CHAPTER 1

Integration of Gastrointestinal Function

Robert J. Washabau

Integration of Function

The digestive system includes the primary gastrointestinal (GI) tract (oropharynx, esophagus, stomach, intestine, and colon), exocrine pancreas, liver, and biliary tract. The role of the digestive system is to provide for nutrition, energy balance, intermediary metabolism, and a mechanism for excretion. To fulfill this role, the digestive system has evolved six major functions: (a) *Motility*—Motility permits the prehension of food and its transit from mouth to anus, while at the same time mixing and reducing the size of the food content. The rate at which food moves through the GI tract is regulated to optimize time for secretion, digestion, and absorption. (b) *Secretion*—Secretions from the salivary glands, stomach, intestine, pancreas, liver, and biliary tract add fluid, electrolytes, acid, bicarbonate, mucus, bile salts, and enzymes to the GI tract lumen. These serve to aid in the digestion and absorption of ingested nutrients. (c) *Digestion*—Ingested nutrients are progressively reduced in size primarily by luminal hydrolytic digestion with some fermentative digestion contributed by colonic bacteria. (d) *Absorption*—The intestine has a highly specialized epithelium, which mediates the absorption of nutrients, electrolytes, minerals, vitamins, and water. (e) *Blood flow*—The major function of the splanchnic circulation is to support the broad range of metabolic activities described above. The splanchnic circulation also serves as a storage site for a large volume of blood that can be mobilized during exercise. (f) *Metabolism*—The liver has a wide range of metabolic functions, including carbohydrate, protein, lipid, and nucleic acid metabolism; coagulation factor synthesis; bile secretion; porphyrin, metal, vitamin, glutathione, hormonal, and xenobiotic metabolism; and immune surveillance. The elements of this highly integrated model are outlined in Figure 1-1. Neural, endocrine, and paracrine control mechanisms serve to regulate and integrate these various functions.

Structural Organization

Primary Gastrointestinal Tract

The structural organization of the primary GI tract consists of a luminally oriented mucosa, submucosa, muscularis externa, and serosa (Fig. 1-2).[1] The *mucosa* consists of a superficial epithelium, lamina propria, and muscularis mucosae. Epithelial cells carry out digestive, secretory, and absorptive functions, as well as immune surveillance. The lamina propria consists of connective tissue, blood, and lymphatic vasculature. The muscularis mucosae is made up of smooth muscle cells that function primarily to change the shape and surface area of the epithelial cell layer in response to luminal distention. The *submucosa* consists of collagen, elastin, secretory glands, and major blood vessels. Motility of the GI tract is provided by circular and longitudinal layers of smooth muscle, interposed between the submucosa and serosa. Two nerve plexuses, the submucosal plexus and myenteric plexus, contain the intrinsic nervous system of the GI tract. The *submucosal plexus* (Meissner's plexus) lies between the submucosa and the circular smooth muscle, and regulates the overlying epithelium. The *myenteric plexus* lies between the circular and longitudinal muscle layers, and regulates their contraction. The *serosa* is a thin external membrane consisting of a layer of serous fluid-secreting cells. Serous secretions serve to reduce friction from the muscular motion of the GI tract. Each segment of the primary GI tract has unique features that promote one or more of the GI functions (Fig. 1-3A to 1-3D).

Pancreas

The pancreas contains exocrine and endocrine elements, which serve to regulate digestion and metabolism, respectively. The exocrine pancreas is a mixed tubuloalveolar or tubuloacinar gland. Acinar cells synthesize and secrete digestive enzyme into a ductal system for transport to the small intestine (Fig. 1-3E).[2,3] Islet cells of the endocrine pancreas are interspersed between the acinar and duct cells. The exocrine pancreas has four major physiologic functions: (a) *acinar cell* secretion of digestive zymogens, which initiate protein, carbohydrate, and lipid digestion; (b) *acinar cell* secretion of antibacterial proteins, which serve to regulate the small intestinal bacterial flora; (c) *ductal cell* secretion of bicarbonate and water, which serves to hydrate and neutralize the duodenal pH; and (d) *ductal cell* secretion of pancreatic intrinsic factor, which facilitates cobalamin (vitamin B_{12}) binding and absorption in the distal ileum.[2,3] The exocrine pancreas does not have a direct arterial blood supply. Acinar cells are instead perfused by venous blood emanating from islet vasa efferentia via an islet–acinar portal system.[4] Arterial blood first perfuses the islets, which secrete their hormones (e.g., insulin, glucagon) into the postcapillary venules and veins that then perfuse the acinar cells. The endocrine pancreas thereby autoregulates exocrine secretions and pancreatic growth. The efferent nerve supply to the pancreas includes both sympathetic and parasympathetic fibers. Sympathetic postganglionic fibers arise from the celiac and cranial mesenteric plexuses and accompany the arteries to the exocrine pancreas. Parasympathetic preganglionic fibers are

distributed by branches of the vagi traversing the stomach and duodenum and terminate at the acini, islets, or intrinsic cholinergic nerves of the pancreas. In general, parasympathetic nerve fibers stimulate exocrine pancreatic secretion, and sympathetic nerve fibers inhibit exocrine pancreatic secretion.[5]

Liver

The *hepatic lobule* is the *anatomic* unit of the liver. In the anatomic model, liver lobules are organized into irregular polygons demarcated by connective tissue and composed of plates of hepatocytes radiating outward from the central vein to the portal triads (Fig. 1-3F). The *hepatic acinus* is the *functional* unit of the liver. In the functional model, hepatocytes are instead oriented around the afferent vascular system (portal veins and hepatic arteries) just as they anastomose into sinusoids (Fig. 1-3F), and the central vein is at the periphery of the acinus instead of centrally located as in the anatomic model. The acinus is divided into three contiguous zones (1-3) that correspond to distance from the arterial blood supply. Hepatocytes closest to the arterioles (zone 1) receive the greatest oxygen content, but are also the first to be affected by toxins transported from the gut to the portal vein. Zone 3 hepatocytes reside at the periphery of the acinus near the central vein, and zone 2 hepatocytes are interspersed between zones 1 and 3. The anatomic model is perhaps easier to understand, but the functional model serves as a better foundation for understanding liver pathology.[6,7]

In either model, portal venous and arterial blood flows centripetally, that is, toward the central vein, whereas bile flows centrifugally, that is, away from the central vein. Hepatocytes extract nutrients and oxygen from portal and arterial perfusion, respectively, and produce bile acids and other bile constituents that are transported from hepatocytes into bile canaliculi, ductules, and ducts.[8] Hepatocytes account for 60% of the liver cell mass and contribute to the wide range of metabolic activities described in the preceding section. Hepatocytes are supported by other cell types, which account for 40% of the liver cell mass.

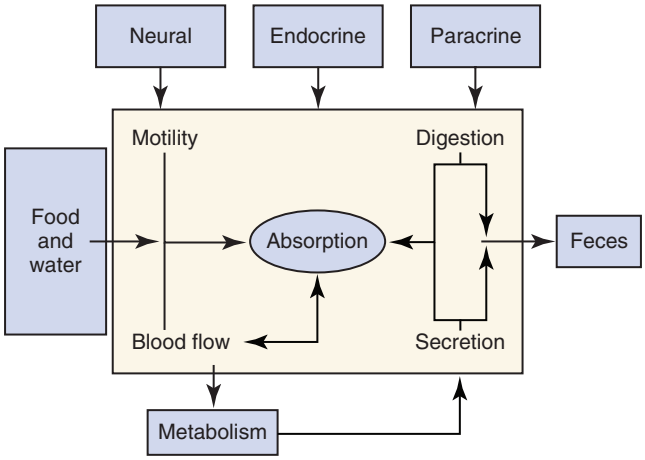

Figure 1-1 Model for the integration of the major functions of the digestive system.

Biliary Epithelial Cells (Cholangiocytes)

These represent 7% to 10% of liver cell mass.[9,10] They secrete water, bicarbonate, and cations into the bile in the physiologic state, but in some diseases they may participate in the immune response as antigen-presenting cells (APCs).

Kupffer Cells

These represent 2% to 5% of the liver cell mass, and serve as resident macrophages lining the sinusoids. Kupffer cells are phagocytic and may contribute to pathology through production of inflammatory mediators, activation of Toll-like receptors (TLRs), and

elaboration of proinflammatory cytokines such as tumor necrosis factor (TNF)-α.[7]

Hepatic Stellate Cells

Formerly known as Ito cells, stellate cells represent 3% to 5% of liver cell mass and store lipid and vitamin A in the healthy liver. When activated in liver damage, stellate cells produce collagen, causing hepatic fibrosis that can progress to end-stage cirrhosis.[11]

Natural Killer Cells

Also known as *pit cells*, these represent 1% of liver cell mass, and serve as part of the immune surveillance in the hepatic sinusoids. Natural killer (NK) cells are cytotoxic in function.

Hepatic Endothelial Cells

Hepatic sinusoidal endothelial cells represent 20% of the liver cell mass and act as resident APCs in health, although they contribute to a heightened immune response in disease conditions.[12]

Smooth Muscle

Representing 2% to 5% of the liver cell mass, smooth muscle cells are located primarily in the hepatic artery and portal vein and their tributaries.

Hepatic Stem Cells

Also known as hepatic progenitor cells, stem cells represent 1% of the liver cell mass, and are capable of regenerating the liver tissue postinjury.[13]

Innervation of the Gastrointestinal Tract

The autonomic nervous system (ANS) innervation of the GI tract has both extrinsic and intrinsic components (Fig. 1-4). The extrinsic component consists of the parasympathetic and sympathetic branches. The intrinsic component is the enteric nervous system that is contained within the submucosal and myenteric plexuses (Fig. 1-5).[14] The enteric nervous system communicates extensively with the parasympathetic and sympathetic nervous systems.

