic anemia, and thrombocytopenia.

Diagnosis

A diagnosis of EHEC infection is based on demonstration of Stx (ELISA) and/or Stx genes (PCR or in-situ hybridization) in extracts of feces or in culture isolates of *E. coli* obtained from the feces. Sensitivity is improved by demonstrating both the toxin and gene and by performing such assays on culture isolates, rather than feces. There is little information on potential sequence heterogeneity of Stx in the dog and cat, and accordingly, the sensitivity and specificity of commercially available tests used for demonstration of Stx genes or antigen. In Greyhound dogs, a significant association was found between the presence of diarrhea and demonstration of the *stx1* gene or *Shiga* toxin in fecal cultures.[81] Although *Shiga* toxin was demonstrated in 43% of Greyhound dogs with diarrhea in the study, 25% of dogs without diarrhea also had *Shiga* toxin-producing *E. coli* present. In cats, *E. coli* strains isolated from feces of diarrheic animals produced verotoxin more frequently than did *E. coli* strains isolated from those without diarrhea.[80]

Treatment

Too few cases in dogs and cats have been described to make solid recommendations on the appropriateness or choice of antibiotic

treatment for EHEC infection. In people, treatment with antibiotics is contraindicated because of increased risk of developing hemolytic uremic syndrome as a consequence of lysis of bacteria with release of additional toxin into the lumen of the intestine. Accordingly, treatment of infection may be limited largely to supportive care.

Prognosis

The prognosis is likely good for hemorrhagic diarrhea alone. The prognosis is guarded for cases characterized by hemolytic uremic syndrome.

Enteropathogenic *Escherichia coli*

Etiology

Enteropathogenic *E. coli* (EPEC), also termed *attaching and effacing E. coli* (AEEC), possess key attributes that enable them to intimately attach to intestinal epithelial cells, into which they inject bacterial proteins, and initiate intracellular signaling pathways leading to diarrhea.

Pathophysiology

EPEC adhere, in part, to intestinal epithelial cells by virtue of an adherence factor plasmid that contains genes encoding bundle-forming pili. The EPEC genome also contains a "pathogenicity island," called the *locus of enterocyte effacement* (LEE), which contains genes encoding a type III secretory system, multiple EPEC-secreted proteins, a bacterial adhesin called *intimin* (*eae*), and a translocated intimin receptor called *Tir*. EPEC use the type III secretory system as a "molecular syringe" to inject Tir into the host cell whereupon it is translocated to the host cell membrane and serves as a receptor for the bacterial-expressed adhesin intimin. Bacterial attachment results in considerable cytoskeletal reorganization leading to the effacement of microvilli, the formation of pedestals beneath the attached bacteria and disruption of epithelial barrier function. Diarrhea is attributed to a combination of malabsorption, water and electrolyte secretion, increased permeability of tight junctions, and epithelial synthesis of cytokines and chemokines that promote mucosal inflammation.

Clinical Examination

Dogs in which EPEC infection has been described are typically younger than 1 year of age, have acute to chronic, sometimes hemorrhagic, diarrhea, and are often concurrently infected with other diarrheal agents such as distemper virus, parvovirus, coccidia, *Giardia*, or *Cryptosporidium*.[78,87] Fatal EPEC infection has been documented in a 2-month-old kitten and an adult cat in which attaching and effacing lesions and acute mucosal inflammation were present in the ileum and colon.[88]

Diagnosis

Diagnosis of EPEC infection is based on documentation of attaching and effacing histologic lesions, and absence of Stx. The latter is important as some strains of enterohemorrhagic *E. coli* can also cause attaching and effacing lesions. Attaching and effacing lesions are characterized by accumulation of F-actin beneath the adherent bacteria and can be demonstrated by transmission electron microscopy or by staining of F-actin with fluorescent-labeled phalloidin. In dogs, attaching and effacing lesions have been reported in both the small and large intestine. Studies seeking to diagnose EPEC by demonstration of LEE-associated genes in feces have found such genes to be commonly present in the flora of both healthy and diseased individuals.[89]

Treatment

Treatment consists of supportive care, parenteral fluid therapy, and administration of antimicrobial drugs with Gram-negative activity including amoxicillin-clavulanate, first- or second-generation cephalosporins, or enrofloxacin.

Prognosis

Prognosis depends on the cause and severity of concurrent intestinal infectious disease. Death in puppies with EPEC and concurrent enteric infection is common.

Table 58-7 discusses the section of intestine most commonly affected, type of intestinal lesion(s), invasiveness, virulence characteristics, and mechanism of diarrhea of enteric *E. coli* infecting dogs.

Salmonella

Etiology

Salmonella are motile, non–spore-forming, Gram-negative bacterial rods. The species most commonly isolated from diseased animals and people is *Salmonella typhimurium*. *S. typhimurium* is ubiquitous in the environment because of direct or indirect fecal contamination of food, water, or fomites. In dogs, infection is most commonly acquired through the practice of feeding raw,[90,91] dehydrated (e.g., dog chews made from animal hide[92]), or improperly cooked meat products. *Salmonella* spp. were isolated from 80% of samples taken from a bones-and-raw-food diet and from 30% of fecal samples from dogs fed the diet.[91] A conservative prevalence of *Salmonella* infection in clinically healthy or hospitalized dogs is 1% to 36% and from healthy cats is 1% to 18%.[93]

Pathophysiology

Following ingestion, *Salmonella* adhere via fimbriae to intestinal epithelial cells and M cells. *Salmonella* translocates bacterial proteins into these host cells by virtue of a type III secretion system. The translocated proteins interact with Rho-family guanosine triphosphate–binding proteins to facilitate internalization of the bacteria into host cell vesicles and stimulate host cell secretion of cytokines such as interleukin-8. A resulting influx of neutrophils transmigrate across the epithelium resulting in loss of barrier integrity. A fraction of *Salmonella*-containing vesicles are transported to the basolateral membrane where released *Salmonella* enters macrophages in which they multiply and disseminate systemically. Factors contributing to susceptibility to *Salmonella* infection include young age, nutritional deficiency, impaired immune defense, concurrent GI infection, and disruption of the normal intestinal flora (e.g., antibiotics) leading to loss of colonization resistance. Intestinal lesions are usually confined to the distal small bowel, cecum, and colon, and consist of mucosal inflammation and epithelial sloughing.

Clinical Examination

Clinical signs of salmonellosis are most severe in puppies and kittens younger than 1 year of age and geriatric animals. Diarrhea varies from watery to mucoid, with fresh blood present in severe cases. In addition to diarrhea, other clinical signs, such as fever, anorexia, vomiting, and abdominal pain, may be present. Patients developing bacteremia or endotoxemia may be obtunded, weak, have pale mucous membranes, tachycardia, hypothermia, and vascular collapse. The clinical and pathologic features of salmonellosis may be indistinguishable from those of canine parvovirus and feline panleukopenia infection.

Table 58-7 Section of Intestine Most Commonly Affected, Type of Intestinal Lesion(s), Invasiveness, Virulence Characteristics, and Mechanism of Diarrhea of Enteric *Escherichia coli* Infecting Dogs

	Disease Localization	Intestinal Lesions	Invasion of Intestinal Epithelial Cells	Virulence Characteristics	
Enteropathogenic *E. coli* (EPEC)	Small and large intestine	Effacement of microvilli and pedestal formation Mucosal inflammation	Variable	Adherence factor plasmid contains genes encoding bundle-forming pili Locus for enterocyte effacement contains bacterial genes encoding intimin (*eae*), a type III secretory apparatus, translocated intimin receptor, and EPEC-secreted proteins	Malabsorption, water and electrolyte secretion, increased permeability of tight junctions, and mucosal inflammation
Enterotoxigenic *E. coli* (ETEC)	Small intestine	Minimal histologic changes or inflammation	Noninvasive	Heat-labile toxins stimulate adenylyl cyclase activity by activational adenosine diphosphate-ribosylation of $G_{s\alpha}$, thereby increasing the synthesis of cyclic adenosine monophosphate Heat-stabile toxins bind to and activate membrane-bound guanylyl cyclase, thereby increasing the synthesis of cyclic guanosine monophosphate	Secretory diarrhea ("traveler's diarrhea" in people): stimulate Cl^- secretion by crypt epithelium and inhibit NaCl absorption by villous epithelium
Enterohemorrhagic *E. coli* (EHEC) and *E. coli* 0127:H7	Large intestine	Edema and submucosal hemorrhage, arteritis, and microvascular thrombosis of intestinal arterioles	Noninvasive	*Shiga*-like verotoxins inhibit protein synthesis resulting in cell death	Hemorrhagic colitis Hemolytic uremic syndrome

Diagnosis

Isolation of *Salmonella* organisms is the most definitive means of confirming infection. Because of the high prevalence of asymptomatic carriage of *Salmonella*, isolation from normally sterile samples (e.g., urine, blood) may allow a definitive diagnosis and indicate disseminated disease. In addition, failure to isolate *Salmonella* does not rule out infection because of the fastidious nature of *Salmonella* in culture. Use of PCR for identification of *Salmonella* in dogs has been described[94] but is not yet widely applied.

Treatment

Treatment varies according to the severity of the clinical signs. Acute gastroenteritis, without clinical signs of systemic disease may be treated with fluid therapy and supportive care. Antibiotic therapy may prolong fecal shedding and induce drug resistance and is therefore reserved for patients with severe hemorrhagic diarrhea, history of immunosuppression, suspected or documented septicemia, evidence of systemic inflammatory response syndrome, or a combination of these symptoms.

Antibiotics reported to be effective for treatment of *Salmonella* include chloramphenicol, amoxicillin, trimethoprim-sulfa, and enrofloxacin. Posttreatment cultures should be performed to confirm eradication, and pet owners should be advised of the public health importance of the disease.

Prognosis

The prognosis for enteritis alone is generally good. The prognosis for patients with disseminated disease, endotoxemia, or sepsis is more guarded. Some patients may remain chronic carriers with recrudescence during periods of stress or unrelated disease.

Yersinia enterocolitica

Y. enterocolitica and *Yersinia pseudotuberculosis* are motile, Gram-negative, coccobacilli that can be isolated from the feces of clinically normal dogs and cats. *Yersinia* has been cultured on rare occasions from the feces of dogs and cats with abdominal discomfort or bloody diarrhea.[95-97]

Viruses

Feline Enteric Coronavirus

Although uncommon, colonic disease may be a primary manifestation of feline infectious peritonitis (FIP) infection in the cat.[98,99] Clinical signs of diarrhea or constipation may be present. Physical examination reveals a palpable abdominal mass of the colon or ileocecocolic junction. Histopathology is consistent with pyogranulomatous inflammation with intralesional feline coronavirus demonstrable by immunohistochemistry. In the majority of cases reported,

cats were euthanized or died from the effects of multisystemic FIP infection.

OBSTRUCTION

Robert J. Washabau

Intussusception

Etiology

Intussusception is an invagination of one segment of the gastrointestinal tract into the lumen of an adjoining segment. The intussusceptum is the invaginated segment of the alimentary tract, whereas the intussuscipiens is the enveloping segment. Invagination may occur in an antegrade (aborad) or retrograde (orad) direction, but is most commonly in the antegrade direction. Any portion of the alimentary tract may be involved, but enterocolic intussusceptions account for almost two-thirds of the published cases in dogs and cats. Enterocolic intussusceptions can be further divided into three types: cecocolic (or cecal inversion), with the inverted cecum forming the apex[1]; ileocolic, with the ileum forming the apex; and ileocecal, with the ileocecal junction forming the apex.[2] Of these three forms of enterocolic intussusception, the ileocolic intussusception is the one most frequently encountered in clinical practice. A number of conditions are reported to predispose to intussusception, including intestinal parasitism, viral enteritis, foreign bodies, and masses, but in dogs and cats most intussusceptions are idiopathic.[3-5]

Pathophysiology

The initiating events in an intussusception are often difficult to identify retrospectively, but all intussusceptions appear to share three important features: (a) inhomogeneity in a bowel segment, a region in which the gastrointestinal tract undergoes a sudden anatomic change in diameter (e.g., ileocolic junction) or a bowel segment that is either flaccid or indurated; (b) mechanical linkage of nonadjacent segments, which can be intraluminal (e.g., linear foreign bodies or parasites) or extramural (e.g., fibrous adhesions or bands); and (c) peristaltic activity of the gut.[2] Invagination begins as a result of peristaltic contraction. Once the invagination has begun, its progress may be rapid, involving as much as several centimeters of intestinal tract within just a few hours. Invagination and intussusception result in luminal obstruction, which may be partial or complete. Obstruction usually results in distention of the bowel segment proximal to the intussusception. The degree of distention is dependent upon the completeness and duration of the obstruction, volume of fluid secretion, degree of vascular compromise, and volume of gas production from bacterial fermentation. Because the mesentery and blood supply are included in the invaginating segment, vascular compromise can occur, which initially leads to intramural hemorrhage and edema and eventually to ischemia and necrosis of the bowel. Full-thickness necrosis may ensue but perforations are rare.

Clinical Examination

The most important clinical signs with ileocolic intussusceptions are intermittent vomiting, progressive loss of appetite, mucoid bloody diarrhea, and a palpable cylinder-shaped mass in the cranial abdomen. Abdominal pain is not a consistent finding in affected animals. Clinical signs may persist for several weeks and affected animals eventually succumb to the effects of starvation rather than dehydration, electrolyte imbalances, or acid–base disturbances.

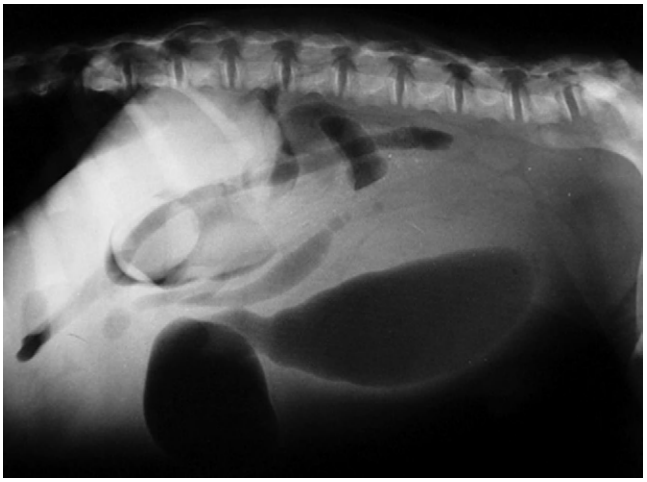

Figure 58-12 Abdominal survey radiographic evidence of intussusception.

Diagnosis

With some ileocolic intussusceptions, the intussuscepted bowel may protrude through the anus and must be differentiated from a rectal prolapse. This is accomplished by passing a blunt probe between the protruding segment and the anal sphincter. If the probe can be passed cranial to the pubis without reaching a fornix, then the protruding bowel is the apex of an intussusception rather than rectal prolapse.

Survey abdominal radiographs are often nondiagnostic, but may reveal distention and obstruction proximal to the intussusception (Figure 58-12). Barium-contrast studies (barium enema or upper GI series) are often diagnostic, but abdominal ultrasonography is the preferred method of diagnosis. The appearance of a target-like mass consisting of two or more hyperechoic and hypoechoic concentric rings in transverse section or the appearance of multiple hyperechoic and hypoechoic parallel lines in longitudinal section is virtually diagnostic of an intussusception (Figure 58-13).[6] The ultrasound scan might also identify a mass associated with the intussusception. Endoscopy may be performed in suspected cases of suspected neoplasia, otherwise endoscopy does not confer any additional benefits over abdominal ultrasound or CT scanning.

Treatment

The surgical management of ileocolic intussusception involves either reduction or resection, and anastomosis, or both.[7,8] Secretory diarrhea may persist following relief of the obstruction and affected animals may need continuous crystalloid and colloidal therapy. If possible, the ileocecal sphincter should be preserved to reduce reflux and contamination of the distal small bowel. Cecocolic intussusceptions or inversions should also be treated with surgical resection. Surgical resection of the cecocolic intussusceptions is generally curative. Enteroplication procedures have been recommended,[9] but they do not appear to reduce recurrence rates.[7,8]

Prognosis

The most common complications following treatment of intussusception are recurrence, dehiscence of the anastomosis, ileus, intestinal obstruction, peritonitis, and short bowel syndrome. The

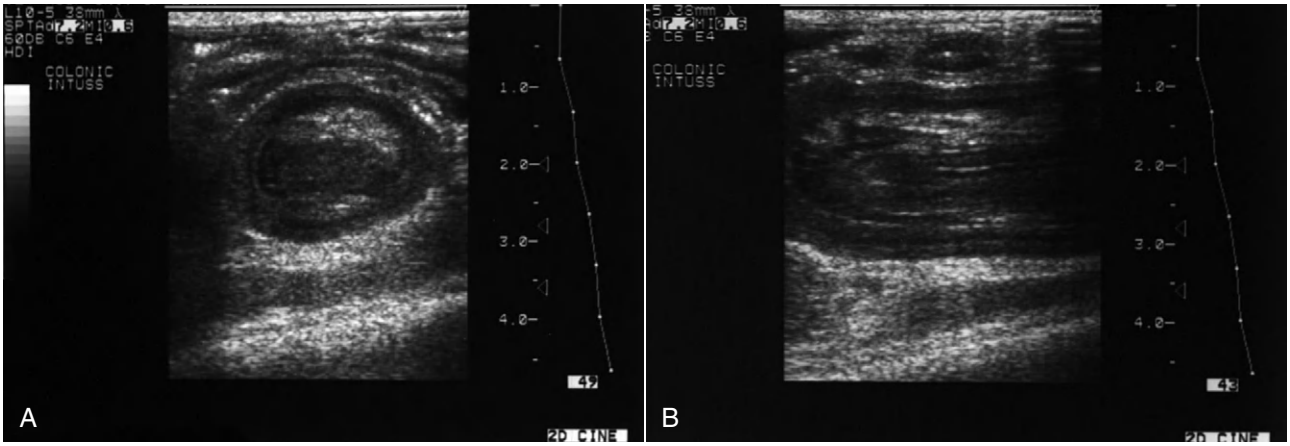

Figure 58-13 Abdominal ultrasonographic appearance of intussusception. Target-like mass consisting of two or more hyperechoic and hypoechoic concentric rings in transverse section (**A**) and the appearance of multiple hyperechoic and hypoechoic parallel lines in longitudinal section (**B**) are virtually diagnostic of an intussusception.

recurrence rate in dogs is reported to be between 11% and 20%. In dogs in which no surgical procedure was performed to prevent recurrence, intussusception recurred in 25% of dogs that underwent manual reduction alone and in 19% of dogs that underwent resection and anastomosis. Enteroplication does not appear to reduce recurrence rates any further.[7,8] Indeed, 19% of dogs undergoing enteroplication in one study experienced severe complications that required a second surgery. Intestinal obstruction was a complication of the enteroplication in those patients.[8]

Pyogranulomatous Inflammation

Histoplasma capsulatum

Etiology

Histoplasmosis is a systemic fungal disease of dogs and cats caused by *H. capsulatum*. In the environment, *H. capsulatum* organisms are mycelial, saprophytic soil fungi. In infected tissue or when cultured at 30°C (86°F) to 37°C (98.6°F), the organism is a yeast. The fungus is endemic throughout most of the temperate and subtropical regions of the world. Most cases of histoplasmosis in the United States occur in the central states, with the geographic distribution following the Mississippi, Ohio, and Missouri Rivers.[10,11]

Pathophysiology

Infection is probably via inhalation or ingestion of infective conidia from the environment. The respiratory system is thought to be the primary route of infection in cats and dogs, although the gastrointestinal tract may also be an important route in the dog. After inhalation or ingestion, conidia transform from the mycelial phase and are phagocytized by macrophages, where they grow as facultative intracellular organisms. Hematogenous and lymphatic dissemination results in multisystemic disease. Organisms can be disseminated to any organ system, but the lungs, gastrointestinal tract, lymph nodes, liver, spleen, bone marrow, eyes, and adrenal glands are the most common organs of dissemination in the dogs; lungs, liver, lymph nodes, eyes, and bone marrow are most commonly affected in cats. Cell-mediated immunity induces a granulomatous inflammatory response in most infection.[12]

Clinical Examination

Dogs with gastrointestinal histoplasmosis are typically presented with mild fever, anorexia, lethargy, weight loss, vomiting, diarrhea, hematochezia, and tenesmus. Cachexia is a common physical examination finding. Other historical and physical examination findings (dyspnea, cough, ascites, lameness, oropharyngeal ulcerations, chorioretinitis, neuropathy) will depend upon organ and tissue involvement. The small intestinal form of histoplasmosis is described in more detail in Chapter 57.

Diagnosis

Organism identification is required for definitive diagnosis. The most common means of organism identification is cytology. Cytology from affected tissue reveals pyogranulomatous inflammation, often with numerous small, round to oval intracellular yeast cells (2 to 4 μm in diameter) characterized by a basophilic center and a light halo. Exfoliative cytology during colonoscopy is particularly useful in diagnosing the disease. Histopathology is helpful if cytology is nondiagnostic or inconclusive. Multiple endoscopic colonic biopsies are usually sufficient to diagnose the disease. The yeast form does not stain well with routine hematoxylin and eosin stains, so special stains such as PAS and Gomori methenamine silver stain are often used to demonstrate organisms. Fungal culture from affected tissue can be used for diagnosis but is rarely needed in clinical cases. Currently available serologies have poor specificity and sensitivity.[12]

Treatment

Itraconazole (5 mg/kg PO BID for 2 to 4 months) is considered the treatment of choice for feline histoplasmosis. In one study, itraconazole therapy cured histoplasmosis infections in all eight study cats.[13] Ketoconazole and amphotericin B have been described as the treatments of choice for canine histoplasmosis. With colonic involvement, additional gastrointestinal therapy may be useful in affected dogs, for example, dietary modification, treatment for small intestinal bacterial overgrowth, and direct antidiarrheal therapy. Corticosteroids may have been used successfully in the treatment of airway obstruction secondary to hilar lymphadenopathy in chronically infected dogs.[14]

Prognosis

There may be important species differences in prognosis although the paucity of reports, especially of prospective clinical trials, makes it difficult to generalize. It would seem that the prognosis is guarded in dogs, but fair to good in cats.

Pythium insidiosum

Etiology

P. insidiosum is an aquatic oomycete that causes severe gastrointestinal pathology in a range of hosts in the tropical and subtropical climates.[15] Based on ribosomal RNA gene sequence data, members of the class *Oomycetes* are phylogenetically distinct from the kingdom *Fungi*, and are more closely related to algae than to fungi.[16] The oomycetes differ from fungi in two important properties: cell wall and cell membrane composition. Chitin is an essential component of the fungal cell wall, but it is generally lacking in the oomycete cell wall. Oomycetes also differ from fungi in that ergosterol is not a principal sterol in the oomycete cell membrane. This difference may explain why ergosterol-targeting drugs like itraconazole are less effective in the medical treatment of pythiosis.[16]

Pathophysiology

The infective state of *P. insidiosum* is thought to be the motile zoospore, which is released into stagnant water in warm environments, and likely causes infection either by encysting in the skin, or by being ingested into the gastrointestinal tract. Ingested zoospores encyst and adhere to the gastric, jejunal, and colonic epithelium with a polarity oriented toward the submucosa for rapid tissue penetration following germ tube eruption. *Pythium* induces a chronic pyogranulomatous response in the gastrointestinal tract and mesenteric lymph nodes. The gastric outflow tract and ileocolonic junction are the most frequently affected portions of the GI tract, and it is not uncommon to find two or more segmental lesions in the same patient.[17] Inflammation in affected regions is typically centered on the submucosa, with variable mucosal ulceration and occasional extension of disease through serosal surfaces, resulting in adhesion formation and peritonitis.

Clinical Examination

Weight loss, vomiting, diarrhea, and hematochezia are the most important clinical signs. Physical examination often reveals emaciated body condition and a palpable abdominal mass. Signs of systemic illness such as lethargy and depression are not typically present unless intestinal obstruction, infarction, or perforation occurs.

Diagnosis

Ileocolonic wall thickening, obliteration of the normal layered appearance, and regional lymphadenopathy are common ultrasonographic features of canine intestinal pythiosis.[18] Of course, these findings cannot be readily differentiated from those associated with intestinal malignancy. Definitive diagnosis requires histologic demonstration or immunohistochemical staining of the organism and/or positive ELISA or PCR assays. The histologic findings associated with pythiosis generally are characterized by eosinophilic granulomatous to pyogranulomatous inflammation with fibrosis. Affected tissue typically contain multiple foci of necrosis surrounded and infiltrated by neutrophils, eosinophils, and macrophages. Discrete granulomas composed of epithelioid macrophages, plasma cells, multinucleate giant cells, and neutrophils and eosinophils may also be observed. *Pythium* zoospores may be cultured directly from affected tissue in antibiotic-containing (e.g., streptomycin and ampicillin) media. More recently, sensitive and specific ELISA and PCR assays have been developed for the accurate diagnosis of pythiosis in dogs.[19-21]

Treatment

Aggressive surgical resection remains the treatment of choice for pythiosis in dogs. Because it provides the best opportunity for long-term cure, complete resection of infected tissue should be pursued whenever possible. Segmental lesions of the GI tract should be resected with 3- to 4-cm margins whenever possible. Medical therapy for the oomycetes has not been very promising. This may relate to the absence of ergosterol (cell membrane target of most currently available antifungal drugs) in the oomycete cell membrane. Clinical and serologic cures have been obtained in a small number of dogs following therapy with amphotericin B lipid complex (2 to 3 mg/kg QOD administered to a cumulative dose of 24 to 27 mg/kg) or itraconazole (10 mg/kg q24h for 6 to 9 months).

Prognosis

Unfortunately, most dogs with GI pythiosis are not presented to the veterinarian until late in the course of the disease, when complete excision is not possible. The anatomic site of the lesion (e.g., pylorus or ileocolic sphincter) may also prevent complete excision. Consequently, the prognosis is usually grave in most animals.[16]

Feline Infectious Peritonitis

FIP is a well-known and widely distributed coronavirus-induced systemic disease in cats, characterized by fibrinous to granulomatous serositis with protein-rich effusions in body cavities and granulomatous inflammatory lesions in multiple organs. One of its morphologic hallmarks is a granulomatous to necrotizing phlebitis and periphlebitis.[22,23] Affected cats develop signs caused by granulomatous lesions in target organs (central nervous system, eyes, and parenchymatous organs) and vasculitis leading to fluid redistribution into third spaces with fluid accumulation in body cavities.[22] In addition to the well-known multisystemic condition, some unusual problems have been described, including focal pyogranulomas of the gastrointestinal tract. In a survey of 156 cats with disseminated FIP, 26 had solitary mural intestinal lesions.[24] Predominant clinical signs included diarrhea and vomiting for 3 months or less before intestinal biopsy. All cats had a mass, believed to be a neoplasm, in the colon or ileocecocolic junction. Affected intestine was markedly thickened, nodular, firm, and white, with multifocal pyogranulomas extending throughout the wall of the intestine, and the regional lymph nodes were uniformly involved. Most cats were euthanized or died within 9 months of histologic findings, many with signs of multisystemic FIP.[24]

Nonneoplastic Stricture

The etiologies for nonneoplastic colonic strictures include foreign bodies, postoperative complications, inflammatory disease (e.g., IBD, diffuse perianal fistula disease), and congenital malformation.[25] Postoperative complications are probably the most important cause of colonic strictures in dogs and cats,[25] which emphasizes the importance of good surgical principles in performing colonic surgery.[26] Nonneoplastic strictures of the colon are fairly rare. Nonneoplastic strictures of the rectum are more common (see Chapter 59).

DYSMOTILITY

Robert J. Washabau

Constipation

Etiology

The etiopathogenesis of idiopathic megacolon is still incompletely understood. Several reviews have emphasized the importance of

Table 58-8 Causes of Constipation

Type	Cause
Mechanical obstruction	
Intraluminal	Bones, hair, neoplasia, rectal diverticulum, stricture, deviation/sacculation associated with perineal hernia
Intramural	Neoplasia
Extramural	Pelvic fractures, neoplasia, prostatic disease
Inflammation	Perianal fistula, anal sac disease, perineal wounds
Neuromuscular dysfunction	Lumbosacral disease, cauda equina syndrome, sacral spinal cord deformities (Manx cat)
	Hypogastric or pelvic nerve disorders–trauma, neoplasia, dysautonomia
	Colonic smooth muscle–idiopathic megacolon
Metabolic, endocrine	Dehydration, hypokalemia, hypocalcemia
	Hypothyroidism, nutritional secondary hyperparathyroidism, obesity
Pharmacologic	Opioids, atropine, anticholinergics, diuretics, barium sulfate, phenothiazines, β-agonist drugs
Environmental	Soiled/absent litterbox, inactivity, hospitalization, multicat households, competition

Adapted from Washabau RJ, Hasler AH: Constipation, obstipation, and megacolon. In: August JR, editor: Consultations in Feline Internal Medicine, ed 3. Philadelphia, 1997, Saunders, p 106.

considering an extensive list of differential diagnoses (e.g., neuromuscular, mechanical, inflammatory, metabolic/endocrine, pharmacologic, environmental, and behavioral causes) for the obstipated cat (Table 58-8). A review of published cases suggests that 96% of cases of obstipation are accounted for by idiopathic megacolon (62%), pelvic canal stenosis (23%), nerve injury (6%), or Manx sacral spinal cord deformity (5%).[1,2] A smaller number of cases are accounted for by complications of colopexy (1%) and colonic neoplasia (1%); colonic hypo- or aganglionosis was suspected, but not proved, in another 2% of cases. A definitive case of colonic hypoganglionosis was reported in an 11-week-old female domestic shorthaired cat.[3] Inflammatory, pharmacologic, and environmental/behavioral causes were not cited as predisposing factors in any of the original case reports. Endocrine factors (e.g., obesity and hypothyroidism) were cited in several cases, but were not necessarily impugned as part of the pathogenesis of megacolon. It is important to consider an extensive list of differential diagnoses in an individual animal, but it should be kept in mind that most cases are idiopathic,[1,2] orthopedic,[1,2] or neurologic[4] in origin. Behavioral (e.g., stress) and/or environmental (e.g., competition for the litterbox) factors very likely play an important role in the development of this lesion, but this has been poorly studied in retrospective or prospective studies.

Pathophysiology

Megacolon develops through two pathologic mechanisms: *dilation* and *hypertrophy*. *Dilated megacolon* is the end stage of colonic dysfunction in idiopathic cases. Cats affected with idiopathic dilated megacolon have permanent loss of colonic structure and function. Medical therapy may be attempted in such cases, but most affected cats eventually require colectomy. *Hypertrophic megacolon*, on the other hand, develops as a consequence of obstructive lesions (e.g., malunion of pelvic fractures, tumors, foreign bodies). Hypertrophic megacolon may be reversible with early pelvic osteotomy or it may progress to irreversible dilated megacolon if appropriate therapy is not instituted.[5]

Constipation and *obstipation* are earlier manifestations of the same problem. Constipation is defined as the infrequent difficult evacuation of feces but does not necessarily imply a permanent loss of function. Many cats suffer from one or two episodes of constipation without further progression. Intractable constipation that has become refractory to cure or control is referred to as *obstipation*. The term *obstipation* implies a permanent loss of function. A cat is assumed to be obstipated only after several consecutive treatment failures. Recurring episodes of constipation or obstipation may culminate in the syndrome of *megacolon*.

The pathogenesis of idiopathic dilated megacolon appears to involve functional disturbances in colonic smooth muscle. In vitro isometric stress measurements have been performed on colonic smooth muscle obtained from cats suffering from idiopathic dilated megacolon.[6,7] Megacolonic smooth muscle develops less isometric stress in response to neurotransmitter (acetylcholine, substance P, cholecystokinin), membrane depolarization (potassium chloride), or electrical field stimulation, when compared with healthy controls.[6,7] Differences have been observed in longitudinal and circular smooth muscle from descending and ascending colon. No significant abnormalities of smooth muscle cells or of myenteric neurons were observed on histologic evaluation. These studies initially suggested that the disorder of feline idiopathic megacolon is a generalized dysfunction of colonic smooth muscle, and that treatments aimed at stimulating colonic smooth muscle contraction might improve colonic motility. The lesion begins in the descending colon and appears to progressively involve the ascending colon over time.[8]

Clinical Examination

History

Constipation, obstipation, and megacolon may be observed in cats of any age, sex, or breed, however, most cases are observed in middle aged (mean: 5.8 years), male cats (70% male, 30% female) of domestic shorthair (46%), domestic longhair (15%), or Siamese (12%) breeding.[1] Affected cats are usually presented for reduced, absent, or painful defecation for a period of time ranging from days to weeks or months. Some cats are observed making multiple, unproductive attempts to defecate in the litterbox, while other cats may sit in the litterbox for prolonged periods of time without assuming a defecation posture. Dry, hardened feces are observed inside and outside of the litterbox. Occasionally, chronically constipated cats have intermittent episodes of hematochezia or diarrhea as a result of the mucosal irritant effect of fecal concretions. This may give the pet owner the erroneous impression that diarrhea is the primary problem. Prolonged inability to defecate may result in other systemic signs, including anorexia, lethargy, weight loss, and vomiting.

Physical Examination

Colonic impaction is a consistent physical examination finding in affected cats. Other findings depend upon the severity and pathogenesis of constipation. Dehydration, weight loss, debilitation, abdominal pain, and mild to moderate mesenteric lymphadenopathy may be observed in cats with severe idiopathic megacolon. Colonic impaction may be so severe in such cases as to render it difficult to differentiate impaction from colonic, mesenteric, or other

abdominal neoplasia. Cats with constipation caused by dysautonomia may have other signs of autonomic nervous system failure, such as urinary and fecal incontinence, regurgitation as a consequence of megaesophagus, mydriasis, decreased lacrimation, prolapse of the nictitating membrane, and bradycardia. Digital rectal examination should be carefully performed with sedation or anesthesia in all cats. Pelvic fracture malunion may be detected on rectal examination in cats with pelvic trauma. Rectal examination might also identify other unusual causes of constipation, such as foreign bodies, rectal diverticula, stricture, inflammation, or neoplasia. Chronic tenesmus may be associated with perineal herniation in some cases. A complete neurologic examination with special emphasis on caudal spinal cord function should be performed to identify neurologic causes of constipation, for example, spinal cord injury, pelvic nerve trauma, or Manx sacral spinal cord deformity.

Diagnosis

Although most cases of obstipation and megacolon are unlikely to have significant changes in laboratory data (e.g., complete blood cell count, serum chemistry, urinalysis), these tests should nonetheless be performed in all cats presented for constipation. Metabolic causes of constipation, such as dehydration, hypokalemia, and hypercalcemia may be detected in some cases. Basal serum T_4 (thyroxine) concentration and other thyroid function tests should also be considered in cats with recurrent constipation and other signs consistent with hypothyroidism. Although hypothyroidism was documented in only one case of obstipation and megacolon, obstipation is a frequent clinical sign in kittens affected with congenital or juvenile-onset hypothyroidism.[1] Constipation could also theoretically develop following successful treatment of feline hyperthyroidism.

Abdominal radiography should be performed in all constipated cats to characterize the severity of colonic impaction, and to identify predisposing factors such as intraluminal radiopaque foreign material (e.g., bone chips), intraluminal or extraluminal mass lesions, pelvic fractures, and spinal cord abnormalities (Figure 58-14). The radiographic findings of colonic impaction cannot be used to distinguish between constipation, obstipation, and megacolon in idiopathic cases. First or second episodes of constipation in some cats may be severe and generalized but may still resolve with appropriate treatment.

Ancillary studies may be indicated in some cases. Extraluminal mass lesions may be further evaluated by abdominal ultrasonography and guided biopsy, whereas intraluminal mass lesions are best evaluated by endoscopy. Colonoscopy may also be used to evaluate the colon and anorectum for suspected inflammatory lesions, strictures, sacculations, and diverticula. Barium enema contrast radiography may be used if colonoscopy is not possible. Both colonoscopy and barium-contrast enema radiography require general anesthesia and evacuation of impacted feces. Cerebrospinal fluid analysis, CT or magnetic resonance imaging (MRI), and electrophysiologic studies should be considered in animals with evidence of neurologic impairment. Finally, colonic biopsy or anorectal manometry will be necessary to diagnose suspected cases of aganglionic megacolon.

Treatment

The specific therapeutic plan will depend upon the severity of constipation and the underlying cause.[2] Medical therapy may not be necessary with first episodes of constipation. First episodes are often transient and resolve without therapy. Mild to moderate or recurrent episodes of constipation, on the other hand, usually require some medical intervention. These cases may be managed, often on an outpatient basis, with dietary modification, water enemas, oral or suppository laxatives, and/or colonic prokinetic agents (Table 58-9). Severe cases of constipation usually require brief periods of hospitalization to correct metabolic abnormalities and to evacuate impacted feces using water enemas, manual extraction of retained feces, or both. Followup therapy in such cases is directed at correcting predisposing factors and preventing recurrence. Subtotal colectomy will become necessary in cats suffering from obstipation or idiopathic dilated megacolon. These cats, by definition, are unresponsive to medical therapy. Pelvic osteotomy without colectomy may be sufficient for some cats suffering from pelvic canal stenosis and hypertrophic megacolon.[9] Figure 58-15 provides an algorithm for the therapeutic approach to the constipated, obstipated, and megacolonic cat.

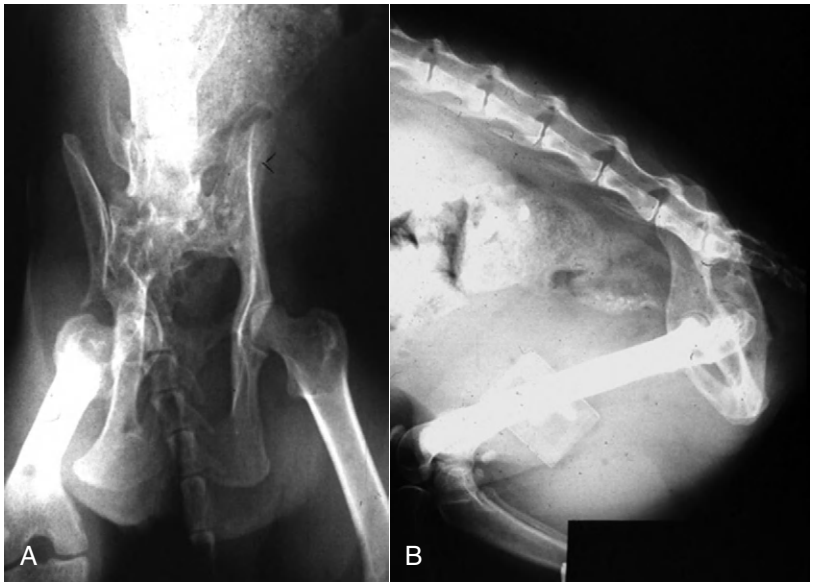

Figure 58-14 Lateral and ventrodorsal radiographs of the pelvis of a cat with megacolon. Note the healed malaligned fracture of the ilium obstructing the pelvic canal.

Table 58-9 Mechanisms, Sites of Activity, Indications, and Doses of Currently Available Gastrointestinal Prokinetic Agents

Drug Classification/ Mechanism	Sites of Activity	Indications	Dose	Other properties
Dopaminergic D_2 Antagonist Drugs				
Metoclopramide	GES, stomach, intestine, CRTZ	Vomiting disorders, gastroesophageal reflux, delayed gastric emptying, ileus/pseudoobstruction	0.2 to 0.5 mg/kg PO, IV TID; 0.01 to 0.02 mg/kg/h infusion	α_2-Adrenergic antagonist β_2-Adrenergic antagonist 5-HT_4 serotonergic agonist 5-HT_3 serotonergic antagonist
Domperidone	GES, CRTZ	Vomiting disorders, gastroesophageal reflux	0.05 to 0.10 mg/kg PO BID	α_2-Adrenergic antagonist β_2-Adrenergic antagonist
Serotonergic 5-HT_4 Agonist Drugs				
Mosapride	Stomach	Delayed gastric emptying	0.25 to 1.0 mg/kg PO BID	None
Prucalopride	Stomach, colon	Delayed gastric emptying, constipation	0.01 to 0.20 mg/kg PO BID	None
Cisapride*	GES, stomach, intestine, colon, CRTZ	Gastroesophageal reflux, delayed gastric emptying, ileus/pseudoobstruction, constipation, chemotherapy-induced vomiting	0.1 to 0.5 mg/kg PO TID (doses as high as 0.5 to 1.0 mg/kg have been used in some dogs)	5-HT_3 serotonergic antagonist 5-HT_1 serotonergic antagonist 5-HT_2 serotonergic agonist
Tegaserod*	Intestine, colon	Constipation, ileus/ pseudoobstruction	0.05 to 0.10 mg/kg PO or IV, BID	5-HT_1 serotonergic antagonist
Motilin-Like Drugs				
Erythromycin	GES, stomach, intestine, colon	Gastroesophageal reflux, delayed gastric emptying, constipation (dogs)	0.5 to 1.0 mg/kg PO IV TID	5-HT_3 serotonergic antagonist
Acetylcholinesterase Inhibitors and Cholinomimetic Agents				
Ranitidine	Stomach, colon	Delayed gastric emptying, constipation	1 to 2 mg/kg PO BID-TID	H_2 histaminergic antagonist
Nizatidine	Stomach, colon	Delayed gastric emptying, constipation	2.5 to 5.0 mg/kg PO SID	H_2 histaminergic antagonist
Bethanechol	Esophagus	Canine idiopathic megaesophagus	Dog: 5 to 15 mg/dog PO TID	
Nitric Oxide Donors				
AMU-301	Stomach	Diabetic gastroparesis	Not yet established	
Prostanoids				
Misoprostol	Colon	Constipation	Dog: 2 to 5 µg/kg PO TID-QID	

*Removed from many international markets.
CRTZ, chemoreceptor trigger zone; GES, gastroesophageal sphincter.

Removal of Impacted Feces

Removal of impacted feces may be accomplished through the use of rectal suppositories, enemas, or manual extraction.

Rectal Suppositories. A number of pediatric rectal suppositories are available for the management of mild constipation. These include dioctyl sodium sulfosuccinate (emollient laxative), glycerin (lubricant laxative), and bisacodyl (stimulant laxative). The use of rectal suppositories requires a compliant pet and pet owner. Suppositories can be used alone or in conjunction with oral laxative therapy.

Enemas. Mild to moderate or recurrent episodes of constipation may require administration of enemas and/or manual extraction of impacted feces. Several types of enema solutions may be administered, such as warm tap water (5 to 10 mL/kg), warm isotonic saline (5 to 10 mL/kg), dioctyl sodium sulfosuccinate (5 to 10 mL/cat), mineral oil (5 to 10 mL/cat), or lactulose (5 to 10 mL/cat). Enema solutions should be administered slowly with a well-lubricated 10 to 12 rubber catheter or feeding tube. Enemas containing sodium phosphate are contraindicated in cats because of their propensity for inducing severe hypernatremia, hyperphosphatemia, and hypocalcemia in this species.[10]

Manual Extraction. Cases unresponsive to enemas may require manual extraction of impacted feces. Cats should be adequately rehydrated and then anesthetized with an endotracheal tube in place to prevent aspiration should colonic manipulation induce vomiting. Water or saline is infused into the colon while the fecal mass is manually reduced by abdominal palpation. Sponge forceps may also be introduced rectally (with caution) to break down the fecal mass. It may be advisable to evacuate the fecal mass over a period of several days to reduce the risks of prolonged anesthesia and perforation of a devitalized colon. If this approach fails,

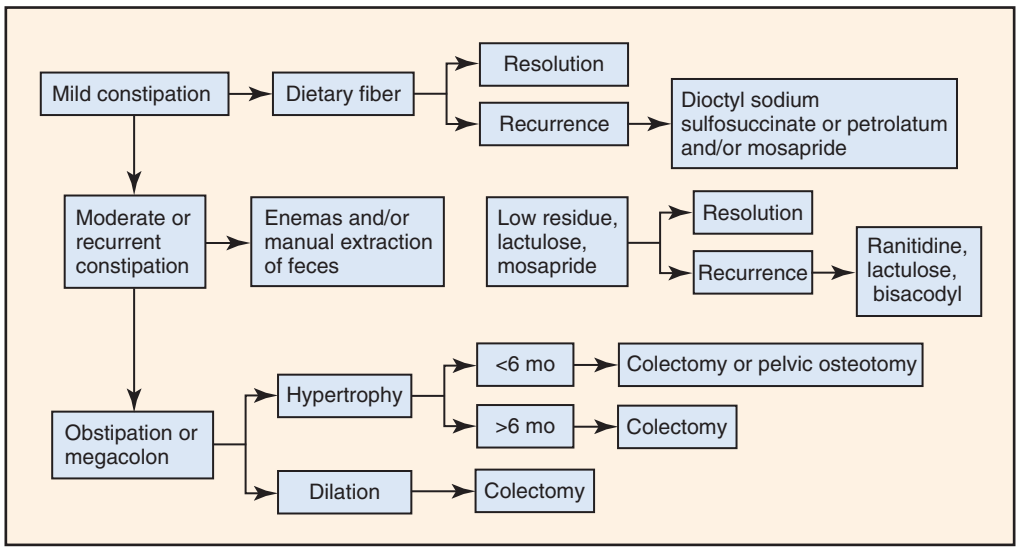

Figure 58-15 Suggested management of mild, moderate, or recurrent constipation and obstipation or megacolon.

colotomy may be necessary to remove the fecal mass. Laxative and/or prokinetic therapy may then be instituted once the fecal mass has been removed.

Established Laxative Agents

Laxatives promote evacuation of the bowel through stimulation of fluid and electrolyte transport or increases in propulsive motility. They are classified as bulk-forming, emollient, lubricant, hyperosmotic, or stimulant laxatives according to their mechanism of action. There are literally hundreds of products available for the treatment of constipation. Chapter 50 provides more detail about laxative agents.

Bulk-Forming Laxatives. Most of the available bulk-forming laxatives are dietary fiber supplements of poorly digestible polysaccharides and celluloses derived principally from cereal grains, wheat bran, and psyllium. Some constipated cats will respond to supplementation of the diet with one of these products, but many require adjunctive therapy (e.g., other types of laxatives or colonic prokinetic agents).[11] Fiber supplemented diets are available commercially, or the pet owner may wish to add psyllium (1 to 4 tsp per meal), wheat bran (1 to 2 tblsp per meal), or pumpkin (1 to 4 tblsp per meal) to canned cat food. Cats should be well hydrated before commencing fiber supplementation to maximize the therapeutic effect. Fiber supplementation is most beneficial in mildly constipated cats, prior to the development of obstipation and megacolon. In obstipated and megacolon cats, fiber may in fact be detrimental. Low-residue diets may be more beneficial in obstipated and megacolonic cats.

Emollient Laxatives. Emollient laxatives are anionic detergents that increase the miscibility of water and lipid in digesta, thereby enhancing lipid absorption and impairing water absorption. Dioctyl sodium sulfosuccinate and dioctyl calcium sulfosuccinate are examples of emollient laxatives available in oral and enema form. Dioctyl sodium sulfosuccinate at a dosage of 30 mg/kg/day had no effect on fecal consistency in Beagle dogs.[12]

Lubricant Laxatives. Mineral oil and white petrolatum are the two major lubricant laxatives available for the treatment of constipation. The lubricating properties of these agents impede colonic water absorption, as well as permit greater ease of fecal passage. These effects are usually moderate, however, and, in general, lubricants are beneficial only in mild cases of constipation.

Hyperosmotic Laxatives. This group of laxatives consists of the poorly absorbed polysaccharides (e.g., lactose, lactulose), the magnesium salts (e.g., magnesium citrate, magnesium hydroxide, magnesium sulfate), and the polyethylene glycols. Lactose is not effective as a laxative agent in all cats.[13] Lactulose is the most effective agent in this group. The organic acids produced from lactulose fermentation stimulate colonic fluid secretion and propulsive motility. Lactulose administered at a dosage of 0.5 mL/kg of body weight every 8 to 12 hours fairly consistently produces soft feces in the cat. Magnesium salts are not currently recommended in the treatment of feline constipation and idiopathic megacolon. Anecdotal reports of therapeutic successes have been reported with the polyethylene glycols.

Stimulant Laxatives. The stimulant laxatives (bisacodyl, phenolphthalein, castor oil, cascara, senna) are a diverse group of agents that have been classified according to their ability to stimulate propulsive motility. Bisacodyl, for example, stimulates nitric oxide–mediated epithelial cell secretion and myenteric neuronal depolarization.[14] Diarrhea results from the combined effect of increased mucosal secretion and colonic propulsion. Bisacodyl, at a dosage of 5 mg every 24 hours PO, is the most effective stimulant laxative in the cat. It may be given individually or in combination with fiber supplementation for long-term management of constipation. Daily administration of bisacodyl should probably be avoided, however, because of injury to myenteric neurons with chronic usage.[14]

Newer Laxative Agents

Chloride Channel Activators. Chloride channels are voltage-gated anion channels that allow the transport of chloride ions across cell membranes and play a critical role in fluid transport, maintenance of cell volume, and intracellular pH.[15,16]

Lubiprostone. Lubiprostone is a member of a group of compounds referred to as *prostones*.[17] Prostones are naturally occurring

bicyclic fatty acids formed by enzymatic oxidation of the 15-hydroxyl group of prostaglandins to the keto form. Lubiprostone is approved by the U.S. Food and Drug Administration for the treatment of chronic idiopathic constipation in humans. Lubiprostone activates type 2 chloride channels in the apical membrane of intestinal epithelial cells. This activity stimulates chloride secretion, followed by passive secretion of sodium and water (see Figure 1-17 in Chapter 1). The fluid-induced bowel distention secondarily induces peristalsis, but lubiprostone has no direct stimulatory effect on gastrointestinal smooth muscle. Insufficient safety and efficacy data are currently available to recommend the routine use of lubiprostone in dogs and cats.

Guanylate Cyclase Activators. Activation of the guanylate cyclase-C receptor increases cyclic guanosine monophosphate, thereby inducing signaling pathways that stimulate chloride and bicarbonate secretion through CFTR chloride channel–dependent mechanisms and, to a lesser extent, CFTR chloride channel–independent mechanisms, and inhibit sodium absorption by a sodium-proton exchanger.[15,16]

Linaclotide is a guanylate cyclase-C receptor agonist and intestinal secretagogue that improves bowel symptoms and accelerates colonic transit in chronic constipation.[18,19] Linaclotide has also been shown to attenuate nociceptive reflexes in response to colonic distention in three rodent models of visceral hypersensitivity.[18] Insufficient safety and efficacy data are currently available to recommend the routine use of linaclotide in dogs and cats.

μ-Opioid Antagonists. Postoperative ileus has multiple pathogenetic mechanisms. A dominant theme is the activation of enteric μ-opioid receptors resulting in inhibition of enteric nerve activity.[15,16]

Methylnaltrexone is a quaternary derivative of the μ-opioid receptor antagonist naltrexone.[20] N-terminal methylation reduces lipid solubility and prevents the drug from crossing the blood–brain barrier. Methylnaltrexone's reversal of opioid-induced inhibition of enteric nerve activity increase propulsion and secretory activity. Methylnaltrexone is clearly beneficial in the treatment of opioid-induced constipation; its efficacy in the treatment of postoperative ileus has not yet been definitively established. Insufficient safety and efficacy data are currently available to recommend the routine use of methylnaltrexone in dogs and cats.

Alvimopan has all of the same properties as methylnaltrexone; additionally, alvimopan accelerates colonic transit in healthy individuals, suggestive of a direct prokinetic effect.[20] Insufficient safety and efficacy data are currently available to recommend the routine use of alvimopan in dogs and cats.

Colonic Prokinetic Agents

Previous studies of feline colonic smooth muscle function have suggested that stimulation of colonic smooth muscle contraction might improve colonic motility in cats affected with idiopathic dilated megacolon.[6,7,21] Unfortunately, many gastrointestinal prokinetic agents have not proved useful in the therapy of feline constipation either because of significant side effects (e.g., bethanechol), effects limited to the proximal gastrointestinal tract (e.g., metoclopramide, domperidone, erythromycin), or market withdrawal because of cardiac 5-HT_4 effects. Some of the 5-HT_4 serotonergic agonists (e.g., cisapride, prucalopride, tegaserod) appear to have the advantage of stimulating motility from the gastroesophageal sphincter to the descending colon with relatively few side effects. Cisapride, for example, increases gastroesophageal sphincter pressure, promotes gastric emptying, and enhances small intestinal and colonic propulsive motility.[12,22] Cisapride enhances colonic propulsive motility through activation of colonic neuronal or smooth muscle 5-HT receptors in a number of animal species.[23,24] In vitro studies show that cisapride stimulates feline colonic smooth muscle contraction,[7,24] although it has not yet been conclusively shown that cisapride stimulates feline colonic propulsive motility in vivo. Anecdotal experiences suggest that cisapride is effective in stimulating colonic propulsive motility in cats affected with mild to moderate idiopathic constipation; cats with long-standing obstipation and megacolon are unlikely to show much improvement with cisapride therapy. Cisapride was widely used in the management of feline colonic motility disorders throughout most of the 1990s,[22,25,26] until it was withdrawn from the American, Canadian, and certain Western European markets in July 2000 following reports of untoward cardiac side effects in human patients. Cisapride causes QT interval prolongation and slowing of cardiac repolarization via blockade of the rapid component of the delayed rectifier potassium channel (I_{Kr}).[27] This effect may result in a fatal ventricular arrhythmia referred to as *torsades de pointes*. Similar effects have been characterized in canine cardiac Purkinje fibers,[28] but in vivo effects have not yet been reported in dogs or cats. The withdrawal of cisapride has created a clear need for new GI prokinetic agents although cisapride continues to be available from compounding pharmacies throughout the United States and other countries. A recent evidence-based data review of cisapride's efficacy in the treatment of human constipation and constipation-predominant irritable bowel syndrome (IBS) was carried out by the Cochrane Collaboration.[29] The authors concluded that "no clear benefit could be demonstrated with cisapride."[29]

Tegaserod is a potent partial nonbenzamide agonist at 5-HT_4 receptors and a weak agonist at 5-HT_{1D} receptors.[30,31] Tegaserod has definite prokinetic effects in the canine colon, but its effects in the feline colon are not known. Intravenous doses of tegaserod (0.03 to 0.3 mg/kg) accelerate colonic transit in dogs during the first hour after intravenous administration.[30] Tegaserod at doses of 3 to 6 mg/kg PO has also been shown to normalize intestinal transit in opioid-induced bowel dysfunction in dogs,[32] suggesting it could prove useful in other disorders of intestinal ileus or pseudoobstruction. Eventually, tegaserod was also shown to prolong the QT interval and delay cardiac repolarization as had been reported with cisapride. Tegaserod was marketed under the trade name of Zelnorm in the United States in September 2002 and subsequently removed from American and other markets in 2006. As with many other drugs in companion animal medicine, tegaserod was not licensed for the treatment of canine or feline gastrointestinal motility disorders.

Prucalopride is a potent 5-HT_4 receptor agonist that stimulates GMCs and defecation in the dog and cat.[33,34] Prucalopride also appears to stimulate gastric emptying in the dog.[35] In lidamidine-induced delayed gastric emptying in dogs, prucalopride (0.01 to 0.16 mg/kg) dose-dependently accelerates gastric emptying of dextrose solutions. Prucalopride is marketed as Resolor by Movetis in Europe.

Mosapride citrate, a substituted benzamide, is a novel 5-HT_4 receptor agonist that increases gastric emptying in rats and dogs, and increases electrically evoked contractions in the isolated guinea pig ileum.[36,37] Mosapride stimulates acetylcholine release from the myenteric plexus via activation of 5-HT_4 receptors, but has no real affinity for D_2 dopamine, 5-HT_1, 5-HT_2 receptors, or α_1-adrenoceptors. Mosapride restores gastric motility in dogs with vincristine-induced gastric hypomotility,[38] and therefore may be clinically useful in other

gastric emptying disorders. Mosapride is apparently without effect on distal gastrointestinal tract motility, and therefore may not prove useful in disorders of constipation. Mosapride is marketed as Pronamid by DS Pharma Animal Health in Japan.

Misoprostol is a prostaglandin E_1 analogue that reduces the incidence of nonsteroidal antiinflammatory drug-induced gastric injury. The main side effects of misoprostol therapy are abdominal discomfort, cramping, and diarrhea. Studies in dogs suggest that prostaglandins may initiate a giant migrating complex pattern and increase colonic propulsive activity.[39] In vitro studies of misoprostol show that it stimulates feline and canine colonic smooth muscle contraction.[40] Given its limited toxicity, misoprostol may be useful in cats (and dogs) with severe refractory constipation.

Ranitidine and nizatidine, classic histamine H_2 receptor antagonists, may also stimulate canine and feline colonic motility. These drugs stimulate contraction apparently through inhibition of tissue acetylcholinesterase and accumulation of acetylcholine at the motor endplate. It is not yet clear how effective these drugs are in vivo, although both drugs stimulate feline colonic smooth muscle contraction in vitro.[41] Cimetidine and famotidine, members of the same classification of drug, are without this effect.

Surgery

Colectomy should be considered in cats that are refractory to medical therapy. Cats have a generally favorable prognosis for recovery following colectomy, although mild to moderate diarrhea may persist for weeks to months postoperatively in some cases.[42,43] Pelvic osteotomy without colectomy has been recommended for cats with pelvic fracture malunion and hypertrophic megacolon of less than 6 months duration.[44] Symphyseal distraction-osteotomy with spirally fashioned orthopedic wire has also been used in the surgical management of this disorder.[45] Pathologic hypertrophy may be reversible with early pelvic or symphyseal distraction osteotomy in such cases. Some surgeons still prefer colectomy in this instance because of the technical difficulty of some pelvic osteotomies.[46]

Subtotal colectomy is an effective treatment for feline idiopathic megacolon or megacolon secondary to the mechanical obstruction created by old, healed pelvic fractures. Recommendations for removal of the ileocolic valve and ileum vary in cats with megacolon. The ileocolic blood vessels tether the distal ileum and proximal ascending colon, preventing anastomosis to the distal colon; thus if a complete colectomy is performed, these vessels must be sacrificed. This necessitates removing the ileum, which has important normal functions in water, vitamin B_{12}, and bile salt resorption, and performing a jejunocolic anastomosis. In spite of this concern, postoperative intestinal function was normal in four cats evaluated after subtotal colectomy and jejunocolic anastomosis.[43,47] The ileocolic valve also minimizes colonic bacterial access to the small intestine,[44] so preservation of the valve would be ideal to minimize small intestinal bacterial overgrowth and deconjugation of bile salts. However, preservation of the ileocolic junction necessitates leaving several centimeters of the ascending colon to ensure a tension-free anastomosis, possibly predisposing these cats to recurrent constipation. To evaluate these concerns, cats with megacolon treated with colectomy were studied retrospectively. Cats with excision of the ileocolic junction had significantly looser stool on long-term followup.[43] However there was no difference in the incidence of constipation between cats with preservation versus excision of the ileocolic junction.[48] This is perhaps explained by in vitro experiments with ascending and descending colonic smooth muscle from cats with clinical megacolon showing that smooth muscle dysfunction is less severe in the ascending colon.[8]

When the ileocolic junction is preserved, the ascending colon is transected approximately 3 cm distal to the ileocolic junction to ensure a tension-free anastomosis. An end-to-end colocolostomy is performed using single interrupted sutures of 4-0 polydioxanone.[47] The successful use of a biofragmentable anastomosis ring has also been reported.[46] The omentum is wrapped around the anastomotic site and the abdomen is thoroughly lavaged with a warm, balanced electrolyte solution. All lavage fluid is aspirated from the peritoneal cavity before the incision is closed.

Cats recovering from colectomy are maintained on intravenous fluids until they commence eating and drinking. Electrolytes are supplemented if necessary. Bowel movements may be soft or loose and more frequent than normal. A highly digestible, low-residue diet is fed. In cats with profuse postoperative diarrhea in which small intestinal bacterial overgrowth is suspected, a short course of antibiotics is administered.

Prognosis

Many cats have one or two episodes of constipation without further recurrence, although others may progress to complete colonic failure. Cats with mild to moderate constipation generally respond to conservative medical management (e.g., dietary modification, emollient or hyperosmotic laxatives, colonic prokinetic agents). Early use of colonic prokinetic agents (in addition to one or more laxative agents) is likely to prevent the progression of constipation to obstipation and dilated megacolon in these cats. Some cats may become refractory to these therapies, however, as they progress through moderate or recurrent constipation to obstipation and dilated megacolon. These cats eventually require colectomy. Cats have a generally favorable prognosis for recovery following colectomy, although mild to moderate diarrhea may persist for 4 to 6 weeks postoperatively in some cases.

Irritable Bowel Syndrome

IBS is a human chronic gastrointestinal tract disorder of unknown origin that is characterized by abdominal pain and altered bowel habits in the absence of detectable biochemical or structural abnormalities.[49] IBS is one of the most common functional GI disorders with an estimated prevalence of 10% to 15% in Western adult populations. Direct and indirect costs of IBS reach up to $30 billion per year in the United States alone.[49] IBS is commonly subdivided into different phenotypes depending upon the most prevalent bowel habit: diarrhea-predominant IBS (IBS-D), constipation-predominant IBS (IBS-C), and mixed features IBS (IBS-M).[50] Because of the inability of animal species to describe clinical symptoms such as abdominal pain and discomfort, IBS is not a very-well-defined syndrome in veterinary medicine. Nonetheless, recurring vomiting and diarrheal disorders are seen in companion animal species that are unaccompanied by mucosal morphologic change, and are presumed therefore to be of functional or physiological origin.[51] The reader is referred to Chapter 41 for a more detailed discussion of IBS and its management.

A fiber-responsive large bowel diarrheal syndrome similar to IBS in humans has been characterized in dogs.[51] Affected animals have a chronic idiopathic large bowel-type diarrhea characterized by excessive fecal mucus, hematochezia, and tenesmus. Abdominal pain and weight loss are occasionally reported by pet owners. Multiple diet changes and empirical medications fail to relieve clinical signs. Medical investigation is negative for bacterial and other pathogen infections, colitis, and colonic neoplasia, and the term chronic large bowel diarrhea is applied to the patient's disorder. Dogs

affected with this syndrome may respond to the feeding of a highly digestible diet that is supplemented with soluble fiber.[51]

The reader is referred to Chapter 41 for more detailed discussion of IBS and its management.

NEOPLASIA

Robert J. Washabau

Etiology

In dogs, tumors of the large intestine are more common than tumors of the stomach and small intestine. The mean age of dogs affected with colonic neoplasia is variably reported between 7 and 11 years of age.[1] Most colonic tumors of dogs are malignant and include the adenocarcinomas, lymphosarcomas, and gastrointestinal stromal tumors (Table 58-10). Other reported tumors include leiomyosarcoma, neurofibrosarcoma, fibrosarcoma, and ganglioneuroma.[2-11] Leiomyosarcomas are the most common (91%) of the gastrointestinal stromal tumors.[12-15] Most colonic neoplasia develop in the descending colon and rectum, although leiomyosarcomas more frequently develop in the cecum.[4,6] Local tumor invasion apparently occurs at a slower rate with canine colonic neoplasia, and metastasis to distant sites is relatively uncommon. Benign colonic neoplasia (e.g., adenomas, adenomatous polyps, and leiomyomas) also occur, although they are less common than malignant tumors. Malignant transformation of adenomatous polyps to carcinoma in situ and invasive adenocarcinoma has been demonstrated in the dog just as it has in humans.[1,16,17] Extramedullary plasmacytomas are uncommon tumors of the gastrointestinal tract, but many of these occur in the large intestine and rectum.[12,13] All of the aforementioned tumors are associated with signs of inflammation and obstruction (e.g., hematochezia, tenesmus, and dyschezia). Carcinoids (rare 5-hydroxytryptamine [5-HT] secreting tumors) are occasionally associated with diarrhea because of the effects of 5-HT on secretion and motility.

In cats, adenocarcinoma (46%) is the most common tumor of the large intestine (see Table 58-10), followed by lymphosarcoma (41%) and mast cell tumors (9%).[14,15,18] The mean age of cats affected with colonic neoplasia is 12.5 years. The descending colon (39%) and the ileocolic sphincter (28%) are the most common sites of colonic neoplasia in the cat. Unlike colonic tumors in the dog, feline colonic tumors have a high rate (63%) of metastasis and, of course, metastasis is associated with decreased survival time. Metastatic sites include colonic lymph nodes, mesenteric lymph nodes, liver, spleen, bladder, urethra, omentum, mesocolon, lungs, duodenum, and peritoneum.

Table 58-10 Distribution of Colonic Neoplasia in Dogs and Cats

Tumor Type	Dog	Cat
Adenocarcinoma	43%	46%
Lymphosarcoma	19%	41%
Mast cell tumors	<1%	9%
Stromal tumors	19%	2%
Adenomas/polyps	17%	1%
Plasmacytomas	2%	<1%

Alimentary lymphoma is less common in dogs than in cats, representing only 7% of all canine lymphomas.[19] Lymphoma is the most common malignancy in cats, and the GI tract is the most common predilection site for this tumor. Feline alimentary lymphoma may affect any component of the digestive system (stomach, intestine, colon, liver, biliary tract, and pancreas), but it most commonly involves the small intestine.[19-25] Lymphoma can be classified histologically into small cell (lymphocytic; low grade; well differentiated) or large cell (lymphoblastic; high grade; undifferentiated) types.[19] Low-grade lymphocytic lymphoma has a higher reported incidence than high-grade lymphoblastic lymphoma in most case series.[20-25] Large granular lymphoma is a subtype that is characterized by the presence of natural killer T lymphocytes with intracytoplasmic granules. Clinically, these types of lymphoma are distinct entities with different clinical presentations, therapies, and outcomes.[19]

Although infection with FeLV and FIV are major risk factors for the development of feline lymphoma, cats with GI lymphoma are usually serologically negative for both infections.[19] Feline gastrointestinal lymphoma has been associated with *Helicobacter* infection[26] and exposure to household cigarette smoke.[27]

Pathophysiology

Mechanical obstruction is the most common pathophysiologic consequence of locally invasive colonic tumor. Other nonneoplastic processes such as intussusception, FIP granuloma, fibrosing stricture, linear and nonlinear foreign bodies, hematoma, and phycomycosis lesions also cause intraluminal obstruction. Prolonged obstruction induces smooth muscle hypertrophy proximal to the site of the obstruction.[28] Other pathophysiologic consequences of intestinal obstruction are pronounced fluid secretion and malabsorption of water and solutes; fluid, electrolyte, and acid–base disturbances; proliferation and translocation of luminal bacteria; and inflammation, devitalization, and perhaps even perforation of the colon. Secretory diarrheas have been reported with carcinoids of the rectum, colon, and intestine.

Clinical Examination

Most affected dogs have signs of hematochezia, mucoid feces, tenesmus, and dyschezia of varying severity. Importantly, the clinical signs observed with colorectal neoplasia are often indistinguishable from other causes of obstruction or chronic colitis. Hematochezia is infrequently reported with leiomyosarcomas or leiomyomas presumably because these tumors do not typically involve the mucosa. Other clinical signs depend on the tumor type and location. Vomiting, malabsorption, and cachexia may be observed, for example, when multifocal or diffuse tumors (e.g., lymphosarcoma) involve the proximal portions of the gastrointestinal tract. Gastrointestinal stromal tumors, particularly the leiomyomas, have been associated with hypoglycemia and the resulting clinical signs of muscular weakness and seizure activity.[29] Functional plasmacytomas secrete a single class of immunoglobulin and affected animals may go on to develop hyperviscosity syndrome, for example, retinal bleeding and epistaxis. If colonic perforation has occurred, animals may be presented moribund with fever, lethargy, anorexia, vomiting, abdominal pain, and collapse.

Vomiting (65%), diarrhea (52%), and weight loss (46%) are common clinical signs in cats with colonic neoplasia.[16] Most cats with colonic (and alimentary) lymphosarcoma are FeLV-negative. These lymphomas are still believed to be caused by FeLV,

Table 58-11 Characteristics of Feline Alimentary Lymphocytic and Lymphoblastic Lymphoma

Feature	Lymphocytic Lymphoma	Lymphoblastic Lymphoma
Clinical signs	Gradual weight loss, vomiting, diarrhea, decreased appetite	Rapid weight loss, anorexia, vomiting, diarrhea
Duration of clinical signs	Typically prolonged (weeks to months)	Typically acute (days to weeks)
Physical examination and ultrasonographic findings	May be normal; thickened bowel loops; palpable masses uncommon	Palpable mass lesions common
Diagnostic workup	Aspiration cytology, endoscopy, full-thickness surgical biopsy	Aspiration cytology, endoscopy, full-thickness surgical biopsy
Pitfalls of diagnostic testing	False negatives on aspiration cytology; differentiation of LSA from IBD	False negatives on aspiration cytology, differentiation of LSA from IBD
Surgical intervention	Useful for definitive biopsy	Therapeutic if obstructing mass lesions are present
Therapy	Chemotherapy–prednisone and chlorambucil; radiation therapy–may prolong survival	Chemotherapy–CHOP, CCNU, MOPP; radiation therapy–may prolong survival
Response to therapy	75% to 90% response rate	50% to 60% response rate
Outcome	Most cats live >2 years and are managed long-term with chemotherapy	Median survival 6 to 7 months; if complete response to therapy 40% chance of living a year or longer

CHOP, cyclophosphamide, doxorubicin, vincristine, prednisone ± L-asparaginase ± methotrexate; CCNU, lomustine; IBD, inflammatory bowel disease; LSA, lymphosarcoma; MOPP, mustargen, vincristine, prednisone, procarbazine.

with integrated virus causing neoplastic transformation in the absence of viral replication. Although most lymphomas in cats appear to be comprised of malignant T lymphocytes, most colonic (and alimentary) lymphomas are of B-cell origin. Alimentary and colonic lymphomas originate primarily from submucosal lymphocytes and/or mucosal lymphoid follicles, although two studies reported an epitheliotropic form of T-cell intestinal lymphomas.[30,31] Epitheliotropic T-cell lymphomas have not yet been reported in the feline colon. Feline lymphocytic lymphoma is typically a slowly progressive disease with a protracted history, whereas lymphoblastic lymphoma is more often characterized by an acute onset (Table 58-11).[19]

Diagnosis

Canine rectal adenocarcinomas are palpable in 60% to 80% of clinical cases, but colonic and cecal lesions are not as readily apparent on physical examination.[1,13,28,32,33] More than 50% of cats with colonic masses have a palpable abdominal mass.[16]

Survey and contrast radiographic and ultrasonographic studies have been employed with varying levels of success in the diagnosis of canine and feline colonic neoplasia. Annular stenotic lesions associated with adenocarcinoma of the colon may manifest as proximal colonic dilation on survey radiographs. Radiographic contrast material more precisely outlines the narrowing of the lumen at the site of the tumor. Although still of some clinical utility, contrast studies have been largely superseded by ultrasonography and other imaging modalities. Ultrasonography is presently considered to be the most effective means of diagnosing colonic tumors in dogs and cats and appears to be useful in evaluating mural lesions and associated abdominal changes such as lymphadenopathy (Figure 58-16).[33] Ultrasonography was reported to be useful 84% of the time in localizing feline colonic neoplasia in one study.[16] Ultrasonographic features of colonic tumors include transmural wall thickening with complete loss of the normal wall layering, fluid accumulation proximal to the lesion, and reduced regional motility.[33] Transabdominal fine-needle aspiration, peritoneal fluid cytology, and endoscopic

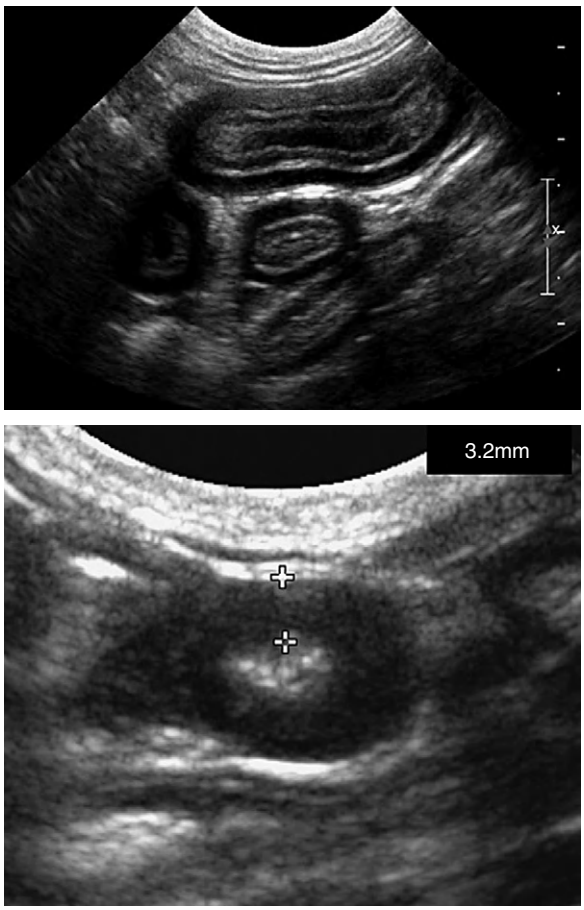

Figure 58-16 Abdominal ultrasonogram of a cat with lymphocytic lymphoma. (Reprinted with permission from Gieger T: Alimentary lymphoma in cats and dogs. Vet Clin North Am Small Anim Pract 41:419–432, 2011.)

exfoliative cytology may be useful in the diagnosis of lymphoma, but histopathology is generally required for a definitive diagnosis of other colonic neoplasia. CT and MRI scanning have not been sufficiently evaluated for reasonable comparisons to be made with ultrasonography.

Flexible colonoscopy with mucosal biopsy is the preferred method of diagnosis for colonic neoplasia. Endoscopic abnormalities may include mass effect, mucosal bleeding, increased mucosal friability, erosions and ulcers, and circumferential luminal narrowing with submucosal infiltrative lesions. Multiple biopsy specimens should always be taken from diseased tissue, adjacent healthy tissue, as well as the transition zone between healthy and diseased tissue. With tumor necrosis, the pathologist has a much better chance of diagnosing and staging the disease by evaluating nonnecrotic tissue.

Treatment

The treatment of colonic neoplasia will depend upon tumor type, anatomic location, and presence and extent of metastases (Box 58-2; see Tables 58-12 and 58-13). Complete surgical excision is the recommended therapy for focal adenocarcinomas, cecal leiomyosarcomas, and obstructive lymphomas. Multiagent chemotherapy (prednisone, vincristine, cyclophosphamide) has been used to treat colonic lymphoma, but it does not appear to alter survival time in affected cats.[16] Cyclooxygenase (COX)-2 upregulation may contribute to the growth characteristics of some canine colonic neoplasia.[34-36] Consequently, selective COX-2 inhibitors (e.g., piroxicam, meloxicam) may be useful in the treatment of some canine colonic neoplasia. Plasmacytomas may be managed with adjuvant chemotherapy (e.g., prednisone and melphalan) following surgical excision. Radiation therapy has been used to palliate recurrent adenocarcinomas with varying results and complications; however, postradiation peritonitis and perforation have been reported in some cases.[37]

Surgery

Preoperative Considerations

In dogs with rectal or colonic tumors, appropriate staging is vital to determine the extent of local and systemic disease. In many cases, a careful digital rectal examination can delineate the extent of local disease in the rectum and provide subjective information on the enlargement of regional lymph nodes. Thoracic radiographs are

made to rule out pulmonary metastatic disease. Abdominal ultrasonography is used to rule out abdominal metastatic disease and to guide aspiration and biopsy of enlarged iliac lymph nodes. Proctoscopy and colonoscopy often reveal the local extent of neoplastic disease. It is vital that colonoscopy be continued oral to rectal tumors as additional neoplasms are reported in the colon in a percentage of these cases.[38,39]

Mechanical cleansing is recommended before surgery of the large intestine in human, although preoperative enemas are contraindicated in cases of suspected large intestinal perforation. Perioperative antibiotics are administered to minimize the chance of surgical infection. Randomized, controlled clinical trials of antimicrobial prophylaxis in canine and feline colonic surgery have not been conducted, but based on human trials,[40] antibiotics effective against aerobes, especially the anaerobes that predominate in the large intestine, are administered intravenously once at the beginning of surgery. Antibiotics are not administered again unless either there is contamination at surgery or the procedure takes longer than 2 hours. In the latter case a second intravenous dose of antibiotics is administered. Antibiotics are continued postoperatively in cases with preoperative or surgical contamination based on the results of operative culture and sensitivity testing.

Operative Considerations

In animals requiring surgery for cecal or colonic disease, a ventral midline laparotomy is performed. After conducting a thorough abdominal exploration for concurrent or metastatic disease, the affected area of the large intestine is packed off with moistened laparotomy sponges. Resection of the cecum can be performed with or without preservation of the ileocolic junction, depending on the extent of the local disease. In most cases of cecal neoplasia a complete resection and jejuno- or ileocolonic anastomosis is performed to ensure adequate tumor resection.

Various techniques and surgical approaches have been described for removal of rectal tumors.[39] The approach and technique vary with the extent and location of the mass(es). Tumors in the proximal rectum may be accessed by a ventral midline laparotomy combined with a pelvic osteotomy. Healing of the distal colon and/or proximal rectum is complicated by the poor blood supply to this area of the large intestine.[41] A dorsal approach has been described for tumors involving the middle third of the rectum[39,42]; however, many tumors in this area are also amenable to resection via a rectal pull-through.[39,43] The plexus of pelvic nerves at the peritoneal reflection is vital to postoperative fecal continence. In an experimental study on healthy dogs, both transection alone and resection of 4 cm of rectum via a dorsal approach resulted in fecally continent dogs. Resection of 6 cm of the rectum, including the peritoneal reflection, caused fecal incontinence.[42] This limitation on resection is problematic in animals with larger rectal tumors, as a 2-cm gross margin is recommended on both sides of the tumor.[39,44,45]

Postoperative Considerations

Postoperative treatment depends largely on the underlying reason for cecal, colonic, or rectal surgery. Pre- or postoperative epidural anesthesia using a combination of local anesthetic and narcotic provides effective pain relief. Animals receiving epidural anesthesia may not be able to urinate normally for 12 to 24 hours, hence bladder size must be evaluated frequently and the bladder gently expressed or catheterized if needed. Narcotics, narcotic agonists/antagonists, partial μ-agonists, and COX-2 inhibitory class nonsteroidal antiinflammatory drugs are alternatives for pain management in dogs. Narcotic agonists/antagonists are effective in cats.

Adequate nutrition is vital for dogs and cats recovering from large intestinal surgery. Early feeding increases anastomosis strength and promotes enteric epithelial proliferation and function.[46,47] Ideally, the diet should provide a source of soluble fiber which, when hydrolyzed to short-chain fatty acids, stimulates colonic mucosal proliferation.[46] In animals with fecal continence difficulties after extensive rectal resection, a low-residue diet is fed twice daily. The animal is then walked for 20 to 30 minutes after eating. In many cases, the gastrocolic reflex will result in defecation and near complete emptying of the colon during this time, minimizing subsequent fecal soiling in the house.

Prognosis

The prognosis for adenomatous polyps, leiomyomas, and fibromas is generally favorable. Adenocarcinomas, lymphosarcomas, and plasmacytomas tend to recur and/or metastasize to distant sites. Dogs with annular colorectal adenocarcinomas have a particularly poor prognosis with a mean survival time of only 1.6 months.[1,32] The prognosis for most malignant tumors is generally guarded. Surgical resection alone results in 22 month (dogs) and 15 month (cats) average survival times in dogs and cats.[1,16] It should be noted that cats undergoing subtotal colectomy for colonic adenocarcinoma had a longer survival time than those receiving mass resection only (median survival time of 138 days versus 68 days).[16] Not surprisingly, cats with metastatic lesions had much shorter survival times, 49 days versus 259 days.[16]

Ulcer Associated with Intervertebral Disk Disease and Steroid Treatment

Etiology

Colonic ulcers may develop following glucocorticoid therapy and neurosurgery in dogs with spinal cord injury. Gastric ulcers are of greater prevalence in this circumstance, but colonic ulcers may be equally devastating.[1-4] Affected dogs were most often Dachshunds with thoracolumbar disk disease treated with decompressive surgery and dexamethasone at doses of 0.25 to 4.4 mg/kg/day. Colonic ulcer is not a frequent complication of either intervertebral disk disease or corticosteroid therapy. In the initial report of the condition, colonic perforation was described in two dogs out of "several thousand."[1] Ten additional cases were subsequently reported until 1986,[2-4] and since then no additional reports have been published. This may represent increased awareness of the condition, reluctance to publish on a previously described condition, or perhaps a shift away from the use of dexamethasone in dogs with intervertebral disk disease. Colonic perforation is infrequent in humans treated with corticosteroids for neurologic disease[5] but may occur more commonly when dexamethasone is used.[6] In nonneurologic conditions, the frequency of perforation is influenced by the underlying disease and the presence of a diverticulum in the sigmoid colon.[7] Why this lesion develops in some dogs but not others is not readily explained.

Pathophysiology

There are many factors that probably interact to cause colonic perforation in this cohort of dogs. Spinal cord injury and sympathetic nerve stimulation associated with pain likely slow colonic transit and increase fecal retention. It is also likely that immobility and pain associated with abdominal muscle contraction inhibit voluntary defecation in dogs with intervertebral disk disease. This leads to fecal retention and colonic distention. In humans, it is postulated that prolonged increases in colonic intraluminal pressure lead to mucosal ischemia resulting in progressive necrosis, ulceration, and perforation.[6]

The effects of corticosteroids have not been extensively studied in the colon and are largely extrapolated from information gained in gastric studies.[8] Corticosteroids are presumed to decrease colonic mucus production, alter the composition of colonic mucus, and decrease mucosal repair in the colon, leading to perturbations in the colonic mucosal barrier.[3] These effects are thought to be secondary to depletion of local prostaglandin production. In addition, glucocorticoids inhibit the expression of inducible nitric oxide synthase in vascular endothelial cells,[9] perhaps further affecting colonic blood supply.[10] Together, these factors coalesce to induce erosion of the colonic mucosa, colonic perforation, and peritonitis.[3] The relationship between intervertebral disk disease, corticosteroid treatment, and colonic perforation is highlighted by a report describing 29 dogs with gastrointestinal perforation associated with administration of a COX-2 inhibitor. None of the latter dogs were treated for intervertebral disk disease, and none of the perforations were in the colon.[11]

The left colic flexure or proximal portion of the descending colon appears to be at greatest risk for colonic ulceration and perforation; two-thirds of the published cases were reported at this site.[3,4] Nonambulatory neurosurgical patients treated with dexamethasone are at greatest risk for development of colonic perforation. Colonic perforation is often preceded by variable nonspecific signs, most frequently depression, anorexia, and emesis. Perforation appears to be associated with 100% mortality, emphasizing the importance of prevention and early clinical recognition.

Clinical Examination

Middle aged, male dogs are most often affected, usually within 5 to 7 days of surgery. Depression, anorexia, emesis, abdominal pain, constipation, melena, and fever are the most important clinical signs. Many of these signs are subtle and easily missed by some pet owners. The immunosuppressive properties of glucocorticoids may mask the initial signs of peritonitis associated with colonic perforation.

Diagnosis

If suspected, patients at risk should be carefully evaluated for perforation and peritonitis. Imaging studies (radiography and ultrasonography), abdominocentesis, peritoneal lavage, and exploratory surgery, if indicated, should be considered in patients at risk. A diagnosis of peritonitis is made from cytologic evaluation of peritoneal fluid or measurements comparing glucose, pH, and lactate concentrations in peripheral blood and peritoneal fluid.[12] The perforations most often occur on the antimesenteric surface of the proximal descending colon.[3]

Treatment

Treatment involves rapid circulatory resuscitation with crystalloids and colloids, administering broad-spectrum bactericidal antibiotics, and emergency laparotomy. The perforation of the colon is identified, the affected area of bowel is resected, and the remaining colon is anastomosed. The abdominal cavity is thoroughly lavaged with warm balanced electrolyte solution. All of the lavage fluid and associated peritoneal contaminants are aspirated. Depending on the degree of residual peritoneal contamination, the abdomen is either closed, closed after placement of closed suction drains, or left open to facilitate drainage and covered with a sterile bandage.

Prognosis

Colonic ulcer and perforation is generally associated with a poor prognosis. A preventive approach to this complication appears to be warranted in high-risk patients: (a) use of less-potent glucocorticoids (e.g., prednisone or prednisolone) instead of dexamethasone, and (b) limited or no use of glucocorticoids.

Histiocytic Ulcerative Colitis (Granulomatous Colitis of Boxer Dogs)

Etiology

HUC was first reported by Van Kruiningen in a kennel of Boxer dogs in 1965.[13] A number of other cases have been reported since then, and a similar disease process has been reported in the French Bulldog. The pathognomonic lesion of this disease is a mucosal infiltration with large numbers of macrophages staining positively with PAS, and accompanied by mucosal ulceration and loss of goblet cells.[14] Although the term *histiocytic ulcerative colitis* describes many features of the disease, it understates the mixed lymphocytic plasmacytic component of the inflammation, and the term *granulomatous colitis* has been adopted to more completely characterize the histopathology. For the most part, the disease is localized to the large intestine and regional lymph nodes; however, in some instances PAS-positive macrophages may be found in lymph nodes remote from the intestine, suggesting that there is limited systemic distribution of the disease. Historically, an infectious etiology had been speculated but never proved. At least two independent lines of investigation now point to an adherent and invasive *E. coli* as the underlying etiology of granulomatous colitis.[14,15] The pathophysiology, clinical examination, diagnosis, and therapy of granulomatous colitis of Boxer dogs and other breeds are discussed in the "Inflammation" section.

CHAPTER 59

Anorectum

STRUCTURE AND FUNCTION

Debra L. Zoran

The structures that make up the anorectum are responsible for the distal storage and voluntary evacuation of feces, and maintenance of fecal continence. These functions are controlled by a complex interaction of the intrinsic and extrinsic nervous system, and include coordination of the muscles, nerves, and supporting tissues that make up the anorectum. Fecal continence is one of the most important functions of the anorectum, and is defined as the ability to retain fecal content, to perceive that the rectum is full, and to determine appropriate conditions for defecation.[1] Diseases or disorders of the anorectum may cause fecal incontinence or constipation when there is a loss of coordination of the activities of the smooth and striated muscles of the anorectum. Conversely, disorders of the mucosa lining the anorectum result in signs of inflammatory disease, also known as proctitis, which are observed clinically as tenesmus, hematochezia, or frequent defecation. Because of the important social impact associated with anorectal disorders, and particularly in diseases resulting in fecal incontinence, they are an important cause of euthanasia in pet animals when the problem cannot be corrected or improved.

Anatomy of the Rectum and Perineum

The anorectum consists of the rectum, anal canal, internal and external anal sphincters, muscles of the pelvic canal, and the skin and subcutaneous structures of the perineum (Figure 59-1).[1] Although the rectum and anus are confluent, they have separate embryologic origins that account for many differences in blood supply, innervation, and structure.[2] The rectum is a short segment of the distal GI tract that begins at the pelvic inlet as a continuation of the distal colon, and extends approximately 5 cm in length to end at the anal canal.[3] The majority of the rectum lies within the peritoneal cavity and the serosal surface serves as the visceral peritoneum. The cranial portion of the rectum is suspended by the short mesorectum, a tissue which is continuous with the mesocolon and helps to form the pararectal fossa.[3] The rectum is primarily distinguished from the anal canal by the columnar epithelium that lines the mucosal surface.[2] The rectum is surrounded by the perineum, which comprises the tissues that make up the boundary of the pelvic outlet. Internally, the perineum is delineated by the ischial arch ventrally, the third coccygeal vertebra dorsally, and laterally (in the dog only) by the sacrotuberous ligament.[4] In cats, the lateral margin of the perineum is less-well defined because of the lack of a sacrotuberous ligament.[3] Nevertheless, the perineum surrounds the anal and urogenital canals and provides the external structural support for these tissues. The rectum is bounded by the right and left ventral sacrococcygeal muscles dorsally, and the levator ani muscle laterally. The levator ani and coccygeal muscles make up the pelvic diaphragm—the division between the pelvic canal and the ischiorectal fossa. These muscles are crucial in supporting the rectum, and are important not only as a physical partition, but are essential in acting as a counterbalance to the effects of increased intraabdominal pressure. When these muscles fail, as in perineal hernia, abdominal viscera may herniate through the pelvic canal. There are two ischiorectal fossae, each found above the pelvis and lateral to the root of the tail (see Figure 59-1). This fat-filled space contains the arteries, veins, and nerves that supply the distal GI and urogenital tracts—namely the internal pudendal artery and vein, and the pudendal nerve.[3] Lymphatic drainage for the perineum also courses through the fossa draining to the medial iliac nodes.

As an extension of the colon, the rectum contains the same tunics (layers) that exist in the colon: the mucosa, submucosa, muscularis, and serosa. The submucosa and serosal layers are essentially the same as in other regions of the alimentary tract. However, there are two main differences in the mucosa of the rectum compared to the colonic mucosa: the presence of a large number of solitary lymph nodules and the presence of non-effacing folds in the anal canal, which may be longitudinal or circular, depending on their location. The rectal mucosa also contains columnar epithelium, as in the distal colon, which is rich in goblet cells that secrete mucous. The lymph nodules can be visualized endoscopically in the normal rectal mucosa as either raised or punctate depressions in the rectal mucosa, the so-called rectal pits. Secretion of mucous from the goblet cells is regulated by a submucosal neural plexus in the rectal mucosa. Inflammation of the mucosa results in stimulation of this neural plexus, and this is responsible for the clinical signs often observed in anorectal disease: increased mucus on feces, hematochezia, or tenesmus. At the junction of the rectum and anus, the mucosal epithelium is replaced by a squamous epithelium. This transition point defines the junction of the rectum and internal anal sphincter (or beginning of the anal canal). Embryologically, this transition point marks the site of the cloacal membrane that separates the endoderm from the ectoderm in the embryo.[2] Abnormal development of these structures leads to the development of atresia ani and other congenital disorders of anorectal structure such as fistula and clefts.[5] The serosal surface of the rectum is continuous with the serosa of the colon; however, the serosa of the anal canal and most caudal portion of the rectum become retroperitoneal as part of the

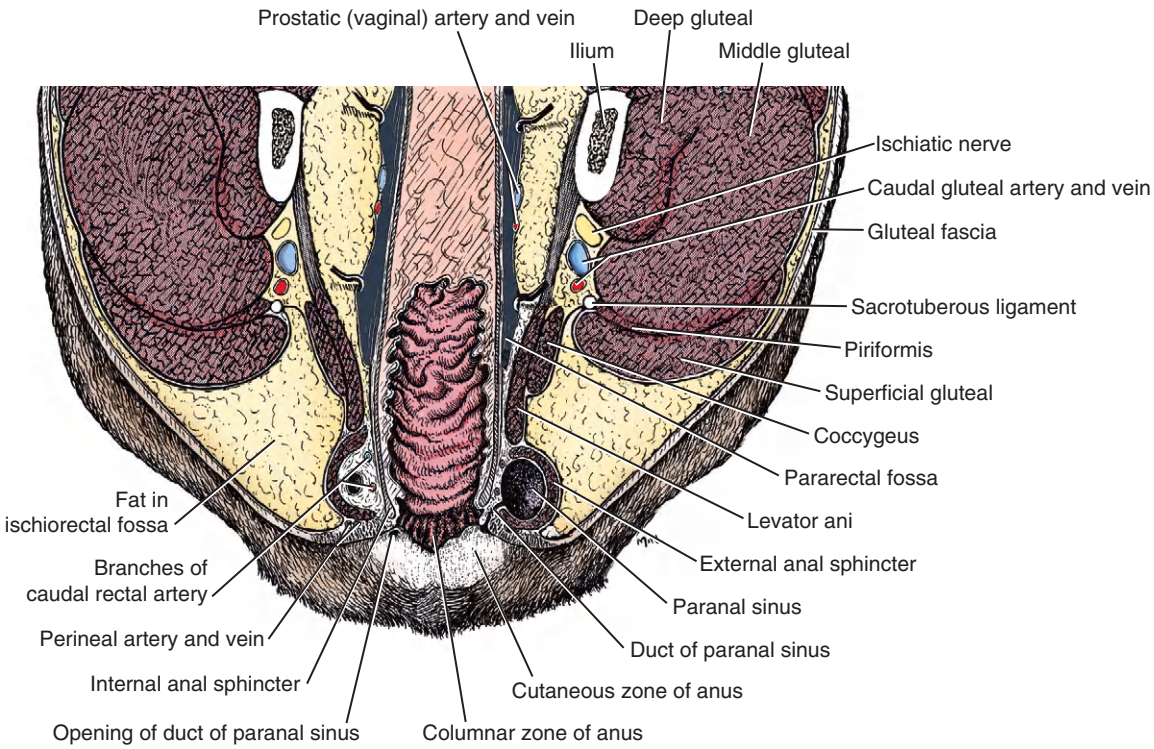

Figure 59-1 Cross-sectional anatomy of the anorectum. (Reprinted and modified with permission from Evans HE, de Lahunta A. *Guide to the Dissection of the Dog*, ed 7, St. Louis, 2010, Saunders, p 696.)

pararectal fossa.[3] The muscularis layer of the rectum includes the longitudinal muscles, which are continuous with the longitudinal muscle layer of the colon. The longitudinal and inner circular muscle layers provide tone and structural support to the mucosa and submucosa. In the distal rectum, the fibers of the longitudinal layer sweep dorsocaudally from the sides of the rectum to form the rectococcygeus muscle.[3] This muscle passes dorsal to the external anal sphincter and attaches to the bodies of the fifth and sixth coccygeal vertebrae. Anchoring the rectococcygeus muscle on the tail serves not only a means of supporting the anal canal, but also permits movement of the tail during defecation. In the distal rectum the circular muscle layer eventually forms the internal anal sphincter. The internal anal sphincter is composed of smooth (involuntary) muscle, is much smaller than the external anal sphincter, and has questionable significance in maintaining fecal continence.[2] Innervation of the rectum is via autonomic nerves from the pelvic plexus, and its blood supply is provided by the caudal rectal arteries.[3]

Anatomy of the Anal Canal

The terminal portion of the alimentary tract is the anal canal: a short (e.g., 1 cm), highly specialized segment that extends from the rectum to the anal opening. The involuntary smooth muscle of the internal anal sphincter, and voluntary striated muscle of the external anal sphincter are the most important muscles controlling the anal canal. Of these, the external anal sphincter is the most important structural determinant of fecal continence. The external anal sphincter is largely a circular band (approximately 1 to 1.5 cm in width in the dog) of striated muscle that serves as the chief guardian of anal control. The muscle attaches dorsally to the coccygeal fascia and ventrally it blends into the muscles of the external genitalia. Laterally, the sphincter is united by fascia to the levator ani muscles. The mucosa of the anal canal is divided into three zones: columnar, intermediate, and cutaneous.[3] The columnar zone connects the rectum to the anus, and is composed of longitudinal ridges of columnar mucosa. The columns formed in this zone encircle the anal canal as an anorectal line. Caudally, these columns loop around to unite as the anal valves, each loop enclosing a tiny pocket called an *anal sinus*. The ring of anal valves and sinuses forms the dentate line that marks the caudal limit of the deepest part of the anus.[2] The intermediate zone (also called the *anorectal line*) is the transition area between the columnar mucosa and the stratified squamous epithelium that makes up the cutaneous zone. Most caudally, the cutaneous zone is subdivided into an internal and external region. The inner most region contains the anal sacs and the termination of the anal sac ducts. The outer most aspect of the cutaneous zone is keratinized and hairless, and peripheral to the anus itself. The anal opening (or anus) is formed by the plane that separates these two regions of the cutaneous zone. The arterial blood supply to the anus is via the caudal rectal artery, a branch of the internal pudendal artery, which is a large vessel that courses through the ischiorectal fossa. However, venous drainage is via cranial rectal and caudal mesenteric veins to the portal system, and via the caudal rectal and perineal veins to the systemic circulation via the caudal vena cava.[3] Lymphatic drainage from the anal canal is also to the medial iliac lymph nodes. Innervation of the anus is supplied by the pudendal nerve.

Anatomy of the Anal Sacs and Glands

In dogs and cats, there are paired anal sacs, which lie ventrolateral (i.e., 4 and 8 o'clock) to the anus in the internal cutaneous zone, lying between the internal and external anal sphincters.[3] Anal sacs were first described as structures lined with keratinized epithelium and wrapped in glandular tissue and a connective tissue stroma that is diffusely infused with lymphoid tissue.[6] These sacs are sometimes termed *paranal sinuses* and are now known to contain coiled,

apocrine, sudoriparous glands, as well as a few sebaceous glands.[3] In cats, there are very few apocrine glands in the anal sacs, with sebaceous glands being found in both the fundus and the ducts of the glands.[7] The ducts emptying the canine anal sac open into the lateral margin of the anus at the intermediate zone; however, the anal sac duct in cats opens on a pyramidal prominence 2 mm lateral to the anus.[5] It has been suggested that either the increased lipid secretion from the increased sebaceous glands in cats, the location of the duct opening lateral to the anus, or possibly both in combination are responsible for the reduced occurrence of anal sac impaction and abscessation in the cat. The composition of secretions from the anal glands in dogs varies from serous to pasty, and accumulates in the anal sacs, along with desquamated epithelium, bacteria, and yeasts.[8,9] The normal canine anal sac secretion is highly variable in its color, consistency, and presence or absence of solid material, even in the anal sacs from the same dog (e.g., right vs. left sacs).[8,9] The typical cytologic composition of canine anal sac material contains mostly corneocytes, Gram-positive cocci, and a large amount of amorphous basophilic debris.[8] It is also not unusual to find a small number of neutrophils, yeasts, or a few rod-shaped bacteria in normal dogs.[9] However, intraepithelial bacteria, undifferentiated epithelial cells, or erythrocytes are not normal components of anal sac secretions and typically indicate the presence of a disease state.[8] Under normal circumstances, the anal sacs are emptied when the animal defecates voluntarily or involuntarily (e.g., fear) contracts the external anal sphincter muscle; however, their primary function in the wild is for territorial scent marking.[3,3a] These sacs are of clinical importance because they may become impacted as a result of anatomic disruption of the ducts caused by increased perineal obesity, anatomic disruption from hernia or neoplasia, or if the secretions become too thick or hardened to allow proper emptying. Impaction of the anal sacs often causes discomfort that is evidenced by scooting or increased licking of the area, and can lead to infection or abscessation. In dogs, anal sac impaction was the third most commonly diagnosed condition in a study of 559 dogs presented for dermatologic assessment.[10] In that study, otitis externa and pyoderma were more commonly reported, but these three conditions were clearly the most common reasons dogs were presented for evaluation of dermatologic conditions in private clinical practice, representing 20% of overall admissions in that study.[10] In addition to the anal sacs, there are two other types of glands present in the anal area. Circumanal, or hepatoid, glands are nonsecretory, subcutaneous sebaceous glands located in the anal subcutaneous zone. These perianal glands may become clinically important in intact male dogs, as they continue to grow throughout life because of the presence of androgens and may grow to form perianal adenomas late in life.[2] In one study, 85% of intact male dogs developed this tumor, making it the most common anal tumor of the dog.[4] It is rarely reported in the cat, likely a consequence of the fact that most pet cats are neutered and have fewer numbers of these glands. The "true" anal glands are tubuloalveolar sweat glands located craniolateral to the circumanal glands. These glands produce a fatty secretion that drains into the intermediate zone of the anus and whose function is unknown.

Physiology of Defecation and Fecal Continence

The innervation of the distal alimentary tract is complex and vital to the normal functions of storage, continence, and defecation (Figure 59-2).[1] Innervation of the rectum is similar to the colon, in that there is a well-defined enteric nervous system consisting of a myenteric and a submucosal plexus.[3] These segments of the autonomic nervous system control the many sensory, integrative and motor neurons that characterize the functions of the rectum, and more specifically control and integrate movements that ensure appropriate storage and transport of feces. The secretions of the goblet cells are also controlled by these systems. The innervation of the anus is more complex (Figure 59-2). The pelvic plexus, specifically the sacral nerve branches of the pelvic nerve, provides parasympathetic fibers which are excitatory to the rectum and inhibitory to the internal anal sphincter. Conversely, sympathetic fibers arise from the hypogastric nerves of the caudal mesenteric ganglion are inhibitory to the rectum (e.g., causing relaxation) and excitatory to the internal anal sphincter (e.g., causing contraction), thus allowing appropriate storage of feces. Relaxation of the internal and external anal sphincters in conjunction with rectal contraction permits defecation. The external anal sphincter is a striated muscle with several muscle bundles that surround the internal sphincter. These muscles are reflexively able to increase anal sphincter pressure, mediated via somatic nerve fibers in the anal branch of the pudendal nerve, while still allowing accommodation of feces within the rectum. The function of the external anal sphincter allows maximal distention (e.g., storage of feces in the rectum) while maintaining anal control. When the pudendal nerve is damaged, the external anal sphincter is incompetent and results in the development of fecal incontinence.

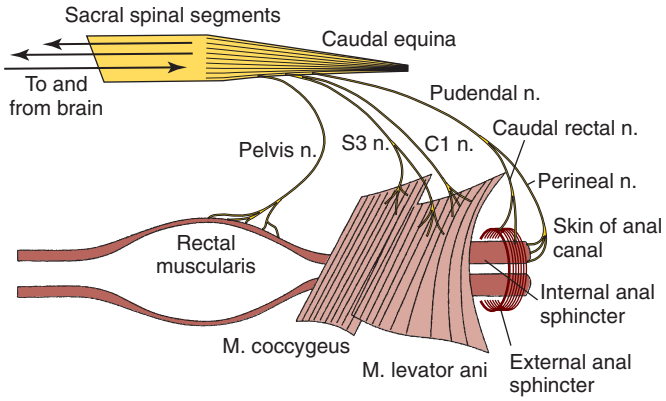

Figure 59-2 Nervous control of defecation. (Reprinted with permission from Guilford WG: *Strombeck's Small Animal Gastroenterology*, ed 3, Philadelphia, Saunders, 1996, p. 507.)

Normal anorectal function and the act of defecation are primarily pressure-based functions that rely heavily on complex interactions between peripheral pressure receptors, myenteric neurons, somatic and autonomic afferent nerve fibers, spinal cord, brainstem, somatic and autonomic efferent nerve fibers, and smooth and striated muscle of the rectum and anal sphincters (see Figure 59-2).[5] When the rectum is empty, intraluminal rectal pressure is low. Increased intraluminal pressure is generated by contraction of the internal anal sphincter, either in response to a sudden increase in intraabdominal pressure (e.g., coughing or sneezing) or an increase in rectal filling, and is the primary component of maintenance of fecal continence.[11] The main stimulus for defecation is increased pressure in the rectum because of distention. The rectoanal inhibition reflex relaxes the internal anal sphincter along with contractions of the external anal sphincter to allow slow, but continuous filling of the rectum.[11,12] As the fecal volume increases in the rectum, conscious awareness of the rectal filling is perceived by sensory signaling of information transmitted via sacral afferent fibers to the cerebral cortex. The rectoanal inhibition reflex allows continued filling of the rectum until defecation is appropriate. If the volume

of feces remains small (i.e., stretch is minimal) or defecation is inappropriate, the internal anal sphincter returns to a state of contraction, resulting in propulsion of feces back into the colon.[13,14] This activity is also stimulated by descending inputs from motoneurons in the sacral spinal cord and pudendal nerve, which mediate voluntary contractions of the external anal sphincter and levator ani. This back-and-forth process is repeated until the volume of feces is sufficient to initiate rectal distention as well as come into contact with the anal mucosa, resulting in a stronger urge to defecate. When defecation is initiated, distention of the rectum activates parasympathetic efferents which control contraction of colonic smooth muscle (resulting in mass movement of the distal colon), and inhibition of the external anal sphincter and pelvic muscles (resulting in relaxation of the sphincters.)[12] Because the rectum itself produces only small contractions that are not propulsive, the main propulsive force to dispel feces out of the body is the contraction of colonic smooth muscles.[12] Thus, the rectum serves primarily as a conduit during the process of defecation and as a storage depot in the periods between this process. Defecation is facilitated by proper posture and generation of increased abdominal pressure (closure of the glottis, fixation of the diaphragm, and contraction of the abdominal wall muscles). Conscious suppression of defecation is facilitated by descending impulses to sacral nerves and the pudendal nerve, which mediate contraction of the levator ani and external anal sphincter, resulting in maintenance of fecal continence.

DIAGNOSTIC EVALUATION

Robert J. Washabau

History and Physical Examination

Because the anorectum is not importantly involved in digestive or absorptive processes, dogs and cats with anorectal disease do not typically manifest signs of maldigestion or malabsorption (e.g., steatorrhea, diarrhea, and weight loss). Instead, dogs and cats affected with anorectal disease manifest signs of inflammation (hematochezia, tenesmus, mucoid feces, or frequent and painful defecations) or abnormal motility (dyschezia, incontinence).

Observation of the animal during the act of defecation should be an important part of the physical examination as many pet owners misinterpret signs of anorectal disease. Pet owners frequently confuse the signs of dyschezia (painful or difficult defecation) and tenesmus (straining to defecate) with constipation. Constipation is best defined as infrequent defecation, excessively hard or dry feces, or diminished fecal volume. The finding of true constipation would be associated with a different set of differential diagnoses.

The perineum is visually inspected for inflammation, tumors, herniation, rectoanal prolapse, and fistulas prior to rectoanal palpation. The anorectum is then digitally palpated for size and texture of the anal sacs, tone of the anal sphincter, integrity of the pelvic diaphragmatic musculature, diameter of the rectal lumen, and texture and regularity of the rectoanal mucosa. Rectoanal palpation may be impossible in some pets because of severe inflammatory disease, in which case palpation may be delayed until the animal is anesthetized for proctoscopy or other procedures. Rectoanal palpation is difficult in the unsedated cat. Abdominal palpation is also important, as anorectal disease may be a manifestation of more diffuse gastrointestinal disease (e.g., proctocolitis or colorectal carcinoma).

Special Examination

Proctoscopy is often performed in conjunction with colonoscopy because the rectum is frequently involved in canine colitis. However, discrete lesions of the anorectum may be evaluated with proctoscopy alone. Proctoscopy is technically less difficult and the instrumentation less costly than with total colonoscopy. A rigid proctoscope, for example, is sufficient for the evaluation of the anorectal structures in most patients. As with colonoscopy, the anorectum is evaluated for color, texture, friability, and bleeding. Mucosal biopsies may be readily obtained with a variety of forceps instruments. Lesions of the terminal rectum and anus can be visualized following gentle prolapse of the rectum and anus using an Allis tissue forceps, or by doing a retroflex endoscopic procedure following intubation of the anorectum and descending colon.

Radiographic examination is not especially useful in the evaluation of inflammatory lesions of the anorectum. However, survey and contrast radiographs may be useful in the evaluation of rectal tumors and rectal stricture. Ultrasonographic studies have assumed increasing importance in the evaluation of lesions of the anorectal canal. Intrarectal ultrasonography, for example, was accurate in assessing depth of rectal tumor penetration as well as the involvement of pararectal lymph nodes in experimentally induced rectal tumors in the dogs.[1]

Manometric evaluation of anorectal function is useful in selected cases of anorectal disease, for example, external anal sphincter incompetence (see Chapter 14) and congenital aganglionic megacolon (see Chapter 58). Animals with external anal sphincter incompetence may be more objectively evaluated for anal sphincter tone.[2]

INFLAMMATION

Debra L. Zoran

Perianal Fistula

Perianal fistula is a chronic, progressive, often debilitating, disease characterized by one or more ulcerated fistulas or draining tracts affecting the perianal skin and associated tissues surrounding the anus (Figure 59-3). *Anal furunculosis* is an alternate term for this

Figure 59-3 Perineal region of a dog with severe ulcerated, draining tracts surrounding the anal orifice.

condition, and may be more appropriate, as true fistulous tracts from the anal canal to the perianal skin are rare. The disease has not been described in cats. The ulcerative lesions are very painful and malodorous because of associated tissue destruction and infection. In most severe and chronic cases, the entire anus is surrounded with open draining tracts that can lead to secondary infection, infestation with ectoparasites, and ultimately to fecal incontinence or rectal stricture if left untreated.

Etiology

Perianal fistula (PF) most commonly affects dogs of the German Shepherd breed or German Shepherd mixed breeds, but Irish Setters, Labrador Retrievers, Old English Sheepdogs, Bulldogs, Spaniels, and Collies are also notably affected.[1-5] In one study, German Shepherds accounted for 84% of the reported cases.[2] PF primarily affects middle-aged to older dogs of either sex, but the disease has been described in dogs of ages ranging from 1 to 14 years.[2,3,6] At this time, the effect of sex hormones on the development or maintenance of PF in dogs is still debated, but it appears that both intact and neutered animals have equal risk of developing PF.[5] The cause of PF remains unknown and only partially defined, but anatomic, bacterial, endocrinologic, and immunologic etiologies have all been proposed. Similarities in clinical appearance between canine PF and human Crohn's disease have caused speculation that these diseases may share a common immunopathogenesis.[2,7-10] This notion has been further supported by clinical improvements reported in dogs treated with cyclosporine and other immunomodulating or immunosuppressive drugs (e.g., tacrolimus, azathioprine, prednisone).[3,4,9-13] Evidence of immune dysregulation has been reported in some studies, including increased plasma cells, CD 3+ T lymphocytes, immunoglobulin (Ig) A- and IgG-secreting B lymphocytes, and macrophages in affected tissue.[14,15] However, immunohistochemical analysis of the number and distribution of B and T lymphocytes has not revealed any simple immunologic defect.[15] An alternative hypothesis has been proposed that IgA deficiency in German Shepherds predisposes this particular breed to anal furunculosis.[15] This hypothesis is further supported by the findings of House et al. who showed that dogs with PF have increased expression of messenger RNA for interleukin (IL)-1β, IL-6, tumor necrosis factor-α, IL8, IL-10, and transforming growth factor-β.[15] Matrix metalloproteinases (MMPs) may contribute to this tissue pathology. MMPs 2, 9, and 13 were found to be significantly increased in tissue biopsies of dogs with PF.[16] MMP-9 and MMP-13 are primarily produced by macrophages, and tissue ulceration may occur as a result of the aberrant activation of macrophages in affected dogs.[16] It has been suggested that pathologic macrophage activity could result from T-cell secretion of interferon-γ, which might explain why lesions resolve following cyclosporine therapy.[16]

Pathophysiology

The pathologic changes that occur in dogs with PF are well described and are typical of chronic inflammation.[2] In particular, anal furunculosis is characterized by mononuclear infiltration of the fistulous or sinus tracts. Dense aggregates of lymphocytes trigger granulation tissue formation in areas adjacent to the sinus tracts. The inflammatory process can affect the anal sac and its associated duct, the circumanal glands, and the muscles of the external anal sphincter. Sinus tracts form in areas of degenerative squamous epithelium and produce obliteration and ulceration of perineal tissue.[2] Erosions and ulcerations typical of PF are believed to result from cell-mediated inflammatory responses and MMP enzyme expression.[16] MMPs are enzymes in the family of zinc-dependent endopeptidases, are produced by macrophages, and are involved in the degradation of extracellular matrix. There are several different families of MMPs: collagenases, gelatinases, stromelysins, and membrane-type MMPs. These enzymes play important physiologic roles in the detachment and migration of cells as well as in tissue remodeling for repair and angiogenesis. MMPs can also play a pathologic role in ulcerogenic diseases such as Crohn's disease, rheumatoid arthritis, periodontitis, and tumor cell invasion and metastasis.[17-19] In a pathologic role, MMPs cause tissue destruction instead of extracellular matrix remodeling.[16] In ulcerative diseases such as inflammatory bowel disease and Crohn's disease, significant elevations in MMP-9 and MMP-13 have been documented,[20,21] and increased MMP-9 expression is specifically associated with fistulous lesions in Crohn's disease.[22] The finding of MMPs in PF tissues adds further credence to the suggestion that tissue destruction, ulceration, and fistulation are a result of an aberrant cell-mediated inflammatory response.

Clinical Examination

Perianal fistulas are most commonly reported in middle-aged to older, large-breed dogs with a broad-based, lower tail carriage that may provide an environment conducive to worsening inflammation and infection once the disease starts. It may also contribute to the fact that the disease is often not noticed by the pet owner until obvious lesions are present, or the discharge or odor becomes overpowering. The only abnormality reported by some owners, especially early in the course of development of PF, is persistent licking of the anus. Other clinical signs that may be reported include hematochezia, dyschezia, perianal discharge, constipation, and tenesmus caused by the irritation and discomfort associated with defecation. In severely affected dogs, anorexia, weight loss, and behavioral changes may be reported as a consequence of the discomfort or associated infection surrounding perianal tissues.

Physical examination may be difficult, if not impossible, without sedation because of the pain associated with the condition. It may be necessary to clip hair and cleanse the area to get a full appreciation of the full extent of the disease. In severe cases, visual inspection will reveal multiple, ulcerated, draining tracts extending into the tissues surrounding the anus (see Figure 59-3). Fistulous lesions are often malodorous and may contain ectoparasites, particularly if the patient resides in warmer climates. Rectal strictures, abnormal anal tone, and granulomatous rectal mucosa may be found during digital rectal examination. In some dogs, the anal sacs are involved in the fistulation resulting in anal sac obstruction and abscessation. In dogs with early disease, the lesions will be more subtle and may require more careful inspection or digital palpation to differentiate other causes of perianal swelling, pain or redness (Figure 59-4). Nevertheless, whether there is one small draining tract or multiple, ulcerated areas with deep fistulas, the diagnosis is the same.

Diagnosis

A diagnosis of PF is made on the basis of signalment, history and clinical signs, and relevant physical examination findings. There are several important differentials for this condition that must be considered, including chronic anal sac abscessation with secondary fistulas, aggressive perianal tumors (e.g., adenocarcinoma), caustic

Figure 59-4 A milder version of perianal fistulas with hyperemia, a few draining tracts, and evidence of perianal swelling.

injury, and untreated bite wounds. Although history and physical examination findings are usually sufficient to rule out these other potential causes of perianal disease, a digital rectal examination and probing the extent of the lesions under general anesthesia will confirm the diagnosis. In a recent study of dogs with anal furunculosis, colonoscopy was performed in each case—whether or not the dog had concurrent signs of colitis or colonic disease—and results showed that 50% of the dogs had concurrent colitis.[23] The relationship between colitis in dogs and PF is unknown; also unknown is the effect of therapy of colitis on the outcome of dogs with PF. Nevertheless, the study authors recommended that flexible colonoscopy should be performed to obtain colonic biopsies in all dogs with perianal fistulas.[23]

Treatment

Because of the uncertain etiology of perianal fistulas, a number of medical and surgical treatments have been proposed. Previously, medical therapy included antibiotics, perineal cleansing, antiinflammatory drug therapy (e.g., prednisone), and analgesic drug therapy, all of which were palliative at best.[2-4,24] Surgical excision was frequently cited as the only treatment option in early studies[24-26]; however, remission rates were highly variable (48% to 97%), complication rates were equally variable (3% to 100%), often involving fecal incontinence, rectal strictures, and delayed wound healing, and recurrence rates were generally near 50%.[3,6,24-26] Cryotherapy, Nd-YAG (neodymium:yttrium-aluminum-garnet) laser therapy, and chemical cauterization have been reported with variable success, remission, and recurrence rates.[27,28] Following recent accounts of successful use of cyclosporine therapy with remission rates of 72% to 100%,[3,29] current therapeutic approaches have been aimed at blunting the immune response that appears to be at the core of disease development.

Immunomodulating drug therapies have been used in PF dogs, including high-dose glucocorticoids,[8] cyclosporine,[3,4,9,10,29] tacrolimus,[12] and azathioprine (alone or in combination with antibiotics or prednisone).[11,13,26,29] Low-dose prednisone therapy has been recommended for the initial treatment of the inflammatory component of PF, but as with other earlier medical therapies, low doses of prednisone were found to have mostly a palliative effect.[2] Immunosuppressive doses of prednisone may be more effective, but only 33% of dogs in one study achieved resolution of disease.[8] Topical tacrolimus, a potent immunosuppressive medication, achieves a resolution of lesions in 50% of dogs and improvement in as many as 90% of dogs.[12] Although this approach may provide a viable alternative to other therapies, it is likely to be effective only in dogs with mild to moderate PF, and therefore is not recommended for use in dogs with more severe forms of the disease. Cyclosporine therapy may be the best therapeutic option for this disease. Early studies of cyclosporine showed that upward of 85% of dogs had complete healing with several weeks of therapy.[9] Several other studies of cyclosporine, either alone or in combination with ketoconazole or other therapy (including surgery), confirmed the efficacy of cyclosporine in the treatment of canine PF.[3,4,10,26,30,31] Success rates of 60% to 98% with cyclosporine have been reported, but most studies also revealed that when the drug was discontinued, recurrence rates were very high, confirming the presence of ongoing immune dysfunction. One of the persistent problems with use of cyclosporine in the treatment of this condition in dogs is the very high cost of the drug—both for the medication, and for the drug-level monitoring that is recommended to assure proper dosing. One approach to reduce the cost of cyclosporine therapy is to combine cyclosporine with ketoconazole. Because cyclosporine is transformed by the hepatic cytochrome P450 3, a mixed-function oxidase, addition of ketoconazole to the therapy acts to competitively inhibit this pathway and effectively increase the half-life of cyclosporine in dog.[30] As a result, using this combination of drugs results in an equivalent therapeutic responses, but at a reduction in cost of 50% to 60%.[3,30] In another study, investigators showed that cyclosporine at a dose rate of 5 mg/kg q24h is effective in reducing the surface area and severity of lesions in dogs with PF.[10] However, an important finding in that study is that doses less than 5 mg/kg q24h are ineffective in resolving PF lesions. Thus, in dogs that are intolerant of ketoconazole combined with cyclosporine, single-dose therapy can be used at a slightly lower dose to make the therapy more cost-effective. Finally, because of the high recurrence rate and, in some dogs, incomplete resolution of lesions, studies have investigated using immunosuppressive therapy with concurrent surgical excision of affected tissues as a combination approach.[5] In a recent study, cyclosporine therapy was administered for up to 12 weeks followed by surgical excision of any remaining draining tracts, along with cryptectomy and anal sacculectomy.[26] In that study, all 18 dogs were reported to have resolution of the disease, and only one of the 18 had recurrence of the disease 9 months after completion of the therapy and surgery.[26] This result suggests that there may be significant merit to using the combination of immune suppression and removal of diseased tissue to achieve the best long-term resolution.

Prognosis

The overall prognosis should be considered guarded in dogs with perianal fistulas, even though most methods, whether medical or surgical, have met with some degree of long-term success. The most common complications of surgical approaches are recurrence and fecal incontinence; thus, for most dogs, medical therapy with cyclosporine alone or in combination with ketoconazole should be used as the first-line approach, followed by surgical resection of residual diseased tissue once immune suppression achieves its fullest extent. In this scenario, with less-invasive surgery required, the risk of severe complications, such as fecal incontinence, is reduced, but this also increases the chances of a prolonged remission in affected dogs.

INFECTION

Debra L. Zoran

There are several common diseases affecting the anal sacs, including anal sac impaction, anal sacculitis, and abscessation of the anal sacs. Although each of these may present as different diseases, they likely are variations of the same disease process. These diseases are more common in dogs than in cats, and affect up to 12% of the canine population.[1,2]

Etiology

The initiating events and exact cause of anal sac disease are unknown in many instances. Nevertheless, a variety of contributing factors likely play contributing or causative roles, including fecal consistency, inactivity, diet, body weight, pudendal nerve dysfunction, generalized seborrheic disorders causing increased anal sac secretions, perianal fistulas or intestinal inflammatory disease, and previous perineal surgery resulting in scar tissue that disrupts normal anal sac function.[3-5] In some breeds, such as German Shepherd dogs, the anal sacs lie deeper in the perianal tissues near the rectum, and as a result, may predispose them to an increased risk of impaction or infection within the sac.[5] Small-breed dogs, on the other hand, may have an increased risk of anal sac disease because of anatomically small ducts emptying the sacs that are more likely to become obstructed if anal sac secretions become thicker than normal.[5,6] Finally, any inflammatory disease occurring in the region (proctitis, perianal fistulas, or dermatitis) can result in secondary inflammation of the anal sacs, leading to anal sacculitis or subsequently abscess formation.

Pathogenesis

The most common cause of inflammation or infection of the anal sac is ductal obstruction, which prevents normal secretion and permits proliferation of bacteria and secondary infection. Bacterial species commonly found in the normal canine anal sac include *Streptococcus faecalis*, *Streptococcus faecium*, *Escherichia coli*, *Bacillus* spp., *Clostridium perfringens*, *Staphylococcus intermedius*, and *Proteus* spp.[1,7] In dogs with pyoderma, a significant increase (from 10% to 30%) in the carriage of *S. intermedius* in the anal sacs has been reported.[7] In addition to these bacteria, yeast (e.g., *Malassezia pachydermatis*) are often found in anal sacs, often as opportunistic pathogens.[7] Dogs with atopic dermatitis have also been found to have higher numbers of bacteria and yeasts in their anal sacs, which could predispose them to an increased incidence of infection and anal sacculitis. Anatomic conformation may play an important role in the tendency to develop anal sacculitis or abscessation, such as small ductal anatomy or aberrant duct placement on the anus that decreases effective emptying. Other contributing factors may include secretions that are thicker than usual, development of abnormal anal tone, production of soft feces, and recent estrus in females.[5] Anal sac infection or anal sacculitis can culminate in anal sac abscessation if the secretions and bacteria are retained with ductal obstruction. In dogs with anal sac abscesses, the most common bacteria isolated are *E. coli* and *Proteus* spp.[8] If the duct is completely obstructed, infection will eventually extend beyond the wall of the sac (anal sacculitis) into the surrounding perineal tissues to induce cellulitis and abscess that will eventually rupture through the skin and perineal tissues via draining tracts. The purulent, malodorous, and often bloody discharge will drain once the abscess ruptures, but the surrounding cellulitis may cause significant pain and swelling of the area. In dogs with recurring episodes of anal sacculitis or impaction that are poorly responsive to medical management, surgical correction with anal sacculectomy should be considered.

Clinical Examination

The most commonly reported clinical signs of anal sac disease are associated with anal pruritus or pain: licking or biting at the tail base or anal region, "tail chasing" behavior, scooting or rubbing the anus on the ground, reluctance to sit, and discomfort when sitting.[3,5,8] In more severely affected cases, dyschezia, tenesmus, or reluctance to defecate may result from severe pain. Dogs with long-standing anal sac disease may develop large swellings in the area over the anal sac, and if the abscessed sac ruptures, a draining fistula will be present extending from the affected anal sac.

External or internal digital palpation of the anal sacs may be required in some cases to determine the presence of diseased or impacted anal sacs in some dogs. Normal anal sac secretions are liquid, brown, and foul smelling, but are easily expressed from the sac through ductal openings on the anus. In dogs with anal sac impaction, the material often becomes pasty or even dried, and may be very difficult to express without the animal experiencing severe pain. The material present in infected or abscessed anal sacs is often thicker, may be purulent or bloody, and is frequently very malodorous.

Diagnosis

In most dogs, anal sacculitis is suggested by the history of anal pruritus along with either palpable or visual inspection of a perianal swelling at either the 4 o'clock or 8 o'clock positions lateral to the anus. In the absence of significant external evidence of anal sac enlargement, a digital rectal examination is sufficient to confirm the presence of an enlarged, often painful, anal sac(s). Some dogs, and all cats, will require sedation to safely perform a rectal examination because of the accompanying discomfort. Impaction of the anal sacs is confirmed by expression of thick, pasty anal sac material, or inability to easily empty the sacs with otherwise appropriate technique. If the anal sacs are painful when gently palpated, or the material expressed is bloody or purulent, anal sacculitis should be suspected, but not confirmed until cytologic examination finds the presence of a large number of red blood cells and intracellular bacteria in neutrophils.[7,9] If the anal sac is abscessed or the surrounding tissues severely infected, fever may be present. An unruptured anal sac abscess presents in affected dogs as a painful, perianal swelling in the region of the anal sac that cannot be expressed using appropriate technique. In dogs with long-standing anal sac abscessation, the skin overlying the sac will be thin, edematous, erythematous, and painful to the touch (Figure 59-5). If the abscess is untreated, the infection will erode through the skin leaving a draining tract surrounding the infected tissues (Figure 59-6). The major differentials to consider in dogs with these clinical signs include perianal fistulas, perianal or anal tumors, bite wounds or other trauma (especially in cats), and in the female dog, the possibility of vaginal infection.

Treatment

Treatment of simple anal sac impaction is straightforward, requiring that both of the anal sacs be manually emptied by gentle digital manipulation of the sac during digital rectal examination. If the sacs

Figure 59-5 Anal sac swelling.

Figure 59-6 Open, draining tract associated with an anal sac abscess that has ruptured.

cannot be easily or completely emptied, the sacs should be gently flushed with warm saline or mineral oil to loosen concretions and pasty material. Once the sacs are emptied, an antibiotic and steroid ointment or solution can be instilled into the sac to reduce local infection and inflammation. If possible, the anal sacs should be emptied by frequent gentle expression for several weeks to prevent recurrence or possible abscessation. In dogs with chronic impactions, pet owners can be shown how to digitally express the anal sacs at home, or the anal sacs can be surgically removed.

Dogs with anal sacculitis or abscessed anal sacs must have expression of the anal sacs, but because of the associated discomfort, sedation or anesthesia is usually required. In dogs with anal sacculitis alone, the sacs should be gently flushed with an antiseptic solution, such as dilute (0.5%) chlorhexidine, and then antibiotic solution instilled into the sacs.[10] Broad-spectrum, oral antibiotic therapy is recommended for 10 to 14 days, along with hot compresses to reduce swelling and pain, and at least weekly emptying of the anal sacs. Antiinflammatory therapy in the form of topical steroids or short-term oral prednisone may be needed to reduce the inflammatory process associated with infection. In the majority of cases managed this way, inflammation and infection resolve and further therapy is not necessary. For dogs with recurring bouts of anal sacculitis, anal sac surgery and removal should probably be considered. Abscessation of the anal sacs is managed as for other abscessed tissue: the abscess must be surgically opened, flushed, and debrided. Even in dogs or cats where the abscess has already opened, the affected area must be flushed and debrided to remove any remaining necrotic and infected tissue. This procedure should be repeated daily for 2 to 4 days to help keep the area open and draining, as well as to help remove any additional material forming in the sacs. Antibiotic therapy should be administered for 10 to 14 days, using a broad-spectrum antibiotic, and preferably based on culture of the contents if the dog has had repeated episodes of anal sac disease requiring antibiotic therapy. Application of hot compresses several times daily for 3 to 5 days will also help reduce the swelling and pain associated with the abscess. As with anal sacculitis, surgical removal of the anal sac is not recommended unless there is recurrence following otherwise appropriate therapy. Surgery should not be performed on the abscessed anal sac until antibiotic therapy has been administered to assure resolution of infection. In general, anal sac removal is recommended only when all other options fail, primarily because of the risk of complications, especially fecal incontinence.

Anal sacculectomy can be performed via either open or closed techniques. Preservation of the caudal rectal artery and pudendal nerve during the surgical procedure is crucial to maintain anal sphincter function. The open technique of anal sac resection is associated with a greater number of complications compared with the closed or modified technique.[11] The closed technique using a Foley catheter to distend the anal sac for visualization during removal appears to facilitate the delineation of the sac and surrounding surrounds, so that the risk of surgical trauma to important vascular and neural structures is greatly reduced.[12]

Prognosis

The prognosis for anal sac impactions and anal sacculitis is generally very good, as they typically respond completely to appropriate medical management. Most dogs or cats with anal sac abscesses also respond well to aggressive medical management, but because they may be more difficult to treat or recur, surgical anal sac removal may be required. The prognosis for animals requiring anal sacculectomy is fair to good when the surgery is performed by an experienced surgeon using techniques designed to reduce the risk of damage to the external sphincter or the associated blood vessels and nerves in the region that control its function. However, even with all due precautions taken, the risk of fecal incontinence cannot be ignored, especially in older dogs who may already have some reduced anal sphincter tone or function, or in dogs that have had significant disease in the area that makes the surgical procedure more difficult.