Parasympathetic Innervation

Parasympathetic innervation is supplied by the vagus and pelvic nerves. The vagus innervates the upper GI tract, and the pelvic nerve innervates the lower GI tract. Parasympathetic neurons have long preganglionic fibers that synapse in ganglia in or near the target organs. Postganglionic neurons of the parasympathetic nervous system are classified as either cholinergic or peptidergic. Cholinergic neurons release acetylcholine (ACh) as the neurotransmitter, whereas peptidergic neurons release one or more enteric neuropeptides, including substance P (SP), vasoactive intestinal peptide (VIP), neuropeptide Y (NPY), and gastrin-releasing peptide (GRP). The vagus nerve is a mixed nerve in which 75% of the fibers are afferent and 25% are efferent. Afferent fibers transmit sensory information from mechanoreceptors and chemoreceptors in the wall of the GI tract to the central nervous system (CNS). Efferent fibers deliver motor information from the CNS back to cells in the periphery, for example, smooth muscle, secretory, and endocrine cells. Thus, mechanoreceptors and chemoreceptors in the GI mucosa

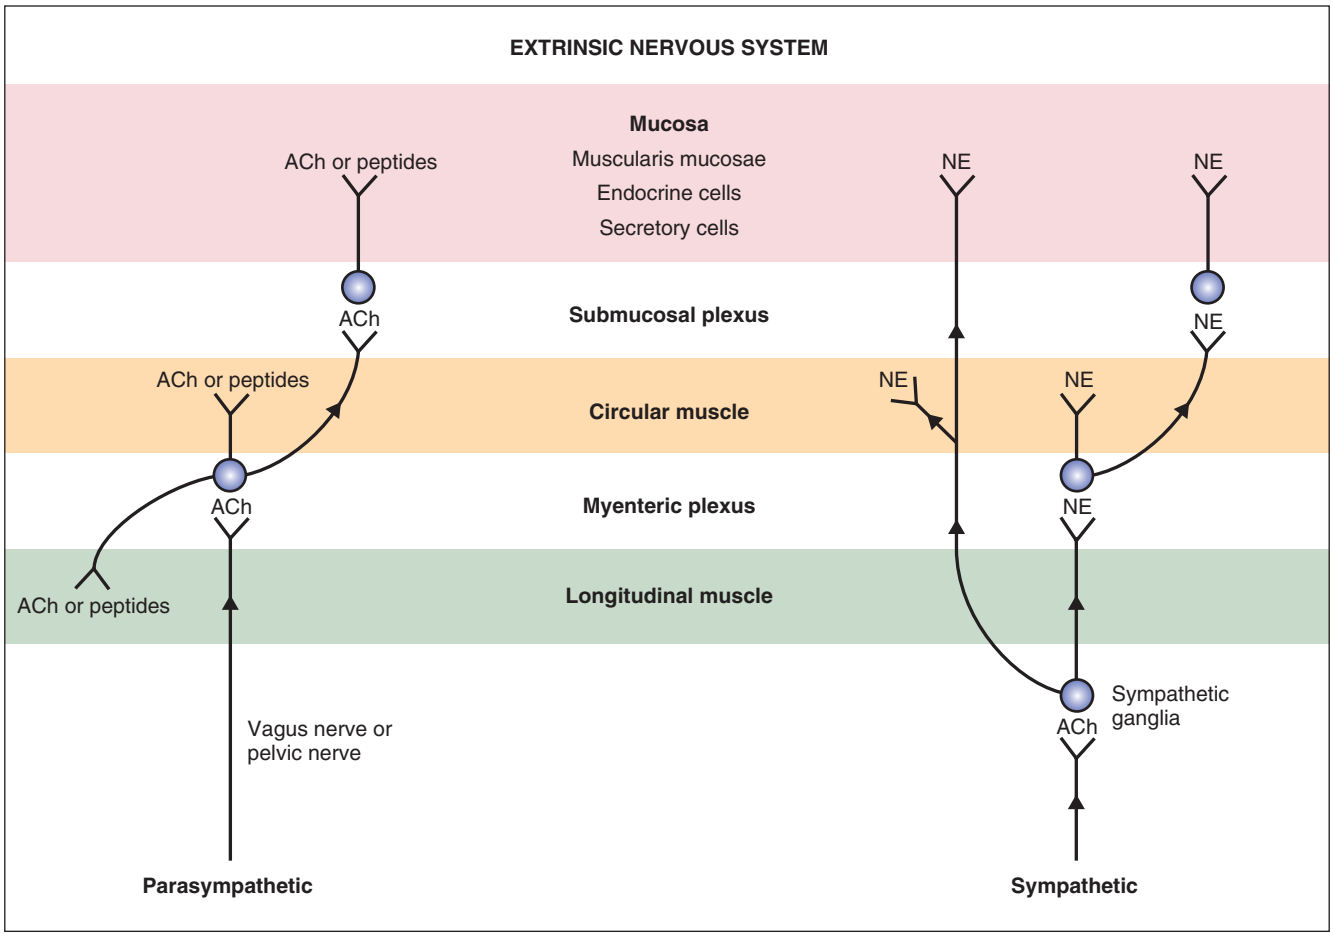

Figure 1-4 Extrinsic nervous system of the gastrointestinal tract. ACh, acetylcholine; NE, norepinephrine. (From Costanzo L [ed]: *Physiology*, 4th ed. Philadelphia: Saunders, 2010.)

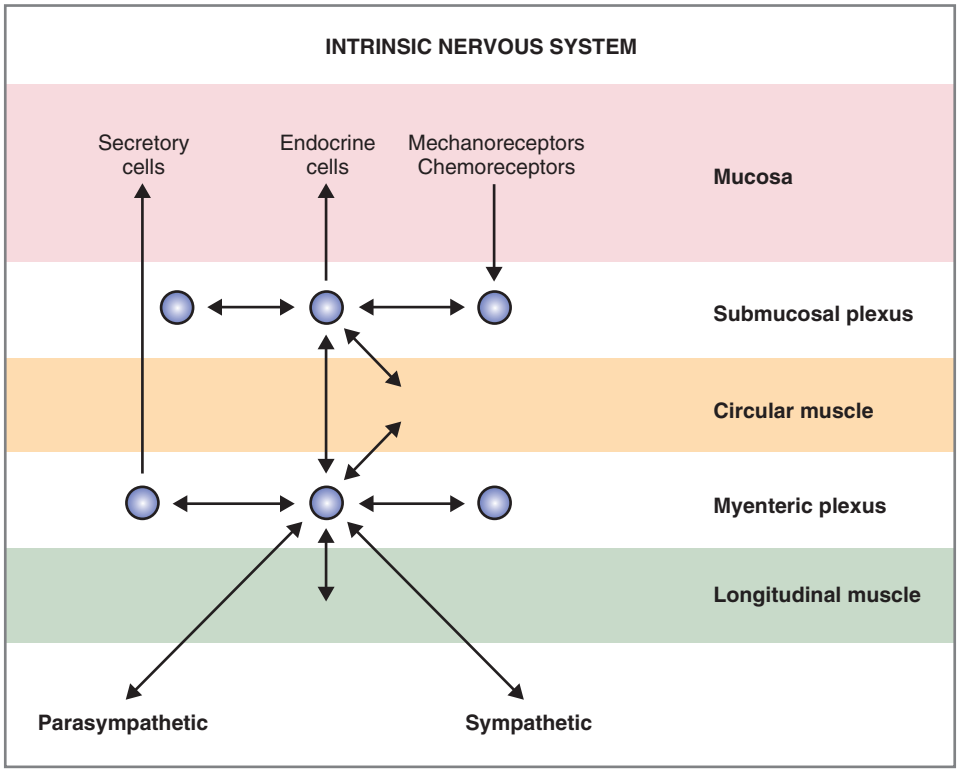

Figure 1-5 Intrinsic nervous system of the gastrointestinal tract. (From Costanzo L (ed): *Physiology*, 4th ed. Philadelphia: Saunders, 2010.)

relay afferent information to the CNS via the vagus nerve, which triggers reflexes whose efferent limb is also in the vagus nerve.

Sympathetic Innervation

Sympathetic innervation is supplied by spinal segments T1 to L3 of the thoracolumbar spinal cord. As part of the "fight-versus-flight" response, the sympathetic nerves innervate the heart, blood vessels, bronchi, and GI tract. Sympathetic neurons have short preganglionic fibers that synapse at ganglia (celiac, superior mesenteric, inferior mesenteric, and hypogastric) outside the GI tract. Postganglionic neurons of the sympathetic nervous system are adrenergic and release norepinephrine as the neurotransmitter. Approximately 50% of the sympathetic nerve fibers are afferent and 50% are efferent. As with parasympathetic innervation, sensory and motor information is relayed between the GI tract and the CNS, and is coordinated by the submucosal and myenteric plexuses.

Intrinsic Innervation

The ganglia of the enteric nervous system are located in the submucosal and myenteric plexuses, and control the contractile, secretory, and endocrine functions of the gut.[15,16] Enteric ganglia receive inputs from the parasympathetic and sympathetic nervous systems, which serve to modulate their activity. Enteric neurons are cholinergic, adrenergic, and/or peptidergic, and may secrete one or more neurotransmitters (Fig. 1-5).

Gastrointestinal Smooth Muscle

Significant structural and functional differences exist between skeletal and smooth muscle, from innervation and gap junctions to sarcomeric organization, nuclear density, spread of depolarization, regulatory proteins, sources of calcium, contractile patterns, slow waves, and bioenergetics (Tables 1-1 and 1-2).[17]

Table 1-1 Structural Differences Between Striated and Smooth Muscles

Feature	Skeletal Muscle	Smooth Muscle
Innervation	Somatic	Autonomic
Nerve density	Each cell	Sparse (unitary)
Appearance	Striations	Nonstriated (smooth)
Nuclei	Multinucleated	Single nuclei
Depolarization	T tubules	Caveolae
Gap junctions	None	Many (unitary)
Thin filaments	Troponin	Calmodulin
Ca^{2+} source	Ca_i^{2+}	Ca_i^{2+}, Ca_o^{2+}

Table 1-2 Bioenergetic Differences Between Striated and Smooth Muscles

Parameter	Skeletal Muscle (Frog Sartorius)	Smooth Muscle (Hog Carotid Artery)
Stress	250 mN/mm^2	223 mN/mm^2
$T_{1/2}$ P_{max}	0.2 sec	70.0 sec
Velocity	1.9 L_o/sec	0.12 L_o/sec
J_{ATP}	50 µmol/g/min	1.2 µmol/g/min
Economy	930 µmol ATP/min/g/mN/mm^2	6.0 µmol ATP/min/g/mN/mm^2

ATP, adenosine triphosphate; JATP, joules of ATP consumed. L_o/sec, optimal muscle lengths per second; $T_{1/2}$ P_{max}, time to reach half-maximal contraction.

Innervation and Gap Junctions

Skeletal muscle contraction is voluntary and under the regulation of the somatic nervous system. Each skeletal muscle cell is innervated by a motoneuron, and each muscle fiber behaves as a single unit. Smooth muscle, on the other hand, is involuntary and under the regulation of the autonomic nervous system. GI smooth muscles are only sparsely innervated (referred to as unitary smooth muscle), and it is instead the gap junctions that permit the rapid spread of electrical activity from cell to cell followed by coordinated contraction. The multiunit smooth muscles of the iris and vas deferens have fewer gap junctions and little or no coupling between cells, and therefore are more dependent upon neural activation.

Sarcomeric Organization

Smooth muscle lacks striations because the thick and thin filaments are not organized into sarcomeres as they are in skeletal or cardiac muscle.

Nuclear Density

During embryonic development, skeletal muscle fibers develop through the fusion of myoblasts into multinucleated skeletal muscle cells. Nuclei are usually found at the periphery of the muscle fiber and the contractile proteins (e.g., myosin, active, troponin) are located more centrally in the fiber. Smooth muscle cells typically are uninucleate.

Spread of Depolarization

The rapid spread of depolarization of striated muscle is facilitated by an extensive transverse T-tubule system coupled to the sarcoplasmic reticulum. Smooth muscles are devoid of the T-tubule system and instead rely on a system of subplasmalemmal caveolae representing invaginations of the cell membrane. Caveolae link extracellular stimuli with intracellular effectors in smooth muscle cells. Caveolae, and their integral caveolin proteins, are believed to be the smooth muscle equivalent of the T-tubule system of striated muscle.

Regulatory Proteins

Contraction of striated muscle is a *thin*-filament regulated process. Ca^{2+} binds to troponin C, one of the thin filament proteins, producing a conformational change in the troponin–tropomyosin complex. The conformational change permits binding of actin to the myosin heads, activation of myosin adenosine triphosphatase (ATPase), and cross-bridge cycling. Contraction of smooth muscle is instead a *thick*-filament regulated process. Troponin C is not expressed in smooth muscle, and Ca^{2+} instead binds to the calcium-binding protein, calmodulin. In turn Ca^{2+}–calmodulin activates myosin light-chain kinase, permitting phosphorylation of the 20-kDa myosin light chains, activation of myosin ATPase, and cross-bridge cycling (Fig. 1-6).[18]

Sources of Calcium

Striated muscle cells derive calcium solely from internal stores, specifically the sarcoplasmic reticulum. Depolarization of the T-tubule system causes a conformational change in its voltage-sensitive dihydropyridine receptor, which, in turn, causes opening of the Ca^{2+}-release channel in the adjacent sarcoplasmic reticulum. Many GI smooth muscles have a similar dependence on sarcoplasmic reticulum Ca^{2+} release, but most smooth muscles also have a major (or minor) dependence on influx of extracellular Ca^{2+} through voltage-gated, ligand-gated, and inositol triphosphate (IP_3)-gated Ca^{2+} channels (Fig. 1-7).

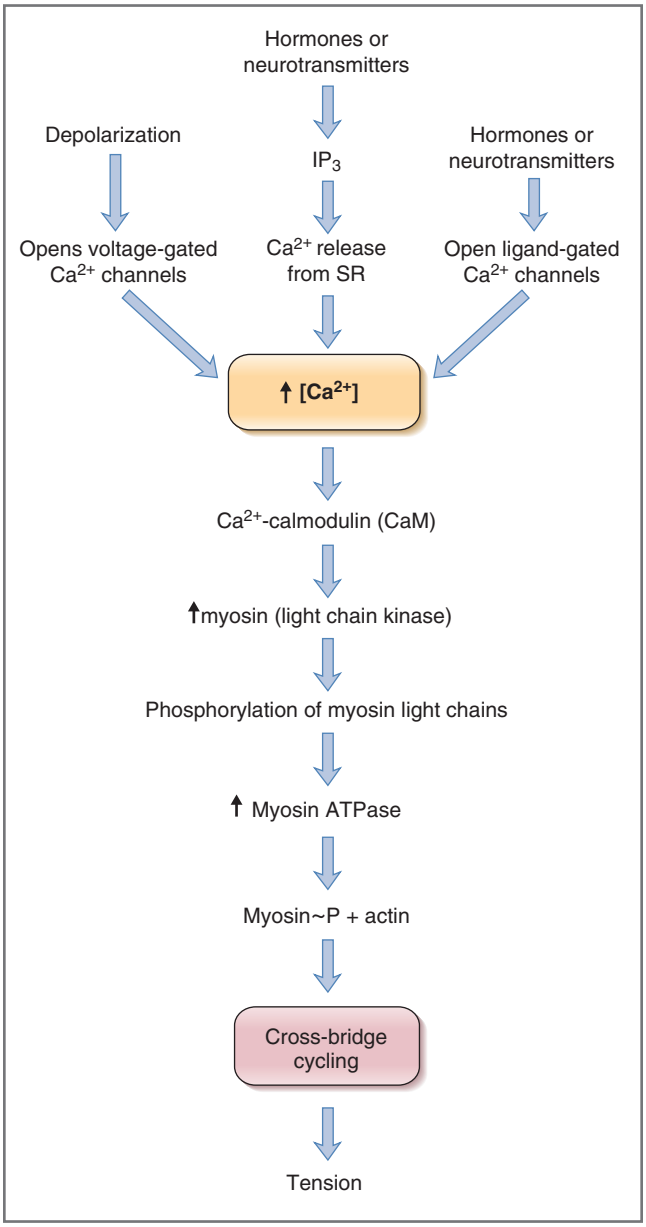

Figure 1-6 Biochemical activation of smooth muscle contraction. (From Costanzo L (ed): *Physiology*, 4th ed. Philadelphia: Saunders, 2010.)

Contractile Patterns

Length–tension and force–velocity relationships are apparent in both striated and smooth muscles, although some differences have been noted. Tetanic or tonic contractions are physiologically possible in striated muscle, but most striated muscle contractions are of the twitch or phasic type. Contractions of GI smooth muscle can be either phasic or tonic. Phasic contractions are periodic contractions followed by relaxation. Phasic contractions are often propagating and are found in the esophageal body, gastric antrum, small intestine, and colon. Tonic contractions maintain a constant level of contraction or tone with only intermittent periods of relaxation. They are found in the gastric fundus and in the gastroesophageal, pyloric, ileocolic, and internal anal sphincters.

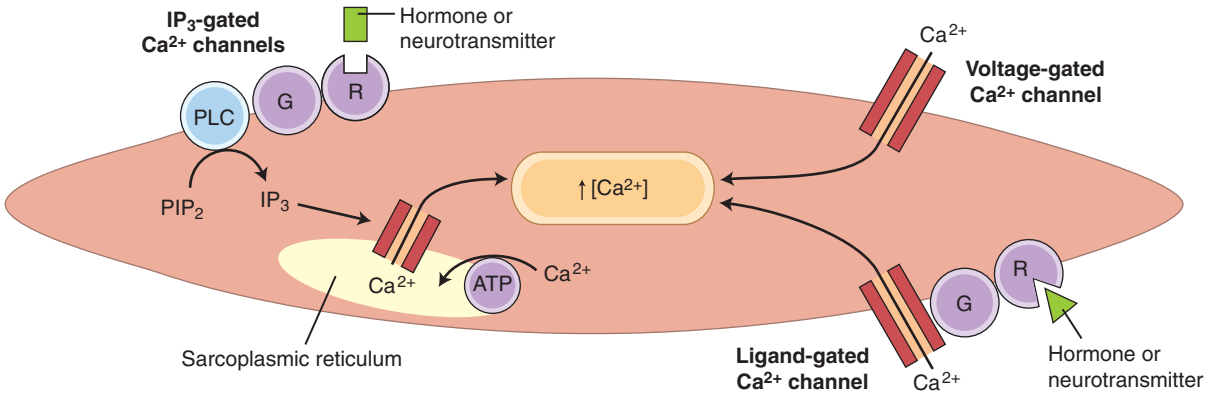

Figure 1-7 Dependence of gastrointestinal smooth muscle contraction upon extracellular and intracellular sources of Ca^{2+}. ATP, adenosine triphosphate; Ca, calcium; G, G protein; IP_3, inositol tris-phosphate; PIP_2, phosphatidyl inositol bisphosphate; PLC, phospholipase C; R, receptor. (From Costanzo L (ed): *Physiology*, 4th ed. Philadelphia: Saunders, 2010.)

Slow Waves

Action potentials in smooth muscle are triggered by oscillating depolarization and repolarization waves referred to as "slow waves."[19] Slow waves are a unique feature of the electrical activity of GI smooth muscle. The origin of the slow waves is still unsettled,[20] but it has been proposed that slow waves originate in the interstitial cells of Cajal (ICC) in the myenteric plexus.[19] Cyclic depolarizations and repolarizations of the ICC are postulated to rapidly spread to adjacent smooth muscle via low-resistance gap junctions. In this way the ICC could serve as "pacemakers" and set the slow wave frequency (from 3 to 12 slow waves per minute) along the GI tract. When slow waves depolarize the membrane potential to threshold, action potentials are superimposed on top of the slow waves giving rise to strong contractions.[19]

Bioenergetics

Smooth muscles contract much slower (P_{max} $t_{1/2}$ = 70 sec; shortening velocity = 0.12 Ls/sec) than striated muscle, but they nonetheless achieve the same overall force production (Ss = 223 mN/mm^2; see Table 1-2). Smooth muscles can develop and maintain this force at surprisingly low adenosine triphosphate (ATP) consumption (J_{ATP} = 1.2 μmol/g/min). Consequently smooth muscle contraction is more economical from a bioenergetics standpoint. It is this property (high-force output at low ATP consumption) that permits some smooth muscles, notably the GI tract sphincters, to maintain tone for prolonged periods of time.

Motility

Oropharynx and Esophagus

In the oropharyngeal phase of swallowing, the animal prehends food and water with teeth and tongue, masticates and mechanically reduces the size of the food particles, forms a bolus at the base of the tongue, and propels the bolus caudally to the cricoesophageal sphincter. The sphincter relaxes and the bolus passes into the cranial esophageal body. Oropharyngeal mechanoreceptors transmit mechanical forces through an afferent neural pathway to the brainstem and efferent neural pathway to induce cricopharyngeal relaxation, esophageal body contraction, and primary esophageal peristalsis. Following swallowing, the cricopharyngeus contracts, pharyngeal muscles relax, and the oropharyngeal phase is repeated until feeding is completed (Fig. 1-8).