OBSTRUCTION

Robert J. Washabau

Diseases of the Rectum

Perineal Hernia

Etiology

In dogs, perineal hernia is characterized by disruption of the muscles of the pelvic diaphragm and herniation of the rectum and other pelvic organs (e.g., urinary bladder, prostate) into the ischiorectal fossa.[1] Four types of perineal hernia have been described, but the most common form is the caudoventral perineal hernia, a hernia that develops between the levator ani, external anal sphincter, and internal obturator muscles.[2] Perineal hernia is a condition seen almost exclusively in intact male dogs with a mean age of approximately 8 years; it has been reported in female dogs on rare occasions.[2] Perineal hernia is a rare occurrence in the domestic cat. The pathogenesis of perineal hernia appears to differ between the two species. It is associated with neurogenic atrophy of the levator ani in the dog,[1] whereas in the cat it is often a secondary lesion associated with perineal urethrostomy or idiopathic megacolon.[3]

History and Physical Examination

Dogs with perineal hernia present with one or more of the following complaints: a reducible perineal swelling, tenesmus, dyschezia, constipation, and obstipation. Perineal swelling and tenesmus are reported in 90% to 95% of affected dogs.[2] The perineal swelling is usually ventrolateral to the anus on one side, but severely affected dogs may have bilateral ventral swellings (Figure 59-7). Some dogs have signs of acute urethral obstruction because of retroflexion of the urinary bladder into the perineal hernial space. Tenesmus and constipation are reported in 95% of affected cats; perineal swellings are reported only 22% of the time.[3]

Physical examination findings are usually straightforward. A hernial sac is palpated externally in some cases. Rectal examination reveals a defect in the pelvic diaphragm, confirming the diagnosis. In the dog, perineal hernia contents include, in order of prevalence, retroperitoneal fat, serous fluid, rectum, prostate, urinary bladder, and small intestine.[2] Herniation of peritoneal contents appears to be relatively rare in cats.[3]

Diagnosis

History and physical examination findings are usually sufficient in making a diagnosis of perineal hernia. A hernial defect may be palpated externally, just lateral to the external anal sphincter. Digital palpation of the rectum and anal canal confirms the presence of unilateral or bilateral hernia. Rectal wall abnormalities may also be present (e.g., rectal deviation, sacculation, or diverticulum).

Pathogenesis

The pathogenesis of the disorder is incompletely understood. Anatomic factors, gonadal hormonal imbalance, lesions of the pudendal nerve, and excessive straining because of prostatic or rectal disease have all been cited as factors important in the pathogenesis of the disease. A predisposition in brachycephalic breeds suggests that inherent anatomic defects may contribute to the disease. Boston Terrier, Boxer, Welsh Corgi, and Pekingese breeds are all at apparent increased risk for perineal hernia.[2] As the levator ani is frequently atrophied, it has been suggested that the muscles of the pelvic diaphragm (levator ani, coccygeus) are inherently weakened in these breeds.[2]

Gonadal hormonal imbalance has been proposed as a pathogenesis because greater than 95% of cases are older male dogs, and because of the protective effect of castration reported in some studies.[2] It has been suggested that either excessive production of estrogens or diminished production of androgens by the aging testes results in atrophy and weakening of the muscles of the pelvic diaphragm.[1,2] Evidence in support of this idea comes from studies in female rats showing that testosterone administration prevents involution of the levator ani. However, serum testosterone and 17β-estradiol concentrations in dogs with perineal hernia do not

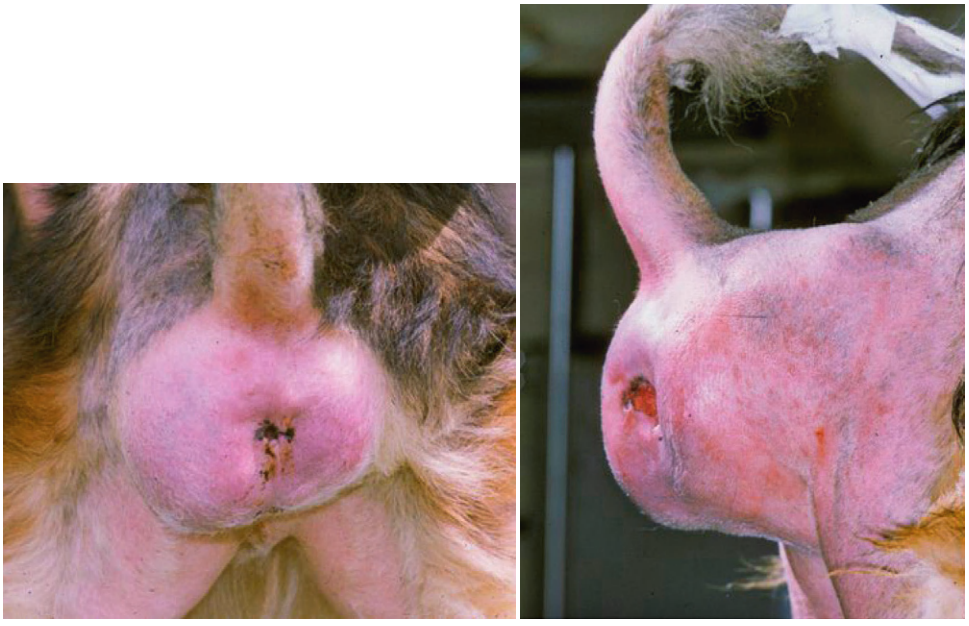

Figure 59-7 Severe bilateral perineal herniation in a dog. (Reprinted with permission from Craven M: Rectoanal disease. In: Ettinger S, Feldman EC, editors: *Textbook of Veterinary Internal Medicine*, ed 7, St. Louis, 2010, Elsevier, p 1598.)

differ from those of normal dogs of the same age and gender.[4] Furthermore, the putative beneficial effects of castration on perineal hernia have not been substantiated in other studies.[2] In a retrospective study of cats affected with perineal hernia, 19 of 20 (95%) cats were either castrated or spayed, suggesting that gonadal hormones are unimportant in this species.[3] It is possible that hormones other than estrogens or androgens are involved. It has been suggested, for example, that the peptide hormone relaxin of prostatic origin may cause weakening of the pelvic diaphragmatic musculature in the dog through a local paracrine effect.[5-7] More recent studies suggest that levator ani dysfunction in canine perineal hernia is associated with increased expression of epidermal growth factor, caspase-3 activation, and decreased expression of transforming growth factor-α, resulting in the further weakening of the levator ani.[8]

Lesions of the pudendal nerve have been suggested as the pathogenesis because of histopathologic evidence of neurogenic atrophy of the levator ani in many dogs affected with perineal hernia.[2] This finding has been substantiated by other histopathologic studies as well as by electrophysiologic evidence (e.g., fibrillation potentials, positive sharp waves, fasciculation potentials, and complex repetitive discharges) of neurogenic atrophy of the levator ani, coccygeus, and anal sphincter muscles.[1] Although it can be concluded that damage to the first, second, and third sacral nerves or to the pudendal nerve or its muscular branches is an important aspect of perineal hernia, it is not known whether nerve damage precedes development of perineal hernia.[1] It is entirely possible that nerve damage follows or occurs as a result of perineal hernia. For example, tenesmus resulting from prostatic disease may cause traction of the nerves of the sacral plexus, and thus prevention or relief of straining could have a role in preventing ·or retarding the progression of development of perineal hernia.[2] It should be noted, however, that dogs with perineal hernia have a rather low incidence of prostatic disease.[9] The exact role of pudendal nerve lesions in the pathogenesis of perineal hernia will require further investigation.

Preexisting rectal disease might be a risk factor for perineal hernia. Rectal sacculation and rectal diverticulum have been reported in the absence of perineal hernia and thus could precede the development of perineal hernia.[2] However, many dogs with perineal hernia do not have such rectal wall abnormalities.[9] Rectal wall abnormalities such as sacculation and diverticula are more frequent in long-standing perineal hernias than in recent perineal hernias, suggesting that rectal disease is a consequence, rather than a cause, of perineal hernia.

Perineal urethrostomy, which causes disruption of the fascial connections between the external anal sphincter and medial coccygeus, and idiopathic megacolon are definite risk factors for the development of perineal hernia in the cat.[3]

Therapy

Medical therapy may be attempted in mild cases of perineal hernia. It has been anecdotally reported that 20% of dogs can be maintained free of signs by the use of fecal softeners and occasional enemas.[10] However, the pet owner should be advised that the signs may become refractory to medical therapy, and that urinary bladder retroflexion can occur at any time.

Herniorrhaphy is indicated for most cases of perineal hernia. In the standard herniorrhaphy technique, the external anal sphincter is approximated to the coccygeus dorsally and laterally, the internal obturator muscle ventrally, and the sacrotuberous ligament laterally.[2] The technical deficiencies of this method are the deformity of the external anal sphincter and the inability to obliterate large ventral hernias. The internal obturator transposition technique overcomes some of these deficiencies by elevating the obturator muscle from the ischium and suturing it to the external anal sphincter medially and to the sacrotuberous ligament laterally. Excellent results have been reported with this technique.[11] Several modifications to this widely accepted technique have been proposed. If the internal obturator is thin or friable, it has been suggested that fascia lata graft be used during primary repair of the hernia.[12] Porcine small intestinal submucosa as a biomaterial has also been used successfully for perineal hernia repair in dogs in which the internal obturator is excessively thin or friable.[13] It should be emphasized that regardless of the technique, improved outcomes may be obtained in some patients in which concomitant lesions (rectal, prostatic, bladder) are first treated in a staged laparotomy approach.[14]

Rectal diverticula should be corrected at the time of surgery. Surgical correction of rectal deviation and sacculation is controversial and may not be warranted. Routine castration of all perineal hernia patients is also controversial. Because there are few contraindications to castration, it may be performed unless it unnecessarily prolongs anesthesia in a high-risk patient.

Cats in which idiopathic megacolon appears to be the primary problem, with secondary development of perineal hernia, probably should be treated with subtotal or total colectomy.[3]

Prognosis

The prognosis for successful repair of long-standing perineal hernias is still guarded. These patients may suffer from rectal wall abnormalities, atrophy of the pelvic diaphragmatic musculature, and large ventral hernias that are not easily repaired by the standard technique. The recurrence rates in these patients have been variably reported to be between 10% and 46%.[9] Patients with perineal hernias of shorter duration have much better prognoses.

Rectal Tumors

Etiology

Primary tumors of the rectum are uncommon in small animals. However, tumors of the colon and rectum represent 36% to 60% of all canine and 10% to 15% of all feline alimentary tract neoplasms.[10,15] The most common tumors of the rectum are benign adenomatous polyps. Polyps of the rectal mucosa are usually focal, pedunculated, or sessile tumors that do not metastasize (Figure 59-8). Occasionally, these rectal polyps invade the lamina propria and submucosa and, although they appear histologically benign, are referred to as carcinoma in situ. These tumors may have a greater propensity for metastasis. Colorectal adenocarcinomas tend to spread beyond the rectal wall to regional lymph nodes, liver, and lung. It has been suggested that, as in humans, the rectal polyp may represent a precancerous lesion.[10,15] Colorectal adenocarcinoma would represent the endpoint in this polyp-cancer sequential hypothesis. However, circumstantial evidence for such a sequence of events has been documented in only a few cases,[10] thus polyps and adenocarcinomas may have entirely different pathogeneses in dogs and cats.

Other tumors that have been reported in the rectum include leiomyoma and leiomyosarcoma, lymphosarcoma, plasmacytoma, and fibrosarcoma.[15,16] Colonic and rectal lymphosarcomas are the most common colorectal tumor of the cat. Most of these tumors occur in the ileocecal sphincter of the cat.[10] Colorectal lymphosarcoma is less common in the dog, but most of these occur in the rectum. Extramedullary plasmacytomas are an uncommon tumor of the gastrointestinal tract, but many of these also occur in the large intestine and rectum.[17] All of the aforementioned tumors are associated with signs of inflammation and obstruction (e.g., hematochezia, tenesmus, and dyschezia). Carcinoids (rare 5-hydroxytryptamine

Figure 59-8 Perianal adenoma in a male dog. (Reprinted with permission from Craven M: Rectoanal disease. In: Ettinger S, Feldman EC, editors: *Textbook of Veterinary Internal Medicine*, ed 7, St. Louis, 2010, Elsevier, p 1606.)

[5-HT]-secreting tumors) are occasionally associated with diarrhea because of the effects of 5-HT on secretion and motility (see Chapter 58).

History and Physical Examination

Most affected animals have signs of hematochezia, mucoid feces, tenesmus, and dyschezia of varying severity. Other signs depend on the tumor type and location. Malabsorption and cachexia, for example, may be observed when tumors (e.g., lymphosarcoma) concurrently involve the proximal gastrointestinal tract.

Digital rectal examination typically reveals a prominent mass involving the rectal mucosa or submucosa, narrowing of the rectal lumen, pain on palpation, and blood or mucous. An annular stenotic lesion ("napkin-ring lesion") is often suggestive of a colorectal adenocarcinoma. Colonic distention might be detected on abdominal palpation in such animals owing to partial to complete obstruction of the rectal lumen. These animals may develop rectal prolapse as a consequence of severe tenesmus.

Diagnosis

A rectal mass can usually be palpated on digital rectal examination. Survey and contrast radiography may do little more than confirm the physical examination findings. Intrarectal ultrasonography is increasingly importance in the evaluation of these lesions. In experimental models of rectal tumors in dogs, for example, intrarectal ultrasonography was accurate in assessing depth of wall penetration of rectal tumors as well as the involvement of pararectal lymph nodes.[18] Proctoscopy and biopsy are required for definitive diagnosis. Mucosal tumors are readily diagnosed by proctoscopic biopsy, but submucosal tumors (e.g., lymphosarcoma) may require pararectal aspiration or incisional biopsy for diagnosis.

Pathogenesis and Therapy

The pathogenesis of rectal tumors is poorly understood. Tumors of the rectum are likely to have a multitude of inciting etiologies.

Tumors of the rectum, excluding lymphosarcoma, are best treated by complete surgical excision. Good to excellent results with few recurrences are generally obtained with resections of rectal polyps or carcinoma in situ. Radical full-thickness resection of adenocarcinomas has been recommended in the past, but wound dehiscence, infection, rectal stricture, and fecal incontinence have been reported with radical excision,[19-21] and for that reason several alternative procedures have been recommended, including cryosurgery,[19] transanal pull-through procedures,[22,23] transanal endoscopic resection,[24] carbon dioxide laser surgery,[25] and photodynamic therapy with motexafin lutetium.[26]

Rectal lymphosarcomas are probably best treated initially with chemotherapy. Local resection could be recommended in an animal's failing chemotherapy.

Prognosis

The prognoses for rectal polyps, carcinoma in situ, leiomyomas, and fibromas are generally favorable. Adenocarcinomas, lymphosarcomas, and plasmacytomas tend to recur. Dogs with annular colorectal adenocarcinomas have a particularly poor prognosis with a mean survival time of only 1.6 months.[19]

Rectal Foreign Bodies

Ingested sticks, bones, and metal may traverse the entire alimentary tract with only minor pathology before lodging in the rectum and causing painful obstruction. Rectal foreign bodies are usually diagnosed and removed during digital examination, although general anesthesia may be required because of extreme pain. Foreign bodies in the rectum are probably the most important cause of proctitis in the dog.[27] Complications of rectal foreign bodies include rectal fistula and perirectal abscesses if the rectal wall is compromised.[27] Secondary colonic impaction may also develop in animals that suppress defecation.

Rectal Prolapse

Etiology

Rectal prolapse is a protrusion of one or more layers of the rectum through the anal orifice. The prolapse may be partial or complete, depending on which structures are involved. In partial rectal prolapse, only the rectal mucosa protrudes through the anal orifice, whereas in complete prolapse, all layers of the rectum are involved. Occasionally, a portion of the anal canal also prolapses.

History and Physical Examination

Neither breed nor sex predilections have been described, although several authors anecdotally report an increased incidence in younger animals.[10,28] Affected animals often have an antecedent history of dyschezia and tenesmus associated with anorectal or colonic inflammatory disease (e.g., typhlitis, colitis, or proctitis). Other cited predisposing factors include tumors of the colon, rectum, and anus; rectal foreign bodies; perineal hernia; cystitis; prostatitis; urethral obstruction; and dystocia.[10,27,28] Relative risks for each of these conditions have not been determined, however. In general, rectal prolapse is uncommon, even in animals with long-standing dyschezia and tenesmus.

On physical examination, an elongated, cylindrical mass is evident with complete prolapse of the rectum. Only the rectal mucosa is evident with partial rectal prolapse.

Diagnosis

The presence of an elongated, cylindrical mass protruding from the anal orifice is usually diagnostic. However, this protrusion must be carefully differentiated from a prolapsed ileocolic intussusception (see Chapter 58). Differentiation may be made by passing a well-lubricated finger between the prolapsed mass and anus. With a

prolapsed ileocolic intussusception, the finger may be easily passed 5 to 7 cm further into the fornix than in rectal prolapse. Contrast radiography usually differentiates these two conditions.

Pathogenesis

Because of the low incidence of rectal prolapse even in animals with long-standing dyschezia and tenesmus, it has been suggested that an individual predisposition must be present to contribute to the development of prolapse.[27] Contributing factors were held to be weakness of the perirectal and perianal connective tissues or musculature, uncoordinated peristaltic contractions, and/or inflammation and edema of the rectal mucosa.[27] None of these putative factors have been rigorously investigated, however.

Therapy

Therapy and prognosis depend on recognition of the underlying etiology, degree of prolapse, time elapsed since the prolapse, tissue viability, and the recurrence rate of previous prolapses.[27,28] Incomplete rectal and anal prolapses are usually easily reduced manually with the aid of saline compresses or lubricants.[27] A purse-string suture may be placed if a tendency toward recurrence seems obvious. Topical corticosteroid creams or lotions are useful in treating concurrent proctitis/anusitis.

Complete rectal prolapses characterized by short duration and good tissue viability are probably best managed by manual reduction and placement of an anal purse-string suture. It has been suggested that colopexy be considered in animals suffering from multiple recurrences, or in cases in which manual reduction is impossible.[10] Prolapses of longer duration, in which there is substantial tissue devitalization, should instead be managed either by mucosal resection or complete resection and anastamosis.[27,28] Because of postoperative stricture formation, complete resections and anastomoses are not recommended in cats. Colopexy is currently recommended for cats suffering from rectal prolapse.[27,28] In any case, postoperative management should consist of high-fiber diets and bulk (psyllium) or emollient laxatives (dioctyl sodium or calcium sulfosuccinate) to soften the feces.

Prognosis

Incomplete prolapses, prolapses of short duration, and first occurrences all carry a good prognosis. Complete prolapses, prolapses of longer duration, and multiple recurrences carry a more guarded prognosis. Prolapses requiring complete rectal resection carry a worse prognosis because of the possibility of rectal stricture formation.[20]

Rectal Stricture

Etiology

Rectal stricture is a narrowing of the rectal lumen that results from fibrosis or cellular proliferation. Fibrosing rectal strictures result from anorectal trauma or surgery, whereas proliferative rectal strictures typically result from cancer.

History and Physical Examination

There are no sex or breed predilections for rectal stricture. Rectal strictures do tend to occur in older animals, however, because of the increased incidence of rectal tumors and other anorectal disease.[10,27,28] Clinical signs vary with the severity of the lesion. Most animals have dyschezia, tenesmus, and passage of a thin ribbon of feces. Animals with inflammatory lesions of the anorectum have signs of hematochezia and diarrhea. The history may also provide evidence of recent anorectal trauma or surgery.

Digital rectal examination typically reveals a firm, circumferential fibrotic band in an animal with fibrosing stricture, or an asymmetric mass in an animal with rectal stricture resulting from cellular proliferation. Occasionally, annular strictures associated with colorectal adenocarcinoma are indistinguishable from fibrosing strictures associated with anorectal trauma or surgery.

Diagnosis

History and physical examination findings are usually sufficient in making a diagnosis of rectal stricture, although contrast radiography may be useful in identifying the proximal extent of rectal stricture. Intrarectal ultrasonography is likely to assume increasing importance in the evaluation of proliferative strictures (see "Rectal Tumors" above).[18] Proctocolonoscopy, while theoretically useful, has some practical limitations. The endoscope cannot be passed more than a few centimeters in some cases, and visualization of these lesions is difficult.[10,29] Furthermore, superficial endoscopic biopsies may not identify a tumor of the underlying submucosa or muscularis. Biopsy and histologic examination are recommended if there is any doubt about the pathogenesis of the lesion.

Pathogenesis

Fibrosing rectal strictures result from one of three possible entities: rectal inflammatory disease (e.g., perianal fistula, rectal foreign body, chronic anal sac disease), anorectal trauma, or anorectal surgery (e.g., perianal fistulectomy, rectal tumor resection). The fibrous tissue response usually involves the circumference of the rectum. Proliferative rectal strictures are most commonly associated with colorectal adenocarcinomas and, to a lesser extent, with invasive prostatic adenocarcinomas.[27] Obstruction, without stricture formation, occasionally occurs with rectal polyps or other mucosal tumors.

Therapy

Mild cases of rectal stricture have shown improvement with bougienage or balloon dilation, although the results may be only temporarily palliative.[27,28] Surgical correction is required in most cases. Surgery involves either myotomy of the rectal muscularis, a complete resection-anastomosis procedure, or a rectal pull-through procedure.[27,28,30]

Prognosis

Fibrosing rectal stricture would seem to have a better prognosis than proliferative rectal stricture based purely on biologic behavior. However, the prognosis is guarded to poor in both because of wound dehiscence, fecal incontinence, and recurrences of stricture that accompany attempts at surgical correction.[20]

Congenital Abnormalities of the Rectum

Rectovaginal Fistula and Imperforate Anus

Rectovaginal fistula is a rare congenital disorder of dogs and cats that may occur with or without imperforate anus.[31] Congenital abnormalities of the anus and/or rectum tend to occur in association with urogenital malformations as a consequence of abnormal embryonic development of the cloacal region.[31] In either case the vagina is contaminated with feces, resulting in vaginitis, vulvitis, and perivulvar and perianal dermatitis. Other physical examination findings may include abdominal distention and bulging of the perineum with concurrent imperforate anus. Diagnosis may be achieved either by vaginography or barium enema.

The treatment of rectovaginal fistula is surgical correction of the malformation. Surgical correction consists of excision of the fistula

with reconstruction of the rectovaginal shelf, and creation of a terminal opening for the intestinal tract.[27,28,32,33] The prognosis for return to normal anorectal function is guarded as animals with imperforate anus have an incomplete anal sphincter. Animals suffer postoperatively from fecal incontinence, wound dehiscence, and constipation.[20,27]

Rectal Vascular Ectasia

Rectal hemorrhage associated with vascular ectasia or angiodysplasia of the rectum has been reported in a young dogs.[34] Affected animals have intermittent and undiagnosed hematochezia for weeks to months. Attempts at resection of the affected segment may be complicated by postoperative fecal incontinence.

Diseases of the Anus

Anal Sac Tumors

Etiology

Although their incidence is low, neoplasms arising from the glandular epithelium of the anal sacs are almost invariably malignant adenocarcinomas. These tumors invade the surrounding soft tissues and frequently metastasize to regional lymph nodes. Anal sac adenocarcinomas have been reported in dogs but not in cats.

History and Physical Examination

Most studies report an older age distribution (>10 years) and a predilection for females, intact or spayed,[10,27] although one study reported an equal sex distribution.[35] No breed predispositions are reported. Dyschezia and a noticeable perineal swelling are the most frequent complaints made by pet owners, although anal sac tumors may occasionally be identified as an incidental finding during rectal examination.[36] This finding emphasizes the importance of rectal palpation as part of a complete physical examination. In some dogs, complaints of polyuria/polydipsia, muscular weakness, vomiting, and constipation may be made. These features are secondary to a paraneoplastic syndrome (humoral hypercalcemia of malignancy) sometimes associated with this tumor.[37,38]

Tumors of the anal sac are usually detected during routine anorectal examination. Most tumors are unilateral, although bilateral tumors have been reported.[36] The small size of some tumors (0.2 to 1.0 cm) belies their metastatic and paraneoplastic potential These tumors have often metastasized at the time of initial examination. The external iliac (sublumbar) lymph nodes are a common site of metastasis. The liver, spleen, and lungs are also occasionally involved. Many animals are systemically ill at the time of initial presentation because of the effects of hypercalcemia on kidney, nerve, and muscle function.

Diagnosis

Complete blood cell count, serum biochemistry, urinalysis, and survey radiographs of the chest and abdomen are warranted in any dog with a palpable anal sac mass. It is estimated that more than 50% of affected dogs have physical or radiographic evidence of metastasis at the time of presentation, and that 25% to 50% of affected animals are hypercalcemic and hypophosphatemic.[36]

Pathogenesis

The molecular events leading to the transformation of glandular epithelial cells to adenocarcinoma cells are poorly understood. The humoral hypercalcemia results from expression of the gene for parathyroid hormone-related protein, a peptide with biologic functions similar to those of parathyroid hormone.[37,38] The hypercalcemia mediated by this peptide may be severe enough to induce renal failure. If detected early enough, hypercalcemia may resolve following adequate resection of tumor mass, only to return with recurrence of metastases.

Therapy

Surgical excision of the primary anal sac mass is the recommended treatment for adenocarcinoma of the anal sac. Surgery is fairly straightforward, but postoperative complications have included wound infection and fecal incontinence in a small number of animals.[20,36] Excision of regional metastases has been advocated in several reports,[10,27,39] although one retrospective study of 32 cases of anal sac adenocarcinoma failed to demonstrate improved survival with excision of regional metastases.[36] The role of chemotherapy in the treatment of this disease remains controversial,[10,27] although responses to platinum chemotherapy have been reported.[40] Radiation therapy and immunotherapy have not proved useful in the treatment of this disorder.

Prognosis

Early, complete surgical excision of the primary tumor and regional lymph nodes is recommended as the treatment affording the best outcome.[41] Four negative prognostic indicators have been reported: lack of therapy, presence of distant metastases, presence of lymph node metastases, and primary tumor size.[39] Although controversial and incompletely studied, an association between hypercalcemia and survival has not been established.[40] Lymph node extirpation is a positive prognostic indicator.[39]

Anal and Perianal Tumors

Tumors of the anus and perianal integument are common in the dog. The perianal gland adenoma is a benign lesion arising from the circumanal glands of older intact male dogs. A number of other benign and malignant tumors also occur in the perianal region.

Perianal Gland Adenomas

Adenomas of the perianal glands (circumanal gland or "hepatoid cell" adenomas) affect all breeds, and breed predispositions have been reported in the Cocker Spaniel, Bulldog, Beagle, and Samoyed breeds.[10,27] Development and growth of these tumors seem to be closely related to plasma androgen levels. Thus, 85% of perianal gland adenomas are found in older intact male dogs.[10,27,28] Most of these tumors occur in the perianal integument, but they may also be found in the prepuce, inguinal area, thighs, and ventral skin of the tail root. The majority are firm, single or multiple nodular masses of variable size, but some may eventually ulcerate, bleed, and necrose. They may cause an intensely pruritic anusitis and eventually interfere with defecation. Aside from these features, perianal adenomas are neither invasive nor metastatic.

These tumors can be effectively treated by surgical excision.[27,28] Radiation therapy and cryosurgery are reported to be as effective as surgery.[27,28] Regardless of the technique employed, affected dogs should be castrated because of the androgen-dependence of the tumor. Castration causes regression of existing tumors and reduces the risk of new tumor growth.[27] Estrogen therapy could be considered if the pet owner is unwilling to accept castration; however the myelosuppressive effects of estrogens make this option much less desirable.

Other Perianal Tumors

With the exception of the perianal gland adenoma, other neoplasms are infrequently seen in the perianal area. Adenocarcinomas of the perianal glands, for example, are rare. Other tumors arise from glandular structures such as sweat glands and sebaceous glands or from any other cell type commonly found in the skin and subcutis. Thus, fibromas, lipomas, trichoepitheliomas, melanomas, and squamous cell carcinomas have all been described in the perianal area.[16,27] Anal squamous cell carcinomas, and melanomas to a lesser extent, are highly invasive and metastatic.[27]

DYSMOTILITY

Robert J. Washabau

Fecal incontinence in dogs and cats is defined as the inability to control defecation and retain feces until voluntary, conscious defecation is initiated. Incontinence of feces may result from *reservoir* or *sphincter* incontinence and either condition may be transient or permanent. Reservoir incontinence occurs when there is a reduction in the reservoir capacity of the colon best typified by total or subtotal colectomy.[1,2] Affected animals defecate more frequently, as fecal storage capacity is diminished. This is not an uncommon finding in cats undergoing subtotal colectomy for the treatment of idiopathic megacolon.[3] Sphincter incontinence, on the other hand, results from denervating lesions of the external anal sphincter (called neurogenic sphincter incontinence) or with primary external anal sphincter injury (called non-neurogenic sphincter incontinence). Affected animals experience unintentional anal dribbling. In general, sphincter incontinence is usually more severe and more permanent than reservoir incontinence; consequently the rest of this discussion is devoted to sphincter incontinence. The reader is referred to Chapter 14 for details of the medical workup of sphincter incontinence.

History and Physical Examination

Animals with sphincter incontinence have uncontrolled flatus, accumulate fecal material at the anal opening between defecations, involuntarily eliminate feces with excitement, and have constant anal dribbling. Some animals may be concurrently affected with urinary incontinence. Concurrent urinary incontinence would implicate a neural lesion since micturition and defecation share common neural pathways and regulation.[4-6]

Digital rectal palpation usually reveals a subjective sense of decreased tone of the anal sphincter and rectum in most cases of neurogenic and nonneurogenic sphincter incontinence. Injuries to the external anal sphincter (e.g., perineal surgery, trauma) may be evident in some dogs with nonneurogenic sphincter incontinence. Dogs with neurogenic sphincter incontinence may evidence other neurologic deficits (e.g., hind limb paresthesia or hyperesthesia, gait abnormalities, lumbosacral pain, large atonic bladder, and depressed myotatic reflexes).[7,8] The anal and pudendoanal reflexes should be assessed to determine the integrity of the reflex arcs involving the perineal afferent fibers, sacral spinal segments, pudendal efferent fibers, and external anal sphincter. The anal reflex may be evaluated by pinching the perianal skin and observing contraction of the external anal sphincter. The pudendoanal reflex in a male dog may be evaluated by applying digital pressure to the penis and observing similar contractions of the anal sphincter. These reflexes may be diminished or absent in animals with neurogenic sphincter incontinence. Figure 59-9 outlines the differentiation of neurogenic and nonneurogenic sphincter incontinence.

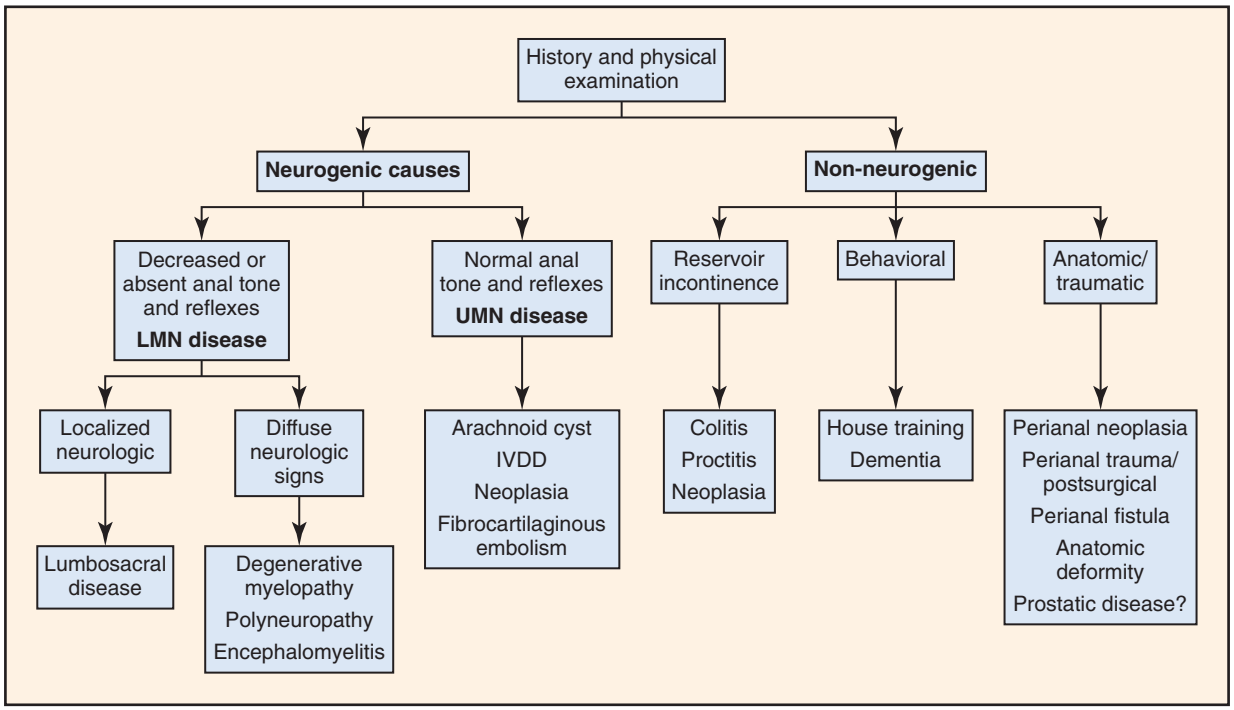

Figure 59-9 Algorithm for the investigation of fecal incontinence.

Table 59-1 Nonneurogenic and Neurogenic Causes of Fecal Incontinence

Disease	Causes
Nonneurogenic Causes	
Colorectal disease	Inflammatory bowel disease
	Colorectal neoplasia
	Idiopathic constipation
	Spinal arachnoid cyst
Anorectal disease	Anorectal trauma
	Anal/perianal surgery
	Anorectal neoplasia
	Perianal fistula
Miscellaneous causes	Secretory diarrheal disorder
	Irritable bowel syndrome
	Cognitive dysfunction
Neurogenic Causes	
Sacral spinal cord disease	Sacral vertebral fracture
	Lumbosacral instability
	Diskospondylitis
	Degenerative myelopathy
	Sacral spinal cord neoplasia
	Vertebral malformations
	Meningomyelitis
	Sacrococcygeal subluxation
	Meningomyelocele
Peripheral nerve disease	Traumatic nerve injury
	Iatrogenic–perineal herniorrhaphy
	Iatrogenic–perineal urethrostomy
	Dysautonomia
	Endocrinopathy–hypothyroidism, diabetes mellitus
	Penetrating wounds

Diagnosis

A diagnosis of sphincter incontinence is usually apparent from history and physical examination findings. Complete neurologic examination generally discriminates neurogenic from nonneurogenic causes of sphincter incontinence. Confirmation of sphincter incontinence may be obtained by direct anal sphincter electromyography[9] or anorectal manometry,[10] although these techniques may require referral to a specialty hospital. Survey spinal radiography, myelography, and magnetic resonance imaging may be indicated in the further evaluation of suspected spinal cord or cauda equina lesions (e.g., lumbosacral dislocations, severe spondylosis). Epidurography and computer-assisted tomography may also be useful in documenting such cases.[7,8] Table 59-1 outlines the causes of neurogenic and non-neurogenic fecal incontinence.

Pathogenesis

Sphincter incontinence may result from spinal cord (e.g., cauda equina syndrome), somatic nerve (e.g., polyneuropathy), autonomic nerve (e.g., dysautonomia), or muscle dysfunction (e.g., anorectal disease).[7,8] In the anorectal disease group, iatrogenic sphincter incontinence is a complication following difficult perianal surgery (e.g., anal sacculectomy, perineal herniorrhaphy, and perianal fistulectomy).[11] Central nervous system disease such as multifocal distemper encephalomyelitis[11] has also been occasionally associated with sphincter incontinence.

Therapy

Neurogenic and nonneurogenic sphincter incontinence are usually permanent and untreatable. It has been suggested that mild cases of incontinence may improve with empirical use of loperamide (Imodium, 0.05 mg/lb [0.1 mg/kg] q8h).[12] Loperamide increases anal canal pressure and attenuates the rectosphincteric relaxation reflex, but is without effect on the external anal sphincter.[6,13] Therefore, most cases of external anal sphincter incompetence are unlikely to be improved by loperamide. Moderate to severe cases of incontinence are refractory to these therapies. A variety of surgical techniques have been employed to replace the muscles of continence with silicone or autogenous muscle grafts, repair the external anal sphincter, and improve the anorectal angulation.[14-17] The success rate with these techniques is still unacceptably low.

NEOPLASIA

Shelby L. Freda and Michael H. Goldschmidt

Anorectal Structure

The rectum, a continuation of the distal colon, is located within the pelvic canal, and in the terminal region is associated with the anal sphincter muscles at the rectoanal junction. The rectum has similar macroscopic and microscopic anatomy to the colon and is covered by a mucosa which consists of elongated glands. These glands are lined primarily by undifferentiated cuboidal epithelial cells at their base and by goblet cells on the luminal surface. The rectal epithelial cells are separated from the lamina propria by a basement membrane. Within the lamina propria are occasional plasma cells and lymphocytes. At the base of the mucosa is the muscularis mucosa, external to which are the submucosa, the inner circular and the outer longitudinal muscle layers, and the serosa. The transition from the mucosa of the rectum to the stratified squamous epithelium of the anus is abrupt. At the rectoanal junction within the subcutis are modified apocrine glands, the anal sacs, which empty directly onto the anal mucosa via long ducts.

Tumors of the Anorectum

Tumors of the GI tract are relatively uncommon in the dog and rare in the cat. Retrospective studies confirm that GI neoplasms most commonly occur in the large intestine of dogs and the small intestine of cats.[1,2] In dogs, adenocarcinoma is the most common malignant intestinal neoplasm, with a reported prevalence of 0.13%, whereas in cats lymphoid tumors and adenocarcinomas arising at the ileocecocolic junction are common. Canine colorectal carcinomas/adenocarcinomas occur more frequently in the rectum than in the colon. Older dogs (mean age: 8.5 years) are more commonly affected, with a higher prevalence in males than females, and purebreds are more often affected. Benign epithelial tumors arising from the rectal mucosa have been referred to as adenomatous polyps, rectal polyps, papillary adenomas, papillotubular adenomas, and villous adenomas, but in the following discussion they are referred to as *rectal adenomas*. These occur most often at or close to the anorectal junction. Malignant mesenchymal tumors, although less common, include leiomyosarcoma and hemangiosarcoma, whereas the most common benign mesenchymal tumor is the leiomyoma. Malignant lymphoma is less common than benign plasmacytoma in

this anatomic location. Up to 50% of primary rectal tumors are reportedly malignant, so rectal neoplasia may be a clinically significant disease. Rectal tumors are uncommon in cats.

Clinical Findings

The most common presenting clinical signs associated with rectal tumors are hematochezia, tenesmus, and dyschezia. Hematochezia is observed because rectal tumors are often well-vascularized, friable, intraluminal masses that readily bleed as feces pass over and abrade the mucosal surface. The masses may also cause irritation of the large bowel or stricture, leading to tenesmus and dyschezia. The duration of clinical signs before a diagnosis is made can vary from 2 weeks to 5 years. Tumors arising in the submucosa or muscular tissue may produce similar clinical signs by impinging on the lumen of the rectum. The duration of clinical signs can be variable with adenomas having the longest duration of signs before treatment. Other clinical complaints associated with rectal tumors include, diarrhea, melena, prolapse of the mass through the anus, abdominal pain, anorexia, anemia, and weakness, the latter a result of anemia.

Histopathology

Adenomas

These are the most common rectal tumors in the archives of the Laboratory of Pathology and Toxicology at the University of Pennsylvania, School of Veterinary Medicine. Affected dogs range in age from 2 to 14 years and there is a 3:2 male-to-female ratio. Boxers, Labrador Retrievers, Rottweilers, and Shetland Sheepdogs have a higher incidence of adenomas.

Most adenomas appear macroscopically as raised, dome shaped, sessile lesions or as pedunculated polyps.[3,4] Microscopically, the neoplastic tissue is sharply demarcated from the adjacent normal rectal mucosa (Figure 59-10). In many lesions the neoplastic tissue occupies the superficial mucosa while the crypts at the base of the neoplastic mass are normal. The branching lamina propria supports the neoplastic epithelium and is often infiltrated by increased numbers of plasma cells and lymphocytes. Ulceration is accompanied by hemorrhage from the vessels in the lamina propria and exocytosis of neutrophils. Neoplastic cells covering the lamina propria are usually columnar with basally located nuclei. They exhibit little pleomorphism, but retain their polarity to the basement membrane and are actively mitotic.

Adenomas do not invade through the basement membrane nor is there invasion through the lamina propria at the base of the crypts. When there is marked nuclear and cellular atypia and atypical mitoses then the neoplasm should be classified as carcinoma in situ (Figure 59-11).

Surgical removal of the entire neoplastic mass allows the pathologist to evaluate margins and ensure that invasion through the basement membrane is not present. The submission of multiple small pieces from polypoid lesions is suboptimal and precludes evaluation of the tissue for evidence of invasion through the basement membrane, primarily at the base of the crypts.

Adenocarcinoma

Adenocarcinomas (carcinomas) are found less frequently in the rectum than adenomas.[5] Affected dogs range in age from 4 to 15 years, but the majority are older than 9 years. There is a 2.5:1.5 male-to-female ratio. Australian Sheepdogs, Great Danes, Shetland Sheepdogs, and West Highland White Terriers have a higher incidence of this tumor.

Most rectal adenocarcinomas appear macroscopically as soft masses or strictures (annular constriction) of the rectum, or there may be a cobblestone appearance to the mucosa. Enlargement of the sublumbar and/or colonic lymph nodes because of metastatic spread may also be evident on clinical examination. Infiltration through the serosa leading to carcinomatosis is infrequent.

Microscopically, all layers of the rectal wall may be infiltrated by neoplastic cells, forming cords, clusters, and acinar structures. The neoplastic cells are large, and exhibit both nuclear and cellular pleomorphism and there is a variable nuclear-to-cytoplasmic ratio. Loss of polarity and invasion through the basement membrane and the lamina propria into the submucosa and deeper tissues is common (Figure 59-12).

Leiomyoma and Leiomyosarcoma

These smooth muscle tumors are less common than their epithelial counterparts. Affected dogs range in age from 4 to 13 years. Leiomyomas occur in older dogs (>10 years) compared with leiomyosarcomas. There is no sex or breed predilection.

Most leiomyomas appear macroscopically as a firm mass in the wall of the rectum that may bulge into the rectal lumen resulting in mucosal ulceration. Although rectal leiomyosarcomas may appear

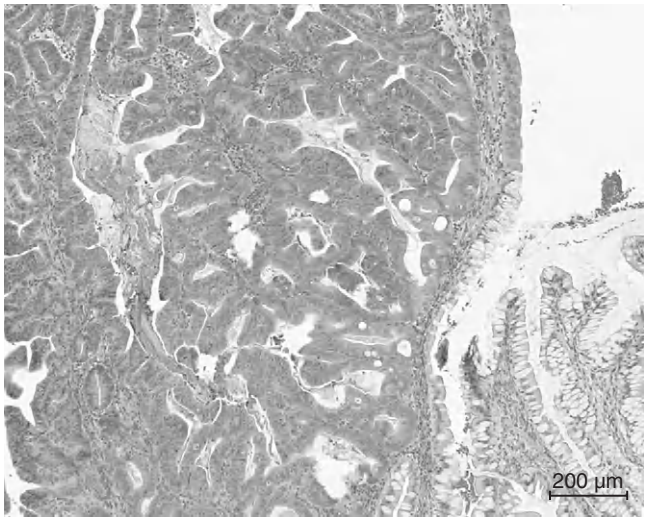

Figure 59-10 Rectal papillary adenoma.

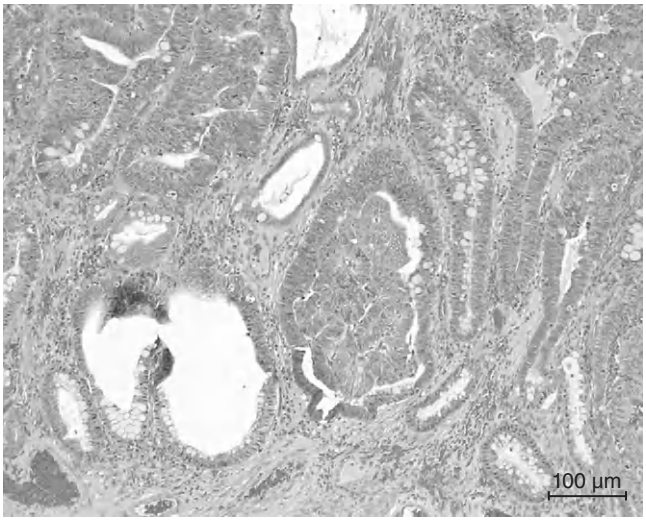

Figure 59-11 Rectal carcinoma in situ.

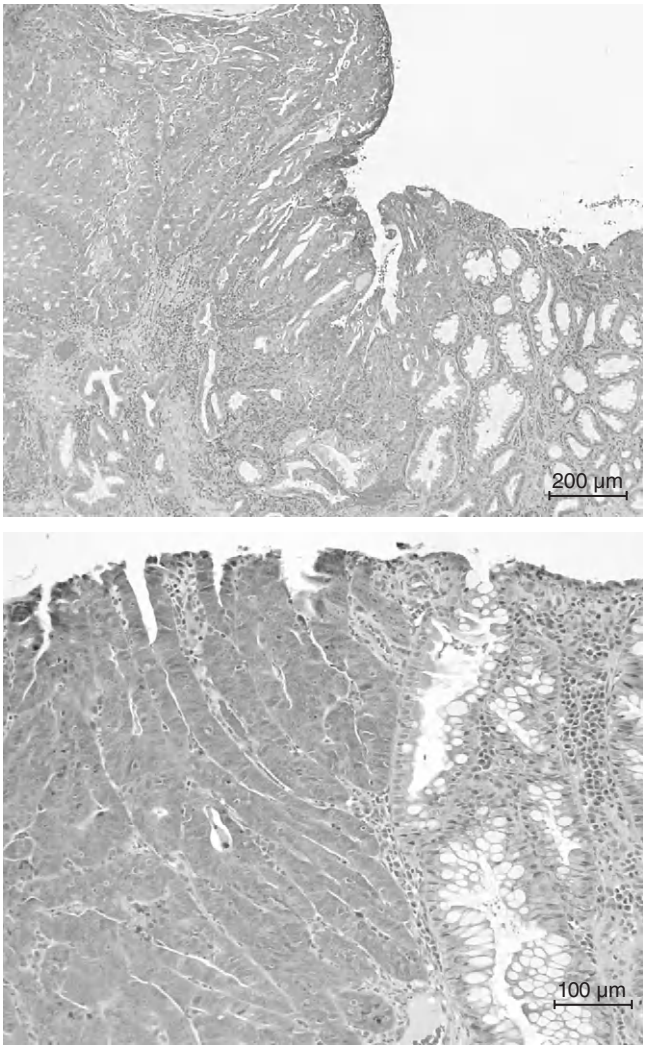

Figure 59-12 Rectal carcinomas.

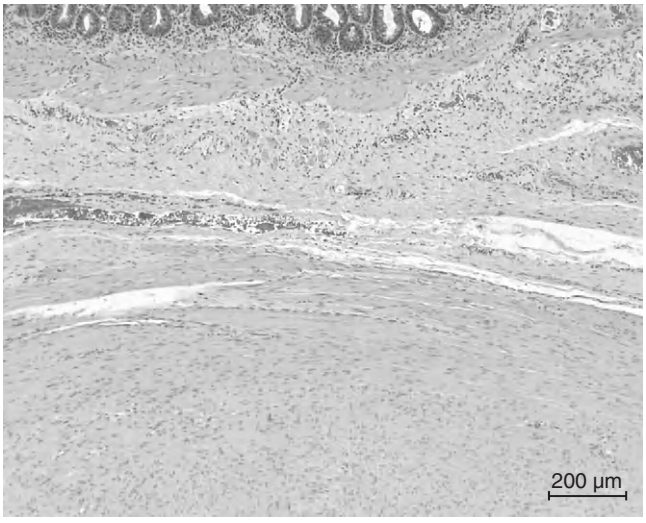

Figure 59-13 Rectal leiomyoma.

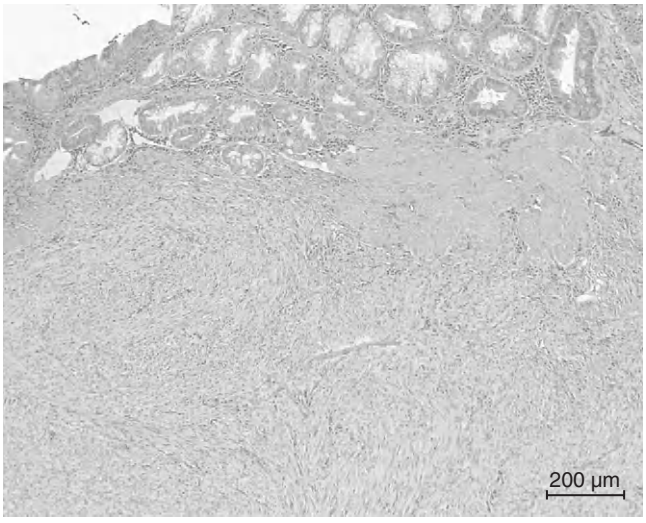

Figure 59-14 Rectal leiomyosarcoma.

similar macroscopically, many feel soft, and in large, rapidly growing tumors there are often areas of hemorrhage and necrosis.

Microscopically in leiomyomas, the mass is present within the submucosa and outer muscle. The overlying mucosa may be ulcerated and covered by hemorrhagic fibrinonecrotic exudate. Neoplastic cells are fusiform with an interwoven pattern. Nuclei are elongated with blunt ends and cells have an extensive eosinophilic cytoplasm (Figure 59-13). Few mitoses are found. Leiomyosarcomas are more cellular and the individual neoplastic cells can be fusiform or round (Figure 59-14). There is usually considerable nuclear and cellular pleomorphism and giant nuclei or multinucleated cells may be present. Metastatic spread is uncommon.

Lymphoma

Lymphoma is uncommon in this anatomic location. Affected dogs range in age from 3 to 17 years. There is no sex or breed predilection. Rectal lymphoma may be found as a solitary, variably sized, soft mass within the wall of the rectum or may be part of a multifocal neoplastic disease with involvement of other areas of the GI tract or other sites. Occasionally the masses have a polypoid appearance and resemble rectal adenomas.

Microscopically, the neoplastic lymphoid cells form sheets. There may be involvement of the lamina propria with extension through the muscularis mucosa (Figure 59-15) and submucosa into the muscle layers. Some cases will show single-cell infiltration of the mucosa or the formation of intraepithelial "microabscesses" of neoplastic lymphoid cells. The majority of cases are lymphoblastic in their cytomorphology, but in some cases there may be plasmacytoid differentiation. Care should be taken to differentiate these cases from rectal plasmacytomas, as their biological behavior is distinct. As noted previously, rectal lymphoma may be part of a multisystemic neoplastic disease or may show metastatic spread from a primary site in the rectum to regional lymph nodes, liver, and spleen.

Plasmacytoma (Rectal Extramedullary Plasma Cell Tumor)

This tumor, although uncommon, is increasing in incidence. Affected dogs range in age from 9 to 15 years. There is no sex predilection, but the Golden Retriever, Briard, and American Pit Bull Terrier have a higher incidence of rectal plasmacytoma.

Rectal plasmacytomas are usually solitary, soft masses that occupy the wall of the rectum, primarily at the rectoanal junction. They are usually quite large before the animal exhibits clinical disease (tenesmus and dyschezia) associated with a space-occupying mass in the

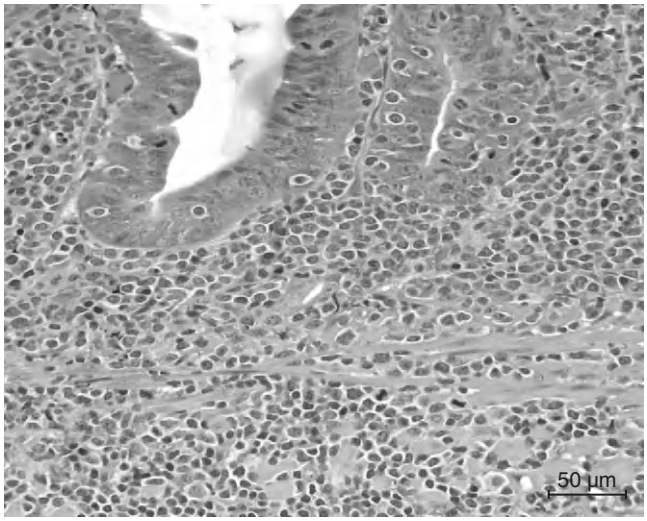

Figure 59-15 Rectal lymphoma.

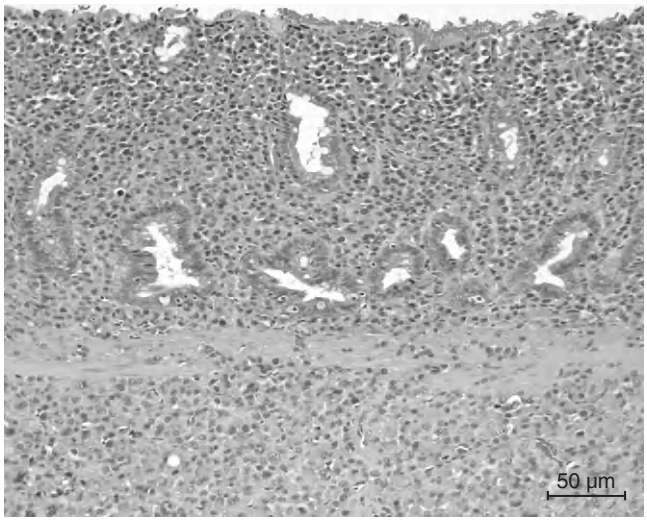

Figure 59-16 Rectal plasmacytoma.

rectal wall. Ulceration of the mucosa is common with hematochezia.

Because these tumors may be large at the time of surgical removal it is often difficult to determine whether they have arisen within the lamina propria with extension into the submucosa and muscular layers or whether involvement of the lamina propria has occurred secondary to invasion of a primary mass in the submucosa (Figure 59-16). Neoplastic cells do not infiltrate into the epithelium as can occur with rectal lymphoma. The neoplastic cells are round and form sheets or nests surrounded by a fine fibrovascular connective tissue stroma. The cells exhibit differentiation to plasma cells, which often have a perinuclear halo (Golgi zone), and plasmablasts. Nuclei are eccentric, and binucleated and multinucleated cells are frequently present. In some tumors amyloid deposition may be evident and these tumors are often less cellular on histopathologic evaluation. Surgical removal of the entire neoplastic mass allows the pathologist to evaluate margins for adequacy of excision. Metastatic spread or involvement of other organs is uncommon and unusual.

CHAPTER 60

Pancreas

STRUCTURE AND FUNCTION

Robert J. Washabau

Structure

Macroscopic Anatomy

The pancreas is a bilobed structure in companion animal species. The right lobe lies in the mesoduodenum in close apposition to the proximal duodenum. The right lobe extends posteriorly from the pylorus to the cecum. The left lobe lies in the greater omentum and lies in close apposition to the transverse colon caudally and the stomach cranially (Figure 60-1). The dog typically has two pancreatic ducts: a ventral or accessory pancreatic duct and a dorsal pancreatic duct. The ventral duct is the larger of the two and drains the right pancreatic lobe, while the dorsal duct drains the left lobe. These ducts usually intercommunicate within the gland. The ventral pancreatic duct is sometimes absent in the cat. In the cat, the dorsal pancreatic duct merges with the common bile duct prior to entry into the proximal duodenum.[1,2]

Microscopic Anatomy

The exocrine pancreas is a tubuloalveolar gland with a division of function between the acinar cells, which secrete the digestive enzymes, and the duct cells, which add water, bicarbonate, chloride, intrinsic factor, and antibacterial proteins. Throughout the pancreatic parenchyma are isolated clusters of cells forming the islets of Langerhans (Figure 60-2). The islets contain four major types of endocrine cells that synthesize and secrete glucagon (A cell), insulin (B cell), somatostatin and gastrin (D cell), and pancreatic polypeptide (PP cell). Although these hormones have other well-known physiologic effects, they also have important endocrine or paracrine effects on the pancreatic acini because of the islet–acinar portal venous system. Insulin appears to have long-term effects on the regulation of the biosynthesis of pancreatic digestive enzymes and short-term effects on the potentiation of pancreatic secretory response to gut hormones and neurotransmitters. Other islet hormones and peptides, including glucagon, somatostatin, and pancreatic polypeptide, probably act as inhibitory regulators of the pancreatic acini.

Blood Supply

The majority of the arterial blood supply of the right lobe of the pancreas arises from the celiac artery via the cranial and caudal pancreaticoduodenal arteries. The pancreatic branch of the splenic artery supplies the left side of the pancreas. Venous drainage of the right lobe of the pancreas is provided by the caudal pancreaticoduodenal vein, whereas the left lobe is drained by two veins that terminate in the splenic vein. Lymphatic drainage is by vessels that course into the duodenal, hepatic, splenic, and mesenteric lymph nodes.

In the dog and cat the exocrine pancreas does not have a direct arterial blood supply. Instead, an islet–acinar portal blood system exists, that is, the acini are perfused by venous blood arising from the islet vasa efferentia. Because some blood courses first to the islets, which secrete hormones into the blood, and then to the acinar cells, which secrete enzymes into the juice in response to stimulation by hormones, the pancreas has the potential to autoregulate part of its own exocrine secretion (see Figure 60-2).

Innervation

The efferent nerve supply to the pancreas is both sympathetic and parasympathetic (see Figure 60-2). Sympathetic postganglionic fibers emanate from the celiac and cranial mesenteric plexuses and accompany the arteries to the organ. Parasympathetic preganglionic fibers are distributed by branches of the vagi coursing down the antroduodenal region. Vagal fibers terminate at either acini and islets or intrinsic cholinergic nerves of the pancreas. In general, the sympathetic nerves inhibit and the parasympathetic nerves stimulate pancreatic exocrine secretion.

Function

Exocrine pancreatic secretions have four major functions: (a) initiate protein, carbohydrate, and lipid digestion through the secretion of digestive enzyme; (b) neutralize the duodenum with bicarbonate, chloride, and water; (c) facilitate cobalamin (vitamin B_{12}) absorption in the distal ileum via secretion of intrinsic factor; and, (d) regulate the small intestinal bacterial flora through secretion of antibacterial proteins.

Duct Cells

Water, anions, and cations are secreted primarily by the pancreatic duct cells. Bicarbonate is necessary to neutralize gastric acid that is emptied into the small intestine during feeding to prevent damage to the intestinal mucosa. Bicarbonate secretion also provides an increase in duodenal pH that is necessary for optimal activity of the secreted enzymes, particularly lipases. A fluid secretion isotonic to plasma and high in bicarbonate concentration is stimulated by the endocrine hormone secretin and the neurotransmitter vasoactive intestinal polypeptide from the duct cells of the exocrine pancreas.

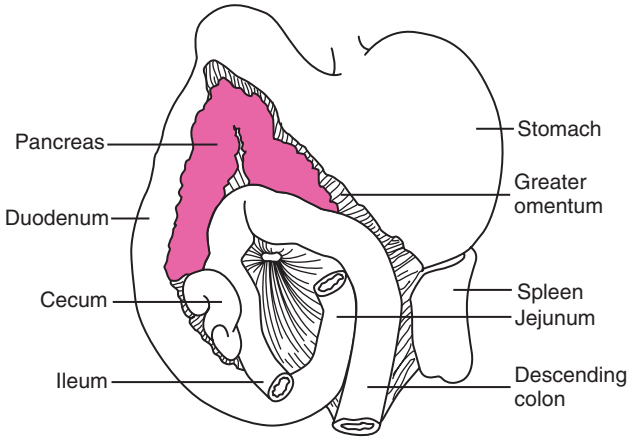

Figure 60-1 Anatomic relationship of the pancreas to other abdominal viscera. (Reprinted with permission from Johnson LR: *Gastrointestinal Physiology*, 2nd ed, Philadelphia, Elsevier, 2007.)

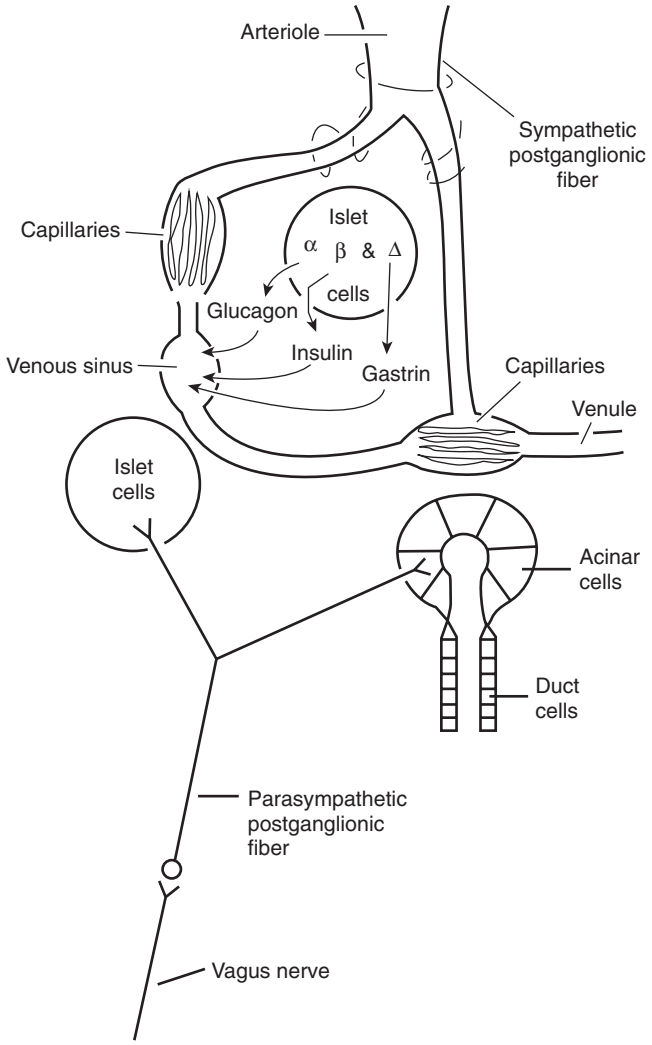

Figure 60-2 The pancreatic acinar and duct cells of the exocrine pancreatic parenchyma with their blood supply and autonomic nervous system innervation. (Reprinted with permission from Johnson LR: *Gastrointestinal Physiology*, 2nd ed, Philadelphia, Elsevier, 2007.)

Box 60-1 Enzymes Secreted from Acinar Cells in the Exocrine Pancreas

Endopeptidases: hydrolyze interior peptide bonds of polypeptides and proteins.
- Trypsin—attacks peptide bonds involving basic amino acids.
- Chymotrypsin—attacks peptide bonds involving aromatic amino acids, leucine, and glutamine.
- Elastase—attacks peptide bonds involving neutral and aliphatic amino acids.

Exopeptidases: hydrolyze external peptide bonds.
- Carboxypeptidase A—active against peptides with aromatic and aliphatic amino acids at the C-terminus.
- Carboxypeptidase B—active against peptides with basic amino acids at the C-terminus.
- Amylase—hydrolyzes dietary starch into the disaccharide maltose and α-limit dextrins.
- Lipase—hydrolyzes triglycerides into free fatty acids, 2-monoglycerides, and glycerol.
- Phospholipase—hydrolyzes phospholipids to 1-lysophospholipids and free fatty acids.
- Ribonuclease—releases pyrimidine nucleotides from polyribonucleotides.

The bicarbonate concentration increases with increasing flow rate, up to 150 mEq/L, while the chloride concentration correspondingly decreases, so that the sum of the anions remains constant. The cation concentrations are plasma-like and do not change with flow rate (Figure 60-3).

Most mammals have developed a complex process for vitamin B_{12} (cobalamin) absorption involving secretion of a gastric intrinsic factor, binding of gastric intrinsic factor to cobalamin, and subsequent attachment of this intrinsic factor–cobalamin complex to specific receptors on ileal enterocytes. The dog and cat appear to have diverged from this pattern and instead rely mostly (dog) or exclusively (cat) on pancreatic intrinsic factor synthesis and secretion. Canine and feline pancreatic duct cells secrete a pancreatic intrinsic factor that is the primary mechanism for binding and receptor-mediated endocytosis of cobalamin in the gut.[3,4]

Duct cells secrete several types of antibacterial proteins that act to regulate the endogenous microbial flora. With exocrine pancreatic insufficiency (EPI), affected animals develop predictable and severe nutrient maldigestion, acid injury to the duodenal mucosa, cobalamin and fat-soluble vitamin malabsorption, and bacterial proliferation in the gut.

Acinar Cells

The pancreatic acinar cell secretes its proteolytic enzymes in precursor form (zymogens). Other enzymes (amylase, lipase, ribonuclease) are secreted in an active form. The enzymes in pancreatic fluid have the ability to hydrolyze dietary starch (amylase), fats (lipase), proteins (trypsin, chymotrypsin, carboxypeptidase, elastase), and nucleic acids (ribonuclease, deoxyribonuclease; Box 60-1). The action of enterokinase, an enzyme secreted by the duodenal mucosa, activates trypsinogen into proteolytically active trypsin. Trypsin then acts autocatalytically to activate trypsinogen and other proteolytic zymogens (Figure 60-4).

Pancreatic acinar cells protect themselves from intraacinar activation of zymogen and acinar cell necrosis through several mechanisms: (a) potentially harmful digestive enzymes are synthesized in the form of inactive precursors or zymogens in the rough

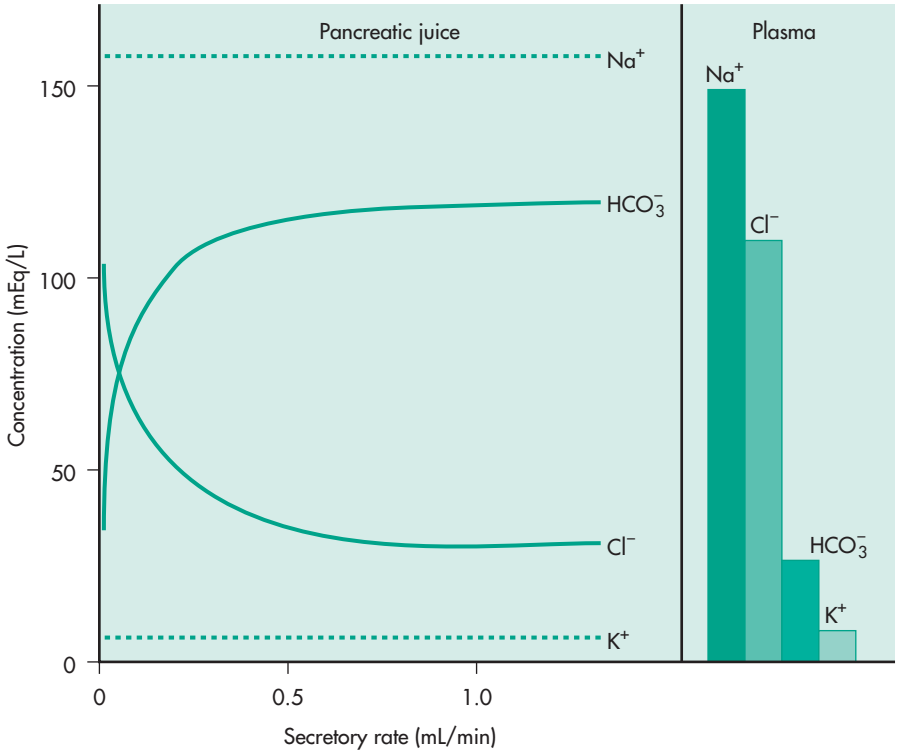

Figure 60-3 Chloride and bicarbonate secretion at low and high secretory flow rates from the canine pancreas. (Reprinted with permission from Johnson LR: *Gastrointestinal Physiology,* 2nd ed, Philadelphia, Elsevier, 2007.)

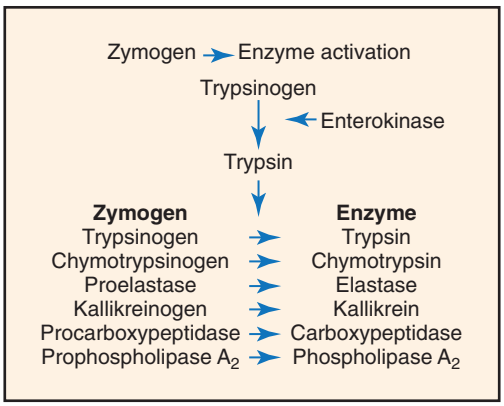

Figure 60-4 Exocrine pancreatic enzyme secretions are initiated by enterokinase activation of active trypsin from inactive trypsinogen.

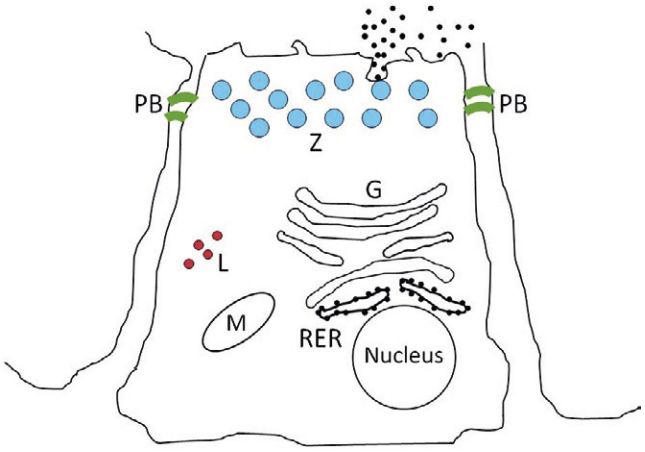

Figure 60-5 Normal pancreatic acinar cell. Zymogen granules are found in the apical region of the cell and their contents are excreted exclusively through the apical surface. Lysosomes are packaged and stored separately from zymogen granules and the paracellular barriers are intact. G, Golgi apparatus; L, lysosome; M, mitochondrion; PB, paracellular barrier; RER, rough endoplasmic reticulum; Z, zymogen granule. (Courtesy of Drs. Panagiotis Xenoulis and Joerg Steiner, Texas A & M University, College Station, Texas.)

endoplasmic reticulum; (b) zymogens are then transported to the Golgi complex where they undergo selective glycosylation. Lysosomal hydrolases that are eventually packaged in lysosomes are separated from zymogens bound for export as they pass through the Golgi complex. Lysosomal hydrolases are first phosphorylated at the six position of mannose residues, bound to receptors specific for 6-phosphoryl mannose, and then transported to lysosomes where the acid pH favors their dissociation from the receptors. Digestive enzymes lack the 6-phosphoryl mannose label, and are instead transported vectorially into a different secretory fraction; (c) packaging of zymogens into maturing zymogen granules sequesters them from contact with other subcellular fractions; (d) pancreatic secretory trypsin inhibitor (PSTI) is incorporated into the maturing zymogen granules. PSTI inactivates trypsin should there be any intraacinar activation of trypsinogen; (e) following stimulation (e.g., feeding and cholecystokinin secretion), mature zymogen granules and their contents are released from the cell into the ductal lumen in a process of membrane fusion and exocytosis; and (f) finally, zymogens are activated physiologically only after they enter the duodenum, where the brush-border enzyme enteropeptidase activates trypsinogen, and trypsin then activates other pancreatic zymogens (Figure 60-5).

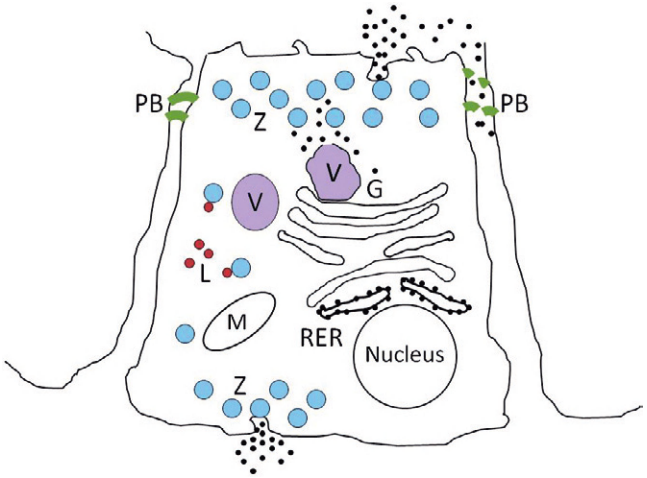

Figure 60-6 Acute pancreatitis. Secretion of the zymogen granules is redirected from the apical pole to the basolateral region of the acinar cell and into the interstitial space. Retention of zymogen granules is followed by co-localization with lysosomes and the formation of large vacuoles and premature intracellular activation of pancreatic enzymes. There is also disruption of the paracellular barrier in the pancreatic duct that allows its contents to leak into the paracellular space. G, Golgi apparatus; L, lysosome; M, mitochondrion; PB, paracellular barrier; RER, rough endoplasmic reticulum; V, vacuole; Z, zymogen granule. (Courtesy of Drs. Panagiotis Xenoulis and Joerg Steiner, Texas A & M University, College Station, Texas.)

A large body of experimental, and some clinical, evidence suggests that the initiating event of acute pancreatitis is the premature activation of digestive zymogens within the acinar cell.[5-8] Premature activation of digestive zymogen results in acinar cell necrosis and pancreatic autodigestion. In acute pancreatic necrosis, protein synthesis and intracellular transport to the Golgi complex appear to be normal, but digestive zymogens then become colocalized along with lysosomal hydrolases in large vacuoles. Cell biology studies reveal that lysosomal and zymogen granule fractions become colocalized through a process known as *crinophagy*, a process used by many cells to degrade accumulated secretory products when the need for secretion is no longer present. Although this process takes place in other cells without adverse consequences, it can be lethal in pancreatic acinar cells because of the peculiarity of their secretion products (digestive zymogens). Lysosomal hydrolases, such as cathepsin B and *N*-acetyl glucosaminidase, activate trypsinogen to the active trypsin form, and the enhanced fragility of these large vacuoles permits release of active enzyme into the cell cytoplasm (Figure 60-6). Trypsin acts autocatalytically to activate other trypsinogen molecules and other zymogens, each inducing a unique chemical pathology in pancreatic and extrapancreatic cells. A variety of inflammatory mediators and cytokines, interleukins, nitric oxide, and free radicals are involved in the further evolution of pancreatic acinar cell necrosis and inflammation, and often determine the outcome.[9] Thus, a bout of pancreatitis begins with an initiating event (e.g., ischemia, inflammation, or ductal obstruction) followed by acinar events (e.g., colocalization, enzyme activation, and cell injury), the outcome of which is influenced by severity determinants (e.g., inflammatory cytokines, reactive oxygen species, altered oxidation-reduction state, and apoptosis).[9] The further evolution of acute pancreatic necrosis to a systemic inflammatory response syndrome (SIRS) and multiple organ dysfunction syndrome is determined by the balance of proinflammatory and antiinflammatory cytokines.[9]

Regulation of Secretion

Exocrine pancreatic secretions are regulated by hormonal, neural, and paracrine input during the cephalic, gastric, and intestinal phases of secretion. In the cephalic phase of exocrine pancreatic secretion, acetylcholine released by vagal postganglionic neurons stimulates H^+ ion secretion by parietal cells (Figure 60-7). Gastric acid evokes duodenal secretin release, which then stimulates pancreatic fluid and bicarbonate secretion. Vagal stimulation also releases gastrin from antral G cells. In the dog, gastrin is equipotent with cholecystokinin (CCK) in stimulating pancreatic enzyme secretion. Gastrin stimulates the parietal cells to secrete H^+.

In the gastric phase of exocrine pancreatic secretion, the same essential mechanisms are involved as those in the cephalic phase of pancreatic secretion (Figure 60-8). Protein digestion products in the stomach release gastrin, resulting in the stimulation of pancreatic enzyme secretion and gastric acid secretion. Gastric distention stimulates gastric mechanoreceptors, which in turn stimulate parietal cells through vagal reflexes. H^+ stimulates duodenal secretin release.

The intestinal phase of exocrine pancreatic secretion is the major phase of secretion (see Figure 60-8). The stimulus for the alkaline component from the duct cells is the hormone secretin. The only potent releaser of secretin is hydrogen ion. CCK is the principal humoral stimulant of enzyme secretion from the pancreatic acinar cells and is released physiologically in response to amino acids and fatty acids in the small intestine.

DIAGNOSTIC EVALUATION OF THE PANCREAS

Panagiotis G. Xenoulis, Jörg M. Steiner

Exocrine pancreatic disorders are common in clinical practice and pancreatitis is by far the most common disorder of the exocrine pancreas in both dogs and cats. Clinical diagnosis of pancreatitis can be challenging and it has been suggested that most cases of canine and feline pancreatitis remain undiagnosed. This is supported by necropsy studies in both dogs and cats that report that histopathologic evidence of pancreatic inflammation is common in both species, even in patients that are not clinical.[1-3] Pancreatitis may be accompanied by relatively uncommon pancreatic complications such as pancreatic abscesses and pancreatic pseudocysts.

Exocrine pancreatic insufficiency (EPI) is the next most common disease of the exocrine pancreas in small animals. It is more common in dogs than in cats. It should be noted that in the past few years EPI has been diagnosed with increasing frequency in the feline population, likely as a result of increased awareness of this condition in cats and the availability of better tests for its diagnosis. In contrast to pancreatitis, the diagnosis of EPI is usually uncomplicated when appropriate tests are utilized.

Uncommon diseases of the exocrine pancreas include pancreatic neoplasia (metastatic or less commonly primary neoplasia), pancreatolithiasis, and pancreatic parasites. Nodular hyperplasia of the pancreas is a very common histopathologic finding, especially in older dogs and cats. However, its clinical relevance is unknown and it is believed that this condition is rarely if ever associated with clinical disease. However, it can potentially interfere with the diagnostic evaluation of the pancreas and display findings that are usually associated with other pancreatic diseases (e.g., pancreatitis, neoplasia).

Although the diagnostic evaluation of any patient, including those with exocrine pancreatic disease, should always take into consideration the clinical presentation and general clinicopathologic findings, this chapter mainly focuses on the diagnostic evaluation of the pancreas using diagnostic modalities that are believed to specifically assess pancreatic structure, function, and/or pathology. Table 60-1 summarizes the clinical performance of commonly used diagnostic modalities with regards to the diagnosis of pancreatitis in dogs and cats.

Pancreatitis

Signalment, History, and Risk Factors

Although dogs of any age, breed, or sex can develop pancreatitis, certain groups might be predisposed. Most dogs presented with pancreatitis are middle-aged or older (usually more than 5 years old).[4,5] Several breeds have been reported or suspected to be at increased risk (e.g., Miniature Schnauzers, Yorkshire Terriers, Cocker Spaniels, Cavalier King Charles Spaniels, Collies, and Boxers) but none of these predispositions are consistent among studies.[3-6] Also, no clear sex predisposition has been identified.

Several pathologic conditions have been identified as potential risk factors for pancreatitis in dogs and, although a cause-and-effect relationship has not been established for most of them, their presence along with compatible clinical signs may raise the concern for pancreatitis. Many dogs with pancreatitis are overweight or obese.[5] Also, endocrinopathies such as hyperadrenocorticism, hypothyroidism, and diabetes mellitus may be risk factors for pancreatitis.[5] A history of drug administration (e.g., potassium bromide, phenobarbital, azathioprine, L-asparaginase, meglumine antimonite) in

PERFORMANCE OF SELECTIVE DIAGNOSTIC TESTS FOR PANCREATITIS			
DOGS			
Pancreatic Enzymes	**Sensitivity (%)**	**Specificity (%)**	**Comment**
Serum amylase	18-69	~50	Somewhat useful for initial evaluation. Both positive and negative results require verification with more sensitive and specific tests.
Serum lipase	14-73	~50	Somewhat useful for initial evaluation. Both positive and negative results require verification with more sensitive and specific tests.
Serum TLI	36-47	Relatively high	Low sensitivity—normal concentrations do not exclude pancreatitis. Renal failure and intestinal disease might give false positive results. High concentrations in the absence of renal or intestinal disease are suggestive of pancreatitis.
Serum PLI	64-93	93	Highly sensitive and specific. Most accurate serum test for pancreatitis currently available.
Serum TAP	53	88	Not adequately evaluated. High cost. Limited availability.
Imaging Methods			
Abdominal radiography	24	Low	Not useful for the diagnosis or exclusion of pancreatitis. Useful for the evaluation of other diseases.
Abdominal ultrasonography	68	Relatively high	Useful for the diagnosis of pancreatitis. It is very operator- and equipment-dependent. Relatively high specificity if stringent criteria are applied. Negative results do not rule out pancreatitis.
Computed tomography	N/A	N/A	Not adequately evaluated. High cost.
Pancreatic Cytology	N/A	High	Minimally invasive. Highly specific, but pancreatic lesions might be missed if they are localized (low sensitivity?).
Pancreatic Histopathology	Can be high	High	The gold standard for confirmation of pancreatitis. It is invasive, it has high cost, and cannot be performed in severely compromised patients. Lesions are often highly localized so multiple biopsies must be evaluated before pancreatitis can be ruled out (potentially low sensitivity if only one biopsy is evaluated).
CATS			
Pancreatic Enzymes			
Serum amylase	Low	Low	Not useful for the diagnosis of pancreatitis.
Serum lipase	Low	Low	Not useful for the diagnosis of pancreatitis.
Serum TLI	28-64	82	Low sensitivity—normal concentrations do not exclude pancreatitis. Renal failure and intestinal disease might give false positive results. High concentrations in the absence of renal or intestinal disease are suggestive of pancreatitis.
Serum PLI	54-100	91	Highly sensitive and specific. Most accurate serum test for pancreatitis currently available.
Serum TAP	100	82	Not adequately evaluated. High cost. Limited availability.
Imaging Methods			
Abdominal radiography	Low	Low	Not useful for the diagnosis or exclusion of pancreatitis. Useful for the evaluation of other diseases.
Abdominal ultrasonography	11-67	Relatively high	Somewhat useful for the diagnosis of pancreatitis. It is very operator- and equipment-dependent. Relatively high specificity if stringent criteria are applied. Negative results do not rule out pancreatitis.
Computed tomography	Low	N/A	Low sensitivity. Not recommended.
Pancreatic Cytology	N/A	High	Minimally invasive. Highly specific, but pancreatic lesions might be missed if they are localized (low sensitivity?).
Pancreatic Histopathology	Can be high	High	The gold standard for confirmation of pancreatitis. It is invasive, it has high cost, and cannot be performed in severely compromised patients. Lesions are often highly localized so multiple biopsies must be evaluated before pancreatitis can be ruled out (potentially low sensitivity if only one biopsy is evaluated).

Pancreatic Histopathology	Can be high	High	The gold standard for confirmation of pancreatitis. It is invasive, it has high cost, and cannot be performed in severely compromised patients. Lesions are often highly localized so multiple biopsies must be evaluated before pancreatitis can be ruled out (potentially low sensitivity if only one biopsy is evaluated).	Useful

conjunction with compatible findings should also raise a concern for pancreatitis.[5,7] Hypertriglyceridemia, when severe (higher than approximately 850 mg/dL), is a risk factor for pancreatitis in Miniature Schnauzers.[8] This might also be true for dogs of other breeds that exhibit severe hypertriglyceridemia, but this has not yet been proven. Dietary factors (e.g., getting into the trash, consuming table scraps, ingestion of "unusual" food) and surgery at any time prior to diagnosis of pancreatitis also have been suggested as risk factors for pancreatitis in dogs.[6]

Similarly to dogs, cats of any age, breed, or sex can develop pancreatitis. Older cats appear to be more likely to develop chronic pancreatitis.[2,9-11] Domestic shorthair and Siamese breeds are reported to be at an increased risk in some studies, but this has not been confirmed by other studies.[2,9-11]

Clinical Signs and Physical Examination Findings

Dogs with pancreatitis can present with a wide variety of clinical signs, which can range from mild partial anorexia with no apparent gastrointestinal signs to cardiovascular shock, disseminated intravascular coagulation (DIC), and death. There is no single clinical sign or combination of clinical signs that is pathognomonic for pancreatitis in dogs. Recent reports suggest that pancreatitis may be subclinical in some cases, or be associated with only mild and nonspecific clinical signs such as anorexia and weakness.[1] In more typical cases, in addition to anorexia and weakness, dogs present with vomiting, diarrhea, and/or abdominal pain.[5,12] The concurrent signs of vomiting and cranial abdominal pain is considered suggestive, but not pathognomonic, of pancreatitis in dogs. Evidence of dehydration, abdominal pain, icterus, fever or hypothermia, icterus, bleeding diathesis, or ascites may be seen on physical examination.[5] Severe systemic complications (e.g., cardiovascular shock, DIC, or multiorgan failure) might occur in patients with severe pancreatitis.[12,13] Other clinical signs may be observed as a consequence of concurrent disease (e.g., polyuria/polydipsia in animals with diabetes mellitus).[5]

The most common clinical signs in cats with pancreatitis do not specifically indicate gastrointestinal disease and include complete or partial anorexia and lethargy.[9-11,14] Vomiting, weight loss, and diarrhea are reported less commonly in the cat.[9-11,14] Abdominal pain may be evident in cats with acute pancreatitis but could be missed during routine physical examination. The most common physical examination findings are dehydration, pallor, and icterus.[9-11,14] Tachypnea and/or dyspnea, hypothermia/fever, tachycardia, signs of abdominal pain, and a palpable abdominal mass may also be noted.[9-11,14] Severe systemic complications (e.g., DIC, pulmonary thromboembolism, cardiovascular shock, and multiorgan failure) occasionally may be seen in cats with severe pancreatitis.

Routine Clinical Pathology[5,9-12,14,15]

Results of complete blood count, serum biochemistry profile, and urinalysis are nonspecific and thus not useful in the definitive diagnosis of pancreatitis in dogs and cats. However, these tests should always be performed in animals with suspected pancreatitis because they are useful for the diagnosis or exclusion of other diseases, and also give important information about the general condition of the patient.

The complete blood cell count, serum biochemistry profile, and urinalysis are often normal in mild cases. Possible hematologic findings in dogs and cats with pancreatitis include anemia or hemoconcentration, leukocytosis or leukopenia, and thrombocytopenia. Coagulopathies and DIC may be seen in more severe cases. Increases in hepatic enzyme activities and hyperbilirubinemia are common in both dogs and cats, and might erroneously direct the clinician to suspect primary liver disease. Azotemia is variably present and is most often associated with dehydration due to vomiting or diarrhea. Other possible findings include hypoalbuminemia, hypertriglyceridemia, hypercholesterolemia, and hyperglycemia. Electrolyte abnormalities are commonly present, most importantly, hypokalemia, hypochloremia, and hyponatremia. Hypocalcemia is much more commonly seen in cats than in dogs, and is one of the most clinically important electrolyte disturbances in this species. Some cats with pancreatitis have hypocobalaminemia, which likely may reflect concurrent intestinal disease.

Clinical Enzymology

Serum Pancreatic Lipase Immunoreactivity Concentration. There are multiple circulating lipases of various cellular origins (e.g., pancreatic, hepatic, and gastric) and all of them share the same function (i.e., hydrolysis of triglycerides). Therefore, in assays of lipase activity, many of the different lipases may contribute to the total serum lipase activity. More recently, it was shown that lipases of different cellular origins are encoded by different genes and consequently have differing amino acid sequences. Pancreatic lipase is expressed exclusively by pancreatic acinar cells and is structurally different from other lipases. Thus immunoassays for the specific measurement of pancreatic lipase have been developed and analytically validated for dogs and cats.[16,17] In contrast to the traditional activity assays for lipase, which indiscriminately measure the activity of lipases of any origin, these immunoassays specifically quantify lipases based on their unique structure. Consequently, they are considerably more useful for exocrine pancreatic disease than assays for serum lipase activity. During pancreatitis pancreatic lipase leaks from acinar cells and enters the circulation in larger than normal quantities and can be detected by specific immunoassays for pancreatic lipase.

The originally developed immunoassays for pancreatic lipase were in-house immunoassays that used polyclonal antibodies and had limited availability. Commercial immunoassays (e.g., Spec cPL for dogs and Spec fPL for cats) are now more routinely available.[18,19]

Canine pancreatic lipase is believed to be exclusively of pancreatic origin.[20-22] An immunolocalization study has identified the pancreatic acinar cell as the cell of origin.[20] Dogs with EPI have near total absence of serum canine pancreatic lipase immunoreactivity (cPLI) again suggesting that cPLI is likely of exocrine pancreatic origin.[21] The specificity of Spec cPL was reported to be 96.8% in another study of 31 dogs with normal pancreatic histology.[22] In a recent multicenter study, the specificity of cPLI was estimated to be at least 78% in dogs with a clinical diagnosis of pancreatitis.[23] Experimentally induced chronic renal failure and prednisone administration have not been found to have any clinically significant effect on serum cPLI concentration.[24,25]

Serum cPLI concentration is also sensitive for the diagnosis of pancreatitis in dogs.[18,23,26,27] The reported sensitivity of cPLI for the diagnosis of canine pancreatitis ranges from 64% to 93%, depending on the severity of the disease. This is considerably higher than the sensitivity reported for serum canine trypsin-like immunoreactivity (cTLI) concentration (36.4% to 46.7%), serum amylase activity (18.2% to 73.3%), and serum lipase activity (13.6% to 69%), and is similar to or higher than that of abdominal ultrasound (67% to 68%) performed by a board-certified radiologist.[5,18,23,26-28] In a recent preliminary report of a multicenter study, the sensitivity of this assay was estimated at 93%.[23] Because of its high sensitivity, normal serum cPLI concentrations make a diagnosis of clinically relevant

pancreatitis very unlikely. However, it remains to be determined if, as a consequence of its high sensitivity, cPLI detects pancreatic pathology that is not clinically relevant. Based on the aforementioned studies, serum cPLI concentration is the most sensitive and specific test currently available for pancreatitis in dogs.

Recently, a point-of-care test for the estimation of pancreatic lipase in serum (SNAP cPL) was released. Studies evaluating the performance of this test are currently lacking and comparative studies (e.g., with serum Spec cPL assay) have not yet been reported. The recommended use of this new test is mainly for rapid rule-out diagnosis in dogs suspected of having pancreatitis. A positive test result should always be followed up by laboratory measurement of serum Spec cPL concentration to confirm the diagnosis and to serve as a baseline for monitoring disease progress. A negative test result makes a diagnosis of pancreatitis unlikely.

Studies in cats with both experimental and spontaneous pancreatitis have shown that serum feline pancreatic lipase immunoreactivity (fPLI) concentration is very sensitive for pancreatitis.[29-31] In one of these studies, fPLI was found to be 100% sensitive for moderate to severe spontaneous feline pancreatitis, which was superior to the sensitivities of serum feline trypsin-like immunoreactivity (fTLI) concentration (28%) or abdominal ultrasound (80%).[29] In a recent preliminary report, the sensitivity of serum fPLI concentration was reported at 78%.[31] Considering the overall sensitivities for pancreatitis reported for serum fPLI concentration (67% to 78%), fTLI (28% to 64%), and abdominal ultrasonography (11% to 67%), serum fPLI concentration currently appears to be the most sensitive test for the diagnosis of feline pancreatitis.[29,31-35] The specificity of serum fPLI concentration of 82% to 91%, has been reported to be superior to that of fTLI (82%) or abdominal ultrasound (73%).[15,29,31] Further studies are needed to confirm the reproducibility of these findings, but serum fPLI concentration currently appears to be the most useful test for the diagnosis of feline pancreatitis.

A point-of-care test for the estimation of Spec fPL (SNAP fPL) has not been released at the time of writing of this chapter, but is expected to be available in the near future.

Serum Amylase and Lipase Activities. Serum amylase and lipase activity assays have long been considered markers for pancreatitis in dogs.[36,37] Serum activities of these two enzymes increase during experimental canine pancreatitis, but studies of spontaneous canine pancreatitis have shown poor sensitivity and specificity.[18,36-41] Gastric mucosal and hepatic parenchymal amylases and lipases are routinely detected in activity assays, which has contributed to limitations in sensitivity and specificity. Moreover EPI and pancreatectomized dogs both have significant residual circulating lipase and amylase activity, indicating that tissues other than the pancreas account for a large portion of the serum activity of lipase and amylase.[21,41] Traditional catalytic assays, are not able to differentiate amylases and lipases according to their tissue of origin. This leads to a low specificity of serum amylase and lipase activities for pancreatitis in dogs.[28,36]

Many dogs that have extrapancreatic disease have increased serum lipase and/or amylase activities.[36] The main nonpancreatic conditions associated with increased serum amylase and/or lipase activities include renal, hepatic, intestinal, and neoplastic diseases, as well as corticosteroid administration (only for lipase activity). It has been suggested that only increases of amylase and lipase activities of more than three to five times the upper limit of the reference range should be considered suggestive of pancreatitis in dogs, so as to increase the specificity of these assays.[42,43] However it has been shown that even such increases can result from nonpancreatic disorders.[28,36,43,44] Therefore increased serum amylase and/or lipase activities do not confirm the presence of pancreatitis in any case and more specific tests need to be utilized.

The sensitivity of serum amylase and lipase activities for spontaneous canine pancreatitis varies but is generally low (32% to 73% for lipase activity and 41% to 69% for amylase activity) and it is even lower when a cutoff value of three or five times the upper limit of the respective reference interval is used (14% for lipase activity and 18% for amylase activity in one study that used a cutoff of three times the upper limit of the reference range).[5,18,27] Thus many dogs with pancreatitis may have normal serum activities , and therefore normal serum amylase and/or lipase activities do not rule out pancreatitis.[5,36] The low sensitivity of serum amylase and lipase activity assays is at least partially associated with the broad reference intervals for these assays, which are the result of extrapancreatic amylase and lipase activities. A new lipase assay (using the substrate 1,2-*O*-dilauryl-rac-glycero glutaric acid-[69-methyl resorufin]-ester (DGGR) was recently evaluated and might be more useful for the initial evaluation of dogs suspected of having pancreatitis because of its higher sensitivity (93%) compared with the traditional assays.[45] However, the specificity of this assay was very low (53%), limiting the clinical usefulness of this assay.[45]

Serum lipase activity increases and serum amylase activity decreases in experimentally induced acute pancreatitis in cats.[30,46,47] Although well-designed clinical studies are lacking, both serum lipase and amylase activities do not appear to be of any clinical value in the diagnosis of spontaneous feline pancreatitis.[10,32,48] Therefore these two tests are not recommended for the diagnosis of pancreatitis in cats.[10,48]

Trypsin-Like Immunoreactivity. Trypsin-like immunoreactivity (TLI) assays are species-specific immunoassays that measure trypsinogen and trypsin in serum. Trypsinogen is the inactive preform (or zymogen) of trypsin, a proteolytic enzyme synthesized exclusively in pancreatic acinar cells and normally secreted into the duodenum where it is activated by enterokinases. Only minimal amounts of trypsin are released into the circulation. During pancreatitis, trypsinogen and prematurely activated trypsin enter the circulation in large quantities, and can be measured with the TLI assay.

Serum cTLI concentrations increase after experimental induction of pancreatitis in dogs, but rapidly decrease to reference interval concentrations within 3 days of disease induction.[40] The sensitivity of serum cTLI for the diagnosis of spontaneous pancreatitis is low (36% to 47%), probably as a result of its short half-life.[18,27,28] In addition, although there is strong evidence that trypsinogen is exclusively of pancreatic origin,[41] it is believed that it is cleared by glomerular filtration, and serum cTLI concentration can be increased in dogs with glomerular and other renal diseases.[28,40] This clearly affects the specificity of the test and complicates the interpretation of increased cTLI concentrations in dogs with azotemia.

In cats with experimentally induced pancreatitis, fTLI concentration increases sharply after induction of pancreatitis, but returns below the cutoff value for pancreatitis within 48 hours.[30] fTLI has been evaluated for the diagnosis of spontaneous pancreatitis in cats and several cutoff values have been suggested.[33-35] When cutoff values allowing adequate specificity of the assay are used (i.e., 100 µg/L), the sensitivity of fTLI for the diagnosis of pancreatitis in cats is generally low (28% to 33%), with the highest reported sensitivity for this cutoff value being 64%.[33-35] In addition, the specificity of fTLI has been questioned, because mildly increased serum fTLI concentrations have been reported in cats with no demonstrable pancreatic disease, but other gastrointestinal disorders (e.g.,

inflammatory bowel disease or gastrointestinal lymphoma) and azotemia.[15,33,35]

In the face of availability of better serum markers (cPLI and fPLI), cTLI and fTLI are currently considered to be of limited usefulness for the diagnosis of canine and feline pancreatitis, respectively.

Other Diagnostic Markers. Several other diagnostic markers for pancreatitis have been developed and studied, but none can be recommended for the diagnosis of canine and feline pancreatitis in clinical practice, either because their diagnostic performance has not been sufficiently evaluated clinically, or because they have been shown to have a low sensitivity and/or specificity. In addition, the availability of most of these diagnostic tests is currently limited. Such tests include the determination of serum concentrations of phospholipase A_2, trypsin-α_1-antitrypsin complexes, and α_2-macroglobulin, plasma and urine concentrations of trypsinogen activation peptide, and lipase activity in peritoneal fluid.

Diagnostic Imaging

Abdominal Radiography. Conclusive diagnosis or exclusion of pancreatitis is not possible based on abdominal radiography alone.[5,9-11,34,43] In the majority of cases of canine and feline pancreatitis abdominal radiographs are normal or reveal nonspecific findings. Despite that, radiography remains a logical initial approach for patients suspected of having pancreatitis because it is relatively inexpensive and useful for the diagnosis and/or ruling out of other differential diagnoses.

In a group of 70 dogs with fatal acute pancreatitis the sensitivity of abdominal radiography was very low (24%).[5] Radiographic findings that have been reported for dogs with pancreatitis include an increased soft tissue opacity and decreased serosal detail in the cranial right abdomen, indicating localized peritonitis.[5] Other findings may include displacement of the stomach and/or duodenum from their normal positions and gaseous dilation of bowel loops adjacent to the pancreas.[5] Abdominal effusion or the presence of an abdominal mass might also be detected. Radiographic findings in cats with pancreatitis are similar to those in dogs.[10,11,34,49] In any case, radiography should always be followed by use of more sensitive and specific tests for the definitive diagnosis or exclusion of pancreatitis.

Abdominal Ultrasound. Abdominal ultrasound is considered the imaging method of choice for the diagnosis of pancreatitis in dogs and cats. However, the performance of ultrasonography in the diagnosis of pancreatitis is highly dependent on the experience of the ultrasonographer and the quality of the instrumentation.

Abdominal ultrasound has been reported to have a relatively high sensitivity of approximately 68% for severe acute pancreatitis in dogs,[5] although with increasing equipment quality the sensitivity might have increased since this report.[5] Abdominal ultrasound has mainly been assessed in dogs with fatal acute pancreatitis, in which lesions are usually pronounced, but its sensitivity would be expected to be lower in cases with mild or moderate pancreatitis.[5] It must be emphasized that a normal pancreas on ultrasound examination does not rule out pancreatitis in dogs.

Ultrasonographic findings in dogs with pancreatitis include hypoechoic areas within the pancreas (possibly indicating necrosis or fluid accumulation), increased echogenicity of the surrounding mesentery (because of necrosis of the peripancreatic fat), enlargement and/or irregularity of the pancreas, dilation of the pancreatic or biliary duct, and abdominal effusion (Figure 60-9).[5,50] On occasion,

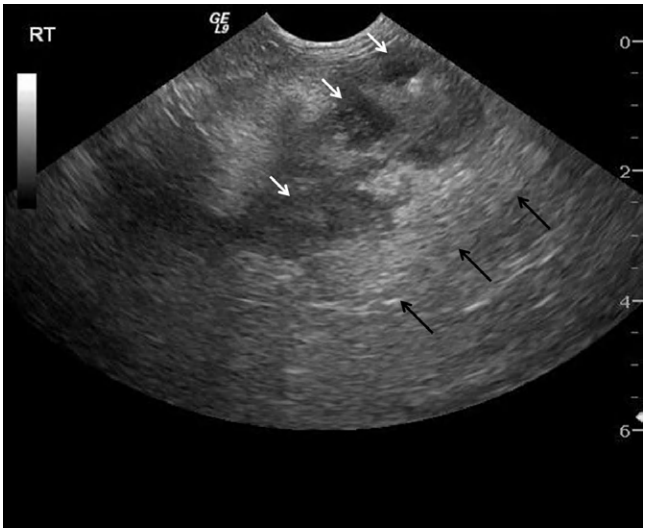

Figure 60-9 Ultrasonographic appearance of the pancreas of a dog with pancreatitis. The pancreas is enlarged and appears heterogenous, with hypoechoic areas (*white arrows*) and hyperechoic surrounding fat (*black arrows*). These findings are highly suggestive of pancreatitis. (Courtesy Dr. B. Young, Texas A&M University.)

hyperechoic areas of the pancreas can be identified, possibly indicating the presence of pancreatic fibrosis. Cavitary lesions, a thickened duodenum, and biliary obstruction might also be noted.[50] If stringent criteria are applied, the specificity of abdominal ultrasonography for canine pancreatitis is considered to be relatively high, although other diseases of the pancreas (e.g., neoplasia, hyperplastic nodules, edema caused by portal hypertension or hypoalbuminemia) may display similar ultrasonographic findings and cannot be differentiated from pancreatitis in many cases.[51,52] In a recent study where ultrasonography was performed in 26 animals (both dogs and cats) with suspected gastrointestinal disease, 6 (23.1%) of the animals had ultrasonographic evidence consistent with pancreatitis, while histopathology revealed either a normal pancreas or pancreatic hyperplasia.[53] In the same study, there was only a 22% agreement between the ultrasound report and pancreatic histopathology in dogs.[53] These data raise concerns regarding the accuracy of ultrasonography in evaluating the canine pancreas and underscore the importance of not overinterpreting ultrasonographic findings.

The reported sensitivity of abdominal ultrasonography for the diagnosis of feline pancreatitis is generally low (11% to 35%), with only one study reporting a sensitivity of 67%.[11,29,33,49] This high range of sensitivity likely reflects differences in the level of suspicion or the skills of the examiner, the equipment used, and the severity of lesions, and highlights the lack of standardized diagnostic criteria.[33,34,49] The low sensitivity of abdominal ultrasonography suggests that many cats with pancreatitis remain undiagnosed if the diagnosis is based solely on ultrasound examination.[11,33,49] The sensitivity of abdominal ultrasonography is believed to have increased since the reports mentioned previously as a result of advances in equipment and an increasing level of awareness of the importance of feline pancreatitis, although this has not yet been confirmed. Abdominal ultrasonography has been thought to be relatively specific for the diagnosis of pancreatitis is cats but, similarly to dogs, other diseases (e.g., pancreatic neoplasia, edema) may be associated with similar findings.[54] In a recent study, there was an overall agreement of only 33% between the ultrasound report and pancreatic histopathology in cats, and some cats that had ultrasonographic evidence of

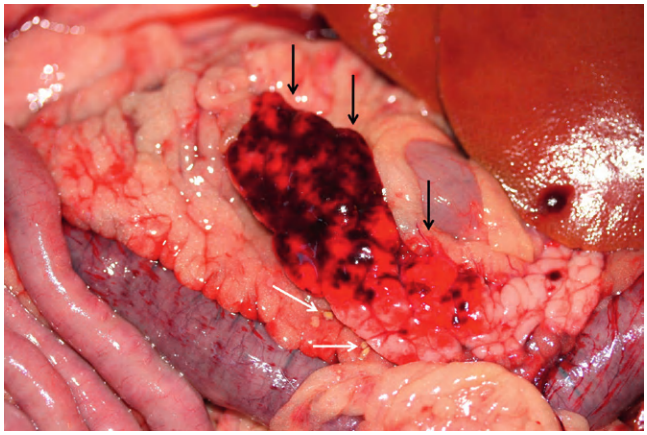

Figure 60-10 Gross Appearance of the pancreas of a dog with acute pancreatitis. The pancreas appears severely hemorrhagic, necrotic, and edematous (*black arrows*). There is also peripancreatic fat necrosis (*white arrows*). Such appearance is highly suggestive of pancreatitis. (Courtesy Dr. D. Ajithdoss, Texas A&M University.)

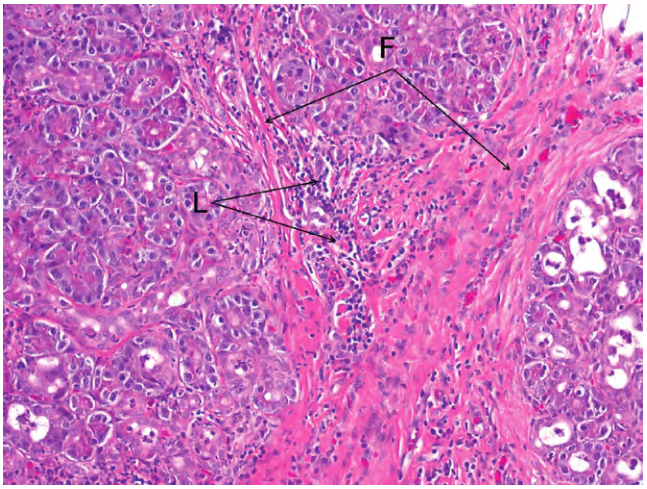

Figure 60-11 Histopathologic appearance of the pancreas of a cat with chronic pancreatitis. There is extensive fibrosis (*F*) and lymphocytic infiltration (*L*). Hematoxylin and eosin; magnification: 200×. (Courtesy Dr. B.F. Porter, Texas A&M University.)

pancreatitis had no evidence of pancreatitis on histopathology.[53] Ultrasonographic findings in cats with pancreatitis are similar to those described in dogs.[11,33,49,50,55] It has been suggested that a dilation of the pancreatic duct is suggestive of pancreatitis in cats, but studies have not confirmed this hypothesis.[56] In general, feline pancreatitis is often difficult to diagnose by abdominal ultrasound examination and it is important to note that a normal ultrasound examination does not rule out feline pancreatitis.[29,33]

Overall, abdominal ultrasonography is very useful for the diagnosis of pancreatitis in dogs and cats, especially when performed by an experienced ultrasonographer. Caution should be taken however not to overinterpret ultrasonographic findings. Abdominal ultrasonography is also helpful in detecting possible concurrent abdominal disease in dogs and cats suspected of having pancreatitis. In addition, ultrasound-guided fine-needle aspiration is a useful tool for the diagnosis of pancreatitis and some of its complications (e.g., pancreatic pseudocyst and pancreatic abscess), as well as the management of noninfectious fluid accumulations (e.g. pancreatic pseudocyst).[55]

Other Imaging Modalities. Although contrast-enhanced computed tomography is an extremely valuable tool for the evaluation of human patients with suspected pancreatitis, initial studies in dogs have not been promising.[57] Also, computed tomography performed in cats with histologically confirmed pancreatitis showed disappointing results and currently cannot be recommended.[29] Other imaging methods (e.g., endoscopic retrograde cholangiopancreatography, endoscopic ultrasonography), have been used in healthy dogs and cats, in dogs with experimentally induced pancreatitis, and in dogs with gastrointestinal diseases, with varying results. Because of the lack of standardized criteria for the diagnosis of pancreatitis, the complexity of these modalities, their limited availability, and the cost of the equipment, they cannot currently be recommended for the diagnosis of canine or feline pancreatitis.

Pathology

Direct visualization of the pancreas is possible during exploratory laparotomy and laparoscopy. Gross pancreatic lesions suggestive of pancreatitis include peripancreatic fat necrosis, pancreatic hemorrhage and congestion, and a dull granular capsular surface (Figure 60-10).[10,18,49] However, gross pathologic lesions may not always be apparent in dogs and cats with pancreatitis.[1,10,49]

At present, a definitive diagnosis of pancreatitis can only be made by histopathologic examination of the pancreas. Histopathology is also the only way to differentiate acute and chronic pancreatitis. Histopathologic scoring systems for the evaluation of severity of pancreatitis have been proposed for both dogs and cats.[1-3,58] However, histopathologic criteria for the classification of pancreatitis have not been universally standardized in veterinary medicine and substantial confusion exists regarding both classification and terminology of canine and feline pancreatitis, underlying the need for a universally accepted multidisciplinary classification system as is available for humans. The presence of permanent histopathologic changes (such as fibrosis and acinar atrophy) is generally considered suggestive of chronic pancreatitis (Figure 60-11).[1,43] Also, the predominant inflammatory cellular infiltrate (neutrophils or lymphocytes) is often used to describe pancreatitis as suppurative or lymphocytic, and some authors consider a suppurative inflammation compatible with acute disease and lymphocytic infiltration compatible with chronic disease (Figure 60-12).[10,11] A significant degree of necrosis is usually used to characterize the pancreatitis as necrotizing. It should be noted that some animals can show histopathologic evidence of both suppurative and lymphocytic pancreatitis.

Several limitations are associated with pancreatic histopathology as a definitive diagnostic tool for pancreatitis. First, determining the clinical significance of histopathologic findings may be challenging. In a recent study, 47 (64%) of 73 dogs that presented for necropsy for various reasons had microscopic evidence pancreatitis.[1] Similarly, histopathologic lesions of pancreatitis were found in 67% of all cats examined, including 45% of healthy cats.[2] Currently, there are no standardized criteria that distinguish microscopic findings leading to clinical disease from those that do not, and it is possible that clinically insignificant pancreatic lesions could lead to a false diagnosis of pancreatitis. At the same time, exclusion of pancreatitis based on histopathology is difficult because inflammatory lesions of the pancreas are often highly localized and can easily be missed.[1,2,10,49] Therefore, multiple sections of the pancreas must be evaluated to increase the likelihood of finding microscopic lesions, although this is not always feasible in clinical practice. The absence of histopathologic findings of pancreatitis must be evaluated with caution, especially when only one section of the pancreas has been examined.[1,2]

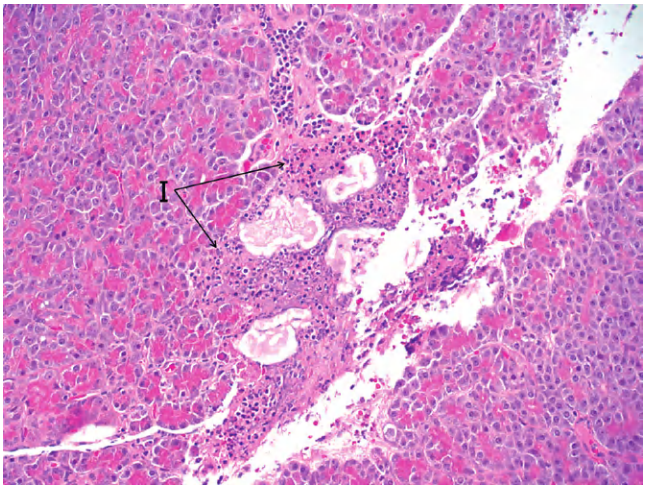

Figure 60-12 Histopathologic appearance of the pancreas of a cat with acute pancreatitis. There are areas of inflammatory infiltration (*I*) but there is no evidence of fibrosis or other permanent histopathologic changes. Hematoxylin and eosin; magnification: 200×. (Courtesy Dr. B.F. Porter, Texas A&M University.)

Finally, although pancreatic biopsy per se is considered safe, it requires invasive procedures that are expensive and potentially detrimental in patients with pancreatitis that are hemodynamically unstable.[53]

Because concurrent inflammation of the intestines and/or liver appears to be a common problem in cats and may also occur in dogs, intestinal and hepatic biopsies should be considered in patients (especially cats) suspected of having pancreatitis that are undergoing exploratory laparotomy. Likewise, cats with inflammatory bowel disease and/or cholangitis that undergo laparotomy or laparoscopy should be considered for pancreatic biopsy.

Cytology

Fine-needle aspiration of the pancreas and cytologic examination is minimally invasive, relatively safe, and can be used for the diagnosis of pancreatitis in both dogs and cats.[59] To date no study has evaluated the sensitivity and specificity of this modality for the diagnosis of canine or feline pancreatitis, but the finding of inflammatory cells is considered specific for pancreatitis. Pancreatic acinar cells constitute the majority of the cells found in fine-needle aspiration smears from a normal pancreas (Figure 60-13).[59] In patients with acute pancreatitis the cytologic picture is mainly characterized by hypercellularity and the presence of intact and degenerated neutrophils and degenerated pancreatic acinar cells (Figure 60-14). In patients with chronic pancreatitis, small numbers of lymphocytes and neutrophils are usually present, and the specimen is often characterized by low cellularity, possibly as a result of replacement of the normal pancreatic tissue by fibrotic tissue.[59]

Fine-needle aspiration cytology should be performed either under ultrasonographic guidance or during laparotomy.[59] It should be noted that, as for histopathology, highly localized lesions might be missed. Thus negative results are not sufficient to rule out pancreatitis. Fine-needle aspiration cytology might also be useful in differentiating other conditions of the pancreas.

Assessment and Prediction of the Severity of Pancreatitis

Assessment of the severity of human acute pancreatitis is based on the application of standardized severity scores.[60] Prediction of the severity of pancreatitis constitutes a very important component of

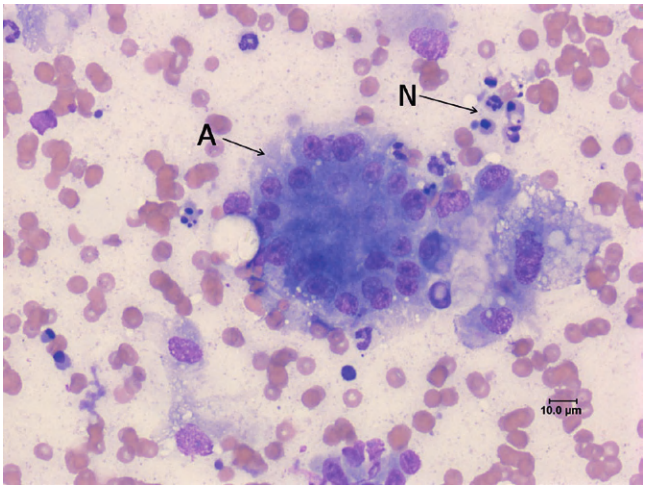

Figure 60-14 Cytologic appearance of a fine-needle aspirate from a canine pancreas with suspected pancreatitis. There is mild to moderate neutrophilic inflammation (*N*) with neutrophilic degeneration. A cluster of normal acinar cells (*A*) can also be seen. Diff-Quik; magnification 500×. (Courtesy of Dr. P.J. Armstrong, University of Minnesota.)

the diagnosis of pancreatitis, because it allows prediction of the likelihood of complications and morbidity, and helps determine the optimal therapeutic plan before the patient enters a critical stage. It is based on a theory that states that the severity of a pancreatitis episode is determined by events that occur within the first 24 to 48 hours of the episode.[61] These events are reflected through clinical, clinicopathologic, and imaging findings that can be used to predict the severity of the pancreatitis.[61]

In veterinary medicine, no well-established and universally accepted severity scores for pancreatitis have been described. Serum PLI and TLI concentrations lack prognostic significance because they correlate poorly with histopathologic severity.[18] Currently, severity of canine and feline pancreatitis is determined based on the clinician's clinical judgment, and typically a diagnosis of severe pancreatitis is made after the animal has entered a critical stage. In

general, evidence of systemic complications (e.g., oliguria, azotemia, icterus, severely increased hepatic enzyme activities, hypocalcemia, hypoglycemia, severe hyperglycemia, leukocytosis, shock, or DIC) are considered as indicators of severe disease and a poor prognosis.[62-64] However, prediction of the severity of pancreatitis has not been sufficiently studied in dogs and cats. Markers that might prove useful in predicting the severity and/or outcome of a pancreatitis episode are serum C-reactive protein concentrations, serum interleukin-6 concentrations, and plasma and urine trypsinogen activation peptide concentration as well as urine trypsinogen activation peptide-to-creatinine ratio.

Concluding Remarks

No single diagnostic modality is 100% reliable for the diagnosis of canine or feline pancreatitis. A careful evaluation of the animal's history, physical examination, and routine clinical pathology findings, as well as the use of highly specific and sensitive tests (serum cPLI and fPLI concentration, abdominal ultrasonography, cytology, and/or histopathology), are crucial for an accurate diagnosis of pancreatitis. In clinical practice, a combination of serum cPLI or fPLI concentration, abdominal ultrasound, and in some cases fine-needle aspiration of the pancreas, currently constitutes the most practical and accurate approach for the diagnosis of both canine and feline pancreatitis.

Exocrine Pancreatic Insufficiency

Clinical Features

The classical and most common presentation of dogs with EPI involves a chronic history of weight loss, a normal or increased appetite, and loose stools, which is usually characterized by passage of large volumes of semiformed feces. However, it is not uncommon for some dogs with EPI to present with a clinical picture that deviates from the classical picture. In those cases, periods of anorexia, absence of loose stools, occasionally watery diarrhea, or vomiting might be seen. Other possible clinical signs include coprophagia, borborygmus, flatulence, abdominal discomfort, and a poor hair coat. In some cases, EPI may be subclinical and those cases can only be diagnosed with appropriate laboratory testing (see "Trypsin-Like Immunoreactivity" section that follows). Cats with EPI have a similar presentation to that of dogs. In cases where chronic pancreatitis is the cause of EPI, polyuria and polydipsia may be seen as a result of concurrent diabetes mellitus.

Trypsin-Like Immunoreactivity

Serum cTLI is the test of choice for the diagnosis of EPI in dogs. This test is highly sensitive and specific for the diagnosis of EPI, and a positive test (usually defined as <2.5 µg/L) in a dog with compatible clinical signs is sufficient to make a diagnosis of EPI.[65] A cTLI result that is well within the reference range is sufficient for excluding EPI, and a normal cTLI result should direct clinicians toward the investigation of other disorders as the cause of the clinical signs observed.[65] Single cTLI results within the equivocal range (usually between 2.5 and 5.7 µg/L) in dogs with clinical signs of gastrointestinal disease need to be interpreted with caution.[66] In these patients, subsequent retesting of serum cTLI concentration shows either a normal concentration or progression to EPI.[66] Therefore, patients with cTLI results in the equivocal range should be investigated for chronic intestinal disease, while reevaluating the cTLI a few weeks later. Some dogs with no clinical signs characteristic of EPI have repeatedly subnormal (<5.7 µg/L) cTLI concentrations.[66,67] These dogs have been shown to have subclinical EPI and some are expected to develop clinical EPI in the future.[66,67] The time of progression from the subclinical to the clinical stage varies greatly and might be from a few months to years.[67] Thus these patients should be closely monitored for the development of clinical signs of EPI and cTLI testing should be repeated every 3 to 6 months.[66,67] Finally, because renal disease might increase serum cTLI concentrations and obscure a diagnosis of EPI, reevaluation of nondiagnostic serum cTLI concentrations in azotemic dogs suspected of having EPI is recommended. Similarly, concurrent inflammation might falsely increase the serum cTLI concentration.

Because EPI appears to be less common in cats than in dogs, diagnosis of this disease has been less-well investigated. Similar to dogs, the fTLI test appears to be the most reliable test for the diagnosis of EPI in cats, having a specificity of at least 85%.[68] The sensitivity of this assay for the diagnosis of feline EPI has not been evaluated to date. Although there are currently two assays that measure fTLI in serum (one radioimmunoassay that is available in the United States and one enzyme-linked immunosorbent assay that is available in Europe), the analytical validation has only been published for the radioimmunoassay, which is available through the Gastrointestinal Laboratory at Texas A&M University. Similar to dogs, it can be recommended that equivocal serum fTLI concentrations in azotemic cats suspected of having EPI be reevaluated, because renal disease might falsely increase serum fTLI concentrations. The same is true for cats with concurrently increased serum fPLI concentrations indicating residual pancreatic inflammation.

Pancreatic Fecal Elastase

An enzyme-linked immunosorbent assay for the measurement of pancreatic elastase in feces is commercially available and is marketed in Europe (Shebo Biotech, Germany) for the diagnosis of canine EPI.[69,70] A recent study reported false-positive results in 23.1% of cases[71] and its sensitivity has not been sufficiently evaluated. The fact that this test is easy and quick to perform might make it a reasonable initial approach for dogs with suspected EPI, but as a consequence of its poor positive predictive value a positive test result must be verified by measurement of serum cTLI concentration. This test might also be useful for EPI cases that are a result of pancreatic duct obstruction. However, to date such a case has only been anecdotally reported in the veterinary literature.

Other Tests

Serum amylase and lipase activities have been shown to have no value in the diagnosis of EPI in either dogs or cats.[21,41,72] Canine PLI concentrations are low or undetectable in most dogs with EPI, but some overlap between healthy dogs and dogs with EPI does exist, making this test inferior to cTLI for the diagnosis of EPI.[21] However, cPLI might be used to diagnose isolated pancreatic lipase deficiency, a rare form of EPI, where serum cTLI and other pancreatic zymogen concentrations are expected to be normal.[73] Commercial assays for the measurement of serum PLI concentration (Spec cPL and Spec fPL) are not useful for the diagnosis of EPI in dogs and cats, respectively, because they have been optimized to detect changes in the higher ranges of their respective working ranges.

Measurement of the fecal proteolytic activity has been used in the past for the diagnosis of EPI in dogs and cats, but are now only used for species for which a TLI assay is not available.[74,75] A plethora of other tests, including microscopic examination of feces and the bentiromide absorption (benzoyl-tyrosyl-paraaminobenzoic acid [BT-PABA]) test, have also been described for the diagnosis of EPI in the past. However, these tests often give false-positive and/or

false-negative results and many of them are impractical, expensive, or of limited availability. Thus none of these tests are recommended for the diagnosis of canine or feline EPI.

Histopathology

Because EPI is a functional and not a histopathologic diagnosis, histopathology is not indicated for the diagnosis of EPI. Given that it has been estimated that more than 90% of the pancreatic parenchyma needs to be destroyed before clinical signs of EPI develop, it is almost impossible to accurately grossly or histopathologically determine the extent of pancreatic atrophy. The only usefulness of histopathology is limited to the determination of the underlying cause of EPI (pancreatic acinar atrophy or pancreatitis). However, in dog breeds that have been shown to be predisposed to EPI because of acinar atrophy (i.e., German Shepherds, Rough-Coated Collies, and Eurasians), histopathology is redundant.[76] Therefore histopathology should only be used in atypical cases where the cause of EPI needs to be definitively determined.

NECROSIS AND INFLAMMATION: CANINE

Panagiotis G. Xenoulis and Jörg M. Steiner

Strictly speaking, *pancreatitis* refers to inflammation (i.e., infiltration with inflammatory cells) of the exocrine pancreas. However, the term pancreatitis is commonly expanded to also include diseases of the exocrine pancreas characterized mainly by necrosis that may have a minimal inflammatory component (often referred to as acute pancreatic necrosis or necrotizing pancreatitis).[1] It is widely believed that pancreatic necrosis is associated with a severe and often fatal course of disease, whereas pancreatitis without necrosis (e.g., edematous interstitial pancreatitis) is usually mild. However, no convincing scientific evidence currently exists to support this assumption in clinical cases of canine pancreatitis.

Pancreatitis is generally divided into acute pancreatitis (which typically includes acute pancreatic necrosis) and chronic pancreatitis (characterized by the permanent histopathologic changes of fibrosis and atrophy). The term *recurrent acute pancreatitis* is sometimes used to describe recurrent episodes of pancreatitis that are not associated with permanent histopathologic changes. A plethora of other clinical (e.g., mild or severe, fatal or nonfatal) and histopathologic (e.g., edematous, interstitial, necrotizing, neutrophilic, lymphocytic) terms have been used to further classify pancreatitis in dogs. However, no universally standardized terminology and definitions exist for pancreatitis in animals, and different authors classify pancreatitis is different ways. It is not clear at this time whether the different forms of pancreatitis (e.g., acute edematous pancreatitis, acute pancreatic necrosis, chronic pancreatitis) represent different phenotypes of the same disease or distinct disease entities, whether they share the same etiologic and pathogenic mechanisms, or which factors determine the development of each form.

Prevalence

Pancreatitis in dogs is common and is associated with significant morbidity and mortality. The prevalence of pancreatitis in dogs varies widely based on the methods used to diagnose the disease. Clinically, its overall prevalence has been estimated at approximately 0.8% in dogs, although certain canine breeds seem to have a higher prevalence.[2] Histopathologic evidence of canine pancreatitis is considerably more common, even in dogs that died from unrelated causes, and has been reported to be as high as 65% when multiple sections of the pancreas are examined.[3] It remains to be determined, however, which degree and/or forms of histopathologic pancreatitis are clinically significant. The mortality for dogs with pancreatitis also varies widely; most dogs with mild pancreatitis recover within a few days and have a very good prognosis, whereas mortality rates in patients with more severe forms of acute pancreatitis have been reported to be 20% to 42%.[4-7]

Pathogenesis and Pathophysiology

Most of our understanding regarding the pathogenesis of pancreatitis is based on animal models and some clinical studies in human patients. There is mounting evidence that genetic and possibly also environmental factors may sensitize the pancreas to injury induced by one or more etiologic factors.[8,9] Regardless of the actual etiology, there appears to be a common pathogenic mechanism in most cases of acute pancreatitis. The initiating events that lead to pancreatitis take place in the acinar cell. Two early intracellular events that precede the development of acute pancreatitis are retention and intracellular activation of zymogens.[8,9] Zymogens are pancreatic enzyme precursors stored in zymogen granules that are normally secreted into the pancreatic duct through the apical membrane of the acinar cell. The factors that lead to retention of zymogen granules and premature intracellular activation of the zymogens are not fully elucidated. One of the most popular theories is the colocalization theory,[8,9] which suggests that zymogen granules accumulate in the acinar cell and colocalize with lysosomes. Lysosomal enzymes, such as cathepsin B, are thought to activate trypsinogen into trypsin, which subsequently activates other zymogens. The cytosolic concentration of free ionized calcium also plays an important role in the intracellular activation of zymogens.[10-12] In addition to decreased secretion and intracellular activation of pancreatic enzymes, there is evidence of disruption of the paracellular barrier in the pancreatic duct that allows its contents to leak into the paracellular space, and also redirection of secretion of zymogen granules from the apical pole to the basolateral region of the acinar cell and into the interstitial space (Figure 60-15).[9]

Once intracellular activation of pancreatic enzymes has taken place, autodigestion of the acinar cell follows and activated enzymes escape into the pancreatic tissue (leading to local effects) and then into the peritoneal cavity and the systemic circulation (potentially contributing to systemic effects). Local effects vary and can range from mild interstitial edema to severe acinar cell necrosis, hemorrhage, and peripancreatic fat necrosis. The extent and severity of local effects determine to a large degree the systemic response. Acinar cell injury leads to recruitment and activation of inflammatory cells (mostly neutrophils and macrophages), which release proinflammatory cytokines and other inflammatory mediators (e.g., IL-1, IL-2, IL-6, IL-18, tumor necrosis factor-α, substance P, platelet-activating factor) that play a crucial role in modulating systemic manifestations.[8,13] Such manifestations include cardiovascular shock, disseminated intravascular coagulation (DIC), SIRS, and multiple organ failure, and are seen in cases of severe acute pancreatitis.[8,13]

Etiology and Risk Factors

In contrast to human patients, in whom an etiology of pancreatitis can be identified in the majority of cases, the etiology of canine

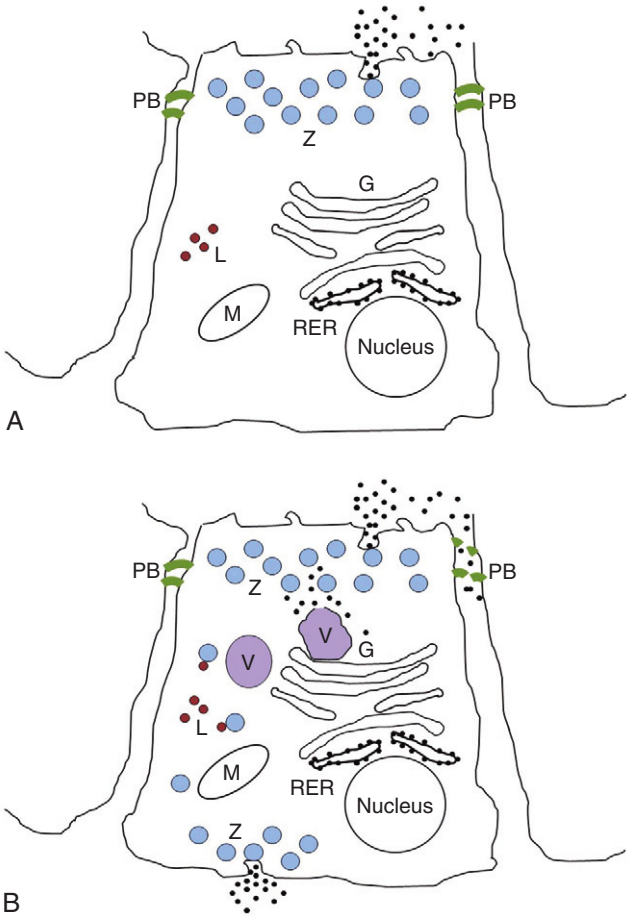

Figure 60-15 Proposed pathogenesis of acute pancreatitis. A, Normal acinar cell. Zymogen granules are found in the apical region of the cell and their contents are excreted exclusively through the apical surface. Lysosomes are packaged and stored separately from zymogen granules and the paracellular barriers are intact. **B,** Acute pancreatitis. Secretion of the zymogen granules is redirected from the apical pole to the basolateral region of the acinar cell and into the interstitial space. Retention of zymogen granules is followed by colocalization with lysosomes and the formation of large vacuoles (*V*) and premature intracellular activation of pancreatic enzymes. There is also disruption of the paracellular barrier in the pancreatic duct that allows its contents to leak into the paracellular space. G, Golgi apparatus; *L*, lysosome; M, mitochondrion; *PB*, paracellular barrier; *RER*, rough endoplasmic reticulum; Z, zymogen granule; *V*, vacuole.

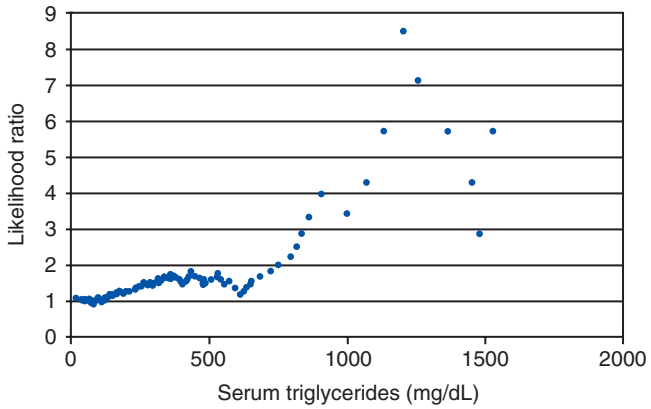

Figure 60-16 Likelihood ratios for different serum triglyceride concentrations for serum cPLI concentrations consistent with pancreatitis (≥200 µg/L; values measured with the original cPLI-ELISA). The likelihood ratio remained between 1 and 2 for serum triglyceride concentrations below approximately 800 mg/dL, and increased sharply for serum triglyceride concentrations of more than 800 mg/dL. (From Xenoulis PG, Suchodolski JS, Ruaux CG, Steiner JM: Association between serum triglyceride and canine pancreatic lipase immunoreactivity concentrations in Miniature Schnauzers. *J Am Anim Hosp Assoc* 46:229, 2010 with permission.)

pancreatitis usually remains unknown (idiopathic pancreatitis).[2,14] It is expected that recognition of new causes of canine pancreatitis will allow etiologic classification in a larger proportion of cases in the future. Several risk factors for canine pancreatitis are described, but the majority of these have been implicated by association, so few definitive causes of pancreatitis have been reported.[2] The main causes of human pancreatitis (i.e., biliary obstruction and alcoholism) do not represent common problems in small animals.[8,14] Other well-defined causes of human pancreatitis (e.g., autoimmune pancreatitis) currently have not been proven in dogs.

Hypertriglyceridemia

Hypertriglyceridemia has been suspected to be a risk factor for pancreatitis in dogs, but convincing evidence was lacking until recently.[15-17] A definitive etiologic association between hypertriglyceridemia and pancreatitis has been difficult to prove, as hypertriglyceridemia might be the result of pancreatitis rather than the cause. Two recent studies suggest that hypertriglyceridemia, which is a known risk factor for human pancreatitis, is also a risk factor for pancreatitis in Miniature Schnauzers.[18,19] Miniature Schnauzers have a high prevalence of idiopathic hypertriglyceridemia, which is often relatively severe.[20] As in humans, the severity of hypertriglyceridemia appears to be important and only Miniature Schnauzers with serum triglyceride concentrations above 862 mg/dL were found to be at increased risk for pancreatitis (Figure 60-16).[8,14,18,19] Interestingly, hypertriglyceridemia appears to be present before the development of pancreatitis and persists after the resolution of the disease, unless a low-fat diet is fed.[19] This supports the hypothesis that, at least in Miniature Schnauzers, severe hypertriglyceridemia is likely a preexisting condition and risk factor for pancreatitis, rather than an epiphenomenon. The exact role of hypertriglyceridemia in the development of pancreatitis, as well as the interaction between hypertriglyceridemia and other risk factors, remains to be determined as not all Miniature Schnauzers with severe hypertriglyceridemia develop clinical pancreatitis. It is not known whether an association between hypertriglyceridemia and pancreatitis also exists in other breeds. Further studies are also needed to determine whether secondary hypertriglyceridemia associated with diseases such as diabetes mellitus, hyperadrenocorticism, and obesity, represents a risk factor for canine pancreatitis.

Hereditary Pancreatitis

A combination of three variants in the serine protease inhibitor Kazal type 1 (*SPINK1*) gene has been identified in Miniature Schnauzers, and an association of these variants with pancreatitis is reported.[21] Mutations in the *SPINK1* gene, although different from those described in Miniature Schnauzers, have also been described and associated with pancreatitis in humans.[22] The product of the *SPINK1* gene, PSTI, is found in acinar cells and acts as one of the defense mechanisms against prematurely activated trypsin. It is possible that the mutant protein lacks this function, therefore leaving

the acinar cell more susceptible to injury, although this has not been shown convincingly. The exact role of the *SPINK1* gene in the development of pancreatitis in Miniature Schnauzers remains to be determined. It is hypothesized that mutations in this gene may not actually cause pancreatitis, but they might sensitize the pancreas to injury through other factors. Genetic causes of pancreatitis have also been suspected in other breeds (e.g., Yorkshire Terriers).[16]

Breed

Several breeds are reported to be at increased risk for pancreatitis, although different studies are not always in agreement with each other. Breed predisposition most likely reflects either genetic causes of pancreatitis or a predisposition to other diseases or conditions that are risk factors for pancreatitis (e.g., hypertriglyceridemia in Miniature Schnauzers). Differences in breed predispositions probably exist in different geographical regions, as blood lines might be different, especially where a breed was introduced to a region decades ago. Miniature Schnauzers, Yorkshire Terriers, and Terriers in general are consistently shown to have a higher risk of developing pancreatitis.[4,16,17,23] Boxers, Cavalier King Charles Spaniels, Cocker Spaniels, and Collies have also been suggested to be overrepresented.[24]

Diet

The role of diet, and more specifically the fat content of the diet, in the development of canine pancreatitis remains unclear. Based on anecdotal clinical observations, high-fat foods increase the risk for pancreatitis. Older experimental studies suggested that diets with a very high fat content may induce pancreatitis and may increase the severity of experimentally induced pancreatitis in dogs.[15,25] The mechanism by which high-fat diets increase the risk for pancreatitis is not known, but it is possible that they may predispose to pancreatitis through hypertriglyceridemia. In a recent retrospective case-control study in dogs, several factors, such as access to trash, consuming table scraps, and ingestion of "unusual" food, were found to be associated with an increased risk of pancreatitis.[23] However, no specific foods were identified that were associated with an increased risk for pancreatitis.

Drugs

As in humans, drug-induced pancreatitis has been reported in the dog, but a cause-and-effect relationship has not been established for most cases.[26] Nevertheless, a history of drug administration in conjunction with compatible findings should raise a concern for drug-induced pancreatitis. Based on the remarkably large number of drugs prescribed in both human and veterinary medicine, and the fact that drug-induced pancreatitis appears to be quite rare, drugs are thought to cause pancreatitis in an idiosyncratic fashion and theoretically, any drug can potentially cause pancreatitis. However, pancreatitis in dogs seems to be more commonly associated with the use of potassium bromide, phenobarbital, L-asparaginase, azathioprine, and meglumine antimonate.[27-29]

Endocrine Disease

In one study, hyperadrenocorticism, hypothyroidism, and diabetes mellitus were reported to be more commonly present in dogs with pancreatitis than in controls.[17] In another study 29 (13%) of 221dogs with diabetes mellitus were reported to have pancreatitis.[30] However, evidence is far from convincing that these endocrine diseases represent risk factors for canine pancreatitis. It has been hypothesized that hypertriglyceridemia associated with these endocrine diseases might be a more significant risk factor for pancreatitis in this species than the conditions themselves.

Obesity

A relationship between obesity and pancreatitis has been suggested for dogs. Studies show that dogs diagnosed with pancreatitis are more frequently obese than are dogs that do not have pancreatitis.[16,17,23] However, a pathogenic link between obesity and pancreatitis has not been convincingly shown to date.

Other Factors

Age is often listed as a risk factor for pancreatitis as most dogs with pancreatitis are middle-aged or older. No clear sex predisposition has been identified. Hypotension (e.g., during anesthesia or after severe blood loss), hypercalcemia (both iatrogenic and as a result of diseases such as neoplasia and hyperparathyroidism), abdominal trauma, extensive surgical manipulation of the pancreas, certain infections (e.g., with certain *Babesia* spp.), and obstruction of the pancreatic duct (e.g., as a consequence of neoplasia) are also suspected risk factors for canine pancreatitis, but evidence is weak or lacking.[2,31] Chronic gastrointestinal (GI) disease might also be a risk factor for pancreatitis in dogs.[32] Primary or metastatic neoplasia of the pancreatic parenchyma is often associated with secondary inflammation of the exocrine pancreas. Previous surgery and epilepsy have also been reported as potential risk factors.[17,23]

Signalment

Dogs of any age, breed, or sex can develop pancreatitis. Most animals are middle-aged to old.[4,17] Miniature Schnauzers and Yorkshire Terriers appear to be at increased risk, while predisposition of other breeds is less clear.[2,16,17,23] In one study some other breeds (e.g., Boxers, Cavalier King Charles Spaniels, Cocker Spaniels, and Collies) were suggested to be predisposed, but this has not been confirmed by other studies.[24] No clear sex predisposition has been identified.

Clinical Signs and Physical Examination Findings

Dogs with pancreatitis can have subclinical disease or present with a variety of clinical signs, ranging from mild partial anorexia with no apparent GI signs to severe systemic signs with cardiovascular shock and DIC. There is no single clinical sign or combination of clinical signs that is pathognomonic for canine pancreatitis. Clinical signs of severe acute pancreatitis may include anorexia (91%), vomiting (with or without blood; 90%), weakness (79%), polyuria and polydipsia (50%), and diarrhea (with or without blood; 33%).[16] Many of the clinical signs are likely to be the result of complicating or concurrent diseases rather than pancreatitis per se (e.g., polyuria and polydipsia are more likely to be the result of concurrent diabetes mellitus). The most common physical examination findings in dogs with severe acute pancreatitis include dehydration (97%), abdominal pain (58%), fever (32%), and icterus (26%).[16] The combination of vomiting and abdominal pain, although suggestive of pancreatitis, is also seen with other diseases (e.g., GI foreign bodies, peritonitis). Other possible findings include shock, hypothermia, cardiac murmur, tachycardia, bleeding diathesis, ascites, a palpable abdominal mass, and harsh lung sounds.[16] Patients with less severe or chronic pancreatitis are typically presented with less-profound clinical signs (e.g., anorexia and depression), or might even be subclinical.

Clinical Pathology[7,16]

Results of the complete blood cell count (CBC), serum biochemistry profile, and urinalysis are nonspecific and thus of limited

usefulness for the diagnosis of pancreatitis in dogs. However, these tests should always be performed in animals with suspected pancreatitis because they are useful for ruling out other differential diagnoses and provide important information about the general condition of the animal.

Often, especially in mild cases, the CBC, serum biochemistry profile, and urinalysis are normal. Possible hematologic findings in dogs with pancreatitis include anemia or hemoconcentration, leukocytosis or leukopenia, and thrombocytopenia. Evidence of coagulopathy, such as prolonged activated clotting time and prothrombin (PT) and partial thromboplastin times, are seen in some cases, and may or may not be associated with spontaneous bleeding. In other cases, there might be evidence suggestive of DIC, such as thrombocytopenia, prolongation of clotting times (activated clotting time, PT, partial thromboplastin time), and a positive D-dimer test. Different combinations of increases in liver enzyme activities and hyperbilirubinemia are common, and might erroneously direct the clinician to suspect primary liver disease. Increases in serum creatinine and blood urea nitrogen (BUN) concentrations are variably present and most often associated with dehydration as a consequence of vomiting, diarrhea, and/or decreased water intake. In severe cases, azotemia might be the result of secondary renal failure. Other possible findings include hypoalbuminemia, hypertriglyceridemia, hypercholesterolemia, and hyperglycemia or hypoglycemia. Electrolyte abnormalities are commonly present and variable, with hypokalemia, hypochloremia, and hyponatremia being the most common.

Clinical Enzymology

Serum Pancreatic Lipase Immunoreactivity

The only cell type known to synthesize pancreatic lipase is the pancreatic acinar cell. An immunoassay for the measurement of canine pancreatic lipase has been developed and analytically validated.[33] In contrast to the traditional activity assays for lipase, which indiscriminately measure the activity of lipases of any origin, this immunoassay specifically quantifies the pancreatic lipase based on its unique antigenic structure. The originally developed in-house immunoassay for canine pancreatic lipase has been replaced by a widely available commercial immunoassay (Spec cPL).[34,35]

Clinical studies suggest that serum cPLI (or Spec cPL) has a high specificity for canine pancreatitis. In one study of 31 dogs with a normal pancreas on histopathology, the specificity of Spec cPL was very high (96.8%).[36] In a recent multicenter study of dogs with clinical evidence of pancreatitis, the specificity of this assay was reported at 78%.[37] Experimentally induced chronic renal failure and prednisone administration do not significantly affect serum cPLI concentration.[38,39] The association between gastritis and serum cPLI concentration requires further evaluation as gastritis was shown to be associated with increased serum cPLI in one study.[40] However, no pancreatic biopsies were examined in that study to exclude pancreatic pathology. The specificity of cPLI also requires further investigation in dogs with various GI diseases but not pancreatitis. It also remains to be determined whether serum cPLI concentration can be increased in patients with histopathologically mild pancreatitis that might be of minor clinical importance and does not contribute to the development of clinical signs. Compared with other serum tests currently available, serum cPLI is considered to have the highest specificity for pancreatitis.[36-39,41-43] However, false-positive results cannot be excluded.

The serum cPLI concentration is also sensitive for the diagnosis of pancreatitis in dogs,[34,37,44,45] ranging from 64% to 93%, possibly depending on the severity of the disease in the patients studied. The sensitivity of serum cPLI is higher than for any other serum test currently available.[34,37,44,45] However, false-negative results are likely to occur, especially in mild cases.

Overall, serum cPLI concentration appears to be a sensitive and specific marker of canine pancreatitis, and is currently considered to be the serum test of choice for the diagnosis of pancreatitis in this species.

Based on clinical observations and the results of studies available to date,[34] serum cPLI concentrations do not appear to correlate with the severity of pancreatitis. Therefore individual measurement of cPLI concentrations cannot be used to determine the severity of pancreatitis. No studies have examined the significance of changes in serum Spec cPL concentrations over time in individual patients.

A point-of-care test for the estimation of pancreatic lipase in serum (SNAP cPL) is available. Published studies evaluating the performance of this test are currently lacking, but it is suggested that it shows the same clinical performance as the serum Spec cPL assay. The recommended use of this test is to rule out pancreatitis in dogs suspected of having the disease. Because of the high sensitivity of Spec cPL, a negative result makes a diagnosis of pancreatitis unlikely. However, false-negative results might occur in some cases. A positive test result should be followed by laboratory measurement of serum Spec cPL concentration.

Serum Amylase and Lipase Activities

Serum amylase and lipase activities have long been considered markers for canine pancreatitis, but several studies show that they have low sensitivity and specificity.[41,46] In one study, approximately 50% of dogs with increased activity of either serum amylase or lipase activity had no histopathologic evidence of pancreatitis.[41] This means that a large proportion of dogs that have diseases other than pancreatitis (e.g., certain renal, hepatic, intestinal, and neoplastic diseases) have increased serum lipase and/or amylase activities.[41] Significant increases of amylase and lipase activities can result from nonpancreatic disorders, and identification of elevated concentrations of these enzymes should always be followed up by the use of more specific and sensitive tests.[15,41,42,47] In addition, the sensitivity of serum amylase and lipase activities for spontaneous canine pancreatitis is generally low (14% to 73% for lipase and 18% to 69% for amylase).[16,34,45] Therefore pancreatitis cannot be confidently diagnosed or ruled out based on serum amylase and/or lipase activities alone.[16,41]

Serum Trypsin-like Immunoreactivity

TLI assays are species-specific immunoassays that measure trypsinogen and trypsin in serum. Trypsinogen is the inactive precursor of trypsin and is synthesized exclusively in the pancreatic acinar cells. The sensitivity of serum cTLI for the diagnosis of canine pancreatitis is low (36% to 47%), probably because of its short half-life.[34,42,45] In addition, although there is strong evidence that trypsinogen is exclusively of pancreatic origin,[48] it is believed that it is cleared by glomerular filtration in dogs, and serum cTLI concentration can be increased in dogs with renal failure.[42,43] In the face of availability of a better serum marker (cPLI), cTLI is currently considered to be of limited value for the diagnosis of canine pancreatitis. If the Spec cPL assay is not available, cTLI might be used to rule in pancreatitis if renal disease has been ruled out. However, a normal cTLI concentration cannot rule out pancreatitis.

Other Diagnostic Tests

Several other tests have been developed and evaluated for the diagnosis of canine pancreatitis. However none can be recommended for

clinical use, either because their clinical value has not been determined accurately or because they have a low specificity and/or sensitivity. In addition, most of these tests have limited availability.

TAP is a small peptide that is released when trypsinogen is activated to trypsin.[42] Under physiologic conditions, trypsinogen is activated mainly in the intestinal lumen, and thus serum TAP concentrations are low or undetectable.[42] During pancreatitis, trypsinogen is prematurely activated in the pancreas and TAP is released into the circulation.[42,49] Plasma and urinary TAP concentrations have been evaluated in healthy dogs, dogs with histopathologically confirmed pancreatitis, and dogs with other systemic diseases.[42] In that study, plasma TAP concentration had good specificity (87.9%), but low sensitivity (53.3%), for the detection of pancreatitis. Urine TAP concentrations did not show any advantage over serum TAP concentrations in diagnosing pancreatitis. Both tests show increases in dogs with severe pancreatitis, but were normal or low in cases of mild pancreatitis. However, this study suggested that, as in humans, serum and urine TAP concentrations might be more useful as a prognostic indicator in dogs with pancreatitis.[42]

Measurement of lipase activity in peritoneal fluid and comparison with serum lipase activity has been evaluated as a tool for the diagnosis of acute pancreatitis in dogs.[50] However, further studies are needed before this method can be recommended for clinical use. Other tests that have been evaluated for the diagnosis of canine pancreatitis include trypsin-α_1-proteinase inhibitor complex concentrations in serum and α_2-macroglobulin concentrations in serum.[51-54]

Diagnostic Imaging

Abdominal Radiography

Conclusive diagnosis or exclusion of pancreatitis is not possible based on abdominal radiography alone.[16] In the majority of cases of pancreatitis, abdominal radiographs are normal or only show nonspecific changes.[16] Despite that, abdominal radiography remains a logical initial approach for patients suspected of having pancreatitis, because it is useful to rule out other differential diagnoses.

Possible radiographic findings in dogs with pancreatitis include increased soft-tissue opacity and decreased serosal detail in the cranial right abdomen, displacement of the stomach and/or duodenum, dilation of bowel loops adjacent to the pancreas, abdominal effusion, and the presence of a cranial abdominal mass.[16]

Abdominal Ultrasound

Abdominal ultrasound is the imaging modality of choice for the diagnosis of pancreatitis in dogs. However, abdominal ultrasonography is also associated with disadvantages, and its performance in the diagnosis of pancreatitis is highly dependent on the experience of the ultrasonographer and the quality of the equipment used. It has been reported to have a relatively high sensitivity of approximately 68% for severe acute pancreatitis in dogs.[16] In a recent study where ultrasonography was performed in 26 animals (both dogs and cats) with suspected GI disease, six (23.1%) of the animals had ultrasonographic evidence consistent with pancreatitis, while histopathology revealed either a normal pancreas or pancreatic hyperplasia.[55] In the same study, there was only a 22% agreement between the ultrasonographic and the histopathologic diagnoses.[55] Although not free of limitations, this study highlights that ultrasonographic findings in animals with suspected pancreatitis should be interpreted with caution. A normal pancreas on ultrasound examination does not rule out pancreatitis.[16,56] If stringent criteria are applied, the specificity of abdominal ultrasonography for pancreatitis is considered to be relatively high, although other diseases of the pancreas (e.g., neoplasia, hyperplastic nodules, pancreatic edema as a consequence of portal hypertension or hypoalbuminemia) may display similar ultrasonographic findings and sometimes cannot be differentiated from pancreatitis.[57,58]

The most important ultrasonographic findings suggestive of pancreatitis in dogs include hypoechoic areas within the pancreas, increased echogenicity of the surrounding mesentery (because of necrosis of the peripancreatic fat), and enlargement and/or irregularity of the pancreas.[16,56,59] Differentiation between necrotizing and edematous pancreatitis might be possible based on ultrasonographic examination (Figures 60-17 and 60-18), although this has not been

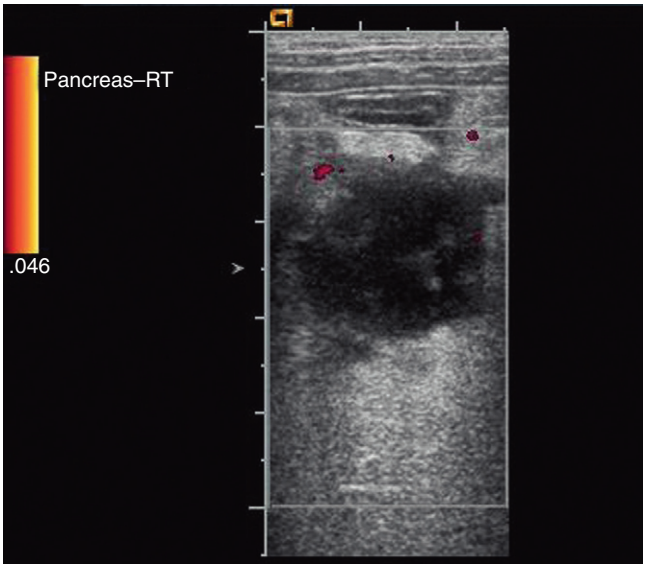

Figure 60-17 Ultrasonographic appearance of the pancreas of a dog with acute necrotizing pancreatitis. The pancreatic lobe is diffusely hypoechoic with a focal anechoic region. No blood flow is present in the necrotic portion, as shown with power Doppler interrogation. (Courtesy of Dr. B. Young, Texas A&M University, College Station, TX.)

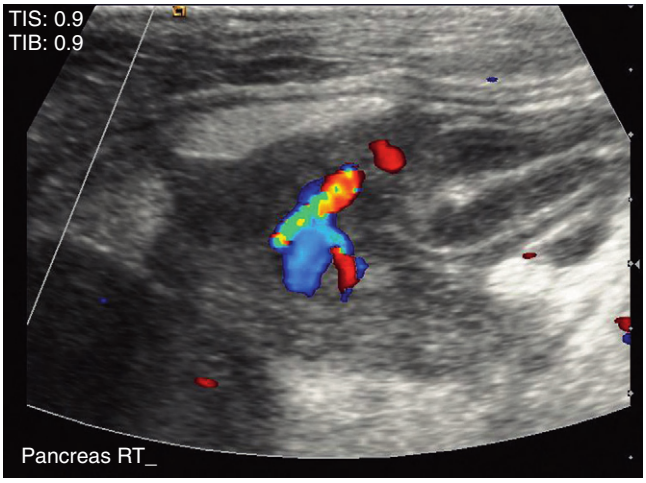

Figure 60-18 Ultrasonographic appearance of the pancreas of a dog with acute edematous pancreatitis. The affected lobe is enlarged, irregularly marginated, and hypoechoic. Note the preservation of blood flow within the pancreas on color flow Doppler interrogation. (Courtesy of Dr. B. Young, Texas A&M University, College Station, TX.)

confirmed in clinical studies. On occasion, hyperechoic areas of the pancreas possibly indicating the presence of pancreatic fibrosis may be present. Less-specific findings may include a dilation of the pancreatic or biliary duct and abdominal effusion. Abdominal ultrasonography is also very useful for the diagnosis of local complications of pancreatitis such as pancreatic abscesses, pancreatic pseudocysts, and biliary obstruction.[59] In addition, ultrasound-guided fine-needle aspiration is a useful tool for the management of noninfectious fluid accumulations of the pancreas (e.g., pancreatic pseudocyst) and for obtaining pancreatic specimens for cytologic evaluation.[60]

Other Imaging Modalities

Several other imaging modalities are routinely used to diagnose or evaluate pancreatitis in human patients. Contrast-enhanced CT is a valuable tool for the evaluation of people with suspected pancreatitis and might also prove to be useful in dogs, but it has not yet been evaluated in an adequate number of canine cases.[61] Other imaging modalities (e.g., endoscopic retrograde cholangiopancreatography, endoscopic ultrasonography) have been studied in healthy dogs and in dogs with GI diseases with varying results.[62,63] However, because of the lack of standardized criteria for the diagnosis of pancreatitis, the complexity of these modalities, their limited availability, and the cost of the equipment, they cannot be currently recommended for the diagnosis of canine pancreatitis.

Pathology

Certain macroscopic lesions identified during surgery, laparoscopy, or necropsy are highly suggestive of pancreatitis and are preferred sites for biopsy collection.[34] Lesions suggestive of pancreatitis may include peripancreatic fat necrosis, pancreatic hemorrhage and congestion, and a dull granular capsular surface (Figure 60-19).[34] However, gross lesions may not always be apparent and in some cases they might be difficult to differentiate from nodular hyperplasia.[3]

A definitive diagnosis of pancreatitis can only be made by histopathologic examination of the pancreas and this is also the only way to differentiate acute and chronic pancreatitis, and in some cases, pancreatitis from pancreatic neoplasia. The presence of permanent histopathologic changes (e.g., fibrosis and acinar atrophy) is considered suggestive of chronic pancreatitis.[3,15] Acute pancreatitis is characterized by absence of permanent histopathologic changes.

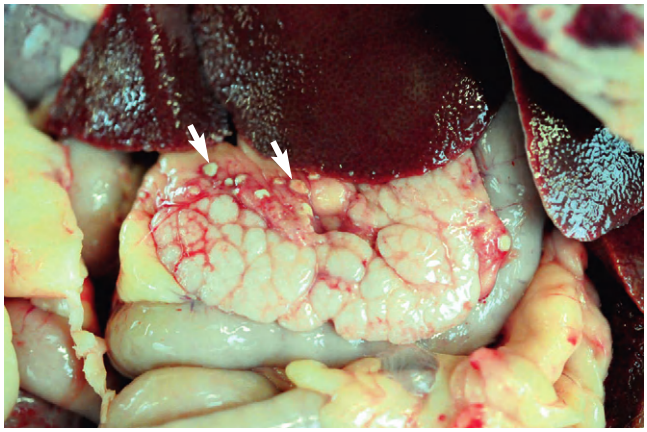

Figure 60-19 Gross appearance of the pancreas of a dog with acute pancreatitis. The pancreas appears edematous and hemorrhagic. Several areas of pancreatic fat necrosis can be seen (*arrows*). Such appearance is highly suggestive of acute pancreatitis. (Courtesy of Dr. John Edwards, Texas A&M University, College Station, TX.)

The predominant inflammatory infiltrate (i.e., neutrophils or lymphocytes) is often used to describe pancreatitis as suppurative or lymphocytic, respectively, and a significant degree of necrosis is usually used to characterize the pancreatitis as necrotizing.

Several limitations are associated with pancreatic histopathology as a definitive diagnostic tool for pancreatitis. First, determining the clinical significance of histopathologic findings may be challenging. At the same time, exclusion of pancreatitis based on histopathology is difficult because inflammatory lesions of the pancreas are often highly localized and can easily be missed.[3] Therefore, multiple sections of the pancreas must be evaluated in order to increase the likelihood of finding microscopic lesions, although this is not always feasible in clinical cases.[3] Finally, although pancreatic biopsy per se is considered safe, it requires invasive procedures that are expensive and potentially detrimental in patients that are hemodynamically unstable.[55]

Cytology

Fine-needle aspiration of the pancreas with cytologic examination was recently introduced as a diagnostic tool for pancreatitis in small animals. It should be performed either under ultrasound guidance or during laparotomy.[64] To date, no studies have evaluated the sensitivity and specificity of this modality for the diagnosis of canine pancreatitis, but the finding of acinar and inflammatory cells in the aspirate is considered specific for pancreatitis. Pancreatic acinar cells constitute the majority of the cells found in fine-needle aspirations from a normal pancreas.[64] In patients with acute pancreatitis there is hypercellularity with intact and degenerate neutrophils and degenerate pancreatic acinar cells. As for histopathology, highly localized lesions might be missed so negative results do not rule out pancreatitis. Cytology might also be useful in differentiating other conditions of the pancreas (e.g., neoplasia) from pancreatitis.

Concluding Remarks on the Diagnosis of Pancreatitis

There is currently no test that is 100% sensitive and specific for the diagnosis of pancreatitis, so false-positive and false-negative results can occur with all tests. The use of careful assessment of the clinical history, physical examination findings, results of routine clinical pathology, diagnostic imaging studies, measurement of cPLI concentration, and when appropriate cytologic and/or histopathologic findings is crucial for a correct diagnosis or exclusion of pancreatitis.

Treatment

Treatment of the Cause

The etiology of pancreatitis remains unknown in the majority of cases, and therefore, treatment of pancreatitis remains almost exclusively supportive. Future recognition of specific causes of canine pancreatitis may lead to the development of more specific treatments for different forms of pancreatitis that are now classified as idiopathic. Until then, the presence of possible risk or etiologic factors should always be investigated. If any of these factors are present, they should be managed where possible. Thus, dogs with pancreatitis should be investigated for the presence of hypertriglyceridemia, hypercalcemia, endocrine diseases, obesity, certain toxicities (e.g., zinc), certain infectious diseases, and inflammatory diseases of the intestine and liver. Important information from the history of the animal include drugs administered (especially potassium

bromide, phenobarbital, and azathioprine), diet offered (especially high-fat diets), and recent surgery or trauma.

Nutrition

Nutritional approaches in people and animals with acute pancreatitis usually include one of the following: (a) enteral nutrition, (b) parenteral nutrition (total or partial), and (c) no nutritional support.[65] In the past, the main concept of nutritional approach during acute pancreatitis was to "rest the pancreas" as it was believed that feeding induced the stimulation of exocrine pancreatic secretion, which might lead to exacerbation of pancreatitis.[15,66] This was based on physiologic observations in normal people and experimental animals, which showed that CCK release during feeding led to stimulation of the exocrine pancreas.[67] Therefore, the standard approach to patients with acute pancreatitis included complete avoidance of any form of enteral nutrition, which was achieved either by providing no supplementary nutrition or by parenteral nutrition.[66] However, subsequent studies showed a decreased exocrine pancreatic secretion in response to CCK in experimentally induced pancreatitis.[67] It is now recognized that both parenteral and enteral routes of alimentation are superior to providing no nutritional support, and thus providing early and adequate nutritional support has become a priority in the treatment of human patients with acute pancreatitis.[66] In addition, several human studies show that enteral nutrition is superior to parenteral nutrition, and enteral nutrition is now the preferred method of alimentation for patients with acute pancreatitis.[65,66] Regarding the location of food delivery through enteral feeding, jejunal feeding is considered by many to be the method of choice, but studies in humans show that nasojejunal feeding offers no advantages compared with nasogastric feeding.[66,67] Thus, gastric delivery of nutrients is preferred in many cases as it is much simpler than jejunal feeding and is well tolerated by most patients.

Unfortunately, studies in dogs with pancreatitis are limited. Information from clinical experience and preliminary studies suggest that enteral nutrition is generally well tolerated and improves, or at least, does not worsen the course of pancreatitis.[68,69] Using this information and applying the knowledge based on studies in experimental animals and humans to dogs, the following recommendations can be made: (a) dogs with pancreatitis should not be kept without enteral nutritional support for more than 24 hours (including times of anorexia before presentation); (b) dogs with acute pancreatitis that are not vomiting should generally be fed by mouth. If they are anorectic, a feeding tube should be used (esophagostomy, nasoesophageal, gastrostomy, nasogastric, or jejunostomy tube) until the animal is eating again. Esophagostomy and nasoesophageal or nasogastric tubes are usually preferred because their placement is less invasive and is associated with few complications[70]; and (c) if the animal is vomiting, antiemetics should be used to control vomiting and enteral nutrition should be given as soon as possible. Jejunostomy tubes should be considered in animals with refractory vomiting or animals that undergo exploratory or therapeutic laparotomy. Their use is relatively safe with severe complications (e.g., breakdown of the surgical site) being reported in 0% to 6% of dogs.[70,71] Endoscopic techniques for percutaneous gastrojejunostomy tube placement might prove helpful in the future.[72]

A diet of choice has not been determined in people or dogs with pancreatitis, but a balanced extra-low-fat diet is currently our preferred choice for dogs. Administration of parenteral nutrition has been reported in dogs, but we rarely recommended its use (unless enteral nutrition is contraindicated in a patient), mainly because of data from human studies (see earlier discussion), its unproven efficacy in dogs with pancreatitis, and the potential for serious complications.[73-75]

Fluid Therapy

Dogs with pancreatitis are often presented with variable degrees of dehydration because of decreased water intake, vomiting, diarrhea, and/or third space losses. In these cases, dehydration results most commonly from isotonic fluid loss. The degree of dehydration can be estimated by evaluating physical parameters (e.g., dryness of mucous membranes, reduced skin turgor), or by detailed serial monitoring of body weight.[76,77] Dehydration might also be evident in clinicopathologic testing (e.g., hemoconcentration, increased total protein concentration, high urine specific gravity, prerenal azotemia, and others).[76,77] Replacement isotonic fluid solutions (e.g., lactated Ringer solution, 0.9% NaCl) are the treatment of choice for dehydrated dogs with pancreatitis. Mild dehydration (approximately 5%) may be treated by subcutaneous fluid administration. If the animal is not vomiting, oral rehydration therapy may also be used. Moderate and severe dehydration (>6%) should be treated with intravenous fluid administration. Severely dehydrated animals might be in shock, in which case they require aggressive intravenous fluid therapy (see following discussion).[76]

In dogs with severe acute pancreatitis, rapid and excessive fluid loss as a consequence of vomiting, diarrhea, and/or third space accumulation of fluid, might lead to hypovolemia and compromised perfusion of organs and tissues. Tissue hypoperfusion and especially diminished pancreatic microcirculation is believed to contribute to the development of major local and systemic complications.[78] Hypovolemic patients may or may not be dehydrated, depending mostly on the volume and rapidity of fluid loss.[76] Severe hypovolemia leading to hypovolemic shock is a life-threatening condition and must always be treated as an emergency. In addition to the volume deficit, some animals have a reduced red blood cell volume as a result of GI blood loss, which further decreases tissue perfusion. Clinical findings indicating hypovolemia include hypotension, reduced peripheral pulses, tachycardia, cold extremities, prolonged capillary refill time, and pale mucous membranes.[76,77]

In human patients, aggressive fluid resuscitation using crystalloid solutions is recommended in most cases, while colloids are used only in specific cases (e.g., where there is hypoalbuminemia).[78] Although studies are lacking in dogs, aggressive intravenous fluid therapy (fluid resuscitation) should be initiated as soon as possible when there is hypovolemic shock, before initiating the rehydration phase (if the animal is also dehydrated).[76] Current recommendations for initial fluid therapy of hypovolemic shock include rapid intravenous administration of one or more small boluses (10 to 20 mL/kg in <5 minutes) or a single bolus (90 mL/kg in 15 to 20 minutes) of an isotonic crystalloid solution and close monitoring of physical parameters for evidence of improvement (e.g., slower heart rate, improved pulse quality and capillary refill time).[77,79] Care should be taken not to cause fluid overload in these patients. Based on the response to initial treatment and the severity of hypovolemia, crystalloid fluids can then be administered at rates of 20 to 90 mL/kg/h. Colloids (e.g., dextran 70, hydroxyethyl starch) may also be added to the isotonic crystalloid solutions for more effective volume expansion of the intravascular space, especially when severe hypoalbuminemia (<1.5 g/dL) is present.[76,77,79] Studies of experimental acute pancreatitis in dogs suggest that hypertonic saline-dextran solutions may be more efficacious than crystalloid solutions in restoring tissue perfusion.[80] However, studies of dogs with spontaneous pancreatitis are lacking and current recommendations in humans favor crystalloid use in most cases.[78]

Plasma and Blood Transfusion

The use of fresh-frozen plasma (10 to 15 mg/kg once a day) is recommended by some authors for dogs with severe pancreatitis because it contains several beneficial components, such as proteinase inhibitors (e.g., α_1-proteinase inhibitor, α_2-macroglobulin), albumin, as well as coagulation and anticoagulation factors.[15,81] Proteinase inhibitors may protect from development or worsening of pancreatitis, and depletion of proteinase inhibitors has been reported in dogs with both experimental and spontaneous pancreatitis.[15,54,82] However, in one study, α_2-macroglobulin concentrations did not correlate with severity of pancreatitis in dogs.[54] Studies in humans show no benefit of plasma administration in the clinical outcome of patients with acute pancreatitis, despite the increase in plasma concentrations of proteinase inhibitors.[83] Therefore fresh-frozen plasma is generally only recommended for the treatment of people with pancreatitis when they have coagulopathies. In addition, in a recent retrospective study, dogs with pancreatitis that received fresh-frozen plasma had a worse outcome than dogs that did not receive fresh-frozen plasma.[7] In that study, there was no significant difference in the severity of pancreatitis before treatment, although treatments were not controlled in the two groups and group allocation was not randomized.[7] Thus, the actual value of plasma administration is highly questionable in dogs with pancreatitis. It is possible that, as in humans, its usefulness is limited to cases where coagulopathies are present.[81] Well designed prospective and randomized studies are needed to critically evaluate the usefulness of plasma administration in dogs with pancreatitis. Fresh whole blood (20 to 25 mL/kg once a day) might be used if fresh-frozen plasma is not available or if there is severe blood loss.

Therapy for Electrolyte and Acid–Base Abnormalities

Electrolyte abnormalities are common in dogs with acute pancreatitis. Various combinations and degrees of hypokalemia, hyponatremia, and hypochloremia can be present as a result of diarrhea, vomiting, fluid therapy, and/or anorexia.[16] Hyperkalemia, hypernatremia, and hypocalcemia or hypercalcemia are reported less frequently.[16] Unfortunately, the nature of electrolyte abnormalities in dogs with pancreatitis cannot be accurately predicted and serum potassium, sodium, chloride, and ionized calcium concentrations should always be measured and corrected in these patients. The variability of electrolyte abnormalities in animals with pancreatitis is further complicated by the presence of concurrent diseases such as diabetes mellitus. Hypokalemia may or may not be associated with clinical signs such as muscular weakness and cardiac arrhythmia. Its correction should be achieved by addition of potassium chloride to intravenous fluids, and it should be administered at a rate of 0.15 to 0.5 mEq/kg/h, depending on the severity of depletion and ongoing losses. Hyponatremia is usually asymptomatic and is usually corrected by administration of crystalloid solutions (lactated Ringer solution or 0.9% saline). Although not as common as in cats, hypocalcemia can also be seen in dogs with pancreatitis, but clinical signs attributable to hypocalcemia are rarely noted.[16,84] The value of supplementing calcium has not been evaluated in dogs. Most hypocalcemic patients with pancreatitis have no clinical signs of hypocalcemia, and thus can be treated with 10% calcium gluconate at a dose of 5 to 10 mg/kg/h of elemental calcium given in the crystalloid infusion.

Acid–base disturbances are also common in dogs with pancreatitis and may occur as a result of vomiting, diarrhea, and/or hypoperfusion. The nature of acid–base disorders in dogs with pancreatitis cannot be accurately predicted and blood gas analysis is recommended. Patients with vomiting of gastric fluid typically develop metabolic alkalosis because of loss of chloride and H^+, while patients with diarrhea are more likely to develop metabolic acidosis as a result of loss of HCO_3^-. In patients with both vomiting and diarrhea, or with vomiting that also includes duodenal content, the acid–base status is more difficult to predict. Mild acid–base disorders are corrected through fluid therapy. Treatment of more severe forms of acid–base disorders depends on the specific type of the disorder.

Analgesic Therapy

Pain is believed to accompany virtually all cases of pancreatitis in dogs, even when pain is not clinically obvious.[85] Pain induces several physiologic changes, including decreased appetite, decreased GI tone, decreased regional blood flow to several abdominal organs (including the pancreas), and tachycardia, and it may produce a catabolic state.[86,87] Therefore, analgesic therapy is extremely important and should be used in all dogs with pancreatitis.

Pain in dogs with pancreatitis can range from mild to severe. Opioid administration is mandatory in the management of pain in acute pancreatitis. The intravenous route is usually preferred because it provides fast results. For mild to moderate pain, administration of buprenorphine (0.005 to 0.015 mg/kg, IV, IM, or SC, q6-12h) is usually sufficient. In dogs with severe pain, administration of morphine (0.5 to 1.0 mg/kg, slowly IV or IM q2h; constant-rate infusion [CRI], 0.05 to 0.2 mg/kg/h), hydromorphone (0.1 to 0.2 mg/kg, slowly IV or IM q2h; CRI, 0.0125 to 0.05 mg/kg/h), methadone (0.1 to 0.5 mg/kg IV, IM, or SQ q2-6h), or fentanyl (0.005 to 0.01 mg/kg IV, IM, or SQ q2h; CRI, 0.002 to 0.006 mg/kg/h) is very effective, especially when used as a CRI. Multimodal pain management might be indicated in some cases with severe pain, because it may be more effective and associated with fewer side effects because of lower dosages of the drugs administered. Combinations commonly used in dogs include morphine (0.1 mg/kg/h), lidocaine (2.5 mg/kg/h), and ketamine (0.6 mg/kg/h). Fentanyl patches (patch size is based on patient size, every 3 to 4 days) are safe and practical, but they should be used only after analgesia has been achieved by use of injectable opioids, as it takes longer for transdermal application to achieve analgesia. Analgesic therapy in outpatients can be achieved with fentanyl patches, buprenorphine, or tramadol (4 mg/kg PO q12h).

Antiemetic Therapy

Antiemetic therapy should be initiated in all dogs with pancreatitis that are vomiting or appear nauseated. Maropitant is a neurokinin-1 (NK-1) receptor antagonist, which acts through inhibition of substance P.[88] Although not specifically tested for pancreatitis, several studies have demonstrated the effectiveness of this drug in both preventing and treating vomiting of different etiologies in dogs.[89,90] Maropitant has been shown to be effective in controlling both peripherally and centrally mediated emesis, because NK-1 receptors are located both centrally (emetic center, chemoreceptor trigger zone) and peripherally (mainly vagal nerve terminals).[89,90] Based on recent unpublished data, maropitant may also have analgesic effects, that may be primary or secondary (Dr. D. Twedt, Colorado State University, Fort Collins, CO, personal communication). For the treatment of acute vomiting, the injectable solution is administered at a dose of 1 mg/kg SC q24h for up to 5 consecutive days. If therapy is needed for longer periods, a 48- to 72-hour washout period is recommended.[88] Maropitant is generally well tolerated in dogs.

5-HT_3 antagonists such as dolasetron (0.6 mg/kg IV, SC, or PO q12h) and ondansetron (0.1 to 0.2 mg/kg, slowly IV, q6-12h) can also be used and seem to be effective in many cases. 5-HT_3 antagonists can be used in combination with maropitant in refractory cases

of vomiting, although the safety of this combination is only anecdotal. Dopaminergic antagonists (e.g., metoclopramide 0.2 to 0.5 mg/kg IV, IM, SQ, or PO q6-8h) are considered to be less effective and might negatively affect the course of pancreatitis because dopamine protects against experimentally induced acute pancreatitis in experimental animals.[91,92] CRIs of metoclopramide (0.3 mg/kg/h IV) seem to be more effective than single doses. Finally, α_2-adrenergic antagonists such as chlorpromazine should be avoided because of their potentially serious side effects (mainly hypotension).

Antibiotic Therapy

Prophylactic use of antibiotics is controversial in human patients with pancreatitis. Prophylactic antibiotics have been recommended in people with pancreatic necrosis.[8] The goal of antibiotic prophylaxis in human patients with necrotizing pancreatitis is to prevent bacterial translocation from the intestinal lumen, prevent or decrease pancreatic colonization, and reduce mortality.[93,94] Meta-analysis studies have often arrived at conflicting results.[8,78,93,94] Because multicenter, double-blinded, placebo-controlled, and meta-analysis studies have failed to show a clear advantage of prophylactic antibiotic use in people with severe necrotizing pancreatitis, most authors do not recommend antibiotic prophylaxis in human pancreatitis.[8,78]

Studies on prophylactic antibiotic use in dogs with spontaneous pancreatitis are lacking. Because infectious complications occur much less frequently in dogs compared with people and given that prophylactic antibiotic use is not clearly efficacious in human patients, prophylactic use of antibiotics is believed to be of no benefit in dogs with pancreatitis. In addition, side effects such as anorexia and vomiting might be associated with some antibiotics, while others might be implicated in the initiation of pancreatitis. The use of antibiotics is recommended in cases where infectious complications are identified (e.g., aspiration pneumonia, infected pancreatic necrosis) or are suspected. Antibiotic selection should be based on culture and sensitivity but cefotaxime, ciprofloxacin, metronidazole, clindamycin, and chloramphenicol achieve therapeutic levels in the pancreas in experimental pancreatitis.[95,96]

Surgery

Surgery for Pancreatitis

Surgical management of canine pancreatitis without pancreatic complications is rarely recommended. Some clinicians recommend peritoneal lavage to treat dogs with severe pancreatitis as it was suggested to remove harmful substances, such as trypsin and inflammatory cytokines, from the peritoneal cavity.[97] However, recent well-designed and metaanalysis studies in humans show that use of peritoneal lavage is not associated with any significant improvement in morbidity or mortality.[97]

In an older study of experimental canine pancreatitis, there was a significant improvement in survival with the use of peritoneal dialysis.[98] However, experimental models for pancreatitis do not represent an ideal model of spontaneous pancreatitis, and no studies have evaluated the usefulness of peritoneal lavage in naturally occurring pancreatitis in dogs. Given that peritoneal lavage is invasive, expensive, often associated with severe complications (e.g., peritonitis, anesthesia of compromised patients), and of unproven value, it is generally not recommended for the management of acute pancreatitis in dogs.

Surgery for Pancreatic Complications of Pancreatitis

Several pancreatic complications of pancreatitis have been reported in dogs, and surgical intervention is used in some cases to treat them. Because these complications of pancreatitis have been reported infrequently in the veterinary literature, evidence-based information regarding the treatment of choice is lacking. In addition, the terminology and definition of pancreatic complications of pancreatitis used in dogs has been adapted from the human literature and does not accurately illustrate these complications in dogs. The human classification of pancreatic complications of pancreatitis is currently being updated[99] and will most likely be adapted for dogs as well. In this chapter, and in order to avoid confusion, the terminology used in the previously published reports in dogs is used.

A *pancreatic abscess*[100-105] is the most commonly reported complication of pancreatitis in dogs, and has been described in association with both acute and chronic pancreatitis. Pancreatic abscesses are believed to occur infrequently, with a reported prevalence of 1.4% to 6.5%. In contrast to people, pancreatic abscesses are usually sterile in dogs, with only up to 22% of the reported cases yielding bacterial growth, although many of these dogs had received antibiotics prior to admission. Surgical intervention is almost always recommended when a pancreatic abscess is identified, and several surgical techniques have been described. Mortality in dogs with pancreatic abscesses ranges from 50% to 86%, making the presence of a pancreatic abscess a poor prognostic indicator.

Pancreatic pseudocysts[105-108] are reported as a complication of pancreatitis (both acute and chronic), but appear to be uncommon. Their pathogenesis is unknown and they are usually sterile. Ultrasound-guided fine-needle aspiration of the cystic fluid may be used for the management of small pseudocysts. In other cases, however, clinical signs persist or worsen despite treatment and enlargement of the pseudocyst may occur over time. In these cases surgical intervention is usually recommended, although surgical techniques are poorly described. Internal drainage appears to be the treatment of choice in humans.

Necrotic masses,[101,105] usually arising from necrotizing pancreatitis, have been reported in a small number of dogs. These dogs were treated surgically (debridement and drainage) but died or were euthanized soon after surgery.

Extrahepatic biliary tract obstruction[109] has also been reported as a result of pancreatitis in dogs, and surgery is usually required in cases of complete obstruction of the bile duct or in cases where the obstruction does not subside within 2 to 3 weeks.

Other Treatments

A plethora of other therapeutic agents (e.g., dopamine, H_1- and H_2-histamine receptor antagonists, somatostatin, anticholinergics, protease inhibitors, antioxidants, platelet-activating factor inhibitors, IL-10, selenium, probiotics) have been recommended by some authors in both veterinary and human medicine. Some of these therapeutic agents have shown potential benefit in feline models of experimental pancreatitis (e.g., dopamine, H_1- and H_2-histamine receptor antagonists)[110,111] or in clinical trials in people (e.g., the protease inhibitor gabexate mesylate),[112] and may prove to be beneficial for clinical use in the future. For the majority of the therapeutic agents mentioned previously, however, either appropriate clinical trials are lacking or have shown no benefit in the treatment of acute pancreatitis in humans.[112] There is currently no convincing evidence that any of these agents is beneficial for the treatment of spontaneous pancreatitis in dogs.

There are anecdotal reports that some dogs with chronic pancreatitis respond to corticosteroid (e.g., prednisone) or other immunosuppressive therapy. It is likely that, as in humans, some cases of canine chronic pancreatitis might have an autoimmune component

and these cases might benefit from corticosteroid administration. The safety and effectiveness of corticosteroids or other immunosuppressive agents in dogs with pancreatitis has not been evaluated, and therefore, these agents should be used with caution and only when all other treatments have failed.

Prognosis

The prognosis for dogs with pancreatitis depends on the severity of the disease. Mild cases usually have a good prognosis, and if recurrent episodes of pancreatitis do not occur, these animals live for long periods of time. In contrast, the prognosis for dogs with severe pancreatitis is usually guarded. The mortality associated with severe acute pancreatitis is high and the existence of pancreatic complications (e.g., pancreatic abscess) or concurrent diseases (e.g., diabetes mellitus) further contributes to a poorer outcome. It is unknown if dogs that have a single episode of pancreatitis are at risk for developing chronic or recurrent acute pancreatitis. The prognosis for dogs with chronic or recurrent acute pancreatitis is difficult to predict, and it depends on the severity of each acute exacerbation of the disease. Unfortunately, no accurate method has been reported to date for the prediction of the outcome of dogs with spontaneous pancreatitis, and the prognosis should be evaluated on an individual basis.

NECROSIS AND INFLAMMATION: FELINE

Robert J. Washabau

Several pathologies involving the feline exocrine pancreas have been identified (Figure 60-20).[1-12] Pathologic classification systems have been used to delineate these disorders,[13,14] although it should be emphasized that significant overlap exists between several disease categories particularly with regard to acute and chronic forms of pancreatitis.[8,10]

- ANP: This lesion is characterized by pancreatic acinar cell and peripancreatic fat necrosis (>50% of the pathology), with varying amounts of inflammation, hemorrhage, mineralization, and fibrosis. Inflammation may be present, but necrosis is the predominant feature. Reports of this condition were uncommon prior to the early 1990s, probably related to difficulties in diagnosis as well as lower incidence of disease. ANP is now a well-recognized gastrointestinal disorder of significant morbidity and mortality in the domestic cat.[1-10]
- Acute suppurative pancreatitis: Acute suppurative pancreatitis differs from ANP in that neutrophilic inflammation accounts for >50% of the pancreatic pathology. Necrosis may be present, but neutrophilic inflammation is the predominant feature. Acute suppurative pancreatitis is less common than ANP, appears to affect younger animals, and may have a differing pathogenesis.[2,5,6,10]
- Chronic nonsuppurative pancreatitis: This lesion is characterized by lymphocytic inflammation, fibrosis, and acinar atrophy. Necrosis and suppuration may be present in small amounts, but lymphocyte infiltration is the predominant feature. Antemortem differentiation of chronic nonsuppurative pancreatitis and ANP cannot be made on the basis of clinical, clinicopathologic, or imaging findings[10]; histopathology remains the only dependable method of differentiating these two disorders.[10] Chronic nonsuppurative pancreatitis and ANP may vary in their pathogeneses or they may represent a continuum of disease from necrosis to inflammation and fibrosis.[1,10]
- Pancreatic nodular hyperplasia: Nodules of pancreatic acinar or duct tissue are distributed throughout the pancreatic parenchyma. Fibrosis, inflammation, necrosis, and hemorrhage are not features of this condition. The clinical significance of this lesion is unknown. Pancreatic nodular hyperplasia is often detected at the time of routine abdominal ultrasonography or as an incidental finding at necropsy. Its importance resides in the need to differentiate its ultrasonographic characteristics from those of ANP.
- Pancreatic neoplasia: Neoplastic disorders of the pancreas may be primary (e.g., adenoma, adenocarcinoma) or secondary, and they are classified as benign or malignant. Pancreatic adenocarcinoma is the most common malignancy of the feline exocrine pancreas and is of ductal (primarily) or acinar origin. Neoplastic infiltration may be accompanied by necrosis, inflammation, fibrosis, hemorrhage, or mineralization in some instances.
- Pancreatic pseudocyst: Pancreatic pseudocyst is a common complication of pancreatitis in humans, and a not-so-common complication in cats and dogs.[15] Pancreatic pseudocyst is a nonepithelial lined cavitary structure containing fluid, pancreatic cells, and/or enzyme. It is observed at the time of ultrasound, CT scan, surgery, or necropsy. Its importance resides in the need to differentiate its ultrasonographic characteristics from those of pancreatic abscessation.
- Pancreatic abscess: Pancreatic abscess is a circumscribed collection of purulent material involving the right or left lobe of the pancreas. Like pseudocyst, pancreatic abscessation appears to be a complication of pancreatitis in humans and dogs.[16] The incidence and significance of this lesion in the cat are unknown. Medical and surgical therapies have been used to manage pancreatic abscesses in the dog.
- Pancreatic atrophy: Atrophy may result from degeneration, involution, necrosis, or apoptosis of the exocrine portion of the gland. Most feline cases are believed to represent the end stage of chronic pancreatitis. The endocrine portion of the gland may or may not be involved in the same process. EPI is the clinical syndrome that results from 95% or greater loss of exocrine pancreatic function. Affected animals develop a classic maldigestion syndrome characterized by weight loss, steatorrhea, and diarrhea.[11,17]

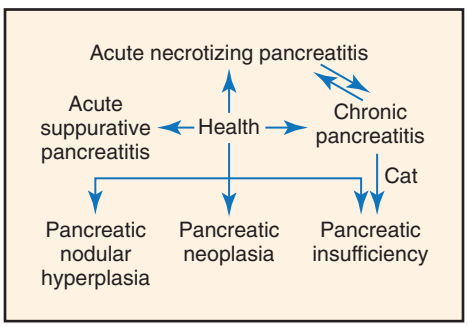

Figure 60-20 Pathogenesis of feline exocrine pancreatic disease.

Etiology

The etiologies of ANP are probably not yet completely recognized. Biliary tract disease, GI tract disease, ischemia, pancreatic ductal obstruction, infection, trauma, organophosphate poisoning, and lipodystrophy all have known associations with the development of ANP in the cat. Hypercalcemia, idiosyncratic drug reactions, and

nutritional causes are suggested but poorly documented causes of the disease (Box 60-2).

Concurrent Biliary Tract Disease

Concurrent biliary tract pathology has a known association with ANP in the cat. Cholangitis is the most important type of biliary tract disease for which an association has been made,[18] but other forms of biliary tract pathology (e.g., stricture, neoplasia, and calculus) have known associations.[2,9] Epidemiologic studies[18] show that cats affected with suppurative cholangitis have significantly increased risk for pancreatitis. The pathogenesis underlying this association is not entirely clear but relates partly to the anatomic and functional relationship between the major pancreatic duct and common bile duct in this species.[19,20] Unlike the dog, the feline pancreaticobiliary sphincter is a common physiologic and anatomic channel at the duodenal papilla (Figure 60-21). Mechanical or functional obstruction to this common duct readily permits bile reflux into the pancreatic ductal system.[21-23] Bile salt perfusion (e.g., 1 to 15 mM sodium cholate or glycodeoxycholate) of the major pancreatic duct induces changes in the permeability of the pancreatic duct,[21,22] and sustained elevations in ductal pressure (>40 cm H_2O) and bacterial infection induce pancreatic acinar necrosis.[1,22] Ductal pressures are readily increased by biliary infection, and ductal compression is a predictable consequence of sustained ductal hypertension and pancreatic interstitial edema.[22,23]

Concurrent Gastrointestinal Tract Disease

Like concurrent biliary tract disease, inflammatory bowel disease (IBD) is an important risk factor for the development of ANP in the cat.[18,24] Several factors appear to contribute to this association: (a) High incidence of IBD—IBD is a common disorder in the domestic cat.[24-26] In some veterinary hospitals and specialty referral centers, IBD is the most common GI disorder in cats. (b) Clinical symptomatology of IBD—Vomiting is the most important clinical sign in cats affected with IBD.[24-26] Chronic vomiting raises intraduodenal pressure and increases the likelihood of pancreaticobiliary reflux. (c) Pancreaticobiliary anatomy—The pancreaticobiliary sphincter is a common physiologic and anatomic channel at the duodenal papilla,[19,20] thus reflux of duodenal contents would perfuse pancreatic and biliary ductal systems. (d) Intestinal microflora—Compared with dogs, cats have a much higher concentration of aerobic, anaerobic, and total (10^9 vs. 10^4 organisms/mL) bacteria in the proximal small intestine.[27,28] Bacteria readily proliferate in the feline small intestine because of differences in GI motility and immunology.[29,30] If chronic vomiting with IBD permits pancreaticobiliary reflux, a duodenal fluid containing a mixed population of bacteria, bile salts, and activated pancreatic enzyme would perfuse the pancreatic and biliary ductal systems.[31]

Ischemia

Ischemia (e.g., hypotension, cardiac disease) is a cause or consequence of obstructive pancreatitis in the cat. Inflammation and edema reduce the elasticity and distensibility of the pancreas during secretory stimulation. Sustained inflammation increases pancreatic interstitial and ductal pressure which serves to further reduce pancreatic blood flow, organ pH, and tissue viability.[32-34] Acidic metabolites accumulate within the pancreas because of impaired blood flow.[34-36] Ductal decompression has been shown to restore pancreatic blood flow, tissue pH, and acinar cell function.[35,36]

Pancreatic Ductal Obstruction

Obstruction of the pancreatic duct (e.g., neoplasia, pancreatic flukes, calculi, and duodenal foreign bodies) is associated with the development of ANP in some cases.[9,37] Pancreatic ductal obstruction has marked effects on pancreatic acinar cell function. During ductal obstruction, ductal pressure exceeds exocytosis pressure and causes pancreatic lysosomal hydrolases to colocalize with digestive enzyme zymogens within the acinar cell.[38] Colocalization is the underlying pathogenesis for digestive enzyme activation within the acinar cell because lysosomal enzymes (e.g., cathepsin B) readily activate trypsin.[38]

Infection

Infectious agents (*Toxoplasma gondii*, feline herpesvirus 1, feline infectious peritonitis) have been implicated in the pathogenesis of feline ANP[39-41] although none have been reported as important causes of ANP in any of the recent clinical case series.[1-10,12] The pancreas is readily colonized by *T. gondii* organisms during the acute phase of infection.[39] In one survey of *T. gondii*-infected cats, organisms were found in 84% of the cases, although organ pathology was more severe in other organ systems.[39] *Feline herpesvirus 1*

and feline infectious peritonitis viruses have been implicated as causative agents in several case reports,[40] and feline parvoviral infection is associated with viral inclusion bodies and pancreatic acinar cell necrosis in young kittens.[41] Pancreatic (*Eurytrema procyonis*) and liver fluke (*Amphimerus pseudofelineus*, *Opisthorchis felineus*) infections are known causes of feline ANP in the southeastern United States and Caribbean Basin.[37,42] Recent reports of virulent caliciviral infections have been reported in multiple cat households or research facilities. Affected cats manifest high fever, anorexia, labored respirations, oral ulceration, facial and limb edema, icterus, and severe pancreatitis.[43-45] Caliciviral infection has not been reported in any of the recent clinical case series of feline ANP,[1-10,12] but some cases of active infection could have been overlooked. The importance of calicivirus infection in the pathogenesis of feline acute pancreatic necrosis remains to be determined.

Trauma

Automobile and fall ("high-rise syndrome") injuries are associated with the development of ANP in a small number of cases.[46,47] These tend to be isolated cases that do not show up as important causes in clinical case surveys.

Organophosphate Poisoning

Organophosphate poisoning is a known cause of ANP in humans and dogs,[48] and several cases have been reported in the cat.[2] In one survey, several cats developed ANP following treatment for ectoparasites, and two cats developed ANP following treatment with fenthion.[2] Diminishing organophosphate usage will probably lead to a reduced incidence of this lesion.

Lipodystrophy

Lipodystrophy has been cited as an occasional cause of ANP in the cat,[49] but it has not been reported in any of the large clinical case series.

Hypercalcemia

ANP develops in association with the hypercalcemia of primary hyperparathyroidism and humoral hypercalcemia of malignancy in humans, and a weak association with hypercalcemia has been reported in dogs.[15] Moderate hypercalcemia was found as a preexisting laboratory finding in 10% of the cases of fatal canine acute pancreatitis.[15] Acute experimental hypercalcemia does indeed cause acute pancreatic necrosis and pancreatitis in cats,[50,51] but it is probably not very clinically relevant. Acute hypercalcemia is an uncommon clinical finding in feline practice. Chronic hypercalcemia, a more clinically relevant condition, is not associated with changes in pancreatic morphology or function.[52]

Idiosyncratic Drug Reactions

Therapy with azathioprine, L-asparaginase, potassium bromide, and trimethoprim-sulfa drugs are associated with the development of ANP in the dog.[15,53] Similar associations have not been made in the cat. Glucocorticoid administration has been suggested as a cause of acute pancreatitis in the dog, but a firm association has not been confirmed in either species. Indeed, antiinflammatory doses of glucocorticoids appear to be beneficial in the management of experimental canine acute pancreatic necrosis.[54]

Nutrition

High-fat feedings[55] and obesity[53] are associated with the development of pancreatitis in the dog, but similar associations have not been made in the cat. Most recent surveys associate underweight body condition with the development of feline ANP.[2,6,8,10]

Pathogenesis

The acinar and ductal cells of the exocrine pancreas are interspersed between the islet cells of the endocrine pancreas. Like the endocrine pancreas, the exocrine pancreas is a secretory organ with several physiologic functions. Exocrine pancreatic fluid contains digestive zymogens that initiate protein, carbohydrate, and lipid digestion; bicarbonate and water that serve to neutralize the duodenum; intrinsic factor that facilitates cobalamin (vitamin B_{12}) absorption in the distal ileum; and antibacterial proteins that regulate the small intestinal bacterial flora. Digestive zymogens and antibacterial proteins are secreted primarily by acinar cells, while bicarbonate, water, and intrinsic factor are secreted primarily by ductal cells. The two most common disorders of the exocrine pancreas, acute pancreatic necrosis and EPI, are readily understood on the basis of these physiologic functions. With acute pancreatic necrosis, premature activation of digestive zymogen within pancreatic acinar cells leads to acinar cell necrosis (trypsin, chymotrypsin, carboxypeptidase), hemorrhage (elastase digestion of blood vessel elastin fibers), and fat necrosis and saponification (lipase digestion of pancreatic, peripancreatic, and mesenteric fat). With EPI, affected animals develop severe nutrient maldigestion, acid injury to the duodenal mucosa, cobalamin and fat-soluble vitamin malabsorption, and bacterial proliferation in the gut (summarized in reference 56).

Pancreatic acinar cells protect themselves from intraacinar activation of zymogen and acinar cell necrosis through several mechanisms: (a) Potentially harmful digestive enzymes are synthesized in the form of inactive precursors or zymogens in the rough endoplasmic reticulum. (b) Zymogens are then transported to the Golgi complex where they undergo selective glycosylations. Lysosomal hydrolases that are eventually packaged in lysosomes are separated from zymogens bound for export as they pass through the Golgi complex. Lysosomal hydrolases are first phosphorylated at the six position of mannose residues, bound to receptors specific for 6-phosphoryl mannose, and then transported to lysosomes where the acid pH favors their dissociation from the receptors. Digestive enzymes lack the 6-phosphoryl mannose label, and are instead transported vectorially into a different secretory fraction. (c) Packaging of zymogens into maturing zymogen granules sequesters them from contact with other subcellular fractions. (d) PSTI is incorporated into the maturing zymogen granules. PSTI inactivates trypsin should there be any intraacinar activation of trypsinogen. (e) Following stimulation (e.g., feeding and cholecystokinin secretion), mature zymogen granules and their contents are released from the cell into the ductal lumen in a process of membrane fusion and exocytosis. (f) Finally, zymogens are activated physiologically only after they enter the duodenum, where the brush-border enzyme enteropeptidase activates trypsinogen, and trypsin then activates other pancreatic zymogen (Figure 60-22).[56]

A large body of experimental, and some clinical, evidence suggests that the initiating event of acute pancreatitis is the premature activation of digestive zymogens within the acinar cell.[38,57-60] Premature activation of digestive zymogen results in acinar cell necrosis and pancreatic autodigestion. In acute pancreatic necrosis, protein synthesis and intracellular transport to the Golgi complex appear to be normal, but digestive zymogens then become colocalized along with lysosomal hydrolases in large vacuoles. Cell biology studies reveal that lysosomal and zymogen granule fractions become colocalized through a process known as *crinophagy*, a process used by

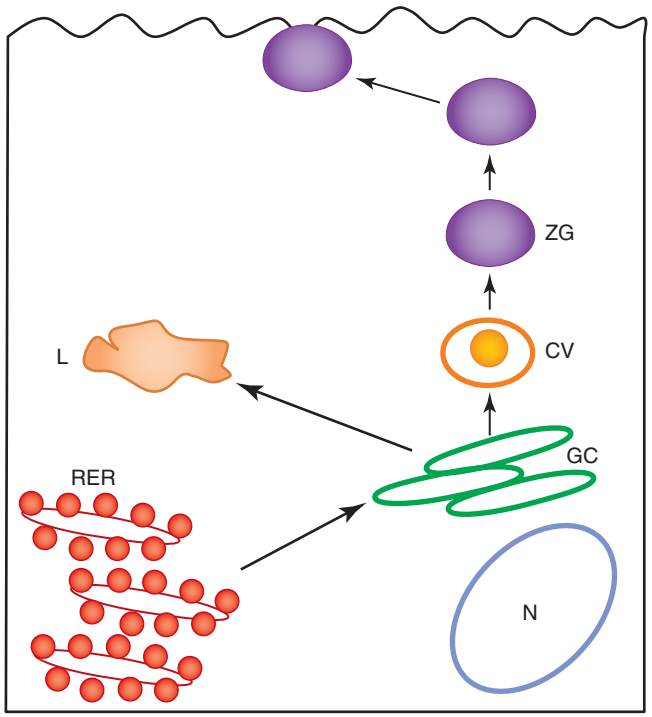

Figure 60-22 Intracellular trafficking of zymogens and lysosomal hydrolases in pancreatic acinar cells. Digestive zymogens and lysosomal hydrolases are synthesized on the rough endoplasmic reticulum (*RER*) and transported to the Golgi complex (GC) where they undergo selective glycosylation. Lysosomal hydrolases are phosphorylated at 6-mannose residues and transported to lysosomes (*L*) via receptors specific for 6-phosphoryl mannose. Digestive enzymes lack the 6-phosphoryl mannose label and are instead transported vectorially into condensing vacuoles (CV). Condensing vacuoles mature into zymogen granules (ZG) whose contents are released into the pancreatic ductal system following feeding. Trypsinogen is converted to active trypsin by intestinal enterokinase, and inactive zymogens are converted to active enzymes by tryptic hydrolysis. *N*, nucleus. (Modified from Steer ML: The early intra-acinar cell events which occur during acute pancreatitis. *Pancreas* 17:31, 1998.)

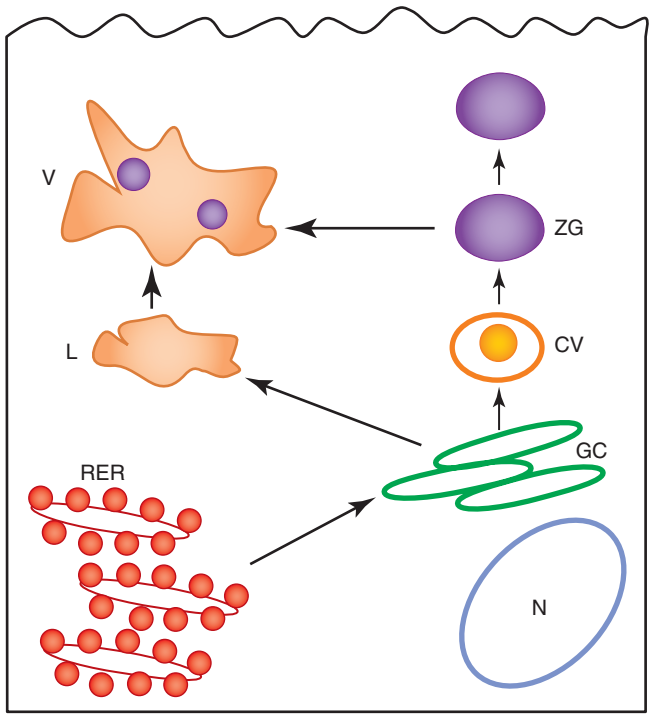

Figure 60-23 Cell biology of pancreatic acinar cell necrosis. Pancreatic enzyme secretion is inhibited and pancreatic zymogens become colocalized with lysosomal hydrolases within large vacuoles (*V*). Lysosomal hydrolases prematurely activate digestive zymogens within pancreatic acinar cells. (Modified from Steer ML: The early intra-acinar cell events which occur during acute pancreatitis. *Pancreas* 17:31, 1998.)

many cells to degrade accumulated secretory products when the need for secretion is no longer present. Although this process takes place in other cells without adverse consequences, it can be lethal in pancreatic acinar cells because of the peculiarity of their secretion products (digestive zymogens). Lysosomal hydrolases, such as cathepsin B and *N*-acetyl glucosaminidase, activate trypsinogen to the active trypsin form, and the enhanced fragility of these large vacuoles permits release of active enzyme into the cell cytoplasm (Figure 60-23). Trypsin acts autocatalytically to activate other trypsinogen molecules and other zymogens, each inducing a unique chemical pathology in pancreatic and extrapancreatic cells. A variety of inflammatory mediators and cytokines, interleukins, nitric oxide, and free radicals are involved in the further evolution of pancreatic acinar cell necrosis and inflammation and often determine the outcome.[56,61-64] Thus, a bout of pancreatitis begins with an *initiating event*, for example, ischemia, inflammation, or ductal obstruction, followed by *acinar events*, that is, colocalization, enzyme activation, and cell injury, the outcome of which is influenced by *severity determinants*, for example, inflammatory cytokines, reactive oxygen species, altered oxidation-reduction state, and apoptosis (Figure 60-24).[63] The further evolution of acute pancreatic necrosis to a SIRS and multiple organ dysfunction syndrome is determined by the balance of proinflammatory and antiinflammatory cytokines (Figure 60-25).[64]

Clinical Signs

History

Siamese cats were initially reported to be at increased risk for the disease in one of the first retrospective studies of feline pancreatitis.[2] Clinical case surveys of the past 10 years suggest that most cases of feline pancreatitis are seen in the Domestic Shorthair breed.[1-10,12] Anorexia (87%) and lethargy (81%) are the most frequently reported clinical signs in cats with acute pancreatitis, but these clinical signs are not pathognomonic for pancreatitis (Table 60-2). Anorexia and lethargy are the most important clinical signs in many feline diseases. Gastroenterologic signs are sporadic and less frequently reported in the cat. Vomiting and diarrhea are reported in only 46% and 12% of cases, respectively.[2-7,9,10,12] In dogs, vomiting (90%) and diarrhea (33%) appear to be more important clinical signs.[15,31,53]

Physical Examination Findings

Physical examination findings in cats with ANP (Table 60-3) include dehydration (54%), hypothermia (46%), icterus (37%), fever (25%), abdominal pain (19%), and abdominal mass (11%).[2-7,9,10,12] These findings suggest that a "classic textbook" description of acute pancreatitis (e.g., vomiting, diarrhea, abdominal pain, and fever) is not consistently seen in the domestic cat. Many of these physical examination findings are more commonly reported in canine acute pancreatitis. Abdominal pain (58% in dogs; 19% in cats) and fever (32% in dogs; 25% in cats), for example, are more commonly reported in dogs with acute pancreatitis.[15,31,53]

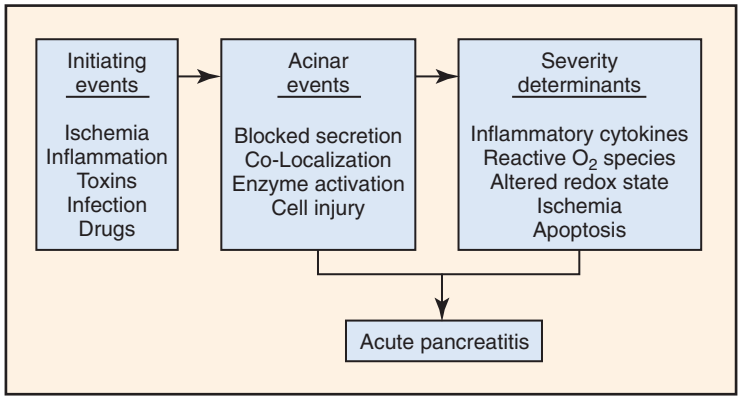

Figure 60-24 The three phases of acute pancreatitis. Pancreatic necrosis begins with an initiating event (e.g., ischemia, inflammation, or ductal obstruction), followed by acinar events (e.g., colocalization, enzyme activation, and cell injury), the outcome of which is influenced by severity determinants (e.g., inflammatory cytokines, oxygen free radicals, ischemia, and apoptosis). (Modified from Steer ML: The early intra-acinar cell events which occur during acute pancreatitis. *Pancreas* 17:31, 1998.)

Differential Diagnosis

The major differential diagnoses for feline ANP include GI foreign body, IBD, alimentary lymphoma, infectious gastroenteritis, GI intussusception and neoplasia, cholangitis, biliary tract neoplasia, and various forms of liver and biliary tract pathology.

Diagnosis

As with the same condition in the dog, diagnosis of ANP requires the careful integration of historical, physical examination, clinicopathologic, and imaging findings. Where appropriate, additional diagnostic support may be obtained at the time of laparoscopy or exploratory laparotomy. Diagnosis should not be made on the basis of a single laboratory or imaging finding.

Laboratory Findings

In cats affected with ANP, laboratory abnormalities (Tables 60-4 and 60-5) have included normocytic, normochromic, regenerative or nonregenerative anemia (38%), leukocytosis (46%), leukopenia (15%), hyperbilirubinemia (58%), hypercholesterolemia (72%), hyperglycemia (45%), hypocalcemia (65%), hypoalbuminemia (36%), and elevations in serum alanine aminotransferase (57%) and alkaline phosphatase (49%) activities.[2-7,9,10,12] Changes in red blood cell counts, serum activities of liver enzymes, and serum concentrations of bilirubin, glucose, and cholesterol are fairly consistent findings in feline ANP, just as they are in dogs.[15,31,53] Important differences between cats and dogs appear to be reflected in white blood cell counts and serum calcium concentrations. Leukocytosis is a more important clinical finding in the dog (62% in dogs; 46% in cats).[15,31,53] Leukopenia is sometimes seen instead of leukocytosis in cats, and a worse prognosis has been attributed to leukopenia in the cat.[2,5,7,10,12] Hypocalcemia also appears to be a more frequent finding in cats (3% to 5% in dogs[15,53]; 45% to 65% in cats[2,5,6,10,12]). Hypocalcemia (total and serum ionized) may result from several mechanisms, including

acid–base disturbances, peripancreatic fat saponification, and parathormone resistance.[65] Regardless of the mechanism, hypocalcemia appears to confer a worse clinical prognosis in cats.[6,10] This finding suggests that cats should be monitored fairly closely for the development of hypocalcemia and treatment should be initiated, accordingly.

Table 60-5 Serum Biochemical Findings in Cats Affected with Acute Necrotizing Pancreatitis

Special Tests of Pancreatic Function

Lipase and Amylase Activity Assays

Serum lipase activities are elevated in experimental feline pancreatitis,[66,67] but serum lipase and amylase activities do not appear to be elevated or of clinical value in the diagnosis of clinical pancreatitis.[68] Serum lipase activity may still have some clinical utility in the diagnosis of ANP in the dog.[15,69] Assays of serum lipase activity are complicated by the fact that there may be as many as five different isoenzymes circulating in the blood[70]; consequently general serum lipase activity assays have been superseded by the development of pancreatic lipase immunoreactivity assays (e.g., cPLI, fPLI).[70,71]

Trypsin-like Immunoreactivity

Serum TLI mainly measures trypsinogen but also detects trypsin and some trypsin molecules bound to proteinase inhibitors.[70] TLI assays are species-specific, and different assays for feline (fTLI) and canine (cTLI) have been developed and validated.[72] Serum TLI concentration is the diagnostic test of choice for feline EPI because it is highly sensitive and specific for this disease in the cat.[11] The use of this test in the diagnosis of feline ANP is less clear. Serum TLI concentrations are transiently elevated in experimental feline acute pancreatitis,[73] but elevations in clinical cases are less consistently seen.[5,7,68] The poor sensitivity (i.e., 33%) of this test precludes its use as a definitive assay for feline ANP.

Trypsinogen Activation Peptide

When trypsinogen is activated to trypsin, a small peptide, TAP, is split from the trypsinogen molecule. Under normal conditions, activation of trypsinogen takes place only in the small intestine and

TAP is undetectable in the blood. During pancreatitis, trypsinogen is activated prematurely in pancreatic acinar cells and TAP is released into the vascular space.[71] Urine TAP assays have shown some promise in experimental models of feline pancreatitis,[74] but serum and urine TAP assays are less promising in clinical studies.[75] Evidence-based data is needed to determine the true specificity and sensitivity of this assay.

Pancreatic Lipase Immunoreactivity

ELISA and radioimmunoassays for the measurement of PLI have been developed and validated in the cat.[76] fPLI elevations have been cited in preliminary reports of experimental[73] and clinical[12] feline ANP, but the true sensitivity and specificity of fPLI in the diagnosis of feline ANP have not yet been reported. As with fTLI assays, there are false positives and false negatives with fPLI in the diagnosis of feline ANP.

Imaging Findings

Radiography

The radiographic findings of feline ANP have not been very well characterized. The radiographic hallmarks of canine acute pancreatitis (e.g., increased density in the right cranial abdominal quadrant, left gastric displacement, right duodenal displacement, and gas-filled duodenum/colon)[15,77] have not been substantiated in the cat. Indeed, in several recent reports, many of these radiographic findings were not reported in cats with documented acute pancreatic necrosis.[1-10,12] In spontaneous clinical cases, hepatomegaly and abdominal effusion may be the only radiographic findings in some cases of feline ANP.[1-10,12]

Ultrasonography

Enlarged, irregular, and/or hypoechoic pancreas; hyperechogenicity of the peripancreatic mesentery; and peritoneal effusion have been observed with abdominal ultrasonography in many cats with spontaneous acute pancreatitis (Figure 60-26).[8,10,12,78] The specificity of this imaging modality appears to be high (>85%), but the sensitivity has been reported as low as 35% in some studies.[5,7,8,78] The low sensitivity suggests that imaging the pancreas in cats with pancreatitis is technically more difficult than imaging the pancreas in dogs or that the ultrasonographic appearance of pancreatitis in cats differs from that reported for dogs. Other potential ultrasonographic findings include corrugation of the duodenum, fluid/gas distended, hypomotile intestines (indicative of paralytic ileus), and ultrasonographic signs of extrahepatic biliary obstruction.[8,79-81]

Endosonography

Endosonography has been used to confirm the diagnosis of feline ANP in a small series of patients, but it appears to confer no additional advantage over routine transabdominal ultrasonography.[82]

Computed Tomography

CT scanning appears to be useful in identifying the normal structures of the healthy feline pancreas,[83] but preliminary clinical reports are somewhat disappointing.[7,12] The sensitivity of CT scanning in detecting lesions consistent with feline ANP may be as low as 20%.[7,12] Additional study is needed to determine the specificity and sensitivity of this imaging modality in the diagnosis of feline ANP.

Biopsy

If clinically indicated, pancreatic biopsy may be obtained by laparoscopy[84] or exploratory laparotomy. Clinicians should always bear in mind that many pancreatitis patients are poor anesthesia risks.

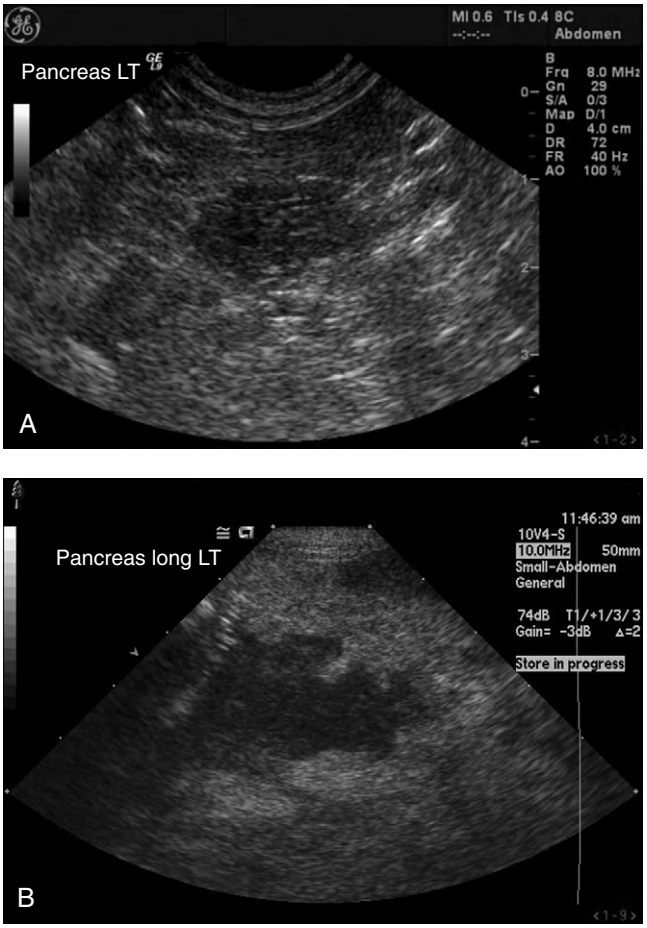

Figure 60-26 Ultrasonographic findings of feline acute necrotizing pancreatitis. A, The pancreas is severely enlarged and hypoechoic, with surrounding hyperechoic mesentery. **B,** Ultrasonographic findings of feline chronic necrotizing pancreatitis. The left lobe of the pancreas is irregularly thickened and hypoechoic.

Gross observation at the time of laparoscopy or exploratory laparotomy may confirm the diagnosis of ANP. In equivocal cases, biopsy may be safely performed as long as blood flow is preserved at the site of the biopsy. Single biopsy may be insufficient to exclude subclinical pancreatitis as inflammation of the canine pancreas occurs in discrete areas within the pancreas rather than diffusely throughout the whole organ.[85] Similar findings are reported in feline ANP.[2] Inspection of other viscera (e.g., intestine, biliary tract, liver) at the time of laparoscopy or exploratory laparotomy is of paramount importance in the cat because of the high rate of disease concurrence in this species.[2,3,9,10,18,24,25,84]

Species Differences

There are many important species differences between dogs and cats with regard to the clinical course and pathophysiology of acute pancreatic necrosis (summarized in Table 60-6 and reference 31). Fever, leukocytosis, vomiting, and abdominal pain are important physical examination findings in dogs with ANP, but these are relatively infrequent findings in cats with ANP. Cats more often have hypothermic reactions, and they may not necessarily manifest the classic gastroenterologic signs (e.g., vomiting, diarrhea, abdominal pain) reported in dogs. The imaging findings in cats are also less

Table 60-6 Clinical Difference between Feline and Canine Acute Necrotizing Pancreatitis

	Feline	Canine
Vomiting	46%	90%
Diarrhea	12%	33%
Fever	25%	32%
Abdominal pain	19%	58%
↑ White blood cell counts	46%	62%
↓ Calcium	65%	5%
Radiography	Not useful	Somewhat useful
Inflammatory bowel disease	Strong association	Weak association

subtle than what has been reported in dogs; the classic radiographic hallmarks of canine ANP have not reported in the cat. Cats have a greater incidence and severity of hypocalcemia following bouts of acute pancreatic necrosis. Serum total and/or ionized hypocalcemia is significantly reduced in 45% to 65% of affected cats, whereas hypocalcemia is reported in only 5% of affected dogs. The pathogenesis of hypocalcemia in cats with ANP is incompletely understood, but it does carry a significantly worse prognosis for recovery.[6] Prior GI tract disease confers slight increased risk for the development of acute pancreatic necrosis in the dog[15,53]; this is especially true of the cat.[2,10,18,24,25]

Therapy

Supportive care continues to be the mainstay of therapy for feline acute pancreatitis (Box 60-3). Efforts should be made to identify and eliminate any inciting agents; sustain blood and plasma volume; correct acid–base, electrolyte, and fluid deficits; and treat any complications that might develop. Important life-threatening complications of acute pancreatitis in cats include hypocalcemia, DIC, thromboembolism, cardiac arrhythmia, sepsis, acute tubular necrosis, pulmonary edema, and pleural effusion.

Historically, a short period of food and water fasting has been recommended for cats with ANP. This recommendation should be applied only in those instances in which there is severe vomiting and risk for aspiration pneumonia. As obligate carnivores, cats develop fat mobilization and hepatic lipidosis during prolonged starvation. Moreover, recent studies suggest that it may be appropriate and necessary to stimulate pancreatic secretion (via feeding) in affected animals.[57-60] Esophagostomy, gastrostomy, and enterostomy tubes may be placed to facilitate nutrition in anorectic animals.

Box 60-3 General Principles in the Treatment of Feline Acute Necrotizing Pancreatitis

1. Eliminate the inciting agent
2. NPO *only* if severe nausea and vomiting
3. Intravenous fluids
4. Supportive therapy—plasma 10 mL/kg
5. Relieve pain—meperidine, butorphanol
6. Antiemetics—α_2-adrenergic antagonists, 5-HT_3 serotonergic antagonists, NK_1 neurokinin antagonists
7. Calcium gluconate supplementation
8. H_1- and H_2-histaminergic receptor antagonists
9. Low-dose dopamine infusion—5 µg/kg/min
10. Broad-spectrum antibiotics
11. Ductal decompression

Other therapies that may be of some benefit in the treatment of this disorder include:

- Relief of pain: Analgesic agents should be used when abdominal pain is suspected. Most cats do not manifest clinical signs of abdominal pain, but clinicians inspect for it. Meperidine at a dose of 1 to 2 mg/kg administered intramuscularly or subcutaneously every 2 to 4 hours or butorphanol at a dose of 0.2 to 0.4 mg/kg administered subcutaneously every 6 hours has been recommended.[86]
- Antiemetic agents: Nausea and vomiting may be severe in affected animals. The α_2-adrenergic antagonists and 5-HT_3 antagonists are somewhat effective antiemetic agents in the cat.[87] Cats may be treated with chlorpromazine (α_2-adrenergic antagonist) at a dose of 0.2 to 0.4 mg/kg administered subcutaneously or intramuscularly every 8 hours, or with any of the 5-HT_3 antagonists (ondansetron 0.1 to 1.0 mg/kg, granisetron 0.1 to 0.5 mg/kg, or dolasetron 0.5 to 1.0 mg/kg, orally or intravenously every 12 to 24 hours). Dopaminergic antagonists, for example, metoclopramide, are less-effective antiemetic agents in the cat.[87] NK_1 receptor antagonists (e.g., maropitant) have been used in the cat (see Chapters 23 and 35), but their comparative efficacy is still unknown.[88]
- Calcium gluconate supplementation: Hypocalcemia is a frequent complication of feline ANP and is associated with a worse prognosis.[6] Calcium gluconate should be given at doses of 50 to 150 mg/kg intravenously over 12 to 24 hours and serum total or ionized calcium concentrations should be monitored during therapy.
- H_1- and H_2-histamine antagonists: Histamine and bradykinin-induced increases in microvascular permeability are associated with the development of hemorrhagic necrosis in experimental feline pancreatitis.[89] Treatment with H_1 (mepyramine, 10 mg/kg) and H_2 (cimetidine, 5 mg/kg; ranitidine, 1 to 2 mg/kg; famotidine, 0.5 to 1.0 mg/kg) histamine-receptor antagonists protects against the development of hemorrhagic pancreatitis in these models.[89] Efficacy has not been established in clinical pancreatitis, but the use of these drugs in suspected or proven clinical cases would appear to have some rationale as they are associated with few side effects. Diphenhydramine (2 to 4 mg/kg) or

dimenhydrinate (4 to 8 mg/kg) are examples of clinically used H_1-histamine receptor antagonists. Cimetidine (5 mg/kg), ranitidine (1 to 2 mg/kg), famotidine (0.5 to 1.0 mg/kg), and nizatidine (2.5 to 5.0 mg/kg) are examples of clinically used H_2-histamine receptor antagonists.

- Low-dose dopamine infusion: Low-dose dopamine infusion (5 µg/kg/min) improves pancreatic blood flow and reduces microvascular permeability in feline experimental pancreatitis.[67] Low-dose dopamine infusion is effective treatment in experimental pancreatitis even when it is given up to 12 hours after induction of the disease.[67] Part of the appeal of dopamine as a potential treatment for feline pancreatitis lies in the diversity of its actions. Dopamine's effect on the kidney in promoting renal blood flow and urinary output, and its cardiac inotropic effect make it a useful agent, although it has not yet been studied in controlled clinical trials.
- Broad-spectrum antibiotics: ANP may begin as a sterile process, but necrosis and inflammation predispose to colonic bacterial translocation and colonization of the pancreas.[90,91] *Escherichia coli* and other coliforms are the principal pathogens.[90,91] High colonization rates suggest that bacteria may spread to the inflamed pancreas more frequently than is currently thought, and that broad-spectrum antibiotics may be appropriate in suspected cases of feline acute pancreatitis. Cefotaxime at a dose of 50 mg/kg administered intramuscularly every 8 hours prevents bacterial colonization of the pancreas.[92]
- Ductal decompression: Surgical decompression of the pancreaticobiliary duct should be considered in cases of acute ductal obstruction, for example, calculus, neoplasia, and fluke infection. Ductal decompression may also be useful in acute cases that have progressed to the more chronic form of the disease. Ductal decompression restores pancreatic blood flow, tissue pH, and acinar cell function.[35,36]

Prevention

In cases in which IBD is the underlying pathogenesis of ANP, therapy should be directed toward regulation of the IBD. The five components of feline IBD therapy are dietary modification, antibiotics, probiotics, antidiarrheal agents, and immunosuppressive therapy.[93]

Complications of Acute Necrotizing Pancreatitis

Chronic Nonsuppurative Pancreatitis

Recurring bouts of ANP may progress to a chronic nonsuppurative form of the disease. This chronic form of pancreatitis has generally been held to be of lesser clinical severity, lower mortality, and better long-term prognosis.[1] More recent reports suggest, however, that chronic pancreatitis cannot be differentiated from acute pancreatitis by clinical, clinicopathologic, or imaging findings.[10] The clinical signs, laboratory data, and imaging findings are indistinguishable between the two groups. Histopathology remains the only dependable method of differentiating acute and chronic pancreatitis. Not surprisingly, cats with chronic pancreatitis more frequently have concurrent systemic disease (e.g., cholangitis, IBD) compared with cats with acute pancreatitis.[10]

Exocrine Pancreatic Insufficiency

EPI is an uncommon cause of chronic diarrhea in cats. Insufficiency results from failure of synthesis and secretion of pancreatic digestive enzymes. The natural history of feline EPI is poorly understood, but most cases are believed to result from chronic pancreatitis, fibrosis, and acinar atrophy. As with dogs, clinical signs reported in cats with EPI include weight loss, soft voluminous feces, and ravenous appetite. Affected cats may have an antecedent history of recurring bouts of acute pancreatitis (e.g., anorexia, lethargy, vomiting) culminating in chronic pancreatitis and EPI.

The diagnosis of EPI in cats has been technically difficult. Clinical signs in affected cats are not pathognomonic for EPI, clinicopathologic data are fairly nonspecific, imaging findings are inconsistent, and the severity of pancreatic histologic changes are not always directly related to the severity of clinical signs. Serum TLI is believed to be diagnostic of the disease.[11,17] In that study, TLI concentrations less than 8 µg/L (reference range: 17 to 49 µg/L) were reported in 27 of 30 cats with clinical signs compatible with EPI (e.g., weight loss, loose voluminous feces, greasy soiling of the hair coat) and at least one other finding, for example, decreased fecal proteolytic activity, exploratory laparotomy or necropsy findings compatible with EPI, or favorable response to pancreatic enzyme replacement therapy.[11,17] Cats affected with EPI have predictable serum cobalamin deficiency because of pancreatic intrinsic factor deficiency and cobalamin malabsorption.[94] Therapy should include subcutaneous vitamin B_{12} injections (100 µg subcutaneously every 3 to 4 weeks) in addition to pancreatic replacement enzymes.

Hepatic Lipidosis

ANP is but one of many examples in which anorexia or starvation predisposes an obligate carnivore to the syndrome of fat mobilization and hepatic lipidosis.[1,3,95] The concurrence of these two syndromes is a particularly poor prognostic sign in that affected cats have high morbidity and mortality rates. This emphasizes the importance of early interventions in the treatment of pancreatitis before the development of the metabolic syndrome of hepatic lipidosis.

Diabetes Mellitus

Several studies have related severe chronic pancreatitis to the development of diabetes mellitus.[1,4,10,11] ANP per se may not necessarily be a risk factor for the development of diabetes mellitus, but disease progression to the chronic nonsuppurative form may increase that risk.

ABSCESS, NECROSIS, PSEUDOCYST, PHLEGMON, AND INFECTION

Michael Schaer

Pancreatic Abscess and Necrosis

Definition

Abscess and necrosis are discussed together in this section because abscess formation is always preceded by necrosis, although necrosis is not always followed by abscess formation. In 1992 the International Symposium on Acute Pancreatitis defined pancreatic necrosis as the presence of one or more diffuse or focal areas of nonviable pancreatic parenchyma.[1] Pancreatic glandular necrosis is usually associated with necrosis of peripancreatic fat. By definition, pancreatic necrosis represents a severe form of acute pancreatitis (Figures 60-27 and 60-28).[2] Pancreatic abscess is a collection of purulent and necrotic pancreatic tissue (Figure 60-29). Abscessation forms if an episode of pancreatitis is severe enough to cause parenchymal

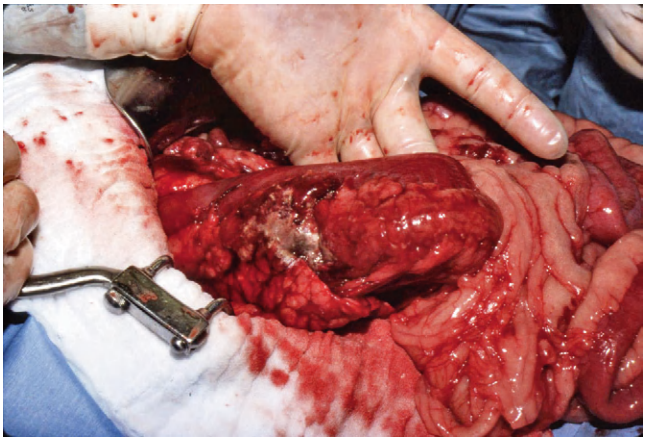

Figure 60-27 Surgical view of focal pancreatic necrosis in a dog.

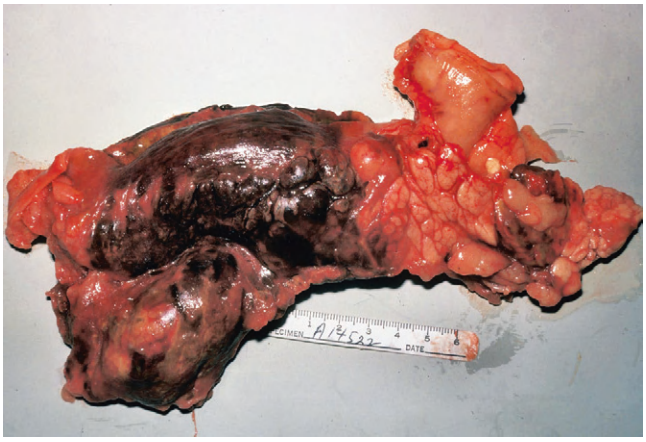

Figure 60-28 A postmortem depiction of severe ischemic necrosis of the pancreas and parapancreatic lymph node.

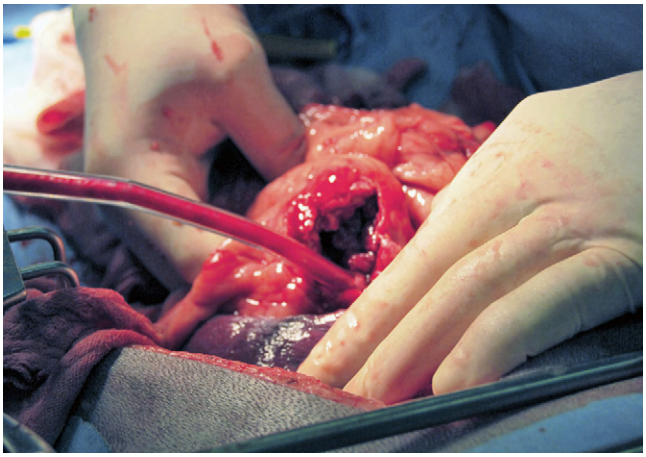

Figure 60-29 Pancreatic abscess at surgery.

necrosis.[3] In some cases, necrotic tissue is secondarily infected by bacteria. There can be multiple foci of necrotic debris rather than a recognizable discrete abscess cavity. In humans, a pancreatic abscess can also be caused by secondary infection of a pseudocyst, but the latter pathogenesis is apparently rare in dogs and cats.

Incidence

Pancreatic abscess is infrequently reported in the veterinary literature,[4] with only 73 total case reports in five separate references , most of which were reported in dogs.[5-9] The largest report of pancreatic abscess described clinical findings in 36 dogs.[9] Mortality numbers were high and ranged from 50% to 86%, but this parallels the high mortality that occurs in all cases of severe necrotic pancreatitis with and without secondary infection. Although viewed as a sequel to acute pancreatitis in some cases, abscess can be a continuation of a single severe inflammatory process with accompanying necrosis that becomes more clinically apparent in the dog 1 to 2 weeks after disease onset.

History and Physical Examination Findings

There is nothing particularly pathognomonic for pancreatic abscess in the dog. The history will always show a sudden onset of mental depression, anorexia, vomiting, and lethargy. Certain "triggers" of acute pancreatitis might be present, such as the ingestion of a fatty meal or other potential causes such as hyperlipidemia, hypercalcemia, or the ingestion of certain drugs such as potassium bromide.[10] Animals with hemorrhagic and necrotic acute pancreatitis are usually critically ill, and may have a spectrum of clinical signs including vomiting, abdominal pain, lethargy, diarrhea, and hypovolemia. Abdominal pain is often reflective of peritonitis that is associated with pancreatitis, but this sign might not be present in a recumbent patient in the advanced stages of acute necrotic pancreatitis. Icterus is seldom present acutely but may evolve with progressive cholestasis. Body temperature ranges from high fever to hypothermic reactions with hypothermia commonly reflecting an advanced decompensated stage of the systemic inflammatory response. Abdominal distention is usually caused by inflammatory ascites characterized as a sterile inflammatory exudate in most cases. Ileus is also present and contributes to abdominal distention. It is not uncommon for these dogs to be prostrate upon initial examination reflecting their grave status.

Clinicopathologic Features

There is nothing in the clinicopathologic profile that distinguishes pancreatic abscess from necrotizing pancreatitis.[3,5,7,9,11] In Anderson's review, anemia occurred in nine of 36 dogs and was likely associated with the anemia of inflammation.[9] Leukocytosis occurred in 25 of 36 dogs and this was likely caused by the systemic inflammatory response. Of these, 25% had increased circulating immature white blood cells. The leukopenia that was reported in three dogs should be seen as a grave sign associated with either insufficient bone marrow production, sequestration of white blood cells in the area of severe inflammation, or both.

Coagulation testing will yield variable responses. Acute pancreatitis itself may cause platelet consumption and thrombocytopenia in some patients. This was seen in 10 of 36 cases in Anderson's review.[9] Prolongations in the PT and activated partial thromboplastin times can occur in severe cases of acute pancreatitis often times reflecting DIC. This latter complication is thought to be an ominous sign if the parameters do not normalize after intense treatment.

Serum chemistry abnormalities accompanying pancreatic abscess cannot be distinguished from those reported in dogs with acute pancreatitis. Reported abnormalities include hypoproteinemia associated with plasma protein leakage into the abdominal cavity ("third spacing"); hyperglycemia (with or without ketoacidosis) as a result of relative insulin insufficiency; hypoglycemia secondary to sepsis or endotoxemia; hypocalcemia associated with hypoalbuminemia and saponification; elevated liver enzymes with or without

hyperbilirubinemia occurring as a result of cholestasis; and normal or below normal concentrations of serum sodium and potassium. Increases in renal parameters (BUN and serum creatinine) reflect a more guarded prognosis if acute renal failure has occurred.

Increases in the serum amylase and lipase concentrations can be present in some cases, but neither of these tests are sensitive or specific for this condition. They might even be normal by the time a pancreatic abscess has formed because of the failure of a damaged pancreas to produce digestive enzymes. Canine and feline pancreatic-specific lipase (cPLI, fPLI) tests have not proved useful in the diagnosis of pancreatic abscess. More discussion about clinicopathologic changes may be found in the section on pancreatic phlegmon.

Abdominal fluid is commonly present in hemorrhagic and necrotizing acute pancreatitis. The fluid is usually exudative but sterile.[12] Pancreatic infection occurs more commonly in humans than in dogs and cats, and in humans it is associated with a guarded to grave prognosis. Sterile cultures in dogs and cats might result from prior treatment with antibiotics. In Anderson's study,[9] two of 13 cases of necrotic pancreatitis were positive for bacterial (*Staphylococcus saprophyticus* and *Klebsiella pneumoniae*) infection while cultures of the abdominal fluid of 12 dogs were positive for bacteria in seven animals (*E. coli*, *Enterococcus*, *Pseudomonas*, *Streptococcus*, and *Bacteroides*). Johnson's review of 15 dogs detected *Staphylococcus epidermidis* in three dogs, but these were interpreted as contaminants.[7] Salisbury's review of six cases makes no mention of bacterial isolation.[5]

Diagnostic Imaging

Radiographic and ultrasonographic pancreatic abnormalities have been reported in dogs with pancreatic abscess, but there are no distinctive features for pancreatic abscess formation when compared with other forms of severe acute pancreatitis. Abdominal radiographs will show an increased fluid pattern in the anterior abdomen that can be diffuse or more localized to the upper right abdomen. This will cause a loss of serosal detail and occasionally a mass effect with organ displacement.

Chest radiographs are usually normal or they might show a pleural effusion consistent with migration of pancreatic fluid into the thoracic cavity and development of serositis. Acute pancreatitis is one cause of the acute respiratory distress syndrome that appears as a diffuse "whiteout" caused by diffuse alveolar infiltrates.

Abdominal ultrasonography usually reveals cavitation of a pancreatic abscess, but it is not readily distinguished from pancreatic pseudocyst or pancreatic phlegmon. In the Anderson study, only one dog had a nondiagnostic study while 26 of 27 dogs had abnormal pancreatic appearance described as hypoechoic, hyperechoic, or mixed echoic patterns (Figure 60-30). Fourteen of the 26 dogs had a "mass effect." Although the mass effect can be caused by an abscess, the same can be described for pancreatic phlegmon or any other combined effects caused by inflammation and adhesions. Abdominal ultrasound does give the radiologist an opportunity to do a transabdominal fine-needle aspiration biopsy of any abnormal abdominal tissue and tissue fluid for bacterial culture and cytology.

Treatment

Most patients will have been treated medically in intensive care for 7 to 14 days before any decision for surgery is made. The extent of sophisticated patient monitoring will be individualized according to the particular facility, the skill of the attending clinician, and the financial restrictions imposed by the pet owner. The medical treatment of many acute pancreatitis patients will require an intensive

Figure 60-30 Abdominal ultrasound examination showing pancreatic abscess.

care setting because it entails meticulous parenteral fluid therapy, analgesics, plasma transfusions, and continuous patient monitoring. Pressor drugs might be necessary to stabilize the hypotensive patient that does not respond well to parenteral fluid therapy. Antibiotics are often administered because of concern about infection caused by transcolonic bacterial migration or the demonstration of bacteria on cytologic examination of a sample of the abdominal fluid.[13] Today, however, the routine use of antibiotics for severe ANP without the demonstration of sepsis is not recommended in human medicine because of a lack of influence on outcome between treated and untreated patient populations.[14-17] Glucocorticoid drugs might be of theoretical benefit because of their antiinflammatory effects, but they might predispose the patient to secondary infection that could have catastrophic effects. Antiemetic agents should be used in those patients that have multiple vomiting episodes per day, but attention to side effects should be made along with the necessary dosage adjustments. Many patients lack nutrition support for the first several days, and eventually require either total parenteral nutrition or jejunostomy tube feedings. The patient with pancreatic abscess and severe necrotizing pancreatitis frequently shows few signs of clinical improvement during the first week. A repeated abdominal ultrasound examination at that time will show the same or worsened abdominal abnormalities. In humans, the decision for abdominal surgery is made on the basis of continuing worsening clinical condition, the need for jejunostomy tube placement, the need to grossly assess the degree of pathology within the abdomen, the demonstration of infected pancreatitis.[18,19]

The accepted principles of surgical management of necrotizing pancreatitis are the removal of the necrotic pancreatic and peripancreatic tissue (necrosectomy), as well as providing drainage of ascites from the peritoneal cavity [2,7,9,11,18,19] Conventional drainage involves necrosectomy with placement of standard surgical drains and reoperation as required. Open or semiopen management involves necrosectomy and either scheduled repeated laparotomies or open packing, which leaves the abdominal wound exposed for frequent changes of dressing. Closed management involves necrosectomy with extensive intraoperative lavage of the pancreatic bed. The abdomen is closed over large-bore drains for continuous high-volume postoperative lavage.[20] Most surgeons in human medicine have abandoned the conventional surgical approach to debridement, as inadequately removed necrotic tissue becomes or remains infected, resulting in significant mortality as high as 40%.[21]

Johnson et al. compared the treatment of pancreatic abscesses via surgical omentalization with abdominal closure versus open

peritoneal drainage in 15 dogs.[7] Five of the eight dogs treated with omentalization survived while only one of four dogs treated with open peritoneal drainage survived. The other three dogs either died or were euthanized.

All 36 dogs with pancreatic abscess in the Anderson study went to surgery. The pancreas was debrided in 13 dogs and partial pancreatectomies were performed in three others. Duodenostomy tubes were placed in three dogs, and seven dogs received jejunostomy tubes. Sump-Penrose drains were placed in three dogs, and 11 were managed with open peritoneal drainage. Overall, 23 of the 36 dogs had one surgery and 13 of 36 had multiple surgeries. Multiple surgical procedures did not influence outcome nor was there any difference in outcome between dogs managed with open abdominal drainage or Sump-Penrose drainage and those managed with primary closure.[9]

Conclusion

The diagnosis of pancreatic abscess will usually not be made until the patient goes to surgery. This particular patient will be one that does not respond well to the standard of care for treating acute pancreatitis and may have evidence of a mass effect on abdominal imaging. The length of hospitalization is substantial, the risks of surgery rather daunting, the cost to the pet owner is often staggering, and the prognosis is fair to grave.

Pancreatic Pseudocyst

Definition and Incidence

A pancreatic pseudocyst is a collection of enzyme-rich pancreatic fluid containing variable amounts of tissue debris and blood. It results from autodigestion and liquefaction of pancreatic tissue during severe pancreatitis and is highly associated with necrosis and hemorrhage. A pseudocyst is not a true cyst in that it is lined by inflammatory tissue instead of epithelium.[3] It is an uncommon sequel to acute pancreatitis in humans, and is rare in the dog and cat.[22] In humans, a pancreatic pseudocyst can resolve spontaneously or it can rupture into the abdominal cavity with potentially life-threatening consequences. Complications in humans include infection, rupture into the peritoneal cavity, and acute hemorrhage. There are only a few case reports of this condition in the dog[22-25] and one in the cat.[26]

History and Physical Examination

Because this condition is a sequel to acute pancreatitis, the initial signs will represent the primary illness and be characterized by any combination of signs including vomiting, anorexia, fever, dehydration, abdominal tenderness, lethargy, mental depression, and occasionally diarrhea.[22] The acute pancreatitis can resolve uneventfully, or it can culminate in a pseudocyst over a period of a weeks. A small cyst might not cause any clinical signs, but a large mass will cause abdominal discomfort and displacement of abdominal organs. Additional signs reported in the literature include vomiting, diarrhea, anorexia, abdominal pain, and a palpable abdominal mass.[23,24]

Clinicopathologic Findings

The laboratory features of pancreatic pseudocyst will vary from normal to those similar to acute pancreatitis. Normal or minimally abnormal test results will depend on the time proximity to the most recent bout of pancreatitis. Minimal abnormalities will be present if the pseudocyst forms after the inflammatory phase has ceased. This trend would also pertain to serum pancreatic enzyme activities (amylase, lipase) or concentrations (cPLI).

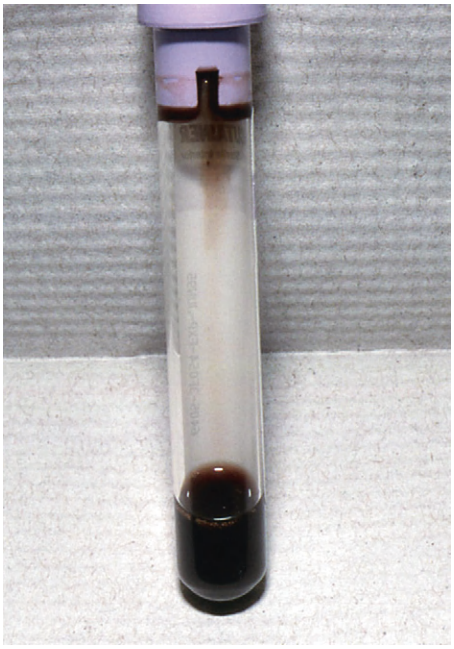

Figure 60-31 Pancreatic pseudocyst fluid containing amorphous debris.

A sample of the cystic fluid can be obtained by ultrasound-guided fine-needle aspiration. The character of the fluid will vary, especially if it is infected. Sterile cyst fluid can vary from being thin to viscous depending on the amount of necrotic debris present (Figure 60-31). In humans, the cyst can contain high concentrations of amylase and lipase, especially if the cyst is connected to the pancreatic duct. The cyst fluid from the canine case reported by Smith et al. contained high concentrations of amylase, lipase, and TLI.[22] This finding has been reported in other canine cases.[27] The cytologic features of the pancreatic cyst fluid can range from minimal cellularity to that of increased cellularity that reflects an inflammatory component. The latter finding in a clinically ill patient with fever might prompt a more aggressive treatment strategy including laparotomy.

Diagnostic Imaging

Pancreatic pseudocyst might have the radiographic appearance of a mass with fluid density in the area of pancreas. Large cysts will displace adjacent abdominal viscera. Radiographs will not distinguish pseudocyst from the inflammation pattern typical of acute pancreatitis. Abdominal ultrasonography has greatly facilitated this diagnosis in humans, and it will probably accomplish the same in veterinary medicine once the technology and the accompanying necessary skills become more widely available. The sonographic appearance of pseudocyst will likely be indistinguishable from other types of pancreatic masses such as pancreatic abscess or cystic neoplasia until a sample of the cyst fluid or the tissue itself is analyzed. Using this technique, it will appear as a hypoechoic mass containing hyperechoic sediment (Figure 60-32). One report showed that the size of the pseudocyst ranged from 2×2 to 7×6 cm,[27] and that the fine-needle aspiration procedure was a practical and efficient way to make this diagnosis, and in some cases to expedite its medical treatment.[11,28]

CT provides an excellent visualization of pancreatic pseudocyst. This technique is more commonly used in humans for general abdominal diagnostic evaluations, but abdominal ultrasound might be more feasible for veterinarians because of its availability, lesser cost, and high degree of diagnostic accuracy.

Figure 60-32 An abdominal ultrasound showing pancreatic pseudocyst.

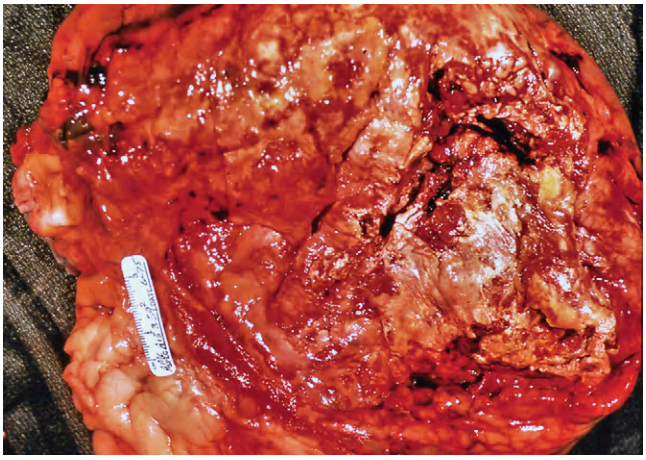

Figure 60-33 Pancreatic phlegmon at postmortem.

Treatment

Physicians will monitor human pancreatic pseudocyst for several weeks so long as they are not infected, not causing pressure on nearby structures, and not showing evidence of spontaneous rupture. In many cases, the cyst will resolve spontaneously.[3,11,28] The incidence of spontaneous resolution in small animals is not known either because of the rarity of the condition or its infrequency of diagnosis. It would seem prudent to conservatively monitor a small cyst for spontaneous resolution if it is of no immediate threat to the patient.

Transabdominal fine-needle aspiration of the cyst contents is commonly performed in humans and this technique has been reported in dogs.[11,23,27] The procedure is performed selectively on those patients who are clinically stable and who do not show signs of a surgical abdomen (fever, prostration, palpable tenderness, cytologic evidence of abdominal sepsis). Potential complications include leakage of cyst fluid into the peritoneal cavity, hemorrhage, and introduction of infection. Patients treated with this technique should be clinically reevaluated for 2 weeks. Other treatment techniques that are used in humans include percutaneous cystogastrostomy, and endoscopic cystogastrostomy, and duodenostomy. Surgical resection is done if the less-invasive techniques fail to resolve the problem or if bacterial infection is present.[3,8,22,26] Procedures include anastomosis of the cyst to an adjacent hollow viscus, Roux-en-Y anastomosis, and external drainage with creation of a pancreatic fistula to the skin.[3,20]

Conclusion

Pancreatic pseudocyst formation occurs as a sequel to acute pancreatitis. Small pseudocysts might be clinically asymptomatic and resolve spontaneously over a few weeks. Large cysts can cause a range of clinical signs related to their physical size, the possibility of secondary infection, or because of spontaneous rupture into the abdominal cavity. Treatment of large intact cysts can be accomplished by transabdominal ultrasound-guided fine-needle aspiration. Surgery is indicated for infected cysts and those that rupture.

Pancreatic Phlegmon

Definition

Adler and Barkin describe pancreatic phlegmon as a mass that results from acute intrapancreatic inflammation with fat necrosis and pancreatic parenchymal necrosis. They are usually found in association with necrotizing pancreatitis and are characterized by necrotic pancreatic and peripancreatic tissue.[11] "Pancreatic ascites" commonly accompanies this condition because of the substantial peritonitis that occurs with this condition. It is characterized as a sterile exudate in the absence of infection.[2] The largest number of reported cases describes this condition in seven dogs.[6] Because of the overlap in defining pancreatic necrosis and pancreatic phlegmon, Edwards et al. use the description provided by Warshaw where pancreatic phlegmon is a solid mass of indurated pancreas and adjacent tissue resulting from edema, inflammatory cells, and some tissue necrosis (Figure 60-33).[29] A fluid pocket is not present. Phlegmon develops within days after a severe bout of pancreatitis and is characterized by the presence of a palpable or radiographic abdominal mass and prolonged leukocytosis. Persistent fever and abdominal tenderness frequently are present. The terms *pancreatic necrosis* and *phlegmonous pancreatic slough* refer to the condition where glandular tissue becomes devitalized. These masses involve peripancreatic tissue more extensively than a phlegmon and can be associated with fluid-filled pockets produced by liquefaction necrosis.[6,30]

Incidence, History, and Physical Examination

There is nothing in particular that distinguishes one particular patient with pancreatic necrosis from another that has pancreatic phlegmon except for the eventual mass-like lesion that develops with phlegmon within 5 to 7 days of severe clinical illness. Edwards et al. reporting on seven dogs described all of them as seriously ill and showing signs typical of severe pancreatitis.[6] The ages ranged from 4 to 12 years (mean: 7.8 years) with a majority (five) in obese female dogs. All seven had signs of anorexia, lethargy or depression, and vomiting, which were present for a few hours to 3 days prior to being seen by a veterinarian. Five were admitted to the teaching hospital within 2 days of onset of clinical signs of acute pancreatitis while two were referred 9 to 10 days after the initial signs of pancreatitis. Fever occurred in five, abdominal pain in three, and diarrhea in two. All of the initial imaging and clinical pathology results were typical of most dogs affected with pancreatitis. One dog had a palpable abdominal mass that resolved, and this dog was discharged after 8 days of hospitalization. Because the pancreas was not grossly visualized in this dog, the diagnosis of a phlegmon was tentative based on imaging and laboratory results. The other six dogs were diagnosed at surgery, which was done after a protracted hospital stay that ranged from to 8 to14 days after initial signs of pancreatitis. The clinical course in some of these dogs fluctuated with varying degrees of illness, but they were persistently ill.

Clinicopathologic Findings

It is important to note that there are no laboratory tests to distinguish between severe acute pancreatitis, pancreatic necrosis, pancreatic abscess, and pancreatic phlegmon. They can all have the same clinicopathologic findings from normal to highly abnormal. All of these conditions cause a leukocytosis, many of which also have toxic changes in the white blood cells. Many cases have a lowered platelet count that is attributable to consumption of platelets because of inflammation. DIC can occur in any patient with severe acute pancreatitis as a result of the systemic inflammatory response or secondary sepsis. Patients with phlegmon usually have elevated serum liver enzyme concentrations and hyperbilirubinemia. Icterus can occur from either cholestasis or secondary to an obstruction of the common bile duct. Serum proteins might be increased initially but then decrease because of "third spacing" of plasma proteins in the peritoneal space because of increased vascular permeability associated with the marked inflammatory response. BUN and serum creatinine concentrations can increase as a result of prerenal effects from hypovolemia and renal hypoperfusion. Acute renal failure can occur as an ominous secondary complication because of acute tubular necrosis, antibody–antigen accumulation at the glomerulus, secondary to drug toxicity, and pathologic thrombi formation at the glomerulus.[20,31,32]

Diagnostic Imaging

The detection of an abdominal mass using diagnostic imaging is the main sign that suggests pancreatic phlegmon formation. In Edwards' review, pancreatic (anterior abdominal) masses were detected by radiography in five cases, with ultrasonography in two cases, and with abdominal palpation in one case. Today we expect a large majority of cases to be discovered using abdominal ultrasonography. The main radiographic abnormalities include a mottled appearance in the peritoneal cavity with a loss of serosal detail. The majority had a mass effect in the pancreatic region that often displaced the pylorus or ascending proximal transverse colon. The main ultrasonographic features were a hyperechoic mass in the pancreatic region containing hypoechoic and anechoic areas.[6]

Treatment

The treatment for pancreatic phlegmon and sterile necrosis can range from purely medical to those that require major surgery. When surgery is selected, it is essential to be aware that the procedure begins on a severely ill patient that might be near death prior to surgery, and that the postoperative outcome could be disastrous. This is evidenced in Edwards' report showing that all six patients that underwent surgery either died or were euthanized.[6] Perhaps part of the reason for this outcome might be the protracted care that was needed in each of those cases. In humans, the decision to operate is controversial, each based on valid opinions, but the one unanimous decision in favor of surgery is the presence of infected necrosis.

Infected necrosis is a serious and potentially lethal complication in humans.[18] Overall, the rate of mortality is 20% to 30%, and in some cases even higher, especially if the condition goes unrecognized until the postmortem examination. Surgery is essential for treating this condition where debridement is carried out by gentle finger dissection of necrotic material which consists of necrotic fat and pancreatic parenchyma. As discussed for pancreatic abscess, the various types of surgical drainage include necrosectomy with closed peritoneal lavage, necrosectomy with wide peripancreatic drainage, necrosectomy with staged reexploration, and necrosectomy with open packing.[20] These same procedures can be done in veterinary patients. Regardless of the species, one of the most important factors regarding surgery is to not delay the surgery while the patient continues to worsen because of sequestered necrosis. The postoperative morbidity in all of these procedures is substantial, and all are associated with a long postoperative stay.

The treatment of sterile necrosis is controversial when considering the option for surgery.[2,18,33] In such cases, intense medical treatment is done before surgery is considered. In humans, most patients found to have sterile necrosis heal successfully without debridement. However there are exceptions to this that usually involve patients who continue to deteriorate despite adequate medical support.

Infected Pancreatitis

Overview

The veterinary literature suggests that cultures of pancreatic tissue are usually negative.[5-7] In Anderson's review of 36 dogs with pancreatic abscess, only two of 13 cultures yielded bacterial growth.[9] However, 12 of the 36 dogs had peritoneal fluid cultured, and seven of these had positive bacterial growth. The results of Anderson's study population raises the possibility of the presence of an undiagnosed peritonitis in the face of ongoing sterile pancreatic necrosis. There is also the question of bacterial isolation from necrotic tissue which might not be conducive to pancreatic growth. It is possible that antibiotics administered to the pancreatitis patient could favor negative bacterial isolation on samples taken several days after the antibiotics have had a chance to take effect. Perhaps veterinary patients might show a higher incidence of infected pancreatitis if tissue and/or abdominal fluid samples were obtained initially by fine-needle aspiration prior to administering antibiotics. The remaining question regarding the indication for antibiotic treatment is also one with answers that have changed over time. Because there is experimental evidence for transcolonic migration of bacteria during acute pancreatitis, there are some clinicians who will administer broad-spectrum antibiotics in the hope of reducing the incidence of pancreatic and peripancreatic infections even though the benefits of doing so have not been proved.[33,34] In a recent study involving 100 human patients with severe necrotizing pancreatitis, using antibiotic treated and untreated controls, there was no statistically significant difference between the antibiotic treated groups and the untreated group for pancreatic or peripancreatic infection, mortality, or the requirement for surgical intervention therefore concluding that early prophylactic antimicrobial use provided no distinct advantage in human patients.[14]

Regardless of its rare occurrence, infected pancreatitis should be suspected in every case of pancreatic necrosis or phlegmon. Diagnosis is established by demonstrating bacteria with fine-needle aspiration of any abdominal fluid or parenchymal tissue samples (Figure 60-34). Treatment should begin with a broad-spectrum antibiotic(s) while the results of culture and sensitivity are pending.

INSUFFICIENCY

Maria Wiberg

Exocrine Pancreatic Insufficiency in Dogs

Exocrine pancreatic function may be diminished by chronic diseases leading to inadequate production of digestive enzymes and classic signs of maldigestion. EPI is a functional diagnosis based on

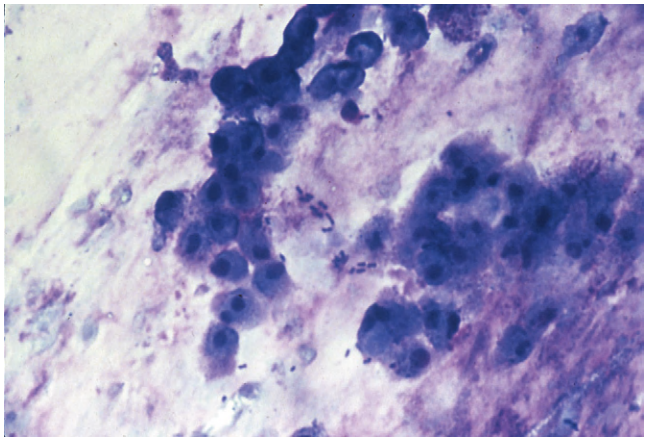

Figure 60-34 Bacteria detected on a fine-needle aspiration cytology sample from a dog with an infected pancreatic phlegmon that was confirmed at surgery.

measuring decreased pancreatic secretion capacity by pancreatic function test. The exocrine pancreas has a large reserve secretory capacity, and maldigestion signs are usually not seen until 90% of the secretory capacity is lost. Exocrine pancreatic diseases that may result in clinical signs of EPI include pancreatic acinar atrophy (PAA; dogs), chronic pancreatitis (dogs, cats), and very rarely reported pancreatic neoplasia (dogs, cats).[1-6]

Etiopathogenesis

EPI has been reported in many different breeds, but some breeds appear to be more predisposed than others. EPI is most commonly found in German Shepherds, followed by Rough-Coated Collies, Chow Chows, and Cavalier King Charles Spaniels.[3,5,7-10] Female association with EPI has been reported.[10] The prevalence of the various pancreatic diseases causing clinical signs of EPI is difficult to assess, because pancreatic morphologic examination is needed for the specific diagnosis. However, PAA is reported to be by far the most common cause of severe EPI in young adult dogs. Of all dogs diagnosed with EPI, approximately 50% to 70% were German Shepherds, and in Finland 20% of the cases are found in Rough-Coated Collies.[3,9,10] With German Shepherds and Rough-Coated Collies, the underlying cause for EPI is PAA. The estimated prevalence of the disease within these two breeds is approximately 1%.[3,8] Similar etiopathogenesis with PAA may also be suspected in other breeds with early onset EPI, such as the Chow Chow and Eurasian dog breeds.[10,11] In contrast, dogs that develop clinical signs of EPI later in life more likely have chronic pancreatitis as the underlying pathogenesis.[10]

Pancreatic Acinar Atrophy

The characteristic of PAA is a selective destruction of the digestive enzyme, producing acinar cells. Loss of acinar tissue leads to inadequate secretion of pancreatic enzymes and to signs of maldigestion typical of EPI. The endocrine function of the pancreas is usually spared in this process.[1,2,5,12] Canine PAA is a unique disease compared with other species. In humans, PAA has been reported, but in association with multiorgan diseases such as Sjögren and Shwachman-Diamond syndromes.[13] Congenital isolated deficiencies in pancreatic enzymes are reported in humans[13] but not in dogs. Experimental studies show that acinar atrophy can be an end result of multiple pathogenetic processes involving the exocrine pancreas, such as pancreatic duct obstruction, ischemia, toxicity, nutritional deficiencies or imbalances, and defective secretory and/or trophic stimuli.[6] That said, there is no evidence to support the involvement of these factors in naturally occurring PAA in dogs.[6,14] Congenital exocrine or compound exocrine and endocrine pancreatic hypoplasia in young puppies is sometimes found.[15-17] Westermarck et al.[18] followed the morphologic changes in the pancreas of a German Shepherd puppy bred from parents with PAA. The puppy was born with a grossly and histologically normal pancreas, but developed EPI later in life. This finding supports the hypothesis that PAA in this breed is neither hypoplastic nor congenital, but rather a progressive disease.