Aside from fluid and electrolyte secretion, the major physiologic function of the esophagus is the transport of ingested liquids and solids from the oral cavity to the stomach. Anatomic structures that permit this function are the striated muscle of the cranial esophageal sphincter (cricopharyngeus), the striated and smooth muscle of the esophageal body, and the smooth muscle of the caudal esophageal (gastroesophageal) sphincter. An important species difference between the dog and cat is in the musculature of the esophageal body. The full length of the canine esophageal body is composed of striated muscle, whereas the distal one-third to one-half of the feline esophageal body is composed of smooth muscle. The striated muscle of the cranial esophageal sphincter and esophageal body are innervated by somatic branches (glossopharyngeal, pharyngeal, and recurrent laryngeal) of the vagus nerve arising from the brainstem nucleus ambiguus. The smooth muscle of the esophageal body and caudal esophageal sphincter are innervated by autonomic branches (esophageal) of the vagus nerve arising from the dorsal motor nucleus of the vagus.[21,22]

Primary peristaltic contractions associated with swallowing are reinforced by a secondary wave of contraction (secondary peristalsis) mediated physiologically by esophageal intraluminal distention. The gastroesophageal sphincter relaxes in advance of the propagated pressure wave to permit food to empty into the stomach. Once the bolus of food has passed into the stomach, the gastroesophageal sphincter resumes its high resting pressure.[23,24]

Stomach

Anatomically, the stomach is composed of five distinct components: cardia, fundus, corpus, antrum, and pylorus. Physiologically, the stomach behaves as a two-component structure: a proximal stomach (cardia, fundus, first one-third of the corpus) characterized by slow tonic contractions, and a distal stomach (distal two-thirds of the corpus and antrum) characterized by phasic propagating contractions (Fig. 1-9).[25] Slow waves without action potentials give rise to the sustained tonic contractions of the proximal stomach. During swallowing, gastroesophageal sphincter and intragastric pressure decrease to accommodate emptying of solids and liquids. This phenomenon, referred to as *receptive relaxation*, takes place with each swallow, and as a consequence, large volumes can be accommodated with minimal increases in intragastric pressure. The proximal stomach becomes much less compliant with fundic disease or fundectomy.

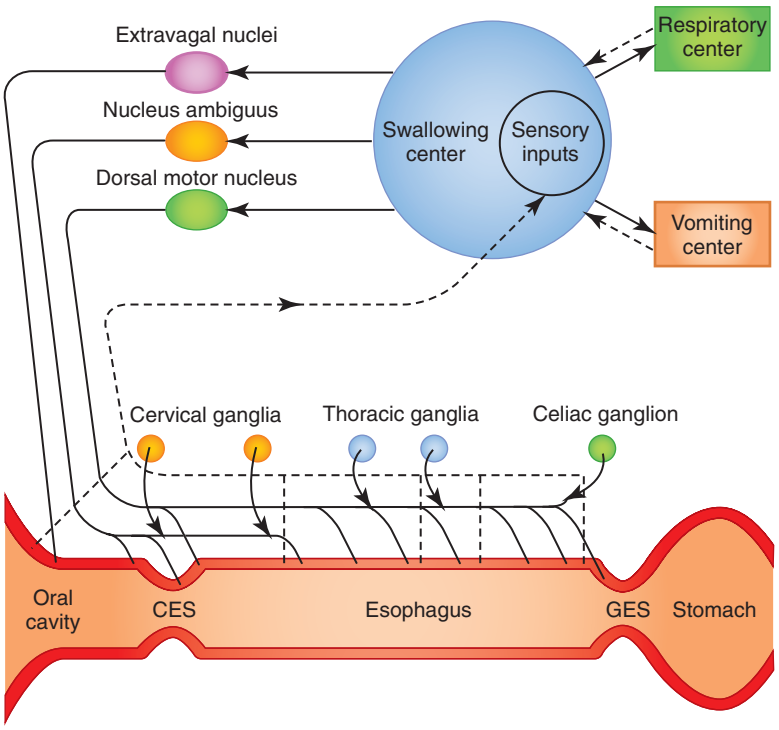

Figure 1-8 Regulation of oropharyngeal and esophageal motility. CES, Cricoesophageal sphincter; GES, gastroesophageal sphincter.

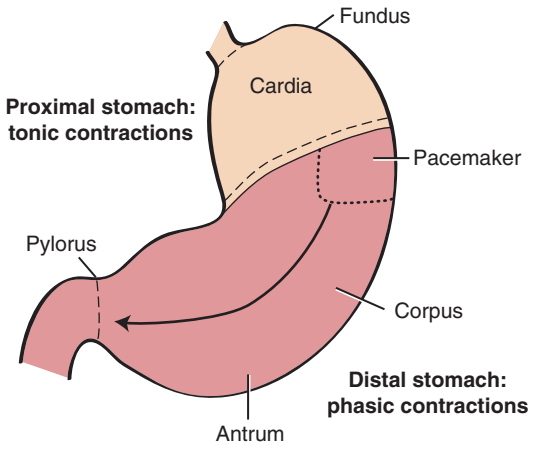

Figure 1-9 Tonic and phasic contractions in the regulation of gastric emptying.

A pacemaker site in the proximal fundus of the greater curvature generates action potentials and phasic contractions that propagate from the site of origin circumferentially and distally to the pylorus.[26] During feeding, phasic contractions of the distal stomach trigger a repetitive cycle of propulsion, trituration, and retropulsion that progressively reduces the size of the ingesta. Thus, the peristaltic qualities of the distal stomach regulate the emptying of solid particles into the duodenum. Antral disease or antrectomy abolishes this physiologic effect resulting in a "dumping syndrome" as a result of accelerated gastric emptying, nutrient overload in the small intestine, and osmotic diarrhea.

Gastric emptying is regulated by several physiologic parameters, including (a) pyloric resistance and pressure differential between the stomach and duodenum; (b) water content—liquids are emptied more rapidly than solids; (c) nutrient composition—carbohydrates are emptied more rapidly than proteins which, in turn, are emptied more rapidly than lipids; (d) nutrient acidity—delayed at acid or alkaline pH; (e) nutrient osmolality—delayed at high osmolality; and (f) hot or cold temperatures. Duodenal, jejunal, and ileal braking mechanisms also feedback inhibit gastric emptying through activation of mucosal sensory receptors for fatty acids, tryptophan, osmolality, and acid. Intestinal braking mechanisms serve to prolong transit time and nutrient contact time.[25]

During the fasting state the stomach is ordinarily empty, aside from swallowed saliva, a small amount of mucus, and cellular debris that collects in the gastric lumen. In addition, there may be particles of indigestible solids left from the previous meal. A mechanism exists to empty this fasting content: the migrating motility complex (MMC). The ability of the MMC to completely empty the stomach of residue is so striking that it is sometimes referred to as the "interdigestive housekeeper" of the GI tract.[25] The GI hormone, motilin, is involved in the regulation of the MMC. Cats and rabbits do not have an MMC, but instead have a less vigorous emptying pattern known as the migrating spike complex (MSC).[27,28]

Intestine

Contractions in the small intestine serve three general functions: mixing of the ingesta with digestive enzymes and other secretions; circulation of the intestinal contents to facilitate contact with the intestinal mucosa; and net caudal propulsion of the intestinal contents. Intestinal contractions are governed by four motility patterns: segmentation, peristalsis, intestinointestinal inhibition, and the MMC.[29]

Segmentation

If a contraction is not coordinated with activity above and below, intestinal contents are displaced both proximally and distally during the contraction and may, in fact, move cranially during the period of relaxation. Such contractions appear to divide the bowel into segments, which accounts for the term *segmentation* given to the

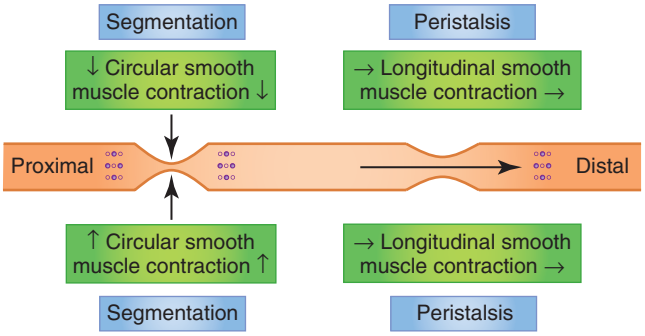

Figure 1-10 Segmentation and peristalsis patterns of the small intestine.

process. Segmentation serves to mix and locally circulate the intestinal contents. Segmentation primarily involves circular smooth muscle contraction (Fig. 1-10).

Peristalsis

The small intestine is also capable of eliciting a highly coordinated contractile response that is propulsive in nature. When the bowel is distended by a bolus of food there is contraction cranial to and relaxation caudal to the point of distention. The neurotransmitters involved in the cranial contraction are ACh and SP, and the neurotransmitters involved in the caudal relaxation are VIP and nitric oxide (NO). These events tend to move the material caudally. Short-segment peristalsis of the bowel is the norm in dogs and cats (Fig. 1-10). If short-segment peristalsis occurs sequentially, it can propel a bolus the entire length of the gut in a short period of time. This peristaltic response, first characterized by Bayliss and Starling, is referred to as the *law of the intestine*, and is less frequent than short-segment peristalsis.

Intestinointestinal Inhibition

If an area of the bowel is grossly distended, contractile activity in the rest of the bowel is inhibited. This reflex prevents the movement of ingesta into more distal segments of intestine that have been severely distended or obstructed. This reflex is mediated by the extrinsic (autonomic) nervous system.[30]

Migrating Motility Complex

The MMC moves indigestible materials, mucus, and secretions from the stomach to the colon during the fasting state. The enteric nervous system regulates the periodicity and migration of the MMC, and the gastrointestinal hormone motilin reinforces MMC activity.

Colon

The colon serves two important functions: (a) extraction of water and electrolytes from the luminal contents in the ascending and transverse colon and (b) storage of feces and control of defecation in the descending colon.[31] This specialization of function has been attributed to regional differences in colonic motility patterns. Electrical slow-wave frequency and rhythmic phasic contractions are slower in the proximal colon (cecum and ascending colon), thus facilitating extraction of water from the fecal mass by diffusion and active transport. Retrograde giant contractions and anti-peristalsis further facilitate mixing of contents in the proximal colon. In contrast, motility of the distal colon (transverse and descending colon) is characterized primarily by migrating spike bursts and powerful giant migrating contractions that propagate the fecal mass toward the rectum (Fig. 1-11).[31,32]

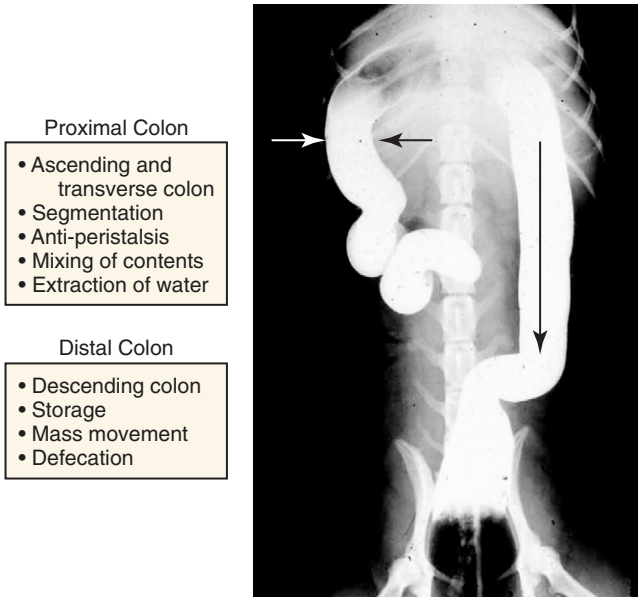

Figure 1-11 Motility patterns of the proximal and distal colon.