The clinical signs of EPI caused by PAA are usually seen in young adults, 1 to 4 years of age, although sometimes the clinical disease may develop later in life.[19] The hereditary nature of PAA has been demonstrated in German Shepherds, Rough-Coated Collies, and recently with Eurasian dogs. Pedigree analyses suggest that the disease in these three breeds is heritable by an autosomal recessive trait.[7,8,11,20,21] Preliminary results of a test mating between two German Shepherds with PAA showed that only two of the six offspring were affected, thus suggesting that EPI is not a single-gene disease but rather a polygenic disease (unpublished data). To date, two studies have attempted to identify the candidate genes for PAA. In German Shepherds, the gene for glycoprotein 25L, located at CFA3, is downregulated by 500-fold in affected pancreata. However, there were no mutations found in the coding sequence (that segregates with PAA).[22] In Eurasian dogs, linkage analysis of CFA3 and CFA23 as canine orthologs of the human cholecystokinin and cholecystokinin A receptor genes excluded them as candidates for PAA.[11] Therefore, additional studies are necessary to identify the molecular defect responsible for PAA in these breeds.

Recent etiopathogenetic studies showed that PAA has some features of autoimmune disease in German Shepherds and Rough-Coated Collies.[23,24] These features include genetic susceptibility to disease and characteristic morphologic and immunologic findings during progression of disease. The ability to diagnose PAA prior to development of total acinar atrophy and manifestation of clinical maldigestion signs, permits the progression to atrophy to be closely monitored.[9] The progression of PAA was divided into a subclinical phase characterized by partial acinar atrophy and a clinical phase with severe end-stage atrophy. In the subclinical phase, both atrophied and normal acinar parenchyma were found. Grossly, the normal pancreatic mass was diminished and scattered areas of atrophied tissue were found among the normal tissue. No hemorrhagic or fibrotic tissue was observed. The histologic findings during the progression of atrophy were typical for an autoimmune disease showing marked lymphocytic inflammation into the partially atrophied acinar parenchyma. The gradual destruction of the acinar structure was found in association with the inflammatory reaction. Lymphocytic inflammation was most extensive in the border zones of the normal and affected acinar parenchyma, and lymphocytes spread into the normal acinar parenchyma and intraacinar areas. As tissue destruction progressed, the findings became more typical of end-stage PAA.[23]

The clinical signs appear in the end stages of PAA. The gross pathologic findings are typical, showing thin and transparent pancreas with no signs of fibrosis. The normal glandular structure is hardly recognizable and the pancreatic ducts are clearly visible. Histologically, no normal acinar tissue is left in the end stages, or if normal tissue is present, it is found in small isolated lobuli. The normal acinar parenchyma is replaced by atypical tissue, and ductal structures are prominent. Fibrous tissue is not generally increased, and in some cases the normal tissue is replaced by adipose tissue.

Inflammatory cells, lymphocytes, and plasma cells may be found, but in general inflammation is less prominent than in the subclinical phase. The endocrine part of the pancreas in dogs with PAA is usually well preserved.[1,5,12,25]

Further immunologic studies with dogs with partial PAA have suggested that both cellular and humoral immune responses play a role in the pathogenesis of acinar atrophy, although tissue destruction appears to be largely mediated by cellular immune mechanisms.[24] Immunohistochemical analysis showed that at the onset of acinar cell destruction, the majority of the infiltrating lymphocytes were T cells, with an almost equal number of CD4+ T-helper and CD8+ cytotoxic T-lymphocytes. Cytotoxic T cells predominated in sections where the gradual destruction of the acinar parenchyma was present.[24] The role of the humoral immune response was previously studied, in which serum pancreatic-specific antibodies in dogs with clinical signs of EPI were compared with those of healthy controls, but the study found no differences between these two groups.[26] A recent study showed that serum autoantibodies reacting at low intensity with pancreatic acinar cells were found in some dogs with partial and end-stage PAA, but not in healthy control dogs, suggesting that the humoral immune response was also activated.[24]

As lymphocytic pancreatitis with active destruction of acinar structures preceded the end-stage atrophy, the term *autoimmune-mediated atrophic lymphocytic pancreatitis* has been suggested to describe the pathologic findings.[23,24] The rate of progression of the atrophy from the subclinical to the clinical phase is variable, and the factors affecting it are not yet identified. Long-term followup of dogs with partial PAA shows that they may remain in the subclinical phase for years or sometimes for life. No diagnostic markers predicting which dogs will develop clinical disease have been found.[27] Autoimmune diseases are often multifactorial. Genetic susceptibility, environmental factors, and immunologic abnormalities are all involved in this pathogenesis. Environmental factors, either microbial or nonmicrobial, are usually needed to initiate a clinical autoimmune disease in genetically susceptible individuals.[28] The possible contribution of various environmental factors, such as feeding, housing, training, stress, and viruses, in the pathogenesis of PAA has been proposed, but there are no comprehensive studies available on their roles. A survey failed to show any common triggering environmental factors in the histories of dogs with EPI.[19]

Chronic Pancreatitis

Chronic pancreatitis is probably an underestimated reason for EPI, because there has been lack of sufficient histologic data. Recent studies show that chronic pancreatitis may be more common in dogs than clinically suspected.[29,30] Unlike the situation in autoimmune atrophic pancreatitis, there is usually a progressive destruction of both exocrine and endocrine pancreas in chronic pancreatitis. Clinical history usually shows more nonspecific GI signs, or the signs of EPI also can develop later in dogs with previous diabetes mellitus. The pathologic findings in chronic pancreatitis are clearly different from those of PAA. Macroscopically, the pancreas is usually hard, shrunken, and nodular, and there may be adhesions. The characteristic histologic findings in chronic pancreatitis involve an increase in interlobular and intralobular fibrosis and disorganized acinar lobuli, with or without inflammatory cells in the interstitium.[1,2,5,29]

Clinical Signs

The typical clinical signs of EPI include increased fecal volume and defecation frequency, yellowish feces, weight loss, and flatulence. Other common signs are polyphagia, poorly digested, loose and pulpy feces, and coprophagia. Nervousness or aggressiveness may occur and these are suspected to result from abdominal discomfort because of increased intestinal gas. Severe watery diarrhea is usually only temporary. Skin disorders have also been reported. Although these signs of EPI are typical, they are not pathognomonic for the disease, as small intestinal diseases may show similar maldigestive or malabsorptive signs.[6,19]

Diagnosis

The diagnosis of exocrine pancreatic dysfunction is based on typical findings in clinical histories and clinical signs and is confirmed with a pancreatic function test. Complete blood cell count and routine serum biochemistry often show unremarkable changes. Serum amylase and lipase activities are not useful in the diagnosis of EPI. Various pancreatic function tests, which measure pancreatic enzyme concentrations in the blood and feces, have been used to diagnose canine EPI. The diagnostic value of these tests lies in their ability to distinguish whether the maldigestion signs are caused by exocrine pancreatic or small intestinal disease, as well as in their practicality. When needed to verify the underlying pathologic process causing the clinical signs, morphologic examination of the pancreas may be performed.[31]

The measurement of canine serum TLI has become one of the most commonly used pancreatic function tests in the diagnosis of canine EPI.[32] Serum TLI measurement is species- and pancreas-specific. The new reference ranges for cTLI in healthy dogs are 5.7 to 45.2 µg/L (Texas A&M, Gastrointestinal Lab, College Station, TX). Abnormally low serum cTLI concentrations (<2.5 µg/L), with the typical clinical signs of maldigestion, are considered highly diagnostic for severe EPI and indicate severe loss of the digestive enzyme-producing acinar cells.[32] Interpretation of the cTLI values is not always straightforward. The pathologic processes affecting exocrine pancreatic function are progressive, and cTLI levels can vary from normal to abnormal depending on the degree of pancreatic tissue lost. Overlapping results between normal and affected dogs can be expected, and a normal cTLI greater than 5.7 µg/L does not necessarily exclude mild to moderate pancreatic dysfunction.[9] In general, the lower the cTLI value, the more valuable a single measurement is in assessing pancreatic dysfunction. When the cTLI value is in a subnormal range (2.5 to 5.7 µg/L), further diagnostic procedures with repeat cTLI measurement are recommended.[9] In German Shepherds and Rough-Coated Collies, breeds predisposed to autoimmune atrophic pancreatitis, it was shown that repeatedly subnormal cTLI values (2.5 to 5.0 µg/L) in dogs showing no typical signs of EPI indicated subclinical EPI and suggested partial atrophy.[9,23]

Fecal proteolytic activity measurement has been used historically for the diagnosis of EPI. The reliability of the different tests varies, and a common problem with these tests is that sometimes normal dogs also showed decreased proteolytic activity.[6,33,34] To avoid this problem, fecal proteolytic activity was measured from repeated fecal samples and after using pancreatic stimulation by giving raw soybeans in the food during the test period.[34] A recent study showed that in dogs with protein-losing enteropathy, increased fecal loss of α_1-proteinase inhibitor is associated with a decrease in fecal proteolytic activity and may result in a false diagnosis of EPI.[35]

A new fecal test for diagnosing exocrine pancreatic dysfunction is the ELISA determination of fecal elastase. Canine fecal elastase is species- and pancreas-specific test with high sensitivity, but relatively low specificity. A single fecal elastase concentration greater than 20 µg/g can be used to exclude EPI in dogs with chronic diarrhea. Values less than 20 µg/g in association with typical clinical signs of EPI are suggestive of severe pancreatic dysfunction.[36-38] For

diagnosing subclinical EPI and partial PAA the fecal elastase measurement was not sufficiently sensitive enough.[39]

Treatment

Enzyme Replacement Therapy

When signs of maldigestion secondary to EPI appear, enzyme replacement therapy is indicated. The basic treatment includes supplementation of the dog's ordinary food with pancreatic enzyme extracts. Various pancreatic enzyme extracts are available in different countries. In dogs, the highest enzyme activity in the duodenum was achieved using nonenteric-coated supplements, such as powdered enzymes or raw chopped porcine pancreas, and these supplements are equally effective in controlling clinical signs.[40,41] The choice among preparations is based on practical properties, availability, and costs. In many countries the use of raw porcine pancreas is not permitted because of possible zoonotic disease. The maintenance dosage for the powdered enzyme is dependent on the preparation used (Viokase-V, Fort Dodge, Fort Dodge, KS, 1 tsp/meal). Raw frozen pancreas has been fed at 50 to 100 g/meal for dogs that weigh 20 to 35 kg.[6,40,41] The value of enteric-coated supplements is limited in dogs as a result of delayed gastric emptying of the preparations.[42] Despite accurate enzyme therapy the digestive capacity does not return to normal, because orally administered enzymes are largely destroyed by gastric acid. Sometimes the increase in enzyme dosage or change to another nonenteric-coated supplement may be beneficial. Inhibition of gastric acid secretion by H_2-histamine receptor antagonists has shown some positive effects. Even if routine use of H_2-histamine receptor antagonists is not needed, they may be indicated when the response to enzyme treatment alone is poor and especially when vomiting or inappetence appear.[6,41,43] A rare complication with oral enzyme powder supplementation is gingivitis and oral bleeding, which is treated either by decreasing the enzyme dose or by changing the supplement or preincubation enzyme in the food prior to feeding.[44,45]

Supportive Treatments

Supportive treatments should be considered when the treatment response to enzyme replacement therapy alone is not satisfactory. EPI also may be associated with secondary problems that may worsen the clinical signs. These include small intestinal bacterial overgrowth or antibiotic-responsive diarrhea, malabsorption of cobalamin, and the coexistence of small intestinal disease.

The most commonly used adjunctive medications in the treatment of EPI are antibiotics. An increased amount of substrates for bacteria in the small intestine, a lack of bacteriostatic factors in the pancreatic fluid, and changes in intestinal motility and immune functions are possible reasons for the accumulation of bacteria in the small intestine of dogs with EPI.[46-48] Antibiotics have been used during the initial treatment when clinical signs, such as diarrhea, increased intestinal gas, and flatulence have not resolved with enzyme therapy, or when these signs have recurred during long-term treatment. Antibiotics reported to be effective include tylosin (10 to 20 mg/kg BID) or metronidazole (10 to 15 mg/kg BID) for 1 to 3 weeks.[6,41]

Clinical feeding studies during long-term treatment of EPI show that the need for special diets is minimal and that dogs may continue to be fed their original diet. Radical dietary changes should be avoided and special attention should be focused on individual needs, since the response to different diets varies among dogs.[41,49-51] In those dogs that do not show satisfactory treatment response, dietary modification may be useful. The severity of some clinical signs of EPI can be decreased with dietary modification. A highly digestible, low-fiber and moderate-fat diet can alleviate clinical signs such as defecation frequency, increased fecal volume, and flatulence.[49] Highly digestible diets may be of particular value in the initial treatment until the nutritional status has improved and possible mucosal damage has been repaired. A low-fat diet was recommended, because enzyme supplements alone are unable to restore normal fat absorption.[52] Lipase is most easily destroyed by exposure to gastric acid during gastric transit. Fat absorption may also be affected by bacterial deconjugation of bile salts in small intestinal disease, producing metabolites, which, in turn, may result in diarrhea. However, feeding the low-fat diet did not significantly alleviate the clinical signs during the long-term treatment.[50] Dietary sensitivities may be a consequence of EPI, and therefore hypoallergenic diets may benefit some dogs, especially those with concurrent skin problems. No obvious clinical benefits were demonstrated by adding medium-chain triglycerides to food.[53]

Cobalamin deficiency in dogs with EPI is partly a result of increased uptake of cobalamin by the intestinal bacteria and partly to the lack of pancreatic intrinsic factor, shown to play a major role in the absorption of cobalamin. Enzyme treatment alone is not helpful for increasing serum cobalamin levels.[54-56] Because cobalamin deficiency is common in canine EPI, serum cobalamin should be measured in dogs that are clinically suspected of having EPI or that do not respond satisfactorily to enzyme treatment. Cobalamin is given subcutaneously and the dose currently recommended is 250 to 1000 µg, depending of the size of the dog.[57] The treatment should be repeated based on serum concentrations.

Although malabsorption of fat-soluble vitamins may be expected with EPI, the clinical importance of vitamins A, D, E, and K deficiency in this syndrome has not been reported. When the treatment response to enzymes and supportive therapies is still unsatisfactory, concomitant small intestinal disease should be suspected, and further diagnostic studies and treatment should be performed.[6]

Treatment of Atypical Cases

The diagnosis and treatment of EPI can be more complicated in dogs with pancreatic dysfunction as a result of chronic pancreatitis or with dogs having only partial PAA. These dogs may show nonspecific chronic or intermittent GI signs associated with serum TLI concentration in the subnormal area of 2.5 to 5.7 µg/L.[9] GI signs may be a result of subnormal pancreatic function or underlying small intestinal disease or a combination of both. The diagnostic workup and treatment for possible concurrent small intestinal disease is recommended (see Chapter 57), and serum TLI measurement should be repeated in 1 to 2 months. If no underlying small intestinal disorder is identified, a trial treatment with pancreatic enzymes should be initiated. Those dogs with diagnosed partial PAA caused by autoimmune pancreatitis, but showing no clinical signs of EPI, need no treatment. The value of early immunosuppressive treatment with azathioprine in slowing the progression of the autoimmune-mediated tissue destruction was shown to be questionable, and is thus not recommended.[27]

Prognosis

When the clinical signs of EPI appear, the loss of pancreatic tissue is already almost totally complete. Changes are considered to be irreversible, and lifelong enzyme replacement therapy is usually required. The response to enzyme treatment is usually seen during the first weeks of treatment, with weight gain, cessation of diarrhea, and decrease in fecal volume.[6,43]

The level of treatment response achieved during the initial treatment period remains fairly stable.[41] Although some dogs show short relapses of clinical signs, the permanent deterioration of the clinical

condition during long-term treatment is uncommon. During long-term treatment with nonenteric-coated enzyme supplements, the GI signs considered typical for dogs with EPI were almost completely controlled in half of the dogs. Although it was not always possible to eliminate all the signs, good resolution was found especially in the more serious signs. Those signs most commonly remaining were increased fecal volume, yellow and pulpy feces, and flatulence. Poor response to treatment was observed in 20% of the dogs, despite similar treatment regimens.[41]

Another study showed similar results, with favorable initial treatment response in 60% of dogs, partial in 17%, and poor in 23%.[58] Severe cobalamin deficiency was associated with shorter survival. Other predictors, such as breed, sex, age, clinical signs at the time of diagnosis, dietary modification, and fat-restricted diet did not affect the favorable initial treatment response or long-term survival. Interestingly, no difference in the treatment response or survival was found between enteric-coated and nonenteric coated supplements. This was clearly a different result than that previously reported[40] and thus should be further investigated.

Approximately 20% of dogs diagnosed with EPI were euthanized during the first year.[41,58] The most common reason for euthanasia was poor treatment response; another reason for euthanasia was owner reluctance for expensive and lifelong treatment. A rare, but severe, complication of EPI is mesenteric torsion.[59] Today mesenteric torsion is more seldom seen, probably because of more efficient enzyme preparations.

Exocrine Pancreatic Insufficiency in Cats

EPI in cats is rare. End-stage chronic pancreatitis is considered to be the most common cause of exocrine pancreatic dysfunction and clinical signs of maldigestion in the cat. Adenocarcinomas of the exocrine pancreas may cause obstruction of the pancreatic duct and thus decreased production of digestive enzymes.[60,61]

Clinical Signs

The clinical signs are similar to those of dogs, including loose and voluminous stools, weight loss, poor body condition, and polyphagia. Cats with EPI may have greasy, wet-looking hair coats, especially in the perineal region. The GI signs are often similar to those of small intestinal IBD and cobalamin deficiency. Other differential diagnoses to be considered are hyperthyroidism and intestinal neoplasia. Because chronic pancreatitis affects both the endocrine and exocrine pancreas, diabetes mellitus is commonly associated with EPI in cats.[60,61]

Diagnosis

The results of routine laboratory tests, abdominal radiography, and ultrasound are generally unremarkable, unless subtle changes of chronic pancreatitis can be recognized. The diagnosis of exocrine pancreatic dysfunction should be based on species-specific measurement of feline serum TLI. The reference ranges for fTLI are 12 to 82 µg/L (Texas A&M, Gastrointestinal Lab, College Station, TX). A severely decreased fTLI concentration equal to or less than 8 µg/L is considered diagnostic for EPI.[62] Fecal proteolytic activity tests can also be used for fEPI diagnosis, but in comparison to fTLI measurement these tests are impractical.[31,60]

Treatment

The basic treatment of feline EPI is pancreatic enzyme supplementation. Powdered formulations are the most effective in cats. With powdered enzyme extracts the initial dose is 0.5 tsp/meal. When possible, raw frozen pancreas can also be used. Tablets or enteric-coated supplements are usually less effective and thus not recommended. Dietary modification is not usually needed, and most cats with EPI can be fed with regular maintenance diets.[31,60] In cats with EPI, serum cobalamin concentrations are often severely decreased, and therefore serum cobalamin should be routinely measured in cats with suspected EPI and also during treatment of EPI in case of poor response to enzyme replacement alone. Some cats do not respond satisfactorily to enzyme treatment until cobalamin is also supplemented. The recommended dose for parenteral cobalamin is 250 µg subcutaneously weekly for 4 to 6 weeks, and thereafter based on the measurement of serum cobalamin concentrations.[31,60,63] EPI can also be associated with small intestinal disease, and in these cases treatment with oral prednisolone and/or antibiotics (oral metronidazole) may be needed.[31]

NEOPLASIA

Sandra Axiak and Kevin Hahn

Cats

Two types of feline exocrine pancreatic neoplasia are described: adenomas, which are usually incidental and benign, and adenocarcinomas. Adenocarcinomas are rare and can be diffuse throughout the pancreas,[1] although some reports show greater incidence in the head of the pancreas than the tail.[2] Age at presentation ranges from 4 to 20 years. Metastasis to the liver is common and less-common sites of metastatic spread include the lungs, lymph nodes, small intestine, and heart. Adenocarcinoma is also associated with diabetes mellitus and hyperadrenocorticism. Diabetes mellitus is thought to be secondary to compression of the islet cells, tumor-derived cortisol inducing β-cell degeneration, or decreased carbohydrate metabolism.[1]

Clinical Examination

Presenting clinical signs are anorexia, vomiting, abdominal pain, weight loss with a normal appetite, and icterus. Physical examination findings include icterus and cranial abdominal mass. Duration of signs is bimodal with 50% of cats having signs for less than 7 days and 50% having signs for more the 1 month.[1]

A rare paraneoplastic syndrome has been described in cats with pancreatic adenocarcinoma. It consists of nonpruritic, symmetrical alopecia of the face, ventral body, and medial limbs. Skin is glistening, but not fragile, and crusty lesions can be seen on the footpads. This syndrome is also reported in cats with bile duct carcinoma. Histopathologically, it is characterized by loss of the stratum corneum and severe follicular atrophy with miniaturized hair bulbs.[3] In one case report, the syndrome resolved following surgical excision of the pancreatic adenocarcinoma, but recurred when metastatic disease became evident, 18 weeks after surgery.[3]

Diagnosis

A CBC may show neutrophilia and serum biochemistry may reveal increased liver enzymes (alkaline phosphatase, alanine aminotransferase) and mild hyperglycemia. Chest radiographs may show pleural effusion indicative of metastasis.[1] Abdominal radiographs may show loss of serosal detail with or without a cranial abdominal mass. A pancreatic mass can be found on abdominal ultrasound. Definitive diagnosis requires fine-needle aspiration and cytology or exploratory laparotomy with biopsies and histopathology.[1]

Treatment and Prognosis

Supportive care is generally ineffective.[1] Surgical excision has been reported in one cat.[3] The prognosis is poor and most cats are euthanized within 7 days of diagnosis because of disease progression.[1] The cat in which surgical excision was reported did well for 18 weeks until euthanized for progressive disease.[3]

Dogs

The etiology of most canine exocrine pancreatic tumors is unknown and no predisposing factors have been identified. However, experimentally intraductal administration of *N*-ethyl-*N*′-nitro-*N*-nitrosoguanidine can induce pancreatic adenocarcinoma.[4]

Pancreatic exocrine tumors are derived from duct or acinar epithelium. Four types of pancreatic carcinoma have been described in the dog: adenocarcinoma, anaplastic carcinoma, alveolar carcinoma, and endocrine-like carcinoma.[5] An additional subset, hyalinizing pancreatic adenocarcinoma, has recently been described in a group of six dogs.[5a] There is no sex predilection, and breeds at higher risk include Airedales, Boxers, Labrador Retrievers, and Cocker Spaniels.[4] The overall incidence of exocrine pancreatic carcinoma is less than 1%, with an incidence of 12% in dogs with pancreatic disease.[5] Unlike the cat, benign neoplasms of the pancreas are not reported in the dog, although hyperplastic nodules are common in older dogs.[5] Location varies and grossly the tumor can appear singular, nodular, or diffuse. Hemorrhage and necrosis are common (Figure 60-35). Metastasis occurs early and affects the liver, omentum, and mesentery most frequently. Other sites of metastasis reported are lungs, thyroid gland, heart, duodenum, and subcutaneous tissue.[5] Histologically, there is extreme variation in cellular structure and central necrosis is common. Reduction in exocrine secretion does occur, however complete pancreatic insufficiency in dogs due to neoplasia has not been observed.[5]

Multifocal necrotizing steatitis has been reported in association with pancreatic carcinomas in three dogs.[6] In these cases, the presenting complaint was of panniculitis. Lesions ranged from ill-defined nondraining soft-tissue swellings to localized subcutaneous lesions with a purulent discharge. The mechanism of steatitis with pancreatic carcinoma is unknown, but is postulated to be a result of systemic release of lipase.[6] Panniculitis with polyarthritis and osteomyelitis also has been reported in two dogs, one with exocrine pancreatic adenoma, and the other with pancreatic adenocarcinoma.[7]

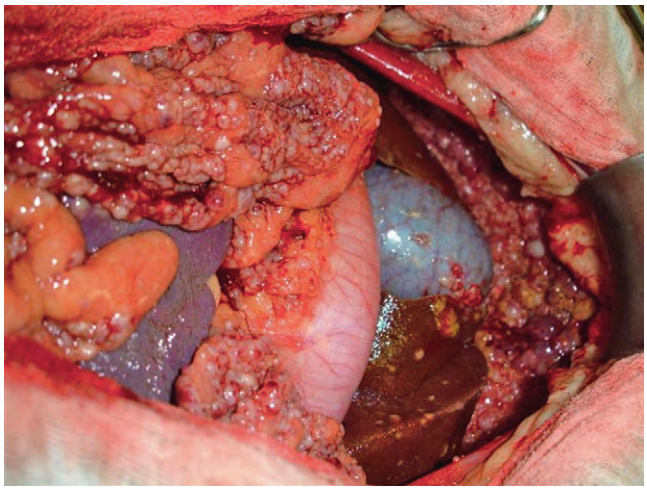

Figure 60-35 Carcinomatosis in a dog with pancreatic adenocarcinoma at surgery.

Clinical Examination

Clinical signs are nonspecific and bimodal, with duration of less than 1 month or of 2 to 4 months.[5] Most patients have a history of weight loss, anorexia, and vomiting. Other less-common signs include depression and weakness.[4] On physical examination, ascites, cranial abdominal mass, or icterus may be noted.[5]

Diagnosis

A CBC may reveal mature neutrophilia, while serum biochemistry may show increased alkaline phosphatase, lipase, or amylase. The increased lipase may occur from associated pancreatitis or from tumor production of lipase.[8] Chest radiographs are usually normal, whereas abdominal radiographs may show a loss of abdominal detail or cranial abdominal mass. Abdominal ultrasound may reveal a pancreatic mass, and can also be used to guide fine-needle aspiration and cytology. Cytology of abdominal fluid, if present, may also provide a diagnosis. Definitive diagnosis is based on ultrasound guided fine-needle aspiration and cytology (diagnostic in eight of 10 cases) or exploratory laparotomy and histopathology.[4] Immunocytochemical labeling for amylase and carboxypeptidase may be of value in diagnosing the primary tumor or metastasis.[9]

Treatment and Prognosis

Treatment is aimed at surgical removal of the pancreatic mass, however disease is usually advanced at the time of diagnosis.[10] One exception may be hyalinizing pancreatic adenocarcinoma, which may progress more slowly than other subtypes of exocrine pancreatic cancer. In one case series of six dogs, two lived greater than 15 months, one dog with no treatment and another with surgical excision. The other four dogs in this series died of complications related to concurrent disease or partial pancreatectomy.[5a] In general, chemotherapy and radiation therapy are ineffective.[10] Overall prognosis is poor as a result of location of the tumor and early onset of metastasis.[10]

CHAPTER 61

Liver

STRUCTURE AND FUNCTION

Robert J. Washabau

Liver Structure

The hepatic lobule is the anatomic unit of the liver. In the anatomic model, liver lobules are organized into irregular polygons demarcated by connective tissue and composed of plates of hepatocytes radiating outward from the central vein to the portal triads (Figure 61-1). The hepatic acinus is the functional unit of the liver. In the functional model hepatocytes are instead oriented around the afferent vascular system (portal veins and hepatic arteries) just as they anastomose into sinusoids (Figure 61-1), and the central vein is at the periphery of the acinus instead of centrally located as in the anatomic model. The acinus is divided into three contiguous zones (1, 2, and 3) that correspond to distance from the arterial blood supply. Those hepatocytes in closest proximity to the arterioles (zone 1) receive the greatest oxygen content, but are also first in line to be affected by toxins transported from the gut to the portal vein. Zone 3 hepatocytes reside at the periphery of the acinus near the central vein, and zone 2 hepatocytes are interspersed between zone 1 and zone 3 hepatocytes. The anatomic model is perhaps easier to understand, but the functional model serves as a better foundation for understanding liver pathology.[1] In either model portal venous and arterial blood flow centripetally, that is, toward the central vein, whereas bile flows centrifugally, that is, away from the central vein. Hepatocytes extract nutrients and oxygen from portal and arterial perfusion, respectively, and produce bile acids and other bile constituents that are transported from hepatocytes into bile canaliculi, ductules, and ducts.

Biliary Tract Structure

The basic elements of the biliary tract are the hepatic canaliculi, bile ductules, intralobular ducts, interlobular ducts, hepatic ducts, cystic duct, gallbladder, common bile duct, and the pancreaticobiliary sphincter (of Oddi).[2] There are many variations on this central theme, the most important of which are (a) the pancreaticobiliary sphincter is a common physiologic and anatomical channel at the duodenal papilla in the cat[3] and (b) there are many anatomic variations in the feline gallbladder, from single gallbladder to bilateral gallbladders, body duplication, fundic duplication, complete duplication, septate, and Y-shaped gallbladder.[4]

Cells of the Liver

Hepatocytes

Hepatocytes account for 60% to 80% of the liver cell mass (see Table 61-1) and contribute to a wide range of metabolic activity, including carbohydrate, protein, lipid, nucleic acid, porphyrin, metal, vitamin, glutathione, hormone, and xenobiotic metabolism; coagulation factor synthesis; biliary secretion; and immune surveillance.[1,5] Hepatocytes have an eosinophilic cytoplasm reflecting numerous mitochondria, and basophilic stippling caused by large amounts of rough endoplasmic reticulum and free ribosomes. Hepatocyte nuclei are round with dispersed chromatin and prominent nucleoli. Anisokaryosis is common and often reflects various degrees of polyploidy, a normal feature of more than 50% of hepatocytes. The average life span of the hepatocyte is 5 to 6 months reflecting their ability to regenerate. Hepatocytes are organized into plates separated by vascular channels (sinusoids), an arrangement supported by a reticulin (collagen type III) network. The sinusoids have a discontinuous, fenestrated endothelial cell lining. The endothelial cells have no basement membrane and are separated from the hepatocytes by the space of Disse, which drains lymph into the portal lymphatics. Hepatocytes are supported by a number of other cell types, which account for 40% of the liver cell mass.

Cholangiocytes

Representing 3% to 10% of liver cell mass, cholangiocytes are also known as biliary epithelial cells.[6] They secrete water, bicarbonate, and cations into the bile in the physiologic state, but they may also participate in the immune response as antigen-presenting cells in disease states. The biliary tract is a convergent system of canals that begins in the canaliculi, followed by the bile ducts, and ending with the common bile duct. Bile secretion depends on the function of membrane transport systems in hepatocytes and cholangiocytes and on the structural and functional integrity of the biliary tract. The hepatocytes, constituting the most abundant liver cell population, generate the so-called primary bile in their canaliculi. Biliary canaliculi are blind tubular structures, with a very high surface-to-volume ratio that by means of osmotic gradients favors the formation of bile flow. Cholangiocytes, which constitute 3% to 10% of the liver cells, modify the canalicular bile by secretory and reabsorptive processes as bile passes through the bile ducts, and they are responsible for approximately 30% of bile volume. In contrast to hepatocytes, where secretion is constant and poorly controlled, cholangiocyte secretion is broadly regulated.[5,6]

Table 61-1 Cells of the Liver and Their Functions

Cell Type	Other Names	Functions	Cell Markers
Hepatocytes	Liver cells	Intermediary metabolism	Albumin, cytokeratin 8 and 18
Cholangiocytes	Biliary epithelial cells	Line the bile ducts, secretion	Cytokeratin 7 and 19
Kupffer cells	Browicz-Kupffer cells, stellate macrophages	Phagocytosis of pathogens and particles	ED-1 and ED-2
Stellate cells	Ito cells, vitamin A–storing cells, lipocytes	Storage of vitamin A; production of myofibroblasts in injury	GFAP, desmin; α-smooth muscle actin
Natural killer (NK) cells	Pit cells, large granular lymphocytes, γδ T cells	Immune surveillance–infection, cancer	CD3
Vascular endothelial cells	Endothelial cells	Line blood vessels	CD34 and CD31
Lymphatic endothelial cells	Endothelial cells	Line lymphatic vessels	Podoplanin
Smooth muscle cells	Myocytes	Regulation of microcirculation	Myocardin, α-smooth muscle actin
Portal tract fibroblast	Fibroblasts	Integrity of portal triads, supporting function	Vimentin
Stem cells	Progenitor cells, oval cells	Bi-potential progenitor cell for hepatocytes and biliary epithelial cells	α-Fetoprotein

GFAP, Glial fibrillary acidic protein.

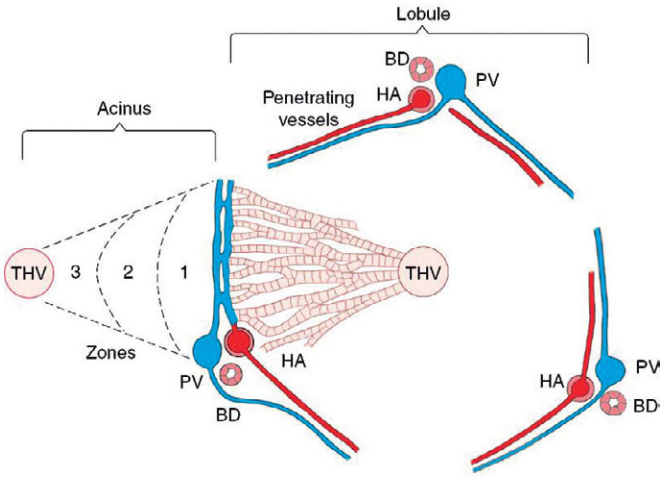

Figure 61-1 The anatomic unit of the liver is the hepatic lobule. The functional unit of the liver is the hepatic acinus. BD, bile duct; HA, hepatic artery; PV, portal vein; THV, terminal hepatic venule. (From Crawford JM: The gastrointestinal tract. In: Cotran RS, Kumar V, Robbins SL, editors: *Robbin's Pathologic Basis of Disease*, Philadelphia, 1994, Saunders.)

Kupffer Cells

Also known as *Browicz-Kupffer cells* or *stellate macrophages*, these cells represent 2% to 5% of the liver cell mass, and are specialized macrophages localized to the sinusoids as part of the mononuclear phagocyte system. Kupffer cells begin their development in the bone marrow with the genesis of promonocytes and monoblasts into monocytes, and then on to peripheral blood monocytes, completing differentiation into Kupffer cells within the liver. In health, Kupffer cells are involved in the metabolism of erythrocyte hemoglobin. During perfusion of the liver, senescent red blood cells are phagocytized by the Kupffer cells, and the hemoglobin molecule is further metabolized into its component parts. Globin chains and amino acids are reutilized; the iron-containing portion of heme is removed, transported, and stored; and heme is further oxidized into bilirubin, conjugated with glucuronic acid within hepatocytes, and secreted into the bile. Kupffer cells also express a complement receptor of the immunoglobulin family, without which the liver cannot clear complement system–coated pathogens.

In disease states, Kupffer cells contribute to the pathology of ethanol and other toxic principles through production of inflammatory mediators, activation of Toll-like receptors, and elaboration of tumor necrosis factor (TNF-α).[7] Kupffer cell activation is responsible for early ethanol-induced liver injury, common in chronic alcoholics. Ethanol activates the Toll-like receptor 4 and CD14, receptors on the Kupffer cell that internalize the endotoxin lipopolysaccharide. Internalization activates the transcription of TNF-α and production of superoxide (a prooxidant). TNF-α then enters the stellate cell in the liver, leading to collagen synthesis and fibrosis. Fibrosis eventually causes cirrhosis or loss of function of the liver (see the role of the stellate cell, which is discussed in "Stellate Cells" section that follows).

Stellate Cells

Hepatic stellate cells (HSCs) (also referred to as vitamin A–storing cells, lipocytes, interstitial cells, fat-storing cells, and Ito cells) exist in the space between parenchymal cells and liver sinusoidal endothelial cells of the hepatic lobule and store 50% to 80% of vitamin A in the whole body as retinyl palmitate in lipid droplets in the cytoplasm.[7-10] In physiologic conditions, these cells play pivotal roles in the regulation of vitamin A homeostasis. In pathologic conditions, such as hepatic fibrosis or liver cirrhosis, HSCs lose vitamin A and synthesize a large amount of ECM components, including collagen, proteoglycan, glycosaminoglycan, and adhesive glycoproteins. The morphology of these cells also changes from that of the star-shaped stellate cell to that of the fibroblast or myofibroblast. HSCs are now considered to be targets of therapy of hepatic fibrosis or liver cirrhosis.[11] Activation of HSCs, a key event in liver fibrosis, is caused by diminished adipogenic transcription.[12] Wnt signaling inhibits antiadipogenic activation of HSCs and liver fibrogenesis; wnt antagonism inhibits HSC activation and liver fibrosis.[9]

Pit Cells

Also known as natural killer (NK) cells or large granular lymphocytes, pit cells represent 1% of liver cell mass, and serve as part of the immune surveillance mechanism in the hepatic sinusoids. Pit

cells belong to the group of sinusoidal cells, together with Kupffer, endothelial, and fat-storing (stellate) cells. Pit cells use the FasL Fas ligand (FasL) and perforin/granzyme pathway to kill target cells. FasL on effector cells binds the Fas that is present on the target cell membrane, which results in oligomerization of Fas and activation of caspase 8. Perforin and granzymes, of which granzyme B is the most potent, reside in granules of the cytotoxic lymphocytes and are released by exocytosis. Intracellular delivery of granzyme B results in the initiation of the caspase cascade by proteolytic activation of caspase 3, either directly or through a mitochondrial-dependent pathway. Caspases play a central role in the execution of apoptosis.

Endothelial Cells

Lymphocyte recruitment from the circulation into tissue is dependent on the ability of the lymphocyte to recognize and bind molecules on the endothelial cell surface that promote transendothelial migration. A multistep model of leukocyte adhesion to vascular endothelium has been described and is broadly applicable, although the details of the signals involved differ between tissues.[13,14] In a generally accepted model, tethering or rolling receptors expressed on endothelial cells capture free-flowing leukocytes. These receptors may be either selectins or members of the immunoglobulin superfamily. Once captured, the leukocyte can receive activating messages presented by endothelial cells in the form of chemokines that activate specific G-protein–coupled receptors on the leukocyte surface. Occupancy of these receptors triggers a cascade of intracellular signals that results in the presentation of high-affinity integrin receptors on the leukocyte surface that bind to immunoglobulin family of counterreceptors on the endothelium to promote leukocyte arrest on the vessel wall. In the presence of the appropriate migratory signals the leukocyte will migrate across the endothelium into tissue, where it follows a hierarchy of chemotactic signals toward the focus of inflammation.

Smooth Muscle Cells

Representing 2% to 5% of the liver cell mass, smooth muscle cells are located primarily in the hepatic artery and portal vein and their tributaries, and serve primarily to regulate the hepatic microcirculation.

Hepatic fibrosis is a common outcome of hepatic injury in the dog. Activated fibroblasts that develop myofibroblastic characteristics play an essential role in hepatic fibrogenesis, and are comprised of three subpopulations: (a) portal or septal myofibroblasts, (b) interface myofibroblasts, and (c) the perisinusoidally located HSCs.

Stem Cells

It is difficult to arrive at a universally applicable definition of a stem cell because some of the defined properties of a stem cell can be exhibited by the stem cells in some tissues or organisms but not in others. In spite of that, a generally acceptable consensus defines a stem cell as an undifferentiated cell that has capacity to self-renew, for production of progeny in at least two lineages, for long-term tissue repopulation after transplantation, and for serial transplantability. In addition, stem cells exist in a mitotically quiescent form and clonally regenerate all of the different cell types that constitute the tissue in which they exist. They can undergo asymmetrical cell division, with production of one differentiated (progenitor) daughter and another daughter that is still a stem cell. The offspring of stem cells are referred to as progenitor cells, also named as transit amplifying cells and therefore cannot be serially transplanted, and are classified as early and late. The early progenitor or stem/progenitor cells have multilineage potential and similar characteristics to stem cells. The late progenitor cells have differentiated further and produce progeny in only a single lineage. Although they divide rapidly, they are capable of only a short-term tissue reconstitution and they do not self-renew.[15]

Early studies in hepatocyte turnover and liver regeneration showed that the parenchymal cell, the hepatocyte, was the primary and only cell involved in tissue renewal. However, new studies of liver regeneration, hepatocarcinogenesis, liver transplantation, and various cell lines show that a variety of cell types participate in maintaining hepatocyte number and mass. Recent studies indicate the presence of both intrahepatic and extrahepatic stem/progenitor cell populations that serve to maintain the normal organ and to regenerate damaged parenchyma in response to a variety of insults. The intrahepatic compartment most likely derives primarily from the biliary tract, particularly the most proximal branches, that is, the canals of Hering and smallest ductules. The extrahepatic compartment is at least in part derived from diverse populations of cells from the bone marrow. Embryonic stem cells are considered as a part of the extrahepatic compartment.[16] The precise role(s) of each of these individual cells remains to be determined, but it is clear that in the aggregate they confer the vast regenerative capacity of the liver .

Liver Function

Metabolism

The liver is involved in many aspects of intermediary metabolism.[1]

Carbohydrates

The liver is at the center of carbohydrate metabolism through its role in maintaining normoglycemia. Glucose is the primary energy source for most mammalian cells, and its metabolism is tightly regulated to guarantee that a sufficient supply is available to glucose-dependent organs, particularly the brain. Glucose can be made available from two sources: absorption of dietary glucose from the intestine, and release of glucose from organs such as the liver and kidney. Early in fasting, the majority of endogenous glucose is generated by glycogenolysis where glycogen in the liver is converted to glucose-6-phosphate under the regulation of debranching enzyme, hepatic glycogen phosphorylase, and phosphorylase kinase. With more prolonged fasting, endogenous glucose is generated by gluconeogenesis from certain substrates such as amino acids, lactate, and glycerol. Both processes generate glucose-6-phosphate, which must then be dephosphorylated in order to transport glucose out of the cell.

- Early fasting: glycogen → glycogenolysis → glucose → normoglycemia
- Prolonged fasting: amino acids → gluconeogenesis → glucose → normoglycemia

The enzyme responsible for the dephosphorylation of glucose-6-phosphate is glucose-6-phosphatase-α. Alterations in quantity, location, or activity of glucose-6-phosphatase, such as those seen in type 1 glycogen storage diseases, effectively result in a lack of all endogenous glucose production and severe hypoglycemia develops during periods of fasting.[17]

Proteins

The liver is an important site of protein metabolism. Amino acids and proteins absorbed from the intestine or produced in the body are delivered to the liver. The liver deaminates amino acids and

converts them to carbohydrates and lipids.[18-21] Deamination produces α-keto acids, which can be metabolized for energy or used for synthesis of monosaccharides and fatty acids.[20] The liver synthesizes amino acids from intermediates of carbohydrate and lipid metabolism by amination and transamination.[21] Examples of amino acid transaminations include:

- Alanine + α-ketoglutarate ↔ pyruvate + glutamate
- Aspartate + α-ketoglutarate ↔ oxaloacetate + glutamate

The liver synthesizes many proteins, including albumin and fibrinogen, most α globulins, and some of the β globulins. Prothrombin and clotting factors V, VII, VIII, IX, and X are produced in the liver, as well as ceruloplasmin, ferritin, and many serum enzymes.

Lipids

Lipid metabolism and transport is organized into three basic transport systems: (a) exogenous transport, which is associated with the metabolism of exogenous (dietary) lipids, (b) endogenous transport, which is associated with the metabolism of endogenously produced lipids, and (c) reverse transport, which is associated with the transport of lipids from the periphery (e.g., skeletal muscle, adipose, connective tissue) to the liver.

Exogenous Transport. Triglyceride is the major dietary lipid, along with cholesterol, phospholipids, and fat-soluble vitamins.[22] The digestion of dietary lipids begins in the proximal GI tract with the action of lingual and gastric lipases, and is completed in the small intestine with the actions of pancreatic lipase, cholesterol ester hydrolase, and phospholipase A_2. Lipid digestion and absorption is more complicated than carbohydrate and protein digestion and absorption because of lipid solubility characteristics, and involves emulsification of lipids by bile salts, hydrolysis by pancreatic lipase and colipase, solubilization of fatty acids and monoglycerides into mixed micelles, absorption, reesterification, chylomicron formation, and transport into the intestinal lymphatics or portal capillaries. Chylomicrons containing short- and long-chain triglycerides, and the newly incorporated B-100 apoprotein, are preferentially absorbed into the intestinal lymphatics where they are transported into the cisterna chyli, thoracic duct, and systemic circulation where they acquire apolipoproteins C and E from circulating high-density lipoproteins (HDLs). Apolipoprotein (apo) C-II activates lipoprotein lipase in the capillary beds of adipose and skeletal muscle, where they are stored as is or hydrolyzed into free fatty acids, β-monoglyceride, and glycerol. The cholesterol-rich remaining particles (now referred to as chylomicron remnants), return apo C-II molecule to HDL and are recognized by specific hepatic apo E and apo B-100 receptors that rapidly remove them from the circulation by endocytosis. The cholesterol found in chylomicron remnants can be used in very-low-density lipoprotein (VLDL), lipoprotein synthesis, bile acid formation, or cholesteryl storage.

Endogenous Transport. While chylomicrons are the apoprotein responsible for transport of dietary lipids, VLDLs, intermediate-density lipoproteins, low-density lipoproteins (LDLs), and HDLs are instead involved in the metabolism of endogenously produced lipids. Triglycerides and cholesterol produced by the liver combine with phospholipids, apo B-100, and apo B-48 to form VLDLs. When secreted from the liver, VLDLs acquire the apo C and apo E from HDL. VLDL apo C-II activates lipoprotein lipase located in the capillary beds, where once again triglyceride hydrolysis takes place with the production of free fatty acids and glycerol. The VLDL molecules remaining after hydrolysis of VLDL triglycerides are either removed from the circulation by the liver or undergo further transformation by lipoprotein lipase and/or hepatic lipase to form intermediate-density lipoproteins and LDLs. LDLs, which are relatively depleted of triglyceride and enriched in cholesteryl esters and phospholipid, circulate in the blood and bind to specific LDL receptors that are widely distributed throughout tissues in order to deliver cholesterol. HDLs produced by the liver play an important role as donors and acceptors of apo C, apo E, and various lipids from other lipoproteins in the circulation.

Reverse Transport. HDLs play an important role in the reverse transport of cholesterol from the periphey to the liver. Lecithin cholesterol acyl transferase esterifies HDL cholesterol and cholesteryl esters move to the core of the HDL molecule to allow more free cholesterol to be absorbed into the particle. Continued absorption of free cholesterol and subsequent esterification by lecithin cholesterol acyl transferase leads to the formation of the larger, cholesteryl ester-rich HDL2s. HDL2 molecules continuously acquire cholesteryl esters, resulting in the formation of the HDL1 molecules. On HDL1, cholesteryl esters are transferred from tissues to the liver for disposal or reuse, and not to LDL or VLDL molecules (as in humans), which transfer cholesterol to peripheral tissues. This function of HDL1s may account for the lower incidence of atherosclerotic disorders in dogs compared with humans.[23,24]

Nucleic Acids

Pyrimidine biosynthesis is one of the classic roles of the liver in nucleic acid metabolism. More recently, microRNAs have been impugned in the normal development and regeneration of the liver, as well as in hepatic pathology. microRNAs are small noncoding RNAs that regulate both messenger RNA and protein expression of target genes, which results in alterations in messenger RNA stability or translation inhibition. microRNAs influence at least one-third of all human transcripts and are known regulators of various important cellular growth and differentiation factors. microRNAs recently emerged as key regulatory molecules in chronic liver disease.[25]

Porphyrins

Porphyrins are intermediates of the heme biosynthetic pathway. Porphyrins are found in hemoglobin, myoglobin, cytochromes, catalase, and peroxidase enzyme. The liver and biliary tract serve as an excretory route for the porphyrins.

Metals

The liver stores iron, which can be toxic in excessive amounts (hemochromatosis). The amount of iron in the body is largely determined by regulation of its absorption in the upper small intestine. Iron is stored intracellularly as ferritin in a number of tissues, with the liver having a large storage capacity. When the capacity of the liver is exceeded, iron accumulates as hemosiderin.

The liver incorporates copper into specific copper proteins such as cytochrome c oxidase, mitochondrial monoamine oxidase, and ceruloplasmin. Mobilization of copper from hepatocytes takes place by at least two mechanisms: ceruloplasmin and bile secretion. Cholestatic liver disease is associated with secondary copper retention, which may then induce hepatocyte injury.[26,27]

Vitamins

The liver is importantly involved in vitamin metabolism. The liver produces bile for absorption of fat-soluble vitamins (A, D, E, K), and the liver is an important site for vitamin storage.

Vitamin A is stored in both stellate cells and hepatocytes. Approximately 95% of total body vitamin A is stored in the liver, representing a 1- to 2-year supply. The liver continues to release vitamin A to maintain normal blood concentrations despite reductions in its content. Liver and plasma vitamin A concentrations are reduced by malnutrition, liver disease, and intestinal malabsorption, but signs of deficiency do not appear until abnormalities become severe.

Fat-soluble vitamins A, D, E, and K require normal bile secretion for absorption. Vitamin K is particularly essential for synthesis of the prothrombin-complex clotting factors.

Water-soluble vitamins, with the exception of vitamin B_{12} (cobalamin), are readily absorbed from the small intestine. These vitamins are used primarily as coenzymes in metabolic processes. Vitamin phosphorylation, occurring primarily in hepatocytes, is required to produce some coenzymes. Thiamine is phosphorylated to thiamine pyrophosphate, for example, primarily in the liver and kidney. Nicotinic acid is a precursor in pyridine nucleotide synthesis, and an initial step in its conversion is nicotinamide synthesis in the liver. Pyridoxine is phosphorylated to its active form in the liver, as is the transformation of pantothenic acid to coenzyme A. Folic acid is converted to its active form in the liver. Large amounts of all water-soluble vitamins except vitamin C are stored in the liver.

Glutathione

Glutathione is synthesized in most if not all mammalian cells. The liver is particularly active and has relatively high levels of glutathione. Glutathione performs a variety of physiologic and metabolic functions, including thiol transfer reactions that protect cell membranes and proteins; thiol-disulfide reactions involved in protein synthesis, protein degradation, and catalysis; reduction of capacity; detoxification of hydrogen peroxide, organic peroxides, free radicals, and foreign compounds; and metabolism of various endogenous compounds.

Bile Secretion

Biliary secretions provide (a) a source of bile acids for fat digestion and absorption, (b) an excretory route for metabolites and xenobiotics, and (c) additional HCO_3^- for buffering of H^+ ion in the duodenum. Bile acids are the major components of bile accounting for about one-half to two-thirds of the total solutes. Bile also contains water, electrolytes, cholesterol, phospholipids, hormones, protein, and bilirubin (Figure 61-2).

Bile components are synthesized, stored, and secreted from the hepatocytes into the biliary ductal system.[28] In the absence of neural or hormonal input (as in the fasting state), the gallbladder is relaxed, the terminal biliary ductal sphincter (sphincter of Oddi) is contracted, and bile is largely stored in the gallbladder. While stored in the gallbladder, water and large portions of the electrolytes are reabsorbed by the gallbladder mucosa, concentrating the remaining constituents. During feeding, neural (acetylcholine) and hormonal (cholecystokinin) mechanisms activate gallbladder contraction, biliary ductal sphincter relaxation, and emptying of bile into the duodenum. Secretin and bile salts stimulate bile salt–independent and bile salt–dependent bile flow, respectively.[2,5,28]

Bile acids are synthesized from the cholesterol nucleus to which are attached a five- or eight-carbon side chain with a terminal carboxylic acid, and hydroxyl groups positioned at the C3, C7, or C12 carbon atom positions (Figure 61-3, *A* and *B*). The major primary bile salts are cholic acid and chenodeoxycholic acid in about equal molar quantities. When these primary bile acids are secreted into the lumen of intestine, a portion of each is dehydroxylated by intestinal bacteria to produce the secondary bile acids, deoxycholic acid, and lithocholic acid.[2,5,28] Prior to secretion, bile acids are conjugated with taurine and/or glycine to form tauro- and glycoconjugated bile salts (see Figure 61-3, *C*). Conjugation lowers the pK_a to well below the physiologic range of biliary and intestinal pH, and conjugated bile acids become ionized anions (referred to as bile salts) rather than undissociated bile acids. In the ionized form, they are less likely to be absorbed by the small intestine and so maintain a higher intraluminal concentration appropriate for emulsification, digestion, and absorption of lipids. Dogs and cats conjugate primarily with taurine. Dogs can convert to glycine conjugation if taurine is deficient, but cats cannot. Cats are obligate taurine conjugators, and have an essential dietary taurine requirement.[2,5,28]

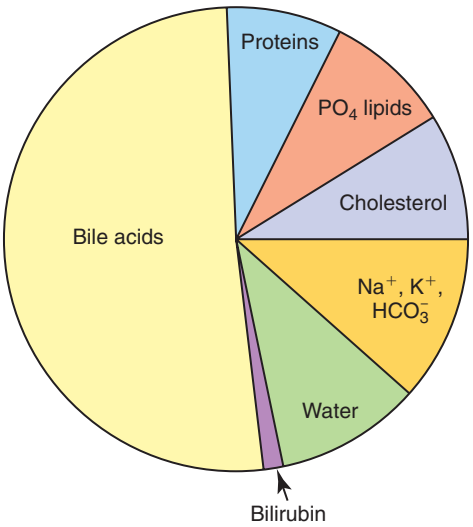

Figure 61-2 The chemical components of bile: bile acids, proteins, phospholipids, cholesterol, water, Na^+, K^+, HCO_3^-, and bilirubin.

Bile salts are amphipathic molecules with polar and nonpolar domains imparting two important functions. Bile salts have an initial detergent effect on fat particles in food permitting the breakup of fat globules into smaller sizes. This is the initial emulsification phase of bile salts that facilitates intraluminal lipid hydrolytic digestion. Bile salts further assist in the absorption of fatty acids, monoglycerides, cholesterol, and other lipids through the formation mixed micelles. These micelles serve to transfer digested lipids across the unstirred layer of the mucosa.

Following emulsification and micellarization of fat, most of the secreted bile salts are transported along the GI tract to the ileum where they are absorbed into ileal enterocytes and portal blood flow via Na^+–bile salt cotransporters.[2,28]

Coagulation Factors

The liver plays an important role in maintaining hemostasis. The liver produces procoagulant, anticoagulant, and fibrinolytic proteins, and also removes normal and abnormal clotting factors from the circulation.[29]

Hepatocytes synthesize most of the clotting factors including clotting factor I (fibrinogen), II (prothrombin), V, VII, IX, X, XI, and XIII. The site of biosynthesis of factor VIII remains controversial, but it is probable that the liver plays an important role in this factor, too. The liver is also responsible for the activation of the vitamin K–dependent factors II, VII, IX, and X and protein C. In addition to the production and activation of coagulation factors, the liver is also essential for the clearance of activated coagulation

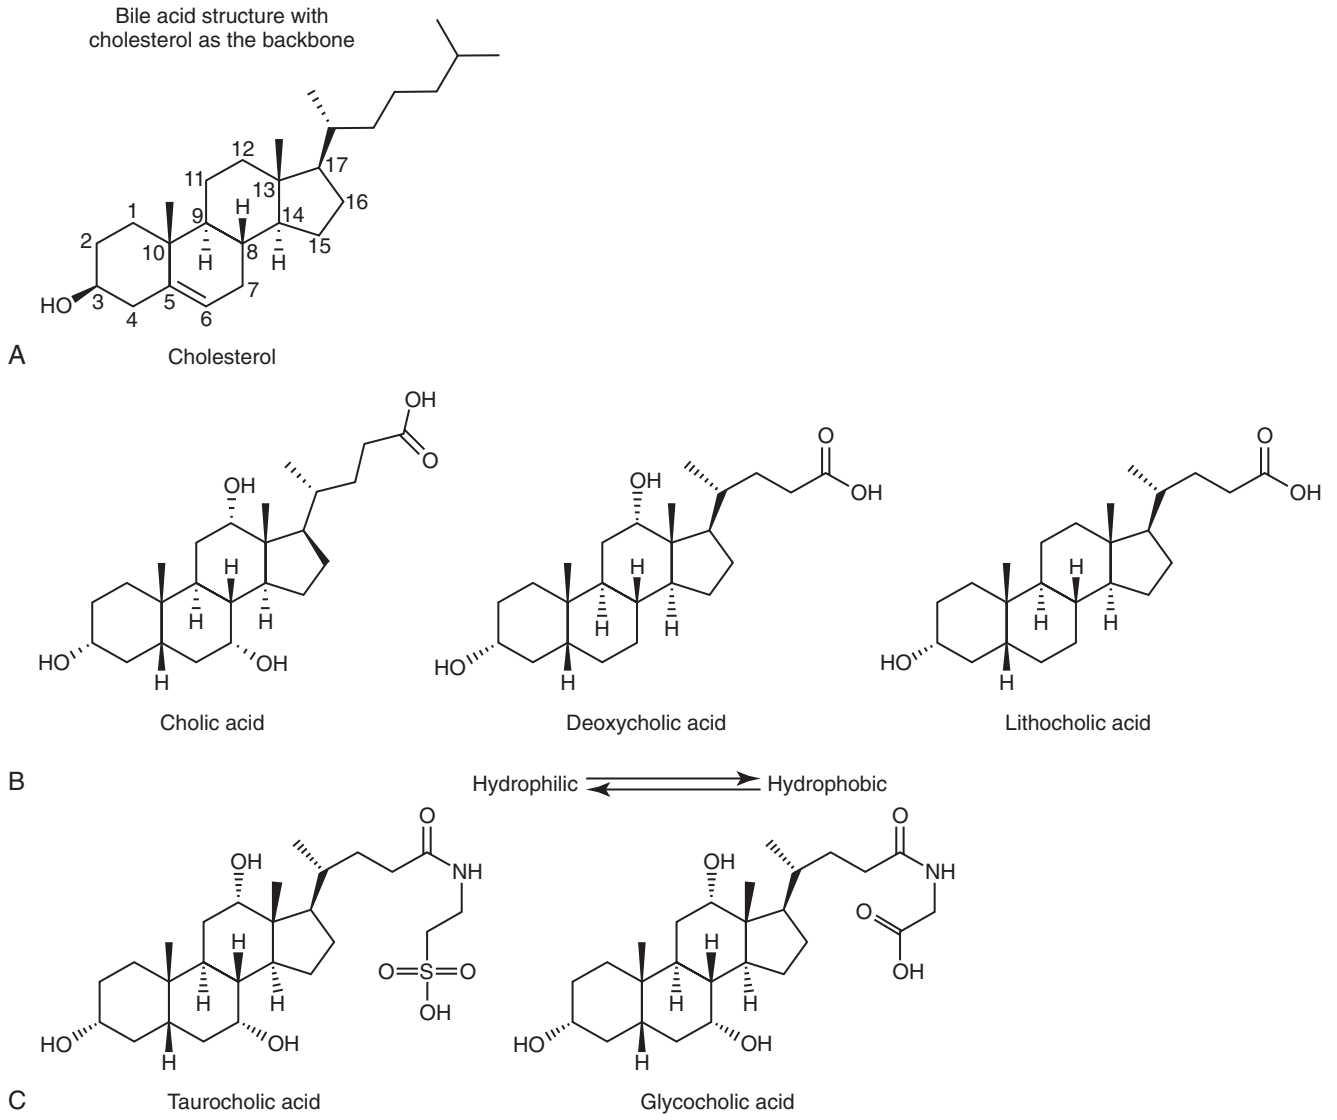

Figure 61-3 **A,** Cholesterol serves as the chemical backbone in bile acid synthesis. **B,** Hydrophilicity and hydrophobicity of bile acids. **C,** Glycine and taurine conjugation of bile acids.

products and the production of clotting factor inhibitors, such as antithrombin and α_1-antitrypsin, as well as fibrinolytic proteins like plasminogen.

In liver disease, factor and inhibitor synthesis and clearance of activated factors in both the coagulation factors and fibrinolytic system may be impaired. The extent of coagulation abnormalities depends upon the degree of disturbed liver function.[29] Patients with hepatic failure may present with the entire spectrum of factor deficiencies and may even develop disseminated intravascular coagulation.

In a study of 42 dogs with histologically confirmed liver disease, one or more coagulation abnormalities were found in 57% of dogs with liver disease.[29] Activated partial thromboplastin time was significantly prolonged in dogs with chronic hepatitis with or without cirrhosis. Mean platelet numbers, antithrombin, and factor IX activity were significantly lower in dogs with chronic hepatitis with cirrhosis, compared to dogs with other hepatopathies. D-Dimers were not significantly increased in any group. Only three dogs, all with different histologic diagnoses, satisfied the criteria for disseminated intravascular coagulation. Hemostatic abnormalities were primarily seen in dogs with chronic hepatitis plus cirrhosis, which may be a result of reduced synthesis rather than increased consumption of coagulation factors.

Detoxification

Xenobiotic Agents

Numerous foreign compounds, including drugs, are so hydrophobic that they would remain in the body indefinitely were it not for hepatic biotransformation. Cytochrome P450 (P450 or CYP) comprises a superfamily of enzymes that catalyze oxidation of a variety of xenobiotic chemicals such as drugs, toxic chemicals, and carcinogens, as well as endobiotic chemicals including steroids, fatty acids, prostaglandins, and vitamins. The cytochrome P450 enzymes in families one to three mediate 70% to 80% of all phase I–dependent metabolism of clinically used drugs and participate in the metabolism of a huge number of xenobiotic chemicals. There are 57 known active *P450* genes and 58 pseudogenes in the human genome. With 54 active genes, dogs are phylogenetically closest to the human. Although there are many similarities between dogs and humans, there also are many important differences.[30-33] Dogs present an

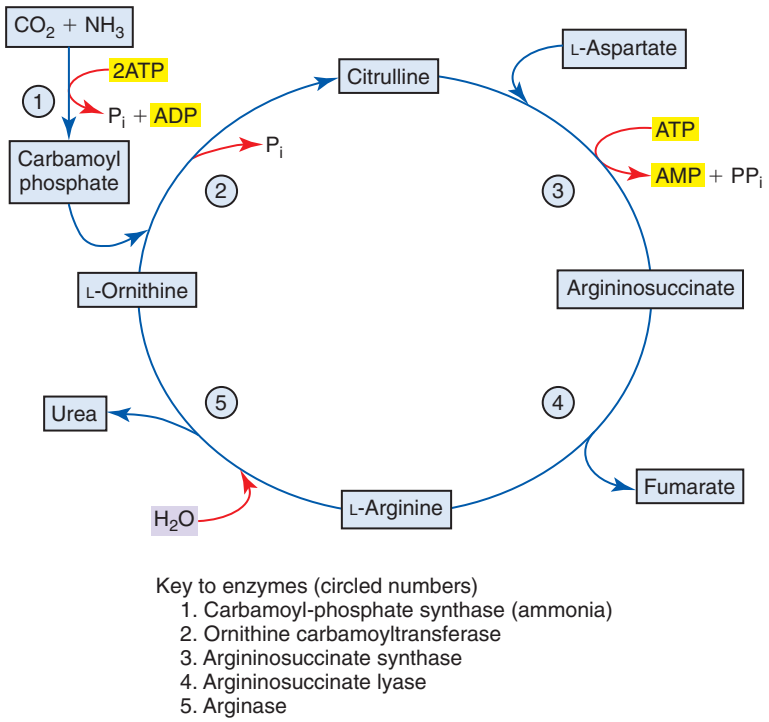

Figure 61-4 Urea cycle. Transformation of toxic ammonia into nontoxic urea.

interesting challenge in the assessment of P450-mediated drug–drug interactions because most of the enzymes have not been completely characterized, diet and aging induce significant changes in gene expression, and dogs are often treated off-label with a number of human drugs with little idea of risk for drug–drug interaction.

Drug metabolism takes two general forms: phase I metabolism (modification reactions) and phase II metabolism (conjugation reactions). Phase I metabolism typically subjects a drug to oxidation or hydrolysis. It involves the cytochrome P450 (CYP) enzymes, which facilitate reactions that include *N*-, *O*-, and *S*-dealkylation; aromatic, aliphatic, or *N*-hydroxylation; *N*-oxidation; sulfoxidation; deamination; and dehalogenation. Phase II metabolism conjugates the drug to hydrophilic substances, such as glucuronic acid, sulfate, glycine, or glutathione. Phase I metabolism usually precedes phase II metabolism, but this is not always the case.[34]

The liver is an important site of drug toxicity and oxidative stress because of its proximity and relationship to the GI tract. Seventy-five percent to 80% of hepatic blood flow comes directly from the GI tract and spleen via the main portal vein. Portal blood flow transports nutrients, bacteria and bacterial antigens, drugs, and xenobiotic agents absorbed from the gut to the liver in a more concentrated form. Drug-metabolizing enzymes detoxify many xenobiotics but might activate the toxicity of others. Hepatic parenchymal and nonparenchymal cells may all contribute to the pathogenesis of hepatic toxicity.

The toxicity of drugs can be considered in five contexts: on-target toxicity, hypersensitivity and immunologic reactions, off-target pharmacology, bioactivation to reactive intermediates, and idiosyncratic drug reactions.[35,36]

Ammonia

Ammonia is an important by-product of amino acid metabolism. Organisms that cannot easily and quickly remove ammonia usually have to convert it to some other substance, like urea or uric acid, which are much less toxic. Insufficiency of the urea cycle occurs in some genetic disorders (inborn errors of metabolism), or more typically, in liver failure. The result of liver failure is accumulation of nitrogenous waste, mainly ammonia, which leads to hepatic encephalopathy.

The GI tract, particularly the colon, is the most important source, through the action of bacterial urease on endogenous urea or dietary amines. Ammonia produced by colonic bacteria enters the portal circulation and is transported to the liver for urea cycle transformation (Figure 61-4). Ammonia is transformed into urea in the urea cycle in the overall equation:

$$2\,NH_3 + CO_2 + 3\ \text{adenosine triphosphate} + H_2O \rightarrow \text{urea} + 2\,ADP + 4\,Pi + AMP + 2\,H$$

where NH3 = ammonia; adenosine triphosphate = adenosine triphosphate; ADP = adenosine diphosphate; P_i = inorganic phosphate; and AMP = adenosine monophosphate.

Endogenous Hormones

Mineralocorticoids (aldosterone), glucocorticoids (cortisol, corticosterone), and sex steroids (androgens, estrogens, progesterone) are metabolized by the liver. Changes in the concentrations of total and free cortisol and of the binding capacity of corticosteroid-binding globulin have been reported in canine liver disease. As a consequence of hypercortisolemia, dogs with liver disease and hepatoencephalopathy have clinical and biochemical characteristics of PDH, including polyuria, high basal cortisol levels, and α-melanotropin.[37,38] Chronic hypercortisolism is associated with impaired osmoregulation of the release of vasopressin and inadequate urinary concentration.[39]

Immune Surveillance

The multiple physiologic functions of the liver require an immune response that is locally regulated. Pathogenic microorganisms must be efficiently eliminated, while the large number of antigens derived

from the GI tract must be tolerated. The liver favors the induction of tolerance rather than the induction of immunity. Although hepatocytes constitute the major cell population of the liver, direct interaction of hepatocytes with leukocytes in the blood is unlikely. Sinusoidal endothelial cells, which line the hepatic sinusoids and separate hepatocytes from leukocytes in the sinusoidal lumen, and Kupffer cells, the resident macrophage population of the liver, can directly interact with passenger leukocytes. In the liver, clearance of antigen from the blood occurs mainly by sinusoidal endothelial cells through very efficient receptor-mediated endocytosis. Liver sinusoidal endothelial cells constitutively express all molecules necessary for antigen presentation (CD54, CD80, CD86, major histocompatibility complex [MHC] classes I and II, and CD40) and can function as antigen-presenting cells for $CD4^+$ and $CD8^+$ T cells.[40,41] Thus, these cells probably contribute to hepatic immune surveillance by activation of effector T cells. Antigen-specific T-cell activation is influenced by the local microenvironment. This microenvironment is characterized by the physiologic presence of bacterial constituents such as endotoxin and by the local release of immunosuppressive mediators such as interleukin-10, prostaglandin E_2, and transforming growth factor-β.[42]

Regeneration

Liver regeneration after partial hepatectomy is a very complex and well-orchestrated phenomenon. It appears to be carried out by the participation of all mature liver cell types.[43,44] The process is associated with signaling cascades involving growth factors, cytokines, matrix remodeling, and several feedbacks of stimulation and inhibition of growth related signals.[45,46] The liver manages to restore any lost mass and adjust its size to that of the organism, while at the same time providing full support for body homeostasis during the entire regenerative process. In situations when hepatocytes or biliary cells are blocked from regeneration, these cell types can function as facultative stem cells for each other.

Gene expression in the regenerating liver is a multistep process with at least two critical steps: the transition of quiescent hepatocytes into the cell cycle ("priming"), and the progression beyond the restriction point in the G_1 phase of the cell cycle. Hepatocytes must first be primed before they can fully respond to growth factors. As many as 70 different genes participate in the early response to hepatectomy, but tumor necrosis factor (TNF), interleukin (IL)-6, and interleukin-22 (IL-22) appear to be the major cytokines involved in the priming of hepatocytes.[47] The proliferative effect of TNF on hepatocytes is further influenced by reactive oxygen species, nitric oxide, and glutathione content, and multiple transcription factors (e.g., nuclear factor kappa B, STAT3, AP-1, and C/EBPβ) play major roles in the initiation of early liver regeneration.[47] Progression through the cell cycle beyond the initiation phase requires growth factors, primarily hepatocyte growth factor and transforming growth factor-α (TGF-α). The subsequent expression of cell-cycle genes establishes the stage at which replication becomes growth factor-independent and autonomous. At this point, the hepatocyte is irreversibly committed to replicate and the cell cycle replication machinery takes over.

The proliferation of hepatocytes advances from periportal to pericentral ares of the lobules, as a wave of mitoses. Hepatocytes surrounding the central veins are the last ones to undergo cell replication. Proliferation of biliary epithelial cells occurs a little later than hepatocytes. Proliferation of endothelial cells starts at 2 to 3 days and ends around 4 to 5 days after partial hepatectomy. The kinetics of proliferation of stellate cells is incompletely understood. The regenerative capacity of the residual hepatocytes may restore liver mass and function after as much as 65% to 70% hepatectomy and it takes place over 7 to 14 days in most animal species.[48] A small wave of apoptosis in hepatocytes occurs at the end of regeneration.

HISTORY AND PHYSICAL EXAMINATION

Hein P. Meyer and Jan Rothuizen

Clinical Importance

The liver is the second largest organ in the body and performs an estimated 1500 essential biochemical functions.[1] These diverse functions include drug metabolism; removal of exogenous and endogenous toxins (e.g., ammonia, food antigens); synthesis of vital substances such as albumin and blood clotting factors; protein, fat, and carbohydrate metabolism; vitamin storage and activation; glycogen, triglyceride, and mineral (e.g., copper, iron) storage; activation, conversion, secretion, deactivation, and excretion of various hormones; bile salt synthesis; conjugation and excretion of bilirubin in bile; among others. Symptoms (defined here as abnormalities noted by the owner), clinical signs (defined here as abnormalities found during the physical examination), and diagnostic results reflect impairments in these functions. Hepatitis represented approximately 1% of the clinical population of the companion animal teaching hospital of Utrecht University. Box 61-1 summarizes the most common liver diseases with their possible etiologies in dogs and cats.

History of Dogs and Cats with Liver Disease

A properly taken history is pivotal to defining the most clinically relevant problems that need to be resolved. A structured interview process and understanding the basics of communication are important success factors to retrieve this crucial information. Fortunately, the knowledge about communication in the medical profession and the focus on the veterinary curriculum, has increased considerably during the last few years.[2,3]

Some basic principles should be kept in mind to understand the symptoms in dogs and cats with diseases affecting the hepatic parenchyma, portal vasculature, and the biliary system. First, for most of its functions, the liver has a tremendous (approximately 80%) reserve capacity and a remarkable potential to regenerate.[4] Symptoms occur only when progressive disease exhausts hepatic reserves. Diseases often remain subclinical for lengthy periods of time; symptoms may be relatively mild and nonspecific because the liver reserve prevents overt abnormalities. Symptoms such as lethargy, vomiting, or mild polyuria and polydipsia (PU/PD) may alert the clinician that a liver disorder could be developing. Serious symptoms may indicate loss of hepatic reserves. The onset of symptoms may be acute, but they may be the end result of a disease that has been present for many weeks or months. Because no specific physical abnormalities occur with most liver diseases, it is important to remember that liver disease may be present when symptoms of illness are unexplained or nonspecific. Sensitive and specific laboratory tests may easily detect such liver diseases.[5]

Second, most liver diseases cause similar signs and symptoms (Table 61-2). One of these is acholic feces, which occurs nearly exclusively in dogs with common bile duct obstruction.[6] Owners

Box 61-1 Causes of Acute Liver Disease in Dogs and Cats

Infectious Agents

Viral
- Infectious canine hepatitis (canine adenovirus I)
- Canine and feline herpesvirus (neonates)
- Coronavirus (feline infectious peritonitis virus)
- Feline *Calicivirus* (virulent form)

Bacterial
- Extrahepatic infections, septicemia, and endotoxemia
- Cholangitis
- *Clostridium piliforme* (Tyzzer disease)
- *Helicobacter canis* (dog)
- *Leptospira* spp.
- Liver abscess

Fungal
- *Histoplasma capsulatum*
- *Coccidioides immitis*
- Others

Protozoal
- *Toxoplasma gondii*
- *Neospora caninum*
- *Babesia* spp.
- *Cytauxzoon felis*

Rickettsial
- *Ehrlichia* spp.
- *Rickettsia* rickettsiae

Parasitic
- Liver flukes[a]
- Heartworms and caval syndrome

Drugs and Anesthetics

Anticonvulsants and Sedatives
- Diazepam (cats)
- Phenobarbital[a] (dogs)
- Primidone[a] (dogs)
- Phenytoin (dogs)

Antiinflammatory and Analgesic Drugs
- Glucocorticoids (dogs)
- Acetaminophen (dogs and cats)
- Carprofen and other nonsteroidal antiinflammatory drugs (dogs)

Antimicrobials and Parasiticides
- Diethylcarbamazine (dogs)
- Doxycycline (dogs)
- Griseofulvin (cats)
- Itraconazole (dogs and cats)
- Ketoconazole (dogs and cats)
- Mebendazole (dogs)
- Oxibendazole (dogs)
- Sulfonamides (dogs)
- Terbinafine (dogs)
- Tetracycline (dogs and cats)
- Thiacetarsamide (dogs)

Anesthetics
- Halothane (dogs)
- Methoxyflurane (dogs)

Miscellaneous
- Amiodarone[a] (dogs)
- Azathioprine (dogs)
- Danazol (dogs)
- Glipizide (cats)
- Lomustine[a] (dogs)
- Methimazole (cats)
- Methotrexate (dogs)
- Mithramycin (dogs)
- Mitotane (dogs)
- Phenazopyridine (dogs)
- Stanozolol (cats)

Herbal and Dietary Supplements
- α-Lipoic acid
- Black cohosh
- Comfrey[b] (pyrrolizidine alkaloids)
- Chaparral leaf[b]
- Chinese herbal medicines[b] (Jin Bu Huan, Ma huang)
- Kava[b]
- Pennyroyal oil
- St. John's wort

Biologic Toxins
- Aflatoxin
- *Amanita* mushrooms
- Blue-green algae
- Cycads (Sago palms)
- Hornet stings
- *Indigofera linnaei* (legume)

Food Additives
- Xylitol (sugar substitute)(dogs)

Chemicals
- Carbon tetrachloride
- Dimethylnitrosamine
- Dinitrophenol
- Pine oil
- Heavy metals (e.g., copper, lead, iron, arsenic)
- Organochloride pesticides
- Phenols
- Many others

Metabolic Disorders
- Acute pancreatitis
- Hemolytic anemia and disseminated intravascular coagulation
- Hepatic copper accumulation[a]
- Inflammatory bowel disease
- Feline hepatic lipidosis

Neoplastic Disorders
- Carcinoma (biliary, pancreatic)
- Lymphoma
- Malignant histiocytosis

Hypoxic/Ischemic Disorders
- Shock
- Liver lobe torsion
- Thromboembolic disease
- Congestive heart failure

Miscellaneous
- Trauma
- Heat stroke

[a]More likely to present with chronic rather than acute liver disease.
[b]Documented in humans, may occur in dogs and cats.

Table 61-2 Common Clinical Signs in Dogs with Liver Disease

Liver Disease with Relative Frequency (%)	PERCENTAGE OF DOGS AFFECTED BY DISEASE WITH SIGNS												
	Apathy, Depression	Inappetence	Reduced Endurance	Vomiting	Diarrhea	Weight Loss	Hepatic Encephalopathy	Polyuria/ Polydipsia	Dysuria	Anesthesia Intolerance	Acholic Feces	Distended Abdomen	Retarded Growth
Acute hepatitis (3)	44	49	–	61	21	12	–	11	–	–	–	–	–
Chronic hepatitis (10)	18	29	14	43	33	39	–	49	–	–	–	–	–
Cirrhosis (7)	25	53	39	61	37	58	9	56	–	–	–	55	–
Lobular dissecting hepatitis (2)	58	21	29	32	20	45	22	39	–	–	–	65	–
Reactive hepatitis (25)	10	34	–	48	77	39	–	9	–	–	–	–	–
Destructive cholangiolitis (1)	76	82	–	68	21	66	–	49	–	–	9	8	–

Extrahepatic cholestasis (2)	10	72	–	81	37	54	–	46	–	–	16	–	–

Figures are from the Utrecht University Clinic population. The relative frequencies are based on 2500 referred cases.

may note the light-gray appearance of stool, which in combination with icterus is virtually diagnostic for extrahepatic cholestasis. Different combinations of clinical signs and symptoms may occur with any liver disease. Statistically, one disease may be associated with a typical pattern of signs and symptoms in dogs and cats. However, overlapping patterns are so great that it is useless to try to identify the exact disease based on clinical signs and symptoms alone (Table 61-2). Clinical signs and symptoms associated with liver diseases of cats are similar to those in dogs, except for PU/PD, which is not clinically overt in most cats. Certain liver diseases cause neurobehavioral signs associated with hepatic encephalopathy,[7] and these signs may wax and wane in their frequency and severity. Any medication given may appear to be effective because of the natural fluctuation of signs. Therefore signs of hepatic origin may be easily missed. Seizures alone are never caused by hepatic encephalopathy; if they do occur, they occur in combination with other signs seen with this syndrome.[5] Furthermore, very few, if any, medications to treat liver diseases have been tested in double-blind, placebo-controlled studies, making decisions about the best therapeutic regimens difficult.[8]

It is usually not possible to differentiate between hepatic diseases and diseases of other organs based on symptoms and clinical signs. Signs associated with hepatic diseases are nonspecific; similar signs may occur in diseases of many other organ systems, most notably the GI, neurologic, renal, and hematologic systems (see Table 61-2).[9] Of the GI tract–related symptoms, nausea expressed as vomiting in acute cases or reduced, irregular appetite with occasional vomiting and weight loss over time, is very common in liver and biliary diseases of dogs and cats. For biliary diseases these are always the most prominent symptoms. Diarrhea, however, is not a major symptom of liver disease, and in cases in which diarrhea is the leading symptom the liver is only rarely the causative organ (except for rare cases with complete common bile duct obstruction). A rare sign (not included in Table 61-2) is an ulcerative form of dermatosis, so-called superficial necrolytic dermatitis, hepatodermal, or hepatocutaneous syndrome. This syndrome occurs rarely in dogs with liver cirrhosis and nodular hyperplasia and whose pathogenesis is poorly understood.[10] This symptom and the more common symptoms of lethargy, inappetence, vomiting, diarrhea, weight loss, PU/PD, and neurobehavioral symptoms are frequently associated with diseases of other organs. Therefore the history often discloses symptoms that may suggest hepatic disease, but may also be caused by other disorders.

Two main reasons account for the nonspecificity of liver-related symptoms. First, the liver is the central organ for many metabolic and detoxifying pathways; consequently, failing liver function may cause dysfunction of other organs. One example is hepatic encephalopathy; metabolic dysfunctions of the liver cause neurotransmitter dysfunctions of the brain, resulting in neurobehavioral signs.[11] Second, toxic factors resulting from diseases of other organ systems (especially from the GI tract) often secondarily affect the liver. Examples include hepatic lipidosis in diabetes mellitus, steroid-induced hepatopathy in Cushing syndrome, reactive hepatitis in GI diseases, and centrolobular liver necrosis in acute, severe anemia.[5] Therefore signs and symptoms of liver disease may be hidden within signs of other organ dysfunction, and vice versa. Because clinical and physical examination findings may be compatible with hepatic disease, and because laboratory tests to detect hepatic disease are also abnormal with primary and secondary hepatopathies, it is often necessary to make a histologic diagnosis of the liver disorder to resolve this dilemma.[12,13]

Lack of specific physical examination findings may prevent recognition of a primary liver disease. Most dogs with illnesses causing the clinical signs listed in Table 61-2 are candidates for having a primary hepatopathy. In all such cases, further diagnostic studies should be performed to confirm or exclude liver disease (Figure 61-5).

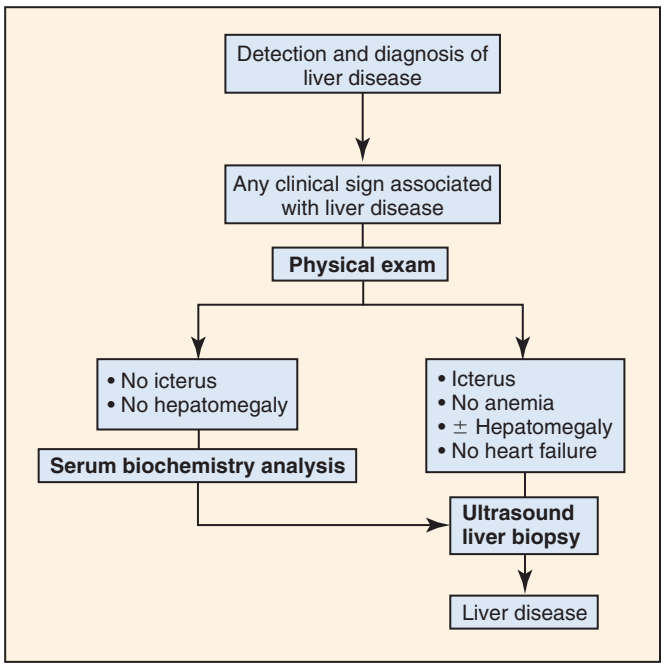

Figure 61-5 Algorithm for the detection and diagnosis of liver disease.

Predispositions

Breed, sex, age, and drugs may predispose dogs and cats to hepatopathies. The presence of numerous risk factors should be a stimulus for an extended diagnostic workup; other diseases should be investigated in the absence of such suspicions. Caused by hypersensitivity to sulfonamides, destructive cholangiolitis is the most common drug-induced liver disease.[14] A recent history of therapy with sulfonamides or other potentially hepatotoxic drugs, combined with icterus makes this condition likely and should prompt immediate discontinuation of the medication. Breed associations may occur when a disease is (in part) determined by genetic factors. Breeders may, by chance, increase the incidence of hepatic diseases by familial selection. Because dog breeds may represent more or less closed populations in a country, breed predispositions may vary among countries. Therefore this section only mentions generally applicable predispositions; locally, other breed associations may be more pertinent.

Chronic hepatitis and cirrhosis, both of which are, as a rule, different stages of one disease, occur more frequently in certain breeds.[15] Hepatitis may develop at any age, but typically not before 2 years of age. Only lobular dissecting hepatitis tends to occur at a young age (i.e., often before 1 year of age).[16] Breeds associated with hepatitis are Doberman Pinschers, Bedlington Terriers, West Highland White Terriers, American and English Cocker Spaniels, Labrador Retrievers, and many other breeds. Recent copper excretion studies have shown that hepatitis is caused by copper retention and not vice versa in Doberman Pinschers.[17] The cause of copper retention remains unclear; many of the tested candidate genes (including Murr 1, the affected gene in Bedlington Terriers) were excluded as monogenetic causes for copper-associated subclinical hepatitis in

Doberman Pinschers.[17] The hepatitis in Doberman Pinschers is sex linked, confined to females, and aggressive.[18] It is responsive to medication with penicillamine,[19] but may terminate in micronodular cirrhosis. This form of cirrhosis, predominantly seen in copper toxicosis, differs from other forms of chronic hepatitis, in which patients typically develop macronodular cirrhosis with large hyperplastic nodules. Hepatitis is overrepresented in female Doberman Pinschers by a factor of 10; a study in Finland showed that approximately 10% of Doberman Pinschers may be affected.[20] Inherited copper toxicosis is also a well described entity in Bedlington Terriers worldwide.[21] Both sexes may be affected. Clinical signs usually develop after 4 years of age as a result of the gradual accumulation of copper. It is caused by a defect in the Murr 1 gene, leading to a severely decreased excretion of copper by hepatocytes. Other affected breeds are West Highland White Terriers (particularly in the United States), Skye Terriers, Dalmatians, Anatolian Shepherd dogs, and Labrador Retrievers.[22-26] Siamese cats may also be predisposed to copper-associated hepatopathies.[9] Although essential for life, copper is usually ingested to excess and must be eliminated by the liver to prevent toxicity. The central role of the liver in copper homeostasis makes it vulnerable if elimination processes fail.[27] Furthermore, increased copper levels add to the oxidative stress, which is an important component in chronic inflammatory and cholestatic diseases in dogs.[25] Spaniels seem to have the form of chronic hepatitis unrelated to copper toxicosis and develop macronodular cirrhosis when left untreated. No sex predisposition exists, but there seems to be a worldwide overrepresentation of hepatitis in this breed.

Congenital portosystemic shunts (CPSS) are seen in both sexes in various breeds. Intrahepatic shunts predominate in large breeds, whereas extrahepatic shunts predominate in small and toy breeds. Although CPSS are most likely inherited in some fashion in all affected breeds, this has only been proven in Irish Wolfhounds[28] and Cairn Terriers.[29] Worldwide predispositions occur in Irish Wolfhounds, Australian cattle dogs, Labrador Retrievers, Dachshunds, Yorkshire Terriers, Cairn Terriers, Maltese Terriers, and Miniature Schnauzers.[7,9] In the United States, an increased prevalence of shunts has also been reported to occur in German Shepherd dogs, Doberman Pinschers, and Golden Retrievers. CPSS occur most often in mixed-breed cats; however, Persian and Himalayan cats are frequently overrepresented. Clinical signs are usually seen in young dogs and cats (<1 year old) with congenital shunts.[5,9]

Pathogenesis of Common Symptoms of Primary Liver Diseases

Vomiting

Vomiting is one of the most common symptoms noted in dogs and cats with liver disease. Vomiting may be caused by direct stimulation of the vomiting center via the chemoreceptor trigger zone in the fourth ventricle by (endo)toxins that are not cleared by the liver.[30] This typically occurs when toxins from the GI system bypass the liver and access other body systems. Vomiting is common in all conditions that share portosystemic shunting and liver dysfunction (e.g., congenital shunts and acquired shunts because of hepatitis, fibrosis, cirrhosis, and portal vein hypoplasia or thrombosis). Hepatic diseases that cause an abnormal liver shape may reposition the upper GI tract and induce nausea and vomiting by vagal stimulation. Causes include hepatic tumors, especially liver cell (or hepatocellular) carcinomas, and unilateral collapse and contralateral hypertrophy, which may occur with thrombosis of a main branch of the portal vein. The gallbladder and larger bile ducts have a rich sympathetic innervation; therefore dilation (e.g., extrahepatic cholestasis), cholecystitis, or cholelithiasis should be suspected in vomiting dogs and cats.[5]

Vomiting is also common in upper GI disease. In many GI diseases, translocation of bacteria and endotoxins may cause secondary, nonspecific, reactive hepatitis.[30] This occurs frequently in dogs, but rarely in cats. Reactive hepatitis is characterized by intrahepatic canalicular cholestasis, liver cell necrosis, and an exudative inflammatory reaction. Clinical signs, symptoms, and diagnostic results associated with primary liver disease and reactive hepatitis are similar; therefore, a further diagnostic workup is important to reveal the primary cause.

Diarrhea

Small bowel-type diarrhea occurs frequently with hepatic diseases (see Table 61-2). Two primary mechanisms may account for clinical signs. First, cholestatic diseases (intrahepatic or extrahepatic caused by common bile duct obstruction) disrupt the normal enterohepatic cycle of bile acids; therefore less bile reaches the duodenum.[30,31] Decreased resorption of dietary fat may cause hyperosmotic intestinal contents and diarrhea. However, studies in rats show that cholestasis must be severe before steatorrhea as a result of disruption of the enterohepatic bile acid cycle occurs. Another mechanism for diarrhea in liver disease is increased resistance to portal blood flow, resulting in portal hypertension and congestion of splanchnic organs. Intestinal vasculature congestion reduces intestinal water resorption and increases intestinal volume content. This is the predominant mechanism underlying diarrhea in diseases such as chronic hepatitis, lobular dissecting hepatitis, portal vein thrombosis, and portal vein hypoplasia.[5] Alternatively, when the primary cause of diarrhea is intestinal disease, the liver may be affected secondarily. In those cases, the hepatic macrophage system should remove the increased absorption of (endo)toxins or bacteria by the affected intestinal wall. Increased exposure, however, can lead to secondary, nonspecific, reactive hepatitis. Endotoxins also effectively inhibit bile formation and flow, leading to cholestasis. It is therefore common to find increased plasma liver enzyme activities and bile acid levels in cases of reactive hepatitis; clinical icterus may even be apparent. The cause of diarrhea can be determined only by further diagnostic methods, including histologic evaluation of liver biopsy specimens. Reactive hepatitis resolves rapidly when the primary disease is treated successfully. In the authors' experience it is very rare to find diarrhea as single or the leading symptom in cases of liver disease. If present, it is usually one of the less prominent symptoms in the spectrum of other more prominent symptoms such as apathy, PU/PD, or vomiting. One may therefore elect to follow liver laboratory values after treatment of the intestinal disease and perform a liver biopsy if liver parameters fail to improve within a few weeks.

Hepatic Encephalopathy and Related Anesthesia Intolerance

Hepatic encephalopathy is a complex of neurobehavioral signs resulting from portosystemic shunting of blood in combination with a reduction of functional liver mass.[11] It may occur in animals with CPSS or in those with APSCAPSC because of portal hypertension. Diseases associated with the latter form are chronic hepatitis, cirrhosis, portal vein hypoplasia, lobular dissecting hepatitis, and portal vein thrombosis.[32] Cats, because of their dependence on some essential amino acids (e.g., arginine), may develop hepatic encephalopathy without portosystemic shunting, especially when they have a severe form of hepatic lipidosis.[33]

Hepatic encephalopathy is caused by derangement of neurotransmitter systems caused by defective metabolic processes in the liver.[34] Inadequate metabolism of ammonia and aromatic amino acids by the liver may reduce the excitatory glutamatergic and monoaminergic neurotransmitter system tones, respectively.[35] In addition, there is an increased tone of the inhibitory γ-aminobutyric acid (GABA) system.[36] These neurotransmitter derangements make anesthesia risky in some animals with liver disease. The liver inactivates many anesthetics and the unforeseen delay of recovery from anesthesia may suggest an underlying liver disease as a cause for nonspecific clinical signs. This occurs especially in dog and cats with portosystemic shunting, either congenital or acquired. In addition to reduced hepatic clearance, anesthetics exert their action via various neurotransmitter systems in the brain, which may already be functioning abnormally as a consequence of hepatic encephalopathy.[34] This is especially true of drugs that act via the GABA-benzodiazepine pathway. That pathway is already overstimulated and may provoke an exaggerated and prolonged anesthetic effect.

Polyuria and Polydipsia

PU/PD is one of the most frequent signs (50% of cases) in dogs with liver disease, but is less common in cats. PU/PD is most common in diseases associated with congenital or acquired portosystemic shunting and, therefore, with hepatic encephalopathy. In affected dogs, abnormal neurotransmitter disturbances lead to increased secretion of adrenocorticotropic hormone (ACTH) from the anterior and intermediate pituitary lobes.[37] Chronically elevated ACTH stimulates increased levels of free cortisol. Increased levels of free cortisol, in turn, affect the posterior lobe of the pituitary creating an increased threshold for the release of arginine vasopressin.[38,39] Thus, a higher plasma osmolality is required to stimulate antidiuresis through arginine vasopressin, and before reaching that threshold, affected dogs become thirsty and start drinking.[38]

PU/PD is not only present in cases with hepatic encephalopathy, but also frequently in all other liver diseases. This may be caused by certain bile acids, which are often increased in plasma of animals with liver diseases. Bile acids may inhibit the activity of 11β-hydroxyl steroid dehydrogenase.[40] This enzyme protects the aldosterone receptor from occupation by cortisol, by converting cortisol into cortisone, which cannot bind to the receptor. Present in plasma in tenfold excess compared with aldosterone, cortisol can occupy and stimulate the aldosterone receptor thereby inducing pseudohyperaldosteronism and PU.[41]

Reduced hepatic formation of urea is another possible but undocumented mechanism that may play a role in the pathogenesis of PU/PD. In urea deficiency states, the kidney does not have sufficient urea available to build up an osmotic gradient in the medulla. Apart from this mechanism, PD also occurs in liver diseases not associated with hepatic encephalopathy (e.g., extrahepatic cholestasis and liver tumors). The mechanism is unclear; however, nausea with an impulse to drink and compensation of water loss by vomiting and diarrhea may play a role.[5]

Dysuria

Dysuria may occur as a result of insufficient liver function when nonmetabolized uric acid is excreted by the kidneys and precipitates to form uroliths. Such calculi are seen in dogs but rarely in cats.[42] There are two main categories of liver dysfunction that cause ammonium urate urolithiasis. Most frequently it is caused by congenital portosystemic shunting, whereby the liver is underdeveloped and fails to metabolize uric acid into allantoin. In urine, uric acid flocculates easily in the presence of high ammonia concentrations to form ammonium urate. Affected dogs usually have clinical signs related to shunting and liver dysfunction, such as hepatic encephalopathy, PU/PD, or vomiting. In the other category, the enzyme uricase, which forms allantoin, is inactive because of an inborn error affecting only this function. Ammonium urate urolithiasis occurs commonly in Dalmatians but may occur in other breeds.[43] Affected dogs only have signs related to urolithiasis (e.g., pollakiuria, stranguria, dysuria).

Acholic Feces

An owner may note acholic feces, which can provide a direct clue to the underlying diagnosis. Steatorrheic feces that do not contain normal bile pigment are seen only when bile flow into the intestinal tract is completely disrupted, usually as a consequence of extrahepatic obstruction of the common bile duct.[6] Destructive cholangiolitis is the only intrahepatic process severe enough to seriously disrupt bile flow. The latter disease is caused by a hypersensitivity reaction to sulfonamide-containing drugs. The smaller bile ductules become necrotic and liver lobuli may be disconnected from the biliary tract. Affected dogs have a history of recent medication with sulfonamides. Acholic feces contain excess fat because resorption is impaired. The lack of normal black-brown fecal pigments occurs because their precursor, bilirubin, does not reach the duodenum. Therefore, the feces from affected animals are gray-white and soft. Animals with this condition often are icteric. The presence of icterus reduces the likelihood of exocrine pancreatic insufficiency as a diagnosis.

Abdominal Distention

Abdominal distention may occur in dogs and cats with liver disease for several reasons. First, ascites is a frequent finding associated with liver disease in dogs as a result of portal hypertension, but is less common in cats. Abdominal distention may also result from organ enlargement, which in the case of liver disease may include the liver and, in the spleen in the presence of portal hypertension. In contrast to dogs, cats often have hepatomegaly with liver disease.

Other Symptoms

Nonspecific symptoms, such as apathy, reduced appetite or anorexia, and weight loss, may occur in dogs and cats with liver disease. Retarded growth is common in young animals. These problems reflect the central role of the liver in many metabolic and detoxifying functions. In addition, nausea, inappetence, vomiting, and diarrhea can result in a catabolic state, which, in turn, may aggravate hepatic encephalopathy. Signs of early hepatic encephalopathy include depression and other nonspecific problems. Anemia, another common finding in liver disease (see below), can cause general malaise. Dogs with liver cell carcinoma often are hypoglycemic,[44] which may be the primary problem underlying apathy and weakness. Production of insulin-like growth factors by the tumor may be responsible.

Physical Examination and Signs of Liver Diseases

As with historical findings, physical examination findings rarely provide enough information to pinpoint the liver as definitive cause of the presenting problems. Possible findings include icterus, hepatomegaly, splenomegaly, ascites, and pale mucous membranes. Petechiae of the skin or mucous membranes occur infrequently. Of these possible findings, only icterus and hepatomegaly are more or less specific for liver diseases; other abnormalities on the physical examination occur more frequently with diseases of other organ systems.

Ascites and hepato- and splenomegaly may have been noted by the owner as abdominal enlargement.[5] Biochemistry analyses are an integral part of the diagnostic process for liver diseases. Most of these analyses are not a decisive factor in the diagnosis of liver disease, but serve to rule out liver disease from the differential diagnosis.[8]

Icterus

Icterus is the most frequently encountered specific abnormality noted on the physical examination in dogs and cats with liver disease. However, only approximately 20% of dogs with hepatobiliary diseases and 30% to 40% of cats are icteric. Icterus results from bilirubin accumulation in the blood and extravascular space as a result of increased production, reduced clearance, impaired conjugation by the liver, and/or impaired bile flow. In most cases, a combination of these factors is involved. Cholestasis is predominant; therefore conjugated bilirubin is the fraction present in greatest quantity. Hemolysis alone does not result in icterus with normal liver function. When hemolysis is severe, however, it may result in such a degree of portal hypoxia that the centrolobular zones of the liver lobules become necrotic. In those cases, icterus results from the combination of increased production and reduced liver function and cholestasis.[45] If hemolysis is the primary cause of icterus, it must be severe, and the mucous membranes will be extremely pale. Primary liver diseases that may cause icterus are commonly accompanied by hemolysis. Whereas the erythrocyte lifetime is reduced to 6 to 10 days in dogs with severe primary hemolytic disease; it is 20 to 60 days (normally 100 days) in hepatobiliary disease. Increased production of bilirubin and liver dysfunction with cholestasis result in a combined conjugated and unconjugated hyperbilirubinemia in dogs and cats with primary hepatic or hemolytic disease.[46] Icterus caused by hemolytic disease is characterized by pale mucous membranes, whereas the mucous membranes in animals with primary liver disease are normal or only slightly pale. The combined evaluation of icterus and the color of the mucous membranes immediately reveal the nature of the underlying process.

Pale Mucous Membranes

As previously discussed, most hepatobiliary diseases are accompanied by increased degradation of red blood cells. The mechanisms behind hemolysis in liver disease are not completely clear. Hypersplenism and reduced portal blood flow due to portal hypertension may drastically prolong the transit time of erythrocytes through the spleen, with a greater chance that they will be trapped when they are slightly abnormal. Increased fragility of red cell membranes may be a result of the high bile acid levels in most liver diseases, whereas a reduced clearance of enteral endotoxins and bacteria by the liver may also induce immune-mediated hemolysis. Apart from hemolysis, nonregenerative anemia also may occur as part of the syndrome of anemia of chronic disease as an expression of catabolism and slight deficiencies of iron and B vitamins. Although common in liver diseases,[12] anemia, in contrast to icterus, is nonspecific.

Hepatomegaly

Like icterus, hepatic enlargement is a distinct sign of an abnormal liver. In dogs, most liver diseases do not cause hepatomegaly. Exceptions include tumors of the liver, liver congestion, and secondary liver involvement in metabolic diseases. Examples of the latter conditions are glycogen accumulation in the liver in Cushing disease, fatty liver with diabetes mellitus, and rare cases of amyloidosis of the liver.

The more chronic liver diseases of dogs tend to reduce liver size, and acute diseases cause little change in size. Liver enlargement as a result of congestive heart disease can, in most cases, be recognized easily by physical examination of the circulatory system. Measurement of central venous pressure is diagnostic. The exception is liver congestion caused by a thrombus in the caudal vena cava proximal to the liver, which is assessed by other methods. When the liver is overtly enlarged because of congestion, ascites is usually present. Ascitic fluid has the typical slightly hemorrhagic appearance of congestive fluid. Dogs with enlarged livers and no signs of congestive disease often have liver cancer, which may be primary, metastatic, or a form of malignant lymphoma. With most tumors, the liver is diffusely enlarged, but primary hepatocellular carcinomas or adenomas may cause enlargement of the affected lobe only. Bile duct carcinomas disseminate easily over the biliary system and usually cause pronounced icterus and hepatomegaly.

Most cats with hepatic disease develop pronounced enlargement of the liver. In cats, liver enlargement occurs with cholangitis, hepatic lipidosis, amyloidosis, hepatic tumors (primarily malignant lymphoma), and congestive disease. When the liver is involved in feline infectious peritonitis, it may not be enlarged. Cats with CPSS have small livers.

Splenomegaly and Ascites

Splenomegaly and ascites in association with liver disease are nonspecific findings. They occur especially with hepatic diseases causing portal hypertension. Both findings are frequent in dogs but rare in cats. There is a positive undulation test with distinct ascites; slight ascites can be found with ultrasonography rather than physical examination. The liver may be enlarged with central causes of venous congestion. Canine liver diseases associated with portal hypertension include chronic hepatitis and cirrhosis, portal vein hypoplasia, and lobular dissecting hepatitis. Portal hypertension is sometimes seen with cirrhosis because of advanced cholangiohepatitis in cats. In these diseases, hepatic encephalopathy is also common. Portal vein thrombosis is a prehepatic cause of portal hypertension that usually causes ascites. Although as a rule the liver is small in these cases, unilateral obstruction of a main branch of the portal vein may cause hypertrophy of the rest of the liver, which may be palpable.

Conclusion

Diseases of the hepatic parenchyma, hepatic vasculature, and biliary tract are relatively common in dogs and cats. Because the symptoms and signs accompanying liver disease are quite nonspecific, and the liver may be secondarily involved in diseases of other organs, liver disease can easily go undetected. Therefore, after taking a thorough history and performing a physical examination, it is critical to perform additional biochemical tests with the highest possible diagnostic accuracy whenever liver disease is included in the differential diagnosis. If liver disease cannot be ruled out based on these examinations, additional testing is necessary to define the type of liver disease, most notably ultrasonography of the cranial abdominal quadrant and examination of a liver biopsy specimen. The algorithm in Figure 61-5 summarizes this approach.

Diagnosis usually depends on histopathologic examination of liver tissue, especially for parenchymal liver diseases, many biliary tract diseases, and tumors of the liver or biliary tract. Although biopsy methods are beyond the scope of this chapter, excellent sources exist.[13] One note of caution: blood coagulation testing is vital before collecting a liver biopsy specimen for histopathology. Most animals, for example, have one or more abnormal coagulation tests.[47-52] Factors involved may include vitamin K deficiency, reduced

production of clotting factors, some degree of disseminated intravascular coagulation (DIC), and severe protein deficiency.[13,52] It should be noted that taking a fine-needle aspiration biopsy should be considered safe, even if abnormalities in coagulation are present. However, its diagnostic value is limited as the liver architecture is lost.

Diagnosis of circulatory hepatic diseases depends on information obtained from laboratory results, ultrasonography (most reliable diagnostic test to date), and histopathology.[13] A recent paper found that fasting ammonia concentration was superior to fasting bile acids for diagnosing portosystemic shunting in dogs.[53] Ammonia is easily measured in practice with dry chemical methods, some of which provide reliable results.[54] Another recent publication showed ultrasonography to be a reliable diagnostic method to noninvasively characterize the underlying hepatic disease in dogs with hyperammonemia.[55]

DIAGNOSTIC EVALUATION

Jonathan A. Lidbury and Jörg M. Steiner

Diagnostic evaluation of the hepatobiliary system has several aims: (a) to determine if hepatobiliary disease is present, (b) to assess liver function, (c) to determine if liver disease is primary or secondary, (d) to definitively diagnose hepatobiliary disease, and (e) to monitor response to treatment. Despite the apparent clarity of these aims, hepatobiliary disease can present a diagnostic challenge for a number of reasons. First, as clinical signs can be nonspecific, hepatobiliary disease should be a consideration when evaluating any patient with signs of systemic disease. Dogs and cats with hepatobiliary disease may not have any clinical signs. Furthermore, because of the liver's central role in metabolism and detoxification of endogenous toxins and xenobiotic agents, a number of extrahepatic diseases can secondarily affect the liver. It is important to distinguish these *secondary hepatopathies* from diseases that originate in the liver (*primary hepatopathies*). Additionally, serum markers of hepatocellular damage, cholestasis, and hepatic function can be abnormal in the absence of hepatobiliary disease. Finally, the liver's large reserve capacity means that detectable loss of liver function often occurs late in the course of disease. Thus, when assessing a patient with suspected hepatobiliary disease, it is important to consider the clinical presentation, results of laboratory testing, diagnostic imaging findings, and the results of cytologic and/or histopathologic evaluation together.

Laboratory Testing of the Liver

Hepatic Enzymology

Hepatic enzymes can be divided into markers of hepatocellular damage and markers of cholestasis. Serum alanine aminotransferase (ALT) and aspartate transaminase (AST) activities are the two most commonly measured markers of hepatocellular leakage, while serum alkaline phosphatase (ALP) and γ-glutamyltransferase (GGT) activities are the two most commonly measured markers of cholestasis.

Although increased serum hepatic enzyme activities are considered to be sensitive, they are not specific for primary liver disease because they are produced by extrahepatic tissues. The relative importance of these extrahepatic *isoenzymes* varies, but their extrahepatic release can lead to increased serum activities. Also, the production of some hepatic enzymes can be induced by certain hormones and drugs, leading to an increase in their serum activities in patients without primary hepatic disease. Additionally, serum hepatic enzyme activities can be increased as a consequence of secondary hepatopathies.

The magnitude of hepatic enzyme activity increases may aid in the assessment of the severity or the extent of hepatic injury but should not be considered to be prognostic. The liver has a large capacity for regeneration, so even in cases of severe hepatic injury, with dramatically raised hepatic enzyme activities, a full recovery is possible. This is especially true when the injury is acute. Conversely, in cases of chronic end-stage liver disease, such as cirrhosis, serum hepatic enzyme activities may not be markedly increased, or may even be within the reference interval as a result of the replacement of hepatocytes with fibrous tissue. Consequently, serial evaluation of serum hepatic enzyme activities is more useful for assessing prognosis than measurement at a single point in time. Consistent decreases of a previously increased activity are considered a favorable sign in acute liver injury, whereas a decreasing hepatic enzyme activity in a patient with chronic liver disease that is clinically deteriorating suggests loss of hepatocytes because of fibrosis. It is important to note that serum hepatic enzyme activities do not provide an assessment of liver function.

Markers of Hepatocellular Damage

ALT is an enzyme found primarily in the cytosol of hepatocytes. ALT is released into the serum when hepatocyte membrane permeability is increased, or if there is hepatocellular necrosis. ALT is considered to be the most liver-specific enzyme. ALT is also produced by cardiac muscle, skeletal muscle, and the kidneys.[1] Apart from the hepatic form, only the muscle isoenzyme is clinically significant. Although uncommon, severe muscle injury can result in an increased serum ALT activity. Hepatic microsomal induction in response to some drugs can also produce small increases in ALT activity.

Some controversy exists regarding the serum half-life for ALT in dogs. The mean serum half-life of ALT was reported as being 149 minutes in one study[1] and 59 hours in another.[2] The serum half-life of ALT is generally believed to be shorter in the cat than in the dog. A mean serum half-life of 207 minutes was reported in an experiment involving three healthy cats.[3] The shorter half-life in cats means that increases in serum ALT activity are considered more clinically important in this species. As ALT is metabolized in the liver its serum half-life may be longer in patients with liver disease.[4]

Increased cell membrane permeability in the absence of hepatocyte destruction can cause a rapid increase in serum ALT activity. Because of this, ALT activity is a considered to be a highly sensitive marker of hepatocyte injury. This also means that an increased ALT activity does not imply severe or irreversible hepatocellular injury. The highest increases in ALT activity are seen during acute hepatic inflammation or necrosis, but because of the capacity for the liver to regenerate these do not indicate irreversible damage. Consequently, a single measurement of ALT activity does not provide an accurate prognosis. However, the degree of the ALT activity increase is believed to have some correlation with the number of hepatocytes that have been injured. Cholestasis can also result in an increased serum ALT activity because of hepatocellular damage caused by the accumulation of bile acids. Certain drugs can lead to increases in serum ALT activity. These are usually minor, for example, phenobarbital used at therapeutic doses frequently leads to small increases in serum ALT activity, in the absence of hepatic insufficiency. These increases are thought to occur as a result of subclinical hepatic injury rather than induction of hepatic microsomal enzymes.[5] Toxic doses

of phenobarbital can cause dramatic increases of serum ALT activity and hepatic insufficiency. Prednisone and other glucocorticoids can cause an induction of ALT (and steroid hepatopathy) and consequently small increases in serum ALT activity. Serum ALT activity can also be increased with any secondary hepatopathy. However, a persistently increased serum ALT activity, even with an apparently normal liver function, is an indication for further diagnostic testing.

Serial evaluation of serum ALT activity can be helpful to prognosticate but must be done while considering the patient's clinical signs and other laboratory values. In general, a declining serum ALT activity after acute liver injury is considered a good sign.

AST is another aminotransferase enzyme that is used as a marker of hepatocellular leakage. AST is found in skeletal muscle, the brain, liver, kidney, cardiac muscle, and to a lesser extent within other tissues.[6] The extrahepatic isoenzymes of AST are relatively more important than they are for ALT. Muscle disease can cause an increase in serum AST activity. Because of this, AST is considered less liver specific than ALT. However, by looking at serum AST activity in conjunction with the activities of other hepatic enzymes and muscle enzymes, it is usually possible to differentiate increases caused by muscle damage from increases caused by hepatic damage.

Again, there is controversy regarding the serum half-life of AST. In dogs one study[1] reported the half-life to be a mean of 263 minutes; another study reported a mean of 22 hours.[2] One study reported the mean half-life to be 78 minutes for cats.[7] Unlike ALT, a considerable proportion of AST (approximately 30%) is found within hepatocyte mitochondria rather than the cytosol.[8] The cytosolic fraction of AST is released into the serum from hepatocytes when cell membrane permeability is increased, or in case of hepatocellular necrosis. In contrast, the mitochondrial fraction is only released during hepatocellular necrosis. Release of AST from hepatocytes into the serum parallels the release of ALT. Therefore, like serum ALT activity, serum AST activity is considered a sensitive marker for hepatocyte injury. It has been suggested that increased AST activity may be more sensitive than increased ALT activity for the detection of hepatocellular injury in cats.[9] Corticosteroids and phenobarbital may cause mild increases in serum AST activity. Because of the considerable overlap in the information provided by the measurement of serum ALT and AST activities, measurement of serum AST activity may be redundant.

Markers of Cholestasis

ALP is an enzyme bound to the membranes of the hepatocytes that comprise the bile canaliculi and the sinusoidal membranes. It is considered a sensitive marker for cholestasis, especially in the dog, but is not liver specific. Cholestasis, canalicular cell necrosis, and increased hepatic synthesis may lead to the release of this enzyme into the circulation. Synthesis of this enzyme can be induced by certain drugs, most notably corticosteroids. The possibility that an increase in serum ALP activity could be caused by extrahepatic disease, or could be induced by glucocorticoids in the dog, can make the interpretation of this finding challenging.

In the dog a wide variety of tissues exhibit ALP activity, including intestinal mucosa, kidney (cortex), bone marrow, pancreas, testicle, brain, lung, kidney (medulla), lymph node, liver, skin, spleen, skeletal muscle, and cardiac muscle.[6] There is disagreement in the literature regarding the relative contributions of ALP activity from each of these tissues in cats.[10-12] There are two genes encoding ALP in the dog. Different forms of ALP arising from the same gene are called *isoforms*. Differences among these isoforms arise because of differing posttranslational processing. Liver ALP (L-ALP), bone ALP (B-ALP), and kidney ALP (K-ALP) are transcribed from the tissue nonspecific ALP gene. The other gene encodes intestinal ALP (I-ALP) and probably glucocorticoid-induced ALP (G-ALP).[13] In dogs the serum half-lives of placental ALP, K-ALP, and I-ALP are less than 6 minutes.[14] In cats the serum half-life of I-ALP is less than 2 minutes. The half-lives of placental ALP and K-ALP are also assumed to be short in the cat as they have similar structures to I-ALP. Because of this, only L-ALP, B-ALP, and, in the dog but not the cat, G-ALP, are believed to contribute significantly to serum ALP activity. The serum half-life of L-ALP is approximately 70 hours in the dog[14,15] and 6 hours in the cat.[16]

L-ALP is bound to the membranes of the hepatocytes by glycosylphosphatidylinositol linkages. Cleavage of these links by glycosylphosphatidylinositol-phospholipase allows the enzyme to be released into the bloodstream.[17] As bile acids have detergent-like properties; accumulation of bile acids during cholestasis facilitates this process. Cholestasis can also result in the induction of synthesis of L-ALP (and G-ALP in the dog). Consequently, serum ALP activity is often severely increased in patients with cholestatic disorders. In the dog, ALP is considered to be a sensitive marker for cholestasis with a sensitivity of 85%.[18] The short half-life of L-ALP in cats means that increases in ALP during cholestasis are not as high as in the dog. Consequently, ALP is a less-sensitive marker of cholestasis in the cat than in the dog, with a reported sensitivity of only 48%.[19] However, the shorter half-life in cats and the absence of G-ALP means that any increase in ALP activity should be considered clinically important in this species. An increased serum ALP activity does not differentiate between intrahepatic or extrahepatic cholestasis. A wide variety of liver diseases can cause intrahepatic cholestasis. This is generally caused by hepatocyte swelling, causing obstruction of the small bile canaliculi. The increase of ALP following a hepatic insult is delayed compared to rises in markers of hepatocellular leakage. The reason for this is that it takes time for the enzyme to be synthesized and released into the systemic circulation. ALP often remains increased for some time after the resolution of liver injury.

B-ALP is released into the bloodstream as a result of the activity of osteoblasts. Therefore any condition that results in increased bone formation can lead to increased serum ALP activity. In animals that are skeletally immature, mild increases in serum ALP activity are commonly observed. Animals with increased osteoblast activity, such as those with hyperparathyroidism, neoplasia involving bones, and osteomyelitis, may have mild to moderate increases in ALP activity. These causes of increased B-ALP activity are unlikely to be confused with primary liver disease because the increases are smaller than would be expected with cholestasis, and because bone diseases are often clinically apparent. Finally, an increased serum activity of B-ALP was reported in a family of asymptomatic Huskies.[20]

In dogs, but not in cats, *G-ALP* and tissue-nonspecific ALP may be induced by corticosteroids. G-ALP is believed to be an isoform of I-ALP with a prolonged serum half-life that is produced by the liver.[13] Posttranslational glycosylation of the G-ALP is believed to be responsible the prolonged half-life. Induction of G-ALP may cause an increase in total serum ALP activity after administration of exogenous corticosteroids. Synthesis of this isoenzyme can also be induced by the administration of anticonvulsant drugs, such as phenobarbital. Similarly, hypercortisolemia frequently causes an increased serum ALP activity because of induction of G-ALP. However, in dogs with excess serum concentrations of endogenous or exogenous corticosteroids, hepatocyte swelling caused by glycogen accumulation (vacuolar hepatopathy) may lead to intrahepatic cholestasis, another potential contributor to increased serum ALP

activity. Before diagnosing primary liver disease in a dog with an increased serum ALP activity, induction of G-ALP by endogenous or exogenous steroids should be ruled out. Recently a group of Scottish Terriers were found to have increased serum ALP activity with no identifiable underlying cause.[21]

It is technically possible to selectively measure the activity of G-ALP using techniques such as levamisole inhibition. Measurement of G-ALP activity was initially investigated as a way to differentiate increases in ALP caused by corticosteroids from those caused by cholestasis. Unfortunately, measuring G-ALP is not clinically useful as G-ALP activity may be increased in a variety of conditions, including hepatic disease, diabetes mellitus, hypothyroidism, and pancreatitis.

GGT is a glycoprotein enzyme that is bound to the membranes of those hepatocytes that form the bile canaliculi and bile ducts and also periportal hepatocytes. In comparison to ALP its distribution includes more distal areas of the biliary tract, but measurement of serum GGT activity is not useful to distinguish between intrahepatic and extrahepatic cholestasis. GGT is also produced by a number of extrahepatic tissues. Most of the GGT activity in serum is thought to be a result of the hepatic isoenzyme. Colostrum also contains GGT, which is responsible for the mild increases in serum GGT activity that are seen in suckling animals.[22]

Changes in serum GGT activity generally parallel those in serum ALP activity, in that activity is often increased in patients with cholestasis. Because GGT is also induced by glucocorticoids, its activity may be increased in patients with hyperadrenocorticism or those exposed to exogenous steroids. In dogs, an increased serum GGT activity is considered to be more specific, but less sensitive than ALP activity for the presence of liver disease.[18] In cats, measurement of serum GGT activity is more sensitive but less specific for the detection of liver disease than ALP. Cats with hepatic lipidosis may be an exception to this as they often have a normal serum GGT activity but an increased serum ALP activity.[19]

Markers of Protein Metabolism

The liver plays a central role in protein metabolism. It is responsible for the synthesis of plasma proteins, deamination of amino acids, conversion of ammonia to urea, amino acid synthesis, and interconversion of amino acids.[23] Consequently, in patients with hepatic disease these functions may be compromised.

Plasma Proteins

Albumin is an important plasma protein that is produced exclusively by the liver. The rate of albumin synthesis must equal the rate of albumin loss to maintain serum albumin concentrations. Mild decreases in serum albumin concentration can occur from a variety of conditions. However, the differential diagnoses for severe hypoalbuminemia (<2 g/dL) are limited to hepatic insufficiency, severe exudative skin disease, protein-losing enteropathy, and protein-losing nephropathy. It is possible to determine the cause of severe hypoalbuminemia from a combination of clinical findings, measurement of the serum globulin concentration, urinalysis (including protein creatinine ratio), tests of GI protein loss, and tests of liver function. As albumin contributes significantly to colloid oncotic pressure,[24] severe hypoalbuminemia can lead to ascites, pleural effusion, and/or subcutaneous edema. The liver has a large reserve capacity for the synthesis of albumin and albumin has a serum half-life of approximately 7 days in dogs.[25] Consequently, hypoalbuminemia is a relatively insensitive marker for hepatic insufficiency and is only likely to be seen in patients with advanced chronic liver disease or *portosystemic shunts* (PSSs).

Globulins are produced in the liver, but not exclusively so. The liver produces α-globulins and β-globulins, whereas lymphoid cells produce immunoglobulins (γ-globulins). Hepatic insufficiency rarely leads to a decrease in serum globulin concentration. Conversely, inflammatory liver disease may be associated with hyperglobulinemia because the nonimmunoglobulin fraction produced by the liver includes several *acute-phase proteins* (C-reactive protein, haptoglobin, and serum amyloid A). The hepatic synthesis of these proteins is increased during systemic inflammation[26-29] possibly leading to a rise in the total serum globulin concentration. Additionally, immunoglobulin production may be increased in infectious, neoplastic, or autoimmune diseases.

Coagulation factors (except factor VIII), anticoagulation factors (antithrombin and protein C), and the fibrinolytic protein plasminogen, are all synthesized by the liver. The liver is also the site of activation of the vitamin K-dependent clotting factors: II, VII, IX, X, and protein C. Furthermore, as bile acids are needed to emulsify fat and aid in the absorption of vitamin K from the intestine, vitamin K malabsorption may develop secondary to cholestasis. Consequently, hepatobiliary disease can affect hemostasis in more than one way.

In canine and feline liver disease, coagulation parameter abnormalities have been reported in specific clotting factor activities, prothrombin time, aPTT,[30-32] proteins induced in the absence of vitamin K,[33,34] fibrin degradation products, fibrinogen, and protein-C activity.[35] These abnormalities of hemostasis are not specific for liver disease but may support its presence. Patients with liver disease may develop DIC, which can be difficult to distinguish from coagulopathy because of reduced hepatic synthesis of clotting factors alone. Although spontaneous bleeding seldom occurs in patients with liver disease, the assessment of the coagulation status of these patients is important, especially when an invasive procedure such as a liver biopsy is being considered.

A recent study investigated the diagnostic value of serum protein C as a marker for hepatobiliary disease and portosystemic shunting in dogs. Serum protein-C measurement was reported to aid in the differentiation of portal vein hypoplasia without portal hypertension (formerly called microvascular dysplasia) from portosystemic shunt (PSS). Dogs with portal vein hypoplasia without portal hypertension had a significantly higher serum protein-C concentration than those with portosystemic shunting.[35]

Protein Catabolism

Urea is produced from ammonia in the liver, released into the systemic circulation, and subsequently excreted by the kidneys. Serum urea nitrogen concentration may be close to or below the lower limit of the reference interval in patients with hepatic insufficiency, PSS,[36] or urea cycle enzyme deficiencies. However, serum urea nitrogen concentration may also be decreased because of medullary solute washout caused by diuresis, malnutrition, or a protein-restricted diet, and is a normal finding in neonates. In a patient with liver disease, a high fasting serum urea nitrogen concentration relative to the serum creatinine concentration suggests GI hemorrhage.

Ammonia (NH_3) is produced in small intestinal enterocytes from the catabolism of glutamine and in the colon as a consequence of bacterial deamination. Ammonia is a highly diffusible gas and passes readily through the bowel wall into the bloodstream. In the blood, at a pH of 7.4, most of the ammonia exists in the form of ammonium ions (NH_4^+). The ammonium is transported in the blood from the intestines through the hepatic portal circulation to the liver. The extraction of ammonia from the portal circulation is highly efficient. Endogenous ammonia is produced from the breakdown of

nitrogenous substances in the body, especially glutamine. In the liver the ammonium is converted to urea by the enzymes of the urea cycle, or is used during the conversion of glutamate to glutamine.[37] Urea enters the circulation and is excreted by the kidneys. Ammonium that is not removed by the liver enters the systemic circulation.

The liver has a large reserve capacity for the conversion of ammonia into urea. Because of this, plasma ammonia measurement is a relatively insensitive marker for hepatic insufficiency. However, measurement of blood ammonia concentration is a sensitive test for congenital PSSs and APSC shunts (also known as acquired PSSs). This is because when portosystemic shunting occurs, the ammonia absorbed from the intestines bypasses the liver and reaches the systemic circulation directly. The sensitivity of plasma ammonia measurement for the detection of PSS is reported to be between 81% and 100% in dogs[38-41] and 83% in cats.[41] The measurement of postprandial venous ammonia is more sensitive than the measurement of fasting ammonia (sensitivities of 91% and 81%, respectively) for the detection of congenital PSS.[42] However, the sensitivity for detecting dogs with hepatocellular disease is only 36%. Generally, hyperammonemia is considered specific for hepatic insufficiency or PSS. However, although they are uncommon, urea-cycle enzyme deficiencies may also cause an increased blood ammonia concentration. These enzyme deficiencies can be hereditary as a result of the absence of a particular enzyme[43] or secondary to cobalamin or arginine deficiency.[44,45] Arginine deficiency is especially relevant in cats with hepatic lipidosis. Ammonia is one of the substances that cause *hepatic encephalopathy* (HE). Therefore blood ammonia measurement is a useful marker for HE. However, other substances can also cause HE and the plasma ammonia concentration of a patient with HE may be within the reference interval.

Ammonium ions are labile in plasma, so sample handling is critical when measuring plasma ammonia concentration. Samples should be collected, placed immediately on ice, and the plasma separated from the red blood cells as soon as possible. The plasma must be kept cooled and should be analyzed within 30 minutes of collection. These handling requirements have meant that ammonia measurement has been mainly confined to practices with immediate access to a commercial laboratory. Measurement of plasma ammonia is available on an in-house dry chemistry analyzer (VetTest, Idexx Laboratories, Westbrook, ME) although this method was only considered to reliably agree with a reference method for serum ammonia concentrations greater than 150 μM.[46] A recent study found that a point of care blood ammonia analyzer (PocketChem BA, Menarini Diagnostics, Florence, Italy) may be suitable for the measurement of blood ammonia concentrations in dogs and cats.[47]

Ammonia tolerance tests (ATTs) have been investigated in an attempt to increase the sensitivity of ammonia measurement for detecting hepatic insufficiency and PSS. However, the oral administration of ammonium salts can cause vomiting and potentially worsen HE signs. Ammonium chloride or sulfate can also be given rectally, which is less likely to produce adverse. This method is sensitive for the detection of PSS in dogs.[48]

Markers of Lipid Metabolism

The liver plays a central role in lipid metabolism and is responsible for oxidation of fatty acids, synthesis of cholesterol, synthesis of lipoproteins, and synthesis of fatty acids from proteins and carbohydrates.[23]

Serum cholesterol concentrations may be increased, normal, or decreased in patients with liver disease. Increased or decreased fasting serum cholesterol concentrations are not sensitive or specific for hepatobiliary disease in dogs or cats. In patients with severe hepatic insufficiency or PSS[49] serum cholesterol, concentration may be decreased as a consequence of impaired hepatic synthesis. Hypocholesterolemia might also occur as a result of inadequate dietary intake, maldigestion, malabsorption, or hypoadrenocorticism. The serum cholesterol concentration of patients with hepatobiliary disease may be within the reference interval. Patients with cholestatic disease can become hypercholesterolemic.[50] Fasting hypercholesterolemia also may be observed in patients with various endocrinopathies, obesity, protein-losing nephropathy, pancreatitis, or primary hyperlipidemias.

Serum triglyceride concentration may be increased or normal in patients with liver disease. However, an increased fasting serum triglyceride concentration is not a sensitive or specific marker for hepatobiliary disease in dogs or cats. A mild increase in serum triglyceride concentration may develop in patients with cholestasis. There is some evidence that hypertriglyceridemia is associated with gallbladder mucocele formation.[51] Hypertriglyceridemia is associated with increased serum hepatic enzyme activities in Miniature Schnauzers.[52] Increased fasting serum triglyceride concentrations are also observed in patients with endocrinopathies, obesity, pancreatitis, and primary hyperlipidemias.

Markers of Carbohydrate Metabolism

The liver plays a central role in carbohydrate metabolism and is responsible glycogen storage, conversion of galactose and fructose into glucose, gluconeogenesis, and the synthesis of many compounds from carbohydrates.[23]

Blood glucose measurement is not a sensitive or specific marker for liver disease. The liver has a large reserve capacity for glucose production. Consequently, hepatic insufficiency must be severe for hypoglycemia to occur. Hypoglycemia occurs in a proportion of patients with congenital PSS.[53] Hepatic neoplasia can also lead to hypoglycemia. This is thought to be caused by release of insulin-like substances.[54] A variety of extrahepatic conditions can also lead to hypoglycemia.

Other Tests of Liver Function

Bilirubin is a yellow pigment produced from the breakdown of *heme*-containing compounds. Measurement of serum bilirubin concentration can be used to assess liver function. Hyperbilirubinemia can be the result of hepatobiliary or extrahepatic disease. Icterus is the yellowish pigmentation caused by the retention of bilirubin in the soft tissues. Laboratory assessment is the most sensitive way to detect increased serum bilirubin concentrations. Hyperbilirubinemia is classified as *prehepatic*, *hepatic*, or *posthepatic* in origin. Bilirubin may be artifactually increased by in vitro hemolysis or by the administration of synthetic hemoglobin polymers. When assessing a hyperbilirubinemic patient it is critical to localize the underlying cause.

Bilirubin is the major product of the degradation of heme-containing compounds by cells of the *mononuclear phagocyte system*. Bilirubin is released from the mononuclear phagocyte system and is transported in the plasma. The bilirubin is reversibly bound to albumin as it is water insoluble. The unconjugated bilirubin is absorbed through the hepatocyte cell membranes and is bound to glucuronic acid (conjugation). Conjugated bilirubin is water soluble and is actively excreted from the hepatocytes into the bile canaliculi, eventually being excreted into the intestines. Once in the intestine some of the bilirubin is converted into urobilinogen by bacteria. Some of the urobilinogen is reabsorbed from the intestines, but most of this is immediately reexcreted by the liver. When

exposed to air the urobilinogen remaining in the intestines is altered and oxidized into the brown pigment sterocobilin.[23]

Prehepatic hyperbilirubinemia is caused by increased production of bilirubin as a result of hemolysis. The liver has a large reserve capacity for bilirubin excretion so, for hemolysis to cause hyperbilirubinemia, hepatic bilirubin clearance must be decreased.[55] This occurs if the hemolytic anemia results in hepatocyte dysfunction because of hypoxia. If hepatic hypoxia occurs serum hepatic enzymes activities are often increased. Prehepatic hyperbilirubinemia is mainly distinguished from other causes of hyperbilirubinemia by the presence of severe anemia. Other supportive evidence includes the presence of a regenerative erythroid response, characteristic changes in red blood cell morphology, and possibly the detection of red blood cell bound antibodies.[56]

Hepatic hyperbilirubinemia is caused by a decreased rate of hepatocyte bilirubin uptake, conjugation, or excretion (as a result of *intrahepatic cholestasis*). Usually, hepatocyte dysfunction and intrahepatic cholestasis occur concurrently. Hepatic enzyme activities (both hepatocellular leakage markers and cholestatic markers) are often increased, although they can also be increased with both prehepatic and posthepatic hyperbilirubinemia. Because of the hepatic reserve capacity, hepatic disease must be severe in order to cause hyperbilirubinemia. A range of primary and secondary hepatopathies can cause hepatic hyperbilirubinemia. Hepatic hyperbilirubinemia can usually be distinguished from prehepatic hyperbilirubinemia by assessment of the patient's hematocrit, and from posthepatic hyperbilirubinemia by abdominal ultrasound. Other markers of hepatic insufficiency, when present, provide additional support for the presence of hepatic hyperbilirubinemia.

Posthepatic hyperbilirubinemia is a result of extrahepatic bile duct obstruction. This is often caused by pancreatic inflammation or, much less commonly, neoplasia. The main diagnostic tool for documenting extrahepatic bile duct obstruction is abdominal ultrasound. Typically, extrahepatic bile duct obstruction leads to dramatic increases in serum cholestatic enzyme activities (compared to hepatocellular leakage enzyme activities) and hypercholesterolemia. When the bile duct is completely obstructed, acholic (pale-colored) feces may be noted. Rupture of the biliary tract frequently leads to hyperbilirubinemia as bilirubin accumulates in the abdomen.

It is possible to measure the concentration of serum conjugated bilirubin. However, this test is not considered to be clinically useful for distinguishing between prehepatic, hepatic, or posthepatic hyperbilirubinemia, and is thus rarely performed.

Bilirubin can covalently (nonreversibly) bind to albumin. This biliprotein cannot be cleared by the liver and thus persists in the plasma. Biliprotein has a serum half-life comparable to albumin. This is of clinical importance because it means hyperbilirubinemia (and icterus) may persist for several weeks after the resolution of its cause.[57]

Bile acids (or bile salts when they are deionized) are formed from cholesterol in the liver and are the major constituent of bile. *Serum bile acids* (SBAs) measurement is a useful test of liver function in dogs and cats. SBAs are either measured as a fasting sample (after withholding food for 12 hours) or by collecting paired fasting and 2-hour postprandial samples.[58] Both of these tests are simple to perform and safe. Enzymatic measurement of the concentration of total bile acids in serum has become widely available and has replaced other techniques such as radioimmunoassays.[59,60] Once collected, the samples of serum can be stored at room temperature, making it possible to send them to an outside laboratory for evaluation. Lipemia and hemolysis of the blood samples should be avoided as both can interfere with the assay. Increased SBA concentrations

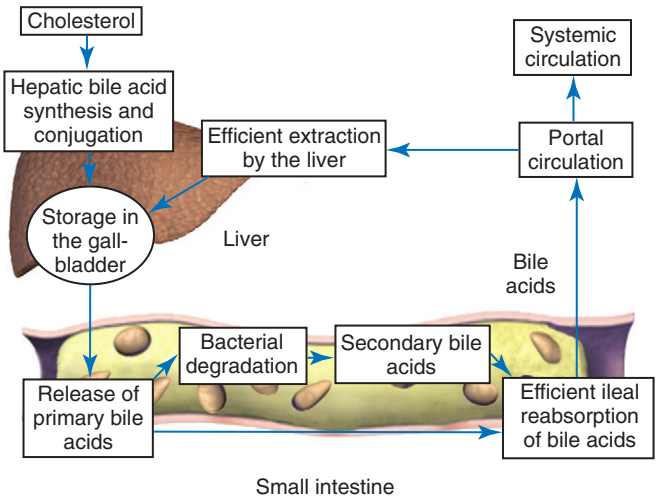

Figure 61-6 The enterohepatic circulation of bile acids.

(fasting or postprandial) suggest hepatic dysfunction, PSS, or cholestasis, but they are not specific for any particular liver disease.

Bile acids are exclusively synthesized in the liver from cholesterol. Nearly all of the bile acids that are produced by the hepatocytes are conjugated to an amino acid. In both dogs and cats conjugation is primarily to taurine, but dogs may also convert to a conjugation with glycine.[61] In contrast, even taurine depleted cats conjugate their bile acids almost exclusively to taurine.[62] The conjugated bile acids produced by the liver are called *primary bile acids*. These are secreted in the bile, and then stored in the gallbladder. *Cholecystokinin* is released from endocrine cells in the small intestine. This hormone stimulates gallbladder contraction and the flow of bile into the duodenum. When the gallbladder contracts the bile acids are released into the intestines. Spontaneous gallbladder contraction also occurs during the interdigestive phase.[63] Bile acids act as ionic detergents, aiding the emulsification of dietary lipids and their subsequent intestinal absorption in micelles.[64]

Bile acids are recycled in a process known as *enterohepatic circulation* (Figure 61-6). Primary bile acids are lipid insoluble and thus are only absorbed from the intestines when they bind to specific high affinity ileal mucosal receptors.[64] This ileal reabsorption is very efficient. The reabsorbed bile acids enter the portal circulation and upon reaching the liver they are efficiently extracted from the plasma and subsequently reexcreted. The total bile acids pool can be recirculated several times in a day. Consequently, the rate of hepatic bile acid synthesis and the fasting serum bile acids concentration in dogs and cats with normal hepatic function is low. Because of the increased release of stored bile acids during the postprandial period, small increases in total SBA concentration occur in animals with normal hepatic function.

Primary conjugated bile acids can undergo bacterial deconjugation in the intestinal lumen. The resulting unconjugated bile acids are called *secondary bile acids*. These are readily absorbed from the colon by passive diffusion. First-pass extraction and reexcretion of secondary bile acids is less efficient than that for primary bile acids. Consequently, secondary (unconjugated) bile acids are often present in postprandial serum samples.[65]

Hepatobiliary disease can cause increased SBA concentrations by interfering with hepatocellular function, by causing decreased bile flow (cholestasis), or by altering the hepatoportal blood flow. The main clinical use of SBA measurement is to assess hepatic function in patients suspected to have hepatic disease, with serum

bilirubin concentrations that are within the reference interval. Measurement of postprandial SBA concentration does not seem to have an advantage over fasting SBA concentrations or *vice versa*. Sensitivity can be increased by collecting paired preprandial and two-hour postprandial samples.[66] Numerous studies show that SBA measurement is a useful test for diagnosing hepatobiliary disease, including PSS in dogs and cats.[41,66-70] A recent study found the sensitivity of fasting SBA measurement for diagnosing PSS (using a cutoff value of 20 µmol/L) to be 93% for dogs and 100% for cats. The reported specificities were 67% for dogs and 71% for cats.[41] However, the sensitivity of SBA measurement for detecting hepatic insufficiency is lower than that for detecting PSS.

Measurements of SBA concentrations have several limitations. First, this test does not allow differentiation between various types of hepatobiliary disease. Also, measurement of serum bile acids in a patient with proven cholestasis is of no clinical benefit. Additionally, there is limited utility in measuring SBAs concentrations in patients with hyperbilirubinemia, although potentially SBA measurement could be useful in distinguishing prehepatic from hepatic or posthepatic causes of hyperbilirubinemia. With prehepatic causes of hyperbilirubinemia, the bile acid concentrations should be within the reference interval. However, in most cases prehepatic hyperbilirubinemia is easily distinguished by the presence of severe anemia. It should also be noted that the magnitude of increases of SBA concentration are not correlated with prognosis or disease severity.

It is important to note that fasting SBA concentrations may be higher than the upper limit of the reference interval or higher than the postprandial value because of spontaneous contraction of the gallbladder in the fasting state, or because of delayed gastric emptying. This could result in an increased fasting SBA concentration in the absence of hepatobiliary disease. Increased fasting and postprandial serum bile acids concentrations can be the result of increased bacterial deconjugation of primary bile acids into secondary bile acids.[71] False-negative results may occur if enterohepatic circulation of bile acids does not occur from a lack of gallbladder contraction. This could be a problem if a patient is anorectic, does not eat enough food, consumes a diet with insufficient protein or fat, vomits the test meal, or has delayed gastric emptying.

Ceruletide is an injectable cholecystokinin analogue that has been used to stimulate gallbladder contraction when using SBA measurement to diagnose hepatobiliary disease.[72,73] This test circumvents many of the factors that influence postprandial SBA concentrations. *Urine bile acids* measurement has been described in dogs and cats. The diagnostic performance was similar to that of SBA measurement in both species. This test does not offer any advantages over SBA measurement.[74-77]

Excretion of exogenous tracers, such as the anionic cholephilic dyes, bromsulphalein, and indocyanine green have been used historically to assess hepatic function in veterinary patients. However, these tests are considered unreliable and have been replaced by the measurement of SBA concentrations.

The metabolism of exogenous substances can be used to assess liver function. A variety of substances have been investigated as markers for hepatic metabolism in human medicine. Assessment of the metabolism of *aminopyrine* has been investigated in dogs and to a lesser extent in cats. The ^{13}C-labeled aminopyrine demethylation blood test involves intravenous administration of ^{13}C-labeled aminopyrine to the subject. The aminopyrine is metabolized by the liver, resulting in the production of $^{13}CO_2$. This is measured in the blood by fractional mass spectroscopy.[78,79] Further investigation of the utility of this test for assessment of liver function is needed. A recent study did not support the use of a ^{13}C-labeled galactose breath test for assessment of liver function in dogs.[80]

The metabolism of endogenous substances has been investigated to find possible markers of hepatic cellular metabolism. Dogs with hepatic disease (hepatitis and neoplasia) had significantly higher serum L-phenylalanine concentrations than did healthy dogs and those with nonhepatic diseases.[81] Further investigations are needed to determine the utility of these tests for assessing liver function in veterinary patients.

Urinalysis

Urine specific gravity can be decreased in patients with hepatic insufficiency or PSS. This can be caused by an inability to fully concentrate urine, resulting in PU, or from primary PD.

Bilirubin is commonly measured semiquantitatively in canine and feline urine using urine dipsticks. Bilirubinuria (<2+ on a dipstick) can be a normal finding in dogs (especially males).[82] Bilirubinuria in dogs without hemolytic or hepatobiliary disease can occur as a consequence of the loss of unconjugated bilirubin that is bound to albumin in proteinuric patients and renal filtration of small amounts of conjugated bilirubin that has leaked from the liver. Additionally, the renal tubular cells of male dogs have the enzymes needed to produce and conjugate bilirubin. As cats have a higher renal threshold for bilirubin than dogs, bilirubinuria should always be considered abnormal in cats. Bilirubinuria in cats and excessive bilirubinuria in dogs implies hemolytic or hepatobiliary disease. Because dogs have a relatively low renal threshold for bilirubin, bilirubinuria is often detected before bilirubinemia or jaundice.

Ammonium biurate crystals are detected in the urine sediment by light microscopy. Uric acid is a product of purine catabolism and is converted to allantoic acid by hepatic urate oxidase. In cases with severe hepatic insufficiency or PSS, the serum uric acid concentration may be higher than the renal threshold. This combined with hyperammonemia may lead to ammonium biurate precipitation in the urine. Urate urolithiasis seems to be more common in patients with PSS than those with other types of hepatic dysfunction. Between 40% and 70% of dogs with PSS were found to have urate crystalluria.[83] However, it should be noted that urate crystalluria is not specific for hepatobiliary disease.

Hematology

The erythrocyte series may be affected by hepatobiliary disease, resulting in erythrocyte dysmorphias and anemia. These abnormalities are suggestive of, but are not specific for, hepatobiliary disease.

Patients with hepatobiliary disease can be anemic as a result of blood loss, in which case signs of a regenerative response are normally present within 3 days of hemorrhage. Acute, severe hemorrhage may occur in patients with hepatobiliary disease following invasive procedures such as liver biopsy or as a consequence of hemorrhage from a hepatic neoplasm or hepatic rupture. Less-severe anemia may occur as a result of GI bleeding.[84] Chronic GI blood loss may eventually lead to iron-deficiency anemia. This is characterized by microcytic hypochromic erythrocytes and a variable regenerative response. Additionally, hepatobiliary disease may lead to anemia of chronic disease, which is typically nonregenerative with normocytic normochromic erythrocytes.

Red blood cell morphologic changes are sometimes observed in dogs with hepatobiliary disease. Poikilocytosis, characterized by the presence of acanthocytes and target cells, may be seen in patients with chronic hepatic disease. This is thought to be a result of altered phospholipid metabolism. Patients with PSS can have microcytic red blood cells. This is more common in dogs than in

Table 61-3 Typical Patterns of Clinicopathologic Changes Associated with Liver Disease in the Dog

Laboratory Test	Acute Hepatitis/ Hepatic Necrosis	Chronic Hepatitis	Cirrhosis	CPSS	Biliary Tract Obstruction	Nonobstructive Biliary Tract Disease	Hepatic Neoplasia
ALT	↑↑-↑↑↑	↑-↑↑↑	N-↑↑	N-↑	N-↑↑	N-↑↑	N-↑↑

Total bilirubin	N-↑↑↑	N-↑↑	N-↑↑↑	N	↑↑-↑↑↑	N	N-↑
Preprandial SBA	N-↑↑	N-↑↑	↑-↑↑↑	N-↑↑	↑↑-↑↑↑	N	N-↑
Postprandial SBA	N-↑↑	N-↑↑	↑-↑↑↑	↑↑-↑↑↑	↑↑-↑↑↑	N	N-↑
Ammonia	N-↑↑	N-↑↑	N-↑↑	↑-↑↑↑	N	N	N-↑

↑, Mild increase; ↑↑, moderate increase; ↑↑↑, severe increase; ALP, serum alkaline phosphatase activity; ALT, serum alanine aminotransferase activity; CPSS, congenital portosystemic shunt; N, within the reference interval; SBA, serum bile acid concentration.

cats.[83] Microcytosis also occasionally occurs in patients with hepatocellular disease. Altered iron metabolism is thought to lead to a delay in red blood cell precursors gaining a sufficient amount of hemoglobin to be released into the circulation. This delay leads to the precursors undergoing an extra cell division in the bone marrow, resulting in microcytosis.[85] Microangiopathy can occur as a result of hepatic neoplasia or DIC, and may lead to the formation of schistocytes.

The leukocyte series may be affected by hepatobiliary disease in a variety of ways. The resultant abnormalities are inconsistent and are not specific for hepatobiliary disease. Leukocytosis, leukopenia, and sometimes an inflammatory leukogram may be present when infectious and, less commonly, inflammatory or neoplastic processes affect the hepatobiliary system. A leukocytosis was found to be present in 44% of dogs with chronic hepatitis.[86]

The thrombocyte series is occasionally affected by hepatobiliary disease, but changes are both inconsistent and nonspecific. Mild to moderate thrombocytopenia may occur in patients with severe liver disease.[86] This may be the result of a decreased production of thrombopoietin by the liver. Disseminated intravascular coagulopathy associated with liver disease also may lead to thrombocytopenia. Additionally, infectious diseases affecting the liver, such as leptospirosis may result in thrombocytopenia.[87]

Other Diagnostic Tests for Hepatobiliary Disease

Genetic testing for copper hepatotoxicosis has been developed in Bedlington Terriers. Affected Bedlington Terriers have an autosomal recessive defect of their COMMD1 gene. Dogs with a homozygous affected genotype develop copper hepatopathy as a result of impaired biliary excretion of copper. Initially, a microsatellite marker that is in linkage disequilibrium with the mutation was discovered and used to identify affected dogs and select dogs homozygous unaffected dogs for breeding.[88] Subsequently, a mutation of the COMMD1 gene (a deletion of exon 2) was identified as the cause of the condition in the majority of Bedlington Terriers.[89] A genetic test for this disease has become commercially available (VetGen, Ann Arbor, MI). This test is run alongside the linked marker as a small proportion of Bedlington Terriers do not have the deletion but are nevertheless affected by the disease. These dogs are likely to have a rare second mutation of their COMMD1 gene which the linkage markers may track.

Hyaluronic acid is a major constituent of the ECM and hyaluronic acid (HA) concentration in blood has been used as a marker for hepatic fibrosis in humans. A recent study investigated the use of HA concentration as a marker for hepatic disease in dogs.[90] This study found that blood HA concentrations were significantly higher in dogs with liver disease than in dogs with extrahepatic disease, and were higher in dogs with cirrhotic liver disease than in dogs with noncirrhotic liver disease. Blood HA concentration may prove be a useful marker for hepatic fibrosis in dogs but further studies are necessary to evaluate its clinical utility.

Patterns of Clinicopathologic Change Associated with Liver Disease

Histopathologic analysis of liver biopsies or identification of a shunting blood vessel is often required to definitively diagnose hepatic disease. However, the pattern of laboratory test abnormalities, particularly when interpreted in conjunction with the patient's clinical presentation, and the results of diagnostic imaging, can increase or decrease a clinician's index of suspicion for specific liver diseases (Table 61-3). It is important to note that there is considerable overlap between the patterns for different diseases. To avoid misinterpretation and misdiagnosis when evaluating a patient for liver disease, it is essential to consider the limitations of the laboratory tests discussed above.

Diagnostic Imaging of the Liver

Diagnostic imaging is an important part of the investigation of hepatobiliary disease in dogs and cats. Diagnostic imaging may help to determine whether or not hepatobiliary disease is present, identify the cause of a secondary hepatopathy, aid in the diagnosis of specific hepatobiliary diseases, and provide prognostic information. However, with the exception of diagnosis of a PSS, imaging seldom yields a definitive diagnosis. Radiography and abdominal ultrasound are the most frequently used imaging modalities for assessment of the hepatobiliary system in dogs and cats, but alternative imaging techniques are now being used more frequently.

Abdominal Radiographs

Abdominal radiographs allow assessment of hepatic size, shape, opacity, and location in most patients.[91] Radiography may also allow identification of extrahepatic abnormalities that affect the liver. However, radiographs provide limited information about the hepatic parenchyma. It is important to note that patients with hepatobiliary disease often have normal abdominal radiographs.

Radiography allows subjective assessment of liver size. Cranial displacement of the gastric axis may be observed on lateral abdominal radiographs when microhepatia is present. However, subtle microhepatia is unlikely to be appreciated radiographically. PSSs and hepatic cirrhosis are the most common conditions causing microhepatia. Mild bilateral renomegaly may also be

appreciated radiographically for patients with PSS. Urate uroliths can be radiolucent so they might not be visible on plain abdominal radiographs.

Hepatomegaly can be generalized or focal. Generalized hepatomegaly can be caused by a number of conditions including neoplasia, vacuolar hepatopathies, congestion, or amyloidosis. Focal hepatomegaly can be caused by neoplasia, abscesses, granulomas, or a liver lobe torsion. Radiographic signs associated with hepatomegaly are rounded hepatic borders, caudal displacement of the gastric axis, and extension of the hepatic silhouette beyond the costal arch. Radiography does not allow appreciation of mild hepatomegaly. Additionally, it can be normal for the hepatic silhouette to extend beyond the costal arch in brachycephalic breeds, chondrodystrophic breeds, neonatal animals, or geriatric animals.[91]

The liver is normally appreciated as an area of homogenous soft-tissue opacity on radiographs. Radiolucent areas within the liver indicate accumulation of gas within the hepatic parenchyma, biliary tract, or portal vasculature. Gas in the parenchyma of the liver can be associated with an hepatic abscess.[92] Gas in or around the gallbladder has been reported in dogs with emphysematous cholecystitis.[93] Although uncommon in dogs and cats, if choleliths or choledocholiths contain enough calcium, they may be appreciated as mineral opacities within the hepatic silhouette.[94] Mineralization of the gallbladder wall can be associated with a biliary adenocarcinoma in the dog.[95] Parenchymal mineralization can be associated with granulomas, abscesses,[96] hematomas, neoplasia, or hepatic necrosis.[91]

Angiography allows the visualization of the hepatoportal vasculature, including abnormal vessels. This often provides a definitive diagnosis of PSS and is indicated in patients that are suspected of having a PSS, where the shunt cannot be adequately evaluated by abdominal ultrasound. Anatomical characterization of congenital PSS is important when planning attenuation, and angiographic procedures often allow this. There are several techniques for mesenteric portography. Operative mesenteric portography is commonly performed immediately prior to surgical attenuation of a congenital PSS and involves catheterization of a mesenteric vein and injection of a contrast agent. Operative contrast portography allows evaluation of the portal vasculature before and after shunt attenuation. This technique has the disadvantage of being relatively invasive. Cranial mesenteric portography can be accomplished less invasively by using ultrasound guidance to percutaneously catheterize the splenic vein.[97] However, this can be technically demanding and may not be possible in smaller patients. Transvenous retrograde portography has been described and involves the catheterization of the jugular vein.[98] This technique allows selective catheterization of the shunting vessel and measurement of portal pressures (Figure 61-7). Transvenous retrograde portography has been applied during percutaneous transjugular coil embolization of intrahepatic shunts.[99] Percutaneous splenoportography involves percutaneous injection of contrast media into the spleen. This technique is simple to perform, but there is a risk of complications such as splenic infarction or hemorrhage.

Abdominal Ultrasound

Abdominal ultrasonography is the most commonly used imaging modality for evaluating small animal patients with suspected hepatobiliary disease. Ultrasonography allows assessment of the hepatic parenchyma and biliary tract. Evidence of extrahepatic disease causing a secondary hepatopathy may also be detected. Additionally, ultrasound guidance is often used when collecting samples for cytologic and histologic evaluation of the liver.

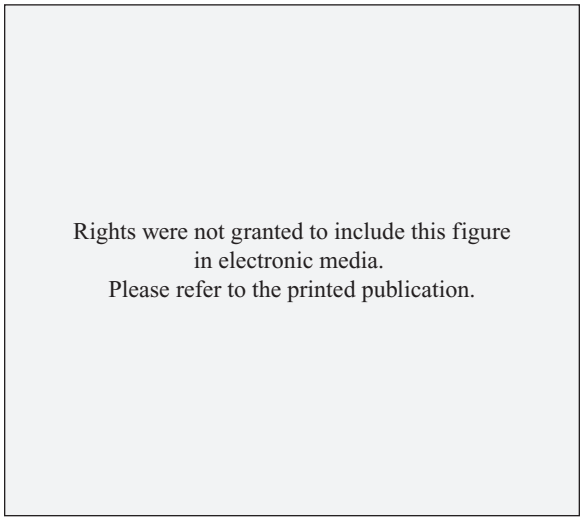

Figure 61-7 Lateral transvenous retrograde portogram of a dog with a single extrahepatic shunt. A balloon-tipped catheter positioned immediately cranial to the diaphragm was used for contrast injection. There is retrograde filling of some hepatic veins (*arrowheads*), there is also a large PSS that filled in a retrograde fashion (*arrows*). (From Miller MW, Fossum TW, Bahr AM: Transvenous retrograde portography for identification and characterization of portosystemic shunts in dogs. *J Am Vet Med Assoc* 221:1586, 2002.)

The size of the liver can be subjectively assessed by abdominal ultrasonography. The findings of a small liver and cranial displacement of the stomach suggest microhepatia. Hepatomegaly is another subjective finding and can be generalized or focal. The finding of rounded liver lobe margins suggests hepatomegaly.

Hepatic parenchymal changes can be classified as being diffuse, multifocal, or focal. A wide variety of disease processes can cause diffuse changes to the hepatic parenchyma. These changes can be isoechoic, hypoechoic, hyperechoic, or of mixed echogenicity. In some cases the architecture of the liver will not be altered, but in other cases changes will occur. Examples of diseases in which the echogenicity of the hepatic parenchyma is diffusely changed but no changes in architecture occur include cholangitis, neoplasia, hepatic lipidosis, other vacuolar hepatopathies, toxic hepatopathy, and early micronodular hyperplasia with various degrees of fibrosis.[100] Hyperechogenicity of the liver compared to the falciform fat, poor visualization of the intrahepatic blood vessels, and increased attenuation of the ultrasound beam have been used as criteria for the sonographic diagnosis of feline hepatic lipidosis.[101] Diseases where the hepatic architecture is altered are easier to detect sonographically. These include neoplasia, micronodular hyperplasia, and chronic hepatitis with fibrosis. Cystic structures, abscesses, hematomas, and granulomas are examples of focal parenchymal liver disease. These lesions are usually easily detected sonographically. Sonography seldom allows a definitive diagnosis of hepatic parenchymal disease to be made. In one study the overall accuracy of ultrasound for discrimination among different categories of diffuse liver disease was 36.5% for dogs and 54.6% for cats. Hepatic lipidosis in cats could be diagnosed slightly more accurately than other diffuse hepatic diseases.[102] Cytologic or histologic evaluation of a hepatic tissue sample is usually needed to make a definitive diagnosis.

Hepatic neoplasia, whether primary or metastatic, can be diffuse, multifocal, or focal in its distribution. Round cell tumors are the most likely tumor type to diffusely infiltrate the liver. These tumors can cause hypoechoic, hyperechoic, or mixed-echoic changes, or

may not affect the echogenicity of the liver at all. Neoplasia can also lead to the appearance of nodules within the hepatic parenchyma. Malignant liver nodules have a variable appearance and size and can be difficult to distinguish from nonmalignant conditions such as cysts, hematomas, benign hyperplastic nodules, granulomas, or abscesses. The finding of one or more target lesions in the liver or spleen had a positive predictive value of 74% for detecting malignancy, and thus should not be considered a specific finding.[103] Cytologic or histologic evaluation of a tissue sample is needed to differentiate between malignant and benign liver nodules. Tumors, such as hepatoma or hepatocellular carcinoma, can also focally infiltrate the liver.

Contrast-enhanced harmonic ultrasound allows assessment of tissue perfusion patterns. Gas-filled microbubbles are administered intravenously to the patient. The microbubbles are relatively echogenic. When they reach the tissue of interest, they produce a more potent harmonic signal than the surrounding tissue. This technique allows enhanced differentiation between tissues with varying perfusion patterns. In one study the sensitivity of contrast enhanced ultrasound for differentiation between benign and malignant liver nodules in dogs was reported to be 100% and the specificity was reported to be 94.1%.[104]

Sonography is also a valuable tool for the evaluation of the biliary system. Biliary disease can be classified as being obstructive or nonobstructive.

The term *cholangitis* refers to a group of nonobstructive biliary diseases, which are more common in cats than in dogs. Typical ultrasound findings in cats include a hypoechoic hepatic parenchyma and prominent portal vasculature.[105] Additional findings can include evidence of pancreatic inflammation, thickening of the gallbladder wall, and dilation of the intrahepatic and extrahepatic biliary system. It is important to note these changes are not always present. Cytologic or histologic confirmation and bacterial culture are needed to confirm this diagnosis. Generalized gallbladder wall thickening can occur as a result of cholecystitis, cholangitis, or hepatitis. However, the gallbladder wall can also appear to be thickened when peritoneal effusion or hypoproteinemia are present. Gall bladder wall masses can be identified sonographically as a focal thickening of the gallbladder wall. Sonography has also been used to assess gallbladder motility in dogs.[106] It should be noted that gravity dependent gallbladder sludge can be found in dogs without hepatobiliary disease, so this finding should be considered incidental.[107]

Abdominal ultrasound is the most commonly used imaging modality for the detection of biliary obstruction in dogs and cats. Findings consistent with biliary obstruction include common bile duct distention, intra- and extrahepatic bile duct distention, and/or gallbladder dilation. A retrospective study showed that common bile duct dilation greater than 4 mm was 97% sensitive for the detection of biliary obstruction in cats.[108] Sonography can also aid in identifying the cause of biliary obstruction. Biliary obstruction can be classified as being luminal or extraluminal. Extraluminal causes include nonneoplastic pancreatic disease, abdominal adhesions, and, rarely, pancreatic neoplasia. Luminal causes include gallbladder mucocele, biliary neoplasia, inflammation, and cholecystolithiasis. Biliary tract obstruction can progress to biliary rupture and bile peritonitis. Sonographic signs of biliary rupture include loss of gallbladder wall continuity, free peritoneal fluid, and signs of localized peritonitis. Gallbladder mucoceles occur in the dog, but have not been described in cats. Mucoceles have a variable sonographic appearance; typical findings include a stellate or finely striated bile pattern with a hypoechoic rim, which is not gravity dependent, and

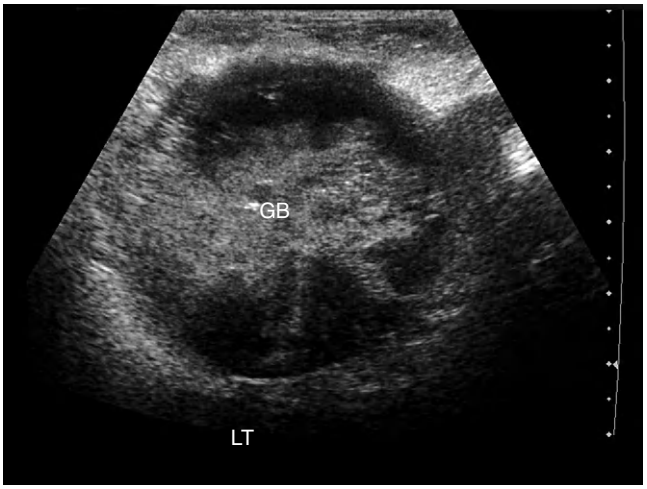

Figure 61-8 Abdominal ultrasound image of a dog with a gallbladder mucocele. There is organized hyperechoic bile within the distended gallbladder (*GB*). The periphery of the bile is stellate in appearance and the gallbladder wall is thickened.

distention of the gallbladder (Figure 61-8). Gallbladder mucoceles can also lead to biliary obstruction, which might also be appreciated sonographically. The sensitivity of ultrasound for the detection of a gallbladder wall rupture in dogs with gallbladder mucoceles is reported to be 85.7%.[109]

Abdominal ultrasound can be used to assess the liver for vascular disease. Congenital PSS is classified as being intrahepatic or extrahepatic. Although angiographic techniques are considered to be the gold standard for the detection and characterization of PSS, abdominal ultrasound is being used increasingly for this purpose. Sonographic assessment of the portal vasculature is time-consuming and highly operator dependent. Because of this there should be a high index of suspicion for PSS before performing these studies. Secondary findings consistent with PSS include mild bilateral renomegaly, urolithiasis (because of urate crystalluria), and microhepatia. Ascites and hepatic parenchymal changes are not consistent with congenital PSS. Extrahepatic shunts typically occur in small-breed dogs and arise from the splenic vein or the right gastric vein while intrahepatic shunts typically occur in larger breeds of dogs and arise from the right or left portal branch. An intrahepatic PSS is usually easier to detect sonographically than an extrahepatic PSS in dogs. Cats typically have single extrahepatic shunts with a wider degree of anatomical variation than in the dog. Ultrasonography has been reported to have a sensitivity of 92% and a specificity of 98% for detecting PSS in dogs.[110] Portal hypertension can develop as a result of chronic hepatitis with fibrosis, hepatic arterioportal fistulas, portal vein thrombosis, primary portal vein hypoplasia, extraluminal compression of the portal vein, or after ligation of a congenital PSS. The finding of hepatofugal or reduced velocity hepatopetal blood flow using Doppler ultrasound is consistent with portal hypertension.[111] However, not all patients with portal hypertension will have these changes. Ascites frequently, but not always, develops secondary to portal hypertension and this can be readily detected on abdominal ultrasound examination. Acquired portosystemic collaterals (also known as acquired PSS) may develop when sustained prehepatic or hepatic portal hypertension is present.[112] Sonography may allow detection of portal hypertension and APSCAPSC although APSC vessels are more difficult to identify than congenital PSS. Posthepatic portal hypertension does not result in the development of

APSC vessels, but can lead to a distention of hepatic veins and ascites.

Nuclear Scintigraphy

Nuclear scintigraphy involves administering a radioactive tracer substance (radiopharmaceutical) to the patient, which localizes to a specific organ or tissue. The radioactive decay of this substance is detected by a gamma camera and used to form images. Scintigraphy has been used to detect PSS and to assess gallbladder emptying in small animals. However, specialized equipment and a license for the use of radioisotopes are required. Consequently, availability of this imaging modality is currently limited to academic institutions and specialty referral hospitals.

Technetium-99m pertechnetate is the most commonly used radiopharmaceutical for assessing the portal circulation of small animal patients. Two techniques have been described: per-rectal portal scintigraphy and transsplenic portal scintigraphy. By analyzing the radiation emitted from regions of interest drawn over the patient's liver and heart, PSS can be detected and a shunt fraction can be calculated. This allows for the minimally invasive diagnosis of PSS, differentiation of PSS from portal vein hypoplasia without portal hypotension (previously known as microvascular dysplasia), and comparison of the degree of shunting before and after shunt attenuation. Transsplenic portal scintigraphy is preferred over per-rectal portal scintigraphy as it is simpler to perform, uses lower doses of the radiopharmaceutical, and is more sensitive (Figure 61-9). Transsplenic portal scintigraphy is 100% sensitive and specific for the diagnosis of congenital PSS, and significantly more likely than per-rectal portal scintigraphy to detect shunt number and termination in dogs.[113]

Nuclear scintigraphy has been used to quantify liver function and to assess biliary tract patency in dogs. In a retrospective study hepatobiliary scintigraphy was found to be 83% sensitive and 94% specific for the detection of extrahepatic biliary obstruction in dogs and cats.[114]

Computed Tomography and Magnetic Resonance Imaging

Computed tomography (CT) (Figure 61-10) and magnetic resonance imaging (MRI) have been used to detect hepatic parenchymal neoplasia in humans. Compared to abdominal ultrasound these techniques have an improved accuracy for the diagnosis of hepatic neoplasia in humans. However, there is limited data in the veterinary literature evaluating their diagnostic performance. In one study the diagnostic accuracy of CT for detecting hepatic masses was not found to be significantly different from that of abdominal ultrasound in dogs.[115] In another study MRI was found to have a sensitivity of 100% and a specificity of 86% for the differentiation between benign and malignant liver lesions in dogs.[116]

CT angiography is being used increasingly in dogs for the diagnosis of congenital PSS and other hepatic vascular diseases. It offers the advantage of being less invasive than operative angiography, allows for improved assessment of the portal vasculature, and allows the creation of a three-dimensional reconstruction. The vasculature detail afforded by CT angiography is particularly useful when planning attenuation of a congenital PSS. The diagnostic utility of CT angiography for detecting and characterizing PSS in dogs was shown to compare favorably to that of other techniques, including surgical exploration.[117] Transsplenic CT portography has been described in dogs without PSS. This technique offers more intense enhancement of the splenic and portal veins than CT angiography.[118] MRI angiography diagnoses PSS in dogs with a sensitivity of 80% and a specificity of 100%.[119] The disadvantages of CT and MRI include their limited availability, cost, and the need for anesthesia.

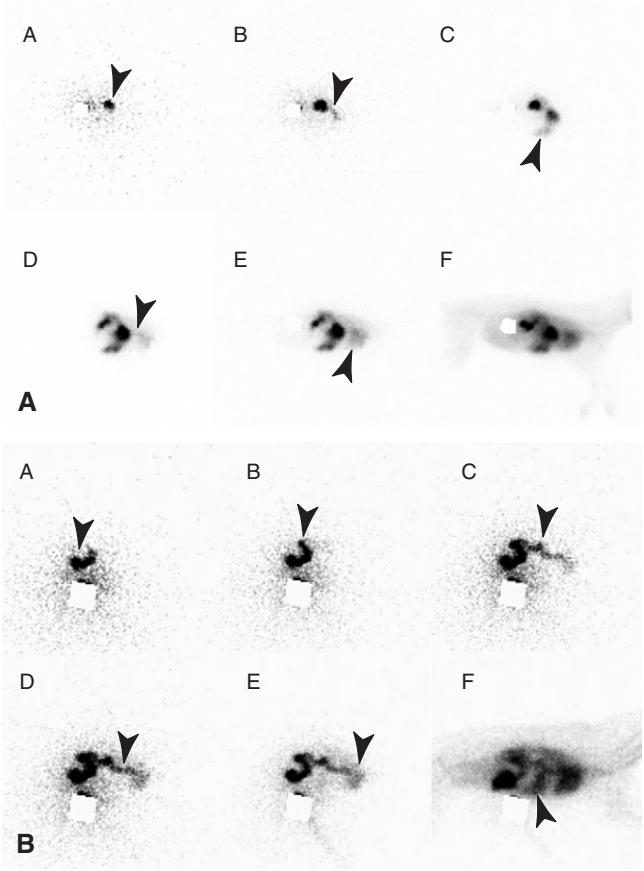

Figure 61-9 **A,** Transsplenic portal scintigraphy of a dog with normal portal vasculature. Images were acquired following ultrasound-guided intrasplenic injection of 2 mCi ^{99m}technetium pertechnetate. The radionuclide exits the spleen via blood flow in the splenic vein then enters the portal circulation. Blood first reaches the liver before entering the caudal vena cava and heart. Cytologic Evaluation of the Liver

Although cytologic evaluation of the liver provides a definitive diagnosis, often histologic examination is also required. There are a variety of techniques to collect cytologic samples of the hepatobiliary system. Abdominal effusion, when present, can be collected percutaneously. Fine-needle aspirates (FNA) of the liver can be collected percutaneously under ultrasound guidance. Cholecystocentesis can also be performed percutaneously with ultrasound

Figure 61-10 Abdominal computed tomography image of a dog with a massive hepatocellular carcinoma. There is a large irregularly shaped mass associated with the ventrolateral right side of the liver (*).

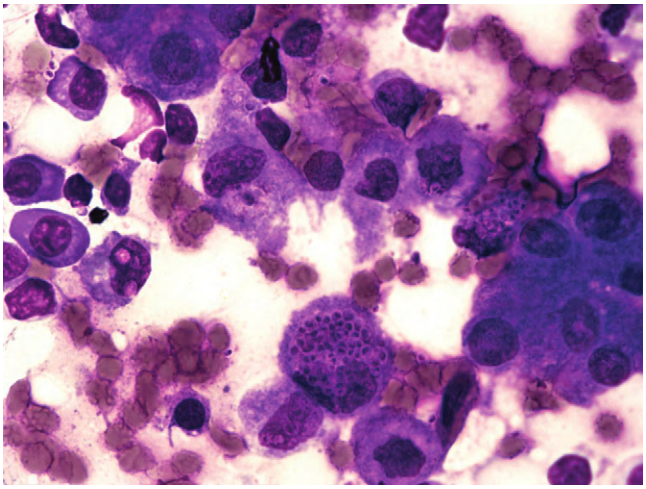

Figure 61-11 **Fine-needle aspirate from the liver of a cat with disseminated histoplasmosis.** Erythrocytes, hepatocytes, lymphocytes, plasma cells, and macrophages containing large numbers of *Histoplasma capsulatum* organisms can be seen (*). guidance. These techniques are minimally invasive and the risk of complications is relatively low but caution should be exercised in patients with bleeding disorders.

Liver disease can cause abdominal effusion by several mechanisms. In cases with hepatic insufficiency, severe hypoalbuminemia (<1.5 g/dL) can occur. This can lead to the formation of a pure transudate as the result of a reduced plasma colloid oncotic pressure. Increased capillary hydrostatic pressure because of portal hypertension may lead to formation of a pure or modified transudate. Hepatic neoplasia can also lead to a formation of a modified transudate. Biliary tract rupture can lead to bile peritonitis and abdominal effusion. An exudate with a bilirubin concentration greater than twice that of the plasma is suggestive of bile peritonitis.[120]

Cytologic evaluation of hepatic FNA can aid in making a diagnosis of liver disease. Suppurative, mixed inflammatory, lymphocytic and, more rarely, eosinophilic patterns of inflammation can be appreciated cytologically. Each pattern of inflammation suggests a group of possible diagnoses. The finding of dark green or black bile casts suggests cholestasis. Infectious diseases such as histoplasmosis can be definitively diagnosed based on the cytologic finding of the infectious agent (Figure 61-11). Hepatocellular vacuolation can be classified as being caused by lipid or not. Lipid vacuolation of hepatocytes is characterized by colorless cytoplasmic vacuoles. Severe lipid vacuolation is suggestive of hepatic lipidosis in cats (Figure 61-12). However, feline hepatic lipidosis often occurs secondary to another disease process. A group of cats with cytologic findings suggestive of hepatic lipidosis were reported to have underlying infiltrative liver disease.[121] Nonlipid vacuolation is characterized by generalized hepatocyte swelling and lacy vacuolation (Figure 61-13). Vacuolar hepatopathy occurs secondary to a wide variety of extrahepatic disease processes in dogs.[122] Metastatic tumors and round cell tumors, such as lymphoma (Figure 61-14), affecting the liver can often be diagnosed cytologically. Additionally, cytologic evaluation can aid in distinguishing liver nodules because of extramedullary hematopoiesis from those caused by neoplasia. However, it is not possible to distinguish hepatic nodular hyperplasia from hepatic adenoma or well-differentiated carcinoma cytologically. Some cases of hepatocellular carcinoma can be diagnosed cytologically if criteria for malignancy are present.

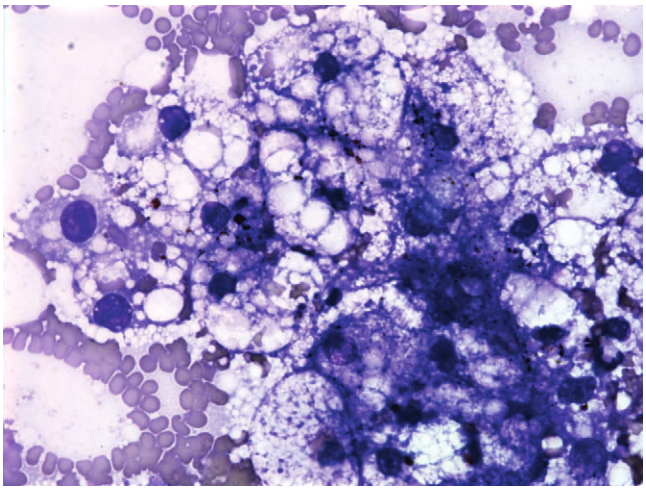

Figure 61-12 **Fine-needle aspirate from the liver of a cat with hepatic lipidosis.** The cytoplasm of the hepatocytes is severely distended by many variably sized clear vacuoles (both microvesicular and macrovesicular type) consistent with lipid that has been cleared during the staining procedure. Diff-Quik 100× objective. (Courtesy of Dr. Mark C. Johnson, Texas A&M University, College Station, TX.)

The findings above may aid in making a diagnosis of liver disease but are not a substitute for histopathologic analysis, as cytologic specimens do not allow assessment of the hepatic architecture. Furthermore, only a tiny proportion of the liver is sampled when cytologic samples are examined. These limitations are reflected by the results of a retrospective study that found the overall agreement between the histopathologic and cytologic diagnosis of liver disease to be 30.3% for dogs and 51.2% for cats.[123]

Cytologic evaluation of bile can also be useful for the diagnosis of biliary disorders, particularly in cats. World Small Animal Veterinary Association (WSAVA) Standards for the Clinical and Histological Diagnosis of Canine and Feline Liver Disease suggest that the cytologic evaluation of bile forms part of the minimum diagnostic requirement for cats with extrahepatic cholestasis and for dogs

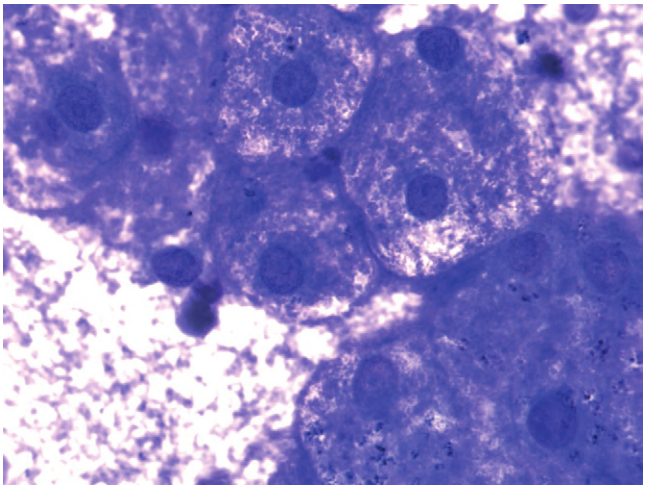

Figure 61-13 Fine-needle aspirate from the liver of a dog with glycogen deposition hepatopathy. Hepatocytes are distended and the cytoplasm is less dense than normal (cytoplasmic rarefaction) consistent with increased glycogen storage. Diff-Quik 100× objective. (Courtesy of Dr. Mark C. Johnson, Texas A&M University, College Station, TX.)

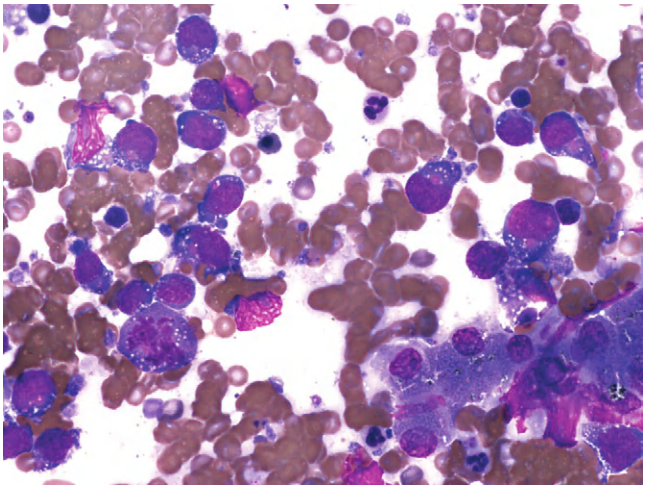

Figure 61-14 Fine-needle aspirate of the liver from a dog with T-Cell lymphoma (confirmed by immunohistochemistry. The predominant nucleated cell population consists of large atypical lymphoid cells. and cats suspected to have cholangitis.[124] The finding of neutrophils and bacteria on bile cytology supports a diagnosis of feline neutrophilic cholangitis. Cytology is essential for the diagnosis of this disease, as cats with neutrophilic cholangitis may not have typical hepatic histopathologic changes and it can be difficult to distinguish these cats from those with lymphocytic cholangitis. Bile should also be submitted for aerobic and anaerobic bacteriologic culture.

Histopathologic Evaluation of the Liver

Histopathologic evaluation is required to make a definitive diagnosis of most liver diseases. Histopathologic evaluation of the liver allows a morphologic and sometimes an etiologic diagnosis to be made (see Chapter 29). In addition to routine staining with hematoxylin and eosin, a variety of other staining techniques can be employed to demonstrate hepatic pathology. To optimize the value of histopathologic evaluation of the liver, particular attention should be paid to specimen collection, specimen handling, and communication between the clinician and the pathologist.

Although liver biopsy is considered to be relatively safe, the patient should be assessed for bleeding disorders before this procedure. This assessment should include a platelet count, coagulation times, and a buccal mucosal bleeding time. Liver biopsies can be collected in a number of ways. Each method has advantages and disadvantages, and there is controversy in the veterinary literature as to which technique is optimal. Laparotomy allows collection of relatively large wedge biopsies, with direct visualization. This technique does not require specialized equipment or training, and excessive bleeding can be readily identified. However, laparotomy requires general anesthesia and is the most invasive biopsy technique. Percutaneous needle biopsy techniques have been described. These techniques may be possible under heavy sedation and are the least-invasive method for collecting liver biopsies. Ultrasound guidance is often used, allowing biopsy of focal lesions. It is also possible to biopsy tissue that is deeper within the hepatic parenchyma than is possible with other techniques. However, the specimens that are collected are relatively small and may be inadequate for accurate assessment in some patients. A prospective study showed that there was agreement between the histomorphologic diagnoses made upon examination of needle biopsies and those made on wedge biopsies collected during laparotomy or necropsy for only 48% of dogs and cats.[125] Excessive hemorrhage after biopsy may not be identified immediately. Laparoscopy allows collection of biopsies using forceps with laparoscopic guidance. This technique requires general anesthesia, but is less invasive than laparotomy. The biopsies collected are larger than needle biopsies and excessive bleeding can be visualized. However, laparoscopy requires specialized equipment and training. The use of biopsy forceps may result in crushing artifact and the tissue collected may be too superficial to identify lesions that lie deeper within the hepatic parenchyma.[126] Regardless of the technique used, a tiny proportion of the organ is sampled and, because liver disease can affect the hepatic parenchyma in a heterogeneous manner, sampling error is possible. To reduce the effect of sampling error, several biopsies from different areas of the liver should be collected and focal lesions should be specifically biopsied.

The clinician should provide the pathologist with all the pertinent information from the patient's history, physical examination findings, the results of laboratory testing, and the findings from diagnostic imaging. In turn the histomorphologic diagnosis that the pathologist makes should be interpreted by the clinician along with the other clinical data. When the histopathologic diagnosis does not fit the clinical picture, the pathologist should be consulted and when necessary a second opinion should be requested. Variation in the assessment of hepatic pathology between pathologists was highlighted by a study that found agreement between examiners for only 44% of needle biopsies and 65% of wedge biopsies examined.[125] Hopefully, the adoption of WSAVA Standards for the Clinical and Histological Diagnosis of Canine and Feline Liver Diseases since the aforementioned study will reduce this interobserver variation.

Quantification of hepatic metal concentrations requires submission of tissue for flame atomic absorption spectroscopy. Although zinc has a role as an antioxidant, hepatic copper and iron retention can lead to oxidative liver injury. Copper is the most frequently

measured of these metals and quantification is essential for the diagnosis of hepatic copper retention. These measurements are usually performed on freeze-dried pieces of liver. Specimens for metal measurement should not be stored in saline and should be kept in metal-free containers. Recently, it was shown that measurements of the concentration of copper and iron, but not zinc, can be ascertained from deparaffinized-archived liver tissue.[127]

BIOPSY TECHNIQUES

Keith Richter

Hepatobiliary diseases can be challenging to diagnose. Although diagnostic tests that employ biochemical, molecular biologic, serologic, functional, as well as imaging techniques are capable of establishing the etiology of some chronic or acute liver diseases, in most instances the gold standard for definitive diagnosis and the assessment of stage and severity of liver diseases is the histologic evaluation of a liver sample. Recent advances in imaging technology, the use of multiple imaging modalities, and newer biopsy methods have resulted in improvement in the ability to safely procure hepatic tissue for evaluation. There are several means of obtaining hepatic samples including fine-needle aspiration, ultrasound-guided biopsy, laparoscopy, and laparotomy. All techniques have both advantages and disadvantages, which should be carefully considered before choosing the appropriate sampling method.

Indications

Many biochemical tests are available to evaluate the anabolic and/or catabolic function of the liver and the hepatic circulation. These include measurement of concentrations of bile acids, ammonia, bilirubin, and the ability to excrete organic dyes. Other tests of hepatic function include measurement of serum albumin, glucose, urea nitrogen, and clotting factor analysis. Hepatic function can be markedly abnormal despite maintenance of the hepatocellular membrane and therefore normal serum activities of hepatic enzymes. Examples include PSSs, terminal cirrhosis, and metastatic hepatic neoplasia. Likewise, the liver can continue normal anabolic or catabolic function despite severe hepatocyte leakage of intracellular enzymes because of its marked reserve capacity. This can occur, for example, in certain cases of hepatocellular necrosis, blunt abdominal trauma, or primary hepatic neoplasia. Thus, the limitations of serum hepatic enzyme activities must be taken into consideration. Hepatocellular leakage enzyme activities include ALT and AST. Enzyme activities that increase with biliary tract obstruction include serum ALP and GGT.

No laboratory test identifies a specific problem, helps determine specific therapeutic management, or predicts an outcome. This is because different diseases produce similar alterations in hepatic function or in laboratory tests. Once biochemical tests identify the presence of hepatic disease, the diagnosis must be pursued further. In some instances, diagnostic imaging can reveal specific abnormalities (e.g., PSSs and extrahepatic bile duct obstruction). When results of imaging do not give a specific etiology, the next step is often to pursue a morphologic diagnosis obtained by analysis of a biopsy specimen. Often it is a judgment call as to when to pursue hepatic biopsy. In cases with severe clinical signs and/or severe biochemical abnormalities, biopsy is usually warranted early in the course of the evaluation. In patients that are asymptomatic and have abnormal biochemical testing, repeat evaluation is sometimes warranted. A general guideline is to obtain a liver biopsy in asymptomatic patients if there are moderate to severe elevations in serum hepatic enzyme activities that persist for at least 3 months, or if there are mild to moderate elevations in serum hepatic enzyme activities that persist for at least 6 months. If clinical signs of hepatic disease develop, then biopsy should not be unreasonably delayed. If there are concurrent elevations in serum bile acids, biopsy should also not be delayed.

Other indications for hepatic biopsy are ultrasound imaging abnormalities. If there are focal hepatic masses or diffuse echotextural changes, a biopsy may be warranted, depending on results of laboratory testing. In one study, abdominal ultrasound findings alone were not reliable for obtaining a diagnosis of infiltrative hepatic disease with diffuse changes in echogenicity (either hypoechoic or hyperechoic, uniform or mottled).[1] In another study, sonographic detection of a hepatic mass greater than or equal to 3 cm, ascites, abnormal hepatic lymph node(s), and abnormal spleen were predictive of liver neoplasia based on cytology.[2] Conversely, sonographic detection of hepatic nodules less than 3 cm was predictive of vacuolar hepatopathy on cytology. Thus several sonographic findings, alone or combined, may be predictive of liver ultrasound-guided fine-needle aspiration cytology results. In light of the fact that ultrasound-guided fine-needle aspiration cytology of the liver has limitations , the results of ultrasound and cytology should be adjuncts to other findings.

Another indication for hepatic biopsy is the need to assess response to therapy. In cases of chronic hepatitis in dogs, it is often difficult to determine if there is ongoing inflammation and resolution/progression of fibrosis during long-term therapy. This is particularly true when the patient is receiving glucocorticoid therapy as these medications cause variable increases in serum ALP and transaminase activities independent of the underlying disease. Repeat or serial hepatic biopsy analysis is often helpful to guide therapeutic decisions in these cases.

Prebiopsy Considerations

Among the most serious complications of liver biopsies are hemorrhage, infections, and injury to the adjacent viscera. Consequently the clinician must take into account the clinical question, the appropriate invasive biopsy method, and methods of managing postbiopsy complications. Postbiopsy hemorrhage is often the first concern, although it is unclear as to what the best predictor of hemorrhage is in patients about to undergo hepatic sampling. In one study of 200 human patients in which bleeding was evaluated laparoscopically, there was no correlation between any in vitro coagulation test and "liver bleeding time."[3] Other studies in man have used laparoscopy and ultrasonography to assess hepatic bleeding time following needle biopsy, and most have shown similar poor correlation between coagulopathies and hepatic bleeding times. Similar studies have not been reported in veterinary medicine. There also have been studies in human and veterinary medicine evaluating risk factors for bleeding complications (as opposed to "hepatic bleeding times").[4,5] Bigge et al. correlated coagulation profile findings and bleeding complications after ultrasound-guided biopsies in 310 dogs and 124 cats.[5] There was no apparent correlation between coagulation parameters and major complications following liver biopsy. Studies show that clotting times assessing proteins induced by vitamin K antagonism are more sensitive in detecting coagulopathies in patients with hepatic disease.[6,7] The

proteins-induced-by-vitamin-K-antagonism test is more than twice as sensitive in dogs and more than three times as sensitive in cats in detecting coagulopathies compared with prothrombin time (PT) and aPTT.[6,7] However, in a pilot study performed by me, hepatic bleeding times assessed via laparoscopy did not correlate with proteins induced by vitamin K antagonism times. Thus it appears that indices of coagulation in the peripheral blood are generally unreliable guides of the risk of bleeding after liver biopsy, and hence, are of limited value in determining contraindications to this procedure. This lack of correlation may be explained by the high concentration of clotting factors in the hepatic parenchyma and by mechanical compression of the needle tract by the elastic tissue within the liver. In most cases of significant hemorrhage, technical errors such as damaging a large vessel are the cause rather than persistent oozing from a needle biopsy site. Controlled studies in veterinary patients will be necessary to make final conclusions regarding postbiopsy hemorrhage in the patient with a coagulopathy.

In one study of normal dogs, biopsies taken from the left lateral hepatic lobe using a biopsy punch, biopsy needle, ligature method, laparoscopic biopsy forceps, and ultrasonically activated scalpel resulted in minimal hemorrhage (<2 mL).[8] However, this investigation did not assess the risk of hemorrhage in dogs or cats with hepatic disease. These risks will be discussed later under each sampling method. With the exception of fine-needle aspirations, each patient should have a prebiopsy packed cell volume and 3 and 6 hours postbiopsy packed cell volume for close monitoring of potential hemorrhage.

Fine-Needle Aspiration

Fine-needle aspiration involves obtaining a small amount of hepatic tissue for cytologic analysis, and is typically performed in conjunction with, and guided by, ultrasound. Ultrasound imaging helps determine if there is a diffuse abnormality (e.g., increased or decreased echogenicity, diffuse mottling) or if there are focal abnormalities (e.g., discrete nodules, cysts, masses, or focal areas of heterogenous mottling). An appropriate site to be sampled is chosen. Often multiple sites are chosen to represent different lobes, and in the case of focal lesions, to sample more than one area of abnormal tissue and sample seemingly normal tissue. The sites are also chosen based on accessibility. For example, a solitary nodule in the dorsocranial aspect of the liver in a large deep-chested dog would be impossible to reach with a 1.5-inch needle. A lesion adjacent to the gallbladder or caudal vena cava would involve considerable risk. The clinician would need to decide whether the relative risk of sampling such lesions is the appropriate decision, or whether other methods of sampling would be more appropriate such as laparoscopy or laparotomy. Figure 61-15 depicts a typical setup for fine-needle aspiration. Usually a 22-gauge, 1.5-inch needle is used. For most patients, the procedure is performed without sedation or local anesthetic. If it is determined that the animal is moving too much during the initial ultrasound examination, a sedative may be necessary (or an anesthetic in extreme cases). The needle is inserted without a syringe using ultrasound guidance. The needle is rapidly agitated in and out (sometimes referred to as mimicking the action of a sewing machine) and simultaneously twisted multiple times for a few seconds to obtain a sample. This method relies on capillary action rather than suction to get tissue into the needle, resulting in less hemodilution. After removing the needle from the liver, a syringe is attached and cells are expelled onto a glass slide for cytologic examination. Often three to five separate attempts are made to increase the sample size and diversity.

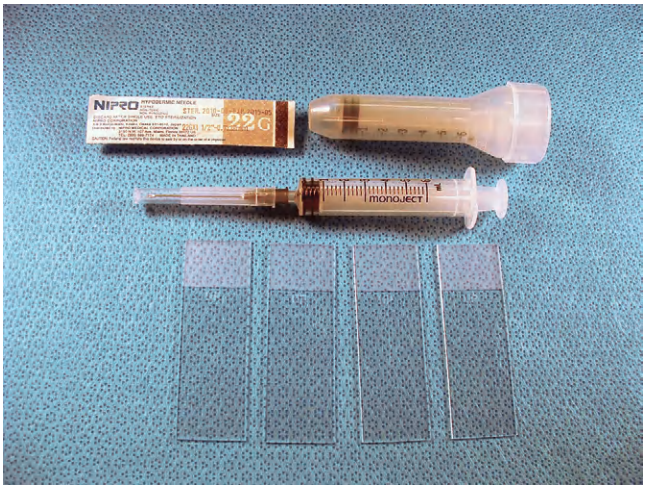

Figure 61-15 Fine-needle aspirate setup including 6-mL syringes, 1.5-gauge 22-inch needles, and glass slides.

Advantages and Disadvantages of Fine-Needle Aspiration

Fine-needle aspiration has several advantages. Little to no sedation is usually required. Because the size of the needle is so small, there is little risk of hemorrhage. Therefore multiple sites can easily be sampled. The procedure is rapid and can usually be performed on an outpatient basis. There is also less cost to the client.

The primary disadvantage of fine-needle aspiration is its questionable accuracy. The sample size often limits the number of available cells to obtain an accurate diagnosis, and hemodilution makes it difficult to assess whether inflammatory cells were present in the liver or peripheral blood. There are several important elements used to interpret pathologic information including lobular architecture, presence and location of inflammation within a lobule, presence and severity of fibrosis, metal accumulation, vascular abnormalities, and lobule heterogeneity. These criteria cannot be accurately determined using a cytologic sample obtained using FNA. Several studies have compared fine-needle aspiration cytology with biopsy with histopathology.[9-12] In one study with a total of 34 cases, there was good correlation in 35% of cases, partial correlation in 35% of cases, and no correlation in 30% of cases.[9] Poor correlation was found with a variety of histologic changes, including vacuolar change, lipidosis, cholestasis, inflammation, and neoplasia. In a similar study with 97 cases, complete agreement between fine-needle aspiration and histopathology was seen in only 30% of cases in dogs: 25% agreement with inflammation, 14% agreement with neoplasia (mainly carcinoma), and 64% agreement with vacuolar hepatopathy.[10] In cats, there was overall agreement in 51% of cases: 27% agreement with inflammation, 33% agreement with neoplasia (lymphoma), and 64% agreement with vacuolar hepatopathy. Although vacuolar hepatopathy was the most sensitive diagnosis, it was also the most common misdiagnosis using cytology. In another study, the best correlation between hepatic cytology and biopsy was seen with lipidosis, lymphoma, and carcinoma, whereas the worst performance was seen with inflammatory and fibrotic disorders.[11] Another study found high sensitivity and specificity with fine-needle aspiration in detecting inflammatory hepatic disease in dogs.[12] However, further information was not provided such as the severity of the inflammation or other histopathologic features. Additionally, for noninflammatory hepatic disease, cytology was inaccurate in 76% of cases.

Summary of Fine-Needle Aspiration

Although fine-needle aspiration is easy to perform, involves little risk, and little to no sedation, the information is of little value if it is inaccurate as often as it is accurate. There is institutional bias regarding its accuracy, which may relate to the experience and expertise of the cytologists. Given its clear limitations, fine-needle aspiration is best used as an adjunctive diagnostic modality in conjunction with other techniques or clinical findings, and does not replace histopathology. The clinician must be aware of its inherent inaccuracy before undertaking fine-needle aspiration and relying on the cytologic findings.

Ultrasound-Guided Biopsy

Ultrasound-guided hepatic biopsy uses a cutting-type needle as a sampling tool. Automated needles are preferred and should be either completely automated or semiautomated. These are spring-loaded needles similar in style to the manual Tru-Cut needle. Completely automated needles thrust the inner obturator (containing the biopsy tray or specimen notch) followed by the outer cutting sheath into the liver in a fraction of a second. These needles can be operated with one hand while the other hand operates an ultrasound transducer to allow precise placement of the biopsy instrument. There is minimal displacement of the liver, a shorter intraparenchymal phase, and a more reliable yield of tissue. This allows a smaller diameter needle to be used and a lighter degree of sedation in some cases. Using the rapid cutting action, the hepatic tissue tends to be less fragmented. Semiautomated needles require manual placement of the internal obturator into the liver, followed by an automatic thrusting of the outer cutting sheath by a spring-loaded mechanism. These needles have the additional advantage of control over the final needle position, as the tip of the needle can be precisely localized before the outer cutting sheath is deployed. I generally use a 16-gauge needle for ultrasound-guided hepatic biopsy. Figure 61-16 depicts a typical setup for ultrasound-guided biopsy.

In most dogs, the liver can be biopsied using local anesthesia and minimal sedation. Most cats require general anesthesia to safely obtain tissue. It must be emphasized that the degree of sedation must be tailored to each individual patient. A careful ultrasound examination is performed prior to biopsy. This allows planning of the procedure based on echo pattern, lesion size, proximity to other organs, proximity to blood vessels, determination of cystic or solid tissue, and optimal approach of the needle path. Care must be taken prior to taking samples to ensure that vessels and other organs are not within the path of the needle. For diffuse lesions, the transducer is typically placed caudal and to the left of the xiphoid, and aimed at the left medial or lateral lobes. In patients with a small liver, it may be difficult to adequately visualize the needle without gastric gas interference. Placing these animals in a 45-degree right lateral oblique position can reduce this interference. If the animal is under general anesthesia, an assistant can compress a rebreathing bag to hold the animal in deep inspiration, which serves to move the diaphragm and liver caudally to improve visualization. The area is surgically prepared. The ultrasound transducer is covered with sterile wrap and sterile lubricant is used to enhance skin contact. A small stab incision is made in the skin at the desired needle insertion site. While one hand maneuvers the transducer, the other hand advances the needle into the liver under direct ultrasound visualization. The image should be optimized to maximize the chance of recognizing the needle within the liver. To allow distinction of the needle from other echogenic structures, the needle can be gently moved in and out with minimal movements (attempting to move the liver within the abdominal cavity rather than the needle within the liver). Occasionally the needle cannot be seen, and indirect evidence of organ penetration must be used such as movement of the liver or visualization of movement at the liver border. The needle is then directed so the trajectory will avoid other structures when it is fired. The needle is then fired, and immediately removed. For most cases, four to five samples are obtained, and are submitted for aerobic/anaerobic culture, histopathologic evaluation, and metal (copper, zinc, and iron) quantification. In one study, liver tissues with high metal concentrations had significantly lower copper and iron in needle-core versus wedge biopsy specimens.[13] Consequently the value of needle-core biopsy specimens for measurement of metal concentrations is questionable. Careful examination for post-biopsy hemorrhage is then performed. External digital pressure may be used to help control hemorrhage in smaller patients. Usually an abdominal compression wrap is ineffective for controlling hemorrhage.

Figure 61-16 Ultrasound-guided biopsy setup including sterile gloves, sterile wrap and lubricant, number 11 surgical blade, and 16-gauge needle biopsy instrument.

Advantages and Disadvantages of Ultrasound-Guided Biopsy

Ultrasound-guided biopsy has many of the advantages of fine-needle aspiration, including the need for minimal sedation in some patients, the ability to sample multiple sites, and low to moderate cost to the client. Additionally, tissue is obtained for histopathology.

One disadvantage of ultrasound-guided biopsy is the risk of bleeding (especially when multiple sites are sampled and larger-gauge needles are used). In one study, 96 percutaneous transabdominal hepatic needle biopsy samples were obtained with no adverse consequences noted[14]; however, this study was performed in normal dogs, and still carries high risk. Additional disadvantages of ultrasound-guided biopsy include the needing sedation or anesthesia in some patients, difficulty of imaging small livers, difficulty of obtaining liver tissue in patients with fibrosis, and, most importantly, the obtaining of samples that have a questionable representation of the underlying hepatic pathology. The diagnostic accuracy of needle biopsy has been questioned by many clinicians, observing that results of needle biopsy analysis often do not adequately reflect the clinical and laboratory features of the patient. This questionable accuracy is in most part a result of potential for sampling error. This method still results in a relatively small sample size, possible

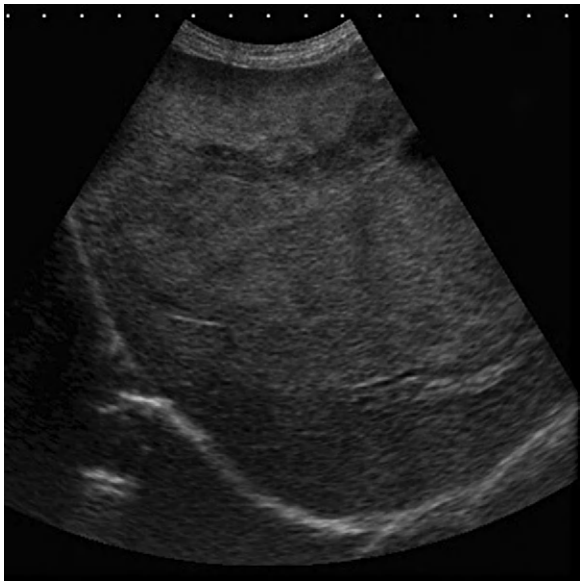

Figure 61-17 Ultrasound image of a focal hepatic mass (hepatocellular carcinoma) in a Pomeranian dog. This mass is amenable to ultrasound-guided biopsy.

fragmentation of fibrous tissue, and may not enable sampling of abnormalities located in other lobes (the left medial or lateral lobes are generally sampled because of their ease of imaging). In one study, percutaneous hepatic sampling using core biopsies resulted in 92% diagnostic quality samples, however these were not compared with large wedge biopsy to assess the accuracy of this method.[15] In another study, the diagnostic accuracy of the Tru-Cut–type needle biopsy was compared with the gold standard of surgical wedge biopsy of the liver in 124 patients.[16] The overall discordance between the two methods was 53% in dogs and 50% in cats, with a greater than 60% discrepancy occurring with chronic hepatitis or cirrhosis, cholangitis/cholangiohepatitis, portosystemic vascular anomalies, microvascular dysplasia, fibrosis, and miscellaneous disorders. These disorders are the most commonly seen among dogs and cats with hepatobiliary disease. The greatest accuracy was with neoplasia (80% concordance). Figure 61-17 is an example of a mass amenable to an ultrasound-guided needle biopsy. Use of a 14-gauge versus 18-gauge needle may reduce this discordance as it raises the number of portal triads sampled from an approximate mean of four to seven, though larger needles carry the risk of increased hemorrhage.

Summary of Ultrasound-Guided Biopsy

In summary, ultrasound-guided hepatic biopsy is relatively easy to perform, but involves more risk to the patient (primarily bleeding). Like fine-needle aspiration, ultrasound-guided biopsy has questionable accuracy. The accuracy may be increased by using a larger-gauge needle, but this carries a greater risk of postbiopsy hemorrhage. If the patient is suspected of having inflammatory disease, vascular abnormalities, or significant fibrosis, or is at risk for hemorrhage, laparoscopy or laparotomy should be considered.

Laparoscopic Biopsy

Chapter 28 provides a detailed description of laparoscopic liver biopsy. Briefly, laparoscopy is performed under general anesthesia with the patient in dorsal recumbency tilted 45 degrees to the left. A Veress needle is placed at the level of the umbilicus into the peritoneal space through a stab incision using a number 11 scalpel blade. After ensuring no obstruction and negative pressure using the infusion and aspiration of saline, the abdomen is insufflated with carbon dioxide gas and maintained at a pressure of approximately 12 mm Hg. A scope port (cannula) is then placed 4 cm right lateral to the Veress needle. The Veress needle is then removed and replaced with an instrument port. Hepatic sampling is achieved using a "spoon" or oval cup biopsy forceps. Multiple samples are obtained under direct visualization, and samples are submitted for aerobic/anaerobic culture, histopathologic evaluation, and metal (copper, zinc, and iron) quantification. Following procurement of all the biopsy specimens, the sites are inspected for hemorrhage. The abdomen is then decompressed, and lidocaine and bupivacaine are infused into the peritoneal cavity through either port. Both the instrument and scope ports are removed, and the port site incisions are closed using either a cruciate or simple interrupted pattern in the body wall, subcutaneous tissue, and skin.

Advantages and Disadvantages of Laparoscopy

This technique enables gross evaluation of the entire liver, extrahepatic biliary system, and surrounding structures while obtaining multiple large specimens of liver. The ability to obtain multiple samples decreases the risk for sampling artifact in cases of regional diversity within the liver. Additionally, by directly visualizing the hepatic parenchyma, the clinician can correlate the histopathologic findings and clinical data with the gross appearance of the liver to render the most accurate diagnosis. This method also enables the visualization of smaller masses and irregularities that may not be evident with ultrasonographic imaging. These masses can also be individually sampled. Laparoscopy also gives the clinician an excellent view of the liver regardless of the hepatic size or conformation of the patient, making it an easy method to sample the liver in patients that are difficult to image with ultrasound.

There is generally minimal bleeding during this procedure, even in patients with in vitro coagulopathies. Using a "spoon" or oval-cup biopsy forceps typically results in a marked decrease in the amount of hemorrhage when compared with needle biopsies. Any hemorrhage can be directly visualized for adequate clot formation. If hemorrhage persists, direct pressure using a blunt probe for 5 minutes can be used. If the site continues to bleed, electrocautery can be applied to the biopsy site or a topical hemostatic agent (Gelfoam) can be placed directly on the biopsy site using laparoscopic forceps.

Disadvantages of laparoscopy include the need for expensive equipment, the need for extensive training, the need for general anesthesia in most cases, and higher cost to the client.

Summary of Laparoscopy

Laparoscopy gives the clinician the advantages of a laparotomy (large sample size, ability to best direct sampling, and ability to take multiple samples, thus resulting in the highest diagnostic accuracy), though with a relatively minimally invasive procedure. The complication rate (especially hemorrhage) is far less than with ultrasound-guided biopsy in my practice. For these reasons, it is my method of choice for obtaining hepatic biopsy specimens in most cases.

Surgical Biopsy

Wedge biopsy via laparotomy is another potential method for obtaining hepatic biopsies. If a random liver biopsy is needed and a section of liver is protruding, a guillotine suture can be used. A preformed encircling ligature of 4-0 monofilament absorbable suture material is placed around the protruding section of liver.

The ligature is then tightened until it has crushed the hepatic parenchyma. After completing several throws in the knot, the sample is excised 1 to 2 mm distal to the ligature using Metzenbaum scissors or a scalpel blade. If a specific area of liver is needed, a sample can be obtained using the transfixation method or a biopsy punch. The transfixation method entails placing a ligature through the liver lobe approximately 8 to 10 mm from its edge. The ligature is tightened to crush through the hepatic parenchyma along one border of the desired biopsy specimen. An additional throw is made at a right angle to the first ligature, and this throw is tightened to crush the parenchyma of the second border of the specimen. The sample is removed 1 to 2 mm distal to the crushed area using a scalpel blade or Metzenbaum scissors. If the desired area does not lie near the edge of a liver lobe, a 6-mm biopsy punch can be used. The biopsy punch should be inserted into the hepatic parenchyma ensuring not to penetrate the opposite surface. If the biopsy site is close to the hilus, extra caution must be used so that no more than half of the thickness of the liver is penetrated. The biopsy sample is removed from the liver using scissors. Hemorrhage can be controlled by filling the defect with a topical hemostatic agent (Gel Foam) and applying digital pressure for 3 to 5 minutes, or by suturing the hepatic capsule with fine, absorbable monofilament suture in a cruciate pattern. Akin to laparoscopy, this method has similar advantages and disadvantages as listed previously. Although it is more invasive, it allows easier biopsy of other abdominal organs (such as intestine and mesenteric lymph node) and the ability to perform therapeutic maneuvers (such as hepatic mass removal or biliary diversion).

PARENCHYMAL DISORDERS

Susan E. Johnson

Inflammation and Necrosis

Acute Hepatitis and Acute Hepatic Necrosis

Etiology

Hepatocyte death (necrosis and apoptosis) in dogs and cats occurs secondary to a broad variety of insults, including infectious agents, drugs and toxins, hypoxia, immunologic events, and metabolic disorders. Hepatic necrosis and acute inflammation often occur together and the relationship between these two processes is complex. Acute inflammation may be the primary event, or necrosis of hepatocytes can be followed by a substantial inflammatory response, the "hallmark" of necrotic cell death.[1] The term *acute hepatitis* traditionally has been used when infectious agents cause hepatocellular necrosis, even though in the early stages, hepatic inflammation can be minimal or absent.[2] Controversy exists among veterinary pathologists regarding the preferred terminology (*acute hepatitis* versus *acute hepatic necrosis*), when necrosis predominates and is caused by noninfectious insults such as toxins or ischemia.[2] For the purposes of this discussion, lesions of acute hepatitis and acute hepatic necrosis are discussed together, recognizing that the primary contributions of each lesion may be variable, depending on the cause, host response, and passage of time. Acute hepatitis, a form of primary hepatitis, should be differentiated from "nonspecific reactive hepatitis," a response of the liver to a variety of extrahepatic disorders that is characterized by focal inflammation without necrosis.[2] Nonspecific reactive hepatitis is discussed in a later section of this chapter.

Acute hepatitis and necrosis are common morphologic hepatic lesions in dogs and cats presenting with acute liver disease caused by infectious, toxic, metabolic, and ischemic disorders (Box 61-1). However, acute liver disease can also be associated with other pathologic processes such as severe hepatic lipidosis (cats), granulomatous hepatitis (fungal infections), intrahepatic cholestasis (bacterial cholangitis, leptospirosis), and malignant infiltration (lymphoma, malignant histiocytosis). Canine adenovirus I, canine and feline herpesvirus in the neonate, *Clostridium piliforme*, and *Toxoplasma gondii* are specific examples of infectious agents that cause acute hepatic necrosis (with variable inflammation), often as part of a multisystemic disorder.[2] Although leptospirosis is a well-recognized infectious cause of acute liver disease in dogs, hepatic necrosis is an uncommon histologic feature and hepatic lesions are typically characterized by cholestasis, liver cell dissociation, and nonspecific reactive hepatitis.[3]

Despite the large number of potential causes of acute hepatitis and necrosis, a specific etiology is often not determined.[4,5] In a recent case series of 101 dogs with primary hepatitis (acute and chronic hepatitis) that were presented to a referral clinic, 21 dogs were diagnosed with morphologic features of acute hepatitis.[4] A cause could not be determined in the majority of these cases, although increased hepatic copper was detected in five dogs with acute hepatitis, suggesting that copper accumulation could be a significant contributing factor.[4]

Pathophysiology

Despite numerous potential causes of hepatocyte death, two general mechanisms are recognized: apoptosis and necrosis.[2] These two mechanisms have traditionally been considered to be distinct events. However, it now appears that apoptosis and necrosis are alternate outcomes of the same initiating causes and signaling pathways.[1] Apoptosis is adenosine triphosphate–dependent (caspase-dependent) programmed cell death that causes shrinkage of the cell (apoptotic bodies or acidophil bodies) with orderly resorption of cellular contents, minimal leakage of cellular components, and minimal secondary inflammation.[1,2] Necrosis occurs when depletion of adenosine triphosphate results in cellular swelling, loss of integrity of the cell membrane and cell lysis, with release of cell contents and secondary inflammation.[1,2]

Diffuse hepatic necrosis is the most consistent histological lesion detected in dogs and cats with acute liver failure.[5] Acute liver failure (ALF) is a rare clinical syndrome (usually fatal) that occurs when a sudden severe insult to the liver compromises at least 70% of functional hepatic mass. Liver cell death exceeds hepatic regenerative capacity, resulting in clinical signs of liver failure.[5] The clinical and laboratory features of ALF are not specific for the inciting cause but reflect disruption of one or more major hepatic functions.

Once hepatocellular injury has occurred (and assuming the patient survives), the morphologic hepatic response to injury may include parenchymal regeneration, fibrosis, and ductular proliferation.[2] Nearly complete hepatic regeneration is possible if hepatocyte injury is limited and the reticulin network remains intact.[2] With severe parenchymal destruction or extensive loss of hepatocytes, periportal ductular proliferation, hepatic fibrosis, postnecrotic scarring, and regenerative hepatic nodules are more likely.[2] Dogs with acute hepatitis may also progress to chronic hepatitis.[4]

Clinical Examination

The clinical presentation of dogs and cats with acute hepatitis and necrosis varies with the underlying cause and the extent and severity of the hepatic lesions. The spectrum of hepatic involvement may

include (a) subclinical (biochemical abnormalities only), (b) clinical signs of acute liver disease, or (c) the clinical syndrome of ALF. When liver injury is mild (focal necrosis and inflammation), clinical signs may be absent, mild, or related to an underlying cause in another organ system. In this setting, hepatic involvement may not be recognized until biochemical evaluation reveals increased liver enzyme activity or mild hyperbilirubinemia. It has been suggested that many dogs with acute hepatitis are not recognized clinically, because signs are mild and self-limiting, and dogs recover spontaneously regardless of treatment.[6] Clinical signs of acute hepatitis include acute onset of lethargy, anorexia, vomiting, diarrhea, PU, and PD, in a previously healthy animal. These are nonspecific findings of acute liver disease, which overlap those of other systemic disorders. The finding of icterus on the physical examination is a more specific indicator of hepatobiliary disease, especially in the absence of anemia.

Dogs and cats with acute diffuse hepatic necrosis often present with ALF. [5] In addition to the signs of acute liver disease described above, animals in ALF show signs of HE (depression, behavioral changes, dementia, ataxia, pacing, circling, blindness, hypersalivation, seizures, and coma) and clinical evidence of a bleeding tendency (melena, hematemesis, or cutaneous and mucosal hemorrhages), which suggest severe hepatic dysfunction.[5] Signs of ALF are rapidly progressive (over hours to days) and this clinical syndrome is often fatal, with reported mortality varying from 25% to 100%.[5]

With acute hepatic disease, the history typically reveals acute onset of signs in a previously healthy animal. However, liver failure that is recently recognized may not necessarily be recent in onset. With occult chronic liver disease, clinical signs may be vague and go unrecognized by the owner until a final phase of hepatic decompensation. The owner should be questioned about any subtle signs of chronic illness that would suggest the underlying liver disease may be chronic rather than acute, and that the current illness may be an exacerbation or decompensation of chronic liver disease. Dogs and cats with ALF are generally in good nutritional status compared with those with chronic hepatic disease. Findings of cachexia, emaciation, ascites, or edema suggest a more protracted illness and are characteristic of chronic rather than acute liver disease. It is important to make a distinction between acute and chronic liver disease as the intensive supportive care indicated in ALF might not be warranted in chronic end-stage liver disease. The long-term prognosis is better for acute hepatitis than chronic hepatitis.[4]

Diagnosis

An initial database consisting of complete blood cell count, serum chemistry, and urinalysis should be obtained in dogs and cats with acute liver disease. Liver enzyme elevations are a common finding in dogs and cats with acute hepatitis and necrosis. With mild hepatic injury or focal hepatic necrosis, increased ALT activity may be the only finding on an otherwise unremarkable biochemical profile. ALT and AST activities are moderately to markedly increased, because of enzyme leakage from damaged hepatocytes.[7] Although ALT activity increases with many hepatic diseases, the largest magnitude of increase is seen with acute hepatic necrosis and roughly correlates with the number of involved cells.[7] ALT activity may be increased as much as 100 times the upper range of normal, with increases in AST activity that parallel but are generally lower (30 times the upper limit of normal) than the ALT. It should be noted that some recognized hepatotoxins (aflatoxin and microcystin in blue-green algae) are not associated with severe or protracted increases in ALT activity because of toxin-suppressed transaminase synthesis.[7] Increased activity of the cholestatic liver enzymes, alkaline phosphatase, and GGT, also commonly occur with acute hepatitis and necrosis, but the magnitude of the increase is much less than for the ALT and AST.

Abnormalities in biochemical tests such as hyperbilirubinemia, increased SBAs, hypoglycemia, and hyperammonemia indicate compromised hepatic function. Hyperbilirubinemia and bilirubinuria support more significant hepatic injury once prehepatic (hemolytic) causes have been discounted. Primary biliary tract disorders including posthepatic mechanisms of hyperbilirubinemia should also be considered in the differential diagnosis. Other considerations for hypoglycemia in conjunction with acute liver disease include xylitol toxicity (excess insulin release) and sepsis. Hypoalbuminemia usually suggests chronic rather than acute liver disease, because of the long serum half-life of albumin. If azotemia is detected, dehydration, GI blood loss, and concurrent renal damage (e.g., leptospirosis, nonsteroidal antiinflammatory drugs [NSAIDs]) should be considered. Interpretation of azotemia is facilitated by concurrent urinalysis. Renal injury is supported by findings of cellular or granular casts, glucosuria, isosthenuria, and proteinuria. The complete blood cell count may reveal an inflammatory response suggesting underlying infectious or inflammatory disorders, and it is also useful for ruling out hemolytic anemia as cause of jaundice. Documentation of a coagulopathy is required for the clinical diagnosis of ALF. Laboratory findings indicative of a coagulopathy include prolonged PT and activated partial thromboplastin time (aPTT), decreased fibrinogen, increased fibrin degradation products, and thrombocytopenia.

Abdominal radiographs are often unremarkable in dogs and cats with acute hepatitis and necrosis. The liver may appear normal or increased in size. On abdominal ultrasound, the liver may appear normal or hypoechoic. Thoracic and abdominal imaging may be helpful to evaluate for other causes of acute hepatic disease (see Box 61-1), and biliary tract disorders.

Because dogs and cats with acute hepatitis and necrosis present with nonspecific signs of acute liver disease, the clinician should maintain a broad perspective regarding the many potential diseases and processes that can acutely affect the liver (see Box 61-1). Prior to obtaining a liver biopsy, ancillary testing (cytology or biopsy of more accessible lesions, infectious disease titers or molecular tests, diagnostic imaging) should be performed to evaluate for systemic disorders with secondary hepatic effects or multisystemic infections (see Box 61-1), thus providing a diagnosis of other causes of acute liver disease in a less-invasive manner.

When acute hepatitis or hepatic necrosis is suspected (or confirmed by liver biopsy), a thorough history is essential to identify exposure to potential hepatotoxins and infectious agents. The owner should be questioned regarding recent medications, including prescription and over-the-counter drugs, and alternative medicines such as herbal and dietary supplements. The potential for exposure to chemicals or hepatotoxins (*Amanita* mushrooms, blue-green algae, Sago palms, aflatoxins, or xylitol) should be assessed (for more details, see "Drug and Toxin-Induced Liver Injury" section). Other pertinent historical questions include current vaccination history (canine adenovirus, leptospirosis), travel history (fungal infections or tick-borne diseases), and exposure to other animals (infectious causes).

Liver biopsy is required to document the presence of acute hepatitis and necrosis; evaluate for specific causes; and differentiate acute from chronic disease. In patients with mild (or absent) clinical signs and liver enzyme elevations that correspond to recent medication administration, a liver biopsy may be postponed, the medication discontinued, and clinical signs and liver enzymes monitored for

improvement over a 2- to 3-week period. For patients with ALF and coagulopathy, the clinician must carefully weigh the benefits of histologic characterization versus the risk of excessive bleeding from the procedure.

Acute hepatitis is characterized histologically by a mononuclear or mixed inflammatory pattern, accompanied by hepatocellular apoptosis or necrosis.[2] Necrosis should be further characterized by the pathologist as to the morphologic pattern of injury (focal, multifocal, confluent, bridging, massive, or piecemeal) because the pattern of necrosis may provide insight into the pathogenesis of the lesion.[2] For example, because centrilobular hepatocytes have an abundance of cytochrome P450 enzymes, these hepatocytes are preferentially affected in drug-induced hepatotoxicity, when cytochrome P450 metabolism of the parent drug results in toxic metabolites.[8] Quantitative copper analysis and histochemical staining for copper are recommended, as copper accumulation may be an underappreciated cause of acute hepatitis in dogs.[4] Infectious causes of acute hepatitis may be diagnosed on liver biopsy, or by additional tests performed on liver tissue (culture, immunohistochemistry, polymerase chain reaction [PCR], virus isolation; Table 61-4).

Table 61-4 Infectious Diseases and the Liver

Classification/ Organism	Species	Hepatic Lesions	Tissue Tropism	Diagnosis
Viral				
Canine adenovirus I (infectious canine hepatitis)	D	Centrilobular necrosis; neutrophilic and mononuclear cell infiltrates; intranuclear inclusions in hepatocytes and Kupffer cells; gallbladder edema; chronic hepatitis?	Liver, vascular endothelial cells	Virus isolation, PCR, immunohistochemistry, histopathology
Herpesvirus (neonates)	D	Multifocal hemorrhagic necrosis; intranuclear inclusions	Kidneys, liver, lung, spleen, lymph node	Virus isolation, fluorescent antibody techniques; PCR, EM, histopathology
Canine acidophil cell hepatitis	D	Acute or chronic hepatitis; cirrhosis; acidophil cells characterized by angular shape, acidophilic cytoplasm and hyperchromatic nucleus	Liver	Histopathology
Coronavirus (feline infectious peritonitis)	C	Pyogranulomatous and granulomatous hepatitis; multifocal hepatic necrosis	Macrophages; vascular endothelium; peritoneum, liver, lymph nodes, kidneys, CNS, eyes	Immunohistochemistry on effusions or lesions with infected macrophages
Calicivirus (virulent form)	C	Massive or centrilobular hepatic necrosis; individualization of hepatocytes	Macrophages; vascular endothelium	Virus isolation, PCR
Bacterial				
Leptospira interrogans	D	Acute cholestasis, liver cell dissociation, and nonspecific reactive hepatitis; chronic hepatitis	Kidneys, liver, vascular endothelium	Serology, PCR on urine, histopathology
Clostridium piliforme (Tyzzer disease)	D, C	Multifocal periportal hepatic necrosis; intracellular filamentous organisms demonstrated on Giemsa or Warthin-Starry stain	Liver, ileum, colon	Histopathology
Sepsis and endotoxemia	D, C	Intrahepatic cholestasis, mild periportal lymphocytic infiltrate, scattered foci of macrophages or neutrophils, and occasional necrotic hepatocyte		Blood and extrahepatic tissue cultures; response to treatment of systemic infection
Mycobacterium spp.	D, C	Granulomatous hepatitis; acid-fast organisms demonstrated on special stains	Lungs, lymph nodes, GI tract; skin (varies with species)	Histopathology; cytology, culture; direct fluorescent antibody; PCR
Bartonella henselae and *clarridgeiae*	D	Granulomatous hepatitis and peliosis hepatis (*Bartonella henselae*); hepatic disease (*Bartonella clarridgeiae*)	Liver, lymph nodes, myocardium, joints	Serology, culture, PCR on liver tissue
Helicobacter spp. (enterohepatic)	D, C	Multifocal necrotizing hepatitis (dog); cholangitis (cats)	Liver and biliary tract	EM, PCR
Abscess (aerobic and anaerobic organisms)	D, C	Unifocal or multifocal hepatic abscesses	Primary liver or multisystemic infection	Aerobic and anaerobic cultures; histopathology

Continued

Table 61-4 Infectious Diseases and the Liver—cont'd

Classification/ Organism	Species	Hepatic Lesions	Tissue Tropism	Diagnosis
Fungal				
Histoplasma capsulatum, Coccidioides immitis, Blastomyces dermatitidis, others	D, C	Granulomatous or pyogranulomatous hepatitis; fungal organisms seen on Grocott or Gridley silver stains	Varies with organism	Serology, cytology, histopathology, urine antigen testing (*Blastomyces*)
Protozoan				
Toxoplasma gondii	D, C	Hepatic necrosis; cholangitis (cats)	Lungs, CNS, liver, pancreas, heart, eyes	Serology, histopathology, PCR
Neospora caninum	D	Hepatic necrosis, neutrophils, hemorrhage	CNS, muscle, nerves, liver	Serology, histopathology, PCR
Cytauxzoon felis	C	Schizont-laden macrophages in the lumen of small vessels in liver; granulomatous hepatitis	Liver, spleen, bone marrow	Organism seen on blood smears; histopathology
Leishmania infantum	D	Multifocal, mild to moderate, granulomatous to pyogranulomatous inflammation; chronic hepatitis: lymphocytic plasmacytic portal inflammation with mild fibrosis	Skin, hemolymphatics; spleen, liver, kidneys	Organisms seen on cytology or histopathology; serology, culture, PCR
Babesia canis, Babesia gibsoni	D	Hepatitis, focal necrosis, bile stasis	Red blood cells	Cytology, serology, PCR
Hepatozoon canis	D	Hepatitis; mononuclear and neutrophil infiltration; meronts	Lymph nodes, marrow, liver, spleen, lungs	Serology, histopathology
Sarcocystis canis	D	Necrosuppurative and eosinophilic hepatitis; vasculitis; schizonts	CNS, liver, skin	Histopathology, EM
Rickettsial				
Ehrlichia canis	D	Portal hepatitis; lymphocytes, plasma cells, macrophages; morulae in mononuclear cells	Monocytes; macrophages	Serology, PCR, immunohistochemistry
Rickettsia rickettsiae	D	Focal hepatic necrosis	Endothelial cells; skin, CNS, heart, kidney	Serology, direct fluorescent antibody staining of tissues
Parasitic				
Visceral larval migrans (*Toxocara* migration)	D	Subcapsular and parenchymal granulomas with fragments of parasitic larvae; portal areas with eosinophils; lymphocytes	GI tract	Histopathology, fecal examination
Heterobilharzia americana (schistosomiasis)	D	Granulomas and schistosome ova; portal fibrosis	Liver, GI tract, lymph nodes	Histopathology, fecal examination, fecal PCR, serology
Dirofilaria immitis (Caval syndrome)	D, C	Passive congestion, cavernomatous change of hepatic veins, centrilobular necrosis and fibrosis, microfilaria in sinusoids with occasional small nodular aggregates; microthrombi	Heart, lungs, liver	Serology, microfilaria identification in blood; thoracic radiographs, echocardiography
Liver flukes: *Platynosomum concinnum, Amphimerus pseudofelineus; Opisthorchis, Metorchis*; others	D, C	Chronic cholangitis (eosinophils; lymphocytes, plasma cells, neutrophils); dilated bile ducts; periductal and portal fibrosis	Biliary tract; pancreas	Identification of ova on fecal exam or cytology of bile; direct visualization at surgery or necropsy
Alveolar echinococcosis (*Echinococcus multilocularis*)	D	Cystic hepatic masses containing amorphous debris; granulomatous inflammation	Intestine	Serology, fecal examination, histopathology
Algae				
Prototheca zopfii	D	Granulomatous hepatitis; organisms stained by periodic acid-Schiff or methenamine silver stain	Eyes, colon, CNS, kidneys, liver	Cytology or histopathology of affected tissues; culture

C, cat; CNS, central nervous system; D, dog; EM, electron microscopy; MAT, microscopic agglutination test; PCR, polymerase chain reaction.

Unfortunately, in most cases, routine liver biopsy is unlikely to reveal a specific cause of acute hepatitis.[2,4] Findings of inflammation and necrosis/apoptosis accompanied by nodular regeneration and fibrosis suggests chronic rather than acute hepatitis. The long-term prognosis is better for acute hepatitis than for chronic hepatitis.[4]

Treatment

If a probable cause of acute hepatitis and hepatic necrosis can be determined, then specific treatment is directed at the primary etiology (e.g., discontinuing potentially hepatotoxic medications, treating for leptospirosis with doxycycline, or chelating hepatic copper with penicillamine). In most cases specific therapy is unavailable and treatment is directed at more general supportive and symptomatic treatment of liver disease. Glucocorticoid therapy is not typically indicated in the treatment of acute hepatitis.[4] Empirical treatment with antioxidants such as *S*-adenosylmethionine (SAMe; 20 mg/ kg PO q24h), milk thistle (Siliphos; 3 to 6 mg/kg PO q24h), or vitamin E (10 to 15 IU/kg q24h) may be warranted, as oxidative stress is believed to play a role in drug (carprofen, potentiated sulfonamides, diazepam, methimazole, lomustine, others), and toxin (aflatoxin, organic solvents, and heavy metal toxicity) induced hepatic injury.[9] SAMe and milk thistle have additional cytoprotective properties that could be beneficial in necroinflammatory hepatopathies and hepatotoxicity. Antioxidants and cytoprotective agents are discussed in more detail in Chapters 40 and 46, respectively. Liver biochemistries should be monitored to assess patient response to therapy. Repeat liver biopsy performed 6 to 8 weeks after the initial diagnosis has been recommended, to confirm that acute hepatitis has improved or resolved, or to document a progression toward chronic hepatitis.[4,6] It has been suggested that most dogs with mild idiopathic acute hepatitis (not in ALF) recover after several days, regardless of treatment.[6]

For patients with ALF, aggressive supportive treatment is required. Goals of therapy are to treat the underlying cause when possible, allow adequate time for hepatic regeneration and repair, and prevent or control complications of liver failure, such as hypoglycemia, coagulopathy and anemia, HE, GI ulcers, and septicemia. Intravenous *N*-acetylcysteine (NAC), a glutathione source/ antioxidant, is the antidote of choice for treatment of acetaminophen toxicity. NAC also appears to have additional potential benefits (improved systemic hemodynamics and tissue oxygen delivery), and should be considered for use in any dog or cat with ALF.[9] The optimal dose regimen when NAC is used for this purpose has not been determined. Treatment of complications of liver failure are discussed in "Complications of Liver Disease" section.

Prognosis

The prognosis for recovery in dogs with acute hepatitis is good, as most dogs recover uneventfully.[4] However, there is a potential for dogs with acute hepatitis to develop chronic disease.[4] If animals present with signs of advanced liver failure (e.g., HE, coagulopathy, hypoglycemia), the prognosis is guarded. If the animal survives, hepatic lesions such as periportal ductular proliferation, hepatic fibrosis, postnecrotic scarring, and regenerative hepatic nodules are likely.[2] If a hepatic drug reaction is suspected, reexposure of the patient to the suspect drug should be avoided.

Hepatic Abscesses

Etiology

Hepatic abscesses from bacterial infection of the liver occur uncommonly in dogs and cats.[10-13] Abscesses may form as solitary or multiple macroscopic masses or microabscesses. In newborn animals, Gram-positive and Gram-negative bacteria cause hepatic abscesses, presumably related to postpartum umbilical infections.[14] In adult animals, Gram-negative enteric bacteria (especially *Escherichia coli*) and anaerobes (especially *Clostridia* spp.) are most commonly identified; multiagent infections are frequent.[10,12] Other organisms such as *Yersinia* spp., *Actinomyces* spp., *Nocardia asteroides* can also cause hepatic abscesses as part of a systemic infection.[14]

Pathophysiology

The pathogenesis of hepatic abscesses in dogs and cats is unclear. Hepatic abscesses are usually associated with extrahepatic infections or regional hepatic parenchymal damage. Small numbers of bacteria, including *Clostridium* spp., can be cultured from liver tissue of healthy dogs. Hypoxia of hepatic tissue caused by hepatic neoplasia, liver lobe torsion, or trauma may predispose to abscess formation, because small numbers of existing anaerobes (e.g., *Clostridium* spp.) can proliferate under these conditions.

Other potential sources of bacteria include hematogenous spread (via the umbilical vein, hepatic artery, or translocation of intestinal bacteria into the portal blood), ascension via bile ducts, penetrating abdominal and caudal thoracic wounds, and direct extension from local suppurative diseases. Concurrent diseases or potential predisposing factors in dogs include systemic infections (pneumonia, pyelonephritis, prostatitis, pyometra, endocarditis), gallbladder rupture, pancreatitis, diabetes mellitus, liver lobe torsion, coexisting hepatic disease such as hepatic neoplasia (infected necrosis), long-term phenobarbital administration, long-term corticosteroid administration, and previous surgical biopsy.[10,11] Concurrent diseases in cats include cholecystitis, pyothorax, and hepatic neoplasia.[12] Solitary abscesses are more common in dogs, whereas cats are more likely to be septic and have multiple hepatic abscesses.[11,12] No association with feline leukemia virus or feline immunodeficiency virus infection has been made.[12] Solitary liver abscesses are more likely to involve the right liver lobe in cats and the left liver lobe in dogs.[11,12]

Clinical Examination

When adult dogs and cats are diagnosed with hepatic abscesses, they are usually older than 8 years of age.[10-12] Clinical signs are nonspecific and can be attributed to sepsis, inflammation, and hepatic dysfunction. The most common signs are anorexia, lethargy, vomiting, and diarrhea.[10,11] Clinical signs of hepatic involvement may be overshadowed by signs of the associated disease process (e.g., neoplasia, pyelonephritis, pancreatitis). Dogs with hepatic abscess may have a history of failure to respond to antibiotics or improvement that relapsed when antibiotics are discontinued.[10]

Physical examination findings are often vague and include depression, dehydration, fever, abdominal pain, hepatomegaly, abdominal mass, and abdominal effusion.[10-12] Hypothermia is a more common finding than fever in cats with hepatic abscesses.[12] Because the clinical findings are vague and nonspecific, hepatic abscesses often go undetected until an abdominal ultrasound is performed or they rupture and are discovered during laparotomy. Rupture of a hepatic abscess leads rapidly to peritonitis, septic shock, and death.

Diagnosis

Clinicopathologic abnormalities are consistent with an inflammatory hepatic disease. Potential findings on the complete blood count include neutrophilia with a left shift (or neutropenia and degenerative left shift if rupture occurs), mild anemia, and thrombocytopenia.[10,12] Increased ALT and ALP activity are common findings although the ALT may be in the normal range.[10] Liver enzyme elevations are a less-consistent finding in cats with hepatic abscesses

(increased ALT and ALP activity occurred in less than 50% of cats).[12] Other potential biochemical findings include hyperglobulinemia, mild hyperbilirubinemia, and hypoglycemia (sepsis). Laboratory abnormalities may also reflect the associated disease processes (e.g., hyperglycemia with diabetes mellitus, increased pancreatic lipase immunoreactivity with acute pancreatitis). If an abscess ruptures, cytology of the abdominal infusion reveals septic suppurative inflammation.

Abdominal radiographs may be normal or reveal hepatomegaly, hepatic mass lesion, or decreased abdominal detail or effusion associated with secondary peritonitis. With proliferation of gas-producing organisms, radiolucent areas may be seen in the liver. Ultrasonographic examination permits earlier detection of hepatic abscesses.[11] Ultrasonographically, a liver abscess appears as a hypoechoic or anechoic structure with irregular, hyperechoic margins.[11,13] The ultrasonographic pattern is similar to that seen with hepatic hematomas, cysts, neoplasia, and biliary cystadenoma. Gas may be seen within the abscess.[11] If abscess rupture has occurred, concurrent abdominal effusion may be detected. Additional ultrasonographic findings may reflect associated disorders such as pancreatitis, cholecystitis, or pyelonephritis. Ultrasound-guided fine-needle aspiration of a suspected liver abscess can be safely performed to obtain samples for cytology and culture to confirm the diagnosis.[11] If ultrasonography is not available, the diagnosis of hepatic abscesses is usually established during exploratory laparotomy (or at necropsy).

An attempt should be made to isolate and identify the organism(s) associated with abscessation so that appropriate antibiotic therapy can be instituted based on sensitivity testing. Aerobic and anaerobic cultures can be performed on abscess contents (by fine-needle aspiration), abdominal exudate, blood or hepatic tissues.

Treatment

Treatment of hepatic abscesses consists of surgical resection or drainage of focal lesions, administration of appropriate antibiotics, correction of associated fluid, electrolyte, and acid–base imbalances, and identification and treatment of any underlying disease process. Treatment of large unifocal hepatic abscesses has typically involved surgical resection of affected tissue, which may necessitate partial or full lobectomy.[10,12] If perforation and peritonitis are present, surgical abdominal drainage and lavage are indicated. Ultrasound-guided percutaneous drainage of a solitary abscess may resolve the abscess or allow stabilization until surgical resection can be performed.[11] The successful management of focal hepatic abscesses (up to 8 cm in diameter) by ultrasound-guided percutaneous drainage and alcoholization has been described in five dogs and one cat.[13]

Broad-spectrum combination antibiotic therapy (directed toward both aerobic and anaerobic bacteria) should be initiated as soon as cultures have been obtained. Results of a Gram stain on the exudate may provide preliminary information as to type of organism and guide the empirical choice of potentially effective antibiotics. Recommendations for broad-spectrum antimicrobial coverage of hepatobiliary infections include either a fluoroquinolone combined with amoxicillin/clavulanate or a fluoroquinolone combined with penicillin and metronidazole, until culture results are available. The dose of metronidazole should be adjusted in animals with hepatic dysfunction (7.5 mg/kg PO q8-12h). Antibiotic therapy should be continued for at least 6 to 8 weeks. Response to treatment can be monitored with serial ultrasound examinations and repeated blood work.

Prognosis

Historically, hepatic abscesses have carried a grave prognosis, with an overall reported mortality rate of approximately 50% in dogs[10] and 79% in cats.[12] The survival rate appears to be better when solitary abscesses are detected.[12,13]

Granulomatous Hepatitis

Granulomatous hepatitis is characterized histologically by focal or multifocal aggregates of activated macrophages with an epithelioid appearance, usually accompanied by lymphocytes and plasma cells.[14] This inflammatory response is distinct from that encountered in canine chronic hepatitis. Systemic infectious diseases are an important cause of granulomatous hepatitis and this lesion has been described with fungal infections (histoplasmosis, coccidioidomycosis, many others), bacterial infections (*Mycobacteria, Bartonella, Nocardia, Actinomyces, Rhodococcus*), protozoal diseases (cytauxzoonosis, leishmaniasis); parasitic diseases (visceral larval migrans, schistosomiasis, alveolar echinococcus, *Hepatozoon americana*), and disseminated protothecosis (see Table 61-4).[15,16] In cats, feline infectious peritonitis (coronavirus) is an important cause of multisystemic granulomatous or pyogranulomatous inflammation.

Other causes of granulomatous inflammation include a local response to foreign material (crystalline material, sutures, plant material) or a drug reaction. In humans, granulomatous liver lesions have been associated with administration of diltiazem, sulfonamides, quinidine, allopurinol, interferon-α, and phenytoin.[17,18] However, drug therapy as a cause of granulomatous hepatitis in dogs and cats has not been specifically reported. Granulomatous lesions in the liver has been described in a small number of dogs with lymphangiectasia, lymphosarcoma, and histiocytosis.[19] Many cases of granulomatous hepatitis are idiopathic.[16] Hepatic lipogranulomas ("fatty cysts"), which are often found in dogs with congenital portosystemic shunt, are aggregates of pigment-laden foamy macrophages and should not be confused with granulomatous hepatitis.

Clinical findings with granulomatous hepatitis are highly variable, depending on the underlying cause. When granulomatous hepatitis is identified on liver biopsy, special stains for fungal and mycobacterial organisms should be performed. Other diagnostics to either identify an organism (cytology, culture, fecal exam, PCR) or detect antibodies against the organism (serology) vary widely with the underlying agent (see Table 61-4). If a cause cannot be found after a thorough diagnostic evaluation, consideration should be given to presumptive treatment for undiscovered infectious agents such as atypical mycobacteria, *Bartonella* spp., or systemic fungal infection. Corticosteroids or other immunosuppressant agents should only be used when diagnostic testing and empirical treatment have been unsuccessful, as steroid-induced immunosuppression may exacerbate an underlying infection.[19]

Eosinophilic Hepatitis

Eosinophilic hepatitis occurs rarely in dogs and cats.[2] Potential causes include visceral larval migrans (*Toxocara)*, schistosomiasis, liver fluke infections, *Sarcocystis canis*, and possibly, fungal infections (see Table 61-4).[2] With parasitic causes, eosinophils are often located at or near the site of the parasitic lesion in the liver. Dogs and cats with systemic allergic, parasitic (heartworms), or hypereosinophilic syndromes, may also have scattered eosinophils in the liver, a variant of nonspecific reactive hepatitis.[2] Hepatic drug-induced liver injury should also be considered. Phenytoin and minocycline are associated with eosinophilic infiltrates in humans with drug-induced liver injury.[18,20] Potentiated sulfonamides have been suggested to cause drug-induced eosinophilic hepatitis in dogs,[2] although a more typical pattern is acute hepatocellular necrosis or a cholestatic hepatopathy.[21] When eosinophilic infiltrates are identified, efforts should be directed at diagnosing parasitic causes (fecal,

heartworm test; see Table 61-4), systemic eosinophilia, and hypersensitivity reactions. If no specific cause can be determined, empirical treatment with fenbendazole should be considered, followed by corticosteroid therapy as described for idiopathic chronic hepatitis.

Nonspecific Reactive Hepatitis

The term *nonspecific reactive hepatitis* is used to describe the slight to moderate widespread inflammatory infiltrates of the liver that occur secondary to a spectrum of extrahepatic disease processes.[2] Lesions of nonspecific reactive hepatitis are associated with febrile and inflammatory disorders, especially those involving the GI tract and pancreas, or they may represent residual evidence of a previous intrahepatic inflammatory disorder.[2] Inflammation occurs in portal or parenchymal areas and necrosis is absent. Neutrophils predominate with acute extrahepatic disorders, whereas mononuclear inflammation occurs with chronic extrahepatic disorders or residual hepatic inflammation. The liver may be secondarily affected by systemic disorders because of changes in liver blood flow, portal blood delivery of bacteria, drugs, hormones, cytokines, or other substances from the GI tract, or activation of intrahepatic Kupffer cells (monocyte-macrophage system) involved in the hepatic immune response. It may be challenging to differentiate nonspecific reactive hepatitis from resolving acute hepatitis or mild chronic hepatitis, without supportive clinical information.

Clinical signs in dogs and cats with nonspecific reactive hepatitis are usually referable to the extrahepatic disorder. Liver enzyme elevations (ALT—two times the upper limit of normal; ALP—three- to fourfold increases) are common, thus mimicking primary hepatic disease. However, tests that reflect liver function, including serum bile acids, are usually normal. It is important to consider extrahepatic disorders that can secondary affect the liver, prior to focusing on primary hepatic disease. Treatment is directed at the underlying extrahepatic disorder.

Canine Chronic Hepatitis

Chronic hepatitis, a heterogeneous group of inflammatory-necrotizing diseases of the liver, occurs commonly in dogs, but is rare in cats. Cholangitis, which is inflammatory liver disease that targets the biliary tract, rather than hepatocytes, is more common in cats but also occurs in dogs.The term *chronic hepatitis*, rather than *chronic active hepatitis* or *chronic persistent hepatitis*, is recommended.[2,15] If the etiology is known, it should be included as an adjective, such as "drug-induced chronic hepatitis," or "copper-associated chronic hepatitis"; otherwise, it is considered "idiopathic chronic hepatitis."

Chronic hepatitis in dogs is defined based on histopathologic features of hepatocellular necrosis or apoptosis associated with inflammation and evidence of regeneration and fibrosis.[2] Lymphoplasmacytic inflammation is characteristic, but a neutrophilic component may be present.[2] The histopathologic features of chronic hepatitis are similar, regardless of the underlying cause. Chronic hepatitis has the potential to progress to cirrhosis.[15,16] Recommendations have been made to include a clinical component to the definition of chronic hepatitis, such as documenting an increase in ALT activity along with histologic evidence of hepatic inflammation for a minimum of 4 months. However, many dogs with chronic liver disease are not clinically apparent until the advanced stages, so duration can be difficult to evaluate. The early stages may not be recognized unless biochemistries are monitored for hepatic injury.

A familial predisposition to develop chronic hepatitis has been suggested by demographic studies, pathologic surveys, and clinical case series (see Chapter 62). Breeds of dogs at increased risk for chronic hepatitis include the Bedlington Terrier,[22,23] West Highland White Terrier,[24,25] Doberman Pinscher,[26-28] American and English Cocker Spaniel,[29-33] Skye Terrier,[34] Dalmatian,[35] Labrador Retriever,[36-38] and English Springer Spaniel.[39] Unfortunately, with the exception of hereditary copper-associated liver disease in Bedlington Terriers, information is lacking for most of the breed-related disorders. Female dogs appear to be at increased risk in some studies,[4,40] while others report that male and female dogs are equally affected.[41,42] Within particular breeds, sex differences have been noted (female Doberman Pinschers, Labrador Retrievers, and English Springer Spaniels; male Cocker Spaniels).[26,29,36,38,39] Dogs diagnosed with chronic hepatitis are generally 4 to 7 years of age, but adult dogs of any age (or breed) can be affected.[4,29,41]

Etiology and Pathogenesis

Ideally, canine chronic hepatitis should be classified on an etiologic basis. However, with the exception of copper-associated liver disease in Bedlington Terriers, the cause, pathogenesis, natural history, optimal treatment, and prognosis of these disorders are unknown (Table 61-5). Idiopathic chronic hepatitis is the most common clinical diagnosis.[4,32,40,41]

Infectious Causes. Viral infections are a common cause of chronic hepatitis in humans, but are not currently recognized as an important etiology in dogs. In humans, viruses have the potential

Table 61-5 Causes of Canine Chronic Hepatitis

Category	Cause	Breed Predisposition

to cause hepatitis either because of a persistent hepatic infection or as a transient infection that triggers an immune response because of a cross-reaction between the virus and liver antigens.[43] In an attempt to identify infectious causes of canine hepatitis, PCR screening of liver tissue was performed in 98 dogs with various stages of hepatitis to look for canine adenovirus type 1, *Hepadnaviridae*, hepatitis A virus, hepatitis C virus, hepatitis E virus, *Helicobacter* spp., *Leptospira* spp., and *Borrelia* spp.[44] Based on negative results, the authors concluded that canine hepatitis is not typically caused by these infectious agents.[44] However, dogs that are experimentally infected with canine adenovirus type I, but are partially immune, can develop chronic hepatitis that progresses to cirrhosis.[45] The virus could not be detected beyond the first week postinfection, although the disease progressed over a period of months.[45] Canine adenovirus antigen has been demonstrated by immunohistochemical techniques in formalin-fixed liver sections from five of 53 dogs with various hepatic inflammatory lesions, suggesting that canine adenovirus 1 (CAV-1) may play a role in spontaneous chronic hepatitis.[46] In contrast, PCR and immunohistochemistry failed to detect canine adenovirus in liver tissue of 45 dogs with chronic liver disease.[47] Whether CAV-1 is a significant cause of chronic hepatitis under natural conditions is unknown.

Another proposed viral cause of chronic hepatitis and cirrhosis is the "canine acidophil cell hepatitis virus," reported from Great Britain in the 1980s.[48,49] This transmissible agent, most likely a virus, is distinct from CAV-1. It was transmitted experimentally by subcutaneous injection of serum or liver extracts from affected dogs, resulting in experimentally induced acute and chronic hepatitis. No further studies have been published to clarify the nature of this infectious agent or the associated hepatitis.

Canine leptospirosis is typically associated with acute cholestatic hepatic disease and acute renal failure. However, persistent infection can cause chronic hepatitis in the absence of azotemia.[50,51] *Leptospira* serovar *grippotyphosa* was incriminated as a cause of chronic hepatitis in a kennel of American Foxhounds, based on serologic evidence and demonstration of spirochetes in the liver.[50] *Leptospira* serogroup *australis* (serovars *australis*, *bratislava*, and *muenchen*) infection was suspected to cause chronic hepatitis in 16 young Beagle dogs in a breeding colony routinely vaccinated against leptospirosis serogroups *canicola* and *icterohaemorrhagica*.[51]

Canine leishmaniasis has been associated with histologic evidence of chronic hepatitis,[52] but clinical features suggestive of hepatic involvement (hepatomegaly, ascites, or icterus) were absent. Histologic findings revealed granulomatous hepatitis in most dogs, but some dogs had marked portal infiltration with lymphocytes and plasma cells, and mild portal fibrosis. *Leishmania* amastigotes were routinely identified in macrophages in liver or other affected tissues. *Bartonella clarridgeiae* DNA was amplified from a liver biopsy of a Doberman Pinscher with copper-associated chronic hepatitis, although the significance of this finding is unclear.[53]

Copper Accumulation. Copper is an essential trace element in diets and is required for a number of physiologically important enzymes. Cells have highly specialized and complex systems for maintaining intracellular copper concentrations. At toxic concentrations, free intracellular copper initiates oxidative damage causing hepatocellular necrosis and inflammation.[54,55] Normal copper metabolism has been reviewed in detail elsewhere.[54,56]

Copper accumulation in the liver can be associated with significant hepatic injury resulting in acute hepatitis, chronic hepatitis, and cirrhosis (Figure 61-18).[4,54,57] It is one of the few well-documented causes of canine chronic hepatitis. In one study, copper-associated

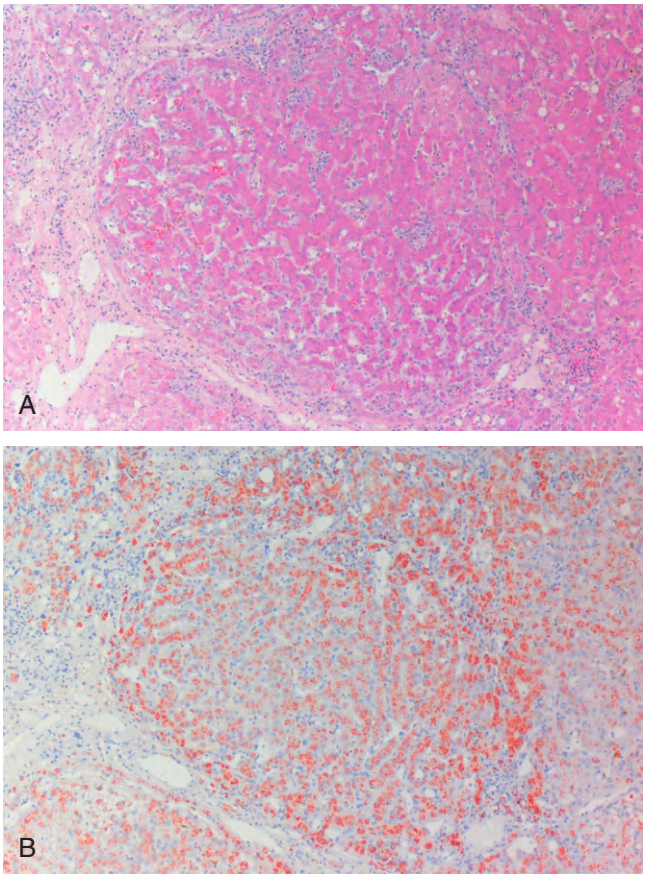

Figure 61-18 Liver biopsy from a 12-year-old Dalmatian/mixed breed dog with copper-associated chronic hepatitis and a quantitative hepatic copper of 8264 µg/g dry weight (normal <400 µg/g). **A,** Periportal hepatitis with portal fibrosis and nodular hepatic regeneration (H&E, 10×). **B,** Rhodanine stain of liver tissue was markedly positive for copper (orange granules, 10×). (Courtesy of Dr. Paul Stromberg.)

hepatitis (acute and chronic) accounted for one-third of all dogs with primary hepatitis.[4] Hepatic copper accumulation and hepatopathy have been described in cats but appears to be rare.[58,59] The severity of hepatic injury correlates with the amount of hepatic copper, but subcellular localization of molecules and the molecular association also plays a role.[54] Serum copper levels do not accurately reflect hepatic copper content and quantitative analysis of copper in the liver is required.[56] Hepatic copper concentration in normal dogs is between 150 and 400 µg/g dry weight (parts per million).[28,57] Inflammatory hepatic injury does not consistently occur until copper concentrations exceed 2000 µg/g dry weight.[60,61] However, there may be breed variations; for example, in Doberman Pinschers hepatic inflammation is present with copper concentrations of less than 2000 µg/g.[27,57] Transient acquired Fanconi syndrome has been described in dogs with excess hepatic copper accumulation.[62,63] Copper granules were demonstrated on renal biopsy in some but not all dogs.

Potential mechanisms for hepatic copper accumulation include primary metabolic defects in hepatic copper metabolism, cholestasis causing impaired biliary excretion of copper, and excess copper absorption.[54,56] A primary defect in hepatic copper metabolism occurs in Bedlington Terriers with a genetic mutation in the gene encoding the copper transport protein, COMMD1 (formerly MURR1), resulting in a defect in biliary copper excretion.[64,65] In

the early stages, copper is sequestered in hepatic lysosomes and hepatic damage is minimal. However, with progressive accumulation of copper, hepatic injury becomes significant. The average copper concentration in Bedlington Terriers with chronic hepatitis is approximately 6000 µg/g dry weight and values up to 12,000 µg/g dry weight have been reported.[23,57] Inherited copper-associated liver disease is also described in the West Highland White Terrier, Skye Terrier, Doberman Pinscher, Dalmatian, and Labrador Retriever, but with the possible exception of Dalmatians, the hepatic copper levels are much lower than in Bedlington Terriers.[25-27,34,35,38] The pathogenesis of copper accumulation and the relationship to chronic liver disease in these breeds is poorly understood. It seems likely that these breeds have a hereditary disorder of copper handling, but it is unlikely to be the same as described for the Bedlington Terrier.

Hepatic copper accumulation in the liver may also be a consequence rather than the cause of chronic hepatitis. Because copper is normally excreted in the bile, chronic cholestasis and impaired bile flow can result in secondary copper accumulation.[57,66] Secondary copper accumulation is predominantly periportal and is usually less than 2000 µg/g dry weight.[57,66] The effect of cholestasis on hepatic copper content was evaluated in three groups of dogs: Bedlington Terriers with copper toxicity, dogs with extrahepatic biliary obstruction (the prototype example of a cholestatic disorder) and chronic hepatitis in breeds not known to be at risk for copper-associated liver disease.[66] Hepatic copper content was evaluated by a semiquantitative method based on copper staining of liver tissue with rubeanic acid, using a scale of 0 (no copper) to 5.[67] Copper staining revealed absent to mild increases (scores of 0 to 2+) in dogs with biliary obstruction and chronic hepatitis when compared with Bedlington Terriers (scores of 5+). It was concluded that copper scores of 3+ or higher were suggestive of a primary copper storage disease.[66] Unfortunately, quantitative copper analysis was not evaluated. Markers of oxidative injury and altered defense mechanisms were similar in the three groups, consistent with the concept that copper, inflammation, and cholestasis can all contribute to oxidative injury.[66]

High dietary copper intake appears to be an unlikely explanation for hepatic copper accumulation and liver disease in dogs.[56] However, the copper content of commercial dog foods ranges from 12 to 16 mg/kg dry matter, which is relatively high compared with recommended minimum daily copper requirements in dogs.[56] There is speculation that the recent increase in pathologically elevated hepatic copper concentrations (specifically evaluated in Labrador Retrievers), may coincide with a pet food industry recommendation to replace cupric/cuprous oxide in feed formulations because of its low bioavailability.[68]

Many dogs with copper-associated chronic hepatitis also have increased hepatic iron concentrations.[69] Hepatic iron accumulation usually correlates with degree of inflammation.[40,69] Whether iron, as an oxidant, interacts with copper to contribute to lesions seen in copper-associated hepatitis remains to be determined.

α_1-Antitrypsin Deficiency. Inherited α_1-antitrypsin deficiency is a well-recognized cause of chronic hepatitis and cirrhosis in humans, and may play a role in the pathogenesis of chronic hepatitis in some dogs.[31] α_1-Antitrypsin is a circulating protease inhibitor that is synthesized and secreted by the liver. α_1-Antitrypsin deficiency in affected humans results in defective formation and impaired hepatic secretion of α_1-antitrypsin, resulting in hepatic accumulation of α_1-antitrypsin and hepatic injury. Serum levels of α_1-antitrypsin are typically low. In a study of 57 dogs with chronic liver disease, α_1-antitrypsin was detected by immunohistochemical staining in the liver of 37 dogs but was not identified in any control samples from healthy livers. None of the dogs had decreased serum levels of α_1-antitrypsin. Positive α_1-antitrypsin staining was a more consistent finding in English and American Cocker Spaniels with chronic liver disease, than in other breeds. The authors concluded that accumulation of α_1-antitrypsin might play a role, but it could not be determined if it was the cause or a result of chronic liver disease.[31]

Drugs and Toxins. Drug or toxin exposure is a potential cause of canine chronic hepatic disease. Drugs that have been incriminated include anticonvulsants (phenobarbital, primidone, phenytoin), oxibendazole-diethylcarbamazine, lomustine, and possibly carprofen.[70-73] Chronic hepatitis and cirrhosis from long-term phenobarbital therapy is most widely recognized.[70,71] Exposure to aflatoxin from contaminated commercial dog food is usually associated with ALF, but low-level long-term exposure in dogs can result in chronic hepatic injury (biliary hyperplasia, fibrosis, nodular regeneration). A breeding colony of German Shepherd dogs developed chronic hepatitis and cirrhosis that was suspected (but never confirmed) to be a result of exposure to a porphyrinogenic substance, based on the finding of aggregates of crystalline pigments with orange birefringence with polarized light.[74] Early recognition of drug- or toxin-induced chronic hepatic injury requires biochemical monitoring of liver enzymes, as dogs are clinically asymptomatic in the early stages.

Autoimmune/Immune Mechanisms. Autoimmune hepatitis has not been documented in dogs. However, some dogs with chronic hepatitis appear to respond to corticosteroid therapy and thus may correspond to autoimmune hepatitis in humans.[41] Autoimmune hepatitis in humans is a progressive chronic hepatitis of unknown cause that is believed to occur when an environmental agent (viruses, medications) triggers a cascade of T-cell–mediated events directed at liver antigens, in a genetically predisposed individual.[43] Women are more commonly affected than men. Hyperglobulinemia is a common finding. An infectious cause is difficult to document, as exposure may have occurred many years prior to the overt autoimmune disease.[43] Certain drugs may induce or unmask an autoimmune hepatitis, or simply cause hepatocellular injury that mimics autoimmune hepatitis.[43] An autoimmune component to Doberman Pinscher hepatitis has been speculated, because of the breed's predisposition, high female predominance, and the finding that expression of MHC class II antigens on hepatocytes of affected dogs correlates with degree of inflammation and decreases after treatment with prednisolone.[75] Dogs with chronic hepatitis may have concurrent disorders associated with immune aberrations (immune hemolytic anemia, hypothyroidism, atopy, glomerulonephritis), but whether this is coincidental or indicative of the presence of multiple immune disorders as seen with autoimmune hepatitis in humans is unknown.[37,76,77]

Autoimmune hepatitis in humans is diagnosed when other causes of acute or chronic hepatitis have been excluded and serum autoantibodies (antinuclear, antismooth muscle, antibody to liver/kidney microsomes type 1, antibody to liver cytosol type 1) are detected.[43] A number of studies have evaluated the role of liver-associated antibodies and cell-mediated response in dogs with chronic hepatitis, but none answers the question of whether the immune response is the primary cause of the hepatitis or a secondary phenomenon. Twenty-four dogs with chronic hepatitis were evaluated for circulating autoantibodies (against cell nuclei, smooth muscle, liver membrane, and mitochondria) by indirect immunofluorescence.[77] Antibodies to cell nuclei and liver membranes were

detected, but were also found in dogs with other types of hepatic disease, suggesting a nonspecific secondary response. Patterns of circulating autoantibodies found in dogs differed significantly from those found in humans with chronic liver disease.[77] In another study, serum anti–liver-membrane-protein antibody-positive dogs (1:40 to >1:1600) had higher ALT activity, total bilirubin concentration, and more severe hepatic lesions than did anti–liver-membrane-protein antibody-negative dogs, but it was not determined whether autoantibodies were primary or secondary.[78] CD3+ lymphocytes are the most common hepatic lymphoid cells in dogs with chronic hepatitis and are associated with hepatic necrosis,[79-81] but also account for 54% of hepatic lymphocytes in normal dogs.[82]

Clinical Examination

Historical and physical examination findings in dogs with chronic hepatitis are indicative of chronic hepatic disease, and are similar regardless of the underlying cause. Signs are often initially vague and nonspecific, such as anorexia, lethargy, vomiting, diarrhea, weight loss, PU, and PD.[4,32] With increased severity of hepatic dysfunction, signs of overt liver failure develop, such as ascites, jaundice, and HE. The presence of ascites and HE suggest that chronic hepatitis has progressed to cirrhosis, and ascites is a negative prognostic indicator.[4,42] Melena associated with gastroduodenal ulceration or coagulopathy is also more likely with advanced liver disease.[32] Because of the large functional reserve capacity of the liver, the onset of signs may appear very recent, initially suggesting an acute rather than chronic hepatic disorder. Clinicopathologic features that support chronicity include poor body condition, ascites, microhepatia, hypoalbuminemia, and histologic evidence of fibrosis.