Segmentation

These types of contractions occur in both the proximal and distal colon. In the proximal colon, segmentation-type contractions serve to move the contents back and forth, mixing and exposing them to the mucosa for absorption of water and electrolytes. In the distal colon, segmentation activity serves to offer resistance and thus retard the flow of contents from more proximal regions into the rectum.

Mass Movement

Most colonic propulsion takes place during a characteristic sequence termed the *mass movement*. Segmental activity is inhibited and the colon undergoes a contraction that sweeps intraluminal contents caudally. Following mass movements, segmentations and phasic contractions return to the colon.

Defecation

Fecal accumulation in the anorectal canal stimulates smooth muscle contraction of the rectal wall and reflex inhibition of the internal anal sphincter (rectosphincteric reflex). Defecation does not occur immediately because the external anal sphincter, which is composed of striated muscle and therefore under voluntary control, is still tonically contracted. If environmental conditions are not appropriate for defecation, voluntary contractions of the external anal sphincter can overcome the reflex. Relaxation of the internal sphincter is transient because the receptors within the rectal wall accommodate the stimulus of distention. The internal anal sphincter regains its tone, and the sensation subsides until the passage of more contents into the rectum. If the rectosphincteric reflex is elicited at a time when evacuation is appropriate, defecation will occur.

Gastrocolic Reflex

Distention of the stomach by food increases the motility of the colon and increases the frequency of mass movements in the large intestine. This long arc reflex, called the gastrocolic reflex, has its afferent limb in the stomach. The efferent limb of the reflex, which produces increased motility of the colon, is mediated by the hormones cholecystokinin and gastrin.

Gallbladder

During fasting, the gallbladder is relaxed and stores bile. When feeding resumes, hormonal (cholecystokinin) and neural (acetylcholine) mechanisms stimulate simultaneous gallbladder contraction and sphincter of Oddi relaxation, thereby facilitating emptying of bile into the small intestine.[33]

Secretion

Salivary Gland

Dogs and cats both have four sets of salivary glands: parotid, mandibular, sublingual, and zygomatic, all under autonomic regulation. The structural unit of the salivary gland is the salivon, consisting of *acinar cells*, which secrete the initial fluid and mucin; *intercalated ducts*, which form a short connection to the striated ducts; *striated ducts*, which are composed of epithelial cells and which modify the final ionic composition; and *myoepithelial cells*, which contract and serve to expel salivary fluid into the oropharynx (Fig. 1-12).

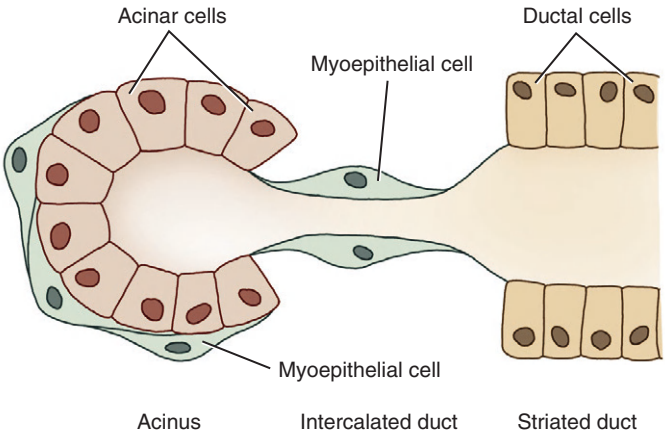

Figure 1-12 The salivon—the anatomic unit of the salivary gland.

Salivary secretions have five major functions: (a) hydration for mastication and deglutition; (b) evaporative cooling; (c) secretion of immunoglobulin (Ig) A; (d) HCO_3^- (bicarbonate) buffering prior to the initiation of digestion; and (e) release of R factor binding proteins for vitamin B_{12} transport.[34,35] Salivary amylase, which initiates starch digestion in man, is not found in dog or cat saliva.[34] Primary secretion from the acinus contains Na^+, Cl^-, and HCO_3^- actively transported from the blood to gland and duct. As saliva is transported down the collecting ducts, it is further modified by exchange of Na^+ for H^+ and K^+ and active reabsorption of Na^+ and Cl^-. At high flow rates, the salivary composition will resemble the primary secretion because there is less time for modification along the ducts (Fig. 1-13).[34]

Stomach

As a secretory organ, the stomach has several major functions, including initiation of protein digestion; inactivation of ingested bacteria, viruses, and parasites; secretion and binding of intrinsic factor to vitamin B_{12}; absorption of ferric iron; hormonal regulation of gastric and pancreatic secretions; mucous lubrication of the gastric contents; and protection of the gastric mucosa from the caustic effects of protons and pepsins.[36] The stomach accomplishes these diverse functions through the secretions of the gastric pit, the structural unit of the gastric mucosa. Gastric pits are branched tubular invaginations bearing multiple cell types and having multiple secretory functions: (a) parietal or oxyntic cells secrete protons and intrinsic factor; (b) chief cells secrete pepsinogens; (c) endocrine cells secrete the hormones gastrin and ghrelin; (d) surface epithelial cells secrete HCO_3^- and prostanoids; (e) neck and surface mucous cells secrete mucus containing sulfated glycoproteins; and (f) enterochromaffin cells secrete histamine (Table 1-3, Fig. 1-14).[36]

Cell Biology of Gastric Acid Secretion

Secretion of hydrochloric acid (HCl) is the major function of the parietal cells. H^+ ion secretion acidifies the gastric contents thereby permitting the conversion of inactive pepsinogens to active pepsins. Parietal cells generate protons through carbonic acid (H_2CO_3) synthesis and dissociation into H^+ and HCO_3^-.[37] Protons are actively

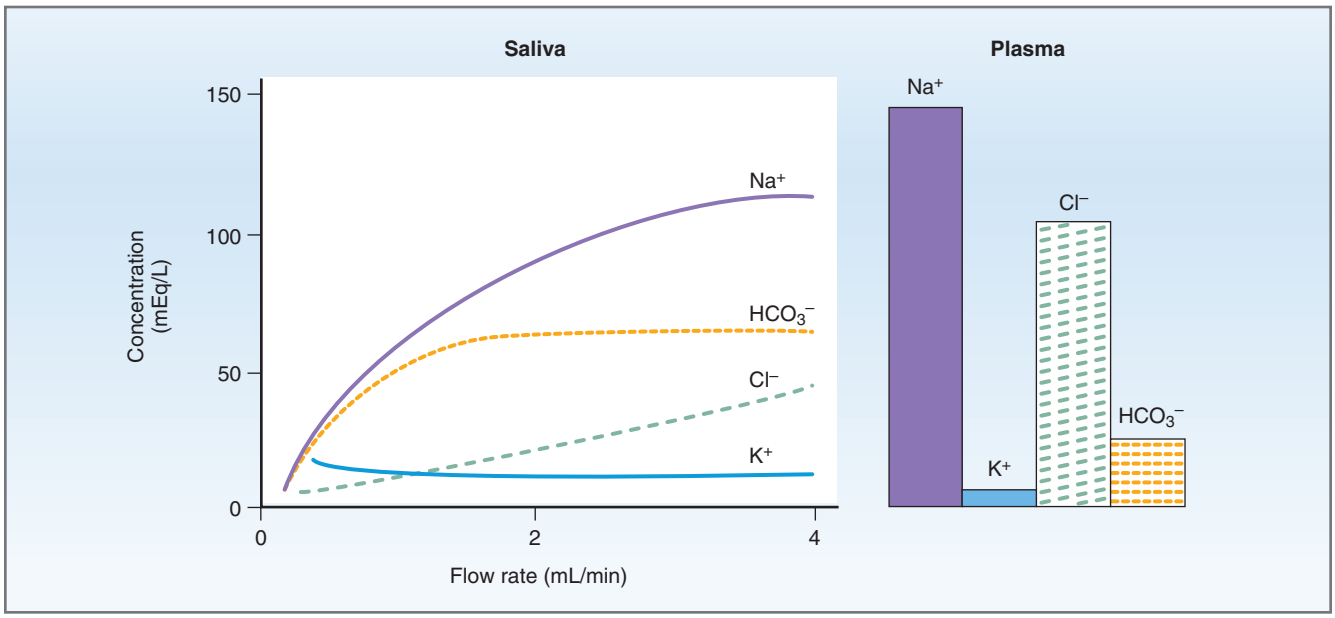

Figure 1-13 Composition of salivary secretion at low and high secretory rates. (From Costanzo L (ed): *Physiology*, 4th ed. Philadelphia: Saunders, 2010.)

Table 1-3 Cell Types, Secretions, and Functions in the Gastric Mucosa

Cell types	Secretion	Function
Parietal (oxyntic) cells	Protons	Activates pepsinogens
	Intrinsic factor	Binds vitamin B_{12}
Chief cells	Pepsinogen	Peptide bond hydrolysis
Mucous cells	Sulfated glycoproteins	Unstirred layer
	Pepsinogen	Peptide bond hydrolysis
Endocrine cells	Gastrin	Stimulates H^+ secretion
	Ghrelin	Stimulates feeding
Enterochromaffin cells	Histamine	Stimulates H^+ secretion
Epithelial cells	HCO_3^-	Neutralizes H^+
	Prostanoids	Gastric mucosal barrier

secreted at the apical membrane along with Cl^- into the lumen of the stomach in exchange for K^+. An apical membrane H^+,K^+-ATPase actively transports H^+ and K^+ against their electrochemical gradients.[37] HCO_3^- is absorbed from the parietal cell into the blood via a Cl^-–HCO_3^- exchanger at the basolateral membrane. The absorbed HCO_3^- is responsible for the alkaline tide that is observed postfeeding. Eventually, this HCO_3^- will be resecreted into the GI tract in pancreatic and biliary secretions.