Diagnosis

In the early (subclinical) stages, dogs are asymptomatic and only identified by biochemical screening for liver enzyme elevations. Increased serum ALT activity, reflecting ongoing hepatic injury, is reported in 75% to 95% of dogs with chronic hepatitis.[4,7] Serum ALT activity may exceed 10 times the upper normal limit.[7] Periods of normal ALT activity may reflect cyclic disease activity and the varying severity of necrosis.[7] Serum ALP activity is also commonly increased, but the magnitude of the increase is generally lower than seen with ALT activity. When chronic hepatitis advances to cirrhosis, liver enzyme activity may be normal, indicating decreased viable parenchymal mass.[7] Abnormalities in biochemical tests such as hyperbilirubinemia, hypoalbuminemia, decreased blood urea nitrogen (BUN), hypoglycemia, and increased SBA indicate hepatic dysfunction and a more advanced stage of disease.[32] Hyperglobulinemia can be seen in dogs with cirrhosis, but it remains to be determined whether this corresponds with increased autoantibodies as occurs in humans with autoimmune hepatitis, or whether it reflects nonspecific systemic antibody production in response to antigens from the portal blood which bypass the liver through acquired PSSs.[83] Mild nonregenerative anemia may be a reflection of chronic disease. Regenerative anemia can occur from blood loss secondary to a coagulopathy or bleeding GI ulcers. Copper-associated hemolytic anemia has only been documented in Bedlington Terriers. Abnormal hemostatic parameters (prolonged aPTT and PT) are indicative of severe hepatic dysfunction or DIC. A prolonged PT and thrombocytopenia may be negative prognostic indicators.[16,37] Analysis of ascitic fluid reveals a transudate or modified transudate.[32,42]

Abdominal radiographs are unremarkable except when advanced stages of disease are accompanied by microhepatia or ascites. In the early stages of chronic hepatitis, ultrasonography of the liver may be normal or reveal nonspecific changes in echogenicity. When chronic hepatitis has advanced to cirrhosis, potential ultrasonographic findings include microhepatia, irregular hepatic margins, focal lesions representing regenerative nodules, increased parenchymal echogenicity associated with increased fibrous tissue, and ascites. Splenomegaly and acquired PSSs may also be detected.

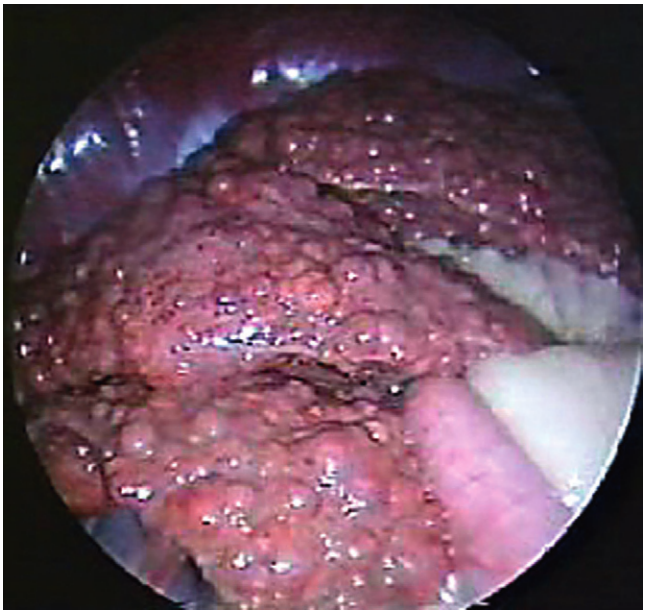

Figure 61-19 Laparoscopic appearance of a cirrhotic liver in a dog with idiopathic epilepsy treated with long-term phenobarbital therapy.

A liver biopsy is essential for the diagnosis of chronic hepatitis. Wedge biopsies are preferred over needle biopsies because they provide more tissue and are more likely to represent pathologic process(es) in the liver. When cirrhosis is present, laparotomy or laparoscopy often provide a better appreciation for the gross nodularity of the liver than can be ascertained from blind percutaneous needle biopsy (Figure 61-19). Chronic hepatitis is characterized histologically by moderate to severe inflammation (usually combinations of lymphocytes and plasma cells) associated with piecemeal necrosis. Piecemeal necrosis, also referred to as interface hepatitis, is necrosis involving the layer of hepatocytes adjacent to the portal tract or "limiting plate."[2] The term *bridging necrosis* is used when necrosis and inflammation dissect across the hepatic lobule from portal areas to central veins or to adjacent hepatic lobules and suggests a severe form of chronic hepatitis.[2] Histopathologic evaluation of the liver should not only consider etiology, but the pathologist should also comment on the activity (amount of inflammation, extent of apoptosis and necrosis) and the stage of disease (extent and pattern of fibrosis; architectural distortion suggestive of cirrhosis).[2]

Biopsies from dogs with chronic hepatitis should routinely be evaluated for copper accumulation. On hematoxylin and eosin staining, excess copper appears as golden brown refractile granules.[28] Histochemical stains, such as rhodanine or rubeanic acid, can be used to semiquantitatively evaluate for copper in the liver (see Figure 61-19). These stains consistently detect copper when amounts exceed 400 μg/g dry weight.[60] Values obtained by quantitative copper analysis have a strong correlation with the number and size of granules seen with histochemical stains within the range of 400 to 1000 μg/g of liver tissue.[60] Zonal distribution of copper

accumulation should be noted, as copper accumulation starting in the centrilobular area is more likely with a primary metabolic defect in copper metabolism.[54] Copper granules can also be detected on cytology of hepatic aspirates or impression smears stained with rhodanine or rubeanic acid. Quantitative analysis for copper, by atomic absorption analysis on fresh hepatic tissue, is the definitive method to document increased hepatic copper content. Needle core biopsy specimens may not be reliable for metal analysis, as copper and iron values are consistently lower in needle core versus wedge biopsy samples.[84] Formalin-fixed tissues should be avoided, because formalin may contain copper or leach copper from the tissue.[57] Hepatic copper can be reliably determined retrospectively on deparaffinized-archived liver biopsy specimens.[84]

Once chronic hepatitis has been confirmed, a careful consideration of known causes of chronic hepatitis is essential (see Table 61-5). Findings that would support a primary metabolic defect in copper metabolism include a previously recognized breed predisposition, copper accumulation that precedes cholestasis or inflammation, centrilobular (zone 3) distribution of copper, histochemical score for copper of 3+ or greater, or quantitative copper measurements that exceed 2000 µg/g dry weight.[54,57,66] Special stains of the liver should be requested to evaluate for infectious agents such as leptospirosis; serum antibody titers for leptospirosis may be indicated. A history of chronic drug therapy should be sought, especially long-term anticonvulsant therapy or other drugs listed in Table 61-5.

Treatment

Recommendations for treatment of chronic hepatitis are empirical at best, because of the lack of controlled therapeutic studies on a well-defined population of dogs with this disorder. If a probable cause or category of injury can be determined, then specific treatment is directed at the primary etiology, for example, discontinuation of phenobarbital, treatment of leptospirosis, or chelation of hepatic copper with penicillamine. In most cases, specific therapy will be unavailable.

Treatment of chronic hepatitis in dogs has traditionally centered on the use of corticosteroids, presuming that, as in humans with the autoimmune form of hepatitis, immunologic mechanisms (inflammatory cells and mediators, local cytokines), contribute to hepatic inflammation and progression to cirrhosis. Corticosteroids have antiinflammatory, immune-modulating, and antifibrotic effects, which may be beneficial in chronic hepatitis. A large retrospective study suggested that corticosteroid therapy at initial immunosuppressive doses (2.2 mg/kg/day; eventually tapered to 0.6 mg/kg/day) improved survival in dogs with chronic hepatitis.[41] However, many concurrent drugs were given and, undoubtedly, a heterogeneous group of disorders were included under the diagnosis of "chronic hepatitis." Corticosteroid therapy appears warranted in dogs with histologic features of active inflammation and persistent increases in serum liver enzyme activity, for which known causes of chronic hepatitis (including infectious causes) have been excluded.[41,85] Glucocorticoid therapy is not indicated for treatment of chronic hepatitis caused by drug therapy, infectious agents, or primary hepatic copper accumulation.

The optimal dose and duration of corticosteroid therapy for treatment of canine chronic hepatitis is unknown, including whether immunosuppressive doses are required, or whether lower, anti-inflammatory levels would suffice.[76] Even in humans with autoimmune hepatitis, immunosuppressive doses of corticosteroids may not be required.[43] Prednisone (or prednisolone) at an initial dose of 1 to 2 mg/kg/day PO and then gradually tapered to 0.5 to 1.0 mg/kg every 48 hours is most often recommended for treatment of canine chronic hepatitis. Complications of corticosteroid therapy include GI bleeding (which may precipitate HE), secondary infections, iatrogenic Cushing disease, and worsening of ascites. Dexamethasone (0.2 mg/kg PO q24h) may be preferred in dogs with ascites or edema, because it lacks mineralocorticoid activity, which could exacerbate these signs.

Prednisone is often used in combination with azathioprine, especially if side effects of prednisone become objectionable. Azathioprine is an antimetabolite with antiinflammatory and immune-modulating effects, and is commonly used in combination with prednisone in humans with autoimmune hepatitis.[43] The dose of azathioprine in dogs is 1 to 2 mg/kg/day PO every 24 hours for 1 to 2 weeks, then tapered to every 48 hours for maintenance therapy. Prednisone (0.5 to 1.0 mg/kg/day) is given on the alternate days. Because azathioprine may cause bone marrow suppression and acute hepatotoxicity, the complete blood count and biochemical profile should be monitored. Antiinflammatory agents and immunosuppressive drugs are discussed in more detail in Chapters 38 and 49, respectively. Because glucocorticoids increase liver enzyme activity (especially serum ALP activity), response to therapy is best evaluated by a followup liver biopsy performed 3 to 6 months after starting therapy. If glucocorticoid therapy is eventually discontinued, clinical and biochemical parameters should be periodically monitored to detect a relapse.

Dogs with hepatic copper concentrations greater than 1500 µg/g, should be treated with the copper chelator penicillamine at a dose of 10 to 15 mg/kg PO every 12 hours.[57] Treatment usually requires months to years to produce significant decreases in hepatic copper. A mean decrease in copper of approximately 1500 µg/g was achieved in Bedlington Terriers treated for 6 months.[86] Dogs with secondary copper accumulation appear to respond more rapidly, possibly because hepatic copper content is lower in these breeds.[86] Doberman Pinschers with subclinical hepatitis treated with penicillamine for 4 months had a mean decrease in copper from 1036 µg/g to 407 µg/g.[87] Penicillamine has additional effects beyond copper chelation, which may be beneficial in dogs with chronic hepatitis, including inhibition of collagen deposition, stimulation of collagenase activity, immunosuppression, and immunomodulation.[54] Common side effects of penicillamine therapy include anorexia, nausea, and vomiting, which can be minimized by giving the medication with a small amount of food. The copper chelator, trientine (10 to 15 mg/kg PO q12h), is also effective for reducing hepatic copper concentrations.[86] It has fewer side effects than penicillamine and is effective in dogs with hemolytic anemia caused by copper release from necrotic hepatocytes. Iatrogenic copper deficiency (microcytosis and hepatic dysfunction) has been described in a dog treated with long-term copper chelation therapy (trientine) and a copper-restricted diet.[88] Decisions on duration of chelator therapy are based on followup liver biopsies with periodic monitoring of quantitative hepatic copper content.

Oral zinc salts can be used for maintenance therapy after copper chelation, or as initial therapy in dogs with hepatic copper concentrations between 400 µg/g dry weight and 1500 µg/g dry weight. Zinc supplementation is typically used in conjunction with dietary copper restriction. Zinc decreases intestinal copper absorption by inducing the intestinal copper-binding protein, metallothionein, within intestinal epithelial cells, which preferentially binds dietary copper and prevents its absorption. Zinc acetate is given at a dose of 100 mg PO BID for 2 to 3 months, then at a maintenance dose of 50 mg PO BID.[89] A minimum of 3 months of zinc therapy is required before copper uptake from the intestinal tract is blocked.[89]

Zinc administration should be separated from meals by at least 1 hour and should theoretically not be prescribed at the same time as a copper chelator.[54] Serum zinc concentrations should be monitored to achieve a level of 200 to 400 µg/dL. Zinc concentrations greater than 500 µg/dL may be toxic (hemolytic anemia).

Low-copper diets are most beneficial for managing early (subclinical) copper accumulation in dogs affected with primary metabolic defects in hepatic copper metabolism.

Feeding a low-copper diet decreases hepatic copper content in Labrador Retrievers with subclinical copper-associated liver disease.[90] Additional treatment with zinc does not appear to increase the copper-lowering effect of dietary management.[90] Foods containing large amounts of copper (liver, other organ meats, shellfish, eggs, bean/legumes, chocolate, nuts, cereals, and copper-containing vitamin supplements) should be avoided.

Because oxidative stress is a significant mechanism for hepatic damage associated with copper accumulation and necroinflammatory hepatic disorders,[66,91] antioxidant therapy with vitamin E (10 to 15 IU/kg/day), or SAMe (20 mg/kg/day) has been advocated.[9] Other cytoprotective agents such as silymarin (milk thistle) and ursodeoxycholic acid may also be beneficial.[9] Chapters 40 and 46 discuss cytoprotective agents used in the treatment of hepatobiliary disease in detail. When end-stage cirrhosis is diagnosed, treatment is mainly supportive, as cirrhosis itself is essentially irreversible. Measures should also be instituted to control the complications of chronic liver failure, such as ascites, HE, gastroduodenal ulcers, and coagulopathy, which are discussed in more detail in "Complications of Liver Disease" section.

Prognosis

The response to treatment of chronic hepatitis is variable, which is not unexpected as it is likely a heterogeneous group of diseases. Some dogs can eventually be taken off medication and remain in remission, but more often, therapy must be continued indefinitely. Other dogs fail to respond, especially those that have advanced disease with cirrhosis.[4,32] In one study, the estimated median survival time in 42 dogs with idiopathic chronic hepatitis was 18 months (range: 0 to 49 months) and in 23 dogs with copper-associated chronic hepatitis it was 17 months (range: 7 to 27 months).[4] Mean survival time in 20 dogs with cirrhosis was 1 week.[32]

Chronic Hepatitis in Specific Breeds

Bedlington Terrier

Bedlington Terriers develop chronic hepatitis and cirrhosis from copper toxicity, as a consequence of an inherited metabolic defect resulting in impaired biliary copper excretion.[23,57,76] The disorder is transmitted by autosomal recessive inheritance. The gene responsible for this metabolic disorder is COMMD1, which is different than that described for copper toxicity (Wilson disease) in humans, in which the gene involved is ATP7B.[64] There is no gender predilection. At one time, it was speculated that as many as 60% of the breed might be affected.[57] Hepatic copper concentration in normal Bedlington Terriers ranges from 91 to 358 µg/g with a mean of 206 ± 56 µg/g dry weight.[23] Bedlington Terrier copper-associated liver disease is associated with progressive, hepatic copper accumulation (copper levels of up to 12,000 µg/g) unless treatment is instituted. The lowest hepatic concentrations of copper are found in the youngest dogs and concentrations increase with age, peaking at around 6 years. Copper content usually declines thereafter in affected dogs, but not to normal. This decline may be a result of replacement of copper-containing hepatocytes by fibrous tissue or regenerative nodules that do not contain copper. The severity of hepatic disease is correlated with the amount of hepatic copper. Hepatic injury is believed to occur when progressive copper accumulation exceeds the storage capacity of the lysosomes; copper is released to the cytoplasm, damaging mitochondria, initiating lipid membrane peroxidation, and eventually causing cell death.

Affected dogs can be asymptomatic (in the early stages) or show signs of acute hepatic necrosis, chronic hepatitis, or cirrhosis.[54] In young dogs, copper accumulates in centrilobular (zone 3) hepatocytes and is sequestered in hepatic lysosomes. During this first stage, copper concentrations are between 400 and 1500 µg/g, dogs are asymptomatic, biochemical testing is within normal limits, and liver biopsy findings are unremarkable. In the second stage, when hepatic copper concentrations are between 1500 and 2000 µg/g, copper granules are also found in midzonal (zone 2) and periportal (zone 1) hepatocytes. Although dogs are still asymptomatic, focal hepatic inflammation (centrilobular mixed cell foci, with necrotic hepatocytes, lymphoplasmacytic inflammation, and copper-laden macrophages) is seen on biopsy, and increased serum ALT activity reflects hepatocellular injury. In the most advanced stage, when hepatic copper concentration exceeds 2000 µg/g, morphologic changes reveal chronic hepatitis that may progress to cirrhosis, and clinical and biochemical evidence of liver disease become apparent. Clinical signs include anorexia, lethargy vomiting, and weight loss. With progression to cirrhosis, findings of jaundice, ascites, and HE may develop. Biochemical findings vary with the stage of disease. Increased serum ALT activity is the most sensitive laboratory indicator, although findings will be normal in young dogs in stage I, because of the lack of hepatic inflammation. Other serum biochemical abnormalities typical of chronic hepatic dysfunction eventually develop. In some cases, acute hepatic necrosis and ALF occur. Hepatocellular necrosis may be associated with release of copper from necrotic hepatocytes, resulting in hemolytic anemia. During episodes of hemolysis, plasma copper levels are increased; other findings include low packed cell volume, hemoglobinemia, and hemoglobinuria. Liver biopsy and quantitative analysis of hepatic copper concentrations is required for definitive diagnosis and staging of the disease. Serum copper or ceruloplasmin concentrations are not helpful to make a diagnosis.[57]

Liver biopsies should be performed in all Bedlington Terriers considered for breeding, in order to identify and remove affected dogs from breeding programs. Screening of asymptomatic dogs with a liver biopsy at 6 months and 15 months of age can determine if an affected dog is homozygous or heterozygous (a carrier).[15] Affected dogs (both homozygous and heterozygous) typically have increased hepatic copper by 6 months of age. However, copper concentrations in dogs who are carriers (heterozygous) return to normal by 1 year of age, whereas copper concentrations in homozygous dogs continues to increase.[57] Selective breeding programs in the Netherlands has decreased the prevalence of Bedlington Terrier copper-associated liver disease from 46% (1976-1986) to 11% (1990-1997).[92]

DNA testing of Bedlington Terriers is available from VetGen (www.vetgen.com). This assay evaluates a linkage-based DNA marker (CO4107, allele 2) that is located in the chromosome close to the gene for copper toxicity.[93] The test can identify normal, affected, and carrier dogs with 90% accuracy. However, the marker can only be relied on for diagnosis of the genetic status of an individual dog when supported by a pedigree study.[93,94] Significant discrepancies were reported in 22 Bedlington Terriers, when comparing results of liver biopsy and the DNA marker.[94] This may be attributed to different subpopulations of Bedlington Terriers with variations in the disease-causing mutation of the COMMD1 gene or a second mutant copper gene could play a role.[94] Liver biopsy for quantitative

copper and morphologic examination remain the best option for diagnosis in the individual dog.[94] A database for certification of Bedlington Terriers is maintained on the Web site (www.caninehealthinfo.org) of the Canine Health Information Center, which is sponsored by the AKC/Canine Health Foundation and the Orthopedic Foundation for Animals.

Affected Bedlington Terriers who are asymptomatic (copper >400 μg/g dry weight but less than 1500 μg/g dry weight) should have dietary copper restriction and zinc supplementation. Bedlington Terriers with copper accumulation (copper >1500 μg/g dry weight) and chronic hepatitis should be treated with a copper chelator such as penicillamine or trientine.[57] Early diagnosis and treatment with either zinc or copper chelators will allow most dogs to lead a normal life.[57] Treatment of hemolytic anemia may require a blood transfusion. Trientine dihydrochloride (but not penicillamine) may be effective in chelating circulating copper during a hemolytic episode. Chapter 43 discusses copper-chelating agents in more detail.

Doberman Pinscher

Doberman Pinschers are at increased risk for the development of severe chronic hepatitis and cirrhosis.[26,28,81,95] Doberman hepatitis accounted for 4% of all deaths in a Dutch population of 340 Dobermans.[96] Middle-aged (4 to 7 years) female dogs are at increased risk, but males also may be affected. Although a hereditary mechanism is suspected, the pathogenesis of this disorder is unclear.[28] Copper accumulation appears to be associated with hepatic damage, but the pathogenesis is different from the Bedlington Terrier disorder.[27] Immune mechanisms may also play a role.[75,81]

Many Doberman Pinschers are diagnosed in the advanced stages of hepatic failure.[26] Evidence of excessive bleeding (gingival bleeding, epistaxis, and melena) are common. Signs of HE often predominate in the terminal stages. Common physical examination findings include ascites, jaundice, and weight loss. Splenomegaly (associated with portal hypertension) is common. Laboratory findings included increased ALT and ALP activity, hyperbilirubinemia, hypoalbuminemia, hyperammonemia, coagulopathy, and thrombocytopenia.[26] Typical histologic lesions include portal inflammation (lymphocytes, plasma cells, and macrophages), piecemeal necrosis, bridging necrosis, bile duct proliferation, and portal fibrosis.

Hepatic copper concentrations are increased in most affected dogs and are typically between 1000 and 2000 μg/g dry weight, although values as high as 4700 μg/g have been reported.[28,81] The significance of the increased hepatic copper concentration in this breed remains controversial. Copper accumulation was originally attributed to secondary mechanisms, as Doberman Pinschers with advanced disease (chronic hepatitis and cirrhosis) have biochemical and histologic evidence of cholestasis. However, evaluation of affected dogs in the early (subclinical) stage, reveals that copper accumulation precedes cholestasis,[27,95] and decreased biliary excretion of radiolabeled copper has been documented.[97] The hepatic distribution of copper and location of inflammation varies with the stage of disease. In the early stages, the copper (and focal inflammation) is centrilobular.[27,81,95] As the disorder progresses, copper accumulation and inflammation are more pronounced in periportal regions and areas of bridging necrosis.[95] Although copper appears to be related to the hepatic inflammatory reaction, copper levels are typically less than 2000 μg/g dry weight, the minimum amount of copper that is believed to cause hepatocellular injury in Bedlington Terriers and West Highland White Terriers.[60,61] A primary copper retention disorder has been proposed,[28] but the genes associated with Bedlington copper toxicity (COMMD1) and Wilson disease in humans (ATP7B) have been excluded.[98]

Recent efforts have focused on identification of affected Doberman Pinschers prior to advanced hepatic disease. In Finland, a survey of 626 randomly selected, clinically healthy Doberman Pinschers, revealed that 8.8% of dogs had increased ALT activity, and 3.4% had hepatitis (parenchymal and portal mononuclear inflammation and positive stains for copper).[99,100] The mean age of dogs with subclinical hepatitis was 3.8 years, compared with clinically affected dogs (5.5 years). The asymptomatic period lasted an average of 19 months. The prevalence of subclinical Doberman hepatitis was investigated in 106 randomly selected 3 year old Doberman Pinschers in the Netherlands.[27] Subclinical hepatitis was identified in 22 dogs (19 females and three males); hepatic copper concentration was higher in dogs with hepatitis (419 ± 414 μg/g dry weight) than those without liver disease (197 ±113 μg/g).[27] Serial liver biopsies over at least a 2-year period, revealed that hepatitis persisted only in dogs with copper levels greater than 400 μg/g dry weight, and copper levels continued to increase in these dogs (939 ± 299 μg/g), supporting a relationship between copper, inflammation and hepatitis.[27]

It has also been proposed that hepatic copper is incidental to chronic hepatitis in this breed, based on the findings that five of 35 Doberman Pinschers with chronic hepatitis had normal copper levels, and histologic changes were similar regardless of copper status.[81,26,75] An immune-mediated mechanism has been suggested, based on the finding that expression of MHC class II antigens on hepatocytes of dogs with Doberman hepatitis was correlated with degree of inflammation.[75] Aberrant MHC class II molecule expression on nonlymphoid cells could be a result of toxins, drugs, viral infection, or autoimmunity, and hepatocytes with MHC class II expression might become a target as an antigen-presenting cell for CD4+ T cells.[75] Dogs treated with low-dose prednisolone (0.1 to 0.5 mg/kg/day) for 4 to 5 months had significantly decreased expression of MHC class II antigens.[75]

Chronic hepatitis should be suspected in any Doberman Pinscher (especially females) with clinical or biochemical evidence of hepatic disease. Definitive diagnosis requires liver biopsy. Other causes of chronic hepatitis should also be considered, since Doberman Pinschers appear to be at risk for drug-induced hepatitis.[71] Early detection of chronic hepatitis provides the best opportunity for treatment. It has been recommended that all Doberman Pinschers older than 1 year of age be screened for ALT activity.[99] Persistent increases in ALT activity suggest further evaluation including liver biopsy is warranted. The magnitude of increased ALT activity is not different between subclinical and clinically affected dogs. Hyperbilirubinemia is suggestive of more advanced disease.[28,99]

Effective treatment for Doberman Pinschers with chronic hepatitis has not been established. However, a preliminary study showed that if diagnosed in the subclinical stage, treatment with penicillamine (200 mg total dose PO BID for 4 months) lowered hepatic copper content and improved hepatic histopathology.[87] Traditionally, antiinflammatory or immunosuppressive drugs such as prednisone with or without azathioprine have been instituted. The efficacy of this treatment remains to be determined but generally, the response is poor if dogs are presented in advanced stages of liver failure. The use of ursodeoxycholic acid (15 mg/kg PO BID) deserves special consideration in this chronic cholestatic disorder, but has not yet been objectively evaluated. Treatment of copper-associated hepatitis in Doberman Pinschers with advanced disease is usually unsuccessful. Most dogs die within weeks to months. The prognosis appears more favorable if the disease is detected in the early stages, but the optimal therapeutic regimen remains to be determined.

West Highland White terrier

West Highland White Terriers are at increased risk to develop chronic hepatitis and cirrhosis.[25,76,101] Males and females are equally affected. The mode of inheritance for the familial copper-associated disorder has not been established.[24] Decreased biliary excretion of radiolabeled copper occurs in affected dogs.[89] Centrilobular (zone 3) copper accumulation occurs during the first year of life, but rarely exceeds 2000 μg/g dry weight.[24] In contrast to the Bedlington Terrier, West Highland White Terriers do not continuously accumulate copper over their lifetime; in fact, copper content may actually decrease with time.[56] In one report of 395 clinically normal West Highland White Terriers, most dogs had hepatic copper levels between 100 and 1500 μg/g dry weight with normal liver biopsies.[25]

In West Highland White Terriers with chronic hepatitis, histologic lesions include multifocal hepatitis, subacute bridging necrosis, massive necrosis, and cirrhosis.[25] The relationship of hepatic copper to chronic hepatitis in the West Highland White Terriers is unclear. There appears to be at least two types of chronic hepatitis.[25] Some dogs have copper-associated hepatitis with elevated copper content (>2000 μg/g) and multifocal centrilobular hepatitis. Copper concentrations do not usually exceed 3500 μg/g dry weight. Lesions of chronic hepatitis can also be seen in the absence of substantial copper accumulation, and have been described as "idiopathic chronic hepatitis."[25] Quantitative copper analysis is necessary to determine if copper accumulation is a significant (>2000 μg/g dry weight) contributing factor.

If chronic hepatitis and cirrhosis are associated with increased hepatic copper content (>2000 μg/g dry weight), treatment for hepatic copper accumulation should be instituted. Mature West Highland White Terriers with chronic hepatitis and less than 2000 μg/g dry weight of copper may not require chelation therapy, as hepatic copper accumulation is not continuous throughout life. Other therapeutic options for treatment of idiopathic chronic hepatitis, such as glucocorticoids, should be considered in these dogs.

Labrador Retriever

Labrador Retrievers are at increased risk for chronic hepatitis.[29,37] Age at presentation ranges from 2.5 to 14 years, with an average age of 7 to 9 years.[36-38] A female predisposition was noted in two studies,[36,38] whereas in another study, males and females were equally affected.[37]

Most affected dogs have increased hepatic copper, which has been described as centrilobular (zone 3) or diffuse.[36-38] Copper concentrations exceeded 2000 μg/g dry weight in 10 of 12 dogs (mean copper: 3369 μg/g; range: 2375 to 4972; reference interval: 120 to 400 μg/g).[38] Most dogs also had elevated iron levels with a mean of 4117 μg/g (reference interval: 350 to 1750).[38] A genetic basis is suspected, based on the finding of increased copper concentrations in asymptomatic related dogs, but the genetic defect remains to be determined.[36] A retrospective survey of hepatic copper content in Labrador Retrievers during two time periods (1980-1997 and 1998-2008), revealed significantly higher copper concentrations in the more recent period both in dogs with chronic hepatitis and in control dogs; no difference in age or gender was noted.[68] It was speculated that increased hepatic copper might reflect increased dietary copper bioavailability, because of pet food industry recommendations to replace cupric/cuprous oxide in feed formulations.[68]

Treatment with penicillamine (15 mg/kg PO q12h) appears to be effective in decreasing hepatic copper content and inflammation.[36,90] However, some dogs appear to respond to immunosuppressive (prednisone, azathioprine), supportive (ursodeoxycholic acid, SAMe, milk thistle), and symptomatic therapies that are not designed to lower hepatic copper.[37] Feeding a low-copper diet to 20 Labrador Retrievers with hepatic copper accumulation (seven of 20 dogs had varying degrees of hepatitis) was effective in decreasing hepatic copper concentrations, but severity of inflammation remained unchanged.[90] Additional treatment with zinc did not appear to increase the copper-lowering effect of dietary management.[90] Long-term survival appears variable.[36,37] Dogs who died within 2 months of diagnosis were more likely to have a prolonged PT and thrombocytopenia.[37]

Dalmatian

Dalmatians are reported to have acute hepatic necrosis, chronic hepatitis, and cirrhosis associated with increased hepatic copper concentrations.[35,102] Cholestasis is not a prominent biochemical or histologic feature until later in the disease, suggesting that hepatic copper accumulation is more likely to be caused by a familial metabolic disorder rather than secondary to altered hepatic biliary copper excretion. Most dogs presented initially with acute GI signs (anorexia, vomiting, and diarrhea). Biochemical findings revealed markedly increased ALT activity with lesser increases in ALP activity. Hyperbilirubinemia and hypoalbuminemia were seen with advanced disease. Glucosuria (in the absence of hyperglycemia) and proteinuria were identified in some dogs. Ultrasound findings were usually unremarkable. Liver biopsy revealed piecemeal necrosis, bridging fibrosis, and inflammation (predominantly lymphocytes or neutrophils). The mean hepatic copper level was 3197 μg/g dry weight (normal <400 μg/g dry weight) with a range of 754 to 8390 μg/g dry weight. In five of nine dogs, copper exceeded 2000 μg/g. Rapid progression of the disease was characteristic. Copper chelation therapy may be beneficial if diagnosed before advanced liver disease occurs.

Skye Terrier

Chronic hepatitis and cirrhosis associated with hepatic copper accumulation (800 to 2200 μg/g dry weight) in genetically related Skye Terriers has been described.[34] In the early stages, copper accumulation is absent, and biopsy findings indicate hepatocellular degeneration with cholestasis and mild inflammation. Chronic lesions are associated with intracanalicular cholestasis, chronic hepatitis, and cirrhosis. Skye Terrier hepatitis is speculated to be a disorder of disturbed bile secretion with subsequent accumulation of copper.

Cocker Spaniel

American and English Cocker Spaniels have an increased incidence of chronic hepatitis and cirrhosis.[29,30] The cause is unknown. Hepatic copper accumulation does not appear to be a consistent feature. It is unclear whether accumulation of α_1-antitrypsin in hepatocytes, a well-recognized cause of cirrhosis in humans, is important in the pathogenesis.[31] Male Cocker Spaniels (average age: 5 years) are at increased risk.[29,30] Despite the chronicity and severity of the underlying hepatic lesions, most affected dogs have a short duration of clinical illness, usually less than 2 weeks. Ascites is the most consistent presenting complaint. Profound hypoalbuminemia (mean: 1.7 g/dL) is a consistent laboratory finding. Total serum bilirubin concentration is normal or only mildly increased, supporting that cholestasis is not a key feature of the disorder. Ascitic fluid analysis is consistent with a transudate or modified transudate. On liver biopsy, hepatic lesions are consistent with chronic hepatitis and cirrhosis. Treatment of Cocker Spaniels with chronic hepatitis consists of general supportive therapy for the complications of liver failure. Corticosteroid therapy prior to progression to cirrhosis may

be beneficial. The prognosis is poor and most dogs die within a month of diagnosis.

A recent report described seven American Cocker Spaniels with histologic features resembling lobular dissecting hepatitis.[33] Males and females were equally affected. In contrast to previous reports of hepatitis in Cocker Spaniels, most dogs in this study improved with corticosteroid therapy.[33]

English Springer Spaniel

A preliminary report has described chronic hepatitis in 34 English Springer Spaniels from Norway and the United Kingdom.[39] Female dogs were overrepresented. Copper does not appear to play a role. The prognosis appears to be poor, with most dogs dying 4 to 7 months after diagnosis.[39]

Hepatic Cirrhosis and Fibrosis

Hepatic cirrhosis (end-stage liver disease), is characterized by fibrosis, regenerative nodules that alter liver architecture and intrahepatic (microscopic) PSSs (see Figure 61-19).[2] Hepatic fibrosis is not synonymous with cirrhosis. Cirrhosis is common in dogs but less so in cats.[2] Cirrhosis can result from postnecrotic scarring after acute massive necrosis or from chronic hepatic injury caused by a variety of insults such as infection (e.g., leptospirosis, CAV-1), hepatotoxins (e.g., copper, phenobarbital, aflatoxin), inflammation (chronic hepatitis), or hypoxia. The common denominator is hepatocyte death, which leads to repair by fibrosis and nodular regeneration. When cirrhosis is fully developed, the histologic features of the original inciting injury often are obscured by the cirrhotic changes.

Substantial hepatic fibrosis (without "cirrhosis") can be seen with long-standing extrahepatic biliary obstruction, noninflammatory fibrosis, congenital hepatic fibrosis (a disorder of biliary system development), and congenital portal vein hypoplasia.[2,103-105] A unique form of macronodular cirrhosis, characterized by noninflammatory regenerative hyperplastic nodules and diffuse vacuolar hepatopathy, is seen in dogs with hepatocutaneous syndrome (superficial necrolytic dermatitis).

Hepatic fibrosis was once considered irreversible, but is now recognized to be a dynamic process, which exists in a balance between synthesis and degradation. A better understanding of the underlying mechanisms may provide potential therapeutic targets.[106] The major fibrogenic cell in the liver is the activated HSC (Ito cell, vitamin A–storing cell), which is normally present in the perisinusoidal space.[106,107] Under the influence of fibrogenic stimuli (inflammation and the immune response, oxidative stress, apoptosis, hypoxia, steatosis), the HSC is activated to a myofibroblast, which produces collagen and other extracellular matrix (ECM) constituents.[106] The cytokine, TGF-β, appears to play a central role in fibrogenesis in humans and dogs.[106,108] Perisinusoidal fibrosis decreases the permeability of normal sinusoids, impairing metabolic exchange between hepatocytes and sinusoidal blood further compromising hepatic function.[106] Excess fibrous tissue also limits the ability of vessels and sinusoids to distend, resulting in increased resistance to hepatic blood flow and portal hypertension. When fibrotic septae become vascularized, these microscopic communications (between portal vein or arterial artery and hepatic vein) lead to portosystemic shunting of blood. Reversal of hepatic fibrosis and improvement in liver function can occur, especially if the underlying cause of injury is treated or removed.[106] Examples in human medicine include antiviral drugs for hepatitis B and hepatitis C and prednisone for autoimmune hepatitis. Although fibrosis is potentially reversible, cirrhosis for all practical purposes is not, because of the accompanying architectural changes and PSSs.[109]

Clinical features of cirrhosis in dogs include ascites (portal hypertension, hypoalbuminemia), HE (intrahepatic and extrahepatic portosystemic shunting of blood), and evidence of decreased hepatic function (hypoalbuminemia, increased SBA, coagulopathy, hyperbilirubinemia). Findings on hepatic ultrasonography (small nodular liver, splenomegaly, and acquired PSSs) are suggestive for cirrhosis, but liver biopsy is required for confirmation. Because cirrhosis is essentially irreversible, treatment is mainly supportive, emphasizing measures that control complications of severe generalized liver failure, such as ascites, encephalopathy, gastric ulcers, coagulopathy, and infection (see "Complications of Liver Disease" section). If clinical signs of liver failure are already present, the prognosis is poor.

Prevention of fibrosis, an important long-term goal, is best achieved by early specific treatment directed at the probable cause of injury (e.g., discontinuing a suspect drug, penicillamine for copper-associated liver disease, antiinflammatory drugs for idiopathic chronic hepatitis, surgical relief of extrahepatic biliary obstruction). Many therapeutic agents used for treatment of liver disease, such as penicillamine, prednisone, azathioprine, milk thistle, ursodeoxycholic acid, and zinc, have potential antifibrotic properties,[9] and are discussed in more detail in other chapters. Colchicine, a microtubule assembly inhibitor which increases collagenase activity, has been recommended for treatment of hepatic fibrosis, but its effectiveness in dogs has not been critically evaluated. The recommended dose in dogs is 0.025 to 0.03 mg/kg/day PO. Reported side effects include nausea, vomiting, and diarrhea. Bone marrow toxicity and myoneuropathy have been reported in humans.

Lobular Dissecting Hepatitis

Lobular dissecting hepatitis is a specific histologic form of cirrhosis seen in neonatal or young adult dogs.[2,4,110-112] It is suggested to be a nonspecific response to a variety of hepatic insults.[111] The age at presentation is younger than for dogs with either acute or chronic hepatitis.[4] In 21 affected dogs, the median age was 11 months, with 12 dogs (54%) being 7 months or younger.[4,110] Females appear to be at increased risk.[4,111] Lobular dissecting hepatitis may occur in an isolated dog or in groups of dogs from the same litter or kennel.[111] Standard Poodles may be at increased risk.[110,112] Clinical features are those of advanced hepatic failure and portal hypertension.[111] The most consistent clinical finding is ascites. Liver enzymes are typically increased and hypoalbuminemia and increased SBA concentrations are common.[4,111]

Liver biopsy is required for diagnosis and to differentiate it from other types of chronic hepatitis and cirrhosis. The lesion is characterized histologically by lobular hepatitis: inflammatory cells (lymphocytes, plasma cells, macrophages, and neutrophils) are scattered throughout the hepatic lobule rather than concentrated in periportal regions. Bands of collagen and reticulin fibers dissect around single or small groups of hepatocytes and disrupt hepatic lobular architecture.[111] Copper stains are negative or moderately positive, consistent with secondary copper accumulation.

Specific treatment has not been reported, but general measures for management of chronic liver failure are appropriate.[4] In a small group of dogs with lobular dissecting hepatitis, the mean survival time was approximately 3 months, which was significantly shorter than for dogs with acute or chronic hepatitis.[4]

Hepatic Infections

Infection of the liver is an important cause of hepatic disease in dogs and cats.[113] The liver may be the primary target of infection (e.g., infectious canine hepatitis, bacterial cholangitis, hepatic abscess) or

it may be one of several organ systems involved in a multisystemic disease process such as feline infectious peritonitis (coronavirus), toxoplasmosis, or histoplasmosis (see Table 61-4). Infectious agents can be associated with widespread invasion of organs with a large mononuclear phagocytic component, including the liver, spleen, lymph nodes, and bone marrow, although clinically significant liver disease is uncommon. Liver biopsy can be diagnostically useful for identification of these organisms in infected animals.

Canine Adenovirus 1

Etiology

Infectious canine hepatitis (ICH) caused by CAV-1 has long been recognized as a cause of acute hepatic necrosis in dogs.[114] This virus is genetically and antigenically distinct from CAV-2, a cause of infectious canine respiratory disease. The incidence of clinical disease caused by CAV-1 is now very low because of effective vaccination procedures. Neutralizing antibodies to CAV-1 are also found in mature, unvaccinated dogs, suggesting that natural exposure to the virus is widespread.

Pathophysiology

CAV-1 has a special tropism for vascular endothelial cells and hepatocytes.[114] Dogs with sufficient immunity (neutralizing antibodies >1:500) do not develop clinical signs of disease. Susceptible dogs (titer <1:4) develop widespread centrilobular to panlobular hepatic necrosis, which is often fatal. Distinctive intranuclear inclusions are present in hepatocytes and the endothelium of other tissues. Experimentally, dogs with an intermediate titer (between 1:16 and 1:500) develop chronic hepatitis that can progress to cirrhosis.[115] Whether CAV-1 is a significant cause of chronic hepatitis under natural conditions is unknown. CAV-1 antigen was demonstrated in formalin-fixed liver sections from five of 53 dogs with various naturally occurring hepatic inflammatory lesions, suggesting that CAV-1 may play a role in spontaneous chronic hepatitis.[46] Other attempts to identify CAV-1 in dogs with chronic hepatitis have been negative.[44,47]

Clinical Examination

ICH is seen most commonly in unvaccinated dogs younger than 1 year of age. Clinical signs vary with the stage of disease. Dogs that are peracutely ill do not have clinical evidence of hepatic disease but simply become depressed and moribund, and die within a few hours. Dogs with a more extended clinical course (5 to 7 days) have signs associated with acute hepatic necrosis that include vomiting, diarrhea, and abdominal pain. A hemorrhagic diathesis may occur during the viremic phase and is manifested by epistaxis, petechial or ecchymotic hemorrhages of the skin, or excessive bleeding from venipunctures. Failure of the liver to clear activated clotting factors and impaired hepatic synthesis of clotting factors probably also contributes to development of DIC. Signs of central nervous system (CNS) dysfunction include depression, disorientation, seizures, and coma and have been attributed to HE or nonsuppurative encephalitis.

Common physical examination findings include fever, enlarged tonsils, pharyngitis, laryngitis, cervical lymphadenopathy, and subcutaneous edema of the head, neck, and trunk. Hepatomegaly, abdominal pain, and abdominal effusion can occur. Jaundice is rare but can develop in dogs that survive the acute fulminant stage of ICH. An uncomplicated clinical course lasts approximately 5 to 7 days before recovery begins. Unilateral or, less frequently, bilateral corneal edema and anterior uveitis ("hepatitis blue eye") are complications that may become evident during the recovery period. These ocular complications occur in approximately 20% of naturally infected dogs, and are caused by corneal endothelial damage and antigen–antibody complexes.

Diagnosis

ICH should be suspected in any young, unvaccinated dog with evidence of ALF. ICH must be differentiated from diseases with similar clinical signs, such as canine distemper, parvoviral enteritis, and hepatotoxicity. Abnormalities on the leukogram are common and vary with the clinical stage of infection. During viremia, neutropenia and lymphopenia are often present. Neutropenia is also a common a feature of canine parvovirus, a much more prevalent disease of puppies. Rebound lymphocytosis and neutrophilia occur in the recovery stages of ICH (7 days after infection). Biochemical findings are characteristic of acute hepatic necrosis and include increased serum ALT and ALP activity, and abnormal liver function tests. Hyperbilirubinemia is a less-consistent finding. Hypoglycemia may complicate the terminal stages of the disease. Coagulation parameters are consistent with DIC. Other potential findings include proteinuria secondary to glomerular damage, abdominal fluid consistent with an exudate, and an increase in protein and mononuclear cells in the cerebrospinal fluid.

The clinical diagnosis of ICH is usually suspected on the basis of age, vaccination history, clinical signs, and laboratory findings, and is confirmed by liver biopsy or necropsy findings. Additional diagnostic tests that are used less frequently include serologic testing, virus isolation, and direct immunofluorescence.

Treatment and Prognosis

Therapy for ALF caused by ICH is primarily supportive care and control of complications that frequently occur such as DIC, HE, and hypoglycemia. The prognosis in dogs with ICH depends on the severity of hepatic necrosis and the incidence of serious complications such as DIC. Hepatic regeneration and recovery is possible unless widespread coagulation necrosis destroys entire lobules. ICH can be effectively prevented by vaccination.

Canine Herpesvirus

Canine herpesvirus causes an acute, afebrile, rapidly fatal disease in neonatal puppies (1 to 3 weeks of age).[116] Hepatic necrosis is one manifestation of the widespread multiorgan necrosis and hemorrhage that occurs in this systemic viral infection. Clinical signs include acute onset of depression, diarrhea, failure to suckle, crying, and abdominal pain in previously healthy puppies. Other findings include petechial hemorrhages and vesicles of the mucous membranes. Jaundice is rare. Seizures and loss of consciousness may be present in the terminal stages, and most pups die within 24 hours of onset of clinical signs. Typical gross pathologic findings include focal areas of necrosis and hemorrhage in the liver, kidneys, lungs, and serosal surfaces of the intestines. Microscopically, these areas are characterized by foci of necrosis with occasional intranuclear inclusions.

Neonates are infected by oronasal exposure to the virus in utero or by secretions from an infected bitch or littermates. Neonates are particularly susceptible, possibly because of their low body temperature and immature mechanisms for temperature regulation. The diagnosis of canine herpesvirus is primarily based on the history, physical examination, and pathologic findings. Laboratory findings are inconsistent but include neutrophilia or neutropenia, and increased serum ALT activity.

Treatment of affected puppies is generally unsuccessful because of the acute fulminant nature of the disease. Maintenance of body

temperature (36.7°C to 37.8°C [98°F to 100°F]) may be helpful. Intraperitoneal infusion of 1 to 2 mL of hyperimmune serum obtained from bitches with previously infected litters may reduce mortality rates. Vaccination for herpesvirus infection is not routinely performed because of the low incidence of disease.

Canine Acidophil Cell Hepatitis

Canine acidophil cell hepatitis, which encompasses a spectrum of hepatic lesions ranging from acute and chronic hepatitis to cirrhosis and liver failure, has been reported in Great Britain.[48,114] It is caused by a transmissible agent, suspected to be a virus that is distinct from CAV-1, although a specific virus has never been identified. The disease is experimentally transmissible by serum or liver extracts from affected dogs. In the experimentally induced disease, acute hepatitis can progress to chronic hepatitis in the absence of clinical signs. Episodic increases in serum ALT activity and fever spikes correspond with histologic evidence of acute hepatitis.

The liver is enlarged and friable in the acute stages, and becomes progressively smaller and nodular with chronicity. The most notable histologic feature, regardless of the stage of disease, is the acidophil cell. Acidophil cells are dying hepatocytes with an angular shape, reduced volume, hyperchromatic nucleus, and strongly acidophilic cytoplasm caused by small acidophilic coalescing granules. End-stage hepatic disease is accompanied by typical findings of cirrhosis.

Most dogs with spontaneous disease are presented with signs of chronic hepatic failure. The duration of clinical signs can exceed 1 year. Based on experimental studies, it is speculated that the early mild stages may go unrecognized until advanced hepatic disease and failure is present. Biochemical findings are consistent with hepatic inflammation and necrosis, evidenced as increased serum ALT activity. With advanced disease, severe hepatic dysfunction is noted. The diagnosis requires liver biopsy. Recommendations for specific therapy of acidophil cell hepatitis await further information on the causative agent. Supportive measures should be instituted as needed.

Feline Infectious Peritonitis (Coronavirus)

Feline infectious peritonitis (FIP) is a highly fatal coronaviral infection of both domestic and wild cats. The liver is one of many organs (kidneys, spleen, pancreas, mesenteric lymph nodes, CNS, uveal tract, omentum, serosal surfaces) that can be affected by widespread immune complex vasculitis and granulomatous or pyogranulomatous inflammation (see Table 61-5).[117]

Clinical findings in cats with hepatic involvement are nonspecific and include lethargy, depression, anorexia, dehydration, weight loss, and fever. Jaundice is a common finding. Extrahepatic findings include nodular renomegaly, abdominal mass (lymph node), and ascites or dyspnea (pleural effusion). Ophthalmoscopic examination may detect chorioretinitis or anterior uveitis, which must be differentiated from similar ocular changes seen with the other systemic disorders that involve the liver such as lymphosarcoma, toxoplasmosis, and the systemic mycoses.

Serum hepatic enzyme (ALP and ALT) activities are usually normal or only mildly increased. Mild to moderate increase in serum bilirubin concentration is common. Other findings indicating hepatic dysfunction include bilirubinuria and increased SBA concentrations. Hyperglobulinemia, neutrophilia, and mild to moderate nonregenerative anemia are other laboratory features of FIP. Abdominal and pleural effusions, when present, are usually pyogranulomatous exudates with greater than 3 g/dL protein. Serologic detection of a high coronaviral antibody titer may support a diagnosis of FIP, but is not definitive because of its lack of specificity. Diagnosis of FIP should be supported by cytologic or histologic evidence of pyogranulomatous inflammation. The currently recommended "gold standard" for FIP diagnosis is immunohistochemistry performed on effusions or lesions containing infected macrophages.[117] The prognosis for recovery is poor.

Leptospirosis

Etiology

Canine leptospirosis is caused by *Leptospira interrogans sensu lato*, with at least 10 serovars appearing to have clinical significance in dogs.[118] Serovars *canicola* and *icterohemorrhagica* have been included in vaccines for more than 30 years and the incidence of clinical disease from these serovars has decreased accordingly. An epidemiologic shift in serovars causing clinical disease has since occurred, with increasing reports of disease associated with serovars *grippotyphosa, pomona*, and *bratislava*.[118] It has been suggested that serovars *icterohemorrhagica* and *pomona* are more likely to be associated with hepatic damage.[118] However, other reports have been unable to correlate serogroups with specific clinical features.[119,120] Chronic hepatitis has been associated with serovar *grippotyphosa*[50] and serogroup *australis*.[51] Reports of clinical leptospirosis in cats are rare, although antibodies to several serovars have been demonstrated.[118]

Pathophysiology

Acute renal failure is the most common clinical disease syndrome in dogs with leptospirosis.[121] The liver can also be a target organ and ALF may occur concurrently in 10% to 20% of dogs with acute renal failure or independent from renal involvement.[121] With acute hepatic involvement, the liver is enlarged, friable, and yellow-brown. Tissues are often markedly jaundiced. Microscopic changes in the liver include intrahepatic cholestasis, liver cell dissociation, and nonspecific reactive hepatitis.[3,122] Hepatic necrosis is an uncommon histologic feature. The liver may not show striking changes, presumably because hepatic dysfunction can be caused by a toxin that produces mainly subcellular damage. Organisms can be identified in tissues with a Warthin-Starry stain.

Clinical Examination

Common clinical signs include anorexia, depression, and vomiting. Hepatocellular involvement is suggested by jaundice. Other findings may include arthralgia or myalgia, PU, PD, fever, and dehydration. Widespread petechial and ecchymotic hemorrhages of the mucous membranes, sclera, and skin are caused by thrombocytopenia and DIC. The terminal stages include signs of cardiovascular collapse, shock, coma, and death.

Diagnosis

A diagnosis of leptospirosis should be considered in dogs with acute cholestatic liver disease, especially when accompanied by acute renal failure. Hematologic findings vary with the stage and severity of disease. Leukocytosis and left shift are frequent, but in the early stages of leptospiremia, leukopenia is more likely. Thrombocytopenia can also be seen. Coagulation parameters are normal unless complicated by DIC. Routine serum chemistry and urinalysis findings reflect involvement of the liver or kidney. Serum liver enzyme activity is usually increased with hepatic involvement, and the magnitude of the increase in serum ALP activity is usually greater than that of serum ALT activity owing to intrahepatic cholestasis. Other findings include hyperbilirubinemia, bilirubinuria, and abnormal liver function tests. An increase in BUN or creatinine may result from renal failure or prerenal uremia. The urinalysis is often compatible with acute nephritis with findings of proteinuria and increased

leukocytes, erythrocytes, and granular casts. Increased serum creatine kinase activity may indicate leptospiral-induced muscle damage. Leptospirosis is most easily diagnosed in the clinical setting by demonstration of a fourfold rise in serum antibody titer (microscopic agglutination test) in paired samples taken at initial presentation and 2 to 4 weeks later. The rise in titer indicates recent or active infection and differentiates a titer from previous exposure or previous vaccination.

Treatment and Prognosis

The optimum treatment regimen for leptospirosis is unknown. Traditionally, intravenous ampicillin, 25 mg/kg every 6 hours (with dose reduction in dogs with renal failure), or penicillin G (25,000 to 40,000 units/kg IV q12h), has been used for initial treatment of leptospirosis.[121] Doxycycline (5 mg/kg PO q12h for 2 to 4 weeks), was recommended as followup therapy to eliminate organisms from renal tubules. However, doxycycline, 5 mg/kg orally or intravenously every 12 hours for 2 weeks, appears to be effective in clearing all phases of leptospiral infection and may be the most effective treatment strategy.[121] Management of fluid, electrolyte, and acid–base imbalances is important supportive therapy. The prognosis generally depends on the degree of renal dysfunction and is poor when oliguria develops.

Clostridium piliforme (Tyzzer Disease)

C. *piliforme* (formerly known as *Bacillus piliformis*), a spore-forming Gram-negative bacteria, is a rare cause of multifocal hepatic necrosis and necrotizing ileitis in dogs and cats.[123] The infection is mainly opportunistic in stressed or immunocompromised animals with a predisposing disorder (e.g., canine distemper, feline panleukopenia, feline leukemia) or familial hyperlipoproteinemia in kittens.[123] Clinical signs include an acute onset of anorexia, lethargy, depression, and abdominal discomfort. Jaundice may be observed, especially in cats. These signs rapidly progress to a moribund state; death occurs within 24 to 48 hours. Marked increases in ALT activity may be detected. Histopathology reveals multifocal periportal hepatic necrosis and necrotic ileitis or colitis. Bacilli are best seen with special staining techniques (Warthin-Starry or Giemsa), or methylene blue–stained impression smears of fresh tissue. Organisms appear as large, slender, intracellular filamentous organisms within hepatocytes surrounding areas of necrosis and in intestinal epithelial cells. Routine culture techniques are ineffective for isolation of this organism. The disease is rapidly fatal, and successful therapy has not been reported.[123]

Sepsis and Endotoxemia

Extrahepatic bacterial infection associated with sepsis and endotoxemia is an important cause of acute functional cholestatic hepatopathy. However, morbidity is generally related to the underlying infection and not overt hepatic failure.[113,124] Studies in humans and experimentally in dogs, suggest that endotoxemia and the subsequent release of cytokines induces functional changes that interrupt the transport and excretion of conjugated bilirubin.[113,125] Microscopically, hepatic lesions are often mild and nonspecific. Intrahepatic cholestasis, characterized by bile canalicular plugs and bile pigment accumulation in hepatocytes, is the most consistent finding.[124] A mild periportal lymphocytic infiltrate can be seen, with scattered foci of macrophages or neutrophils, and occasional individual necrotic hepatocytes. Total serum bilirubin concentrations as high as 30 mg/dL can be seen and are disproportionately high compared to the mild to moderate increases in serum ALP activity. Increased serum ALT activity is a less consistent finding. The serum bile acid concentration can be markedly increased (>200 μmol/L).[124]

Extrahepatic bacterial infection–induced hepatic damage should be considered when evidence of cholestatic hepatopathy is found concurrently with extensive bacterial infection in other organ systems (e.g., pyometra, peritonitis) or with extrahepatic disorders likely to be associated with endotoxemia (e.g., parvoviral enteritis). Associated clinical findings that would be compatible with endotoxemic crisis include shock, fever or hypothermia, hypoglycemia, neutrophilia or neutropenia with left shift, toxic changes of the neutrophils, and hyperbilirubinemia that is disproportionately increased in comparison to serum ALP activity.[124] It is important to recognize that jaundice can occur secondary to extrahepatic infection from a diagnostic standpoint, so that the clinician is not misled into considering that the cause is a primary hepatic or biliary disease. In jaundiced patients with evidence of an inflammatory process, key differential diagnoses include acute pancreatitis, extrahepatic bacterial infections, and primary hepatobiliary disorders such as leptospirosis (dogs only), cholangiohepatitis, cholecystitis, ruptured gallbladder mucocele, and hepatic abscesses. Specific therapy for hepatic disease is not usually required, and hepatic damage is reversible with control of sepsis. Morbidity is related to the underlying disease process and not overt hepatic failure.

Hepatotoxicity

Drug and Toxin-Induced Liver Injury

Etiology

Hepatotoxicity can be caused by a variety of drugs (prescription or over-the-counter), herbal and dietary supplements, or biologic toxins or chemicals (see Box 61-1).[17,126,127] The liver is uniquely susceptible to xenobiotic substances because it is directly exposed to them following absorption from the GI tract. The liver is also vulnerable to toxic injury because it plays a central role in the metabolism of many substances. Hepatic metabolism renders lipophilic substances more hydrophilic, which promotes excretion via the urine or bile.[17] The process is controlled by phase I and phase II reactions. Phase I reactions are catalyzed by the cytochrome P450 enzyme systems, which activate or detoxify (oxidize, reduce, or hydrolyze) a drug or toxin. Phase I reactions may lead to generation of unstable chemically reactive intermediates, which can be toxic. Phase II reactions conjugate drugs or metabolites and produce products that are nontoxic. During biotransformation, the liver can either reduce or enhance the toxicity of the parent compound. For example, after carbon tetrachloride ingestion, the liver converts the nontoxic parent compound into toxic metabolites, which subsequently cause severe hepatocellular damage. Genetic polymorphisms of phases I and II enzymes have the potential to influence drug metabolism in the individual animal.

There has been an increased awareness and recognition that drug-induced liver injury can be a significant cause of liver disease in dogs and cats (see Box 61-1). This information has been gained from isolated case reports, retrospective clinical studies, and experimental studies. Unfortunately, for many of these drug reactions, characterization of the clinical and pathologic features are lacking because only small numbers of affected animals have been described, and liver biopsies are not typically obtained when drug withdrawal results in clinical and biochemical improvement. It is possible that drug-induced liver injury is underrecognized in dogs and cats, as in humans, drug-induced hepatic injury accounts for more than 50% of the cases of ALF in the United States, and is the most frequent reason cited for withdrawal of an approved drug from the market.[17]

The Center for Veterinary Medicine of the Food and Drug Administration, Washington, DC, maintains a registry (http://www.fda.gov/AnimalVeterinary/default.htm) for reporting adverse drug reactions in animals. This service has been useful to accumulate data and to alert veterinarians to suspected drug effects, including hepatotoxicity. However, because reporting of adverse drug reactions is voluntary and the information obtained may be incomplete, only subjective trends can be identified. Furthermore, because mild hepatic injury may not be associated with clinical signs, these cases will not be detected unless biochemical testing is performed while the animal is receiving the drug. Evaluating the incidence of drug-induced liver injury in dogs and cats is further clouded by the fact that there are no pathognomonic clinical, laboratory, or biopsy findings to distinguish drug-induced liver injury from other causes of liver disease. Specific drugs that have been reported to cause drug-induced liver injury are listed in Box 61-1.

Herbal and dietary supplements (herbs or other botanicals, nutraceuticals, vitamins, minerals) have the potential to cause hepatotoxicity, similar to drug-induced injury.[127-129] In humans, herbal and dietary supplements are reported to account for 10% of patients with "drug-induced" liver injury.[127] The incidence of hepatotoxicity may be underrecognized, as only a third of humans taking herbal and dietary supplements reported their use of these products to their health care provider.[127] Causality is difficult to prove, because herbal and dietary supplements are often dispensed without medical supervision, FDA oversight of product quality is minimal, multiple active ingredients contribute to product variability, and product contamination with hepatotoxic substances (toxic herbs or heavy metals) may occur.[127-129] Drug interactions between herbal and dietary supplements and prescription medications may also occur, because medicinal plants can have effects on hepatic P450 enzyme systems.[129] The rate of dietary supplement use in dogs and cats appears to be lower than that reported for humans.[130] However, because these products are often marketed as "all natural," pet owners may assume they are safe and underreport their use to the veterinarian. Reports of herbal and dietary supplement hepatic injury in animals are rare. Pennyroyal oil, a volatile oil derived from plants of the Labiatae family (pennyroyal, squaw mint, or mosquito plant) was associated with fatal acute hepatic necrosis in a dog after topical application for use as a flea repellent. Clinical signs occurred within 1 hour after application and included vomiting, diarrhea, hemorrhage, seizures, and death. Other reports include the finding of increased liver enzyme activity in dogs consuming St. John's wort, and increased ALT activity and hypoglycemia after accidental ingestion of high doses of α-lipoic acid in two dogs.[129,131] The paucity of reported hepatic reactions does not necessarily mean herbal and dietary supplements are safe, and the clinician should maintain a high level of suspicion regarding their potential toxicity. Box 61-1 lists the herbal and dietary supplements that have been incriminated as causing hepatic injury in humans with potential relevance to dogs and cats. For more detailed information on hepatic injury and herbal and dietary supplements, additional sources should be consulted.[127-129]

Hepatic injury may also occur after exposure to a wide variety of industrial chemicals, organic solvents, pesticides, heavy metals, and biologic toxins. Most information on chemical hepatotoxins is derived from experimental studies in dogs or extrapolated from information in other species. Very few clinical case reports are available in the veterinary literature. Isolated reports and case series of clinical liver disease in dogs associated with exposure to biologic toxins, such as aflatoxin, *Amanita* mushrooms, blue-green algae, and Cycads (Sago palms) have been published. Selected hepatotoxins are listed in Box 61-1.

Pathophysiology

Hepatic injury caused by drugs, herbal and dietary supplements, biologic toxins, or chemicals can occur via a number of mechanisms, which influence the histologic pattern of disease.[17,20] Although hepatic necrosis is the most common histologic response, drug- and toxin-induced liver injury can also potentially mimic the full spectrum of acquired hepatic disorders, including acute and chronic hepatitis, granulomatous hepatitis, cholestatic hepatopathy, vacuolar hepatopathy (lipid or glycogen accumulation), hepatic fibrosis and cirrhosis, and venoocclusive disease. Hepatic necrosis occurs when covalent binding of a drug or toxin to intracellular proteins disrupts cellular functions, or formation of drug–enzyme adducts stimulates an immunologic response (antibody- or T-cell–mediated cytotoxicity). Hepatic inflammation (typically lymphoplasmacytic, but may be granulomatous or eosinophilic), suggests an underlying immunoallergic mechanism. Intrahepatic cholestasis occurs when drugs or toxins interfere with hepatic transport proteins at the canalicular membrane, which interrupts bile flow. Hepatic lipid accumulation results when direct damage to mitochondria disrupts fatty acid oxidation and energy production, and is the predominant hepatic lesion seen with stanozolol hepatotoxicity in cats,[132] and tetracycline in dogs and cats.[126] Hepatic vacuolation caused by glycogen accumulation occurs in dogs treated with corticosteroids, and typically does not cause significant clinical evidence of hepatic dysfunction. Damage to the sinusoidal epithelium can result in peliosis hepatic or venoocclusive disease.

Mechanisms of drug-induced liver injury (and also injury from herbal and dietary supplements) can be characterized as either intrinsic (predictable) or idiosyncratic (unpredictable) reactions.[126] Intrinsic hepatotoxic reactions are dose-related and occur shortly after a consistent threshold of toxicity is reached. Because intrinsic hepatotoxins predictably damage the liver in an exposed population, they can be experimentally reproduced and studied. Hepatic injury is caused by a direct toxic effect of the parent compound (or a reliably generated toxic metabolite) on vital cell targets. Acetaminophen is an intrinsic hepatotoxin in dogs and cats and is discussed in more detail later in this section. With intrinsic hepatotoxins, lowering the dose, rather than stopping the drug can be tried. In many cases, most such drugs or chemicals, (e.g., carbon tetrachloride, phosphorus, and chloroform), are no longer used for therapeutic purposes once their intrinsic hepatotoxicity is recognized, but accidental exposures could still occur.

In contrast, idiosyncratic hepatotoxic reactions occur at therapeutic doses in only a small number of individuals in the exposed population. These reactions are unpredictable and infrequent; most individuals treated with the drug do not have a reaction, even at high doses. However, toxicity may be more pronounced at higher doses in susceptible individuals.[72,133] Examples of drugs causing idiosyncratic drug-induced liver injury in dogs and cats that have a dose-related effect are phenobarbital, itraconazole, amiodarone, and lomustine (CCNU).[134] Idiosyncratic reactions are characterized by a variable latency period (5 to 90 days, but may be longer for some drugs, such as phenobarbital, CCNU, amiodarone) from initial drug ingestion to recognition of hepatic injury. Because of the infrequent occurrence (approximately 1 in 100,000), the potential for hepatotoxicity may not be recognized in preclinical screening of a new drug, and cannot usually be reproduced in an experimental setting. Individual differences in susceptibility to idiosyncratic drug-induced liver injury may reflect genetic differences in either (a) alternate metabolic pathways by which a drug is converted to different (potentially hepatotoxic) metabolites, (b) the ability of the individual to detoxify the toxic intermediates, (c) an underlying

immunologic or allergic reaction, or (d) an individual's tolerance or ability to "adapt" to hepatocellular injury (mechanisms unknown) with resolution of injury despite continued medication administration.[20,135] Oral medications with substantial hepatic metabolism are more likely to be associated with adverse hepatic events in humans, presumably because of hepatic generation of reactive toxic metabolites.[136] Because of the unpredictability of an idiosyncratic reaction and the low incidence of occurrence, a cause-and-effect relationship is difficult to establish. If an idiosyncratic reaction occurs, the drug must be discontinued or it could result in death of the patient. An idiosyncratic mechanism is suspected for most of the drugs that cause hepatic injury in dogs and cats.

Susceptibility to hepatotoxicity in humans is influenced by a number of factors such as age, sex, nutritional status, and concurrent drugs.[20] The most important factor may be the effect of genetic polymorphisms on hepatic drug metabolism.[20] In humans, preexisting liver disease does not appear to enhance susceptibility to drug-induced liver injury, but impacts the patient's ability to recover.[20] This may be because drug-metabolizing enzyme systems are remarkably preserved in hepatic disease. Similar information on risk factors for hepatotoxicity in dogs and cats has not been determined. However, because many toxic metabolites are normally detoxified by glutathione, some metabolites may become more toxic when hepatic glutathione stores are depleted (e.g., animals with preexisting chronic necroinflammatory and cholestatic liver disease).[126] A breed predisposition has been suggested for Doberman Pinschers (sulfonamides, amiodarone, diethylcarbamazine/oxibendazole) and Labrador Retrievers (carprofen), which may be a reflection of a genetic predisposition.[21,71,73,134,137]

Clinical Examination

The spectrum of drug- and toxin-induced liver injury and, thus, the associated clinical presentation, can vary from subclinical hepatic injury with only increased serum liver enzyme activity, to severe liver damage manifested as ALF, or chronic end-stage liver disease. Acute rather than chronic liver injury is more likely for most of the drugs and toxins listed in Box 61-1. Clinical features often include acute onset of lethargy, anorexia, vomiting, diarrhea, PU, PD, or jaundice in a previously healthy animal, which corresponds to hepatotoxin exposure. ALF (signs of acute liver disease plus HE and coagulopathy) is most likely with drugs or toxins that cause diffuse hepatic necrosis. Drug- and toxin-induced injury is an important diagnostic consideration in dogs and cats presenting for acute hepatitis and hepatic necrosis.

Drugs or toxins also have the potential to cause chronic hepatic disease, if the initial hepatic injury is mild and goes unrecognized, and exposure to the drug or toxin is continued. For example, phenobarbital, CCNU, or chronic aflatoxicosis can cause chronic liver injury in dogs.[70,72,138]

Diagnosis

There are no pathognomonic clinical, laboratory, or biopsy findings that distinguish drug- or toxin-induced liver injury from other causes of liver disease. The diagnosis of drug-induced liver injury often relies on the clinician maintaining a high level of suspicion, and obtaining an accurate and thorough medication history (including prescription and over-the-counter drugs, and herbal and dietary supplements), in every animal with unexplained increases in liver enzyme activity or clinical liver disease. A definitive diagnosis of hepatic injury caused by biologic toxins or chemicals is rarely possible in a clinical setting, unless the owner specifically observes ingestion of a substance that is a known hepatotoxin.

Increased liver enzyme activity is a common finding with hepatotoxicity. Increased ALT activity (more than three times the upper limit of normal, but can be as high as 100 times the upper limit), suggests hepatocellular injury (often necrosis), and is of more concern than an isolated increase in ALP activity (reflecting cholestasis), although mixed patterns commonly occur. Progressive increases in ALT activity or those accompanied by evidence of hepatic dysfunction (hyperbilirubinemia, increased serum bile acids, coagulopathy, hypoglycemia, hyperammonemia, hypoalbuminemia) are more likely to represent serious hepatic injury.

When drug-induced liver injury is suspected, the diagnostic approach is determined by the clinical presentation. If clinical signs are absent or mild, a minimum database consisting of complete history and physical examination, complete blood cell count, serum chemistry, and urinalysis should be performed. If the only abnormality detected is increased liver enzyme activity, and these increases correspond to the recent administration of a drug (especially those listed in Box 61-1), the drug should be discontinued and serum biochemistries should be repeated in 10 to 14 days. In many instances, clinical and biochemical abnormalities resolve after the suspected hepatotoxic drug is discontinued and a liver biopsy is not performed. Further evaluation of the liver, including SBA concentrations, abdominal radiographs, ultrasonography, and liver biopsy, may be warranted if biochemical abnormalities persist, or if initial clinical and biochemical findings suggest hepatic dysfunction.

With suspected drug- or toxin-induced liver disease, a liver biopsy can be helpful to (a) characterize the histologic changes (are they consistent with previously described lesions caused by this particular drug or toxin?), (b) determine the severity (focal or diffuse necrosis?) or reversibility (is cirrhosis present?) of the lesions for prognostic purposes, and (c) rule out known causes of liver disease. Histologic changes secondary to drug- and toxin-induced hepatic injury are nonspecific and similar to those seen with other non–drug-related causes of acute and chronic liver disease.[126] The most common pathophysiologic response is necrosis without inflammation.[126] Hepatic necrosis may be centrilobular (zone 3) or panlobular (Figure 61-20). Centrilobular hepatocytes have an abundance of P450 enzymes, and are preferentially affected in drug-induced hepatotoxicity when P450 metabolism of the parent drug results in toxic metabolites.[8] Drugs or toxins can also cause a variety of other hepatic lesions, such as cholestasis, lipidosis, or mild inflammation. A chronic response to injury is reflected by findings of biliary

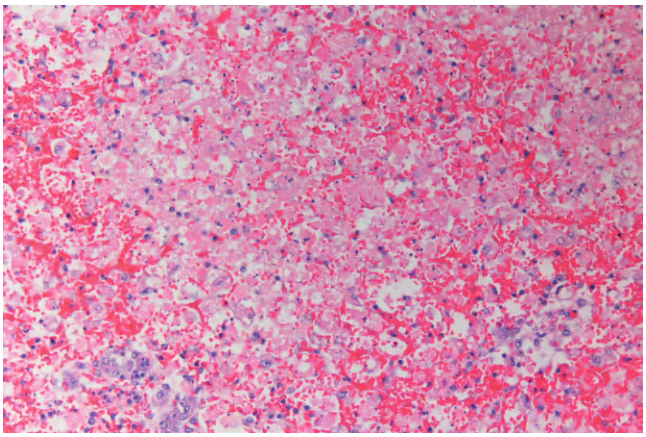

Figure 61-20 Severe panlobular acute hepatic necrosis in a dog with fatal acute liver failure caused by ingestion of *Amanita* mushrooms (20×). (Courtesy of Dr. Paul Stromberg.)

hyperplasia, fibrosis, and cirrhosis. Although individual drugs and drug classes may follow the same pattern, there is often not a consistent reaction for any given drug. For example, hepatic injury in dogs secondary to potentiated sulfonamides may cause hepatic necrosis, primary cholestasis, or marked inflammation.[21] For many of the potentially hepatotoxic drugs listed in Box 61-1, histologic features have not been fully characterized.

It should be emphasized that for most drug-induced disorders, the diagnosis is presumptive and cannot be proved. It can be especially difficult to pinpoint the causative agent when the patient is receiving a combination of drugs. A clinical diagnosis of drug-induced hepatic injury is easier to establish when the hepatotoxicity of the drug has been previously described and the associated clinical and pathologic features have been characterized (see discussion of specific drugs). The diagnosis may be less convincing when the suspected drug has not been previously incriminated as causing liver damage. However, a drug reaction should still be considered, since an idiosyncratic reaction could occur *with any drug*. The clinician should also maintain a level of suspicion regarding the potential for hepatotoxicity in newly marketed drugs that have not yet been used widely in the population, where idiosyncratic reactions are often first detected. The suspected hepatotoxic drug should be discontinued while a complete diagnostic evaluation is pursued for other causes of liver disease, for which a specific treatment might be available.

A diagnosis of drug-induced injury is supported by the following: (a) evidence of liver injury that occurred within the first 3 months of drug therapy (especially if predrug liver enzyme activity was within normal limits); (b) clinical and biochemical improvement when the drug is discontinued; (c) exclusion of other causes of liver disease; (d) reccurrence of hepatic damage after a challenge dose of the same drug (or inadvertent reexposure). It should be emphasized that rechallenge with a suspected hepatotoxic drug is not recommended as a diagnostic consideration, because it is potentially dangerous, especially with a drug that causes acute hepatic necrosis. Rechallenge should only be considered if the association of the drug with hepatic injury is highly questionable and there is no alternative drug available for a significant medical condition. With hypersensitivity or immunologic reactions, the hepatic reaction is more rapid and severe with repeated exposure.[20]

Hepatic injury because of a biologic toxin or chemical is suspected when exposure to a potential hepatotoxin has been documented. A clinical diagnosis of "toxic" hepatic injury is often made when an episode of acute hepatic injury occurs, hepatic biopsy indicates diffuse hepatic degeneration and necrosis, and no other cause for liver disease can be identified. In selected cases, tissues, blood, or food (aflatoxin) samples can be submitted to a toxicology lab to confirm a suspected toxin. Toxin-induced injury should also be considered in the absence of known exposure to toxins, because potential hepatotoxins can be present in contaminated dog food or garbage (aflatoxins), pond water (blue-green algae), and many other unobserved sources.

Treatment

When ingestion of a potential hepatotoxin (e.g., toxic mushrooms, Sago palms) has occurred within the preceding 8 hours, general procedures for GI decontamination are recommended, including induction of emesis or gastric lavage (within first 3 hours), followed by administration of activated charcoal (1 to 3 g/kg).[126,139] Induction of vomiting is contraindicated if the patient is comatose or debilitated in such a way that the gag reflex is diminished, which could predispose to aspiration pneumonia. Whenever possible, the source of toxin exposure should be identified and further exposure prevented. Treatment of drug-induced hepatic disease consists of discontinuing the suspect drug. After a drug is discontinued, clinical (and biochemical) improvement usually occurs within a few weeks, even with chronic drug administration. However, exceptions can occur. For example, in dogs with amiodarone toxicity, liver enzyme elevations can transiently progress despite discontinuation of the drug, and biochemical abnormalities may not resolve for 6 to 8 weeks.[137]

With the exception of NAC for acetaminophen, and silymarin for *Amanita* mushroom toxicity, no specific antidotes are available, and treatment of drug- and toxin-induced liver injury is primarily supportive and symptomatic. However, nonspecific hepatoprotective therapy with antioxidants (vitamin E), glutathione replacement (NAC, SAMe), or milk thistle (silymarin) may be helpful and are discussed in more detail in Chapter 46. Use of NAC (or SAMe) may be beneficial, as glutathione depletion may predispose to hepatotoxicity (e.g., methimazole) or impair metabolism of toxic metabolites to a nontoxic form. NAC has been suggested to be beneficial for treatment of ALF associated with toxicities such as diazepam, methimazole, carprofen, and trimethoprim-sulfa.[9] In addition to treating *Amanita* mushroom hepatotoxicity, silymarin may be beneficial in the treatment of carbon tetrachloride and acetaminophen toxicity.[9,140,141] Corticosteroids are not typically indicated for treatment of drug- and toxin-induced hepatotoxicity.

Prognosis

It is important to consider a drug-induced cause of liver injury because rapid recognition and prompt discontinuation of an hepatotoxic drug can lead to improvement or complete resolution of hepatic disease, depending on the specific drug and the stage of the lesion. When drug- or toxin-induced hepatic injury causes severe or widespread hepatic necrosis, rapid deterioration and death in 3 to 4 days often occur. With less-severe hepatic injury, complete recovery is possible.

Selected Hepatotoxic Drugs

Acetaminophen

Acetaminophen is well known as an intrinsic hepatotoxin in dogs and cats.[142,143] Although acetaminophen is occasionally used as an analgesic in dogs (therapeutic doses up to 15 mg/kg TID), most toxicity occurs because of accidental ingestion of improperly stored medication (dogs) or owner administration without veterinary supervision (dogs and cats).[142] Toxic metabolites of acetaminophen cause oxidative injury to erythrocytes and hepatocytes, resulting in methemoglobinemia, anemia, and hepatic necrosis. In therapeutic doses, acetaminophen is detoxified by a combination of hepatic glucuronidation and sulfation and renal excretion.[144] After acetaminophen overdosage, these pathways become saturated and a greater proportion of acetaminophen is metabolized through the P450 system, leading to production of the toxic metabolite, *N*-acetyl-*p*-benzoquinoneimine (NAPQI). Glutathione detoxifies NAPQI and thus protects hepatic cellular constituents from its direct toxic effect. However, once glutathione levels are depleted by large amounts of NAPQI, centrilobular necrosis occurs. Toxicity occurs in a dose-dependent manner.

There are substantial species differences in both the metabolism of acetaminophen and the toxic manifestations.[142] Cats are uniquely sensitive to acetaminophen because of a deficiency of glucuronyl transferase and limited sulfation capabilities. Clinical signs in cats may develop after administration of as little as 162.5 mg (½ tablet). Signs of methemoglobinemia usually dominate the clinical picture, such as cyanosis, dyspnea, facial edema, depression, hypothermia,

and vomiting. Although increases in serum ALT activity may be detected, centrilobular hepatic necrosis appears to be uncommon. Clinical signs in dogs are more likely when doses exceed 200 mg/kg and can be indicative of methemoglobinemia and/or centrilobular necrosis.[142] Laboratory features include methemoglobinemia, anemia, increased serum ALT activity, and hyperbilirubinemia.

Intravenous NAC is the treatment of choice for acetaminophen toxicity in dogs and cats.[142] NAC increases the synthesis and availability of glutathione, which when conjugated to NAPQI, decreases toxicity. For maximum effectiveness, NAC should be given within 12 hours of acetaminophen exposure; however, there may still be a benefit if given 36 to 80 hours after exposure. NAC (10% solution) is diluted 1:2 or more with saline and given intravenously through a nonpyrogenic 0.25 µm filter at an initial dose of 140 mg/kg over a 20- to 30-minute period. A maintenance dose of 70 mg/kg is given IV or orally every 6 hours for seven treatments. SAMe also serves as a glutathione source and has been shown to have protective effects against acetaminophen-induced oxidative stress on the erythrocytes in cats and dogs.[143,145] In an experimental study in cats, silymarin (30 mg/kg PO) was as effective as NAC for treatment of acetaminophen toxicity when given up to 4 hours after exposure.[140] Vitamin C (30 mg/kg IV q6h) may be helpful in the treatment of acetaminophen toxicity because of its antioxidant effects. Cimetidine (5 mg/kg IV q8h) is also recommended as adjunctive therapy in the early stages (first 16 hours) because it inhibits hepatic P450 enzymes and decreases NAPQI formation.

Amiodarone

The antiarrhythmic drug amiodarone is associated with a reversible hepatotoxicity in dogs.[134,137] Doberman Pinschers may be at increased risk.[134] Toxicity, which appears to be at least partially dose related (doses of 400 mg/day), was identified in 45% of Doberman Pinschers treated with amiodarone in one clinical series.[134] Clinical signs (anorexia, lethargy, vomiting, diarrhea) and biochemical abnormalities (increased ALT and ALP activity ± hyperbilirubinemia) developed 6 days to 8 months after initiation of therapy. Liver biopsy in one dog revealed multifocal hepatocellular necrosis with mild lipidosis and lymphoplasmacytic inflammation.[137] Clinical improvement usually occurs within a few days of stopping the drug, but liver enzyme elevations may not return to normal for 3 months.[134] Transient progression of enzyme abnormalities despite discontinuing the drug has also been noted, which may reflect the long half-life of amiodarone causing a delay in systemic elimination.[137] Biochemical changes precede clinical signs, so monitoring of liver enzymes at least monthly is recommended.

Azole Antifungals

The azole antifungal drugs ketoconazole and itraconazole (and rarely fluconazole) are associated with increased liver enzyme activity and icterus in dogs and cats.[146] Hepatotoxicity is more likely with ketoconazole than with itraconazole. Cats are more sensitive to the hepatotoxic effects than are dogs, but considerable individual variation occurs. Histologic findings are poorly characterized but include bile duct proliferation and infiltration of mononuclear cells. Transient mild subclinical elevations of liver enzymes (ALT and ALP activity) are common, and do not necessarily require a change in therapy. A clinically significant hepatic reaction is suggested by ALT activity that exceeds two to three times the upper limit of normal, especially when accompanied by clinical signs of anorexia and vomiting. Drug therapy should be stopped for 1 to 2 weeks until appetite and liver enzymes return to normal. A rapid recovery usually occurs, and treatment can be restarted at a lower dose (50% of previous dose or given as alternate-day therapy), with careful monitoring of liver parameters every 2 weeks.[146] Hepatotoxicity appears to be at least partly dose related, as dogs receiving higher daily doses of itraconazole (10 mg/kg) are more likely to be affected. Icterus and evidence of hepatic dysfunction suggests a more serious, potentially fatal hepatopathy, requiring discontinuation of medication and symptomatic and supportive care. It is recommended that liver enzymes be monitored on a monthly basis in all animals receiving ketoconazole or itraconazole.

Azathioprine

Azathioprine, a purine analogue commonly used for treatment of immune-mediated disorders in dogs, is commonly listed as a potential hepatotoxin.[126] However, few clinical details regarding the hepatotoxic reaction are available. In a clinical study of 12 dogs with atopic dermatitis treated with azathioprine (2.2 mg/kg daily for 8 weeks) as a single agent, an increase in ALT or ALP activity was noted in the first 2 weeks in 10 (83%) of the dogs.[147] Three dogs had clinical signs suggestive of liver disease, which resolved uneventfully when azathioprine was discontinued. In an experimental study of dogs given azathioprine at a dose of 2 to 4 mg/kg PO daily for 40 days, all dogs had increased liver enzyme activity (ALT >> ALP) within 2 to 7 days of initiating therapy.[148] Values peaked within the first 2 weeks and then declined, but not to normal, despite continued medication administration. Hyperbilirubinemia was absent. Liver biopsies in most dogs revealed centrilobular degeneration and necrosis, with intrahepatic cholestasis but no inflammation.[148] These findings raise the possibility that azathioprine may be an intrinsic (dose related) hepatotoxin in dogs, with possible adaptive tolerance to liver injury. It should be noted that doses used in this study exceeded current clinical recommendations of 1 to 2 mg/kg daily or every other day for maintenance therapy.

Carprofen and Other Nonsteroidal Antiinflammatory Drugs

Hepatotoxicity is considered a class characteristic of NSAIDs, despite the fact that there are many different chemical classes of NSAIDs, and no consistent mechanism of liver injury.[149] With the exception of aspirin, which is an intrinsic (dose-related) hepatotoxin, the mechanism with other NSAIDs is believed to be idiosyncratic (either immune or as a consequence of toxic metabolites).[149,150] Toxicity does not appear to be related to prostaglandin inhibition like the renal or GI side effects.[149] Preexisting hepatic disease has not been shown to be a risk factor for NSAID-induced liver injury.[150] All NSAIDs have the potential to cause idiosyncratic hepatotoxicity in dogs, but hepatic reactions appear to be rare.[150] Carprofen has specifically been reported as a cause of drug-induced liver injury in dogs.[73] Labrador Retrievers were overrepresented in the series, but it is not clear whether this is a true breed predisposition.[150] Clinical signs (anorexia, lethargy, vomiting, PU/PD) occurred within the first 4 weeks of therapy and icterus was a common finding on physical examination. Biochemical evaluation revealed marked increases in liver enzymes (ALT activity usually exceeded ALP activity) and hyperbilirubinemia. Hepatic biopsy findings revealed multifocal to diffuse hepatic necrosis, mild to moderate lymphocytic–plasmacytic inflammation, secondary cholestasis, and variable biliary hyperplasia and bridging fibrosis.[73] Concurrent renal toxicity (glucosuria without hyperglycemia, proteinuria, granular casts) also was noted in some dogs. Most dogs recovered with discontinuation of carprofen and appropriate supportive care, although some dogs died of ALF. General hepatoprotective therapy with SAMe or Silybin has been recommended, although the benefits are unproven. NAC has been suggested for ancillary treatment when carprofen causes ALF.[128]

Early recognition of hepatotoxicity (including periodic monitoring of liver enzymes during the first 3 months) and discontinuation of drug therapy provides the best opportunity for full recovery. Whether dogs with previous carprofen hepatotoxicity can be safely switched to another NSAID without experiencing a hepatic reaction is unknown.

Diazepam

Oral diazepam has been incriminated as a cause of acute idiosyncratic fatal hepatic necrosis in cats.[151,152] Intravenous diazepam, and oral oxazepam, clonazepam, and zolazepam also have been implicated.[126,152] Onset of signs occurs within 5 to 13 days of initiating therapy. Clinical signs and biochemical evaluation are consistent with acute hepatic necrosis and liver failure. Most cats die within 15 days of initial administration of the drug. If treatment of a cat with oral diazepam is unavoidable, liver enzymes should be checked before and within 5 days after starting therapy. If liver enzymes are increased, the drug should be discontinued and symptomatic therapy should be started. Ancillary treatment of ALF with NAC may be beneficial.[9]

Glucocorticoids

Glucocorticoid therapy in dogs is commonly associated with increased serum ALP activity and development of a reversible vacuolar ("steroid") hepatopathy as a result of hepatic glycogen accumulation. These hepatic effects can be seen with virtually any glucocorticoid preparation (including topical ophthalmic and otic preparations) and are influenced by drug preparation (e.g., repositol versus short-acting), dose, duration of therapy, and individual dog susceptibility. In contrast, cats are quite resistant to the hepatic effects of glucocorticoids and only rarely develop these hepatic changes.[153] Increased serum ALP activity can occur within 3 days after initiating glucocorticoid therapy in dogs and is often striking (up to 64 times normal). Glucocorticoids are associated with the induction of a specific corticosteroid-induced isoenzyme of ALP, which may account for 60% to 100% of the total ALP activity.[154] In contrast, serum ALT activity is often normal or only mildly increased. In most dogs, glucocorticoids do not cause significant hepatic dysfunction or clinically relevant hepatic disease and biochemical tests reflecting hepatic function (serum bilirubin, albumin, glucose, blood ammonia concentration, and coagulation tests) are typically normal. Serum bile acid concentrations are normal or only mildly increased (<60 mmol/L). Hepatic glycogen accumulation causes hepatomegaly (which can be detected on abdominal radiographs), and diffuse or multifocal increases in hepatic echogenicity (detected on ultrasonography). The hepatic effects of glucocorticoids are reversible after drug withdrawal. The length of time required for complete resolution is unpredictable, varying from weeks to months.

Lomustine

CCNU [1-(2-chloroethyl)-3-cyclohexyl-1-nitrosourea] is an oral nitrosourea alkylating agent that is used for chemotherapy of lymphoma, mast cell tumor, histiocytic sarcoma, and brain tumors in dogs. Idiosyncratic dose-related hepatotoxicity was described in 11 of 179 (6.1%) dogs given an oral dose of CCNU (50 to 110 mg/m^2), with a dosing interval of 3 to 6 weeks.[72] The median time to detection of hepatic disease (from the last dose of CCNU) was 11 weeks and ranged from 2 to 49 weeks. Delay in onset was noted, with an inverse relationship between the size of dose, and length of time before abnormal serum ALT was detected.[72] A cumulative dose effect was suspected. Clinical findings of hepatotoxicity included decreased appetite, weight loss, PU/PD, vomiting, ascites, and pleural effusion. Ascites was due to a combination of hypoalbuminemia and portal hypertension. Common biochemical abnormalities included increased liver enzyme activity (ALT, AST, ALP, GGT) and hypoalbuminemia. Other less-consistent findings included hyperbilirubinemia, hypercholesterolemia, and increased serum bile acid concentrations. Glucosuria (without hyperglycemia) and renal failure were noted in some dogs, possibly attributable to CCNU renal toxicity.[72] Liver biopsy findings were nonspecific (hemosiderin-laden Kupffer cells, hepatocellular vacuolization, mild to moderate periportal inflammation, and fibrosis) but suggested chronicity. The majority of affected dogs died from progressive chronic liver disease.

In a recent study, routine monitoring of ALT activity prior to each subsequent dose of CCNU suggested that subclinical elevations of ALT activity (greater than five times the upper limit of normal) are common.[155] Thirty-two of 109 dogs (29%) had increased ALT activity, which developed most commonly after one to three doses of CCNU.[155] Increases in ALT activity were not associated with cumulative dose. The lower incidence of clinical hepatotoxicity in this study (3 of 109 or 2.8%) versus the Kristal study (11 of 179 or 6.1%), was attributed to prompt cessation of CCNU treatment in dogs with significant increases in ALT activity.[155] However, it was noted that chronic administration of CCNU could be associated with chronic irreversible hepatopathy, in the absence of a significant ALT elevation. The mechanism of hepatotoxicity is suspected to be a result of generation of toxic intermediate metabolites (e.g., isocyanates, diazonium hydroxide), and depletion of glutathione may play a role.[126] Preliminary results of a clinical study using Denamarin (SAMe and sylibin; Nutramax Labs, Lancaster, SC) for prevention of CCNU hepatotoxicity, suggested that dogs receiving Denamarin had less-severe liver enzyme elevations.[156]

Methimazole

Methimazole, an antithyroid drug, is associated with hepatic injury in cats with hyperthyroidism. Clinical findings include anorexia, vomiting, lethargy, jaundice, markedly increased serum liver enzyme activity, and hyperbilirubinemia that usually occurs within the first month of therapy.[126] Histologic lesions have not been fully characterized, although biopsy findings in one cat revealed hepatic degeneration and necrosis. Clinical signs resolve within a week of discontinuing therapy but biochemical resolution may take up to 45 days. Reduced hepatic glutathione concentrations, which have been documented in other species with hyperthyroidism, may predispose to hepatic injury.[126] Treatment with SAMe may be beneficial.

Phenobarbital, Primidone, Phenytoin

Phenobarbital is associated with chronic hepatic disease and cirrhosis in dogs.[70] Most dogs have been treated with phenobarbital for more than a year before the liver disease is apparent. The mechanism of hepatic injury is not known but higher doses, higher blood levels (>40 μg/mL), and long duration appear to be important risk factors.[70] Clinical signs in dogs reflect chronic liver disease and include sedation, ataxia, anorexia, weight loss, weakness, ascites, jaundice, coagulopathy, and encephalopathy. Phenobarbital-induced hepatic injury should be suspected in any dog with a history of chronic phenobarbital therapy and clinical and biochemical evidence of hepatic dysfunction.

Routine biochemical screening (every 4 to 6 months) of dogs on long-term phenobarbital therapy is recommended for early detection of hepatic injury. However, mild liver enzyme elevations (especially ALP) are commonly seen in dogs treated with phenobarbital, who do not have clinical or histologic evidence of significant liver

disease.[157] Potential indicators of clinically significant liver injury include increases in ALT and ALP activity that exceed five times the upper limit of normal; ALT activity that exceeds ALP activity; any elevation in AST activity; or enzyme elevations accompanied by evidence of hepatic dysfunction (hyperbilirubinemia, hypoalbuminemia, hypocholesterolemia, increased SBA). Hepatic cirrhosis associated with chronic phenobarbital therapy is characterized grossly by a small, nodular liver and histologically by bridging portal fibrosis, nodular regeneration, biliary hyperplasia, and mild inflammation (see Figure 61-19).[70] These lesions are by no means pathognomonic for phenobarbital-induced hepatic damage; however, in the absence of other known causes of hepatic damage, circumstantial evidence would support drug therapy as a likely cause. Chronic phenobarbital therapy also is associated with superficial necrolytic dermatitis (hepatocutaneous syndrome) in dogs.[158] Liver biopsy changes were typical of those seen with hepatocutaneous syndrome (marked vacuolar change and parenchymal collapse), which are distinct from the characteristic chronic hepatitis and cirrhosis as described above.[158]

Phenobarbital should be decreased or discontinued if possible in dogs with biochemical and histologic evidence of hepatic disease. In dogs with phenobarbital-associated toxicosis, clinical, biochemical, and histologic improvement can occur if the drug is discontinued or used at a reduced dosage prior to severe, end-stage liver disease. Improvement in clinical signs can be noted within days to weeks of decreasing serum phenobarbital levels. Primidone also is associated with chronic liver disease in dogs, likely as a consequence of metabolism of primidone to phenobarbital. Phenytoin can cause acute or chronic hepatitis in dogs, as well as jaundice and death. The risk of hepatotoxicity is increased with combination therapy of phenobarbital, primidone, and phenytoin.[126]

Sulfonamides

Potentiated sulfonamides (trimethoprim-sulfadiazine, trimethoprim-sulfamethoxazole, and ormetoprim-sulfadimethoxine) are associated with the acute idiosyncratic drug-induced liver injury in dogs.[21] Trimethoprim-sulfadiazine was implicated in over 20% of hepatic drug reactions in dogs that were reported to the Center for Veterinary Medicine between 1988 and 1990.[71] Doberman Pinschers are suggested to be at risk for development of polyarthropathy from sulfonamide hypersensitivity, but not necessarily the idiosyncratic hepatic reaction.[159] Onset of clinical signs occurs within 5 to 36 days (mean: 12 days) from starting the drug.[159] Previous exposure to sulfonamides is not required. Doses of potentiated sulfonamides are generally higher in dogs who develop the idiosyncratic hepatic reaction, as compared with other systemic manifestations of sulfonamide hypersensitivity (thrombocytopenia, fever, polyarthropathy, other).[159] Biochemical findings include increased liver enzyme activity (ALT > ALP) and hyperbilirubinemia. Liver biopsy usually reveals marked hepatic necrosis; however, cholestasis and marked lymphocytic–plasmacytic inflammation also have been described.[21] The pathogenesis of the idiosyncratic hepatic reaction is unclear. Dogs in general may be at increased risk for sulfonamide reactions because they lack genes that express the *N*-acetylation enzymes, which is a major metabolic pathway of detoxification of sulfonamides in humans.[21] However, this does not explain individual risks among dogs. Hepatotoxicity may be a result of P450 oxidation of sulfonamides to reactive metabolites, such as hydroxylamine and a nitroso metabolite, which may be associated with hapten formation, T-cell proliferation, or direct cytotoxicity.[21] Impaired detoxification of reactive metabolites via a deficiency in glutathione, cysteine, and ascorbate, may play a role, and theoretically supports the use of glutathione precursors (NAC, SAMe) and vitamin C in treatment.[21] Dogs with hepatopathy are less likely to recover (46%) than are dogs with nonhepatic manifestations of sulfonamide hypersensitivity (89%).[159]

Tetracycline and Doxycycline

Tetracycline can predispose to hepatic lipid accumulation because it inhibits protein synthesis and interferes with hepatic secretion of triglyceride-rich lipoproteins.[126] However, it does not appear that these hepatic effects are clinically significant in most dogs and cats, although clinically significant idiosyncratic hepatic injury has been reported. Increased liver enzyme activity was a common finding in dogs treated with doxycycline (increased ALT activity in 39.4%; increased ALP activity in 36.4%), but the clinical significance remains to be determined.[160]

Other Hepatotoxins

Aflatoxicosis

Aflatoxins are metabolites, produced primarily from strains of the saprophytic fungus, *Aspergillus*, which cause toxic hepatitis in dogs and many other species.[138,161] Exposure in dogs may occur through the inadvertent use of aflatoxin-contaminated corn or peanut meal during the commercial production of dog food, or after ingestion of homemade pet foods, moldy garbage, or improperly stored dog food.[161] Dogs are relatively susceptible to aflatoxins and the liver is the target organ. Clinical cases of aflatoxicosis in cats have not been reported. Aflatoxin B1 is most commonly implicated in hepatotoxicity and toxic effects are seen when levels exceed 60 μg/kg of food.[161] Aflatoxin B1 is readily absorbed from the GI tract and undergoes hepatic metabolism by cytochrome P450 enzymes, to a toxic intermediate (aflatoxin B1 8,9-epoxide), which binds to essential molecules within the cell, leading to hepatocyte necrosis and decreased protein synthesis. Detoxification of aflatoxin B1 8,9-epoxide occurs by conjugation to glutathione.

Depending on the amount consumed, dogs may present with acute, subacute, or chronic liver disease. High-dose exposure is associated with acute hepatic failure, jaundice, DIC, and death. Repeated exposure to low doses can lead to chronic liver disease and cirrhosis. In 2005, an outbreak of aflatoxicosis occurred in at least 100 dogs, as a result of eating a commercially available dog food manufactured with aflatoxin-contaminated corn.[138] Severity of clinical signs varied significantly among dogs. Some dogs died suddenly without preexisting signs of illness. Other dogs were presented with signs of anorexia, lethargy, vomiting, jaundice, diarrhea (including melena and hematochezia), abdominal effusion, HE, and evidence of a bleeding disorder. Common biochemical features included increased liver enzyme activity (especially ALT), hyperbilirubinemia, electrolyte disturbances, hypoalbuminemia, hypocholesterolemia, and prolonged clotting times. Reduced plasma antithrombin III and protein C activities and hypocholesterolemia were suggested to be the most sensitive biomarkers of aflatoxin ingestion in dogs with minimal clinical signs, possibly reflecting an early effect of aflatoxin on biosynthesis of certain proteins and cholesterol.[138]

In dogs with acute or subacute aflatoxicosis, the liver is enlarged and pale yellow with histologic features of diffuse hepatic vacuolation (lipid accumulation), scattered individual hepatocyte necrosis, biliary hyperplasia, and modest inflammation. Collapse of zone 3 hepatocytes around the central vein, associated with perivenular inflammation, may explain clinical features of portal hypertension. With chronic low-level exposure, findings include a small liver with regenerative nodules, acquired PSS, and histologic evidence of marked biliary hyperplasia and periportal fibrosis.

Aflatoxicosis associated with consumption of a commercially manufactured pet food product should be suspected when there is a geographic or temporal cluster of cases in a household, kennel, or region. The history may reveal recent changes in diet or feeding from a new bag. It should be noted that some dogs may consume contaminated food for weeks to months before signs develop. Definitive diagnosis of aflatoxicosis is based on chemical detection of increased levels of aflatoxin (>60 µg/kg) in the food. When aflatoxicosis is suspected, the owner should be advised to retain 1 kg of food in an airtight zippered plastic bag (or four cans of food), for laboratory testing. It is also recommended to save packaging information, including product and date code, to help identify contaminated lots of food. If a sample of food is no longer available, serum or liver samples can be submitted for testing for aflatoxin M1 (aflatoxin metabolite), although usefulness may be limited because of the rapid metabolism and excretion of aflatoxin. Detection of aflatoxin M1 in urine is only useful if the dog is still consuming the contaminated diet, as levels fall below detectable levels within 48 hours.

There is no specific antidote for aflatoxicosis and treatment consists of symptomatic and supportive management of liver failure. Nonspecific hepatoprotective therapy with antioxidants (vitamin E), glutathione replacement (NAC, SAMe), milk thistle (silymarin), and L-carnitine have been recommended.[138] The prognosis is guarded if clinical signs of aflatoxicosis are present, with a reported mortality rate of 64% in a series of 72 dogs that consumed aflatoxin-contaminated dog food.[138] Dogs that survive acute liver injury have the potential to develop chronic liver disease. Consequently, monitoring of liver function is recommended in recovering dogs and treatment with thiol donors such as SAMe for 2 months has been empirically recommended.[138]

Amanita *Mushrooms*

Amanita phalloides (and other varieties such as *Amanita verna* and *Amanita bisporigera*), are poisonous mushrooms found throughout North America that can cause acute hepatic necrosis in dogs and cats.[162,163] Toxicity is attributed to extremely toxic cyclopeptide toxins called amanitins. Ingestion of two *A. phalloides* mushrooms can be lethal to an adult dog.[163] Clinical signs occur within 6 to 24 hours after ingestion and are characterized initially by GI signs such as vomiting, bloody diarrhea, and abdominal pain. The late phase (36 to 84 hours after exposure) is characterized by ALF (hemorrhage, marked hypoglycemia, HE, and terminal coma) caused by severe massive hepatic necrosis (see Figure 61-20). Toxin-induced renal tubular necrosis may also result in renal failure.[162] Biochemical features reflect severe hepatic injury and include increased liver enzyme activity (ALT exceeds ALP), refractory hypoglycemia, and hyperbilirubinemia. Diagnosis is usually made based on positive identification of the suspect mushroom, evidence of its ingestion, and consistent clinical features. Mushroom pieces in gastric contents can confirm exposure, but are difficult to identify. Accurate mushroom identification requires consultation with an experienced mycologist. The suspect mushrooms should be wrapped in paper towels and stored in a paper (not plastic) bag.[162] Definitive confirmation can be established by detecting amanitins in liver or kidney tissue (or serum and urine samples collected during the GI phase) by liquid chromatography-mass spectrometry, through the California Animal Health and Food Safety Laboratory.[163]

GI decontamination procedures are recommended as soon as possible after exposure, as described in the "Treatment" section of "Drug and Toxin-Induced Liver Injury". Symptomatic and supportive treatment for ALF is indicated, including close monitoring and treatment of marked hypoglycemia. Silymarin is believed to reduce hepatocyte uptake of amanitins and has been shown to be protective against experimental *A. phalloides* liver damage in Beagles, when given at a dose of 50 mg/kg IV twice, at 5 and 25 hours after exposure.[141] However, an intravenous form of silymarin is not currently available for clinical use in the United States. Experimental studies suggest that penicillin G may also reduce hepatic uptake of amanitins, even several hours after ingestions.[162] IV NAC may be beneficial as described for treatment of acetaminophen toxicity. Overall mortality rate with *Amanita* mushroom toxicity is high.

Blue-Green Algae

Ingestion of toxin-producing blue-green algae (*Microcystis aeruginosa*) is a rare cause of hepatotoxicity and ALF in dogs.[164] Algae proliferate in shallow, stagnant water, especially in hot, dry weather. Dead or dying algae form a thick blue-green scum on the water's surface, and release the toxic principle, microcystins. Toxicity is caused by ingestion of algae-contaminated water. Signs occur rapidly (within 1 hour of ingestion) and include vomiting, diarrhea, and lethargy, followed by progressive tachypnea and dyspnea, icterus, and coma. Biochemical features reflect hepatocellular injury with increased ALT and AST activity (that typically exceed increases in ALP activity), and hyperbilirubinemia. However, profound or protracted increases in ALT activity may not be detected, because microcystins can interfere with transaminase biosynthesis.[7] Hepatic lesions consist of massive hepatic necrosis of the centrilobular to midzonal hepatocytes. Treatment is symptomatic and supportive. Oxidative injury may play a role,[164] which suggests that glutathione supplementation (NAC or SAMe) may be of benefit. The prognosis is guarded.

Cycads (Sago Palms)

Cycads (Sago palms) are native to tropical and subtropical regions, and are used as houseplants and in residential landscaping. Concentrations of cycasin, the primary toxin in cycads, are highest in the seeds and roots, but present in all parts of the plant.[165] Ingestion of as few as one to two seeds can be fatal in dogs. Following ingestion, cycasin is metabolized by GI bacteria to its active compound, methylazoxymethanol, which causes GI and hepatic toxicity in dogs.[165] Most dogs that ingest cycads develop GI signs, including vomiting, diarrhea, and abdominal pain. Neurologic signs (weakness, ataxia, depression, proprioceptive deficits, seizures, coma) are also common, but it is not clear if they are a result of a neurotoxin or HE.[165] Onset of clinical signs ranges from 15 minutes to 3 days and may last from 24 hours to 9 days.[165] Hepatic injury is suggested by findings of progressive depression, icterus, HE, and excessive bleeding accompanied by increased liver enzyme activity, hyperbilirubinemia, hypoglycemia, and hypoabuminemia.[166,167] Centrilobular hepatic necrosis is found on liver biopsy.[166] No specific treatment is available. Mortality has been reported to vary between 32% and 58%.[165,167]

Xylitol

Xylitol, a 5-carbon sugar alcohol used as a sugar substitute, is associated with hypoglycemia and hepatic necrosis in dogs.[168,169] Xylitol is safe in humans and is commonly used in sugar-free gum and other oral care products, and is available as a granulated powder for baking. Xylitol was first introduced into the United States in 2002, and since that time, reports of toxicity to the ASPCA Animal Poison Control Center have increased from two dogs in 2002 to 2512 dogs in 2008.[168] Ingestion of more than 0.1 g/kg in dogs is associated with a rapid, severe, increase in blood insulin, which results in signs of hypoglycemia within 30 to 60 minutes of ingestion. When amounts exceed 0.5 g/kg, ALF may occur within 9 to

72 hours.[169] ALF is not necessarily preceded by early signs of hypoglycemia. The mechanism of hepatotoxicity is unknown, but has been speculated to be caused by cellular depletion of adenosine triphosphate resulting in hepatocellular necrosis, or production of reactive oxygen species causing oxidative injury.[169] In addition to signs of hypoglycemia, dogs with ALF may have vomiting, icterus, and evidence of excess bleeding. Biochemical findings include markedly increased ALT and AST activity, mild to moderate increased ALP activity, hyperbilirubinemia, hypoglycemia, hyperphosphatemia, prolonged PT and aPTT, and thrombocytopenia.

If ingestion occurred within the last few hours, induction of emesis is recommended (unless showing signs of hypoglycemia). Activated charcoal may be of limited value in adsorbing xylitol, but is still recommended if large amounts have been ingested.[168] Treatment recommendations include hospitalization for observation and monitoring, dextrose supplementation for control of hypoglycemia, and symptomatic and supportive care for complications of liver failure. Hepatoprotective therapy with NAC, SAMe, and silymarin may be beneficial. The prognosis is good for recovery in dogs with uncomplicated hypoglycemia and guarded to poor for dogs in liver failure. However, survival after liver failure does not necessarily correlate with amount of xylitol ingested.[169]

VASCULAR DISORDERS

Viktor Szatmari

Vascular hepatic diseases include congenital and acquired disorders of the *portal vein*. *Congenital* anomalies result from (a) hypoplasia or aplasia of the portal vein, (b) macroscopic communications between the portal vein and a systemic vein, or (c) between the portal vein and an artery. *Acquired* diseases result from conditions that increase the hydrostatic pressure in the portal vein (i.e., portal hypertension).

Macroscopic venous connections between the portal and systemic venous systems result in *portosystemic shunting* (i.e., blood flows from the portal to the systemic veins) via a CPSS or *acquired portosystemic collaterals* (APSC).

Clinical Manifestations

Congenital Portosystemic Shunt

Neurologic Signs

HE is a reversible central neurologic manifestation of hepatic insufficiency.[1] CPSS causes chronic HE. The following grades of chronic HE are recognized[2]: *grade 1*—depression, behavior changes; *grade 2*—ataxia, compulsive pacing, circling, hypersalivation, head pressing, blindness; *grade 3*—stupor and seizures; and *grade 4*—coma.

Chronic HE is characterized by periods of severe (grades 2 to 3) signs (lasting usually several hours to a few days alternating with longer periods (days to weeks) of no or mild (grade 1) symptoms.[2] Periods of cortical blindness are accompanied by apparent mydriasis. Signs of HE may be triggered by ingestion of protein-rich meals.

Polyuria and Polydipsia

PD means excessive fluid intake (in dogs >100 mL/kg body weight/24 h and in cats >50 mL/kg body weight/24 h). PU may be more difficult to diagnose than PD, as pet owners cannot readily measure urine volume. Repeated low specific gravity of morning urine (<1.025 in dogs and <1.030 in cats) is compatible with PU.

Lower Urinary Tract Disease

Ammonium biurate uroliths are formed most of the time in the bladder (and rarely in the renal pelvis) and can cause dysuria, urethral obstruction in males, and seldom uroabdomen as a result of chronic inflammation and subsequent devitalization of the bladder wall.[3]

Ammonium biurate crystalluria is not pathognomonic for portosystemic shunting, and it may occasionally occur in normal dogs and cats, or be found in certain breeds, such as Dalmatians, because of an inborn error of metabolism.

Anesthesia Intolerance

Prolonged recovery from anesthesia or sedation may occur in seemingly normal dogs and cats that have CPSS. The liver plays a crucial role in the detoxification process of toxins and drugs, including anesthetics. Patients with CPSS or APSC have insufficient functional hepatic mass for detoxification. In addition, dogs with portosystemic shunting have increased endogenous benzodiazepine and GABAergic activities.[4] Therefore administration of diazepam or barbiturate to these animals may have prolonged and exaggerated effects (see "Pathogenesis" section).

Fever

Recurrent fever together with resultant depression and anorexia can be the only clinical manifestation of CPSS in some dogs.[5] Portosystemic shunting should be excluded in dogs experiencing recurrent fever.

Episodic Weakness

This rare manifestation has only been reported in a few dog.[6] Its pathogenesis is not understood.

Hypercortisolism (Pseudo-Cushing Disease)

Elderly dogs with extrahepatic CPSS may present with characteristic signs of hypercortisolism (e.g., PU/PD, polyphagia, thin skin, symmetric alopecia, muscle wasting, pot belly) as primary complaints. These are unusual clinical manifestations of CPSS.

Stunted Growth

Although small body size is observed in cats with CPSS, it infrequently occurs in dogs.

No Symptoms

Many dogs with extrahepatic CPSS show no or only nonspecific clinical signs throughout their lives and the shunt is detected as a coincidental finding at the time of necropsy. It is not understood why certain dogs become clinically ill and others do not with the same type of portal vein anomaly.

No Jaundice, No Ascites, No Hemorrhagic Diathesis

CPSS never cause icterus, ascites, or spontaneous hemorrhages.

In Cats

Portal vein disorders are much less common in cats than in dogs. Most cats are younger than 6 months of age when the first signs appear.[7] Cats with CPSS are often of smaller stature and have unkempt hair coat. Episodic salivation and/or central neurologic signs, for example, compulsive pacing or seizures, as manifestations of HE are the most typical presenting complains.[8,9]

Portal Hypertension

Clinical signs can develop at any age and arise from the presence of increased hydrostatic portal venous pressure, portosystemic

shunting via APSC, and the underlying disease that led to portal hypertension.

Signs from Acquired Portosystemic Collaterals

Clinical signs of portosystemic shunting are similar, regardless whether it is congenital or acquired in origin (see "Clinical Manifestations" section).

Ascites

Accumulation of a large amount of pure transudate or modified transudate (clear, straw-colored, or slightly turbid blood-tinged fluid) in the abdominal cavity is commonly detected with physical examination and abdominocentesis. The absence of free abdominal fluid does not exclude portal hypertension.

Signs from Acquired Underlying Diseases

Depending on the etiology and the anatomic location of the underlying disease that led to the development of portal hypertension various signs may be seen such as jaundice, periodic vomiting, and anorexia.

Signs from Congenital Underlying Diseases

Jaundice and hemorrhagic diathesis are absent in congenital vascular disorders. Congenital arterioportal fistula causes transudative ascites in puppies between 2 and 6 months of age.[10]

Primary hypoplasia of the portal vein (PHPV), also described as "noncirrhotic portal hypertension,"[11] may result in ascites, vague GI signs, and HE, or may be entirely subclinical.[12,13]

When the PHPV is not severe enough to cause portal hypertension, clinical signs may not be obvious. This mild form of PHPV is also known as *hepatic microvascular dysplasia*[14] and may be detected serendipitously if plasma bile acid concentrations are measured for unrelated reasons.

In Cats

Portal hypertension is rare and is not typically associated with ascites in cats.[15] Portosystemic shunting because of CPSS or APSC tend to cause similar signs, for example, periodic salivation and seizures, as manifestations of chronic HE.

The most common acquired disease causing intrahepatic portal hypertension is biliary cirrhosis caused by chronic bile duct obstruction. Jaundice and acholic feces are typical findings in extrahepatic cholestasis.

Pathogenesis

Hepatic Blood Flow

Normal Hepatic Circulation

The liver receives its blood supply from the portal vein (approximately 75%) and the hepatic artery (approximately 25%). With diversion of portal venous blood flow, a compensatory increase of the hepatic arterial flow occurs. Arterial vasodilation is mediated by adenosine from energy-depleted hepatocytes.

The portal vein transports blood from the spleen and the GI tract to the liver.[16] The smallest portal venous and hepatic arterial branches terminate in the capillary system of the liver, the so-called hepatic sinusoids. A large amount of plasma is filtered through the fenestrated walls of the sinusoids to the space of Disse. From here the filtered plasma is taken by lymphatic vessels to the systemic venous system. The remaining sinusoidal blood is then collected by the hepatic veins, which enter the caudal vena cava. Normally no macroscopic connections exist between major vessel systems or their tributaries.

Portosystemic Shunting

Single or multiple portosystemic venous connections allow the portal venous blood to flow directly to the systemic venous system without first flowing through the hepatic sinusoids. This toxin-rich blood will be delivered to all cells of the body through the following route: gut > portal vein > shunt > systemic vein > right heart > lungs > left heart > arteries. A connection through a single, or rarely double, large-bore vein without the presence of portal hypertension is considered to be a CPSS. Single or multiple connections in the presence of portal hypertension are APSC.

Whenever a macroscopic venous connection is present between the portal vein (or one of its tributaries) and a systemic vein, the blood will flow from the portal vein to the systemic vein, because the pressure in the portal vein is higher (8 to 10 mm Hg) than that in the systemic veins.[8]

Portal Hypertension

Normal portal venous pressure is approximately 8 to 10 mm Hg (10 to 13 cm H_2O). Increased pressure in the portal venous system results in portal hypertension. Anatomically, portal hypertension can be classified[17] as (a) prehepatic (i.e., portal vein), (b) intrahepatic or (c) posthepatic (i.e., hepatic veins, thoracic caudal vena cava, or heart).

Posthepatic Portal Hypertension. All cardiac diseases that result in right-sided congestive heart failure cause posthepatic portal hypertension. These diseases include the (a) congenital or acquired insufficiency of the tricuspid valve (e.g., dysplasia with or without stenosis, myxomatous degeneration, annulus dilation caused by dilated cardiomyopathy, pulmonary hypertension), (b) pericardial diseases (pericardial tamponade caused by idiopathic or neoplastic effusion or constrictive pericarditis), (c) cor triatriatum dexter, (d) intracardiac tumors affecting the right heart, and (e) caval syndrome (caused by *Dirofilaria immitis* heart worms). Kinking or compression of the thoracic caudal vena cava occurs rarely. Compression or thrombosis of the hepatic veins (the so-called Budd-Chiari syndrome) does not occur in dogs and cats.[13]

In posthepatic portal hypertension the portal and caval pressures increase equally, so no pressure gradient is present. Therefore no APSC develop, and the blood ammonia concentration remains within reference range. The high sinusoidal hydrostatic pressure causes a large amount of protein-rich hepatic lymph to be filtered through the hepatic capsule into the abdominal cavity causing accumulation of a modified transudate. Modified transudate has high protein content because the fenestrated endothelial cells of the hepatic sinusoids keep only 10% to 20% of the plasma proteins in the capillary lumen. Marked generalized hepatomegaly and dilated hepatic veins as well as caudal vena cava are hallmarks of posthepatic portal hypertension.

Intrahepatic Portal Hypertension. Chronic *acquired* parenchymal liver diseases lead to hepatocyte necrosis and subsequent collagen deposition. The resultant disorganization of the hepatic architecture and contraction of the connective tissue results in obstruction of the intraparenchymal vessels. The underlying disease processes include viral, bacterial, protozoal, immune-mediated, or copper-associated chronic hepatitis; toxic, drug-induced, or idiosyncratic liver damage; lobular dissecting hepatitis; and chronic bile duct

obstruction. The resultant increase in portal pressure may cause development of APSC as well as ascites.

Modified transudate may accumulate in the abdominal cavity when the disease process predominantly obstructs the postsinusoidal hepatic venules. However, when the disease process affects predominantly the intrahepatic portal vein branches (presinusoidal portal hypertension) pure transudate will accumulate in the abdomen.

Primary hypoplasia of the portal vein is caused by insufficient development of the intrahepatic portal venous branches, the left portal vein branch, or the whole portal venous system.[12,18]

When the hypoplasia is severe enough to cause intra- or prehepatic portal hypertension, APSC develop. This condition is also known as "noncirrhotic portal hypertension."

If hypoplasia is not severe enough to cause portal hypertension, clinical signs will not develop. Because no portosystemic shunting is present, the results of rectal ATT, portal scintigraphy, and portography are all normal (see "Differential Diagnosis" section). If either macroscopic or microscopic portosystemic communications is present, hyperammonemia or abnormal ATT should also be present, but this has never been documented. The only abnormality that could be detected in these dogs is elevation of serum bile acids levels.[14] The most plausible explanation for this is that the hepatic clearance of bile acids by the hypoperfused liver is probably less effective than that of ammonia. The disease can only be diagnosed by histopathologic examination of liver biopsy specimens. This condition also has been described as "hepatic microvascular dysplasia." Although the terms *noncirrhotic portal hypertension* and *hepatic microvascular dysplasia* have been used to describe this syndrome, both have been replaced by the term PHPV.[13] The occurrence of PHPV in the cat is very rare and poorly documented.

The most common congenital cause of portal hypertension in cats is congenital hepatic fibrosis as a part of polycystic kidney and liver disease complex.[19] This disease may cause clinical signs with or without the presence of macroscopic hepatic or renal cysts.[20]

Prehepatic Portal Hypertension. Narrowing of the portal vein lumen may be caused by (a) extravascular compression by a tumor, enlarged lymph node, cyst, abscess, or hematoma, (b) idiopathic circumscribed stenosis,[21] or (c) intravascular obstruction by a thrombus or parasites, all of which can lead to portal hypertension.[22] Portal vein thrombosis is always secondary either to neoplasia, or to a systemic disorder that causes hypercoagulability such as nephrotic syndrome, immune-mediated hemolytic anemia, hypercortisolism, acute pancreatitis, peritonitis, or sepsis.[23] Parasites in the portal vein also may occur, for example, *Heterobilharzia americana* in North America[24] and *Schistosoma japonicum* in East Asia.[13]

Depending on the degree of portal vein occlusion, increased portal pressure with APSC and ascites may develop. As the hydrostatic pressure in the sinusoids does not increase (in contrast to posthepatic portal hypertension), the resultant ascitic fluid will have a low protein content. The narrowed lumen of the portal vein causes reduced portal flow to the liver, resulting in reduction in the size of the liver. Portal vein thrombosis itself rarely causes clinical signs and is usually a coincidental finding.

Congenital Arterioportal Fistula. Single or multiple macroscopic connections between the main portal vein and hepatic artery are rare congenital anomalies. The high arterial blood pressure causes (a) severe dilation and tortuosity of the affected portal venous branch, (b) hepatofugal flow in the portal vein (i.e., flow away from the liver), (c) development of portal hypertension and APSC, and (d) histologically detectable arterialization of the portal venous wall. The hepatofugal portal flow prevents the splanchnic venous blood from entering the liver and causes the development of alternative pathways and often times accumulation of pure transudate in the abdomen. Interestingly, PHPV always accompanies congenital arterioportal fistulas both in dogs and cats.[5,10,25] When a CPSS and arterioportal fistulas are concomitantly present, APSC and ascites generally do not develop.[25] Arterioportal fistula can be extrahepatic in cats..

Acquired Portosystemic Collaterals. In healthy mammals, multiple nonfunctional venous connections may exist between the portal and systemic veins. These virtual communications become functional when their lumen becomes sufficiently widened. Gradual dilation takes place when sustained increase of the portal pressure takes place without the simultaneous increase of caval pressure. The resultant APSC are multiple, usually thin, tortuous veins with species-specific anatomical locations; however, large-bore veins may also develop. These latter cases should not be misinterpreted as simultaneous CPSS and APSC. In the presence of an existing CPSS, no APSC would develop even if hepatic cirrhosis develops as there *is* an already existing portosystemic connection that is able to drain 100% of the portal blood without allowing the development of portal hypertension.[26] Splenorenal collaterals are consistently present in almost every dog with APSC.[10,27] These APSC drain the portal venous blood via the splenic vein through acquired connections to the left gonadal vein. The left gonadal vein enters the left renal vein, which later empties into the caudal vena cava. These splenorenal APSC are thought to prevent the spleen from undergoing congestion,[17] which is why splenomegaly is not a feature of canine pre- and intrahepatic portal hypertensive disorders.[10]

Consequences of Hepatic Hypoperfusion for the Liver

Shunting of the portal blood is not only detrimental for the brain, but for the liver as well. Normal hepatic development and function requires sufficient amount of portal venous perfusion of the hepatic sinusoids. Increased arterial perfusion is unable to compensate for portal hypoperfusion. Regardless of whether the insufficient portal venous perfusion is caused by CPSS or by prehepatic portal hypertension, the result is the same: reduced hepatic mass and function. In both cases, histopathologic evaluation of the liver shows stereotypical reaction: small or invisible portal branches, increased number of arterioles and sometimes bile ductules in the portal tracts, hepatocellular atrophy, and periportal sinusoidal dilation.[13] This *secondary* portal vein hypoplasia is reversible and is histologically indistinguishable from PHPV. Because primary and secondary portal vein hypoplasia show identical microscopic features, histopathologic evaluation of liver biopsy specimens is unable to diagnose simultaneous PHPV and CPSS.

Hepatic Encephalopathy

Glycine and GABA are the most important inhibitory neurotransmitters, whereas glutamate and dopamine are the most abundant excitatory neurotransmitters in the brain. In HE, a net increase in inhibitory transmission occurs.[28] This results from upregulation of GABA receptors and downregulation of dopamine receptors.[29] Activation of GABA receptors causes opening of chloride channels, which leads to hyperpolarization of the postsynaptic membrane. In the presence of GABA, benzodiazepines increase the frequency, whereas barbiturates increase the duration of the chloride channel opening.[30] The cause of increased GABAergic tone in HE is thought to be gut derived,[4] but GABA may also be formed in the neurons from glutamate.[28] Endogenous benzodiazepines are proven to be

produced in the intestines of dogs with CPSS.[4] Their source is not quite clear: they could arise from the diet, intestinal flora, or by endogenous modification of inactive gut precursors.[4]

In all forms of portosystemic shunting the concentration of aromatic amino acids are increased in the systemic circulation whereas the concentration of branched-chain amino acids is decreased. High aromatic amino acid concentration results from impaired hepatic clearance and increased production caused by muscular breakdown exacerbated by hyperglucagonemia.[28,31] The decreased concentration of branched-chain amino acids results from their increased utilization for gluconeogenesis.[28,32] This amino acid imbalance may result in the development of "false" neurotransmitters (e.g., octopamine) in the brain, which contribute to the development of HE.[33,34] These "false" neurotransmitters have a fraction of dopamine's excitatory effect on dopamine receptors. Drugs with dopaminergic effect, such as bromocriptine, may improve signs of HE.[35-37]

Intestinal toxins such as ammonia and bacteria are normally inactivated by hepatocytes and hepatic macrophages (Kupffer cells), respectively, so that toxin- and bacterium-free blood can enter the systemic circulation. In patients with portosystemic shunting the majority of the portal venous blood bypasses the liver, allowing the toxin- and bacterium-rich blood to enter the systemic circulation. Ammonia is a neurotoxin and can contribute to the clinical signs of HE.[38] Other toxins that are believed to play a role in HE are endogenous benzodiazepines, GABA, tryptophan, glutamine, serotonin, mercaptans, indoles, and skatoles.[4,34,39]

Hyperammonemia also leads to impaired glial function through increased intracellular glutamine concentration.[38] Glutamine is made in the glial cells through incorporation of ammonia into glutamate by glutamine synthetase.[28] Chronically increased glutamine concentrations cause swelling of the glial cells resulting in so-called Alzheimer II type degeneration of astroglias.[40,41] Glial dysfunction contributes to the development of HE.[40,42] During hyperammonemia, the reserve capacity of the astrocytic glutamine synthetase is exceeded, and ammonia can enter the neurons.[42] In the neurons ammonia inhibits glutaminase, an enzyme that converts glutamine to glutamate. Because glutamate is an excitatory neurotransmitter, its reduced level contributes to the development of HE.[28]

Portosystemic shunting or an atrophic liver alone is insufficient to allow HE to develop; HE can only develop when they are both simultaneously present.[28] The reserve capacity of the liver ensures that even in advanced chronic parenchymal liver diseases, HE does not develop in the absence of portosystemic shunting. Alkalosis and hypokalemia can worsen the signs of HE. In alkalosis the $NH_3 + H^+ = NH_4^+$ reaction shifts to the left, causing the more lipophilic ammonia to enter the cells of the CNS. During hypokalemia, potassium ions (K^+) move from the cells to the extracellular space in exchange for H^+, which later results in extracellular alkalosis and intracellular acidosis. Intracellular acidosis causes NH_4^+ trapping within the cells. This might explain why the blood concentration of ammonia is not closely related to the severity of the clinical signs of HE in individual cases.

Polyuria and Polydipsia

Several mechanisms contribute to the development of PU/PD in portosystemic shunting.

Hypoosmotic Renal Medulla

High concentrations of sodium and urea in the renal medullary interstitium are essential for the production of concentrated urine. These create a high osmotic gradient between the renal tubular lumen and interstitium, which is necessary for water reabsorption. When the liver receives little portal venous blood, an insufficient amount of substrate (i.e., ammonia) is available for hepatic urea production. This theoretically results not only in a low plasma urea concentration, but also in a lower renal medullary urea concentration, which impairs renal concentrating ability and causes PU.

Hypercortisolism

Increased basal plasma concentrations of ACTH and cortisol as well as increased urinary cortisol-to-creatinine ratios are invariably present in dogs with portosystemic shunting.[43-46] Cortisol interferes with the action of arginine-vasopressin at the renal tubule, causing a *nephrogenic-type* diabetes insipidus.[47] Hypersecretion of ACTH (and α-melanocyte stimulating hormone [α-MSH]) has been shown to arise predominantly from the intermediate lobe of the pituitary.[43,48] The hormone secretion of this lobe is regulated by tonic dopaminergic inhibition. ACTH-hypersecretion can be explained by the production of "false" neurotransmitters (e.g., octopamine), whose effect is about one-fiftieth that of dopamine on the dopamine receptors.[35]

Diabetes Insipidus

Central diabetes insipidus also contributes to PU in dogs with HE. Impaired release of arginine-vasopressin from the posterior lobe of the pituitary is caused by a reduced magnitude of response and a highly increased threshold to increased plasma osmolality.[45] Release of arginine-vasopressin is inhibited by the GABA inhibitory neurotransmitter system, whose activity is increased in HE.[29,45]

Pseudohyperaldosteronism

Cortisol and aldosterone have similar affinities to bind aldosterone receptors. However, cortisol is normally inactivated by 11β-hydroxysteroid dehydrogenase in tissues where aldosterone action is required.[49] High serum bile acids concentrations inhibit this enzyme, and cortisol can bind to aldosterone receptors resulting in increased mineralocorticoid effect.[45] Plasma cortisol concentrations are 10-fold those of aldosterone, causing constant and inappropriate pseudohyperaldosteronism. The resultant sodium retention causes secondary water retention and subsequent PU by pressure diuresis. Hypokalemia caused by hyperaldosteronism also contributes to PU[50,51] according to the following mechanism. The presence of aquaporin-2 channels in the renal collecting ducts' cell membranes is necessary for water reabsorption. Intracellular signaling pathways through cyclic adenosine monophosphate regulate the insertion of these channels. Hypokalemia decreases the sensitivity of cyclic adenosine monophosphate to arginine-vasopressin, which results in decreased insertion of aquaporin-2 channels into the cell membrane.[50] This leads to nephrogenic diabetes insipidus and PU.

Renomegaly and Renal Hyperfunction

Congenital portal venous anomalies in dogs are typically associated with enlarged kidney volume. Increased renal gluconeogenesis as a compensation of insufficient hepatic gluconeogenesis may cause the kidneys to enlarge.[52] In addition, increased systemic circulating growth factor concentrations released from the pancreas may play a role in this increased volume.[53] Normally, these growth factors act only in the liver, as they do not reach the systemic circulation in high concentrations.

Primary Polydipsia

Behavior changes and abnormalities in the thirst center due to HE may contribute to PD; however this is difficult to prove in individual patients.