Physiology of Gastric Acid Secretion

The basal, cephalic, gastric, and intestinal phases of gastric acid secretion[36] were first characterized by Pavlov in his now-classic work on conditioned reflexes in the dog at the turn of the last century. *Basal* phase secretion is that small amount of gastric acid secretion that takes place in the absence of anticipation or physiologic stimulus. Along with the MMC, basal acid secretion serves to moderate bacterial flora and to degrade indigestible solids in the interdigestive state. The *cephalic* phase of gastric acid secretion results from olfactory, visual, and auditory cues, as well as from the mastication and swallowing of food. The cephalic phase accounts for 20% to 30% of the total acid secretory load and is mediated by vagal postganglionic neurons that stimulate parietal secretion directly or indirectly via gastrin release. The *gastric* phase accounts for 50% to 60% of the total acid secretory load and is mediated by the direct and indirect effects of gastric distention and amino acids on parietal and antral G cells (Fig. 1-15). The *intestinal* phase accounts for up to 10% of gastric acid secretion and is mediated by the effects of intraduodenal amino acids.

Pharmacology of Gastric Acid Secretion

Parietal cells are stimulated directly and indirectly by neural (acetylcholine), endocrine (gastrin), and paracrine (histamine) mechanisms.[36] In a neural mechanism, depolarization of vagal postganglionic nerve fibers releases ACh which then binds to the muscarinic M_3 receptor on parietal cells. Binding of ACh to the M_3 receptor activates the phospholipase C, IP_3, and diacylglycerol (DAG) signal transduction pathway whose final pathway is the apical H^+,K^+-ATPase (Fig. 1-16). In a concurrent paracrine mechanism, enterochromaffin cells release histamine into the extracellular space where it binds to a histamine H_2 receptor on parietal cells. Binding of histamine to the H_2 receptor activates the adenylate cyclase, cyclic adenosine monophosphate (cAMP), protein kinase A signal transduction pathway, leading to activation of the final common pathway—the apical H^+,K^+-ATPase. Coincident with the neural and paracrine effects, gastrin is released from antral G cells in response to ACh, gastrin-releasing peptide, and amino acids. Gastrin circulates as a GI hormone having a primary effect of binding gastrin (or CCK_B) receptors on gastric parietal cells. Like ACh, gastrin stimulates parietal cell H^+ secretion through the IP_3/DAG/Ca^{2+} second messenger system. Inhibition of parietal cell H^+ secretion is mediated primarily via the paracrine effects of somatostatin, prostaglandins, and adenosine. All three paracrines inhibit parietal cell adenylate cyclase and cAMP production. Somatostatin has the additional effect of both inhibiting histamine release from enterochromaffin cells and gastrin release from antral G cells.

Gastric Pepsinogen Secretion

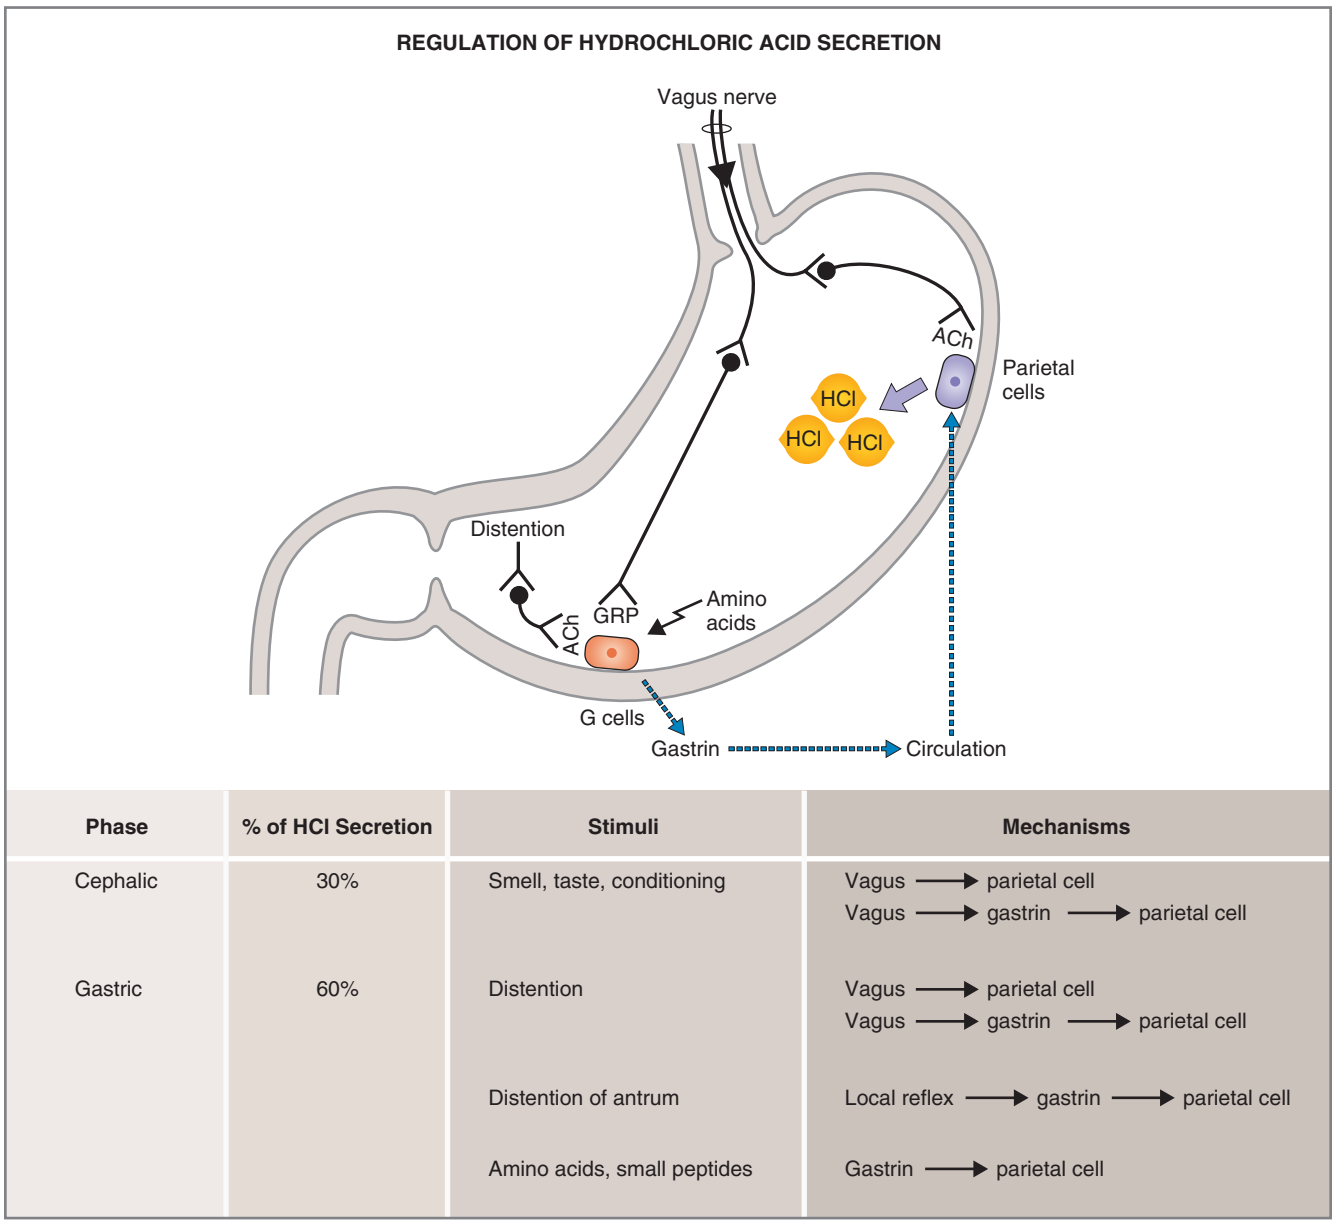
Chief cells and mucous cells secrete pepsinogen during the cephalic and gastric phases of gastric secretion.[38] H^+ ions secreted by the gastric parietal cells facilitate the conversion of inactive pepsinogen to active pepsin. Pepsin is optimally active at a pH of 1 to 2, and denatures at pH >5.0. Pepsin preferentially hydrolyzes peptide bonds containing aromatic amino acids such as phenylalanine, tryptophan, and tyrosine.

Gastric Intrinsic Factor Secretion

Intrinsic factor (IF) is a glycoprotein secreted by gastric parietal cells that serves to bind and transport vitamin B_{12} (cobalamin) to absorptive sites in the distal ileum. IF is produced by parietal cells in the dog, but not in the cat.[39,40] Pancreatic ductal cells are an alternate source of IF synthesis in both species, exclusively so in the cat.[40]

Gastric Mucus Secretion and the Gastric Mucosal Barrier

Sulfated glycoproteins produced by neck and surface epithelial cells are incorporated into the unstirred layer adherent to the gastric mucosa. Mucus serves to trap H^+ ion in this unstirred layer thereby preventing back-diffusion into the mucosa and submucosa. Other factors contributing to this gastric mucosal barrier include epithelial HCO_3^- secretion and acid neutralization, rapid epithelial migration to reconstitute the overlying epithelium, blood flow in the lamina propria to transport and buffer absorbed H^+, and the multiple cytoprotective effects of endogenous prostaglandins.[41]



Phase	% of HCl Secretion	Stimuli	Mechanisms
Cephalic	30%	Smell, taste, conditioning	Vagus → parietal cell Vagus → gastrin → parietal cell
Gastric	60%	Distention	Vagus → parietal cell Vagus → gastrin → parietal cell
		Distention of antrum	Local reflex → gastrin → parietal cell
		Amino acids, small peptides	Gastrin → parietal cell

Endocrine Secretion

In addition to the role of gastrin in gastric acid and pancreatic enzyme secretion, the stomach secretes the hormone ghrelin, a growth hormone (GH)-releasing peptide that stimulates appetite, body growth, and fat deposition. The postprandial gastric expression of ghrelin suggests a GI–hypothalamic–pituitary axis that influences GH secretion, body growth, and appetite that is responsive to nutritional and caloric intakes. Ghrelin and leptin have been characterized as a "yin and yang" system that relays peripheral information to the brain and directs the body in the appropriate maintenance of energy reserves and nutritional intake.

Intestine

Epithelial cells are specialized for membrane brush-border digestion, fluid and electrolyte secretion, and absorption. Motility and blood flow support these processes. The crypt is the germinal center of the intestinal epithelium with stem cells differentiating into crypt and villus epithelia. Crypt epithelial cells are primarily secretory in function—water and electrolytes are secreted into the intestinal lumen to solubilize the chyme and neutralize gastric acid. Villus epithelial cells are primarily absorptive in function—water, solutes, glucose and other monosaccharides, amino acids and small peptides, free fatty acids and glycerol, minerals and vitamins, and other nutrients are absorbed from the lumen into villus epithelial cells. Under normal circumstances, water and electrolytes secreted by the crypt epithelial cells are absorbed by the villus epithelial cells and returned to the plasma volume. In disease states in which adenylate cyclase or calcium gating are maximally activated, fluid secretion by the crypt cells overwhelms the absorptive capacity of the villus epithelium resulting in severe diarrhea and dehydration.

In addition to fluid secretion from the mucosa, the duodenum has the additional function of mucus secretion from prominent

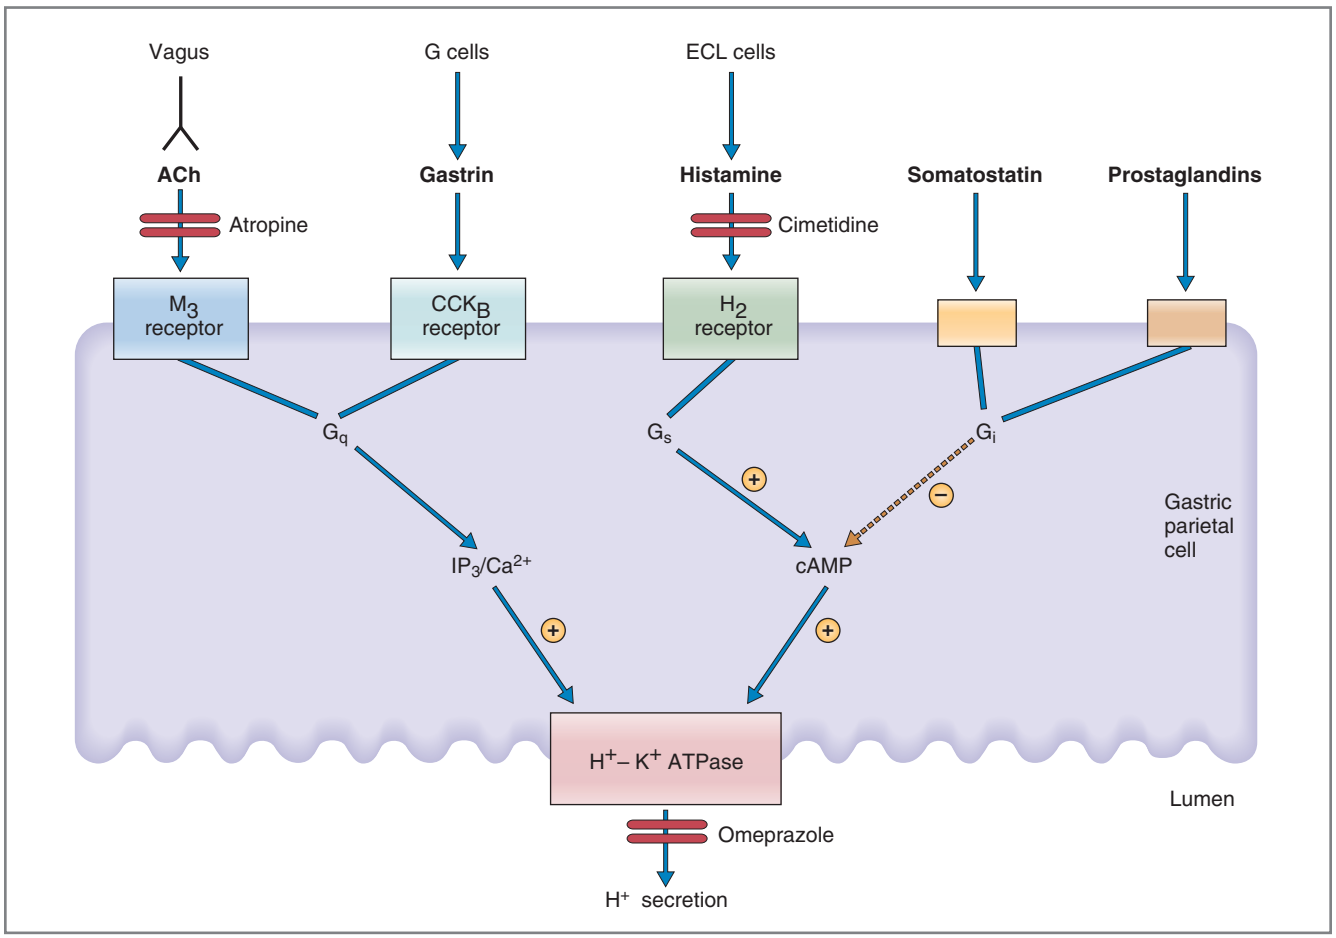

Figure 1-16 Acetylcholine (neurocrine), gastrin (endocrine), and histamine (paracrine) stimulate gastric acid secretion. Prostaglandins (paracrine) and somatostatin (multiple mechanisms) inhibit gastric acid secretion. ACh, acetylcholine; cAMP, cyclic AMP; CCK, cholecystokinin; ECL cells, Enterochromaffin-like cells; G cells, gastrin-producing cells; H, histamine; IP_3, inositol triphosphate; M, muscarinic. (From Costanzo L (ed): *Physiology*, 4th ed. Philadelphia: Saunders, 2010.)

submucosal Brunner's glands.[41] The main function of these glands is to produce a mucus-rich, alkaline secretion to (a) protect the duodenum from the acidic content of the chyme, (b) provide an alkaline environment for the optimal activation of lipase and colipase, (c) lubricate chyme transiting through the GI tract, and (d) trap, inactivate, and regulate intestinal bacteria. Brunner's glands are not found in the jejunal or ileal submucosa.

Chloride is actively secreted from the crypt epithelial cells, followed passively by H_2O, and this secretion is regulated by both branches of the autonomic nervous system (Fig. 1-17). VIP and ACh-containing parasympathetic neurons stimulate fluid secretion from crypt cells. Cholinergic regulation of chloride secretion is coupled to Ca^{2+} second-messenger signaling, whereas VIP regulation is coupled to stimulation of adenylate cyclase, cAMP production, and protein kinase A activation. Norepinephrine-containing sympathetic neurons inhibit fluid secretion from these same cells. Opioid neurons in the enteric nervous system provide an additional level of regulation by innervating crypt epithelial cells and, like sympathetic neurons, serve to inhibit fluid secretion from these cells.[42,43]

Intestinal inflammation is accompanied by crypt epithelial cell hypersecretion. Epithelial cells respond to bacterial infection, for example, by expressing the proinflammatory cytokines TNF-α and interleukin (IL)-1β, chemokines (IL-8), prostanoids, and leukotrienes, some of which activate crypt cells directly. Many enteric infections also involve the enteric nervous system. VIP and ACh secretomotor neurons, for example, are activated indirectly by SP-containing sensory neurons, 5-hydroxytryptamine (5-HT), histamine, and PGI_2 (prostacyclin), leading to excessive crypt fluid secretion and severe diarrhea (Fig. 1-17).[44]

Pancreas

The exocrine pancreas is a secretory organ with several physiologic functions. Exocrine pancreatic fluid contains digestive zymogens, which initiate protein, carbohydrate, and lipid digestion; HCO_3^- and water, which serve to neutralize the duodenum; intrinsic factor, which binds cobalamin (vitamin B_{12}) and facilitates its absorption in the distal ileum; and antibacterial proteins, which regulate the small intestinal bacterial flora.[3,5,39,45] Digestive zymogens and antibacterial proteins are secreted primarily by acinar cells, whereas HCO_3^-, water, and intrinsic factor are secreted primarily by ductal cells.

Pancreatic fluid is an isotonic solution containing Na^+, Cl^-, K^+, and HCO_3^-. The Na^+ and K^+ concentrations are the same as in plasma, but the Cl and HCO_3^- concentrations vary with pancreatic flow rate (Fig. 1-18). The net transport process is one of net HCO_3^- secretion into pancreatic ductal fluid, and net absorption of H^+ causing acidification of pancreatic venous blood. Pancreatic ductal cells secrete HCO_3^- in response to feeding, secretin release, and VIPergic neurotransmission.[46]

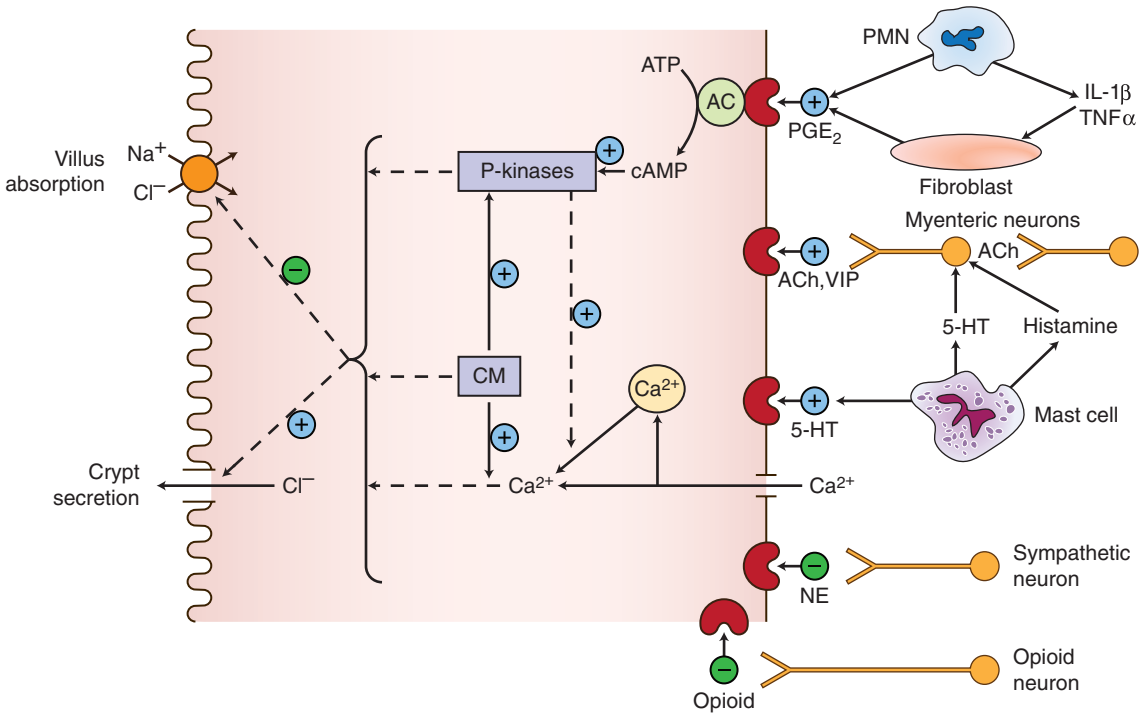

Figure 1-17 Regulation of fluid and electrolyte secretion by crypt epithelial cells, and fluid and electrolyte absorption by villus epithelial cells. 5-HT, 5-hydroxytryptamine; AC, adenylate cyclase; ACh, acetylcholine; ATP, adenosine triphosphate; Ca, calcium; cAMP, cyclic AMP; Cl, chloride; CM, calmodulin; Na, sodium; NE, norepinephrine; P kinases, protein kinases; PGE_2, prostaglandin E_2; PMN, polymorphonuclear leukocyte; VIP, vasoactive intestinal polypeptide.