Urolithiasis

Hyperammonemia results in a higher filtered load and urinary concentration of ammonia. High urinary concentration of uric acid results from decreased hepatic conversion of uric acid to allantoin because of reduced hepatic mass and function.

Fever

The portal vein carries bacteria and endotoxins from the intestines, which are normally phagocytized by the Kupffer cells. Shunting of portal blood permits these bacteria and/or endotoxins to enter the systemic circulation causing bacteremia and/or endotoxemia, and subsequent fever.[5] Systemic antibiotics may result in temporary resolution of clinical signs, however give no definitive cure.

Etiologies

Congenital Portosystemic Shunt

If a CPSS occurs within hepatic parenchyma it is called *intrahepatic*.[54,55] Intrahepatic CPSS arise either from the left or right portal branches. A left divisional intrahepatic CPSS results from the failure of postnatal closure of the embryological *ductus venosus*.[56,57] The intrahepatic CPSS arising from the right portal branch and all *extrahepatic* CPSS are thought to be developmental anomalies with poorly understood etiology. In dogs the anatomy of the shunting vessel is fairly consistent: intrahepatic CPSS may be left, right, or central divisional, whereas extrahepatic shunts drain the portal venous blood via the splenic or the right gastric vein to the caudal vena cava or the azygos vein.[15] The course of the shunting vein in the cat is much more variable.[15,58]

The inherited nature of the disease has been established in several breeds including the Irish Wolfhound and the Yorkshire and Cairn Terriers.[59-61]

Portal Hypertension

PHPV is a congenital anomaly of unknown etiology. Although arterioportal fistulas may develop as a result of neoplasm or trauma (e.g., shot wound or liver biopsy), only the congenital form has been reported in dogs and cats. Congenital hepatic fibrosis caused by polycystic kidney disease (PKD) is a genetic disease.[19,62]

Differential Diagnosis

Hyperammonemia

High fasting venous blood ammonia concentrations together with high fasting serum bile acid concentrations are very specific and sensitive tests for diagnosing portosystemic shunting.[63]

Urea Cycle Enzyme Deficiency

Reduced activity of one or more enzymes of the urea cycle may result in elevated blood ammonia concentration.[10,64] Serum bile acids levels should remain within reference range in patients with urea cycle enzyme deficiencies. Normal hepatic scintigraphy and liver histopathology results should confirm the absence of portosystemic shunting. Certain metabolites (e.g., citrulline) and enzyme activities (e.g., argininosuccinic acid synthetase) can be measured in urine and liver biopsy specimens, respectively, to establish a definitive diagnosis. The condition is rare in dogs. One suspected feline case has been reported.[65]

Irish Wolfhound Puppies

Healthy Irish Wolfhounds commonly have moderate hyperammonemia (<120 µmol/L) at the age of 6 to 7 weeks.[66] This is thought to result from reduced enzyme activity of the urea cycle. As no clinical signs are present, no treatment is required. The condition resolves spontaneously with age because these pups develop enhanced incorporation of ammonia into glutamine.

Uroabdomen

Peritoneal absorption of ammonia-containing urine can cause hyperammonemia, however in such a patient the clinical signs of acute uremia predominate. The presence of urease-producing bacteria (e.g., *Staphylococci*) are necessary to split urinary urea to ammonia.[67]

Fulminant Hepatic Failure

Ingestion of blue algae or certain mushrooms (e.g., *A. phalloides*) results in peracute insufficiency of hepatic function. These animals develop hepatic coma and die shortly thereafter. Hyperammonemia, DIC, and icterus are present in most affected patients.

Arginine Deficiency in Cats

Arginine is an essential amino acid in the cat. In anorectic cats hyperammonemia may develop along with hepatic lipidosis because of the insufficient amount of hepatic arginine needed for urea synthesis in the urea cycle.[68] Thus, in contrast to adult dogs, hyperammonemia in cats can occur without portosystemic shunting.

Miscellaneous Disorders

Methylmalonic acidemia associated with cobalamin deficiency in a cat[69] and a suspected "transient hyperammonemic syndrome" in a German Shepherd dog[70] have been reported as extraordinarily rare causes of hyperammonemia.

Sampling or Laboratory Error

If blood sampling and sample processing are performed inappropriately hyperammonia may be erroneously diagnosed.

High Serum Bile Acid Concentrations

High bile acids concentration may result not only from portosystemic shunting, but also from any primary or secondary hepatic diseases associated with intra- or extrahepatic cholestasis.[71] Therefore, the presence of high serum bile acids concentrations is very sensitive, but not a specific indicator of portal venous disorders.[63]

Ascites

The simultaneous presence of hyperammonemia and a large amount of pure or modified transudate in the abdominal cavity indicates the presence of severe pre- or intrahepatic portal hypertension with APSC. Biochemical and cytologic analysis of the peritoneal effusion, ultrasonography and central venous pressure measurement may be useful in identifying the source of ascites.[17] Suspected intrahepatic causes should be further evaluated by histopathologic examination of liver tissue.

Central Neurologic Signs

In any animal that is presented with central neurologic signs, portosystemic shunting (along with other metabolic encephalopathies, e.g., hypoglycemia or electrolyte imbalance) should be investigated with appropriate blood tests.

Diagnosis

No single finding is pathognomonic for diagnosing vascular liver disorders. Therefore, a combination of history, physical

examination, laboratory tests, diagnostic imaging results and histopathology of liver biopsy specimens are often required to establish a specific diagnosis.

Signalment

Intrahepatic CPSS tend to cause clinical signs between 2 months and 1 year of age in large-breed dogs. Bernese mountain dogs, Irish Wolfhounds, Hovawarts, and Retrievers are predisposed. Australian Cattle dogs and male dogs more likely have right-sided than left-sided intrahepatic CPSS,[72] whereas Irish Wolfhounds tend to have left-sided intrahepatic CPSS. Intrahepatic CPSS in small-breed dogs are very rare. Extrahepatic CPSS usually occur in small breeds and can cause clinical signs at any age.[73] The most commonly affected breeds are Maltese dogs, Miniature Schnauzers, Dachshunds, Yorkshire Terrier, Jack Russell Terrier, and Cairn Terrier. No clear sex predisposition is known.

History

The waxing–waning nature of central neurologic signs is suggestive of chronic HE. Symptoms may improve spontaneously.

Physical Examination

Congenital Portosystemic Shunts

Physical examination often fails to detect abnormalities. Occasionally an enlarged left kidney is palpated. The presence of ascites detectable with physical examination should exclude CPSS. Some authors suggest that copper-colored iris is a typical finding in cats with CPSS; however, no reports exist about its positive or negative predictive value.

Portal Hypertension

Dogs with intra- or prehepatic portal hypertension may have ascites. Jaundice is absent in congenital portal hypertensive disorders, but may be present in acquired parenchymal liver diseases.

Laboratory Examination

Blood Ammonia Concentration

Fasting (12-hour) venous hyperammonemia is a very specific and sensitive indicator of portosystemic shunting. As a single test, increased blood ammonia level is usually sufficient to diagnose portosystemic shunting. Because ammonia is formed from amino groups of proteins and urea also in the collection tube, the blood sample (in an ethylenediaminetetraacetic acid tube) should be placed directly on ice after sampling and the measurement should be performed within 30 minutes. Because contamination of the sample with airborne ammonia may cause false-positive results, samples should be taken using a closed system (needle on a syringe or directly into a Vacutainer). Hemolysis may artificially increase ammonia concentration because erythrocytes contain two to three times more ammonia than the plasma. Measurement of ammonia should be performed in a clean location, where the air is not contaminated with ammonia from congested urine or cigarette smoke. A number of analyzers offer the possibility of ammonia measurement; however some of them are unreliable.[46] Measuring *arterial* ammonia concentration provides no additional value.

Ammonia Tolerance Test

If venous ammonia concentration is within the reference range or only slightly elevated, rectal ATT is the cheapest and quickest test to exclude or justify the presence of portosystemic shunting in patients with a suggestive history. Most of these "suspicious" animals also have high fasting plasma bile acids levels.[74] Ammonium chloride (NH_4Cl) solution of 5% is administered at a dose of 2 mL/ig 10 mg/kg maximum 3 grams to 15 cm into the rectum using a soft feeding tube.[75] Venous blood ammonia is measured before and 20 and 40 minutes thereafter. In the presence of portosystemic shunting the ammonia concentration will increase at least twofold by the 20- and/or 40-minute sampling times. Normal ATT result excludes portosystemic shunting (Figure 61-21). The degree of increment is a semiquantitative measure of the degree of portosystemic shunting. It should be noted that rectal administration of NH_4Cl solution may cause transient irritation of the colonic mucosa during the first 10 minutes. Rectal ATT is a safe procedure, with signs of HE rarely occurring. ATT should not be performed in patients with very high (>150 μmol/L) blood ammonia levels.

Postprandial measurement of ammonia is thought to decrease the possibility of iatrogenic hyperammonemic HE; however the increase of blood ammonia concentration after feeding takes longer and its peak time point is poorly predictable.[76]

Serum Bile Acid Concentrations: Pre- and Postprandial

Markedly increased preprandial (i.e., 12-hour fasting) bile acids concentrations are often found with portosystemic shunting as a result of interrupted enterohepatic circulation of the bile acids.[77,78] High 12-hour fasting plasma bile acid concentration is a sensitive, but nonspecific indicator of portosystemic shunting. Specificity can be increased by simultaneous measurement of venous ammonia. As plasma bile acids concentrations are invariably high in icteric animals, the presence of APSC can only be justified or excluded by measuring blood ammonia concentration or performing an ATT.

In case of a normal 12-hour fasting bile acids concentration (<15 μmol/L), measuring an increased postprandial plasma bile acids concentration (>25 μmol/L) 2 hours after a meal increases the sensitivity, but not the specificity of the bile acids test in diagnosing portosystemic shunting.[79] Meal-induced gallbladder contraction causes an endogenous bile acid load, which will be absorbed in the ileum and will substantially increase the plasma bile acids concentration when portosystemic shunting is present. An abnormal postprandial increase of bile acids occurs also in cholestatic liver diseases.

Miscellaneous Biochemical Alterations

In patients with portosystemic shunting hypoalbuminemia, hypoproteinemia, hypocholesterolemia, and low plasma urea concentration may be found as a result of their reduced hepatic synthesis. Hypoglycemia may be seen as a result of reduced hepatic glyconeogenesis and glycogen storage. Low creatinine concentration reflects the increased glomerular filtration rate.[53] None of these biochemical changes is specific for portosystemic shunting; furthermore, many of these findings may be present in healthy pups. The cause of mild increase of plasma ALT and alkaline phosphatase activities is not fully understood.

Hematologic Alterations

Microcytosis with or without mild nonregenerative anemia and leukocytosis may accompany portosystemic shunting. Relative iron deficiency is thought to cause the microcytosis[80-82] and bacteremia may induce the leukocytosis.

Coagulation Abnormalities

Although aPTT is often moderately prolonged in dogs with CPSS, no spontaneous bleeding tendency or hemorrhage occurs.[83,84] Hemoabdomen is a possible postoperative complication after surgical attenuation of a CPSS. Acquired parenchymal hepatic diseases

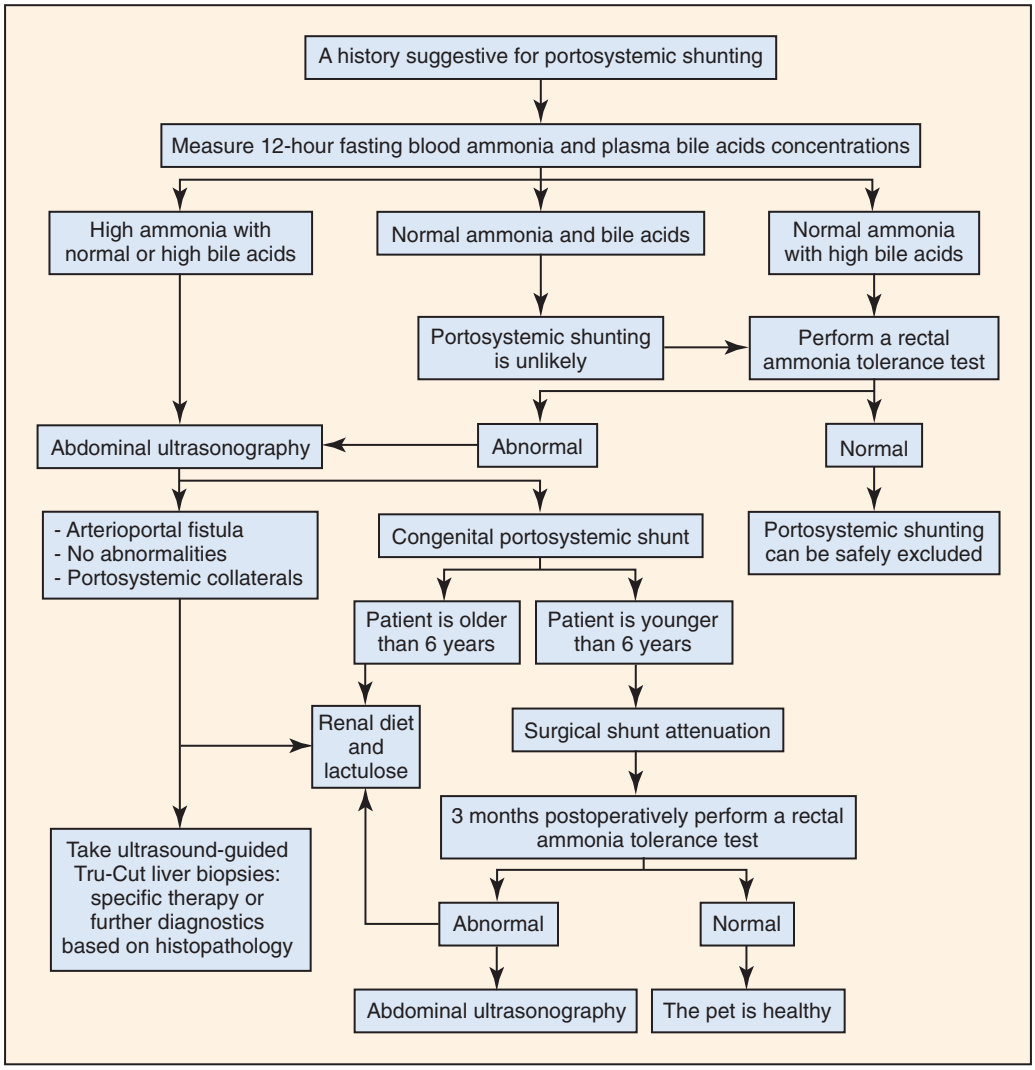

Figure 61-21 Algorithm of diagnostic steps for vascular liver disorders.

may lead to spontaneous hemorrhages because of the presence of DIC.

Diagnostic Imaging

Radiography

Plain radiographs give very limited additional information (such as small liver, possibly enlarged kidneys, and sometimes visible uroliths) to the history and laboratory results, so they don't have to be part of the routine diagnostic workup of vascular liver diseases. Pure ammonium biurate uroliths are radiolucent.

Ultrasonography

Abdominal ultrasonography is the first choice of diagnostic imaging modality, once the presence of portosystemic shunting has been established by fasting hyperammonemia or abnormal rectal ATT (see Figure 61-21). The major advantage is that ultrasonography requires no sedation or anesthesia. Its drawback is in the operator dependence. By using a systematic examination protocol one can accurately differentiate CPSS from APSC, and intrahepatic from extrahepatic CPSS, as well as readily diagnose arterioportal fistulas and prehepatic portal hypertensive disorders.[15,85,86] Although color-flow Doppler highly facilitates evaluation of portal vascular anomalies, a high-resolution grayscale ultrasound is often sufficient to establish a definitive diagnosis.[10]

Although certain secondary changes (such as small liver, large kidneys with hyperechoic medulla, and sediment or stones in the urinary bladder) suggest the presence of CPSS, diagnosing a CPSS requires the visualization of the anomalous vein from its origin to its termination. The urinary bladder should always be evaluated for the presence of urinary calculi. Ultrasonography can be used not only during the initial diagnostic workup, but also during the surgical treatment and postoperative followup of CPSS.[86] Intraoperative grayscale ultrasonography facilitates localizing the course of an intrahepatic CPSS,[26] whereas intraoperative color and spectral Doppler examination helps to determine the optimal degree of shunt attenuation.[87]

Scintigraphy

Free ^{99m}Tc-pertechnetate administered into the colon is absorbed into the portal vein and appears in the healthy liver first or in the heart with portosystemic shunting.[88] Isotopically labeled albumin macroaggregates may be directly administered into a splenic vein with ultrasound guidance.[89] The macroaggregates are trapped in the first capillary bed, which is normally the liver. The fraction of portal

blood that bypasses the liver will be trapped in the pulmonary capillaries. Splenic venous injection of isotopes makes exact calculation of the shunting fraction possible (i.e., activity in lungs/activity in liver + lungs); however, the procedure requires anesthesia.

Scintigraphy is the gold standard diagnostic imaging method to justify or exclude the presence of portosystemic shunting. However, differentiating congenital from acquired portosystemic shunting or intrahepatic from extrahepatic CPSS is not possible. Information provided by a scintigram is a "yes" or "no" answer to the question: Does the patient have portosystemic shunting? This answer can be reached much more easily and without using radiopharmaceuticals by documenting a single high blood ammonia concentration or by rectal ATT.

Angiography

Injection of iodinated contrast agent into the portal vein or into one of its tributaries under fluoroscopy used to be the only form of diagnostic imaging available to diagnose anomalous vessels. Angiography allows identification of extra- and intrahepatic CPSS as well as APSC.[90] The major drawback of selective portography is its invasiveness and the need for general anesthesia. Whereas *mesenteric* portography requires catheterization of a mesenteric vein during laparotomy,[91] *splenic* portography can be performed by ultrasound-guided percutaneous injection of contrast material into a parenchymal splenic vein. Visualizing portal vein segments with hepatofugal flow or shunt segments with hepatopetal flow (Figure 61-22) is problematic, as no contrast reaches these parts of the vessels.

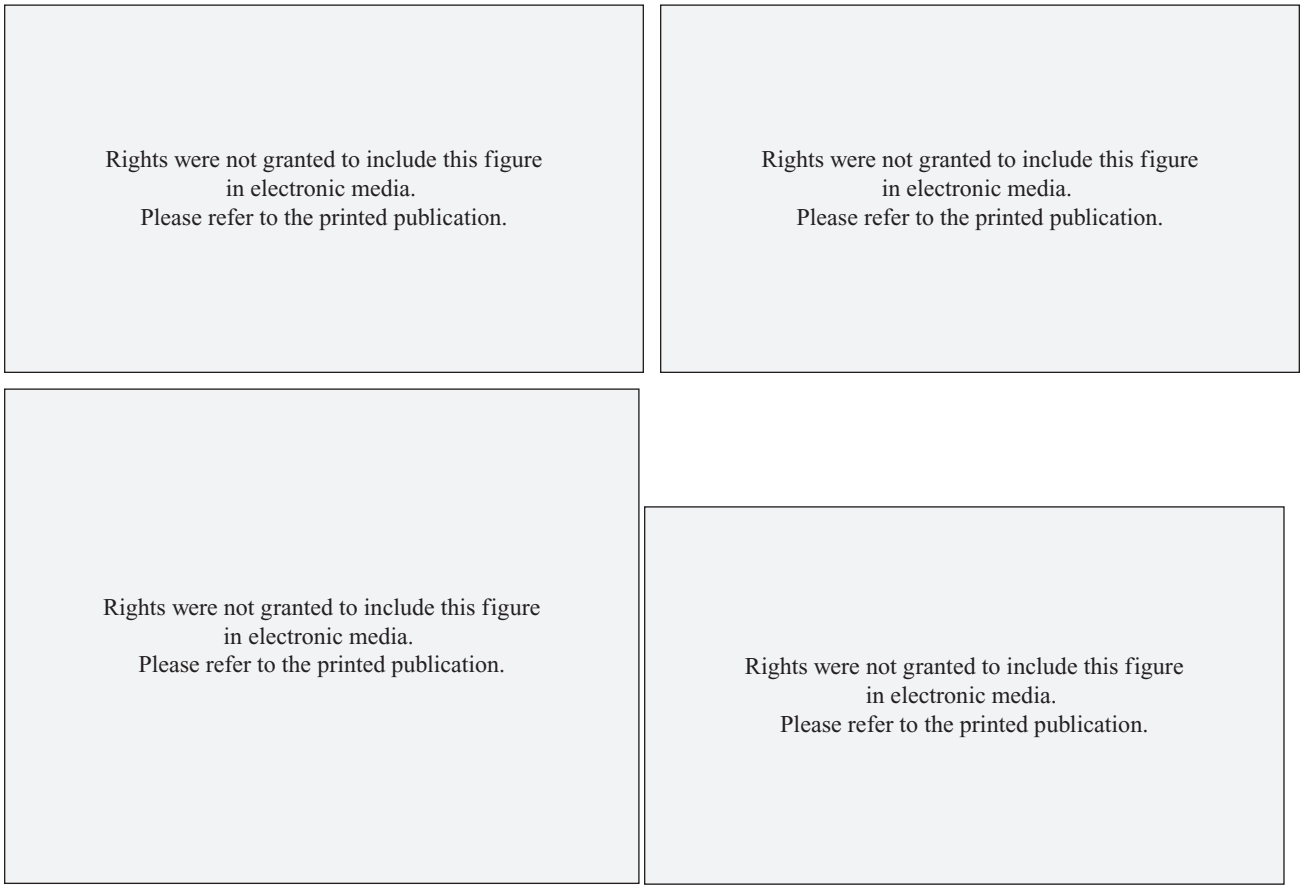

Figure 61-22 Hemodynamic features of the portal flow in the most common type of congenital extrahepatic portosystemic shunt in a dog (**A, C**), and the effect of shunt attenuation (**B, D**). The vascular structures on the schematic pictures (**C, D**) within the rectangle correspond to the vessels shown on the ultrasound images (**A, B**). *Arrows* indicate the direction of blood flow. **A** and **B,** Intraoperative color-flow Doppler ultrasound images of the portal vein at the point where the congenital splenocaval shunt originates. Note that the diameter of the shunt (*SH*) is larger than that of the portal vein (*PVcaudSH*). The portal vein cranial to the origin of the shunt (*PVcrSH*) becomes narrower than the portal vein caudal to the shunt origin (*PVcaudSH*) because of hypoperfusion. **A** and **C,** Because blood always flows toward the lowest resistance, 100% of the portal venous blood flows through the shunt (*SH*) to the caudal vena cava (*CVC*). Note that the blood from the gastroduodenal vein (*GDV*) finds lower resistance to flow caudally toward the shunt, than toward the liver. This creates a hepatofugal flow (i.e., flow away from the liver) in the portal vein segment between the entering point of the *GDV* and the origin of the shunt (*PVcrSH*). Note that the portal vein becomes even narrower cranial to the point where the *GDV* enters it (*PVcrGDV*). The diameter of the various portal vein segments varies because of the varying amount of blood that flows through a certain segment. **B** and **D,** Note that *partial* occlusion of the shunt increases the resistance in the shunt to such an extent that the blood from the splenic vein (*SPLV*) finds lower resistance to flow through the shunting vessel toward the portal vein. This reversed flow in the shunting vessel (*) prevents the portal venous blood from shunting. Thus, even though the shunt is only partially closed, it is *nonfunctional*. Also note that the blood in the whole length of the portal vein is forced to flow toward the liver (i.e., hepatopetal flow direction), establishing normal perfusion of the sinusoids. A portion of the splenic venous blood will continue to flow through the attenuated shunt to the *CVC*, but the splenic blood contains no more toxins than any systemic vein, so no hyperammonemia develops. "Blue," flow from top to bottom, "red," flow from bottom to top; Caud, caudal; Cr, cranial; D, dorsal; PVbrR and PVbrL, right and left portal vein branches; V = ventral. (Reproduced from Szatmári V, van Sluijs FJ, Rothuizen J, Voorhout G: Ultrasonographic assessment of hemodynamic changes in the portal vein during surgical attenuation of congenital extrahepatic portosystemic shunts in dogs. *J Am Vet Med Assoc* 224(3):395, 2004, with permission.)

Computed Tomography

Helical CT, especially the multiscale versions, makes excellent images of the abdominal vasculature (including CPSS) relatively quickly after intravenous injection of iodinated contrast agents.[92] Three-dimensional reconstruction provides impressive anatomic details of shunting vessels.[93] The drawback is the limited availability of the new-generation scanners and the need for patient anesthesia.

Magnetic Resonance Imaging

Although magnetic resonance angiography can provide high-quality images of the abdominal vessels,[94] it has not become popular because of its limited availability and high costs. Patents require general anesthesia and the examination lasts longer than CT angiography.

Characteristic MRI changes have been described in the brains of dogs and cats with CPSS,[95] but these findings are more of research than of clinical interest.

Histopathology

Histopathologic examination of liver biopsy specimens is essential in identifying the underlying disease process in intrahepatic portal hypertensive disorders. In the routine diagnostic workup of canine CPSS liver histopathology gives no additional information.

Currently, the presence of coexistent PHPV cannot be diagnosed preoperatively in dogs with CPSS.[18] This is because the histologic findings of liver biopsies are identical in the following conditions: CPSS, PHPV, CPSS with PHPV, congenital arterioportal fistula, any prehepatic portal hypertensive disorder (e.g., portal vein thrombosis).[13] However, taking liver biopsies for histopathologic examination is recommended in cats before deciding about surgical closure of a CPSS. This is because congenital hepatic fibrosis as part of PKD can be present simultaneously, especially in Persian and Persian crossbreeds.[20] Surgical shunt attenuation is not recommended when congenital hepatic fibrosis and a CPSS are simultaneously present in a cat.

Treatment

Emergency Treatment of Hepatic Encephalopathy

Patients with grades 2 to 4 HE may present on an emergency basis. The source of ammonia and other protein breakdown products, which cause the clinical signs of HE, is the colon. The purposes of the treatment are (a) to reduce the production and amount of ammonia in the colon by removing its content with warm water enema, and (b) to inhibit the absorption of ammonia by administering lactulose syrup into the emptied colon. Lactulose may be given as a retention enema with a soft feeding tube 0.5 to 1.0 mL/kg deep rectally). Lactulose is a nonabsorbable disaccharide, which is metabolized by the colonic bacteria into short-chain fatty acids. These fatty acids acidify the intraluminal content causing to form ammonia (NH_3) and ammonium ion (NH_4^+). Because of its polarity, NH_4^+ will not pass the enterocystic membrane, and is instead trapped in the colonic lumen.[96] It is also essential (c) to correct the acid–base and electrolytic disorders of the patient with IV fluid therapy as alkalosis and hypokalemia can worsen the signs of HE.

Seizures caused by HE can be controlled with intravenous propofol. Administration of benzodiazepines (e.g., diazepam) and barbiturates should be avoided as they can worsen the clinical signs.[97] Binding of a benzodiazepine molecule to its neuronal benzodiazepine receptor increases the effect of GABA on its $GABA_A$-receptor.[4]

Conservative Maintenance Therapy for Hepatic Encephalopathy

The cornerstone of therapy in cases of CPSS (until definitive surgical therapy) and in all cases of APSC is a high-quality, low-protein diet.[32,33,98,99] Commercially available renal prescription diets are ideal and preferable to most hepatic diets, as the protein content is higher in the latter.[28] To decrease colonic transit time and reduce the production of ammonia, oral administration of lactulose is recommended. The dosage of lactulose should be titrated in individual patients to yield soft feces, but not diarrhea. An initial dosage 0.5 mL/kg q12h is recommended. If diarrhea results the dosage should be reduced. Lactulose also stimulates the growth of colonic bacteria that can incorporate ammonia into bacterial protein.

Additional use of antibiotics (e.g., neomycin, metronidazole) has been recommended by some to diminish ammonia-producing colonic flora. Antibiotic administration is usually not necessary to control clinical signs of HE; moreover, neomycin is thought to antagonize the action of lactulose and may cause the release of endotoxins.[100] Furthermore, chronic antibiotic use may contribute to the development of antibiotic resistance.

Surgery of Congenital Portosystemic Shunts

Surgical closure of APSC is generally impossible because of their multiple nature, but also contraindicated, as APSC are usually a compensatory mechanism to resolve high portal venous pressures. Surgical narrowing (i.e., banding) of the caudal vena cava to reduce shunting by increasing the caval pressure is currently not recommended.

In cases of CPSSs, attenuation or complete closure of the shunting vein is the choice of treatment. The goals of shunt occlusion are (a) reducing portal flow via the CPSS and (b) simultaneously increasing portal venous perfusion of the liver.[86] The shunt should be attenuated as close as possible to the point where it enters the systemic circulation. Attenuating intrahepatic CPSS is more risky because of the possibility of major bleeding because of excessive dissection of hepatic parenchyma. There are several techniques described, of which none are perfect.

The major problem with shunt reduction is that blood from the portal vein will be redirected to newly perfuse the liver and its vasculature. Poorly developed portal branches have insufficient capacity to accept even normal amounts of portal venous blood, and in the case of complete shunt occlusion, splanchnic congestion will develop. The goal of surgery is to sufficiently reduce the amount of shunting blood without causing portal hypertension to develop.[86]

Although complete shunt occlusion would theoretically be ideal, partial shunt attenuation is often sufficient because (a) partial attenuation often results in *functional* closure[18] (see Figure 61-22), and moreover (b) complete anatomic occlusion may follow in many cases.[101] Partial occlusion of extrahepatic CPSSs often results in a better outcome because the chance for development of postligation portal hypertension is much smaller compared to complete occlusion.[86]

The liver, which may be less than 30% of its normal size, grows very quickly following successful surgery. Regeneration may take 2 to 3 weeks to complete in uncomplicated cases. The regenerating liver receives progressively more portal blood flow usually resulting in spontaneous complete closure of the CPSS.

Gradual shunt attenuation is believed to reduce the risk of portal hypertension by allowing the portal venous branches to adapt gradually to the increased flow.[102,103] APSC do develop with gradual shunt attenuation techniques (e.g., cellophane banding and ameroid constrictor ring).

Cystic calculi should be removed during the same surgical procedure, because resolution of ammonium biurate uroliths with dietary management can only be achieved in 30% of cases.

Surgical Ligation

The shunting vessel is identified by midline laparotomy and narrowed or completely occluded by a nonabsorbable ligature.[104] Portal hypertension is determined by direct measurement or estimated based on subjective criteria including severe cyanosis, increased intestinal peristalsis, reduction in arterial blood pressure, and compensatory tachycardia as a result of stasis in the splanchnic circulation.[105] Intraoperative Doppler ultrasonography will greatly facilitate determination of the optimal degree of shunt attenuation in extrahepatic CPSS, helping to prevent severe portal hypertension.[86,87]

Cellophane Banding

Instead of a ligature, a 3-mm–thin, three-layer–thick cellophane band is placed around the shunting vessel with or without narrowing of the shunt diameter.[106] Gradual shunt occlusion takes place as a result of inflammation induced by the cellophane.[107,108]

Ameroid Constrictor Ring

A metal ring filled with a thick layer of casein is placed around the shunting vessel. Swelling of the casein occurs as it absorbs fluid. Because of the outer metal ring, the casein can only expand centripetally causing gradual occlusion of the shunt over 1 to 3 months.[102,109,110] The major drawback of this simple technique is that the rate and magnitude of occlusion is uncontrollable and kinking caused by the weight of the device may cause acute fatal portal hypertension. Moreover, because of its relatively large size it can only be easily applied on extrahepatic CPSS.[111,112]

Laparoscopy

Laparoscopic shunt narrowing (by clips) is a less-invasive alternative for shunt ligation (see Chapter 28).[113]

Coil Embolization

With this minimally invasive intravascular technique one or more metal spirals with thrombogenic fibers are placed in the shunting vessel. The coils are delivered via a catheter, which is inserted through the jugular vein into the shunt under fluoroscopic guidance in anesthetized animals.[114,115] The coils cause thrombus formation in the shunt resulting in its partial or complete occlusion. To prevent coil dislodgment from the shunt, an intravascular stent is often placed in the caudal vena cava to cover the point where the shunt enters the caudal vena cava. Coiling is an especially attractive method for treating intrahepatic shunts because liver dissection is thereby avoided.

In my opinion, the safest and most effective way for attenuation of extrahepatic CPSS is Doppler ultrasound-guided *partial* attenuation via surgical ligature.[86,87] For intrahepatic CPSS, coil embolization appears to be an excellent method. Ameroid constrictor and cellophane banding would be ideal in extrahepatic CPSS, when the portal vein cranial to the shunt origin is severely hypoplastic and the patient is at risk for severe portal hypertension.

Postoperative Complications of Shunt Occlusion

Portal Hypertension

Acute Portal Hypertension. Variable degrees of portal hypertension necessarily develop subsequent to any CPSS attenuation. If portal hypertension is severe, circulatory collapse may develop because of sequestration of blood in the splanchnic veins.[116] Slight abdominal enlargement as a result of ascites requires no intervention. This usually resolves spontaneously within 1 week of surgery. Severe ascites with signs of shock (e.g., depression, tachycardia, hypotension, prolonged capillary refill time, hemorrhagic diarrhea) necessitates emergency surgery and removal of the ligatures or constrictor rings from around the shunt. These signs usually develop within 24 hours postoperatively. Unfortunately, the prognosis following emergency surgery is poor.

Portal Vein Thrombosis. This rare postoperative complication causes sudden onset of shock usually within several days of shunt attenuation.[87,117] Exaggerated shunt occlusion, severe portal hypertension, and stasis of portal venous blood are believed to be the cause of the thrombosis. No survivals have been reported.

Chronic Portal Hypertension. When the growth of the liver and development of portal branches is insufficient following partial shunt closure, chronic portal hypertension may induce formation of APSC. This may occur as late as 4 to 8 weeks postoperatively. In such cases, evaluation usually reveals partially patent shunt and increased portosystemic shunting as a result of newly formed APSC. The development of APSC has been documented with all surgical methods. APSC can develop as a result of underdeveloped portal branches or exaggerated shunt attenuation.[18] In most dogs, these APSC remain clinically silent because the hepatic mass has substantially increased following shunt attentuation.[18]

All patients should be re-evaluated at 1 month postshunt attenuation by fasting blood ammonia concentration and abdominal ultrasonography. If fasting blood ammonia concentration is within the reference range, rectal ATT should be performed. If fasting hyperammonemia is present or the ATT is abnormal, ultrasonography should identify whether shunting occurs via the narrowed CPSS, APSC, or both. In the latter cases, lifelong conservative therapy with dietary modifications and lactulose is recommended. A normal ATT result implies complete shunt occlusion and the pet will generally have a very favorable prognosis. A second surgery to reach further shunt attenuation should only be attempted in patients with persistent clinical signs that have high fasting blood ammonia concentration or abnormal rectal ATT result 3 months after the first surgery.[18,86] Spontaneous gradual shunt closure would not occur beyond 3 months after surgical ligation.

Postligation Seizures: Cerebrocortical Necrosis

This rare and usually fatal complication of shunt attenuation causes generalized seizures 1 to 3 days postoperatively, almost exclusively in cats and small-breed dogs (often in Maltese dogs).[31,100,118,119] Its occurrence is unpredictable. The pathogenesis is unknown, but the sudden decrease of endogenous benzodiazepine ligands is thought to play a role (i.e., "benzodiazepine withdrawal syndrome").[4] Because cerebral edema is suspected to be the initial disorder, intravenous mannitol (0.5 to 1.0 g/kg IV, during 20 minutes) may be administered when a patient shows subtle central neurologic signs during the first three postoperative days. Once seizures have developed, the prognosis is usually very poor. Most patients are euthanized because of uncontrollable seizures or persistent neurologic defects. Propofol

(1 to 5 mg/kg, IV) followed by constant rate infusion [CRI]) may be used to control seizures.[120] Prophylactic treatment with phenobarbital does not reduce the risk of development of postligation neurologic complications,[118] but may be used in long-term seizure management. Preventive use of potassium bromide has not been shown to reduce the possibility of postoperative seizures. In every patient with central neurologic signs in the early postoperative period, hypoglycemia and HE should be excluded by measuring venous glucose and ammonia concentrations, respectively.

Blindness and other types of central neurologic signs may develop in cats shortly after surgery. The pathogenesis of these changes is unknown.

Hemoabdomen

Hemorrhage from liver biopsy sites or shunt dissection in cases of intrahepatic CPSS can lead to hypovolemic shock and death in the early postoperative period. Dogs with hepatic insufficiency are prone to develop hemorrhagic complications because of decreased concentrations or abnormal synthesis of coagulation factors.[84] Postoperative portal hypertension may also contribute to bleeding tendency from hepatic parenchymal dissection. Hemoabdomen should be carefully differentiated from severe portal hypertension as they both cause shock and variable degrees of abdominal distention. Coagulation parameters (e.g., PT, aPTT) should be routinely monitored after surgery and if they are abnormal or if there is evidence of clinical bleeding, fresh-frozen plasma transfusion should be administered (10 to 20 mL/kg, IV).

Hypoglycemia

Small-breed dogs are prone to develop hypoglycemia during or shortly after surgery.[100] Blood glucose concentrations should be regularly monitored and hypoglycemia should be treated with glucose-containing infusions.

Portal Hypertensive Disorders

Specific treatment should address the underlying parenchymal liver disease based on the histologic results of liver biopsy. HE can often be controlled with dietary modification and lactulose.

Primary Hypoplasia of the Portal Vein

Currently, no specific treatment exists for portal venous hypoplasias. Renal prescription diets and lactulose may alleviate clinical signs of HE in case of APSC. Diuretic agents may be useful in dogs with ascites.

Congenital Arterioportal Fistulas

Liver lobe resections have been reported in animals with congenital arterioportal fistulas. However, simultaneous presence of PHPV in the whole liver prevents postoperative resolution of portal hypertension and the portosystemic shunting via APSC.[10,25] Therefore, the pet owner should be educated that partial hepatectomy may not result in complete recovery of portosystemic shunting, and that lifelong dietary support and/or lactulose will likely be required.

Ascites

Severe abdominal effusions should be treated with diuretic agents.[121] The first choice is spironolactone (1 to 2 mg/kg q12h), an aldosterone receptor antagonist as (a) chronic hepatic insufficiency is associated with hyperaldosteronism, (b) concurrent hypercortisolemia is associated with cortisol binding to the mineralocorticoid receptor, and (c) potassium-sparing diuretics prevent development of hypokalemia and alkalosis, both of which would worsen signs of HE. If spironolactone alone does not resolve ascites, furosemide may be added to the therapy. Abdominocentesis for removal of abdominal effusion is not recommended because of loss of protein and exacerbation of Starling forces permitting further fluid accumulation.

Prognosis

Congenital Portosystemic Shunts

Conservative Treatment

Dietary and medical management relieves clinical signs only temporarily.[99] Without surgical shunt attenuation, gradual deterioration of liver function occurs; consequently, conservative therapy alone offers a guarded to poor prognosis. In older animals (>6 years) with newly reported signs of CPSS, lifelong conservative treatment may be recommended because of the significantly higher complication rates of surgical therapy in these patients.[105]

Surgical Treatment

The prognosis depends on (a) whether the CPSS is intra- or extrahepatic, (b) the coexistence of PHPV, (c) the extent of shunt attenuation, (d) experience of the surgeon, and (e) the age of the dog at the time of diagnosis. Intrahepatic CPSS generally has poorer prognosis. Complete resolution of clinical signs can be expected in approximately 60% to 80% of dogs with extrahepatic CPSS in the hands of an experienced surgeon. This same parameter is approximately 50% to 70% for intrahepatic CPSS.[102-105] With extrahepatic CPSS, an excellent prognosis can be expected when blood flow is hepatopetal (i.e., toward the liver) in the portal vein segment, which is cranial to the shunt origin. This can be established preoperatively with Doppler ultrasound.[86] In cats, regardless of the shunt type and the surgical method, the success rate is approximately 30% to 50% because of the development of postoperative central neurologic signs.[105,122,123]

Portal Hypertension

The prognosis of portal hypertensive disorders depends on the underlying disease. In the majority of acquired diseases the underlying disorder is chronic and so severe that even stopping the disease process will not cause regression of APSC.

NEOPLASTIC DISORDERS

Josep Pastor and Marta Planellas

Hepatobiliary Neoplasia

Primary liver neoplasms are infrequent in the dog and cat, with an estimated prevalence in necropsy studies of 0.6% to 2.6% in the dog and 1.5% to 2.3% in the cat. Liver metastases are more frequent than primary hepatic tumors in the dog, and tend to originate from the spleen, pancreas, and GI tract. Primary hepatobiliary tumors are more common than metastatic disease in the cat.[1-5]

Etiology

The etiology of liver cancer in dogs and cats is incompletely understood. Potential causes such as aflatoxins, nitrosamines, food additives, parasites, and radioactive compounds have been reported.[6-8] Liver cancer in the dog has many clinical, pathologic, and histologic homologies with liver cancer in humans.[9-12]

In human medicine, chronic diseases of the liver, such as hepatitis B or C infection, as well as cirrhosis, are often associated with

hepatocellular tumors; however, there is no established association between hepatic tumors and viral infections in the dog or cat. Moreover, canine hepatic cirrhosis does not appear to predispose to hepatocellular carcinoma (HCC).[1] A possible association between hookworm or whipworm infection and liver cancer has been reported, and cats with chronic cholangitis may have an increased predisposition to biliary carcinoma.[7,13]

Several liver mitogens and tumor suppressor genes such as epidermal growth factor, TGF-α, vascular endothelial growth factor (VEGF), p53, and TGF-β and its receptors (TGF-β-r) have been associated with liver cancers in humans and these may play a similar role in the dog.[14-17]

In human medicine a small percentage of HCCs or cholangiocarcinomas originate from hepatic progenitor stem cells. Dogs diagnosed with HCC or cholangiocarcinoma do demonstrate activation of hepatic progenitor stem cells in response to liver injury, but hepatic progenitor stem cell expression in liver tumors is relatively low.[18]

Pathophysiology

The hypothesis of cancer development as a multistep process applies to liver tumors in the dog and the cat, as well.[7,19] Precancerous lesions, such as dysplastic nodules, can be identified before the development of overt malignancy in humans. Dysplastic nodules are characterized by cell atypia, cellular crowding, trabecular thickness, microacini, and histochemical markers.[20] Dysplastic nodules have not been reported in the dog or cat and further studies are needed to understand the chronology of hepatic malignancy in domestic animals. Preliminary reports of histochemical markers have been reported in dogs with hyperplastic hepatic lesions and hepatocellular and biliary neoplasms.[11]

Liver tumors cause damage to the liver by several mechanisms: inflammatory effects, obstruction of the biliary system, obstruction of the vascular compartment or adjacent organs, and spontaneous rupture with hemoabdomen.[21]

Hepatic tumors are usually resistant to chemotherapy.[7,19] In one recent study, P-glycoprotein was more highly expressed in HCC than in cirrhosis, which is consistent with the known resistance of HCC to chemotherapy. P-glycoprotein, which is encoded by the multidrug resistance gene (MDR-1), is normally expressed in tissues with excretory function, including the jejunum, kidney, liver, and adrenal gland.[22]

Primary liver neoplasms are usually classified according to their cellular origin and macroscopic appearance. With respect to cellular origin, these tumors may be hepatobiliary, hematopoietic, sarcomas, or metastases of other tumors (Box 61-2). In relation to macroscopic appearance, they can be classified as lobular, multiple nodular, or diffuse (). The combination of histopathologic and morphologic classification has consequences for prognosis and treatment strategy in these animals (Tables 61-6 and 61-7), and the clinician must always address these factors to arrive at correct management decisions. In dogs, malignant tumors are more common than benign lesions. In cats, biliary neoplasms are the most common presentation, particularly intrahepatic benign forms.[6,7]

Clinical Examination

Most animals with liver neoplasia present with nonspecific clinical signs such as anorexia and weight loss. Less-frequent clinical signs include vomiting and diarrhea, PD and PU, pale mucosal membranes, and acute weakness because of anemia and hypovolemia coincident with tumor rupture.[7,19] Up to 25% of affected animals show no clinical signs, and liver cancer is suspected only with increases in serum liver enzyme activities.[3,5,7,23]

Box 61-2 Classification of Liver Neoplasms According to Cellular Origin

Primary

- Hepatobiliary neoplasm
  - Hepatocellular carcinoma
  - Biliary carcinoma (cholangiocarcinoma, biliary adenocarcinoma)
  - Hepatocellular adenoma (hepatoma)
  - Biliary duct adenoma (cystadenoma)
  - Carcinoid tumor (neuroectodermal neoplasm)
- Hematopoietic neoplasm
  - Lymphoma
  - Leukemia
- Sarcomas
  - Hemangiosarcoma
  - Sarcoma
  - Leiomyosarcoma
  - Rhabdomyosarcoma
  - Osteosarcoma
  - Chondrosarcoma

Metastatic

- Gastrointestinal tract
- Spleen
- Pancreas
- Kidneys
- Mammary tissue
- Prostate

The most common physical examination findings are cranial abdominal mass (35%), abdominal bloating (30%), and jaundice (18%). Jaundice is a less common finding in cases of metastatic cancer. Other manifestations include neurologic signs as a result of HE; paraneoplastic syndromes such as hypoglycemia and myasthenia gravis; and skin alterations consistent with hepatocutaneous syndrome.[7,24]

No clear breed predisposition is observed with canine liver cancer, although Poodles, Fox Terriers, Miniature Schnauzers, Labrador Retrievers, and male dogs are overrepresented in some reports of hepatocellular carcinoma.[1,12,19,25,26] Labrador Retrievers and female dogs are overrepresented in reports of bile duct carcinoma.[1,26-28] Whether male and female cats are equally at risk for bile duct carcinomas is unsettled,[28,29] but male cats appear to be at greater risk for bile duct adenomas.[30,31] Neuroendocrine tumors are generally observed in younger animals.[1,32]

Diagnosis

Definitive diagnosis of liver cancer can be made only by liver biopsy. Asymmetrical enlargements of the liver detected on physical examination, abdominal ultrasonography, or survey radiography should not be assumed to be neoplastic in origin. Similarly, laboratory data do not distinguish hepatic neoplasia from other liver pathologies.[33]

The clinical approach to an animal with suspected liver cancer should include basic information such as a complete blood cell count, serum biochemistry, coagulation tests, urinalysis, thoracic and abdominal radiographs, abdominal ultrasound (Figures 61-23 and 61-24), and fine-needle or core biopsy of the liver.

A TNM tumor classification system has been used for staging of liver cancer where T represents tumor (T0, no evidence of tumor;

Table 61-6 Incidence of Histologic Liver Tumor Types, Morphologic Patterns, Metastatic Rates, and Treatment in Dogs

Histologic Tumor Type	Morphologic Pattern	Incidence	Metastatic Rate	Treatment	Reference
Hepatocellular carcinoma		50%			1
	Lobular or massive	53% to 84%	4.8% to 6.6%	Lobectomy	26, 27
	Multiple nodular	16% to 25%	93%	Chemoembolization Metronomic therapy (human medicine)	27, 52
	Diffuse or infiltrating	0% to 19%	100%	Chemoembolization Metronomic therapy (human medicine)	27, 51, 52
Biliary carcinoma		22%	27% to 88%		1, 13, 26, 27
	Lobular or massive	37% to 46%		Lobectomy	26
	Multiple nodular	0% to 21%		Chemotherapy	26
	Diffuse or infiltrating	17% to 54%		Chemotherapy	26
Sarcoma		13%	86%	Lobectomy Metronomic therapy (soft-tissue sarcomas)	1, 7, 19
	Lobular or massive	36%			1
	Multiple nodular	64%			1
	Diffuse or infiltrating	67%			1
Carcinoid tumors		14%	93%		1, 56, 64
	Lobular or massive	0%			1, 56, 64
	Multiple nodular	33%		Cholecystectomy Chemoembolization	64, 66
	Diffuse or infiltrating	0%			1, 56

Diffuse or infiltrating, multiple coalescent nodules in all the lobes, or diffuse disappearance of the liver parenchyma; *lobular*, nodule or large mass in a single liver lobe; *nodular*, several nodules throughout the liver parenchyma, or several affected liver lobes.

Table 61-7 Incidence of Histologic Liver Tumor Types, Metastatic Rates, and Treatment in Cats

Histologic Tumor Type	Morphologic Pattern	Incidence	Metastatic Rate	Treatment	Reference
Hepatocellular adenoma		8% to 22%	25%	Lobectomy	29
Hepatocellular carcinoma		2%	NR		28
Biliary carcinoma		24% to 28%	77%		73
Hepatobiliary cystadenoma		12%	0%	Lobectomy	29, 62
Biliary adenoma		32% to 52%	0%	Lobectomy	29
Sarcoma		2% to 13%	60% to 100%	Lobectomy	29
Carcinoid tumors		4%	100%	Lobectomy, cholecystectomy	64, 65

T1, tumor involving one lobe; T2, tumor involving more than one lobe; and T3, tumor invading neighboring structures); N represents regional lymph nodes (RLNs) (N0, no evidence of RLN involvement; N1, RLN involved; N2, distant LN involved); and M represents distant metastasis (M0, no evidence of metastasis; M1, distant metastasis detected). Although recommended, this system has not been universally adopted.[34]

Table 61-8 illustrates the most typical hematologic and biochemical findings in dogs and cats affected with liver neoplasia. Leukocytosis is a result of inflammation and necrosis of large tumors; anemia tends to be moderate and nonregenerative and is thought to be caused by chronic illness, inflammation, or iron deficiency[19]; thrombocytosis is attributable to a paraneoplastic syndrome characterized by thrombopoietin production, iron deficiency, or anemia.[7]

Serum liver enzyme elevation is a frequent, but not universal, finding in animals with liver neoplasia. It should be noted, however, that the degree of serum enzyme elevation does not correlate with the degree of liver involvement or severity of disease. In one survey, animals with primary liver tumors tended to have greater elevations in serum ALT and ALP activities than animals with metastatic disease, while the latter tended to have greater elevations in serum bilirubin and AST.[35] It also has been suggested that an AST-to-ALT ratio of less than 1 is more compatible with carcinoma, while a ratio of greater than 1 is more indicative of a sarcoma or carcinoid.[1] Other reported biochemical changes include hypoglycemia, hypo- or hyperalbuminemia, and increased serum bile acids. Hypoglycemia as a paraneoplastic syndrome associated with hepatocellular carcinoma is attributed to the secretion of insulin-like growth factor II.[36] Unlike dogs, cats usually present with a high incidence of serum creatinine and BUN elevations.[28,29]

Coagulation factor abnormalities are more commonly associated with hemangiosarcoma, although DIC may be evident in end-stage liver cancer or in decompensated patients. Coagulation studies should always be performed before undertaking invasive diagnostic procedures.[23]

Serum α-fetoprotein has been evaluated in the dog, and increases are reported in 75% of animals with hepatocellular carcinoma, and in 55% of those with biliary carcinomas. The use of this biomarker is limited by the fact that it is increased in cases of hepatic

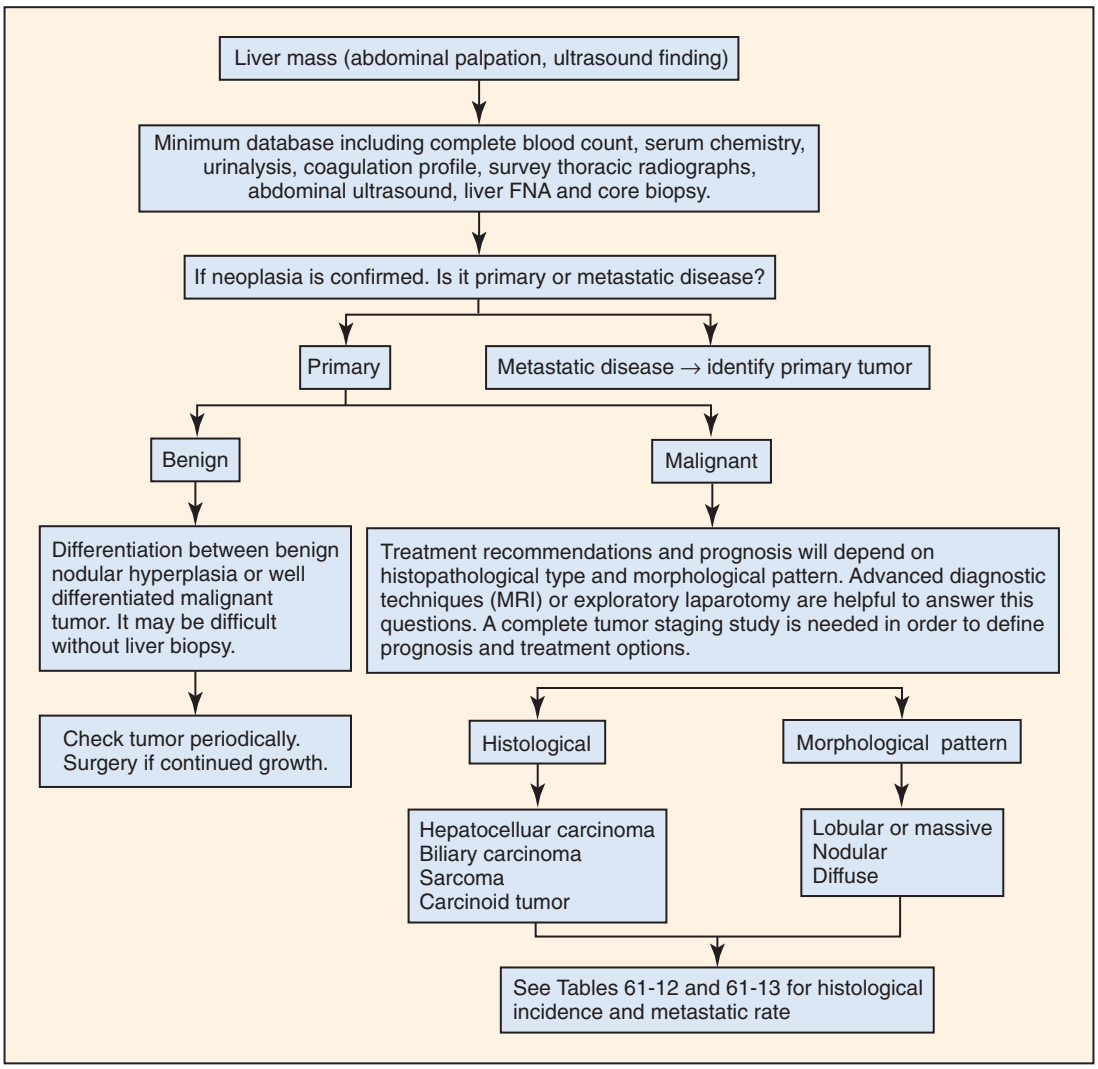

Figure 61-23 Diagnostic decision tree in an animal with a liver mass.

Table 61-8 Hematologic and Biochemical Changes Observed in Dogs and Cats with Liver Neoplasms

Parameter	Change	Incidence in Dog	Incidence in Cat
Hematocrit	Decrease	27% to 50%	ND
Leukocytes	Increase	54% to 73%	ND
Platelets	Increase	50% hepatocellular carcinoma	ND
Alkaline phosphatase	Increase	61% to 100%	10% to 64%
Alanine aminotransferase	Increase	44% to 75%	10% to 78%
γ-Glutamyltransferase	Increase	39%	78%
Total bilirubin	Increase	18% to 33%	33% to 78%
Bile acids	Increase	50% to 75%	67%
Albumin	Decrease	52% to 83%	ND
	Increase	Occasionally	ND
Glucose	Decrease	Occasionally	ND

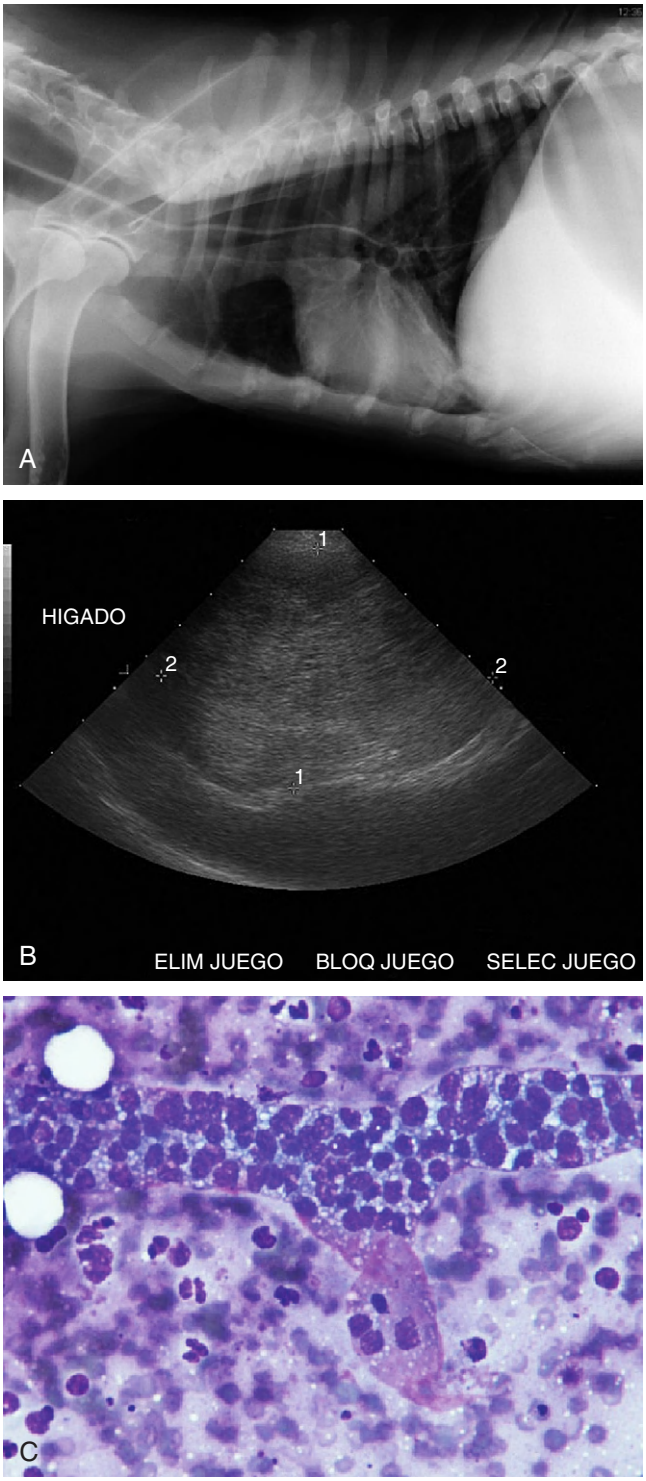

Figure 61-24 **A,** Thoracic radiography of a 10-year-old mixed-breed dog with a large abdominal mass showing megaesophagus. **B,** Abdominal ultrasound of the same dog. Hyperechoic mass with hypoechoic areas in the liver. **C,** Fine-needle cytology of the liver mass, a dense aggregate of large epithelial cells with vacuolated cytoplasm without obvious cytologic criteria of malignancy. A diagnosis of cholangioma or well-differentiated cholangiocarcinoma was made. Histopathologic study of the mass confirmed a cholangioma in this dog.

Box 61-3 Basic Ultrasound Patterns in Liver Neoplasia

Diffuse or multifocal

- Diffuse or multifocal liver neoplasms tend to present with hepatomegaly, but this depends on the degree of infiltration. Liver carcinomas can be diffuse or affect multiple lobes, with variable ultrasound characteristics depending on the presence of necrosis, inflammation, hemorrhage, or cavitation. In these malignant tumors it is common to observe a mixed echogenicity pattern. Lymphoma can affect the liver without detectable ultrasound changes, or cause diffuse hypoechogenicity, hyperechogenicity, or mixed echogenicity with or without hypoechoic nodules. Consequently, if lymphoma is suspected, even if the liver ultrasound findings appear normal, fine-needle aspiration cytology is recommended. Histiocytic neoplasms are more often associated with multiple nodules and hypoechoic masses, although diffuse liver hypoechogenicity has also been described. Mast cell infiltration of the liver tends to produce diffuse hyperechogenicity.
- Nodular patterns
  - Benign nodular hyperplasia is common, particularly in dogs, and accounts for many of the focal liver lesions identified at ultrasound exploration. It has been estimated that 25% to 36% of all nodular masses detected in the liver are nodular hyperplasia.
  - Benign liver adenomas or hepatomas can manifest as a focal mass of variable size and of normally hyperechoic characteristics.
  - The liver is a frequent location of metastatic spread, fundamentally through the portal system that drains most of the abdominal structures.
  - Primary liver neoplasms such as hepatocellular carcinoma can present as focal or multifocal masses, although less often so than in the case of metastases. Focal hypoechoic lesions with a hyperechoic center or core (referred to as target or bull's-eye lesions) are usually associated with metastases, although some benign processes, such as nodular hyperplasia, can generate similar patterns.
- Biliary obstruction: Ultrasound has become an important tool for evaluating biliary obstruction in icteric dogs and cats. Primary tumors of the liver, biliary tract, duodenum, or pancreas are capable of causing biliary obstruction.

lymphoma and other liver pathologies, and only very dramatic elevations in α-fetoprotein may be taken to indicate hepatocellular carcinoma.[37-39]

Abdominal radiographs often reveal a mass effect in the cranial abdomen, although this finding will depend upon the size of the neoplasm and the number and size of metastatic tumors. Other reported findings include dorsal displacement of the stomach, hepatomegaly, loss of abdominal detail (because of the presence of free abdominal fluid), and, occasionally, biliary tract calcification. Thoracic radiography should be considered as part of the staging procedure for animals with metastatic disease.[25,40]

Changes in the ultrasound density of the liver may take a variety of forms (Box 61-3). Most changes are not pathognomonic for a given disease process, and the final diagnosis is established only on the basis of clinical findings, laboratory testing, and results of cytology or histopathology (see Figures 61-24 and 61-25). Ultrasound is also very useful for evaluating other abdominal structures, and for the staging of cancer.[40-42]

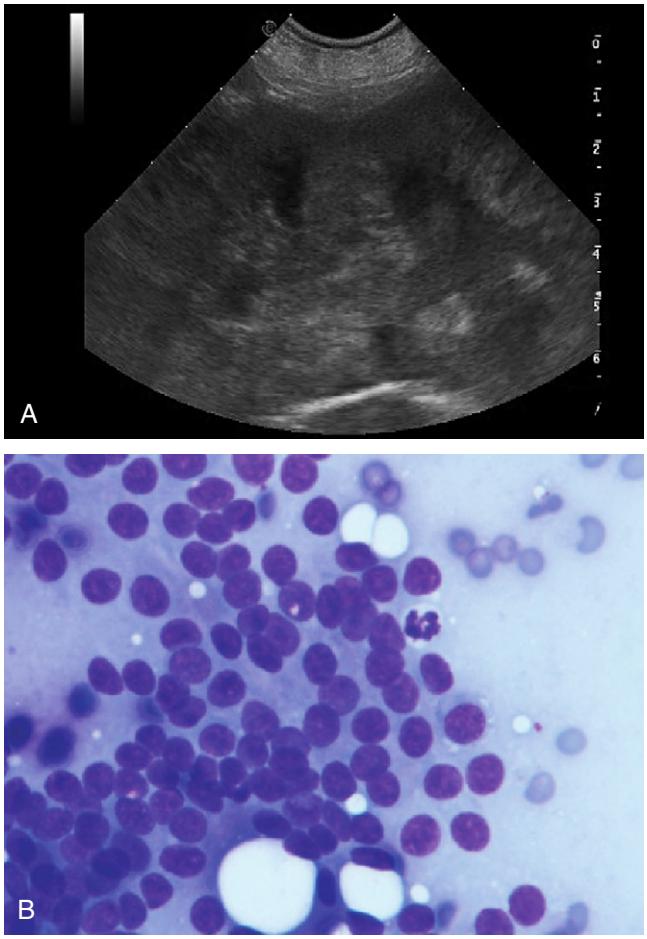

Figure 61-25 **A,** Ultrasonography of a large abdominal mass in a 12-year-old spayed Golden Retriever dog. **B,** Fine-needle aspiration showing round to oval cells that have features consistent with hepatic carcinoid, a neuroendocrine tumor.

High-field MRI scanning has an accuracy of 94% in differentiating malignant from benign lesions with a sensitivity and specificity of 100% and 90%, respectively. MRI classified malignant hepatic lesions as HCC in all confirmed cases and correctly predicted the histologic grade of five HCC lesions. These results suggested that MRI is a useful modality for abdominal imaging in veterinary patients, and that MRI accurately differentiates benign from malignant focal hepatic lesions.[43]

Liver cytology is useful in the initial evaluation of hepatomegaly and usually permits differentiation between primary tumors, metastatic disease, and focal infection (see Figures 61-24 and 61-25). However, cytology does not distinguish between benign focal inflammatory disease and progressive chronic liver disease, and it cannot establish the extent and distribution of disease. Likewise, a definitive diagnosis of regenerative nodular hyperplasia cannot be established, and the technique is unable to differentiate a benign inflammatory reaction from cell changes associated with other pathologies. Contraindications to ultrasound-guided cytology include the following:

- Coagulation abnormalities—If one or more coagulation test parameters are altered, it is advisable to administer vitamin K_1 via the subcutaneous route 12 hours before cytology.
- Cavitary masses—The ultrasound detection of a large cavitary lesion in an elderly dog usually contraindicates cytology, particularly in male German Shepherds or Golden Retrievers, because of the high probability that such lesions correspond to hemangiosarcoma.

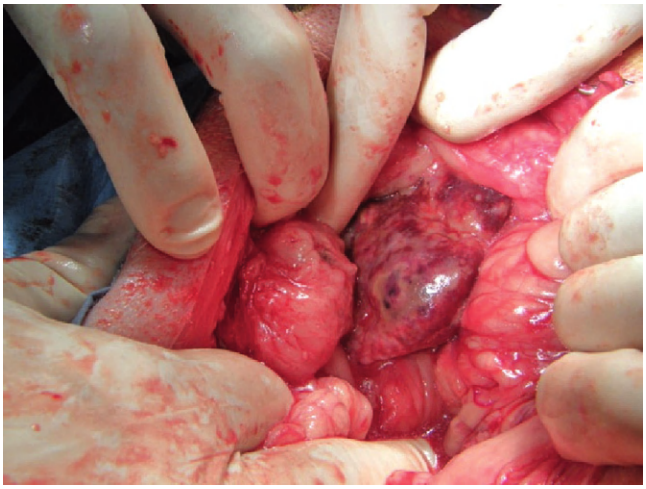

Figure 61-26 Macroscopic appearance of diffuse hepatocellular carcinoma during exploratory laparotomy in a dog. (Courtesy of Félix Gracia.)

Liver cytology has obvious limitations in that it cannot distinguish between liver adenomas and regenerative nodules, and even some hepatocellular carcinoma aspirates may be composed entirely of normal-appearing hepatocytes. In many cases it may prove necessary to resort to ultrasound-guided biopsy, laparoscopy, or exploratory laparotomy. However, cytology may prove useful in determining the presence of lymphoma, mastocytoma, and histiocytic sarcoma, as well as contribute to the initial classification of tumor type. Concordance rates between cytology and histopathology findings may be good for some disease processes, but the reported concordance rate varies from 14% to 86%.[44,45]

Treatment and Prognosis

The treatment to be provided and the prognosis of animals with primary liver cancer depend on the cell of origin, degree of malignancy, and clinical presentation. The clinician should quickly determine if surgery, chemotherapy, radiation therapy, or palliative care is the treatment of choice in individual patients. Palliative treatment is the option for animals that are not surgical candidates, for example, tumors with poor response to systemic chemotherapy, and for whom pain management and general liver failure treatment are the best recommendations.

The success of newer options such as chemoembolization, metronomic therapy, antiangiogenic drugs, and tyrosine kinase inhibitors in the treatment of these patients has not been clearly established.[41-53]

Hepatocellular Carcinomas

The macroscopic presentation is clinically very important (see Figure 61-26), as 100% of the diffuse forms have metastasis at the time of diagnosis, versus 37% of the isolated (massive or nodular) clinical presentations.[27] It should be noted, however, that some dogs with massive HCC present without metastasis, and deaths in these cases may be unrelated to HCC.[1,26,54] Histopathologic subtype and anaplastic characteristics in general influence the prognosis and predictability of metastasis.[1,26,55] Metastatic spread usually affects the regional lymph nodes, lungs, and peritoneum.[26,56]

Prognostic factors in dogs with massive HCC include need for surgery, liver lobe involvement, serum ALT and AST activities, and ratios of ALP to AST and ALT to AST.[26] Liver lobectomy is recommended for cats and dogs with hepatic tumors that have a massive morphologic appearance without metastases. However surgical complications are reported in more than 28% of cases, with a mortality rate of almost 12%.[26] The predilection of massive HCC for left-sided liver lobes has been reported.[27,54] Advanced imaging and intraoperative ultrasonography may provide useful information on the relationship of right-sided and central liver tumors to the caudal vena cava prior to liver lobectomy.[40,41,43] Even though right-sided liver tumors have a poorer prognosis because of intraoperative death, there is no difference in the survival time after successful surgery.[26] The considerable regenerative capacity of the liver can permit successful resection of up to 80% of hepatic mass if the remaining tissue is functionally normal and critical supportive care is provided.[56] The median survival time for dogs with massive HCC following liver lobectomy is greater than 4 years. Without surgery the average life expectancy is 270 days and the prognosis is generally considered poor.[26] Tumor recurrence in dogs with massive HCC is rare and reported to be 0% to 13% after lobectomy.[26,54]

The prognosis for dogs with nodular and diffuse HCC is poor. Surgical resection is usually not possible because of involvement of multiple liver lobes.

No effective systemic chemotherapy or radiation therapy protocols have been described for HCC treatment. HCC is considered chemoresistant in humans although mitoxantrone has been reported to be helpful in some cases.[7,56,57] The most likely reason for the poor response to systemic chemotherapy is the expression of P-glycoprotein in hepatocytes.[22] Treatment options for nodular and diffuse HCC in humans include liver transplantation and minimally invasive procedures for regional control, such as ablation, chemoembolization, immunotherapy, hormonal therapy, and low-dose metronomic chemotherapy.[56,58] A recent report recommends therapy with sorafenib, a multikinase inhibitor and antiangiogenic agent.[47,48]

Chemoembolization is a procedure commonly used in the treatment of diffuse hepatocellular carcinoma in humans with median survival times of 1 to 2 years compared with 3 to 6 months with systemic chemotherapy.[52,51] In veterinary medicine, chemoembolization has been reported with moderate success in the palliation of four dogs with HCC.[52,53] In cats, hepatocellular carcinoma is less frequent, and less data are available.[28,59]

Hepatocellular Adenomas

These tumors are also known as hepatomas and are more common in cats than in dogs. In the dog it is sometimes very difficult to distinguish adenoma from reactive nodular hyperplasia, and biopsy is needed to clarify the diagnosis. The prognosis for adenomas is usually good, but it is advisable to remove focal mass lesions because they can grow and spontaneously rupture with severe bleeding.[19]

Bile Duct Carcinoma (Adenocarcinoma and Cholangiocarcinoma)

Bile duct carcinoma is the most common liver malignancy in the cat, and the second most common liver malignancy in the dog (see Figure 61-27). Tumor behavior is very aggressive in both species, and metastases are present at the time of diagnosis in 60% to 88% of cases. Bile duct carcinomas usually metastasize to the regional lymph nodes, lungs and peritoneum, kidneys, heart, adrenal glands, eye, and bone.[1,60] Bile duct carcinoma can be intrahepatic or extrahepatic, but rarely occurs within the gallbladder. Intrahepatic bile duct tumors are more common in dogs, and extrahepatic bile duct tumors are more common in cats.[1,13, 27,61] Three morphologic forms or presentations have been described: lobular, multifocal, and diffuse. In general, only the lobular form should be considered for surgical removal as long as there is no evidence of metastasis. The prognosis for multifocal and diffuse bile duct carcinomas is very poor, surgery is usually not feasible, and most animals die within 6 months of surgery.[29] No effective chemotherapeutic options have been described for these malignancies in dogs or cats.

Bile Duct Adenomas

Also known as biliary cystadenomas, biliary adenomas, cholangiocellular adenomas, and cholangiomas, these tumors are common findings in aging cats. Males appear to be more frequently affected than females (Figure 61-28). In cats, 50% of these lesions are isolated or lobular and 50% are multifocal.[59] Biliary duct adenomas usually do not cause clinical signs unless they grow and compress other structures.[62] Despite the benign nature of these tumors, surgical removal is usually recommended because malignant transformation is always possible and because expansion into the porta hepatis may cause life-threatening consequences.[63] Liver lobectomy is recommended for cats with single bile duct adenoma or multifocal tumors confined to one or two lobes. In cats, surgical resection of biliary adenomas may provide cure or tumor-free survival of several years.[28,29,31,59,62,63]

Carcinoid Tumors

Neuroendocrine (carcinoid) tumors are infrequent in the dog and cat. In dogs, carcinoids have an aggressive biologic behavior and are usually not amenable to surgical resection as they tend to present as diffuse lesions (see Figure 61-25).[1,27] Carcinoid tumors in dogs have also been described in the gallbladder, and these have been managed successfully with cholecystectomy.[64,65]

Carcinoid tumors in cats can be intrahepatic or extrahepatic involving the bile duct and occasionally the gallbladder.[65] The extrahepatic form of carcinoid tumors may cause biliary tract obstruction, icterus, and increases in serum hepatic enzyme activities. Biliary tract diversion procedures should be considered for obstructive lesions involving the extrahepatic biliary tract. Unlike the circumstance in dogs and humans, female cats are more often affected by these tumors than males (female-to-male ratio of 5:1).[66]

The prognosis of carcinoid liver tumors in dogs and cats is generally poor, and metastatic disease is present in 90% of the cases at

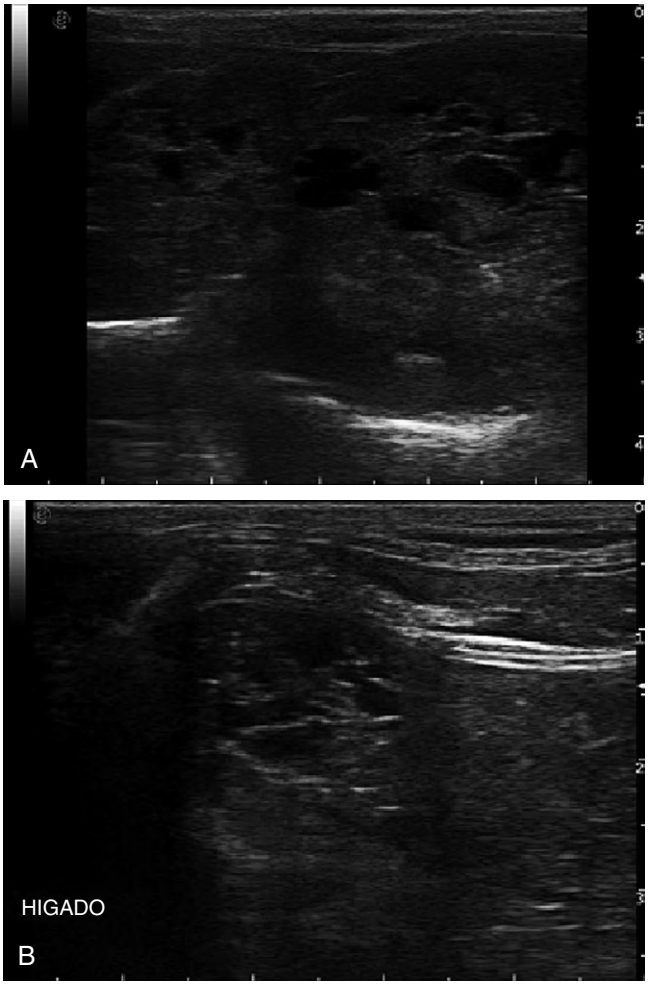

Figure 61-28 **A** and **B,** Liver mass in two cats with multiple anechoic cavities consistent with biliary cystadenomas.

the time of diagnosis.[7] A better prognosis is observed with extrahepatic carcinoids with a life expectancy of more than a year.[64,65]

Liver Sarcomas

Primary liver sarcomas are rare in the dog and cat. Hemangiosarcoma is the most frequent primary hepatic sarcoma in cats and leiomyosarcoma the most common in dogs.[7,19] There also have been reports of hepatic fibrosarcoma, rhabdomyosarcoma, osteosarcoma, liposarcoma, and histiocytic sarcomas in both animal species.[1,28,29,55] These are usually very aggressive tumors, metastasizing in 86% to 100% of cases to the spleen and lungs, or spreading diffusely within the liver.[5] Chemotherapy has not been studied in the treatment of primary hepatic sarcomas, although, similar to other solid sarcomas, response rates are likely to be poor. Histiocytic sarcomas respond partially to CCNU, with a mean duration of remission of 85 days and a survival of 172 days.[67] Continuous low-dose oral chemotherapy may be an effective alternative to conventional high-dose chemotherapy for adjuvant therapy of dogs with hemangiosarcoma.[50] Mass resection may offer some palliation in the circumstance of tumor hemorrhage despite irrefutable evidence of metastasis. A cat with a primary extraskeletal hepatic osteosarcoma was treated with surgery and carboplatin and was alive 42 months after diagnosis with no clinical evidence of disease.[68] On the other hand, metastases must always be considered as a possibility when a hepatic tumor is diagnosed.

Benign mesenchymal neoplasms, such as fibroma and hemangioma, have been described but are quite rare.[6,1,29,59]

Lymphoma

In dogs the liver can be involved in variable forms of lymphoma, including multicentric, alimentary, and hepatosplenic forms. A study in cats documented that abdominal lymphoma is currently the most common anatomic location and the liver occasionally is the only organ involved.[69,70] Many protocols are recommended for treatment of lymphoma in dogs and cats; most include vincristine, cyclophosphamide, and prednisone, with variable combinations of L-asparaginase, methotrexate, and doxorubicin. Careful evaluation of liver function is necessary before starting chemotherapy because many drugs undergo hepatic metabolism and altered hepatic clearance may lead to unpredictable and potentially increased toxicity.[5]

Other Neoplasms

Surgical resection with liver lobectomy is recommended for cats with primary hepatic myelolipoma and the prognosis is excellent with prolonged survival time and no reports of local recurrence.[7]

In dogs with advanced disease, mast cell tumors can metastasize to the liver. Primary visceral mast cell tumors are more common in cats than dogs. The spleen is usually the primary site with metastasis to the liver and bone marrow, and the survival time with splenectomy alone can be a year or more.[71] The overall prognosis for disseminated mast cell tumor in the dog is grave. The median survival time reported in one study was 43 days despite therapy with various chemotherapy agents.[72] Canine mastocytoma involving the liver can be controlled with cyclophosphamide, vinblastine, and prednisone.[73] Recently, tyrosine kinase inhibitors have shown some promise and CCNU has been shown to be active against feline mast cell tumors.[49,74]

Hepatic Nodular Hyperplasia

Hepatic nodular hyperplasia is a common benign lesion observed in the liver of older dogs that can occasionally be observed in some cats. It is characterized by a discrete accumulation of hyperplastic hepatocytes arising as either macroscopic or microscopic hepatic nodules. It reportedly occurs in 70% of dogs older than 6 years and 100% of dogs over 14 years.[75-77] The WSAVA standards for clinical and histologic diagnosis of canine and feline liver diseases include hepatic nodular hyperplasia in its classification system of hepatocellular neoplasia so that it may be differentiated from true neoplasia.[78]

Etiology

The etiology of hepatic nodular hyperplasia is unknown. It has been suggested to be a preneoplastic lesion,[76] but this has not yet been reported in the dog.[77] Because of hepatocyte microscopic changes, it is suggested that nutritional and metabolic disorders play a role in the pathogenesis of this lesion.[77]

Pathophysiology

Hepatic nodular hyperplasia is characterized microscopically by well-differentiated hyperplastic hepatocytes with increased mitotic activity.[75-77] Hyperplastic nodules may be accompanied by concurrent focal intrahepatic cholestasis, mechanical compression on

surrounding hepatic parenchyma, as well as alterations in the microvascular circulation. Vacuolar changes are seen frequently, suggesting a reactive or metabolic condition such us hyperadrenocorticism, lipidosis, or hypothyroidism.[77]

Clinical Examination

Nodular hyperplasia affects older dogs with a mean age of 11 years without gender or breed predisposition. Hepatic nodular hyperplasia does not appear to cause clinical signs or illness.[77]

Laboratory findings may include mild to marked increases in serum alkaline phosphatase activity and, less commonly, increases in serum ALT activity. Liver function tests are usually normal with hepatic nodular hyperplasia.[77]

Diagnosis

Hepatic nodular hyperplasia is usually discovered as an incidental finding during a diagnostic workup for other medical problems. Nodular hyperplasia is clinically important because it may easily be confused with primary or metastatic hepatic neoplasia during abdominal ultrasound or at surgery. Even microscopically, it may be impossible to differentiate hepatic nodular hyperplasia from hepatocellular adenomas, and a large sample (wedge rather than needle biopsy) may be required to confirm hyperplasia from well-differentiated HCCs.[75-77]

Routine abdominal radiographs are generally unremarkable and ultrasonographic features are inconsistent because of the varied hepatocellular morphologic characteristics and size of the nodules.[79] Multiple nodules varying in size, distributed randomly among the liver lobes, being superficial or deep within the parenchyma are found in most cases.[77]

Hyperplasic nodules of hepatocytes need to be differentiated from regenerative nodules. Hyperplasic nodules develop in livers of normal mass, whereas regenerative nodules arise as a result of compensatory hyperplasia of surviving hepatocytes in a background of hepatic injury, atrophy, and fibrosis.

Treatment

No treatment is usually required. Rupture of large nodules may require emergency mass removal and blood transfusion (rare).

Prognosis

Hepatic nodular hyperplasia has no significance in the morbidity of affected patients.[77]

METABOLIC DISORDERS

Deborah S. Greco

Metabolic disorders of the liver are commonly encountered in companion animal practice. This section focuses on the metabolic liver disease induced by concurrent endocrinopathies (hyperthyroidism, hypothyroidism, diabetes mellitus, and hyperadrenocorticism), lipid disturbances (lipoproteinemias, feline hepatic lipidosis, and hyperlipidemias), and metabolic infiltration (amyloidosis). Hepatic lipidosis and hyperthyroid hepatopathy are the primary metabolic hepatopathies in cats. In dogs, steroid (or glycogen vacuolar) hepatopathy is the most frequent metabolic liver disorder; diabetic hepatopathy and hyperlipidemic hepatopathies (lipoproteinemias, hypothyroidism) occur less commonly.

Box 61-4 Factors Predisposing the Domestic Cat, an Obligate Carnivore, to Fat Mobilization and Hepatic Lipidosis

- Essentiality of dietary arginine[6]
- Low levels of hepatic ornithine[7]
- High dietary protein requirements[7]
- Lack of hepatic enzyme adaptation to low protein[8]
- Insufficiency of hepatic glutamate reductase[7]
- Insufficiency of intestinal ornithine transcarbamylase[7]
- Diversion to orotic acid metabolism[9]
- Differences in lipoprotein metabolism (HDLs)[10,11]

Feline Hepatic Lipidosis

Etiology

Feline hepatic lipidosis (HL) is a metabolic syndrome found in obese, middle-aged cats that undergo a period of acute anorexia and catabolism. Morbidly obese cats are at increased risk and more than 85% of cats with HL suffer from an underlying disorder that contributes to the initial anorectic event. [1-5]

Pathophysiology

Although the underlying pathogenesis of hepatic lipid accumulation in cats has not yet been completely elucidated, several unique biochemical and nutritional features place this obligate carnivore at risk for fat mobilization and fatty infiltration of the liver during periods of anorexia or starvation (Box 61-4).[2,6-11] There is a general consensus that reduced caloric intake and protein-calorie malnutrition are important predisposing factors. The result is a rapid mobilization of peripheral fat culminating in fatty accumulation in the liver.[1] Intracellular processing of fats is an important function of the hepatocyte. During fasting or starvation, fatty acid metabolism becomes deranged in an obligate carnivore as a result of obesity, catabolism, chronic overnutrition, impaired fatty acid oxidation or VLDL secretion, and enhanced hepatic fatty acid synthesis (Figure 61-29).[1,6-11]

Clinical Examination

HL is a disorder of middle-aged to older cats; domestic short-haired cats are more commonly affected. Cats with HL often present with a history of acute stress and/or near-complete anorexia of several days duration.[1-3] Icterus is a variable feature of HL. When serum bilirubin concentrations exceed 1.5 mg/dL, clinical icterus can be observed on the pinnae, mucous membranes, sclera, and hard palate in the cat. In general, most cats with HL are obese at the time of presentation, with many cats being 20% to 30% over ideal body weight prior to an episode of HL. Other physical features of HL include hepatomegaly, dehydration, vomiting, and weakness. If HE develops as a consequence of HL, neurologic abnormalities such as ptyalism, stupor, coma, ataxia, and seizures may be observed.[1-3]

A minimum database, including complete blood cell count, serum chemistry, and urinalysis, almost always reveals severe liver enzyme elevation and other abnormalities such as nonregenerative anemia, stress leukogram, poikilocytosis, and bilirubin crystalluria.[1] The pattern of liver enzyme elevation is typically cholestatic in nature and characterized by marked increases in serum ALP activity, followed by smaller increases in serum ALT and serum AST activities. Serum GGT activity is often normal in affected cats. Increased serum bile acids and bilirubin are often observed in cats with HL, and electrolyte abnormalities, such as hypophosphatemia and

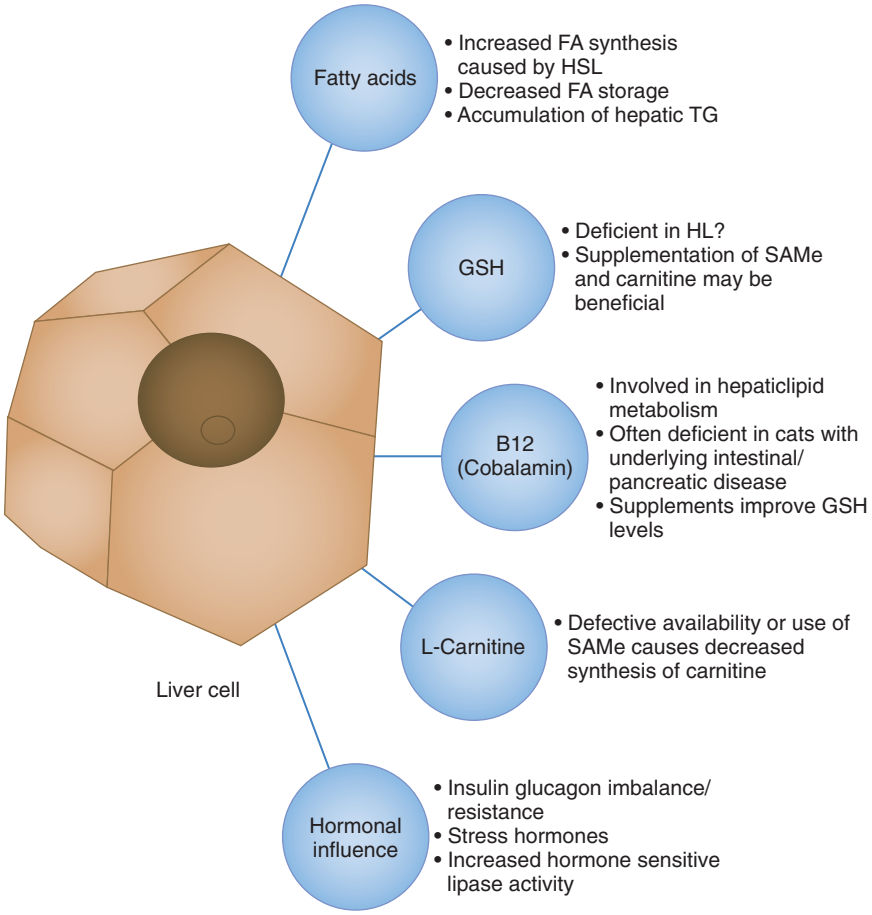

Figure 61-29 Fat metabolism in the feline hepatocyte during hepatic lipidosis.

hypokalemia, may be frequently observed. In particular, the presence of hypophosphatemia should alert the clinician to the possibility of refeeding syndrome.[12]

Diagnosis

Presumptive diagnosis of feline HL can be made on the basis of clinical history, physical examination, clinicopathologic features, ultrasound examination, and liver aspirates.[1,13-15] Ultrasound examination of the liver often reveals hepatic parenchyma that is hyperechoic to that of falciform fat, but a thorough ultrasound evaluation of the gallbladder, pancreas, intestines, kidneys, bladder, and other abdominal structures is essential to rule out other primary disorders, such as acute pancreatic necrosis, which may be the basis of the anorectic event precipitating an episode of HL. Definitive diagnosis is best achieved through liver biopsy[16]; however, anesthesia and biopsy may not be possible in acutely ill patients because of the presence of coagulopathies from vitamin K deficiency.[17] A liver aspirate that reveals more than 80% fatty infiltration of the hepatocytes may be used for presumptive diagnosis of HL. If there is no response to treatment after 3 to 5 days, liver biopsy may be necessary to rule out other underlying hepatobiliary conditions such as cholangitis.

Treatment

A catabolic state develops quickly in the anorexic cat and prompt measures should be taken to place an enteral feeding tube (Table 61-9). Nasoesophageal, esophageal, and gastrostomy tubes can be used for this purpose. The caloric needs should be approximately 60 to 90 kcal/kg body weight in most cats.[1,18] Unless HE is present, dietary protein should not be restricted (ideal is 35% to 45% protein on a dry matter basis) and even then protein restriction is controversial as protein is needed to support hepatic regeneration. Feeding multiple small frequent meals may help to maintain euglycemia and lessen the metabolic impact on the liver. The protein content of the diet should be considered when HE is present (see Chapter 32). Dairy and vegetable-based proteins are higher sources of branched-chain amino acids than meat-derived proteins and may lessen the signs of HE. Diets high in fiber generally should be avoided because they decrease the nutrient density of the diet.

Cats with HL occasionally may experience a refeeding syndrome, a condition that results in metabolic and electrolyte disturbances.[12] With the reintroduction of food, insulin secretion promotes intracellular uptake of phosphorus, potassium, and magnesium. Hypophosphatemia can result in muscle weakness and hemolytic anemia. Gradual reintroduction of food and correction of electrolytes diminishes the risk of refeeding syndrome.

Glucose intolerance and hyperglycemia are common in cats with HL and can be addressed by decreasing the carbohydrate content of the diet. Canned low-carbohydrate, high-protein formulations without added fiber are ideal for the treatment of feline HL as they provide amino acids, limited carbohydrates, and water, and are easily administered through a feeding tube. Small amounts of food should be administered via the feeding tube after residual gastric fluid contents have been removed. Trickle feeding can be performed by placing liquefied food into an empty fluid bag and allowing gravity to force flow into the feeding tube. Alternatively, a large-bore

Table 61-9 Nutritional and Therapeutic Support of Cats with Hepatic Lipidosis

Feeding Tubes	General Tips	Diet to Feed	Fluid Therapy and Supplements	Drugs and Supplements
Nasogastric Nasoesophageal	Trickle feed 60 kcal/kg/day	Liquid high-protein, low-carbohydrate diet	Crystalloid fluids Avoid dextrose and lactate KCl, KPO_4 B vitamins	Maropitant 1-2 mg/kg SC, PO, IV q24h Ondansetron 0.1 to 1.0 mg/kg q12-24 h Vitamin K_1 0.5 to 1 mg/kg SC q12h for 3 transfusions
Esophagostomy or gastrostomy	Multiple times daily 60 to 90 kcal/kg/day	Canned high-protein diet*		L-Carnitine 250 to 500 mg/day Taurine 250 to 500 mg/day SAMe 20 to 40 mg/kg/day Vitamin E 10 IU/kg/day PO

*Less than 10% carbohydrate, >40% protein on dry matter basis.

syringe attached to a syringe pump may be useful in delivering the food through the feeding tube.

Crystalloid fluids supplemented with fortified B vitamins, including thiamine, riboflavin, niacinamide, D-panthenol, pyridoxine, and cyanocobalamin, should be used.[1] Nutritional supplements to enhance antioxidant function, such as vitamin E and glutathione precursors (e.g., SAMe) may also be beneficial. Amino acid supplements that support hepatic regeneration and metabolism include carnitine and taurine.[1,18-20] Carnitine functions in the transport of fatty acids into hepatic mitochondria for energy production. Taurine is an essential nutrient for cats and is involved in CNS, cardiac, and biliary functions. Signs of taurine deficiency may be similar to those associated with HE.

Antiemetic therapy is necessary to control vomiting and facilitate feeding of an appropriate type and quantity of diet (see Chapters 23 and 35). Injectable antiemetics, such as maropitant (Cerenia, Pfizer Animal Health, Kalamazoo, MI), a selective NK-1 receptor antagonist, at a dosage of 1 mg/kg SC or IV on a daily basis, is preferred.[21] Oral maropitant at the same dosage or oral ondansetron, a 5-HT_3 receptor antagonist at a dosage of 0.1 to 1.0 mg/kg q12-24 h may be used in cats with larger-bore feeding tubes. Persistent vomiting should be investigated to identify feeding tube occlusion or other undiagnosed disease.

Prognosis

The prognosis depends upon duration of illness, and the time frame of resolution of hepatic enzyme elevation, hyperbilirubinemia, and other biochemical changes. Cats that survive an episode of HL have a greater than 50% reduction in liver enzyme and bilirubin concentrations within 10 days of therapy, whereas cats that die usually do so within 7 days of hospitalization.[1] Long-term prognosis for recovery is good with the majority of cats having resolution of HL as long as the underlying disease process (e.g., pancreatitis) is identified and treated.

Hyperthyroid Hepatopathy

Etiology

Hyperthyroidism in cats is caused by adenomatous hyperplasia of the thyroid gland resulting in increased circulating concentrations of thyroxine and triiodothyronine.[22,23] Hyperthyroxinemia increases hepatic metabolism without proportionate increases in hepatic blood flow with the overall consequence of reduced oxygen delivery to hepatocytes.[24]

Pathophysiology

Increases in serum AST and ALT activities have been reported in approximately 80% of hyperthyroid cats.[22,23] Liver enzyme elevation has been attributed to increased liver metabolic activity compared to blood flow. Long-term untreated hyperthyroidism in human beings can ultimately lead to cirrhosis.[24-26]

Clinical Examination

Middle-aged to older cats are typically affected, and there is no breed or sex predilection. Because hyperthyroidism is characterized by hypermetabolism, polyphagia, weight loss, PD, and PU are prominent features of the disease.[22,23] Hyperactivity, tachycardia, pupillary dilation, and behavioral changes are also characteristic of the disease and are associated with activation of the sympathetic nervous system. Long-standing hyperthyroidism leads to hypertrophic cardiomyopathy, high-output heart failure, and cachexia. Long nails, dermatologic conditions, panting, elevated body temperature, and poor grooming or overgrooming are additional clinical signs of feline hyperthyroidism.

Clinicopathologic features of hyperthyroidism include erythrocytosis and stress leukogram (neutrophilia, lymphocytosis) caused by increased circulating catecholamine concentrations. Increased catabolism of muscle tissue in hyperthyroid cats may result in increased BUN, but not serum creatinine. Most cats will have decreased urine specific gravity, particularly if they are exhibiting PU as a clinical sign. Increased metabolic rate results in liver hypermetabolism, therefore serum activities of liver enzymes (ALT, AST) are increased in more than 80% of hyperthyroid cats.[22,23]

Diagnosis

Diagnosis of feline hyperthyroidism is achieved by measurement of serum total thyroxine (TT_4) concentration. Serum thyroxine concentrations are elevated in more than 90% of hyperthyroid cats, making this a very sensitive test of thyroxine-induced hypermetabolism.[22,23] False-positive test results are rare to nonexistent, suggesting that hyperthyroxinemia is a specific test for feline hyperthyroidism.

In a clinically hyperthyroid cat, thyroid hormones still fluctuate on a daily (and hourly) basis with hormone concentration intermittently decreasing into the normal range.[27] To avoid this type of diagnostic error the clinician should repeat blood sampling 1 to 2 weeks after the first test. Nonthyroidal disease can have a significant effect on circulating thyroid hormone concentrations.[28-30] In the case of persisting nonthyroidal illness (e.g., renal disease), the

measurement of unbound thyroxine (T_4) or free T_4 may be preferable to repeated TT_4 measurements.

Free T_4 concentrations are a very sensitive test for the diagnosis of hyperthyroidism with 98% of hyperthyroid cats exhibiting elevated serum free T_4 concentrations. The specificity of free T_4 is not as good as its sensitivity; as many as 12% of euthyroid cats with concurrent illness will have high free T_4 concentrations for reasons that remain unclear.[29] As a result, free T_4 should not be used as a screening test, and free T_4 values should be interpreted in light of the TT_4 concentrations. The combination of a high free T_4 with a low TT_4 is indicative of nonthyroidal illness; however a high free T_4 with a high-normal TT_4 is suggestive of hyperthyroidisim.[31]

Treatment

Methimazole (Tapazole) is the antithyroid drug most often recommended (2.5 to 5 mg q12h). It is available as a transdermal gel or as an oral tablet. Methimazole is often used to prepare the patient for surgical thyroidectomy or radioiodine therapy. Antithyroid drugs have several side effects. Anorexia and vomiting are common side effects of methimazole, whereas rare side effects include self-induced excoriation of the face, thrombocytopenia, bleeding diathesis, agranulocytosis, development of serum antinuclear antibodies, and cholangitis. Bleeding, jaundice, and agranulocytosis necessitate immediate withdrawal of the drug. Hepatic injury related to antithyroid therapy such as methimazole is well documented in humans and reported in the cat.[22,32] Mild histologic changes are common, but cases of fulminant hepatic failure with central lobular necrosis have been described.[33]

Prognosis

Prognosis is excellent with definitive therapy of the hyperthyroidism (surgery or radioactive iodine). Hepatic reactions to methimazole will necessitate discontinuation of therapy.

Diabetic Hepatopathy (Hepatocutaneous Syndrome, Superficial Necrolytic Dermatitis)

Etiology

The etiology is unknown, but hypoaminoacidemia may play a role in the development of diabetic hepatopathy.[34,35] Fatty acid, niacin, and zinc deficiencies also may be involved in the pathogenesis. Increased serum glucagon, originally thought to be the cause of diabetic hepatopathy, is found in only one-third of the reported cases. A much stronger association between the skin lesions of superficial necrolytic dermatitis and glucagonoma, hyperglucagonemia, and poorly regulated diabetes mellitus have been observed in both humans and dogs.[34,35]

Pathophysiology

Hepatopathy is thought to occur secondary to the metabolic abnormalities associated with diabetes mellitus, glucagonoma, or nutritional deficiencies.[34-37] Hepatic features include vacuolar hepatocyte degeneration, hepatic parenchymal collapse, and hepatic nodularity.

Clinical Examination

The disorder is seen most frequently in middle-aged male dogs, and has been reported in one cat.[34-37] Acute presentations may include clinical signs such as vomiting, diarrhea, lethargy, weight loss, PD, PU, icterus, and lameness because of dermatopathy of the footpads. In some cases clinical signs are mild or nonexistent. Physical examination may reveal poor body condition, lethargy, and characteristic lesions of superficial necrolytic dermatitis (hard, cracked foot pads and elbows). Painful feet caused by footpad lesions are common.

Clinicopathologic features include mild nonregenerative anemia, microcytosis (with advanced liver dysfunction), increased serum liver enzyme (ALP and ALT) activities, hypoproteinemia, hypoalbuminemia, and fasting hyperglycemia. Serum bile acids are usually increased. Serum glucagon is inconsistently elevated, but plasma amino acid concentrations are often less than 50% of normal.[34,37]

Diagnosis

Abdominal ultrasonography may reveal small, normal or increased liver size; however, there usually is a characteristic "Swiss cheese" appearance of the hepatic parenchyma as a result of hepatic degeneration, nodularity, and collapse.[36,38] Pancreatic imaging and biopsy are indicated if a glucagonoma is suspected.

Treatment

Symptomatic palliative therapies may be beneficial and include high-protein diets with egg white (approximately 2 to 4 egg whites/day for a 25-kg dog), zinc (2 mg/kg q24h PO) niacinamide (250 to 500 mg/dog q24h PO), ursodeoxycholic acid (10 to 15 mg/kg/day PO), vitamin E (10 IU/kg daily PO), SAMe (20 mg/kg/day PO 2 hours before feeding), and fatty acid supplementation. Some patients will respond to 10% parenteral amino acid solutions (Aminosyn, Abbott Laboratories, Chicago) given at a dose of 500 mL over 8 to 12 hours intravenously through a large-bore central venous catheter. If no response is observed following the initial amino acid infusion, therapy should be repeated every 7 to 10 days for a total of four treatments.

Prognosis

Prognosis is poor for most cases; however, remissions of longer than 2 years have been reported with intensive amino acid and hepatic support therapy.[37]

Steroid Hepatopathy

Etiology

Steroid hepatopathy develops following exogenous corticosteroid therapy, or from endogenous hyperadrenocorticism of pituitary or adrenal origin. The dog liver is uniquely susceptible to both glucocorticoid- and sex steroid–induced liver enzyme elevation, glycogen accumulation, and vacuolar degeneration.[39,40]

Pathophysiology

In healthy dogs, glucocorticoid administration results in significant liver enzyme (ALP and ALT) elevation in 2 to 3 days. Increased ALP and GGT activities develop in parallel as the enzymes undergo induction and release from sinusoidal and canalicular membranes. Within 7 days of glucocorticoid administration, the glucocorticoid-induced ALP isoenzyme increases significantly. Glycogen accumulates within the hepatocyte resulting in a vacuolar degeneration typical of the syndrome.[1,39,40]

Clinical Examination

Steroid hepatopathy occurs primarily in the dog. There is only one reported case of steroid hepatopathy in the cat.[41] A history of corticosteroid administration or signs consistent with endogenous steroid overproduction (Cushing syndrome) are usually evident, for example, PD, PU, panting, potbellied appearance, bilaterally symmetric alopecia on the trunk, and polyphagia. In dogs affected with

atypical hyperadrenocorticism caused by sex steroid overproduction, dermatologic changes (alopecia, poor hair coat) and reproductive manifestations (perianal adenoma in a castrated male or female dog) are often the only signs suggestive of sex steroid imbalance. Atypical hyperadrenocorticism with sex steroid excess may present with no clinical signs except increased serum liver enzyme activities.[1]

Diagnosis

Diagnosis of steroid hepatopathy should be based on a history of exogenous steroid administration or endocrine function testing with or without liver biopsy. Classically, liver enzyme elevations consist of moderate to marked increases in ALP and GGT, and mild to moderate increases in ALT and AST. Bile acids may also be increased.[40]

The low-dose dexamethasone suppression (LDDS) test is considered the screening test of choice for endogenous canine hyperadrenocorticism.[42,43] The LDDS test has a high sensitivity at 92% to 95%. Only 5% to 8% of dogs with PDH will exhibit suppressed cortisol concentrations at 8 hours. In addition, 30% of dogs with PDH will exhibit suppression at 3 or 4 hours followed by "escape" of suppression at 8 hours. This pattern is considered diagnostic for PDH, making further testing unnecessary.[43] The major disadvantage of the LDDS test is the lack of specificity in dogs with nonadrenal illness.[44]

The corticotropin (ACTH) stimulation test is used to diagnose a variety of adrenopathic conditions, including endogenous or iatrogenic hyperadrenocorticism, as well as spontaneous hypoadrenocorticism.[42,45,46] As a screening test for the diagnosis of naturally occurring hyperadrenocorticism, the ACTH response test has a diagnostic sensitivity of approximately 80% to 85% and a higher specificity than the LDDS test.[45,46] In a study by Kaplan and Peterson, only 15% of dogs with nonadrenal disease exhibited exaggerated response to ACTH stimulation.[44] I prefer the ACTH response test over the LDDS test as the ACTH response test is more accurate for the diagnosis of iatrogenic hyperadrenocorticism (if the history is incomplete) and sex steroid imbalance in addition to PDH or adrenal-dependent hyperadrenocorticism.

The urine cortisol-to-creatinine ratio (UCCR) is highly sensitive in separating normal dogs from those with hyperadrenocorticism; however, the test is not highly specific for hyperadrenocorticism because dogs with moderate to severe nonadrenal illness also exhibit elevated ratios.[47-49] An elevated UCCR should always be confirmed with an LDDS test. In the UCCR test, urine is collected for 2 days for a baseline UCCR. The animal then is given three doses of dexamethasone (0.1 mg/kg, PO q6-8 h) and the final UCCR is collected 24 hours after the first dose of dexamethasone. Failure of the UCCR to suppress into the normal range is diagnostic for hyperadrenocorticism.

Treatment

Treatment for exogenous hyperadrenocorticism consists of discontinuation of exogenous steroids by slowly weaning the patient to prevent the development of addisonian crisis. Treatment for endogenous hyperadrenocorticism can be achieved with chemotherapy (o,p′-DDD, or trilostane) or surgery (hypophysectomy or adrenalectomy). Treatment of sex steroid imbalance can be achieved with mitotane or trilostane.

Prognosis

Prognosis for steroid hepatopathy is good to excellent if diagnosed early and if corticosteroid injury can be abated by discontinuation of steroid therapy or treatment of the underlying disorder.

Miscellaneous Metabolic Hepatopathies

Lipoproteinemias

Etiology

Genetic abnormalities in lipid metabolism lead to diffuse vacuolar hepatopathy and biliary mucoceles.[1]

Pathophysiology

Increased circulating cholesterol and triglyceride cause a vacuolar hepatopathy associated with excess lipid accumulation and/or hepatocyte glycogen synthesis and storage. Chronic hypercholesterolemia increases biliary cholesterol content and predisposes to cystic hyperplasia, dysmotility of gallbladder smooth muscle, and biliary mucocele.[1]

Clinical Examination

Familial hypercholesterolemia and other hyperlipidemias are found in certain breeds of dogs including the Miniature Schnauzer, Shetland Sheepdog, Briard, West Highland White Terrier, Scottish Terrier, Cairn Terrier, and Beagle. Mixed-breed dogs may also be affected. Clinical signs are usually associated with necrotizing cholecystitis and may include icterus and cranial abdominal pain. More often, dogs are asymptomatic and biliary mucoceles are identified serendipitously during ultrasound evaluation for some other medical problem (such as pancreatitis). Clinical pathology findings usually include hypercholesterolemia or hypertriglyceridemia, and elevated liver enzyme activities, particularly ALP. Necrotizing cholecystitis may be accompanied by leukocytosis, neutrophilia, and hyperbilirubinemia.

Diagnosis

Diagnosis may be made by characteristic ultrasound findings of nongravitational gallbladder sludge, increased gallbladder wall thickening, "kiwi"-shaped mucosal image, and bi- or trilaminar appearance of the gallbladder wall. The hepatic parenchyma may have a pattern of multifocal hyperechogenicity and hypoechoic nodules.[1]

Treatment

The best treatment for biliary mucoceles is surgical removal of the mucocele and/or cholecystectomy and may become an emergency procedure if the clinical signs of necrotizing cholecystitis are severe. Medical therapy following surgical removal is usually necessary and includes a fat-restricted diet and lifelong treatment with ursodeoxycholic acid (15 mg/kg PO q24h).

Prognosis

Prognosis is good for patients undergoing successful removal of the mucocele as long as lifelong medical therapy is continued.

Amyloidosis

Etiology

In dogs and cats, amyloid deposition is usually secondary to sustained systemic inflammatory response, for example, chronic infection, chronic inflammation, immune disorders, and malignancy.[50] Amyloidosis is a familial disorder in the Chinese Shar-Pei dog, and in Abyssinian, Oriental, and Siamese cats.[51-54] Hepatic amyloidosis has also been reported secondary to vitamin A toxicity in cats.[55]

Pathophysiology

Deposition of amyloid fibrils within and between hepatic sinusoids results in progressive organ dysfunction. Light deposits are found in the space of Disse and heavier deposits are often found in the

sinusoidal lumen. Amyloid fibrils are readily detected on routine hematoxylin and eosin or Diff-Quik staining. Amyloidosis is confirmed on examination of Congo red–stained aspirates or biopsies under polarized light where the extracellular material shows characteristic green birefringence.[50] Concurrent amyloid deposition in the kidneys, liver, spleen, and adrenal glands can occur, but clinical manifestations of liver failure are most common.

Clinical Examination

Chronic progressive liver failure with clinical signs of anorexia, weight loss, and lethargy, is the typical clinical course in many cases. Some animals may instead present with acute collapse following hepatic rupture and intraabdominal hemorrhage.[50] Pallor of mucous membranes, hypothermia, and hepatomegaly are the most frequently recognized physical examination findings. Typical laboratory findings include regenerative anemia, leukocytosis, thrombocytopenia, marked elevations in serum ALT and AST, and marked prolongations in aPTT and PT times.

Diagnosis

Radiography is useful in detecting free peritoneal fluid, hepatomegaly, and irregular hepatic borders. Ultrasonography reveals a diffuse, heterogeneous echogenicity with highly echogenic ("sparkling") areas and hypoechoic foci.[50] Definitive diagnosis requires tissue biopsy and Congo red staining.

Treatment

There are no specific treatments for this disorder. Colchicine has been recommended because it may block formation of amyloid in the early stages of the disease, but it is of unproven benefit and has been associated with significant side effects. Dimethyl sulfoxide has been recommended because it may promote resorption of amyloid. As there are no specific therapies for this disease, treatment is instead largely symptomatic and supportive.

Prognosis

With progressive amyloidosis lesions, the prognosis for long-term survival is poor.

Lipoprotein Lipase Deficiency

A familial hyperlipoproteinemia has been reported in cats that is characterized by fasting hyperchylomicronemia, elevated circulating concentrations of VLDLs, and hypertriglyceridemia.[56,57] Serum cholesterol is only minimally elevated. The underlying biochemical lesion is a reduction in the activity of lipoprotein lipase, and the disorder is transmitted as an autosomal recessive gene. Xanthomas accumulate in the soft tissues, including the liver, but clinical signs are more often related to involvement of the peripheral nerves. Dietary fat restriction improves clinical signs in some affected animals.[58]

Hypothyroid Hepatopathy

Etiology

Decreased circulating thyroid hormone concentration affect hepatic metabolism and cholesterol turnover in the liver. Liver function tests are mildly disturbed in almost 50% of patients with hypothyroidism despite normal histologic findings.[59]

Pathophysiology

Decreased hepatic metabolism in hypothyroidism is reflected by reduced oxygen consumption.[33,59,60] Patients with a common bile duct stone and gallbladder stone have, respectively, sevenfold and threefold increases in the frequency of hypothyroidism.[61] The pathogenesis of stone formation in hypothyroidism is believed to involve hypercholesterolemia, gallbladder dysmotility, and bilirubin retention.[61]

Clinical Examination

The most common clinical symptoms of hypothyroidism are lethargy, weight gain, depression, hypothermia, and bradycardia. GI signs such as reflux esophagitis, gastric atony, constipation, diarrhea, and hepatopathy with mucocele formation are rare clinical signs of hypothyroidism in dogs.[62] Symmetric truncal or tail-head alopecia are a classic findings in hypothyroid animals.[62] Hyperkeratosis, hyperpigmentation, secondary pyodermas, and demodicosis are also observed.

Clinicopathologic findings such as normocytic normochromic anemia, hypertriglyceridemia, and hypercholesterolemia are seen in the majority of hypothyroid animals because of altered lipid metabolism and binding proteins (increased HDLs), decreased fecal excretion of cholesterol, and decreased conversion of lipids to bile acids.[63]

Diagnosis

Total serum T_4 concentration and endogenous thyroid-stimulating hormone (TSH) may be used to confirm the diagnosis of hypothyroidism. This combination of tests has been shown to have the highest specificity, sensitivity, and lowest overall cost. If the TT_4 is in the low normal or below normal range and the TSH is high, the animal is suffering from primary hypothyroidism.[64,65] If the TT_4 and TSH are both low, free T_4 by dialysis should be determined to distinguish euthyroid sick syndrome (normal free T_4) from true secondary hypothyroidism (low canine thyroid stimulating hormone [cTSH] resulting from pituitary TSH deficiency).[66]

Treatment

Synthetic thyroid hormone supplementation is the treatment of choice for hypothyroidism. Levothyroxine sodium therapy is started at a dosage of 0.02 mg/kg given orally twice daily.[66] Thyroid function should be monitored every 6 to 8 weeks for the first 6 to 8 months of treatment and then once or twice yearly thereafter. In stable well-controlled animals, the total treatment may be given once daily with excellent clinical results, as long as adequate peak hormone concentrations are achieved.[67]

Prognosis

With thyroid hormone replacement therapy in hypothyroid dogs, the prognosis is excellent.

INTRAHEPATIC BILIARY DISORDERS

Mark P. Rondeau

Cholangitis

Inflammatory disease involving the intrahepatic bile ducts is commonly encountered in veterinary practice. Cholangitis is recognized more commonly in cats than in dogs, but both species can be affected. The WSAVA Liver Standardization Group suggests that cholangitis be considered in the following four groups: neutrophilic cholangitis (NC), lymphocytic cholangitis (LC), chronic cholangitis associated with liver fluke infestation, and destructive cholangitis.[1]

Feline Cholangitis Complex

Cholangitis is a common hepatobiliary disorder of cats, second only to HL.[2] Although varying terminology has created some confusion regarding this syndrome, it is clear that feline cholangitis includes a spectrum of disease processes, including forms displaying neutrophilic inflammation and those lacking neutrophilic inflammation.

Neutrophilic Cholangitis

Histologically, NC is characterized by the presence of neutrophils in the lumen and/or epithelium of the bile ducts.[1] The disease is recognized to occur in acute and chronic forms. In acute neutrophilic cholangitis (ANC) edema and neutrophilic inflammation are seen in the portal areas, with occasional extension of inflammation to the hepatic parenchyma. In chronic neutrophilic cholangitis (CNC) there is a mixed inflammatory infiltrate consisting of neutrophils, lymphocytes, and plasma cells. Varying degrees of bile duct hyperplasia and fibrosis will be present depending on the chronicity of disease.

Etiology. Although the true etiology remains unknown, NC is largely suspected to be caused by ascending bacterial infection from the intestine.[1-3] Rates of bacterial isolation using traditional methods have varied greatly, from less than 20% to more than 60% in affected cats.[3,4] Recently, fluorescence in-situ hybridization (FISH) with a 16S rDNA probe that recognizes bacteria in general has been used to identify and localize bacteria in cats with cholangitis.[5] Combining traditional culture and FISH, bacteria were isolated in three of three (100%) cats with ANC and eight of 13 (61%) with CNC. The localization of the bacteria identified using FISH supports translocation of enteric bacteria as the cause of infection. Although it appears that bacteria play an important role in the etiology of NC in many cases, it is important to note that they are not identified in all affected cats. Some authors theorize that NC, and CNC in particular, may have an immune-mediated etiology with persistent inflammation following an initial bacterial infection or other unknown initiating factor.[3,6]

Pathophysiology. NC in cats is commonly associated with inflammatory bowel disease and pancreatitis.[3,4,7] The pathophysiology underlying the relationship of these diseases is unknown, but rational theories revolve around the unique anatomy of the feline biliary and pancreatic duct systems. In the cat, the common bile duct and pancreatic duct merge prior to entering the duodenum at the major duodenal papilla.[7] Cholangitis may develop secondary to reflux of ascending bacteria from the duodenum during vomiting. Pancreatitis may result from bacterial reflux into the pancreatic duct, or from pancreatic duct obstruction secondary to cholangitis.[7] In most reported cases, the inflammatory bowel disease associated with cholangitis is moderate or severe, whereas the pancreatitis tends to be mild chronic interstitial disease.[7]

NC is also commonly associated with extrahepatic bile duct obstruction (EHBDO). EHBDO has been identified in 40% of cats with ANC and 76% of cats with CNC.[4] Cholangitis and/or pancreatitis are the most common cause of EHBDO in the cat.[8] In one study, 64% of cats with EHBDO had cholangitis, representing 93% of cats that did not have a neoplastic cause.[8] It is unknown whether cholangitis is the cause or the result of EHBDO. Histologic changes consistent with CNC have been seen in the livers of cats with EHBDO secondary to pancreatic carcinoma, cholelithiasis and surgical occlusion of the common bile duct.[8] In contrast, cholangitis has been implicated as the sole cause of EHBDO resulting from proliferation of mucosa within the common bile duct.[8] Bacterial infection of bile has been commonly identified in cats with EHBDO,[4,8] but whether that infection is a cause or effect of EHBDO remains unknown.

Clinical Examination. Previous literature has highlighted differences in clinical presentation between cats with different forms of cholangitis. However, we have recognized few differences between the various forms[4,9] and suggest that any statistically significant differences cited previously hold little clinical relevance given the large degree of overlap within data ranges. NC can occur in cats of any age, breed, or sex. Clinical signs are nonspecific and include anorexia, lethargy, vomiting, and weight loss. The duration of these clinical signs ranges from a few days to a few months and may be shorter in cats with ANC than in those with CNC,[3] but this is not a consistent finding.[4,9] Physical examination findings commonly include dehydration and icterus. Fever is present in 19% to 37.5% of cases.[4,10] Some reports suggest that fever is more commonly associated with ANC than CNC,[10] while others recognize no difference.[4,9] Hepatomegaly is seen in fewer than half of the cases. Abdominal pain is noted occasionally.[3,4,9]

Diagnosis. Definitive diagnosis is made by examination of liver biopsy specimens, with ancillary diagnostics providing supportive information. Hematologic findings are variable and may include poikilocytosis, neutrophilia, and left shift, although these abnormalities are present in fewer than one-third of cases.[3,4,9,10] Biochemical analysis commonly reveals increased activity of ALT, AST, ALP, and GGT ranging in severity from mild to severe. However, increased liver enzyme activity may be absent in some cases. Serum total bilirubin is increased in most cases. Serum cholesterol may become increased in cases with EHBDO. Imaging findings are nonspecific for cholangitis, but may provide useful information regarding concurrent disease. Abdominal radiographs are rarely helpful. Ultrasonographic appearance of the liver in cats with NC can vary greatly, with the most common abnormality being a diffuse change in echogenicity ranging from hypo- to hyperechoic.[11] Dilation of intra- and/or extrahepatic bile ducts, gallbladder distention, increased gallbladder sediment, and thickening of the gallbladder or bile duct walls may be seen. Gallbladder distention and bile duct dilation may indicate EHBDO, but these changes may occur in cats with cholangitis lacking obstruction. Ultrasonography will also provide information regarding the presence of concurrent disease, such as pancreatitis and inflammatory bowel disease.

Wedge liver biopsy during laparotomy is the optimal method for obtaining a definitive diagnosis. Other biopsy techniques that may be considered include laparoscopic and ultrasound-guided Tru-Cut needle approaches. Tru-Cut needle biopsy diagnoses correlate with wedge biopsies in fewer than 50% of cases.[12] Diagnostic accuracy of laparoscopic liver biopsies compared with wedge biopsies have not been evaluated. Laparotomy and laparoscopy provide the additional benefit of evaluation and sampling of extrahepatic structures. Laparotomy should be performed in any cat suspected of having EHBDO. While the optimal sampling strategy is unknown, biopsies should be obtained from multiple liver lobes, as we have recognized wide ranges of severity between different lobes in the same cat. In patients that are not stable enough for liver biopsy, such as those with hypotension, coagulopathy or HE, fine-needle aspiration with cytology offers a less-invasive diagnostic approach as it can usually be performed quickly with light sedation. However, liver cytology correlates with biopsy results in only 39% to 60% of cases.[13,14] Cytology is sensitive for identifying the presence of HL, however this is the most common misdiagnosis when using cytology.[14] Cytology is

insensitive for identifying cholangitis in cats, diagnosing fewer than 30% of cases.[14] Cytologic examination of bile may prove more sensitive for the diagnosis of NC in cats. In five of seven cats with CNC evaluated at this institution, bile cytology revealed neutrophilic inflammation, presence of bacteria, or both. Techniques have been described for safely obtaining bile via ultrasound-guided percutaneous cholecystocentesis in lightly sedated cats.[15]

Samples for aerobic and anaerobic bacterial cultures should be obtained in any cat suspected of having cholangitis. Gallbladder bile is preferred to liver tissue as the culture source. In a group of 58 cats suspected of having hepatobiliary disease, bile cultures isolated pathogens in 36% compared with only 14% of liver cultures.[16] In the same study, 22 dogs and cats had both liver and bile cultured and none had a positive liver culture in the absence of a positive bile culture.[16] In a group of cats with cholangitis, bile cultures were more likely to isolate pathogens (75% vs. 33%) and less likely to yield contaminants (4% vs. 29%) than liver cultures.[4] In a small study comparing bile versus liver cultures in 22 cats with various hepatobiliary diseases, bile culture was positive in five (four had CNC) while liver culture was positive in only two. In the two cats with positive liver cultures, the same organism was isolated from bile.[17]

It is important to recognize that many cats with NC (and other hepatobiliary diseases that mimic it clinically) are not stable enough to tolerate diagnostic testing. In such patients, the risk of aggressive diagnostics may outweigh the benefits of obtaining a definitive diagnosis. In these cases, the diagnosis may be suspected based on clinical response to supportive care, including broad-spectrum antibiotic therapy.

Treatment. Optimal treatment protocols for cats with NC are unknown and the recommendations herein are based solely on anecdotal clinical experience. Antibiotics are the mainstay of treatment. Drug selection is ideally based on results of bacterial culture and susceptibility testing. In cases where cultures are not performed, or while results are pending, broad-spectrum coverage should be provided. The most commonly isolated pathogens are aerobic and anaerobic bacteria of enteric origin,[16] including *E. coli*, *Enterococcus* spp., and *Clostridium* spp., among others.[3,4,16] Effective empiric antibiotic combinations would include a penicillin, a fluoroquinolone, and metronidazole. The optimal duration of antibiotic therapy is unknown, but we recommend a 4- to 6-week course for initial treatment.

Supportive care and treatment of specific sequelae of liver disease should be included as indicated. Nutritional support is required in many cats and is best accomplished by use of enteral feeding tubes. We recommend placement of esophageal feeding tubes in cats with cholangitis if they are anorexic and stable enough for general anesthesia. In unstable patients, nasoesophageal feeding tubes offer a less-invasive method of providing short-term support.

Several medications and nutritional supplements (including ursodeoxycholic acid [UDCA], SAMe, milk thistle, vitamin E, vitamin C, carnitine, taurine, and phosphatidylcholine) have been suggested for treating cats with cholangitis. While most of these compounds have theoretical benefits, a clinical benefit has not been proven. To optimize client compliance and avoid adverse drug reactions, I prefer to minimize the number of medications given to feline patients. Because most cats with ANC respond well to antibiotic therapy, I rarely include other medications in our treatment protocol. However, in cats with ANC that do not quickly respond to antibiotics and in many cats with CNC, I like to use UDCA. Among its theoretical benefits, UDCA has immunomodulatory and choleretic properties that make it a rational choice for treating cholangitis.

Because of the possibility of immune-mediated mechanisms in the perpetuation of NC, particularly with CNC, corticosteroids may be appropriate in some cases. Initial treatment should always involve antibiotics in cats with NC. Failure to improve within 2 weeks of antibiotic therapy, or clinical deterioration prior to that time, warrants initiation of corticosteroid therapy. Prednisolone at 1 to 2 mg/kg twice daily is given initially and gradually tapered to the lowest effective dose. Antibiotics should be continued concurrently with corticosteroids for a minimum of 4 weeks. The duration of corticosteroid therapy varies between individual patients. Many cases can be gradually tapered off of corticosteroids over 4 to 6 months, while others require lifelong therapy.

Surgical intervention is required in cats with EHBDO; however, the optimal surgical procedure is unknown. Biliary diversion (cholecystocholedochostomy, choledochoduodenostomy, or cholecystojejunostomy) and choledochal stenting are the most common procedures. Surgery in cats with EHBDO is associated with significant perioperative morbidity. In many cases, profound hypotension develops intraoperatively after 45 to 60 minutes as a result of decreased vascular responsiveness and decreased myocardial contractility and is often refractory to interventions such as fluid or vasopressor therapy.[8,18,19] Whichever surgical procedure is chosen, it is clear that anesthesia time should be minimized and long-term medical management will be necessary. Biliary diversion is associated with short-term mortality rates of 36% to 57%[8,18] and is associated with long-term complications.[8,19] In a small case series describing choledochal stenting in cats with pancreatitis and cholangitis, five of seven experienced long-term survival (≥7 months), but reobstruction occurred in two of seven and chronic vomiting and recurrent cholangitis were reported.[19]

Prognosis. The prognosis for cats with NC is typically good.[3,4,10] Survival to discharge was reported in 72% of all cats with cholangitis in one study.[4] Median survival time of 29.3 months has been reported in cats with NC, with no difference between ANC and CNC.[10] Prognostic factors have not been identified. Given the high rate of perioperative morbidity and mortality, it seems likely that cats with EHBDO have a worse prognosis than those without EHBDO. Thirty percent to 40% of cats with EHBDO secondary to inflammatory disease die within a week of surgery.[8,18] However, in those that survive to discharge, long-term survival has been reported.[18]

Lymphocytic Cholangitis

The WSAVA Liver Standardization Group describes LC as a common, slowly progressive, chronic disease of cats characterized histologically by infiltration of small lymphocytes (and occasionally plasma cells or eosinophils) restricted to the portal areas associated with varying degrees of fibrosis and bile duct hyperplasia.[1] They remark that inflammation centered on the bile ducts may be present, but is not a hallmark of the disease. It is also stated that well-differentiated lymphoma may be difficult to differentiate from LC. Based on the existing literature regarding LC in cats, the description from the WSAVA group includes several clinically and histopathologically different subsets that may or may not revolve around a common pathogenesis. Recognition of these different subsets within the umbrella of LC may have therapeutic and prognostic ramifications.

Several investigators describe a group of cats with LC where inflammation is confined to portal regions and there is a lack of targeting of bile ductules or biliary epithelium.[2,20,21] This has been

referred to as *lymphocytic portal hepatitis*.[2,21] The connection between this histopathologic finding and clinical disease in cats is unknown, as it may represent a common change associated with aging. It was identified in 82% of cats older than 10 years of age and 96% of cats older than 15 years of age from a necropsy population that did not have primary liver disease.[21] It is also possible that this lesion represents a response to inflammation at a distant site, as it is similar to the lesion of nonspecific reactive hepatitis associated with chronic extrahepatic disease.[1] Although clinical signs have been described in cats with lymphocytic portal hepatitis,[10] the common occurrence of concurrent disease in these cats makes it difficult to know if the clinical signs are attributable to the lesions in the liver.

In another subset of cats, LC is marked by inflammation targeting bile ductules and infiltrating biliary epithelium, leading to progressive ductopenia.[20,22,23] These cases seem more likely to have clinical disease attributable to their liver pathology, although side-by-side comparisons of cases with and without bile duct targeting have not been performed. Cats with this form of LC in the United States have a similar clinical picture to cats with NC.[9] In the United Kingdom, this lesion has been associated with ascites, icterus, and hyperglobulinemia in young cats and termed *progressive lymphocytic cholangitis*.[22,23]

Etiology. Although the etiology of LC is unknown, theories suggest that it is an immune-mediated or infectious phenomenon. Genetic factors may also play a role, as Persian cats are overrepresented in the United Kindgom.[22,23] Immunohistochemistry in affected cats has provided evidence for an immune-mediated pathogenesis, although the inciting antigen is unknown.[20,23] Bacteria have been identified in the liver or bile of fewer than 20% of cats with LC.[3-5,17,20] Although *Helicobacter pylori* has been isolated from the liver and bile of cats with cholangitis, the evidence for this organism playing an important role in feline cholangitis is not compelling at this time.[24,25]

Pathophysiology. As with NC, concurrent inflammatory bowel disease and pancreatitis appear to be common in cats with LC,[3,4] although some authors report it to be uncommon.[23] The theory that reflux of duodenal bacteria into the biliary and pancreatic ducts incites inflammation may hold true for cats with LC, although a common immune mechanism must be considered.

Clinical Examination. The clinical picture of cats with LC varies widely and has significant overlap with other forms of hepatobiliary disease in cats, including NC.[4,9] Although some studies describe a predominance of older cats,[3] others describe more younger cats.[22,23] Nonspecific clinical signs, including anorexia, lethargy, vomiting, and weight loss, may be chronic and intermittent.[3,6,22] Physical examination findings may include icterus, hepatomegaly, or ascites, but none are consistent findings. Signs of HE (dullness, ptyalism, seizure) may develop in severely affected cats.

Diagnosis. Definitive diagnosis is made by liver biopsy. As discussed for NC, ancillary diagnostics will provide information to support hepatobiliary disease, but are not specific for LC. Hematology results may be unremarkable, even though marked lymphocytosis has been described in some cases.[3] Activity of serum liver enzymes is increased in many, but not all cases and varies in severity. Hyperglobulinemia has been described.[3,6,22] Abdominal radiographic and ultrasonographic findings are nonspecific, but may aid in the recognition of concurrent disease.

Distinction between LC and well-differentiated (small cell) lymphoma can be a challenge even for experienced pathologists. Preliminary data using immunohistochemistry and PCR for T-cell receptor clonality has not proven useful in differentiating between the two conditions. Surprisingly, cats with both LC and lymphoma had monoclonal T-cell receptors, oligoclonal T-cell receptors, and polyclonal T-cell receptors.[20] Using light microscopy, the following features were unique to LC and not present in cats with lymphoma: ductopenia, bile duct targeting by lymphocytes, and the presence of lipogranulomas within portal regions (representing a residual marker of cell death).[20] Until more studies are done evaluating molecular techniques, these features may prove useful in differentiating the two conditions. Interestingly, bile duct hyperplasia and fibrosis were present in cats with LC and those with lymphoma. This may suggest that an inflammatory state precedes the development of lymphoma,[20] which has been reported anecdotally.

Treatment. The therapeutic approach to cats with LC should be similar to that described for cats with NC in regards to supportive care and symptomatic treatment of the sequelae of liver disease. Because bacteria have been isolated from some cats with LC, I recommend treatment with broad-spectrum antibiotics while awaiting results of bacterial cultures. In contrast to NC, long-term treatment of culture negative cats with antibiotics is not warranted. Immunomodulation and immune suppression are the major components of treatment based on a presumed immune-mediated etiology. Cats that are culture negative, or that have failed to respond to antibiotics within a few days, should be treated with prednisolone at 1 to 2 mg/kg twice daily. Responders should be tapered gradually over 4 to 6 months to the lowest effective dose. Other drugs that are useful for immunomodulation include metronidazole and UDCA. Cats that fail to respond completely to corticosteroids and/or other immunomodulators, or who relapse while being treated, may require additional immunosuppressive drugs. Although these drugs have not been well evaluated in cats with LC, chlorambucil and methotrexate are suggested by some authors.[3] Cats with small cell lymphoma often respond to combination therapy with prednisolone and chlorambucil, but they may require a multidrug weekly sequential chemotherapy protocol.

Prognosis. Cats with LC have a variable prognosis,[3,6] likely a result of being diagnosed at different stages of a chronic disease process. Survival of greater than 5 years has been reported, and many cats that die appear to succumb to disease unrelated to the liver.[22] Other cases have been reported that fail to respond to treatment and die more acutely,[6] though this is uncommon in my experience. This is a disease that likely requires lifelong management and monitoring with relapse of illness possible as medication doses taper.

Chronic Cholangitis Associated with Liver Fluke Infestation

Trematode parasites of the families *Dicrocoeliidae* and *Opisthorchiidae* may inhabit the gallbladder and bile ducts of cats and rarely dogs.[26] There are multiple species with worldwide distribution. The most commonly identified species include the dicrocoelid *Platynosomum concinnum* and the opisthorchid *Amphimerus pseudofelineus*.[27-29] *P. concinnum* is mainly found in tropical and subtropical areas, including the southeastern United States.[26] *A. pseudofelineus* has a wider area of distribution throughout North and South America.[26] The life cycle is similar for both dicrocoelids and opisthorchids.[26] Parasite eggs are ingested by a land snail (*Subulina octona* or *Eulota* [*Bradybaena*] *similaris*), develop into cercariae and enter a second

intermediate host.[26,27,29] The dicrocoelids tend to use an arthropod, while opisthorchids utilize fish. Typically cats acquire infection by ingesting the second intermediate host. In the case of *P. concinnum*, the sporocysts leaving the snail intermediate host may be eaten by a paratenic terrestrial isopod host (pill, sow, or dung bugs).[26,29] Cats are infected by ingesting this form in a variety of lizard or amphibian intermediate hosts. Cercariae migrate from the cat intestine to the gallbladder and bile ducts, where they develop into adults. Eight weeks or more after infection eggs are passed in the feces to complete the life cycle.[27]

Clinical signs are proportional to parasite burden. Cats with light infections are often asymptomatic.[27,28] Clinically ill cats may present with nonspecific signs such as anorexia, lethargy, vomiting, or diarrhea. Severely affected cats present with signs of EHBDO such as icterus and acholic feces.[27-30] Preliminary diagnostics are nonspecific for fluke infestation. Eosinophilia proportional to the parasite burden may be present.[29] Serum liver enzyme activity may be mildly to moderately increased, although it is normal in many cases.[28-30] Abdominal ultrasound often reveals evidence of EHBDO.[28-30] Definitive diagnosis by identification of flukes or fluke eggs in the feces is difficult as small numbers of eggs are shed daily, the eggs have varying morphology at different stages of development, and the eggs are quite small.[27] Fecal concentration-sedimentation using the formalin-ether technique is the most reliable method of identifying eggs in stool.[27,29] Eggs may also be identified in cytologic preparations of bile.[28,30] Eggs or adults may be seen in liver biopsy specimens, but they are inconsistently identified.[1,27,28,30] Histopathologic changes seen in the liver are characterized by dilation of larger intrahepatic bile ducts associated with papillary projections and marked periductal and portal fibrosis. Mild to moderate inflammation may be present within the ducts (neutrophils and macrophages) and in the portal areas (neutrophils, lymphocytes, plasma cells). Eosinophils may be present in limited numbers.[1] Rarely, chronic cholangitis associated with liver flukes can result in the development of cholangiocarcinoma.[1,29]

Optimal treatment protocols have not been established, but praziquantel at 10 to 20 mg/kg daily for 3 days appears to be the most effective.[26-30] Doses as high as 40 mg/kg daily have been used successfully,[28] but this dose has also been fatal in cats.[26] Sporadic resumption of egg shedding following praziquantel has been reported, suggesting that it does not completely eliminate infection.[26,27] For this reason, continued treatment at 12-week intervals has been recommended.[29] Symptomatic and supportive therapy should be tailored to the individual patient. Cats with EHBDO require surgical decompression. Glucocorticoids and UDCA may have some benefit in controlling inflammation and providing choleresis. Although infected cats may remain asymptomatic, patients with EHBDO appear to have a grave prognosis. Long-term survival has only been reported in rare cases.[28,30]

Canine Cholangitis

Cholangitis is rarely reported in dogs. Reports of cholangitis in dogs include two distinct entities: destructive cholangitis and NC.

Destructive cholangitis is characterized histopathologically by a loss of bile ducts (ductopenia) within the smaller portal areas, associated with cholestasis, portal inflammation consisting primarily of macrophages, neutrophils, and occasionally eosinophils, and progressive portal fibrosis.[1,31,32] This is a rarely reported lesion of unknown etiology. It has been postulated that the lesion represents an idiosyncratic drug toxicity. However, of the eight cases reported in the literature only three had a prior drug history: two having received potentiated sulfonamides and the other having received amoxicillin-clavulanate, milbemycin oxime, and amitraz prior to the onset of clinical signs.[31,32] The proposed toxic etiology is based on these case histories and histopathologic similarity to humans with idiosyncratic drug toxicity. Other toxic insults and viral infection, such as canine distemper, can also result in destructive cholangitis.[1] Affected dogs typically present for signs referable to cholestasis, including anorexia, icterus, vomiting, and acholic feces.[31,32] Activities of serum liver enzymes and total bilirubin are moderately to markedly increased. Abdominal ultrasound may be unremarkable, showing only mild dilation of intrahepatic bile ducts.[32] Definitive diagnosis is made by liver biopsy. Optimal treatment options are unknown, but should undoubtedly involve discontinuation of any medications that preceded illness. Corticosteroids for immune suppressive and antiinflammatory effects and UDCA for immunomodulatory and choleretic effects would be rational treatments options, but their efficacy has not been documented. The prognosis appears to be poor, as six of the eight reported cases were euthanized within 6 weeks and the remaining two had only short-term followup (<6 months).[31,32]

NC, as described in the cat, has been rarely reported in dogs.[33-37] Bacteria have been isolated from the majority of cases reported, including *E. coli*, *Klebsiella* spp., *Proteus mirabilis*, *Streptococcus* spp., and *Clostridium* spp.[34-37] Although the bacterial species would support ascending infection from the intestine, the literature is too sparse to make conclusions about the pathophysiology of this disease in dogs. Bacterial infection could also spread hematogenously or via translocation from the portal circulation. The clinical presentation and diagnostic findings are similar to those reported for cats with NC. Affected dogs present with lethargy, anorexia, vomiting, and icterus usually of acute onset. Fever is reported in approximately half of the cases.[33-37] Neutrophilia with or without a left shift is common. Activity of serum liver enzymes is typically increased and most dogs have mild to moderate elevation of serum total bilirubin. Ultrasonography is nonspecific, with the liver varying from normal to hyperechoic with some heterogeneity.[34,36] Thickening and hyperechogenicity of the gallbladder wall is common.[36] Definitive diagnosis is made by liver biopsy with changes similar to those reported in cats with NC. Most dogs have some degree of mixed inflammatory infiltrate, similar to CNC.[33-37] This infiltrate extends into the hepatic parenchyma in the majority of cases. Aerobic and anaerobic culture of bile or hepatic tissue should be performed, though bile has been the source of bacterial isolation in most cases. Treatment involves antibiotic therapy guided by culture and susceptibility results. Duration of treatment should be prolonged, as antibiotic courses of 8 to 12 weeks or greater have been required to completely eliminate bile infections. Clinical improvement precedes bacterial eradication.[36] The prognosis appears to be good in most cases, although dogs with concurrent disease may have a worse prognosis.

Congenital Disorders

Cystic Disease

Liver cysts arising from the intrahepatic bile ducts are rarely encountered in veterinary practice. Although cysts may be acquired secondary to trauma, neoplasia, inflammation, or biliary obstruction,[1,38] the vast majority of cases described in the literature are congenital in origin. Congenital cystic liver diseases result in dilation of various segments of the intrahepatic bile ducts, and they are associated with varying degrees of hepatic fibrosis and cysts in other organs (most commonly the kidneys). Little is known about inheritance patterns of cystic disease in dogs and cats. The various morphologic patterns of cystic disease likely represent abnormalities of bile duct

development at different stages of their formation. The WSAVA Liver Standardization group suggests that cystic disorders be classified into one of the following groups: congenital dilation of the large and segmental bile ducts; juvenile polycystic disease/congenital hepatic fibrosis; and adult polycystic disease.[1]

Congenital dilation of the large intrahepatic bile ducts (i.e., the hepatic ducts and segmental ducts) has been described in dogs.[39-41] The lesion is similar to that of Caroli disease in humans and it is thought to represent an early defect in the formation of the intrahepatic bile ducts.[1,40] The disease is marked by extreme, diffuse, grossly evident dilation of the extrahepatic portion of the large intrahepatic bile ducts containing pale-yellow viscous fluid. The gallbladder and common bile duct are normal, as these have a separate embryologic origin from the intrahepatic bile ducts. The liver is normal to mildly increased in size, with diffuse cysts of varying sizes throughout. Histologically there are areas of marked bridging portal fibrosis containing multiple dilated bile ducts. The lobular architecture of the liver is normal. Although concurrent ascending cholangitis commonly occurs in humans, this is rarely reported in dogs.[39-41] In addition to the hepatic lesions, affected dogs have fusiform, radially arranged renal cysts with moderate to marked fibrosis throughout the renal cortex and medulla.[39-41] Affected dogs are presented early in life, ranging from 13 weeks to 3.5 years.[39-41] Clinical signs include vomiting, weight loss/failure to thrive, decreased appetite, lethargy, ascites, and rarely icterus and neurologic signs. The clinical signs are typically chronic in nature. GI signs, neurologic signs, and ascites are likely a result of portal hypertension caused by pressure of the cysts on the portal vein. Hepatomegaly may be noted on physical examination. Activity of serum liver enzymes is typically normal to mildly increased, although marked increases in activity of ALT and ALP have been reported.[40] Renal azotemia is present in some patients. Ultrasonographically, cystic dilations of the intrahepatic ducts (most with associated calcification) are easily recognized, even though the renal cysts are not always apparent. Definitive diagnosis is made on the basis of the gross and histologic findings described above. Rational treatment options and prognosis are unknown, as only one dog in the literature has been treated. This dog was doing well on a low-protein diet at 5 months of followup.[40] Most of the affected dogs have been fairly stable, and supportive care may be warranted despite the appearance of severe cystic disease.

Juvenile polycystic disease/congenital hepatic fibrosis has been described in litters of Cairn Terriers, West Highland White Terriers, and cats.[42-44] This form is analogous to autosomal recessive polycystic kidney disease in humans, and the inheritance appears to be autosomal recessive in the few families of veterinary patients that have been described.[42,43] The liver cysts are thought to represent an intermediate defect in the development of the intrahepatic bile ducts.[1,40] The liver involvement is primarily microscopic including fibrotic portal areas containing abnormally structured, dilated small bile ducts. The result is a grossly enlarged and firm liver.[40] Renal cysts are present and are identical to those described for dogs with dilation of the large and segmental bile ducts.[40] Affected animals are usually presented at less than 8 weeks of age for abdominal distention because of renomegaly and hepatomegaly.[42,43] However, one 12-year-old cat with similar lesions has been reported.[44] Most affected animals are ill or have died at the time of presentation.[42,43] Liver enzyme activity has been increased in the few animals in which it was evaluated.[43] Abdominal ultrasound may identify cysts and definitive diagnosis is made based on histologic findings as described. Treatment has not been attempted, and the prognosis appears to be grave.

Adult polycystic disease is most commonly recognized as polycystic kidney disease in Persian cats.[44,45] It has also been reported in cats of other breeds and in dogs.[39,43] This is similar to autosomal dominant polycystic kidney disease in humans. Inheritance in Persian cats is autosomal dominant.[45] Liver cysts are thought to represent a late defect in the development of peripheral intrahepatic bile ducts. The liver may contain multiple cysts ranging from less than 1 mm to greater than 12 cm in diameter. These cysts typically contain clear, colorless fluid. Discrete fibrotic areas containing small, irregularly formed bile ducts, referred to as *Von Meyenburg complexes*, may be present.[1] In the kidneys, multiple cysts may form in any segment of the kidney but may involve only a small percentage of the nephron population. This is in contrast to the diffuse cysts seen with congenital dilation of the large and segmental bile ducts and juvenile polycystic disease.[1,40] Hepatic cysts are present in 10% to 40% of cats with polycystic kidney disease, while hepatic fibrosis is recognized in up to 48%.[44,45] The hepatic cysts are usually incidental findings and the animals are not clinically ill unless they develop renal failure secondary to cysts in the kidneys, which happens in adulthood.

Biliary Atresia

Biliary atresia is an extremely rare congenital disorder, having been reported in only one dog and one cat.[46,47] In both cases, the common bile duct was not patent because of atresia. In the dog, the occluded segment of bile duct was histologically comprised of fibrous tissue with minimal inflammation.[47] The etiology is unknown, but this lesion likely represents an embryologic nonfusion of the cranial (hepatic) and caudal (cystic) anlages of the bile ducts during development.[1] Other possible explanations include ischemic, toxic, traumatic, or infectious insults occurring pre- or postnatally.[47] Affected animals have presented at 4 to 6 months of age with clinical signs of depression, anorexia, vomiting, or lameness associated with rickets because of inadequate vitamin D absorption.[46,47] Affected animals show icterus, hepatomegaly and acholic feces. Serum biochemistry abnormalities are consistent with EHBDO. Definitive diagnosis is made at exploratory laparotomy. Surgical biliary diversion is a viable treatment option depending on the location of atresia, but it was unsuccessful in the one case reported.[47] A guarded prognosis should be given as for any animal undergoing a biliary diversion procedure (see discussion under "Neutrophilic Cholangitis").

Intrahepatic Cholestasis

Cholestasis is impaired bile flow resulting in the accumulation of bile components in the blood.[1] Intrahepatic cholestasis occurs secondary to a variety of primary or secondary hepatobiliary diseases.[1,48,49] Increased activity of serum liver enzymes, particularly ALP and GGT, is common with intrahepatic cholestasis but is not specific for the condition. Clinically patients may appear jaundiced, but the predominant clinical sign will be related to the underlying disease process. Cholestasis is marked by the presence of bile plugs in canaliculi, phagocytosed bile in Kupffer cells, and bile granules within hepatocytes. These changes are easily recognized in cytologic and frozen preparations, but are less apparent in paraffin-embedded specimens, particularly in cats.[1] When cholestasis is identified, EHBDO should be ruled out. This should be easily accomplished by abdominal ultrasonography as animals with intrahepatic cholestasis lack the dilation of intra- and extrahepatic bile ducts that is typical of EHBDO.[48] However, exploratory laparotomy should be considered in highly suspicious cases for confirmation.

Intrahepatic cholestasis is associated with extrahepatic bacterial infection in dogs.[49] This syndrome is well characterized in humans and may occur in other species such as the cat. It represents an important differential diagnosis for hyperbilirubinemia in animals without primary liver disease, as over 40-fold increases in total bilirubin have been reported. The physiology behind this mechanism is incompletely understood, but it is thought to result from reduction of bile salt–dependent and –independent bile flow caused by bacterial toxins and/or inflammatory mediators.[49]

Neoplastic Disorders

Tumors of biliary origin in dogs and cats include cholangiocellular adenoma, cholangiocellular carcinoma, and carcinoid.[50] They are uncommon, representing less than 1% of all canine and feline neoplasms.[51-54] The tumors of epithelial origin, cholangiocellular adenoma and carcinoma, are the most common, comprising 40% of all hepatic neoplasms in dogs[51-53] and 56% to 80% of all hepatic neoplasms in cats.[54-56] Tumors showing characteristics of both hepatocellular and cholangiocellular carcinoma have been reported rarely.[50,52] In dogs, 70% to 100% of biliary epithelial tumors are malignant,[51,52] while in cats 35% to 43% are malignant.[54-56] Cholangiocellular adenomas commonly contain cystic components, especially in cats, and have been referred to as biliary or hepatobiliary cystadenomas in this species.[57,58] Cholangiocellular tumors arise predominantly from intrahepatic bile ducts in both species. Extrahepatic location is more common in cats than in dogs and is always associated with malignancy.[51-54,56] In both species, cholangiocellular carcinomas are more likely to present as multiple or diffuse tumors than are adenomas.[51,52,54] Carcinomas are highly metastatic (70% to 90% rate) with local lymph nodes, peritoneum, and lung being the most common sites of metastasis.[51,52,54] The etiology of biliary neoplasia is unknown. Affected dogs and cats are typically middle-aged to older, although animals with malignancy may present at a younger age than those with benign disease.[52,56] Clinical signs are usually vague (such as anorexia and lethargy) and somewhat chronic. Malignant tumors are more likely to cause clinical signs, as many benign tumors are incidental findings not associated with illness.[51,56-58] Hepatomegaly or the presence of a cranial abdominal mass may be identified on physical examination. Increased activity of serum liver enzymes is more commonly associated with malignancy, often being absent with benign tumors.[51,56,58] Even though abdominal radiographs will often identify the presence of hepatomegaly or an hepatic mass, ultrasonography is the preferred imaging method for identification of biliary neoplasms. This modality allows for determination of the cystic nature of the tumors[58] and for the evaluation of metastatic potential. Fine-needle aspiration and cytology are of limited utility for diagnosis of biliary epithelial tumors. Carcinoma was correctly identified via liver mass aspiration in only 20% of cases in one study.[14] However, cytology is recommended as it likely exhibits high specificity, especially for metastatic lesions. Surgical excision and biopsy is the optimal diagnostic and therapeutic technique for tumors confined to one or two liver lobes. Surgical excision appears to be curative in cats with benign tumors,[56,57] but malignant tumors carry a poor prognosis in both dogs and cats with many cases not surviving to discharge and survival greater than 6 months not reported in any case.[56,59] Adjunctive chemotherapeutic protocols have not been reported.

Carcinoids, also referred to as neuroendocrine tumors, are far less prevalent in dogs and cats than the tumors of biliary epithelial origin.[52,54,55] These tumors are thought to develop from neuroendocrine cells in the epithelium of bile ducts or gallbladder or from hepatic progenitor cells.[50] They may be identified at intrahepatic or extrahepatic locations. They appear to have a more aggressive course than cholangiocellular carcinomas, with the majority being present in multiple lobes and greater than 90% having metastasized at the time of diagnosis.[52,54,55]

EXTRAHEPATIC BILIARY DISORDERS

Michael D. Willard and Theresa Fossum

Etiology

The major pathogenetic mechanisms of canine and feline extrahepatic biliary tract disease are obstruction, inflammation, and exudation. The major causes of extrahepatic biliary tract obstruction (EHBO) are pancreatitis, gallbladder mucoceles (in dogs), cholelithiasis, parasitic infections (in cats), and tumors. EHBO is more common in dogs than cats. Biliary tract inflammation (e.g., cholecystitis, cholangitis) is primarily caused by bacterial infection, but can be nonseptic or parasitic, especially in cats. Gallstones may be associated with biliary tract disease (e.g., infection, obstruction), but the majority of them appear to be clinically silent. Stones in the gallbladder are termed *choleliths* while stones in the biliary tract are termed *choledocholiths*. Biliary tract exudation or leakage can be caused by traumatic (primarily of the bile ducts) or spontaneous rupture (primarily of the gallbladder). The latter is caused by necrotizing cholecystitis, which can be caused by sepsis (e.g., infectious cholecystitis), pressure necrosis (e.g., mucocele), or infarction. Biliary tract *tumors* are rare and of uncertain cause.

Pathophysiology

Extrahepatic Biliary Tract Obstruction

The common bile duct passes through the lesser omentum and the pancreatic parenchyma before entering the mesenteric wall of the duodenum. In the dog, it empties near the opening of the minor pancreatic duct at the major duodenal papilla, whereas in the cat it joins with the major pancreatic duct before emptying into the duodenum. Inflammation and edema with pancreatitis may be sufficient to cause compression and obstruction of the bile duct. This is probably the most common cause of canine EHBO.[1] There is, however, no consistent relationship between clinical severity of the pancreatitis and likelihood of EHBO, possibly because pancreatitis can affect different regions of the pancreas. Pancreatitis is a rare cause of EHBO in the cat. Chapter 60 discusses the breeds at increased risk for pancreatitis and causes.

Gallbladder mucoceles occur primarily in dogs. In such cases, the gallbladder is filled with inspissated, semisolid mucus that may extend into the bile ducts causing obstruction. Mucoceles can exceed the storage capacity of the gallbladder thereby causing pressure necrosis on the wall of the gallbladder. They can also spontaneously rupture (often at the fundus)[2,3] causing bile peritonitis. The cause of gallbladder mucocele is unknown, but might include dysfunction/hyperplasia of mucus-secreting cells in the gallbladder mucosa. Mucoceles may become secondarily infected.[2]

Gallstones are often clinically silent and observed incidentally only at the time of abdominal imaging. They can be associated with cholecytitis,[4] but they rarely cause EHBO because they must be small enough to enter the cystic bile duct but large enough to lodge there.

Parasites occasionally cause obstruction. *Platynosomum fastosum* (i.e., *P. concinnum*) is a fluke that inhabits the gallbladder and/or bile ducts of cats that are infected by eating lizards or toads.[5] Natural infections are found primarily in Florida, Hawaii, and the Caribbean. It may be asymptomatic or may cause obstruction or fibrosis. They are rare causes of cholecystitis.

Tumors may cause obstruction, and may be one of the more common causes in cats.[6,7]

Inflammation and Necrosis

Cholecystitis is most commonly caused by bacterial infection, ostensibly from bacterial migration up the bile duct. Various Gram-positive, Gram-negative, aerobic, and anaerobic bacteria (e.g., *Clostridium*, *Staphylococcus* spp., *Enterococcus* spp., *Streptococcus* spp., *Klebsiella* spp., *E. coli*, *Helicobacter* spp.) have been reported.[8-11] Infections caused by gas-producing bacteria can produce emphysematous cholecystitis. Because of a shared biliary and pancreatic ductal system in the cat, hepatobiliary disease is a well-established risk factor for pancreatitis in the cat. Aseptic infection of the gallbladder (necrotizing cholecystitis) has been reported, and infarction is one such cause.[11,12]

Exudation

Leakage of bile into the abdomen can be a result of mechanical forces (e.g., automobile trauma) that cause a shearing effect resulting in transaction of the common bile duct or one of the other bile ducts. Mechanical rupture has also been reported following gunshot trauma. Necrosis of the gallbladder raises the risk for rupture of the gallbladder and occasionally the bile ducts.

Gallstones

Canine and feline gallstones are typically composed of cholesterol, bilirubin, or may be mixed (as opposed to human gallstones which are usually caused by cholesterol).[4] Feline gallstones are typically calcium carbonate or mixed stones.[13]

Clinical Examination

Biliary tract diseases can cause severe clinical signs (e.g., anorexia, depression, vomiting, icterus, abdominal pain) or they may be relatively asymptomatic. Most symptomatic patients have serum biochemical abnormalities (e.g., increased serum ALT, ALP, and serum bilirubin). Hypercholesterolemia is common in patients with EHBO. Hyperbilirubinemia by itself does little besides cause icterus; therefore, patients with extremely high serum bilirubin concentrations can be relatively asymptomatic. Renal failure has been attributed to excessively high serum bilirubin concentrations, but it is unclear that bilirubin is the cause or that this is common. Shetland Sheepdogs[14] appear to have an increased risk for biliary tract disease, and Cocker Spaniels might also (see Chapter 62).

Besides icterus, clinical signs in patients with EHBO are primarily a result of the cause of the obstruction, not the obstruction itself. Canine pancreatitis in particular may cause severe clinical signs (e.g., anorexia, vomiting, abdominal pain—see "Complications of Liver Disease" section). However, not all patients with pancreatitis-induced EHBO have severe pancreatitis. Causes of EHBO that are insidious (e.g., mucoceles, tumors, and stones) are often unsuspected until the patient becomes icteric.

Biliary tract inflammation such as septic cholecystitis is well-documented in dogs and cats. Shetland Sheepdogs appear to be at a greater risk of inflammatory biliary tract disease than most other breeds.[14] Clinical signs vary, but most animals are clinically ill with anorexia and vomiting as more prominent symptoms. Fever is uncommon, icterus inconsistent, and leukocytosis is often insignificant, even with marked bacterial infections of the biliary tract.

Gallstones are generally asymptomatic. They can be associated with cholecystitis or EHBO.

Bilious abdomen can be a clinically mild condition, or it can be associated with life-threatening signs. Septic bilious abdomen causes extremely severe peritonitis with systemic inflammatory response syndrome (e.g., anorexia, vomiting, abdominal pain, poor perfusion, fever, and death). These patients may be in the initial hyperdynamic state (e.g., red mucus membranes, bounding pulse, fever, or hypothermia) or, if initially undiagnosed, can be in the late hypodynamic state (e.g., pale mucus membranes, weak pulse, and hypothermia). Intraperitoneal bile seems to make septic peritonitis more severe. In contrast, some animals with sterile bilious abdomen (e.g., as a consequence of automobile trauma) are essentially normal except for ascites and icterus.

Diagnosis

Plain radiography is occasionally diagnostic of biliary tract disease. Some gallstones are radiopaque (Figure 61-30).[4] Finding air in the gallbladder or in the wall of the gallbladder (i.e., emphysematous cholecystitis; Figure 61-31) is diagnostic of infection with a gas-producing bacterium. "Porcelain" gallbladder (i.e., a radiopaque gallbladder because of intramural mineralization of the gallbladder) is associated with carcinoma.[15]

Ultrasound is generally accepted as the most important and sensitive method for diagnosing extrahepatic biliary tract diseases.[7] Many patients that are not suspicious for biliary tract disease are fortuitously diagnosed when ultrasound or radiographs are requested for various reasons.[14] In difficult cases (e.g., partial EHBO versus complete EHBO), nuclear scintigraphy techniques can be used[16]; however, this seems to be rarely required.

Diagnosis of EHBO generally relies upon the use of ultrasound. Dilation of the bile ducts (normal canine bile ducts are ≤3 mm; normal feline bile ducts are ≤2 to 2.5 mm) is primarily caused by EHBO, and is generally seen by 3 days postobstruction. If one is unsure whether the ducts are dilated, repeating the examination in 3 days should be helpful. Enlargement of the gallbladder is not diagnostic of EHBO because anorexia and starvation of any cause may do the same thing. However, failing to find a dilated gallbladder

Figure 61-30 A lateral radiograph of a cat. There are several radiodense choleliths. These were serendipitous findings; the cat had no signs referable to abdominal disease. The cat was not treated for the stones and did well.

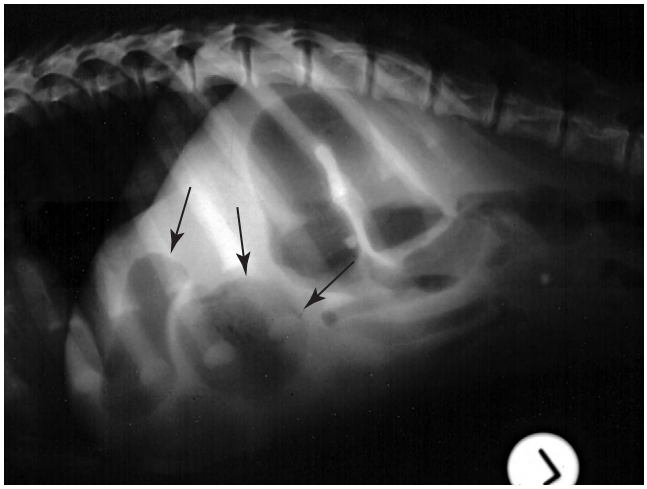

Figure 61-31 A lateral radiograph of a dog with emphysematous cholecystitis. The air-filled structure pointed out by *small arrows* is the pylorus; the air-filled structure pointed out by *larger arrow* is an air-filled gallbladder.

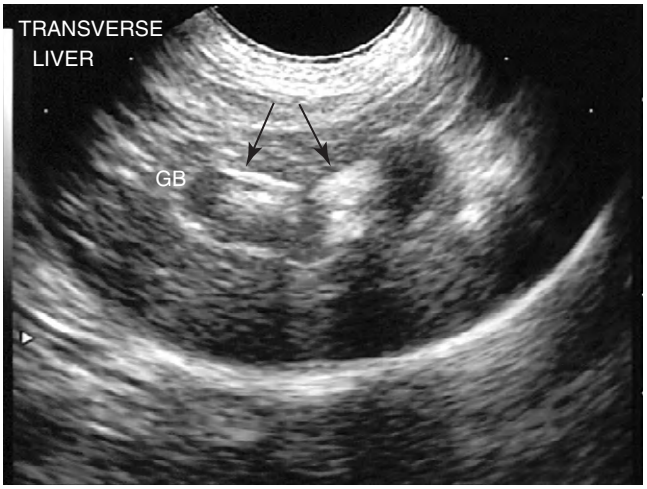

Figure 61-33 An ultrasonographic image of the gallbladder of a dog with gallstones (*arrows*). The stones were found fortuitously during an abdominal ultrasound; there was no evidence that they were causing any clinical signs.

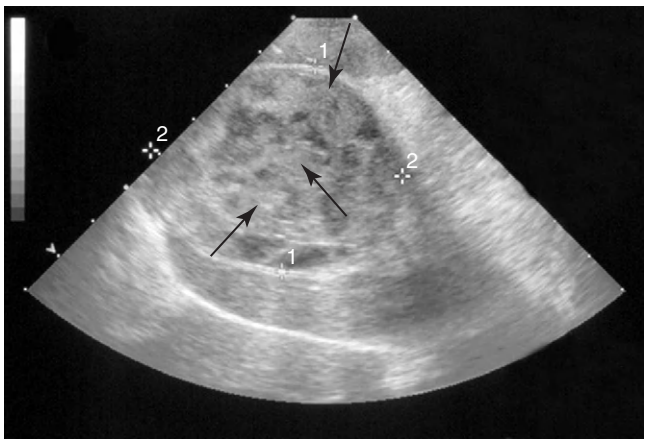

Figure 61-32 An ultrasonographic image of a Dachshund's gallbladder. The gallbladder is filled with hyperechoic material (*arrows*) that was not gravity dependent. The dog was asymptomatic for biliary tract disease and was still in good health without therapy for the gallbladder 10 months after this image was taken.

in a patient with clearly dilated bile ducts suggests biliary tract inflammation or prior EHBO. Any dog with EHBO should be suspected of having acute pancreatitis until proven otherwise. Chapter 60 details the diagnosis of pancreatitis. If acute pancreatitis is eliminated in a patient with EHBO, then one should look for gallstones and tumors, first by imaging and then by exploratory surgery or laparoscopy if imaging fails to provide a diagnosis.

Mucoceles are readily diagnosed by ultrasound, although there is some debate about what constitutes a mucocele. "Classic" mucoceles are described as producing a "kiwi fruit" appearance without gravity-dependent bile movement. "Sludge" in the gallbladder is a common finding (and it has gravity-dependent movement), but is not clinically significant.[17] The gallbladder of clinically normal dogs may appear abnormal on ultrasound examination (Figure 61-32), while patients with significant biliary tract disease may appear essentially normal. Whether or not patients with ultrasonographic abnormalities of the gallbladder will become symptomatic cannot be reliably predicted.

Cholecystitis is often diagnosed by ultrasound-guided percutaneous aspiration of gallbladder bile for cytology and culture. This is a relatively sensitive and specific procedure for diagnosing biliary tract infection.[2,18] The finding of a dilated bile duct coincident with a normal-size gallbladder suggests cholecystitis, prior EHBO, or a rare congenital problem such as Caroli disease.[19] It is important to note that patients with bacterial cholecystitis may have no ultrasonographic or gross abnormalities. Ultrasound may be suggestive, but is relatively insensitive for cholecystitis.[8,20] Consequently, it is probably best to routinely aspirate bile for cytology and culture in patients with hepatobiliary disease.

Gallstones are relatively easy to diagnose, most of them are easy to find by radiographs, more so by ultrasonography (Figure 61-33).

Treatment

With EHBO, the underlying cause is always the primary concern. EHBO in and of itself is not the primary consideration when deciding upon therapy. Pancreatitis, for example, is primarily a medical disease (see Chapter 60). Surgery is rarely appropriate in the management of pancreatitis even when it is causing EHBO. If deemed necessary, EHBO caused by pancreatitis can be relieved by percutaneous aspiration[21] or placement of a biliary tract stent.[22] If absolutely necessary, a cholecystoduodenostomy may be performed, but this surgery should be avoided if possible. These procedures are seldom necessary because almost all patients with EHBO caused by pancreatitis will experience resolution of the obstruction with medical therapy.

Gallstones should be removed only if they are causing obstruction or cholecystitis. It is usually better to perform a cholecystectomy[4,13] as opposed to a cholecystotomy; the former has a lower morbidity and mortality rate in people and presumably in dogs and cats as well. Biliary tract tumors can seldom be cured surgically.

If a patient has EHBO caused by something that cannot be treated medically (e.g., mucocele, tumor, pancreatic stricture, traumatically torn bile duct), then a biliary bypass procedure can be performed. Cholecystoduodenostomy can relieve the obstruction, although the surgery requires special surgical skills. This surgery can predispose the patient to recurrent, ascending cholecystitis or other complications[10,23] and should only be performed in patients that

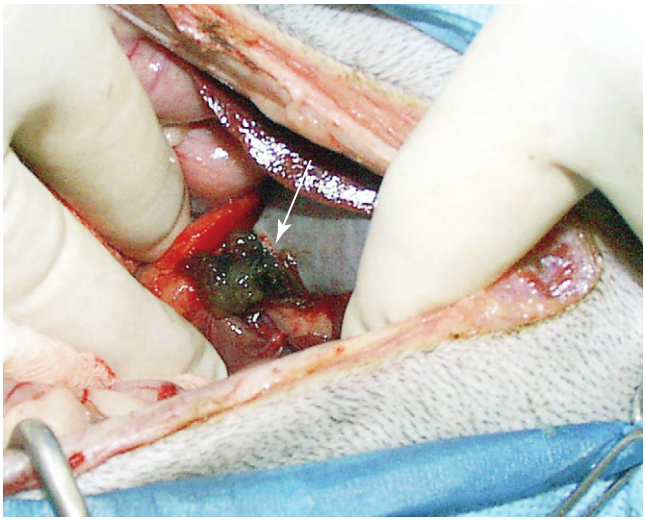

Figure 61-34 A photograph taken at surgery. The abdomen has just been opened, and bile has just begun to escape from a spontaneous rupture of the gallbladder wall (*arrow*) caused by necrotizing cholecystitis.

absolutely require it. Generally speaking, EHBO caused by pancreatitis that is not resolving as quickly as desired is not necessarily a good indication for this procedure; patience and medical therapy generally resolve the problem. In fact, pancreatitis can be a complication of surgery in this region.[24]

Many animals with hepatic disease are concurrently treated with antioxidants and other hepatoprotectants. Although most of these drugs will not hurt patients with biliary tract disease (in fact, they may be beneficial if the disease is extending into the hepatic parenchyma, such as cholangitis/cholangiohepatitis), care must be taken before administering UDCA. UDCA is a choleretic agent that stimulates bile flow. This could be disadvantageous in a patient with complete EHBO.

Mucoceles usually need to be removed surgically.[2,3,14] Medical management may be attempted (e.g., fat-restricted diet plus UDCA), but there is a substantially increased mortality rate for patients that experience gallbladder rupture (Figure 61-34); consequently, surgery is probably the safest course. Most patients are not at risk of immediate rupture. As long as ultrasonography does not suggest impending rupture, one should make sure the patient is an optimal anesthetic risk.

Bacterial cholecystitis, uncomplicated by EHBO or stone, should generally first be treated with antibiotics, usually for 4 to 6 weeks. However, some patients with bacterial cholecystitis cannot be cured with antibiotic therapy, ostensibly because the infection has localized in the gallbladder mucosa. These patients consistently relapse after discontinuation of antibiotics, and therefore a cure may be achieved only with antibiotics plus cholecystectomy. When performing this surgery, great care should be taken to avoid causing a stricture or obstruction of the common bile duct. Postcholecystectomy bile duct obstruction may prove fatal. It is also very important to be avoid traumatizing the pancreas to avoid severe pancreatitis.[24]

Biliary tract leakage is treated based upon the underlying cause. If the gallbladder has ruptured, cholecystectomy is usually most appropriate. If the bile duct has ruptured, it is very difficult to successfully anastomose the two ends. In that instance, one generally must perform a cholecystoduodenostomy and ligate both ends of the torn bile duct. It is important to avoid biopsying the gallbladder as that has a risk of dehiscence. In general, one should either remove the gallbladder, aspirate gallbladder bile, gently express the gallbladder, or leave it undisturbed. If the leakage is associated with septic peritonitis, then that is a true emergency and requires immediate, aggressive medical and surgical therapy.

Gallstones may be monitored if the patient is asymptomatic.

Tumors can rarely be resected; they are generally inoperable when found. Rare examples exist of patients with biliary tumors being cured surgically.

Biliary flukes can be treated with praziquantel (20 to 40 mg/kg SQ for 3 days).

Prognosis

Chapter 60 discusses pancreatitis in greater detail. Biliary mucoceles that have not ruptured often have a good prognosis; however, one report found a 32% mortality rate in patients without a rupture versus 68% mortality in patients with bile peritonitis.[14] The report authors recommended a more preemptive approach (i.e., versus waiting until the patent is symptomatic). Another group found no difference in mortality between rupture and nonruptured mucoceles (i.e., 21%).[3] Gallstones generally are innocuous, and even when they are causing signs have a good prognosis as long as rupture has not occurred. Bacterial cholecystitis has a good prognosis as long as the gallbladder is intact and not at risk for rupture. Septic bilious peritonitis has a very guarded to poor prognosis, depending upon the severity of the peritonitis. Gallstones are usually asymptomatic, but can occasionally cause a problem. They are usually easily removed and resolved. Biliary tumors are usually a poor prognostic finding[6,7] because of late diagnosis. Flukes can be treated, but without early recognition, extensive tissue injury may or may not resolve after therapy.

COMPLICATIONS OF LIVER DISEASE

Penny Watson

The liver serves many important functions including metabolism (carbohydrate, protein, lipid, nucleic acid, xenobiotics, porphyrins, vitamins, minerals, glutathione, endogenous hormones), coagulation factor synthesis, biliary secretion, and immune surveillance (see Chapter 1). It is not surprising, therefore, that animals with liver disease experience a broad range of complications reflecting perturbations in one or more of these functions.

Portal Hypertension and Its Consequences

The hepatic portal venous system accounts for up to 75% of the total hepatic circulation and serves to transport nutrients from the GI tract to hepatic sinusoidal capillaries (and hepatocytes) before coalescing once again into central veins, hepatic veins, and caudal vena cava. In health, the multiple branching of the main portal vein, venules, and capillaries reduces the overall resistance to blood flow (circuits in parallel reduce resistance), and therefore the pressure required to perfuse these capillaries is maintained at a low level of less than 5 to 6 mm Hg.[1,2] Disease processes that obstruct flow through the intrahepatic branches of the portal vein or sinusoids elevate this pressure and result in significant portal hypertension. Hepatocyte swelling impedes portal flow in acute pathophysiologic states, and fibrosis further impedes this flow in

chronic pathophysiologic states. Sustained portal hypertension is associated with many, but not all, of the complications of liver disease.

Portal hypertension is an important, potentially life-threatening complication of liver disease in the dog. It is rare or poorly documented in the cat. Portal hypertension develops most often in dogs with chronic liver disease and cirrhosis. It is occasionally recognized as a congenital lesion in young animals with arteriovenous fistulas,[3] or as a hypoplastic disorder of the intrahepatic portal vein branches resulting in a condition referred to as *noncirrhotic portal hypertension*.[4,5] Prehepatic portal hypertension can develop secondary to portal vein thrombosis or congenital hypoplasia of the extrahepatic portal vein, but these are less common. Sustained portal hypertension may progress to splanchnic congestion, GI ulceration, ascites, and encephalopathy.

Gastrointestinal Ulceration

Portal venous hypertension produces vascular stasis and venous congestion and increases the risk of GI ulceration, particularly in conjunction with other risk factors such as anorexia and steroidal and nonsteroidal antiinflammatory drug usage. Portal hypertension–related ulceration in the dog is typically duodenal although bleeding esophageal varices, similar to those reported in humans, are occasionally observed.[3] Glucocorticoids should be used only with great caution in dogs with portal hypertension.

Ascites

Reduced systemic blood pressure is another consequence of portal hypertension and splanchnic venous congestion. Changes in systemic blood pressure activate the renin–angiotensin–aldosterone system (as described in Chapter 8) and renal sodium retention, and thus increase total circulating fluid volume. The increase in circulating fluid volume (the "overfill" hypothesis) is believed to be the triggering event for the development of ascites in animals with portal hypertension.[6] This is why aldosterone antagonists are the initial treatment of choice in ascites caused by portal hypertension (for more details see Chapter 8). Ascites is a negative prognostic indicator in dogs with chronic hepatitis,[7] although individual animals with chronic hepatitis and ascites can be managed and maintained for many months.

Acquired Shunts

With sustained portal hypertension, multiple acquired PSSs develop and serve as a conduit for portal blood flow directly into the systemic circulation. Shunts serve to dissipate some of the increased portal pressure thus reducing the risk of adverse complications such as venous congestion, GI hemorrhage, and ulceration. They do, however, raise the risk of yet another complication of liver disease—hepatoencephalopathy.

Hepatoencephalopathy

HE is a syndrome of potentially reversible brain dysfunction resulting from impaired liver function. It results from either severe hepatocyte dysfunction or more commonly the presence of portosystemic collateral circulation, either congenital or acquired, where a variable combination of shunting of portal blood and hepatocyte dysfunction contributes to the clinical signs. It can be acute or chronic in presentation. Acute HE is most often a result of acute fulminating liver failure (see "Consequences of Hepatocyte and Biliary Tract Injury" section) and carries a poor prognosis. More chronic HE is usually a result of congenital or acquired PSSs.[2]

Table 61-10 Clinical Signs Attributed to Pathophysiology

Clinical Sign	Dysfunction
Anorexia, weight loss	Decreased metabolism; hepatic inflammation
Icterus	Biliary obstruction (intra- or extrahepatic) or dysfunction
Melena, hematuria	GI ulceration as a consequence of portal hypertension; coagulopathy
Ascites	Portal hypertension; hypoalbuminemia (reduced production in liver)
Polyuria/polydipsia	Multifactorial and poorly understood; may be contributions from hepatoencephalopathy; decreased urea cycling; increased antidiuretic hormone and cortisol and other factors
Hepatoencephalopathy	Hyperammonemia and other triggers (see text)
Depression, weakness	Hypoglycemia, anemia, hepatoencephalopathy
Vomiting, diarrhea	Portal hypertension (GI congestion); ascites; hepatic inflammation; hepatoencephalopathy; decreased xenometabolism

Clinical signs associated with HE in dogs and cats include depression, behavioral changes, circling/head-pressing, ataxia, apparent blindness, abnormal swallowing or salivation, stupor, seizures, and coma (Table 61-10). Salivation is much more common in cats than dogs with HE.

Brain dysfunction in HE was historically considered to be a neurotransmitter dysfunction but current evidence suggests low-grade cerebral edema caused by astrocyte swelling is the predominant pathologic change.[8] There is consensus that ammonia is the key toxin in HE but blood ammonia concentrations do not always correlate with severity of clinical signs. This is because a large number of other factors interact with the effects of ammonia to precipitate HE. Astrocytes play a central role because they express glutamine synthetase and detoxify the ammonia that reaches the CNS. Intraastrocyte accumulation of osmotically active glutamine in HE results in astrocyte swelling and thus low-grade cerebral edema.[8] This is largely reversible if the precipitating factors are treated, but edema can become severe and result in irreversible CNS changes in severe and acute HE. Precipitating factors include inflammatory cytokines, benzodiazepine-type sedatives, and disturbances in amino acid metabolism and dopaminergic neurotransmission.[8-10] The source of ammonia is primarily absorption from the gut, although other sources also exist as a result of interorgan metabolism. Gut-derived ammonia was traditionally assumed to be a by-product of intestinal bacterial metabolism in the colon. This remains an important source in some conditions such as melena. However, recent studies in other species suggest that small intestinal enterocyte metabolism of glutamine as their main energy source is the most important source of postprandial ammonia absorption in the portal vein.[9,10] This is also likely the case in most dogs on normal diets as it is very unusual for undigested protein to reach the colon, although the source of gut-derived ammonia has never been investigated in dogs. In normal dogs, ammonia is transported to the liver via the main portal vein, and further metabolized

to urea by hepatocytes in the Krebs-Henseleit cycle. With portosystemic shunting or severe hepatocyte dysfunction, ammonia accumulates in the brain (and other tissues) where it is taken up by astrocytes and results in edema as described previously. Dogs with HE also show disturbances in CNS aromatic amino acid metabolism.[11,12] The aromatic amino acids (tyrosine, tryptophan, and phenylalanine) accumulate in, the CNS in portasystemic shunting. In the brain, β-phenylalanine and tyrosine are metabolized to phenylethanolamine and octopamine, both of which can act as false neurotransmitters. However, dietary supplementation with branched-chain amino acids (e.g., leucine, isoleucine, valine) does not convincingly improve HE in either dogs or humans.[9,12] However, some dietary protein sources appear to be better than others in dogs with HE. Dogs on soya protein diets show a lower plasma ammonia concentration than those fed meat protein.[13] Dogs with HE have also traditionally been fed a protein-restricted diet. However, protein restriction is no longer advocated in humans with HE[9] and it may be the digestibility and type of protein rather than a reduced amount that are most important in dogs. More studies are needed to investigate this.

Several other metabolic alterations exacerbate clinical signs associated with HE, including acid–base disorders, electrolyte abnormalities, particularly hypokalemia, hypoglycemia, hypoxemia, and arginine deficiency (cats). An important trigger in humans and rodents is inflammation: Recent studies confirm that inflammatory cytokines are synergistic with ammonia in precipitating HE and that controlling inflammation in other organs is an important part of managing the patient with HE.[14,15] There is anecdotal evidence that this is also true in dogs.

Consequences of Hepatocyte and Biliary Tract Injury

Functional Reserve

The liver has significant structural and functional reserve capacity to support ongoing metabolic needs during mild to moderate forms of liver injury. Moreover, the liver has the ability to regenerate liver volume and cell mass during the recovery phase of most forms of liver injury. Signs of liver failure develop earlier with acute forms of liver injury than with chronic, progressive liver disease.

Zones 1, 2, and 3 hepatocytes of the hepatic acinus have differing functions. Zone 1 (periportal) hepatocytes, for example, have a high capacity to cycle ammonia through the urea cycle thereby reducing the toxicity of ammonia. Zone 3 hepatocytes (nearer the hepatic vein) have a lesser capacity for ammonia and instead convert it to glutamine.[16,17] In health, zonation permits flexibility in hepatic function such that in metabolic acidosis, for example, the liver can rapidly divert ammonia toward glutamine production, which is necessary for H+ ion excretion in the kidney. In severe acute liver injury, this becomes an important "tradeoff" because acute selective destruction of periportal (zone 1) hepatocytes more readily results in signs of encephalopathy because of the reduced ability of zone 3 hepatocytes to detoxify ammonia. In chronic liver disease, if hepatocytes undergo piecemeal necrosis at different rates in different zones, the remaining hepatocytes can assume some of those functions, so that clinical signs of deficiency are not seen until later in chronic disease processes.

Coagulopathy

Coagulopathy is a complication of both acute and chronic liver disease in dogs and cats. A recent study reported one or more coagulation abnormalities (prolongation of coagulation times, changes in platelet counts, D-dimers, fibrinogen, or protein C) in 24 (57%) of 42 dogs affected with liver disease.[18] Coagulation abnormalities are also common in cats with liver disease and one study found abnormalities in 18 (82%) of 22 cats with liver disease.[19]

Multiple mechanisms of coagulopathy are possible in liver disease patients. In ALF cases such as xylitol toxicity in dogs,[20] HL in cats,[21] and cirrhosis in dogs,[18] loss of normal hepatocyte function results in severe coagulation factor deficiency. Vitamin K deficiency has also been implicated in coagulopathy particularly in cats in which cholestasis impedes bile salt secretion, emulsification, and micellarization of fat and fat-soluble vitamins and fat-soluble vitamin absorption.[21] Concurrent inflammatory bowel disease and pancreatitis exacerbate this condition in many cats with cholangitis.[21] Finally, platelet abnormalities (cytopenia and cytopathy) may contribute to coagulopathy in dogs with liver disease.[18,22]

Regeneration

The liver has the unique ability to regulate its growth and mass. Hepatocyte loss caused by viral, bacterial, or chemical injury, or partial hepatectomy triggers hepatocyte replication.[23,24] Liver injury not only stimulates hepatocyte turnover but may also stimulate biliary proliferation and activation and proliferation of HSCs. These changes usually occur together in an orchestrated wound-healing response. In the case of hepatocyte loss, normally quiescent hepatocytes replicate to restore the liver functional capacity and mass. These are the main cells that regenerate liver mass. However, in severe injury or where hepatocyte turnover is inhibited by senescence, a progenitor cell reserve may also replicate and regenerate liver mass.[24] Although hepatocytes are capable of replication, they have very slow turnover in a normal liver and there are negative consequences of long-term increased stimulation and turnover in chronic liver disease. It has been shown that cycling hepatocytes suffer irreversible erosion of telomeres, which leads to senescence.[25] Functional capacity is a relative rather than absolute parameter. The set point for growth regulation is the ratio between liver mass and body mass rather than liver mass per se. The optimization of the ratio indicates that the liver reaches a state in which it performs the amount of metabolic work needed to meet the functional requirements of the body.[24]

Gene expression in the regenerating liver is a multistep process with at least two critical steps: the transition of quiescent hepatocytes into the cell cycle ("priming"), and the progression beyond the restriction point in the G_1 phase of the cell cycle. Hepatocytes must first be primed before they can fully respond to growth factors. As many as 70 different genes participate in the early response to hepatectomy, but TNF and IL-6 appear to be the major cytokines involved in the priming of hepatocytes.[20] The proliferative effect of TNF on hepatocytes is further influenced by reactive oxygen species, nitric oxide, and glutathione content, and at least four transcription factors (nuclear factor kappa B, STAT3, AP-1, and C/EBPβ) play major roles in the initiation of early liver regeneration.[23,24] Progression through the cell cycle beyond the initiation phase requires growth factors, primarily hepatocyte growth factor and TGF-α. The subsequent expression of cell-cycle genes, particularly cyclin D_1, establishes the stage at which replication becomes growth factor–independent and autonomous. At this point, the hepatocyte is irreversibly committed to replicate and the cell-cycle replication machinery takes over. The regenerative capacity of the residual hepatocytes may restore liver mass and function after as much as 65% to 70% hepatectomy.[23,24] Progenitor cells are only activated in severe liver injury. They appear to reside in a "niche" that is a particular regulatory environment.[24] A recent immunohistochemical

study suggests that canine and human liver progenitor cells are functionally very similar.[26] Further characterization of the molecular events regulating hepatocyte replication and liver regeneration should improve outcome in animals affected with severe liver disease.

Fibrosis and the Wound-Healing Response

The normal ECM of the liver provides cells with positional information and a mechanical scaffold for adhesion and migration. The ECM consists of collagens, glycoproteins, proteoglycans, glycosaminoglycans and molecules that are bound specifically by the ECM, such as certain growth factors, cytokines, matrix metalloproteinases, and processing enzymes such as tissue transglutaminase and procollagen propeptidases. A normal liver contains a very small amount of fibrous tissue as a percentage of its total mass.[27,28] Acute or chronic liver injury causes a dynamic wound-healing response with both production and removal of fibrosis.[29] HSCs are the major source of the collagens that comprise fibrosis and cirrhosis, as well as of the tissue inhibitors of metalloproteinases (TIMPs) that inhibit collagen degradation. It is the balance between collagen production by HSCs and its degradation by matrix metalloproteinases that determines the severity and reversibility of the fibrotic response. Following acute or chronic liver damage, HSCs are stimulated to multiply and to undergo a complete phenotypic transformation from quiescent vitamin A–storing cells to contractile myofibroblasts which synthesize large amounts of ECM.[25,29] Important stimuli for HSC transformation and multiplication in liver injury include oxidative stress; chemokines including platelet-derived growth factor; VEGF and TGF-β; adipokines; and parts of the innate immune system including Toll-like receptor ligands.[29] The role of adipokines in stimulating fibrosis is increasingly being recognized in humans, where nonalcoholic fatty liver disease can lead to fibrosis and cirrhosis. They are produced by HSCs themselves, as well as fat cells, and increased leptin and reduced adiponectin drive fibrosis.[29] Their importance in dogs is unknown and it is also unknown whether vacuolar or fatty liver diseases progress to fibrosis in dogs, but these are important questions to answer in the future given the widespread occurrence of obesity in dogs.

The contractile function of activated HSCs contributes significantly to the development of portal hypertension,[28] and increases in angiogenic chemokines such as VEGF and platelet-derived growth factor not only contribute to fibrogenesis by HSCs, but also to the development of portal hypertension, so that the two pathologic processes are inextricably linked.[29]

Activated HSCs have greatly increased production of TIMPs, particularly TIMP1 and TIMP2, which prevent the action of matrix metalloproteinases in the ECM. The degree of fibrosis and reversibility then depend on the balance between perpetuation of HSC proliferation and secretion and resolution of HSC by either apoptosis or senescence of HSCs or, indeed, their reversion to an inactive state. Many factors contribute to HSC apoptosis, senescence, or reversion, including reduction in TIMPs and nuclear factor kappa B and increased Fas and p53.[29] However, in spite of all this understanding of the molecular mechanisms of fibrosis, a truly effective treatment for hepatic fibrosis in either humans or dogs has yet to be found.[29]

It is important to remember that a normal fibrotic response (scar) is important in walling off pathogens and tissue injury and inhibiting this response without removing the inciting cause (e.g., a viral cause) could lead to spread of the pathology.[28] Future treatment strategies for fibrosis should therefore incorporate treatment of the underlying cause of disease. This is clearly a problem in dogs where the cause of chronic hepatitis is usually unknown.[30] There is increasing evidence that fibrosis and even some forms of cirrhosis in humans and rodent models are reversible if the underlying cause is removed.[28,31] The challenges are removing the cause and also defining the point at which cirrhosis moves from a reversible to irreversible state. Increased fibrous septal thickness, smaller nodule size, and reduced cellularity together with increased collagen cross-bridging have all been associated with an irreversible cirrhotic state in rodents and humans.[28]

It is unknown whether liver fibrosis or cirrhosis in dogs is reversible clinically. Cases of chronic hepatitis in dogs very rarely have sequential liver biopsies over a long period of time to assess progression of disease and noninvasive markers of fibrosis remain to be validated. Serum hyaluronic acid is increased in dogs with cirrhosis[32] as is TGF-β[33] but the usefulness of these markers in following progression in clinical cases has not been assessed. Identifying a reliable noninvasive marker of fibrosis for sequential studies in humans and dogs remains a challenge.[34]

CHAPTER 62

Breed-Related Diseases

GASTROINTESTINAL TRACT

Robert J. Washabau

Breed predispositions are suspected in many medical disorders of dogs and cats, not just those of the digestive system. Heritability has been established for many of these disorders, and even the specific genetic locus. Gene therapy, however is still many years away for most of these disorders. Understanding and recognizing breed associations is important for several reasons. First, known or suspected associations help guide the clinician in considering a list of reasonable differential diagnoses, and in narrowing down the list of costly or invasive diagnostic tests. Second, knowledge of breed predispositions assists veterinarians in providing advice to pet owners and aspiring pet owners. A well-educated pet owner is always a better (and happier) pet owner. Finally, although a specific genetic deficiency may not be treatable, knowledge of the underlying pathogenesis may help to develop better therapies, even if nonspecific, thereby improving the patient's long-term prognosis.

In addition to breed predispositions, the medical investigation should always include a problem-solving method. The DAMNIT system of disease diagnosis (Box 62-1) is but one of several pathogenetic methods used in disease diagnosis. The final diagnosis should always explain all of the problems on the problem list, including breed identity. If the final diagnosis is inconsistent with the problem list or breed, the diagnosis may be incorrect, or there may be more than one diagnosis.

Tables 62-1 to 62-6 outline the breed-related diseases of the primary GI tract. Disorders are outlined for each of the segments of the GI tract, for example, oropharynx, esophagus, stomach, small intestine, large intestine, and anorectum, but it is important to bear in mind that one disease process may affect several segments of the GI tract, particularly those that are contiguous. References for each of these disorders may be found in the literature citations.[1-138]

LIVER AND BILIARY TRACT

Penny Watson

The diseases of the liver and biliary tract described in this book (Chapter 61) can be found in both purebred and crossbred animals. A number of these diseases have an increased incidence in certain breeds. In some cases, the inheritance patterns and genetic loci are well understood. In most cases, however, increased breed prevalence is simply an observation in published studies and the underlying genetic basis has not yet been determined. Some breed-related disorders appear to be worldwide in their distribution, whereas others occur only in certain countries or regions, either as a result of different breed genetics in different countries or simply increased recognition in those countries.

The recognition of increased breed prevalence of any disease is important as it helps increase diagnosis in the breed, although it is important to remember that not all cases will be "typical." For example, not all Bedlington Terriers with increased serum liver enzyme activities will have copper storage disease. Breed recognition is important for the dog or cat breeder as it should ultimately permit development of a genetic test to breed the disease out of the population. Breed recognition is also important for the clinical researcher as it allows focused investigation into the genetic underpinning of these diseases.

It is important to establish clear evidence for increased breed prevalence in liver, biliary, pancreatic, or GI disease. It is all too easy for erroneous data on proposed breed-related disease to become established fact once they are published. Lobular dissecting hepatitis in Standard Poodles is an example where published reports resulted in book chapters and reviews reporting this disease as a breed-related association, even though the original report suggested it may be infectious and not inherited. To ensure that there really is an increased prevalence, and not just a bias introduced by the researcher or local conditions, the prevalence of disease in that breed should be compared to a standard control population such as the normal hospital caseload, Kennel Club, or Cat Fancy registrations in that region, pet insurance, or similar database. Box 62-2 outlines potential reasons for a falsely increased breed prevalence.

Canine Hepatitis

Canine hepatitis can be classified as acute or chronic and some cases of acute disease progress to chronic hepatitis.[1] The majority of acute hepatitis cases are infectious or toxic, but a proportion of cases of copper storage disease in dogs present acutely. Copper storage disease can also be a cause of chronic hepatitis although most other cases of chronic disease are idiopathic. The majority of breed relationships reported are for copper storage disease and chronic hepatitis, and these two conditions are considered separately.

Canine Copper Storage Disease

Pertinent Breeds

Hepatitis associated with copper storage disease in dogs can be acute, subacute, or chronic, although it is often characterized as *chronic hepatitis*. The breeds affected with copper storage disease are

Table 62-1 Breed-Related Diseases of the Oropharynx

Disease	Breed	References
Cleft palate	English Bulldog, Great Pyrenees, Foxhound, Beagles, Brittany Spaniels, Australian Shepherd dogs	1-5

Chronic hypertrophic pyloric gastropathy	Lhasa Apso, Shih Tsu, brachycephalic breeds	43-45
Eosinophilic granuloma	Scottish Terrier	46
Gastric neoplasia	Belgian Shepherd, Chow, Collie, Staffordshire Bull Terrier, Dutch Tervueren, Lundehund	22, 47-56
Gastric dilation/volvulus	Greyhound, Irish Wolfhound, Blood Hound, Grand Bleu De Gascogne, German Longhaired Pointer, Neapolitan Mastiff, Otterhound, Irish Setter, Weimaraner, Akita, Newfoundland, large and giant breeds, Saint Bernard, Standard Poodle, Great Danes	57-66
Gastroparesis	Siamese cat	67
Hemorrhagic gastroenteritis	Newfoundland, Rottweiler	68
Hypertrophic gastritis	Basenji, Drentse Partrijshond	69-73
Pyloric stenosis	Boston Terrier, brachycephalic breeds	74,75

Box 62-1 DAMNIT System for Disease Diagnosis in Dogs and Cats

D Degenerative, developmental, drug-induced
A Anatomic, allergic, autoimmune
M Metabolic, mechanical
N Neoplastic, nutritional
I Inflammatory, infectious
T Traumatic, toxic

Box 62-2 Reasons for a "False" Impression of Increased Breed Prevalence of a Disease

- Congenital lesions—congenital, e.g., infectious, nutritional, but not inherited diseases affecting several or all dogs in a litter
- Selection bias:
  - Investigators actively recruiting cases in one breed to their research center
  - Local breeder breeding increased numbers of affected dogs which are then sent on to the local referral center
  - Purebred dogs may be more likely to be referred or investigated than crossbred dogs
  - Some breed health coordinators may be more likely to alert the veterinary profession to a perceived problem in their breed than others (some breed societies may even actively discourage reporting of the problem)

Table 62-4 Breed-Related Diseases of the Small Intestine

Disease	Breed	References
Bacterial overgrowth	Beagle, German Shepherd	76-79
Cobalamin malabsorption	Border Collie, Chinese Shar-Pei, Giant Schnauzer	80-83
Eosinophilic enteropathy	Rottweiler	84
Gluten enteropathy	Irish Setter	85-90

Perianal fistulas	German Shepherd, Irish Wolfhound	135-138

listed in Table 62-7 along with evidence of heritability. Some of these same breeds are affected by a separate idiopathic chronic hepatitis not associated with copper storage disease (Table 62-8) and there are geographical variations in the relative proportions of each of these diseases (Tables 62-7 and 62-8). Consequently, liver biopsies and copper determinations are very important for effective diagnosis and treatment of hepatitis in these breeds. Bedlington Terriers are the original, and best understood, example of canine copper storage disease, but other breeds have been more recently reported. Copper storage disease has only been reported in a small number of cats (Table 62-7).

Disease Association

Copper storage disease in dogs affects the liver and not other organs, unlike Wilson's disease in humans, which affects other parts of the body such as the eyes and basal ganglia. In one feline case report, copper was found in the epithelium of the proximal convoluted tubules and collecting ducts of the kidney, and alveolar epithelium and macrophages in the lung.[2]

Evidence of Heritability

Heritability of copper storage disease has been reported extensively in the Bedlington Terrier and to a lesser extent in the Labrador Retriever and West Highland White Terrier breeds (see Table 62-7). Evidence in other breeds is restricted to isolated case reports (see Table 62-7).

Definitive Diagnosis

In the normal liver, copper is excreted in the bile. Consequently, it can build up in the periportal area (zone 1) secondary to cholestasis. It is important to differentiate this "secondary" copper retention from "primary" copper storage disease where the degree of pathology is directly related to the amount of copper found in the centroacinar area (zone 3). Any breed of dog will show evidence of copper-associated hepatotoxicity if there is a large excess of copper in the diet. What is accepted as a "normal" hepatic copper concentration has increased over the last 30 to 40 years. Increasing reports of copper storage disease in dogs may represent an interaction between genetic susceptibility and dietary copper content. Diagnosis can only be definitively obtained with liver biopsy. Ideally, a large sample (at least 1 g of tissue) should be submitted for copper determination, and histopathology should be performed with a copper stain (rubeanic acid or rhodanine) to show copper distribution in the liver and its association with pathology. If measurement of copper content is not possible, a semiquantitative estimate of copper content can be made with histologic scoring as described by Hoffman and others.[3] A genetic screening test is now available for copper storage disease in Bedlington Terriers, but there are inconsistent results in some cases, as detailed in Table 62-7.

Therapy

Copper storage disease can be successfully managed with diet and chelating agents (see Chapter 43), particularly if diagnosed early, or, better still, it can be prevented in susceptible individuals by feeding a low-copper diet from weaning. Chapters 32, 43, and 61 describe the details of therapy.

Idiopathic Canine Chronic Hepatitis

Pertinent Breeds

Chronic hepatitis is the most common liver disease recognized in dogs, with a reported prevalence of 12% in older dogs in the United Kingdom.[4] The current prevalence in the United States is unknown. In those cases not associated with copper storage disease, the cause remains unknown. It can occur in any breed or crossbreed, but there

Table 62-7 Breed Relationships in Copper Storage Disease in Dogs and Cats

Breed	Countries Reported	Strength of Evidence for Copper Storage Disease*	Evidence of Heritability
Dogs			
Bedlington Terrier	USA,[13] UK,[14] Australia,[15] Holland[1,16]–probably worldwide	Good–copper is centrilobular in distribution; copper concentrations in liver are clearly increased and degree of copper accumulation correlates with severity of clinical signs.	Inheritance pattern is simple autosomal recessive.[17] Genetic studies initially identified a microsatellite marker[18] and subsequently the genetic defect was proposed to be causative–a deletion in the MURR1 (COMMD1) gene.[19] A genetic test is available at the Animal Health Trust in the UK (http://www.aht.org.uk/genetics_toxicosis.html). However, recent cases have been described that do *not* have the COMMD1 deletion so there appears to be more than one genetic defect predisposing to copper storage disease in Bedlington Terriers.[20,21]
Dalmatian	Only USA[22-24] and Canada[25] to date	Good–as Bedlingtons. The mean hepatic copper concentration for 9 Dalmatians was 3197 µg/g dry weight liver (dwl) (normal, <450 µg/g).[22]	None. Suspected to be inherited because of breed relationship.
Labrador Retriever	USA[26] and Holland[1,3]; seems uncommon in UK where most Labrador hepatitis cases are idiopathic and not associated with copper[27]	Good–as Bedlingtons. However, only a proportion of Labrador Retrievers with hepatitis have copper storage disease. The remainder have idiopathic chronic hepatitis (see Table 62-8)	Hoffman and others reported increased mean copper concentration in unaffected relatives of affected dogs suggesting a heritable disease; (mean hepatic copper concentrations in related Labradors 1317 µg/g dwl (range: 402 to 2576 µg/g). Mean hepatic copper concentration of unrelated normal Labradors 233 µg/g dwl (range: 120 to 304 µg/g). No breeding or genetic studies yet reported.
Doberman Pinschers	Holland[28] and probably USA.[29,30] Two types of chronic hepatitis proposed in the breed–one copper associated and the other possibly autoimmune	Dogs with proposed copper storage disease have increased hepatic copper concentrations. Chelation reduces copper concentration and histologic lesions.[31] However, the role of copper in chronic hepatitis in Dobermans has long been debated. It is likely there are at least two different diseases in the breed.	None. Suspected to be inherited because of breed relationship.
West Highland White Terriers (WHWT)	Copper storage disease in the breed only reported in the USA[32] and Holland[1] to date, although chronic hepatitis in WHWT also reported in Sweden.[7]	Only a proportion of WHWT with chronic hepatitis have copper storage disease; in those, the copper is classically distributed centrilobularly and the concentration is >2000 parts/million on a dry weight basis.[33] Other WHWT have idiopathic chronic hepatitis with no increase in copper accumulation (see Table 62-8).	Breeding studies show that affected dogs produced affected puppies.[32] No further genetic studies have been performed.
Skye Terriers	UK only to date[34,35]	Unsettled pathogenesis. Copper builds up to high concentrations in zone 3 but is not present at initiation of disease. It has been proposed that the primary defect is in membrane transport systems of zone 3 and that copper retention is secondary. Excess copper (801 to 2257 µg/g) was related to the severity of cholestasis.[34]	The original report was of 9 related dogs, suggesting a possible inherited basis.[33] Only one subsequent case report has been published in a single dog[34] and there no further studies on an inheritance pattern.

Continued

Table 62-7 Breed Relationships in Copper Storage Disease in Dogs and Cats—cont'd

Breed	Countries Reported	Strength of Evidence for Copper Storage Disease*	Evidence of Heritability
Cats			
Siamese cat	Only one individual cat in USA.[2]	Good–acute disease + other organs affected. The liver copper value was 4074 µg/g dry weight, whereas normal hepatic copper levels in cats are 148 to 180 µg/g dry weight.[2]	None.
European Shorthair cat	Only one individual cat in Holland.[36]	Good–disease was chronic and severe, no report of other organs affected. Copper was largely centrilobular and the liver copper content was elevated at 4170 µg/g dry weight. Normal controls ranged from 26 to 174 µg/g dry weight	None.

*See text. The question is: Is there clearly increased copper content in the liver and is pathology associated with amount of copper buildup, ideally with copper accumulating in zone 3?

Table 62-8 Breed Associations in Canine Idiopathic Chronic Hepatitis

Breed	Countries Reported	Any Proposed Mechanism of Disease in Breed (see Table 62-4 for Potential Causes)	Evidence of Heritability
Doberman Pinschers	USA,[37] Scandinavia,[7,38] UK[8]	Role of copper is strongly debated (see Table 62-7). A separate form of chronic hepatitis is postulated to be autoimmune based on marked female predominance and increased expression of major histocompatibility complex class II.[38]	The only evidence is increased prevalence in the breed.[7,8] No breeding or other studies have been reported.
Labrador Retrievers	USA,[37] Sweden,[7] UK,[8] and Holland[1]; most Labradors reported with hepatitis in the UK do not have copper storage disease,[27] whereas many in the USA and Holland do have copper storage disease (see Table 62-7)	A proportion have copper storage disease (see Table 62-7). In those without significant copper accumulation, cause is unknown.	The only evidence is increased prevalence in the breed.[7,8] No breeding or other studies have been reported for idiopathic chronic hepatitis in the breed, only copper storage disease (see Table 62-7).
West Highland White Terrier	USA,[33] Holland,[1] and Sweden[7]	A proportion have copper storage disease (see Table 62-7). Most have no significant copper accumulation and cause of the hepatitis is unknown.	The only evidence is increased prevalence in the breed.[7] No breeding or other studies have been reported for idiopathic chronic hepatitis in the breed.
English Cocker Spaniel	Sweden,[7] Holland,[1] UK[8]	Unknown. Early reports of accumulation of abnormal α_1-antitrypsin in liver of affected dogs[39] but blood concentrations in affected dogs were not reduced, so significance of this finding remains unknown.	The only evidence is increased prevalence in the breed.[1,7,8] No breeding or other studies have been reported.
American Cocker Spaniel	Sweden,[7] Holland[1]	Unknown	The only evidence is increased prevalence in the breed.[1,7] No breeding or other studies have been reported.
English Springer Spaniel	UK, Norway,[40] and Australia (personal communication); no reports yet in the USA	Unknown. Hypothesized to be "toxic/metabolic" or the result of an infectious agent because of histologic appearance.[40]	The only evidence is increased prevalence in the breed.[8,40] Initial pedigree analysis of UK dogs failed to reveal a clear inheritance pattern, but did identify show lines were more affected than field lines.[41]

Other breeds recently also identified in the UK as at increased risk of idiopathic chronic hepatitis in one study were Cairn Terriers, Great Danes, and Samoyeds.[8] Causes and inheritance patterns unknown. For lobular dissecting hepatitis in Standard Poodles and other breeds, see text.

Table 62-9 Potential Reasons for Genetic Susceptibility to Chronic Hepatitis in Dogs

Genetic Reason for Susceptibility	Examples in Humans	Evidence in Dogs
Susceptibility to infectious causes of chronic hepatitis and/or to chronicity of infection rather than recovery	Reported nonresponsiveness to hepatitis B vaccine and tendency to chronic carrier state and chronic hepatitis in certain human leukocyte antigen (HLA) alleles[42]	None for hepatitis; some for other diseases, e.g., increased parvovirus susceptibility reported in certain breeds[43]
Susceptibility to autoimmune disease	Strong genetic predisposition to autoimmune hepatitis in certain HLA classes[44]	None for hepatitis; some suspected for other autoimmune diseases[45]
Mutation of gene coding for protein involved in metal transport/storage/excretion	Wilson's disease (copper storage disease); also iron storage disease	Copper storage disease in Bedlington terriers; possibly also other breeds (see Table 62-7 for details)
Gene mutations resulting in hepatic accumulation of glycoprotein protease inhibitor	α_1-Antitrypsin deficiency	No examples; reported α_1-antitrypsin abnormalities in Cocker Spaniels are not true deficiency (see Table 62-8 for details)
Increased susceptibility to chronic hepatic injury with toxic causes	Genetic susceptibility to alcoholic cirrhosis[46]	No clear examples but Dobermans reportedly have impaired detoxification of potentiated sulphonamides[47]

Adapted from Watson PJ: Chronic hepatitis in dogs: a review of current understanding of the aetiology, progression, and treatment. *Vet J* 167: 228-241, 2004.

are reports of increased prevalence in certain breeds as outlined in Table 62-8. These increased prevalences provide opportunities for research in to the cause(s) of this disease, and the causes are likely to be different in different breeds. Table 62-9 outlines the potential reasons for increased breed associations in canine chronic hepatitis, and Table 62-8 details any evidence or suggestions of causes reported in breeds in the literature.

Lobular dissecting hepatitis is a histologically distinct form of chronic hepatitis reported predominantly in young dogs, particularly Standard Poodles, Rottweilers, and Mastinos.[5,6] This has led to the suggestion of a breed-related disease in Standard Poodles. However, the original authors suggested an infectious rather than inherited etiology[6] and the occurrence in litters could be because of environmental rather than inherited factors. Of course, both could interact (an inherited predisposition to an environmental trigger) but the absence of any prevalence data[1,7,8] argues more strongly for an environmental cause. Lobular dissecting hepatitis has been reported anecdotally by breeders with increased prevalence in Finnish Spitz dogs in the United Kingdom (personal communication) but no studies have yet confirmed this.

Evidence of Heritability

Most of the published breed prevalence data come from a study performed in Sweden in 1991[7] that reviewed 299 cases of histopathologically confirmed chronic hepatitis between 1984 and 1989 and compared them with a control population of Swedish Kennel Club registrations. This study found Labrador Retrievers, American Cocker Spaniels, English Cocker Spaniels, West Highland White Terriers, Scottish Terriers, and Dobermans at increased risk of disease. A recent study in the United Kingdom[8] that reviewed 4,551 cases of histologically confirmed chronic hepatitis in dogs between 2001 and 2008 compared with a control population of dogs registered by a UK microchip company (175,442 dogs in 2001 and 311,085 dogs in 2008) found overrepresentation of Labrador Retrievers, American and English Cocker Spaniels, Dalmatians, and Dobermans. In addition, English Springer Spaniels, Cairn Terriers, Great Danes, and Samoyeds were significantly overrepresented with idiopathic chronic hepatitis in the UK compared with the control population. A clinical study in Holland of 101 dogs with hepatitis identified a significantly different breed distribution involving English and American Cocker Spaniels, Labrador and Golden Retrievers, West Highland White Terriers, Jack Russell Terriers, and German Pointers.[1] The latter study did not separate acute and chronic hepatitis and copper storage disease.

Definitive Diagnosis

Definitive diagnosis of canine chronic hepatitis can only be made on the basis of hepatic histopathology as outlined in Chapters 29 and 61. Finding elevated serum liver enzyme activity and compatible signs on hepatic ultrasound is not sufficient to make a diagnosis, as these findings are very nonspecific and do not differentiate primary chronic hepatitis from other liver pathologies.

Therapy

Chapters 40, 43, 46, and 61 detail treatment for canine chronic hepatitis.

Canine Vacuolar Hepatopathies

Vacuolar hepatopathy is generally considered to be a reversible secondary disease characterized by hydropic degeneration of hepatocytes or accumulation of fat or glycogen within these cells (see Chapters 29 and 61).[9] These are recognized in a wide variety of breeds and for a variety of reasons,[10] but one specific canine breed relationship is currently recognized. There is no reported breed predilection for feline hepatic lipidosis.

Pertinent Breeds

Scottish Terriers in the United States have been diagnosed with a specific type of vacuolar hepatopathy associated with elevated serum alkaline phosphatase activity.[10a,10b]

Disease Association

The cause of vacuolar hepatopathy in Scottish Terriers is unknown. They do not have overt hyperadrenocorticism but it has been suggested that they may suffer from adrenal dysfunction.

Table 62-10 Breed Relationships in Biliary Tract Disease and Gallbladder Mucocele

Disease: Canine or Feline	Breeds Involved	Evidence of Heritability
Feline lymphocytic cholangitis	Purebred cats appear to be overrepresented.[48]	None except apparent increased prevalence in studies.
Feline polycystic disease of liver	Recognized as part of polycystic disease in Persian cats[49,50] and also probably Exotic Shorthair cats. Polycystic kidney disease (PCKD) has been reported in these breeds worldwide, including USA, UK, Australia, Italy, France, and Slovenia.	Much evidence for polycystic renal disease (PCKD), which appears to be linked to polycystic hepatic lesions. Persians have an autosomal dominant PCKD[51] that was found in 27.5% of Persian and Exotic Shorthair cats tested in one study in the UK and proposed to be the most common inherited disease in cats,[52,53] although other genetic forms of the disease are also suspected.
Canine polycystic disease of liver	Much less common than cats but reports in Cairn Terriers,[54] West Highland White Terriers,[55] and Golden Retrievers (where it was proposed to be equivalent to Caroli disease in humans).[56]	Evidence in Cairns: one case report of 3 related puppies.[54]Evidence in West Highland White Terriers from one case report of 7 dogs born from the same parents (2 matings) but none of other relatives suggested autosomal recessive.[55] Evidence in Golden Retrievers: one case report of 2 siblings.[56] Other large case series fail to show any clear breed prevalence.[57,58]
Canine gallbladder mucocele	Reported to have increased prevalence in Shetland Sheepdogs in the USA,[59] and possibly Cocker Spaniels and Miniature Schnauzers.	High numbers of Shetland Sheepdogs in one published case series.[59] Recent study demonstrated a mutation in the gene coding for a phosphatidylcholine transporter was strongly associated with mucocele in Shetland sheepdogs and also 3 dogs of other breeds. Another recent study suggests hyperadrenocorticism is a strong risk factor,[60] so some genetic predisposition may be to the underlying cause and not the mucocele itself.

Evidence of Heritability

The only evidence of heritability in the Scottish Terrier is a report of increased prevalence in the breed.

Definitive Diagnosis

Definitive diagnosis is based on liver biopsy as described in Chapter 61.

Canine and Feline Biliary Tract Diseases

Acute and chronic cholangitis can affect both cats and dogs, but are more common in cats where breed predilections have been suggested for lymphocytic cholangitis. Gallbladder mucocele is recognized in dogs with some suggested breed predispositions but is very rare in cats, where there is no recognized breed disposition. Cystic lesions in the liver in cats are usually biliary in origin and part of an inherited polycystic disease in a number of organs, particularly the kidney. Table 62-10 provides details of known breed relationships in canine and feline biliary tract disease.

Canine and Feline Congenital Hepatic Vascular Defects

The most common congenital vascular defect is the congenital portosystemic shunt (PSS) which is usually a single vessel and may be either intra- or extrahepatic in location. Microvascular dysplasia and portal vein hypoplasia are less commonly reported congenital defects. The latter two conditions may represent similar abnormalities in the development of intrahepatic smaller portal vein branches during embryonic development. Portal vein hypoplasia, noncirrhotic portal hypertension, and idiopathic juvenile hepatic fibrosis may be synonymous. Microvascular dysplasia and/or portal vein hypoplasia can coexist with a single congenital PSS in the same dog (described in greater detail in Chapter 61). It is very possible that all of these vascular defects represent a continuum of developmental abnormalities and that the final defect results from the interaction between genetic predisposition and uterine environment in that individual.

Congenital Portosystemic Shunt

Pertinent Breeds

There are well-recognized breed associations for congenital PSSs in dogs. It has long been recognized that large-breed dogs develop intrahepatic PSS primarily and small-breed dogs develop extrahepatic PSS primarily. It is also known that purebred dogs are at greater risk than crossbred dogs for congenital PSS. Some limited breeding and genetic studies have been undertaken, the details of which are outlined in Table 62-11. It is also important to note that not all breeds will have "typical" anatomic shunts and that there are some exceptions, which means that the anatomy of the PSS needs to be confirmed in each case prior to surgery. Hunt et al.[11] reported that PSS found in breeds not at risk for PSS were significantly more likely to be unusual or inoperable compared with those in dogs from breeds at risk.

Congenital PSS is less common in cats than dogs, and intra- and extrahepatic PSS is found in approximately equal proportions in cats.[12] There may be some breed predispositions to PSS in cats, but these are less-well investigated than predisposition in dogs (see Table 62-11).

Evidence of Heritability

Table 62-11 outlines the evidence of heritability for congenital PSS.

Table 62-11 Breed Relationships in Canine Congenital Hepatic Vascular Abnormalities

Type of Congenital Vascular Abnormality	Breeds Involved	Evidence of Heritability
Canine congenital portosystemic shunt (PSS)	Large-breed dogs tend to develop intrahepatic PSS and small breed dogs develop extrahepatic PSS.[11,61] Irish Wolfhounds usually (but not always[62]) have patent ductus arteriosus.[11] Cairn Terriers, Yorkshire Terriers, West Highland White Terriers, Maltese, Havanese, other Terriers, and Miniature Schnauzers were reported to have increased risk in a large study of PSS in the USA.[61] Maltese, Silky Terrier, Australian Cattle Dog, Bichon Frise, Shih Tzu, Miniature Schnauzer, Border Collie, Jack Russell Terrier, and Irish Wolfhound are reported to be at increased risk of intra- and extrahepatic PSS.[11]	Evidence in most breeds is confined to increased prevalence in published studies. Pedigree analysis and breeding studies in Holland in Irish Wolfhounds with PSS are supportive of a familial disorder that is likely genetic and suggests a digenic, triallelic trait.[63,64] A breeding study in Cairn Terriers with PSS in Holland suggests an autosomal inheritance that is most likely polygenic, or monogenic with variable expression.[65]
Feline congenital portosystemic shunt (both intra- and extrahepatic)	Purebred cats are overrepresented, but any breeds, including mixed breeds, can be affected.[11,12,66,67] In one study in Australia, Himalayan cats were overrepresented.[11] There is no reported association between breed and shunt types (unlike in dogs) although in one study in the UK, 6 of 13 cats with an intrahepatic PSS were Siamese.[12]	No evidence apart from increased prevalence in published studies.
Canine microvascular dysplasia	Increased prevalence reported in small-breed dogs, particularly Yorkshire Terriers[68] and Cairn Terriers.[69]	Pedigree analysis in a family of affected Cairn Terriers suggested an autosomal inheritance pattern.[69] Evidence in other breeds confined to increased prevalence in published studies.
Canine noncirrhotic portal hypertension/portal vein hypoplasia	Increased prevalence suggested in large breeds in some studies, particularly in Dobermans.[70,71] A Dutch study reported portal vein hypoplasia in a variety of small and large breeds, including 6 related English Cocker Spaniels.[72] It is also likely that an early report of idiopathic hepatic fibrosis in young German Shepherd dogs was a similar condition.[73]	Evidence limited to small published cases series. Three of 4 Dobermans reported in one study were littermates.[70] Six of 6 English Cocker Spaniels in another study were from the same breeding colony.[72]

Microvascular Dysplasia and Portal Vein Hypoplasia

Table 62-11 summarizes breed relationships and evidence for heritability of these conditions.

PANCREAS

Elias Westermarck

Exocrine Pancreatic Insufficiency in Dogs

Canine exocrine pancreatic insufficiency (EPI) is a disease characterized by inadequate synthesis and secretion of digestive enzymes by pancreatic acinar cells. This is almost without exception the result of pancreatic acinar atrophy (PAA), and the abbreviations EPI and PAA are often used synonymously in the literature.[1] Affected dogs show typical clinical signs, including polyphagia, weight loss, yellowish poorly digested loose feces, increased fecal volume, and defecation frequency.[2] In German Shepherd dogs and Rough-Coated Collies, the disorder has been shown to be an autoimmune disease.[3] Although EPI may occur at any age, signs of maldigestion appear before the age of 4 years in most dogs (93%).[2] Cavalier King Charles Spaniels have been reported to be at an older age at the time of diagnosis (mean 6 years), and it has been suggested that a different pathogenesis may be involved in this breed.[4] Male and female dogs are usually equally affected,[1,5,6] although a stronger association between EPI and female gender has been reported.[4] A number of tests have been developed to aid in the diagnosis of EPI. Serum canine trypsin-like immunoreactivity has been reported to be 100% sensitive and specific in the diagnosis of canine EPI.[7] When clinical signs of maldigestion appear, enzyme replacement therapy is almost always indicated. Various pancreatic enzyme extracts are available and the highest enzyme activity in the duodenum has been obtained with noncoated enteric supplements, for example, raw chopped pancreas and lyophilized enzyme powder.[8] Lifelong enzyme treatment is usually needed, and the response to treatment is variable. In 50% to 60% of dogs, GI signs are almost always completely controlled, but in approximately 20% of dogs a variable to poor response is obtained.[9-11]

The earliest reports of EPI in dogs provided no indication of breed predisposition.[12-15] Since the 1960s, however, almost all reports assert that the disease is found more frequently in German Shepherd dogs than in other breeds (Table 62-12). Hence, EPI has been postulated to be a hereditary disease in this breed.[1,16-18] Freudiger reported that the morbidity of EPI is 8% in German Shepherd dogs and only 0.3% in all other breeds.[18] The incidence of EPI in German Shepherd dogs in Finland has been estimated as approximately 1%.[1] In other studies, the incidence in German Shepherd dogs as compared with all clinically diagnosed EPI dogs has varied

Table 62-12 Breed-Related Diseases of the Exocrine pancreas

Disease	Breed	References
Exocrine pancreatic insufficiency	German Shepherd, Rough-Coated Collie, Cavalier King Charles Spaniel, Chow	1-22,24,25
Acute pancreatitis	Miniature Schnauzer, Yorkshire Terrier, Cocker Spaniel	26,27
Chronic pancreatitis	Cavalier King Charles Spaniel, Collie, Boxer, Cocker Spaniel	27
Pancreatic carcinoma	Airedale Terrier	28

between 50% and 70%.[1,4] In the United Kingdom, a retrospective study of more than 1000 dogs with EPI revealed that German Shepherd dogs, Rough-Coated Collies, Cavalier King Charles Spaniels, and Chows are at risk for the development of EPI.[4] To date, genealogic studies have only been performed in German Shepherd dogs and Rough-Coated Collies.

In 1977, the first inheritance study of EPI in German Shepherd dogs was conducted by Weber and Freudiger.[19] They analyzed a pedigree comprising 19 German Shepherd dogs with EPI and 33 unaffected German Shepherd dogs. All 19 affected dogs were found to have a common ancestor born in 1918. Eighteen of the dogs were inbred more than once with a descendant of this common progenitor. On the basis of the degree of inbreeding within this pedigree, Weber and Freudiger hypothesized that EPI was an autosomal recessive trait.

Westermarck studied the hereditary nature of EPI in two kindreds, which included 59 German Shepherd dogs.[20] The male progenitors were the same in both kindreds. In the four litters of the first kindred, the incidence of EPI was 24%, and there was at least one affected dog in each litter. In the second kindred, when an EPI-affected bitch and a clinically healthy male (suspected carrier) were mated, two of the resultant six offspring were found to suffer from EPI. The results of the study indicated that EPI is a disease inherited as an autosomal recessive trait, although the possibility of dominant inheritance with incomplete penetrance could not be excluded.

Moeller et al.[21] assessed the heritability of EPI in German Shepherd dogs in the United States. The study included two pedigrees consisting of 135 dogs. Of 102 dogs that were tested, 19 were definitively diagnosed with EPI. The first family consisted of 59 dogs, and nine (18.8%) of the 48 tested dogs were affected. The second family consisted of 76 dogs, and 10 (18.5%) of the 54 tested dogs were affected. Several litters from parents of which at least one parent was affected had unaffected individuals. Conversely, there were several litters with affected individuals from unaffected parents. This provides evidence that the putative trait for EPI is recessive, although the rate of affected dogs is slightly lower than would be expected (25%) for a simple autosomal recessive inheritance. The study concluded that EPI is inherited as an autosomal recessive trait in German Shepherd dogs in the United States. The same pedigree material was used in a study to identify the gene and the mutation causative for EPI.[22] Five genes of interest were found, and these were further assessed by quantitative real-time reverse-transcription polymerase chain reaction. One gene, *gp25L*, was downregulated by more than 500-fold in affected pancreas and was further investigated as a candidate gene. Sequence data did not reveal a mutation in the coding sequence that segregates with EPI.

The preliminary results of a test mating between two German Shepherd dogs with EPI revealed that only two of the six offspring were affected.[23] The dogs were studied for 11 years, and pancreatic biopsies were obtained four to six times from each dog during their lifetimes. This study showed that EPI is not a single-gene disease but likely a polygenic disease, where environmental factors may also have a role. Only one survey has examined the role of different environmental factors, including feeding, housing, and training, in the development of EPI in dogs.[2] This study failed to identify any common factors in the histories of the dogs with EPI. Such factors as stress and viruses are difficult to evaluate, however, and require further research.

Besides German Shepherd dogs, EPI has also often been diagnosed in Rough-Coated Collies in Finland. Of all dog breeds diagnosed with clinical EPI, approximately 20% of the cases have been reported in Rough-Coated Collies. The Smooth-Coated Collies appears to be unaffected. The prevalence of EPI in the Rough-Coated Collies breed is estimated to be approximately 1%.[1] In a study including 51 Rough-Coated Collies with EPI, 44 could be placed in one composite pedigree.[24] An affected dog in that pedigree had, on average, 17 affected relatives distributed over 11 different litters. Thus clustering strongly suggested that EPI is a hereditary disease in Rough-Coated Collies. The pedigree data indicated that EPI could be an autosomal recessive trait, although the estimated proportion of affected offspring within litters (0.13) was lower than the expected mendelian frequency (0.25).

Pancreatitis in Dogs

The high prevalence of acute pancreatitis in the Miniature Schnauzer suggests a possible hereditary component; however, no pedigree studies have been published, and a recent study failed to identify any mutations in the cationic trypsinogen gene in this breed.[25] The Yorkshire Terrier breed has been reported to be at increased risk for acute pancreatitis, and the Labrador Retriever has been reported to be at reduced risk.[26] In another study, the Cavalier King Charles Spaniel, Collie, and Boxer breeds were reported to be at increased for chronic pancreatitis.[27] The Cocker Spaniel breed was found to be at increased risk for both acute and chronic pancreatitis (see Table 62-12).[27]

Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

I dedicate this work to my parents, Brady and Anna Washabau; my wife, Rosalie Stoner Kreider; and my children, Ethan and Noah Washabau, all of whom gave me inspiration, insight, and abiding love.

Robert Washabau

I dedicate this work to my children, Christopher and Natalie Day.

Michael Day

Preface

Profile

The book was planned as a comprehensive reference standard for the discipline of canine and feline gastroenterology. It has an international focus, including 85 authors from 17 different countries, reflecting the latest in clinical practice and research. The content covers the breadth and depth of gastroenterology from biology to pathobiology, diagnosis, and treatment of disease of the gastrointestinal (GI), pancreatic, and hepatobiliary systems. An initial basic overview of the GI system in health provides up-to-date information on microflora, immunology, cellular growth, and systems integration as a foundation for understanding and treating clinical problems. Disease coverage spans the digestive system from the oral cavity to the esophagus, stomach, small and large intestine, anorectum, liver and biliary tract, exocrine pancreas, peritoneum, and associated vasculature. Our focus on patient management examines the full range of procedures and techniques essential to diagnosis and treatment—from clinical signs and diagnosis to nutritional support, and pharmacologic management of disease. A stand-alone section on pharmacologic approach to GI disease also serves as an easy drug reference. Clear explanations of current diagnostic modalities include laboratory tests, molecular methods, diagnostic imaging, endoscopy, and histopathology, showing how to interpret and utilize results. Practitioners will appreciate the emphasis on need-to-know information for managing the common and not-so-common GI clinical problems of every day practice. Problem-based algorithms are included for diagnosing every GI clinical problem from A to Z. The text is supplemented by full-color photographs and illustrations that depict concepts, conditions, and procedures. An evidence-based medicine perspective reflects the latest research as well as the modern practice of veterinary medicine. Logical, coherent, and consistent internal organization makes this a reader-friendly edition, and a necessary and essential reference standard for veterinary students, practitioners (clinicians, clinical pathologists, and histopathologists), educators, and biomedical researchers.

Format

The book contains 62 chapters organized into six sections. Each section provides a unique perspective on the function and dysfunction of the digestive system.

Section I: Biology of the Gastrointestinal Tract

The book opens with a proposed model for understanding the complexities of the digestive system. The components of this system—food intake, motility, secretion, digestion, absorption, blood flow, and defecation—and their regulation are described in some detail, including the neural, endocrine, and paracrine regulatory elements that coordinate and integrate these functions. The first three chapters (physiology, GI microflora, and immunology) highlight the digestive system in health, whereas the last two chapters (inflammation and cellular growth) highlight the digestive system in disease. The practitioner who masters the basic precepts of Section I will have a firm foundation upon which to move on to clinical problem-solving (Sections II to VI).

Section II: Approach to Clinical Signs in Gastrointestinal Disease

This section contains 19 chapters describing the history, physical examination findings, laboratory data, imaging findings, pathophysiology, differential diagnosis, treatment, and management of the major digestive system clinical presentations including abdominal pain, anorexia, ascites, coagulopathy, constipation, diarrhea, dyschezia, dysphagia, fecal incontinence, gas, hemorrhage, hepatoencephalopathy, icterus, polyphagia, polyuria, polydipsia, regurgitation, salivation, vomiting, and weight loss. This section illustrates the use of clinical algorithms in problem-solving GI clinical signs.

Section III: Diagnostic Approach to Gastrointestinal Disease

This section contains five comprehensive chapters on laboratory testing, diagnostic imaging, endoscopy, laparoscopy, and histopathology, all provided by international experts in the field.

Laboratory Testing

This chapter reviews laboratory tests (hematology; serum chemistry; serum enzymology; serology; serotyping; PCR, RT-PCR, fluorescence in situ hybridization; fecal parasitology; fecal microbiology; cytology; and GI, pancreatic, and liver function) and how to interpret test results.

Diagnostic Imaging

This chapter illustrates the use of imaging technology in the diagnosis of GI pathology, including those techniques used in every-day practice (e.g., survey and contrast radiography, ultrasonography) and those used more often in secondary and tertiary referral centers (e.g., scintigraphy, CT, MRI, and PET-CT). Each chapter outlines the indications and contra-indications for each of the imaging modalities. Each of the chapters includes multiple examples of normal (e.g., size, shape, volume, density) and abnormal conditions.

Endoscopy

The chapter on endoscopy contains an introduction to basic endoscopic equipment, care and cleaning, indications for endoscopy, patient preparation, specific procedures (esophagus, stomach, intestine, colon), interventional procedures, and complications.

Laparoscopy

As with endoscopy, this chapter contains an introduction to basic laparoscopic equipment, care and cleaning, indications for

laparoscopy, patient preparation, and specific procedures (liver, biliary tract, pancreas).

Histopathology

The histology and histopathology of the stomach, intestine, colon, pancreas, liver, and biliary tract are summarized in great detail in this chapter. Internationally recognized scholars from the WSAVA Gastrointestinal and Liver Standardization groups were recruited to write these chapters.

Section IV: Nutritional Approach to Gastrointestinal Disease

This section opens with a chapter on the nutritional assessment and management of the GI patient, including mechanisms of malnutrition and obesity, followed by chapters on pathophysiology of adverse food reactions, nutritional strategies for adjunct therapy, and advances in enteral and parenteral nutrition.

Section V: Pharmacologic Approach to Gastrointestinal Disease

This section has a comprehensive discussion of drug therapies used in the treatment of GI disease, including drug classifications and mechanisms of action, commonly used examples within drug classifications, formulations and doses, rational use in the diagnosed and undiagnosed patient, and contra-indications and side effects. Specific pharmacologic therapies described in this chapter include anti-diarrheal agents, anti-emetic agents, anti-fungal agents, anti-helmintic agents, anti-inflammatory agents, anti-microbial agents, anti-oxidant agents, anti-spasmodic agents, behavioral modification, chelating agents, chemotherapy, cytoprotective agents (gastric), cytoprotective agents (hepatobiliary), enzyme supplementation, fluid therapy, immunosuppressive drugs, laxative agents, probiotic agents, prokinetic agents, and vitamins and minerals.

Section VI: Diseases of the Gastrointestinal Tract

Each of the chapters of this Section opens with structure and function, followed by diagnostic evaluation, and finally diseases of that part of the digestive system. Mechanisms of disease included in each of these chapters cover inflammation, infection, obstruction, dysmotility, neoplasia, ulceration, metabolic, congenital/genetic, and vascular disorders. Each of the diseases is discussed in a standard format, including etiology, pathophysiology, clinical examination, diagnosis, treatment, and prognosis.

Intended Audiences

The book has several intended audiences—practicing veterinarians (clinicians, clinical pathologists, and histopathologists), veterinary students, residents in training, and biomedical researchers—and was tailored accordingly.

General and specialty practice veterinarians, particularly those wanting to practice at a high level of expertise and confidence, will uniquely benefit from this book, and were seen as our first intended audience. The utilization of an evidence-based medicine approach to reflect the latest science and research, complemented by principles of problem-solving, algorithms to improve clinical diagnoses, and extensive full-color illustrations should make this a required reference on the bookshelf of every serious practitioner. Residents in training will also find this to be a very useful resource in their study of the discipline and in preparation for general and specialty certification examinations. The book should also become a major reference source for clinical pathologists and histopathologists. Chapters are devoted to full explanation of current and future laboratory diagnostic tests, and the histology and histopathology of each region of the alimentary tract are described in individual chapters that present a library of supportive histopathological images.

Veterinary students are our second intended audience. We aimed to produce a high-quality reference standard for the discipline that would be used by students as a supplement to their studies of physiology, pharmacology, biochemistry, and pathology in the pre-clinical years of the veterinary curriculum, and as a primary reference in their studies of GI medicine and surgery in the clinical years of the curriculum. Foundation material on GI immunology, microflora, inflammation, cellular growth, and systems integration, for example, should serve to more readily bridge the student from basic to clinical concepts.

Biomedical researchers are seen as our third intended audience. The biomedical researcher will appreciate the extensive literature citation; scientific rigor; emphasis on the histologic, immunologic, and molecular basis of disease; summary of breed-related diseases; and, relevance to animal models of human disease.

Acknowledgments

I wish to acknowledge three Veterinary School Deans (Drs. Bob Marshak, Ed Andrews, and Alan Kelly) at the University of Pennsylvania who, during the formative years of my training, emphasized the importance of science and discovery thereby setting a standard to emulate in veterinary medicine.

I thank those veterinarians who trained, inspired, and encouraged me during my residency training years at the University of California, Davis, notably Drs. Don Strombeck, Niels Pedersen, and Larry Cowgill. A special note of thanks to Don Strombeck who introduced me to the discipline of gastroenterology, opened up his laboratory, and encouraged me to seek additional scientific training and an academic career.

I am grateful to those who taught me muscle biology during my PhD training, most notably, Drs. Jim Ryan, Michael Wang, and Steve Driska, all at Temple University School of Medicine; and, Dr. Robert Moreland at Graduate Hospital in Philadelphia.

Dr. Ken Bovée was an outstanding mentor to me during my internship, graduate training, and early faculty years at the University of Pennsylvania. Ken epitomized the role of the *sempai* in a mentor-protégé relationship, and he helped me to understand the importance of focus and resilience.

Dr. Bruce Blazar, physician-scientist and principal investigator of the NIH Clinical and Translational Science Award (NIH CTSA) at the University of Minnesota, was an early advocate of the Comparative Medicine program who supported us in the development of spontaneous animal models of human disease, in gastroenterology especially, as well as in other disciplines.

Great textbooks require great publishing firms, editors, and editorial staff. With Elsevier, we were blessed with all three. I would particularly like to thank (in alphabetic order) Celeste Clingan, Kate Dobson, Brandi Graham, Lauren Harms, Whitney Noble, Penny Rudolph, and Tony Winkel, all of whom contributed time, expertise, and hard work to the production of this book.

The book was a grand undertaking with the recruitment of an extensive international authorship. Our task could not have been accomplished without the engagement of an elite group of Section Editors: Marge Chandler (Nutrition), Jörg Steiner (Diagnostic Techniques), Rebecca Syring (Therapy), David Twedt (Biology), and Michael Willard (Clinical Problem-Solving). Effusive thanks to all.

In addition to the dedication, I wish to further acknowledge Rosalie Stoner Kreider: wife, mother of our children, attorney-at-law, university professor, and guiding light. I couldn't have accomplished any of it without her.

Robert Washabau

My interest in small companion animal gastroenterology has been sparked and fostered by two colleagues and friends with whom I have been privileged to work over the past 20 years. Professor Ed Hall first introduced me to the complexities of canine chronic enteropathy and Professor Tim Gruffydd-Jones to the equivalent feline disorders. Together, we have unraveled some of the incredible immunopathology of the alimentary tract of the dog and cat in a perfect clinicopathological partnership. We have been fortunate to have worked with a series of talented postgraduate students, postdoctoral fellows and visiting scientists including Drs Alex German, Iain Peters, Andrea Lynch, Eshan Esfandiari, Jurgen Zentek, Nashwa Waly and Ross Harley.

From 2004 to 2008 it was a pleasure to work with Robert Washabau and colleagues on the WSAVA Gastrointestinal Standardization Group. The outcomes from this very worthwhile project repeatedly appear throughout the pages of this book. It was therefore an honour and pleasure to accept Robert's invitation to join him as co-editor of *Canine and Feline Gastroenterology* in what has proven to be a further example of the benefit of clinical and pathological collaboration. The book has had a long gestation, but the finished product should serve as a standard reference for clinicians and pathologists alike.

I can only re-iterate Robert's acknowledgments to our ever-patient Section Editors and the Elsevier production team. It has been a pleasure working with all of you.

Bedford Hills, New York 10507
Small Intestine—Neoplasia

Antonella Borgatti, DVM, MS, DACVIM (Oncology), DECVIM-CA
Assistant Clinical Professor of Oncology
Department of Veterinary Clinical Sciences
College of Veterinary Medicine
University of Minnesota
St. Paul, Minnesota
Chemotherapy

Mary Bowles, DVM, DACVIM
Associate Professor
Department of Veterinary Clinical Sciences
Center for Veterinary Health Sciences
Boren Veterinary Teaching Hospital
Oklahoma State University
Stillwater, Oklahoma
Probiotic Agents

Mary Beth Callan, VMD, DACVIM
Professor of Medicine
Department of Clinical Studies
School of Veterinary Medicine
University of Pennsylvania
Philadelphia, Pennsylvania
Coagulopathy

Nick Cave, BVSc, MVSc, PhD, MANZCVS, DACVN
Senior Lecturer in Small Animal Medicine
Centre for Companion Animal Health
Institute of Veterinary, Animal and Biomedical Sciences
College of Sciences
Massey University
Palmerston North, New Zealand
Fecal Incontinence
Gastrointestinal Gas
Adverse Reactions to Food
Small Intestine—Obstruction

Christopher J. Chamness, DVM
Director Global Business Development—Veterinary
KARL STORZ GmbH & Co. KG
Santa Barbara, California
Endoscopy—Endoscopic Instrumentation

Marjorie L. Chandler, DVM, MS, MACVSc, DACVN, DACVIM, DECVIM-CA, MRCVS
Senior Lecturer in Clinical Nutrition and Small Animal Internal Medicine
Head of Small Animal Nutrition Service
Hospital for Small Animals
Royal (Dick) School of Veterinary Studies
University of Edinburgh
Edinburgh, Scotland, United Kingdom
Nutritional Approach to Gastrointestinal Disease

John M. Cullen, VMD, PhD, DACVP
Professor
Department of Population Health and Pathobiology
College of Veterinary Medicine
North Carolina State University
Raleigh, North Carolina
Histopathology—Hepatobiliary

Michael J. Day, BSc, BVMS (Hons), PhD, DSc, DECVP, FASM, FRCPath, FRCVS
Professor of Veterinary Pathology
School of Veterinary Sciences
University of Bristol
Langford, North Somerset, United Kingdom
Gastrointestinal Inflammation
Histopathology—Intestine

Linda DeBowes, DVM, DACVIM, DAVDC
Veterinarian
Shoreline Veterinary Dental Clinic
Seattle, Washington
Oropharynx—Diseases

Olivier Dossin, DVM, PhD, DECVIM-CA
Associate Professor of Small Animal Internal Medicine
Department of Clinical Sciences—Clinical Research Unit
National Veterinary School
University of Toulouse-INP
Toulouse, France
Endoscopy—Complications

Daniel A. Feeney, DVM, MS, DACVR
Professor of Radiology
Department of Veterinary Clinical Sciences
College of Veterinary Medicine
University of Minnesota
St. Paul, Minnesota
Diagnostic Imaging of the Gastrointestinal Tract—Radiography

Theresa W. Fossum, DVM, MS, PhD, DACVIM
Professor of Surgery;
Tom and Joan Chair in Veterinary Surgery
Department of Small Animal Clinical Sciences
College of Veterinary Medicine
Texas A&M University
College Station, Texas
Liver—Extra Hepatic Biliary Disorders

Diane Frank, DVM, DACVB
Associate Professor of Animal Behavior
Department of Clinical Sciences
Faculty of Veterinary Medicine
University of Montreal
Saint-Hyacinthe, Quebec, Canada
Behavioral Intervention

Shelby L. Freda, VMD
Veterinarian
East Side Animal Hospital
New York, New York
Anorectum—Neoplasia

Robert Furman, BVMS, MRCVS
Veterinarian
Southern California Veterinary Dental Specialties
San Diego, California
Salivation

Oliver A. Garden, BSc, BVetMed, PhD, FHEA, MSB, MRCVS, DACVIM, DECVIM-CA
Reader in Internal Medicine and Immunology
Department of Veterinary Clinical Sciences
Royal Veterinary College
Camden Campus, London, United Kingdom
Queen Mother Hospital for Animals
Royal Veterinary College
North Mymms, Hatfield, United Kingdom
Gastrointestinal Immunology

Frédéric P. Gaschen, Dr.med.vet, Dr. habil., DACVIM, DECVIM-CA
M.L. Martin Professor of Companion Animal Medicine
Department of Veterinary Clinical Sciences
School of Veterinary Medicine
Louisiana State University
Baton Rouge, Louisiana
Large Intestine—Inflammation

Lorrie Gaschen, DVM, Dr.med.vet., PhD, DECVDI
Professor of Diagnostic Imaging
Section Chief of Diagnostic Imaging
Department of Veterinary Clinical Sciences
School of Veterinary Medicine
Louisiana State University
Baton Rouge, Louisiana
Diagnostic Imaging of the Gastrointestinal Tract—Ultrasonographic Imaging of the Gastrointestinal Tract

Alexander James German, BVSc (Hons), PhD, CertSAM, DECVIM-CA, MRCVS
Senior Lecturer in Small Animal Medicine
Department of Comparative and Molecular Medicine
Small Animal Teaching Hospital
School of Veterinary Science
University of Liverpool
Liverpool, Merseyside, United Kingdom
Nutritional Assessment and Management—Obesity
Small Intestine—Inflammation
Small Intestine—Bacterial Overgrowth

Michael H. Goldschmidt, MSc, BVMS, MRCVS, DACVP
Professor of Veterinary Pathology;
Head of Surgical Pathobiology
Department of Pathobiology
School of Veterinary Medicine
University of Pennsylvania
Philadelphia, Pennsylvania
Anorectum—Neoplasia

Jody L. Gookin, DVM, PhD, DACVIM (SAIM)
Associate Professor
Department of Clinical Sciences
College of Veterinary Medicine
North Carolina State University
Raleigh, North Carolina
Large Intestine—Infection

Deborah S. Greco, DVM, PhD, DACVIM (Internal Medicine)
Senior Research Scientist
Department of Product Technology
Nestle Purina Petcare
St. Louis, Missouri
Liver—Metabolic Disorders

Massimo Gualtieri, DVM, PhD
Professor of Surgery;
Head of Surgery Unit
Department of Veterinary Clinical Sciences—Section of Surgery
Faculty of Veterinary Medicine
University of Milan
Milan, Italy
Endoscopy—Interventional Endoscopy

Kevin A. Hahn, DVM, PhD, DACVIM (Oncology)
Chief Medical Officer
Hill's Pet Nutrition, Inc.
Topeka, Kansas
Pancreas—Neoplasia

Edward J. Hall, MA, VetMB, PhD, DECVIM-CA
Professor of Small Animal Internal Medicine
School of Veterinary Science
University of Bristol
Langford, Bristol, England
Small Intestine—Structure and Function
Small Intestine—Diagnostic Evaluation

Jean A. Hall, DVM, PhD, DACVIM
Professor
Department of Biomedical Sciences
College of Veterinary Medicine
Oregon State University
Corvallis, Oregon
Abdominal Pain
Stomach—Obstruction
Stomach—Dysmotility

David E. Holt, BVSc, DACVS
Professor of Surgery
Department of Clinical Sciences
School o Veterinary Medicine
University of Pennsylvania
Philadelphia, Pennsylvania
Large Intestine—Ulcer

Tim Hyndman, BSc, BVMS, MANZCVS (Veterinary Pharmacology)
Lecturer in Veterinary Pharmacology
School of Veterinary and Biomedical Sciences
Murdoch University
Murdoch, Western Australia, Australia
Gastric Cytoprotective Agents

Albert E. Jergens, DVM, PhD, DACVIM
Professor of Medicine
Department of Veterinary Clinical Sciences
College of Veterinary Medicine
Iowa State University
Ames, Iowa
Dyschezia and Tenesmus
Endoscopy—Gastric Endoscopy

Susan E. Johnson, DVM, MS, DACVIM (Internal Medicine)
Professor of Small Animal Internal Medicine
Service Head—Small Animal Internal Medicine
Department of Veterinary Clinical Sciences
College of Veterinary Medicine
The Ohio State University
Columbus, Ohio
Liver—Parenchymal Disorders

Chand Khanna, DVM, PhD
Head, Tumor and Metastasis Biology Section;
Senior Scientist
Center for Cancer Research
National Cancer Institute
Bethesda, Maryland
Cellular Growth/Neoplasia

Dorothy Laflamme, DVM, PhD, DACVN
Veterinary Nutritionist
Research and Development
Nestle Purina Pet Care
St. Louis, Missouri
Polyphagia

Michael R. Lappin, DVM, PhD, DACVIM (Internal Medicine)
The Kenneth W. Smith Professor in Small Animal Clinical Medicine
Department of Clinical Sciences
College of Veterinary Medicine and Biomedical Sciences
Colorado State University
Fort Collins, Colorado
Anthelmintic Agents
Small Intestine—Infection

Jennifer A. Larsen, DVM, PhD, DACVN
Assistant Professor of Clinical Nutrition
Veterinary Medicine Teaching Hospital
Department of Molecular Biosciences
School of Veterinary Medicine
University of California, Davis
Davis, California
Nutritional Strategies—Pancreas

Patrick LeCoindre, DVM, DECVIM-CA
Veterinarian
Clinique Véterinaire des Cerisioz
St. Priest, France
Endoscopy—Colonic Endoscopy

Michael S. Leib, DVM, MS, DACVIM
CR Roberts Professor of Small Animal Medicine
Department of Small Animal Clinical Sciences
Virginia Maryland Regional College of Veterinary Medicine
Virginia Tech
Blacksburg, Virginia
Endoscopy—Esophageal Endoscopy

Diane Monsein Levitan, VMD, DACVIM
Owner
Peace Love Pets Veterinary Care, PLLC
Commack, New York
Director
Helping Promote Animal Welfare, Inc. (Helping PAW)
Syosset, New York
Endoscopy—Care and Cleaning of Instruments

Jonathan A. Lidbury, BVMS, MRCVS, DACVIM
Graduate Student and Clinical Scientist
Gastrointestinal Laboratory
Department of Small Animal Clinical Sciences
College of Veterinary Medicine and Biomedical Sciences
Texas A&M University
College Station, Texas
Liver—Diagnostic Evaluation

Remo Lobetti, BVSc (Hons), MMedVet (Med), PhD, DECVIM (Internal Medicine)
Veterinarian
Bryanston Veterinary Hospital
Bryanston, South Africa
Esophagus—Infection

Jill E. Maddison, DVM, BVSc (Hons), DipVetClinStud, PhD, FACVSc, MRCVS
Director of Professional Development
CPD Unit
The Royal Veterinary College
North Mymms, Herts, United Kingdom
Hepatoencephalopathy

Joanne Mansell, DVM, MS, DACVP
Professor
Department of Veterinary Pathobiology
College of Veterinary Medicine and Biomedical Sciences
Texas A&M University
College Station, Texas
Endoscopy—Biopsy Guidelines

Caroline S. Mansfield, BSc, BVMS, MVM, MANZCVSc, DECVIM-CA
Hill's Senior Lecturer in Small Animal Medicine
Faculty of Veterinary Science
The University of Melbourne
Werribee, Victoria, Australia
Ascites
Gastric Cytoprotective Agents
Stomach—Ulcer

Stanley L. Marks, BVSc, PhD, DACVIM (Internal Medicine, Oncology), DACVN
Professor
Department of Medicine and Epidemiology
School of Veterinary Medicine
University of California, Davis
Davis, California
Diarrhea
Enteral/Parenteral Nutrition

Karol Mathews, DVM, DVSc, DACVECC
Professor Emeritus
Department of Clinical Studies
Ontario Veterinary College
University of Guelph
Guelph, Ontario, Canada
Non-Steroidal Anti-Inflammatory Analgesics

Dennis J. Meyer, DVM, DACVIM, DACVP
Executive Director, Navigator Services
Principal Clinical Pathologist
Charles River Preclinical Services
Reno, Nevada
Laboratory Approach—Liver

Hein P. Meyer, DVM, PhD, DECVIM-CA
Director, Professional and Veterinary Affairs
Hill's Pet Nutrition—Europe, Middle East, and Africa
Prague, Czech Republic
Liver—History, Physical Examination

Kathryn E. Michel, DVM, MS, BA, DACVN
Professor of Nutrition
Department of Clinical Studies
School of Veterinary Medicine
University of Pennsylvania
Philadelphia, Pennsylvania
Anorexia

Takeo Minami, DVM, MS, PhD, JCVS
Histo-Vet
Pet-Vet
Yokohama, Japan
Stomach—Neoplasia

Eric Monnet, DVM, PhD, DACVS, DEVCS
Professor of Small Animal Surgery
Department of Clinical Sciences
College of Veterinary Medicine and Biomedical Sciences
Colorado State University
Fort Collins, Colorado
Laparascopy—Liver and Biliary Tract

Antony S. Moore, BVSc, MVSc, MANZCVS, Diplomate ACVIM (Oncology)
Veterinary Oncologist
Veterinary Oncology Consultants
Wauchope, New South Wales, Australia
Oropharynx—Neoplasia

Federica Morandi, DVM, MS, DACVR, DECVDI
Associate Professor of Radiology
Department of Small Animal Clinical Sciences
College of Veterinary Medicine
University of Tennessee
Knoxville, Tennessee
Diagnostic Imaging of the Gastrointestinal Tract—Nuclear Scintigraphy

Brook Niemiec, DVM, DAVDC, FAVD, BS
Veterinarian
Southern Cailfornia Veterinary Dental Specialties
San Diego, California
Salivation

Mark G. Papich, DVM, MS, DACVCP
Professor of Clinical Pharmacology
Department of Molecular Biomedical Sciences
College of Veterinary Medicine
North Carolina State University
Raleigh, North Carolina
Antimicrobial Drugs

Josep Pastor, DVM, PhD, DECVCP
Patología Médica
Department de Medicina i Cirurgia Animals
Facultad de Veterinària
Universitat Autònoma de Barcelona
Bellaterra, Spain
Liver—Neoplastic Disorders

David J. Polzin, DVM, PhD, DACVIM
Professor and Chief, Small Animal Internal Medicine
Department of Veterinary Clinical Sciences
College of Veterinary Medicine
University of Minnesota
St. Paul, Minnesota
Polyuria/Polydipsia

Keith Richter, DVM, DACVIM
Hospital Director
Veterinary Specialty Hospital of San Diego
San Diego, California
Laparoscopy—Instrumentation
Liver—Biopsy Techniques

Mark P. Rondeau, DVM, DACVIM (SAIM)
Staff Veterinarian
Department of Clinical Studies
School of Veterinary Medicine
University of Pennsylvania
Philadelphia, Pennsylvania
Liver—Intra-Hepatic Biliary Disorders

Jan Rothuizen, DVM, PhD, DECVIM-CA
Professor of Internal Medicine
Department of Clinical Sciences of Companion Animals
Faculty of Veterinary Medicine
Utrecht University
Utrecht, The Netherlands
Liver—History, Physical Examination

Craig G. Ruaux, BVSc (Hons), PhD, MACVSc, DACVIM
Assistant Professor, Small Animal Medicine
Department of Clinical Sciences
College of Veterinary Medicine
Oregon State University
Corvallis, Oregon
Nutritional Strategies—Liver and Biliary Tract
Vitamins and Minerals

Alexandra Sahora, DVM
Oncology Associate
The Oncology Service, LLC
Washington, District of Columbia
Cellular Growth/Neoplasia

Sherry Lynn Sanderson, BS, DVM, PhD, DACVIM, DACVN
Associate Professor
Department of Physiology and Pharmacology
College of Veterinary Medicine
The University of Georgia
Athens, Georgia
Nutritional Strategies—Gastrointestinal Tract

Travis C. Saveraid, DVM, DACVR
Founder
VetRadiologist, LLC
Saint Paul, Minnesota
Diagnostic Imaging of the Gastrointestinal Tract–CT/MRI

Michael Schaer, DVM, DACVIM (Internal Medicine), DACVECC
Professor Emeritus
College of Veterinary Medicine
University of Florida
Gainesville, Florida
Pancreas—Abscess, Necrosis, Pseudocyst, Phlegmon, and Infection

Gabriela S Seiler, Dr.Med.Vet., DECVDI, DACVR
Associate Professor of Radiology
Department of Molecular Biomedical Sciences
College of Veterinary Medicine
North Carolina State University
Raleigh, North Carolina
Diagnostic Imaging of the Gastrointestinal Tract—Ultrasonographic Imaging of the Pancreas and Liver

Rance Sellon, DVM, PhD, DACVIM
Associate Professor
Department of Veterinary Clinical Sciences
College of Veterinary Medicine
Washington State University
Pullman, Washington
Fluid Therapy
Immunosuppressive Drugs

Robert G. Sherding, DVM, DACVIM
Professor Emeritus
Department of Veterinary Clinical Sciences
College of Veterinary Medicine
The Ohio State University
Columbus, Ohio
Icterus
Esophagus—Diagnostic Evaluation

Kenneth W. Simpson BVM&S, PhD, DACVIM, DECVIM
Professor of Small Animal Medicine
Director, Simpson Gastroenterology Research Laboratory
Department of Clinical Sciences
College of Veterinary Medicine
Cornell University
Ithaca, New York
Stomach—Structure and Function
Stomach—Inflammation
Stomach—Infection

Thomas Spillmann, DVM, Dr.Med.Vet.
Professor of Small Animal Internal Medicine
Department of Clinical Veterinary Sciences
Faculty of Veterinary Medicine
University of Helsinki
Helsinki, Finland
Endoscopy—Intestinal Endoscopy
Laparascopy—Pancreas

Anette Spohr, DVM, PhD
Owner;
Veterinarian
Faxe Dyrehospital
Copenhagen, Denmark
Stomach—Diagnostic Evaluation

Jörg M. Steiner, med.vet., Dr.med.vet., PhD, DACVIM, DECVIM-CA
Professor and Director
Gastrointestinal Laboratory
Department of Small Animal Clinical Sciences
College of Veterinary Medicine & Biomedical Sciences
Texas A&M University
College Station, Texas
Diagnositc Approach—Pancreas
Liver—Diagnostic Evaluation
Pancreas—Necrosis and Inflammation: Canine
Pancreas—Diagnostic Evaluation

Kevin Stepaniuk, BSc, DVM, FAVD, DAVDC
Assistant Clinical Professor
Dentistry & Oral Surgery Department
Veterinary Medical Center
University of Minnesota
St. Paul, Minnesota
Oropharynx—Trauma

Jan S. Suchodolski, med. vet., Dr. med. vet., PhD
Clinical Assistant Professor
Associate Director
Gastrointestinal Laboratory
Department of Small Animal Clinical Sciences
College of Veterinary Medicine and Biomedical Sciences
Texas A&M University
College Station, Texas
Gastrointestinal Microflora
Laboratory Approach—Stomach and Small Intestine

Viktor Szatmári, DVM, PhD, DECVIM-CA (Cardiology)
Assistant Professor
Chief Section Cardiology and Pulmonology
Department of Clinical Sciences of Companion Animals
Faculty of Veterinary Medicine
Utrecht University
Utrecht, The Netherlands
Liver—Vascular Disorders

Kendall Taney, DVM, DAVDC, FAVD
Partner
Center for Veterinary Dentistry and Oral Surgery
Gaithersburg, Maryland
Oropharynx—Structure and Function

David C. Twedt, DVM, DACVIM
Professor
Department of Clinical Sciences
College of Veterinary Medicine & Biomedical Sciences
Colorado State University
Fort Collins, Colorado
Laparascopy—Liver and Biliary Tract
Chelating Agents

Thomas John Van Winkle, VMD, DACVP
Professor of Pathology
Department of Pathobiology
School of Veterinary Medicine
University of Pennsylvania
Philadelphia, Pennsylvania
Histopathology—Pancreas

Anjop J. Venker van Haagen, DVM, PhD, DECVS
Former Associate Professor of Veterinary Ear, Nose, Throat Diseases
Department of Clinical Sciences of Companion Animals
Faculty of Veterinary Medicine
Utrecht University
Utrecht, The Netherlands
Esophagus—Structure and Function

Cynthia R. Ward, VMD, PhD, DACVIM
Professor
Chief Inpatient Medicine
Department of Small Animal Medicine and Surgery
College of Veterinary Medicine
The University of Georgia
Athens, Georgia
Weight Loss and Cachexia

Robert J. Washabau, DVM, VMD, PhD, DACVIM
Professor of Medicine and Department Chair
Director of the Comparative Medicine Program
Department of Veterinary Clinical Sciences
College of Veterinary Medicine
University of Minnesota
St. Paul, Minnesota
Integration of Gastrointestinal Function
Constipation
Dysphagia and Gagging
Regurgitation
Vomiting
Diagnostic Imaging of the Gastrointestinal Tract—Assessment of Gastrointestinal Motility
Antidiarrheal Agents
Antiemetic Agents
Antifungal Drugs
Antispasmodic Agents
Laxative Agents
Prokinetic Agents
Oropharynx—Dysmotility
Esophagus—Inflammation
Esophagus—Obstruction
Esophagus—Dysmotility
Stomach—Infection
Stomach—Dysmotility
Small Intestine—Dysmotility
Large Intestine—Structure and Function
Large Intestine—Diagnostic Evaluation
Large Intestine—Obstruction
Large Intestine—Dysmotility
Large Intestine—Ulcer
Large Intestine—Neoplasia
Anorectum—Diagnostic Evaluation
Anorectum—Obstruction
Anorectum—Dysmotility
Pancreas—Structure and Function
Pancreas—Necrosis and Inflammation: Feline
Liver—Structure and Function
Breed-Relationships—GI Tract

Penny J. Watson, MA, VetMD, CertVR, DSAM, DECVIM, MRCVS
Senior Lecturer in Small Animal Medicine and Clinical Nutrition Department of Veterinary Medicine
The Queen's Veterinary School Hospital
Cambridge Veterinary School
University of Cambridge
Cambridge, United Kingdom
Liver—Complications of Liver Disease
Breed-Relationships—Liver and Biliary Tract

Craig B. Webb, DVM, MS, PhD, DACVIM
Associate Professor
Department of Clinical Sciences
College of Veterinary Medicine & Biomedical Sciences
Colorado State University
Fort Collins, Colorado
Antioxidant Drugs

Cynthia R.L. Webster, DVM, DACVIM
Professor
Department of Clinical Sciences
School of Veterinary Medicine
Tufts University
North Grafton, Massachusetts
Cytoprotective Agents—Hepatobiliary

Elias Westermarck, DVM, PhD, DECVIM-CA
Professor
Department of Equine and Small Animal Medicine
Faculty Veterinary Medicine
University of Helsinki
Helsinki, Finland
Enzyme Supplementation
Breed-Relationships—Pancreas

Maria Wiberg, DVM, PhD
Clinical Professor
Department of Clinical Veterinary Sciences
Faculty of Veterinary Medicine
University of Helsinki
Helsinki, Finland
Pancreas—Insufficiency

Brian Wilcock, DVM, PhD
Professor Emeritus
Department of Pathobiology
Ontario Veterinary College
University of Guelph
Guelph, Ontario, Canada:
Chief Pathologist
Histovet Surgical Pathology
Guelph, Ontario, Canada
Histopathology—Stomach
Histopathology—Colon

Michael D. Willard, DVM, MS, DACVIM
Professor of Small Animal Medicine and Surgery
Department of Small Animal Clinical Sciences
College of Veterinary Medicine
Texas A&M University
College Station, Texas
Hemorrhage (Gastrointestinal)
Endoscopy—Biopsy Guidelines
Esophagus—Neoplasia
Small Intestine—Malabsorption
Liver—Extra Hepatic Biliary Disorders

Panagiotis G. Xenoulis, DVM, Dr.med.vet., PhD
Clinical Scientist
Gastrointestinal Laboratory
Department of Small Animal Clinical Sciences
College of Veterinary and Biomedical Sciences
Texas A&M University
College Station, Texas
Diagnostic Approach—Pancreas
Pancreas—Necrosis and Inflammation: Canine
Pancreas—Diagnostic Evaluation

Debra L. Zoran, DVM, PhD, DACVIM-SAIM
Associate Professor
Chief of Medicine
Department of Small Animal Clinical Sciences
College of Veterinary Medicine and Biomedical Sciences
Texas A&M University
College Station, Texas
Anorectum—Structure and Function
Anorectum—Inflammation
Anorectum—Infection