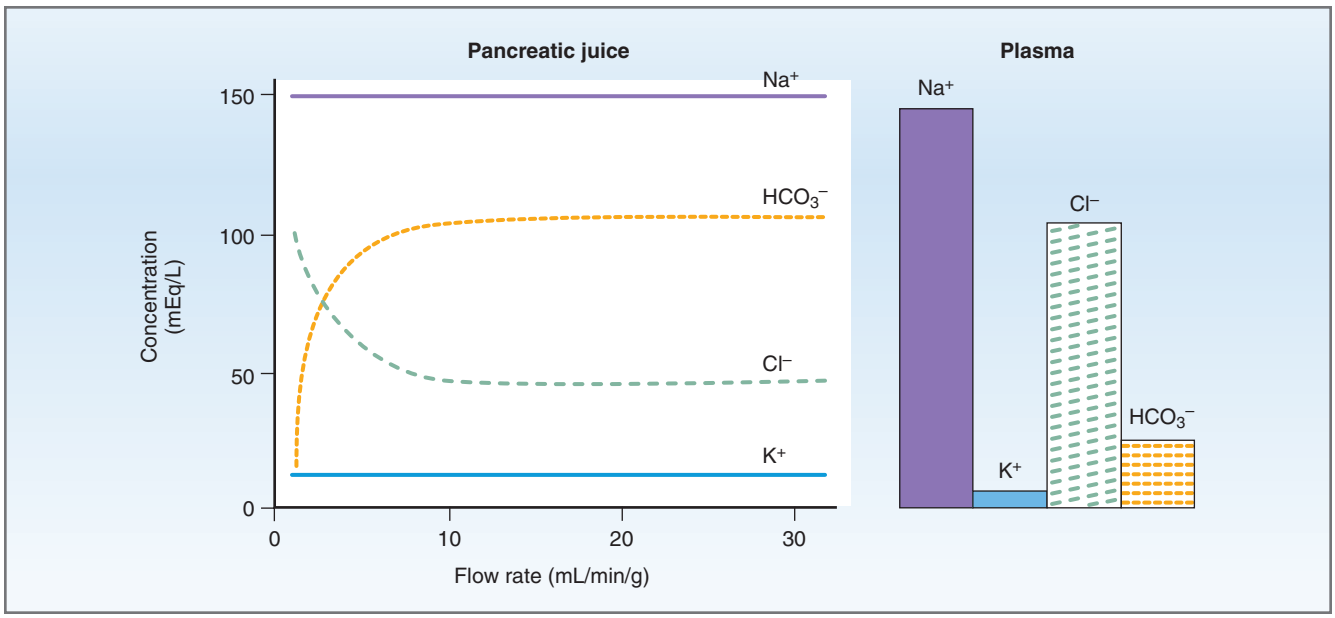

Figure 1-18 Relationship between composition of pancreatic fluid and pancreatic flow rate. (From Costanzo L (ed): *Physiology*, 4th ed. Philadelphia: Saunders, 2010.)

Pancreatic acinar cells secrete inactive zymogens into the pancreatic ductal system in response to feeding, cholecystokinin release, and cholinergic neurotransmission.[45] Pancreatic amylase and lipase are secreted in their active forms, but all other pancreatic enzymes are secreted in inactive zymogen form (e.g., trypsinogen, chymotrypsinogen, procarboxypeptidase, prophospholipase). Intestinal enteropeptidase removes the trypsinogen activation peptide to convert inactive trypsinogen to active trypsinogen, and trypsin acts catalytically to active other pancreatic proteases (Fig. 1-19).

Pancreatic acinar cells protect themselves from intraacinar activation of zymogen and acinar cell necrosis through several mechanisms.[47] (a) Digestive enzymes are synthesized in the form of inactive precursors or zymogens in the rough endoplasmic reticulum. (b) Zymogens are then transported to the Golgi complex where they

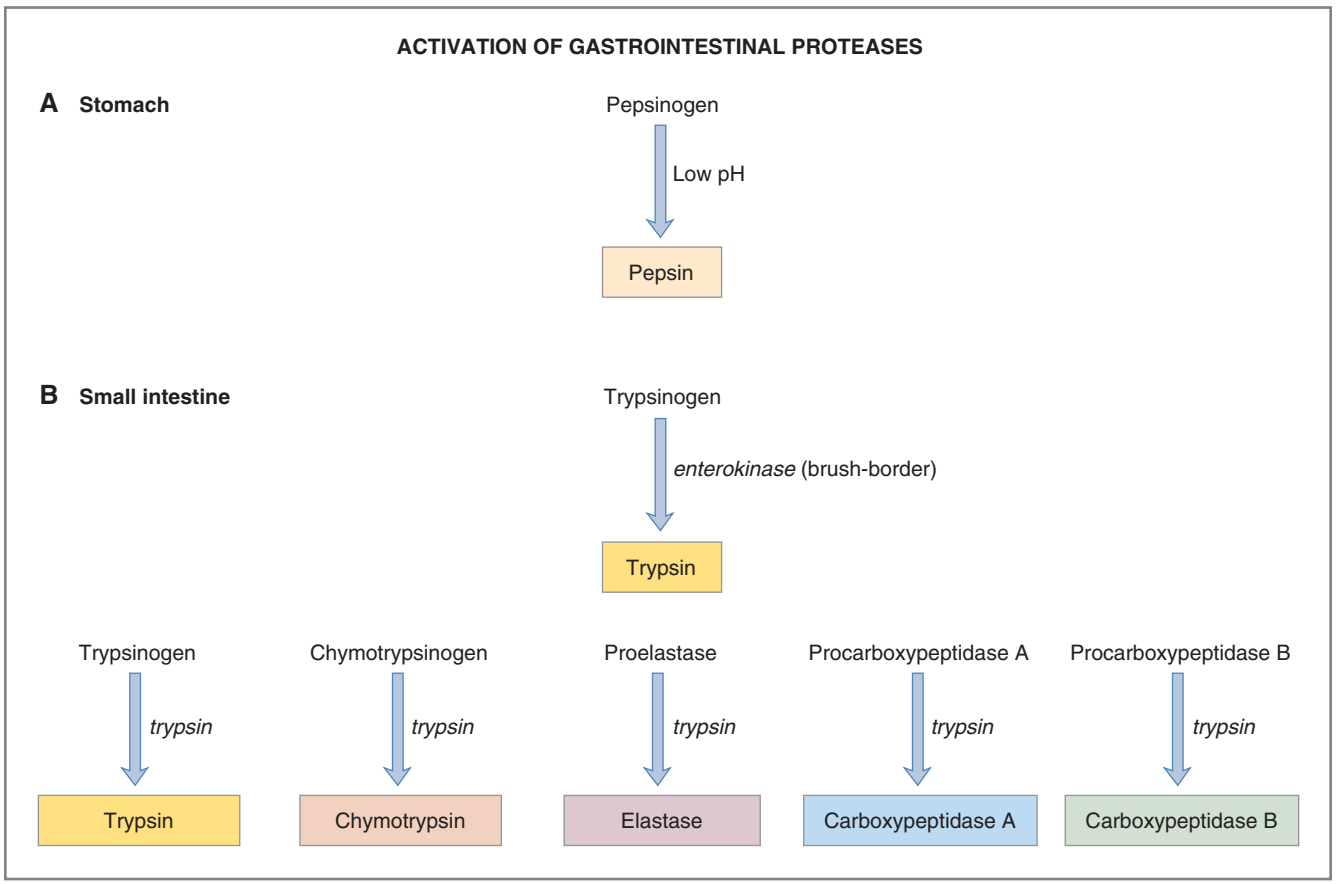

Figure 1-19 Activation of proteases in stomach and small intestine. (From Costanzo L (ed): *Physiology*, 4th ed. Philadelphia: Saunders, 2010.)

undergo selective glycosylation and phosphorylation. Lysosomal hydrolases that are eventually packaged in lysosomes are separated from zymogens bound for export as they pass through the Golgi complex. Lysosomal hydrolases are phosphorylated at the 6 position of mannose residues, bound to receptors specific for 6-phosphoryl mannose, and then transported to lysosomes where the acidic pH favors their dissociation from the receptors. Digestive enzymes lack the 6-phosphoryl mannose label, and are instead transported vectorially into a different secretory fraction. (c) Packaging of zymogens into maturing zymogen granules sequesters them from contact with other subcellular fractions. (d) Pancreatic secretory trypsin inhibitor (PSTI) is incorporated into the maturing zymogen granules. PSTI inactivates trypsin should there be any intra-acinar activation of trypsinogen. (e) Following stimulation (e.g., feeding and cholecystokinin secretion), mature zymogen granules and their contents are released from the cell into the ductal lumen in a process of membrane fusion and exocytosis. (f) Zymogens are activated physiologically only after they enter the duodenum, where the brush-border enzyme enteropeptidase activates trypsinogen, and trypsin then activates other pancreatic zymogens.[45,47]

As with gastric secretion, pancreatic secretion is stimulated during cephalic, gastric, and intestinal phases. During the *cephalic* phase, neural (ACh), endocrine (gastrin), and paracrine (histamine) inputs stimulate parietal cells to secrete H^+ ions, which in turn stimulate secretin release from duodenal endocrine (S) cells. Secretin circulates as a GI hormone, binds to secretin receptors on pancreatic ductal epithelium, and stimulates water and HCO_3^- secretion.[46] The *gastric* phase of pancreatic secretion is mediated by gastric peptides and gastric distention, both of which stimulate gastric H^+ secretion, intestinal secretin release, and secretin-induced pancreatic ductal HCO_3^- secretion. The *intestinal* phase of pancreatic secretion is the most important phase and has both endocrine and neural components. Gastric emptying of amino acids, peptides, and fatty acids stimulate duodenal (I) endocrine cells to release cholecystokinin (CCK). CCK circulates as a GI hormone, binds to CCK receptors on pancreatic acinar cells, and stimulates enzyme secretion.[45] Cholinergic neurotransmission stimulates pancreatic enzyme secretion parallel to the CCK endocrine effect.[45]

Biliary

Biliary secretions provide a source of bile acids for fat digestion and absorption, an excretory route for metabolites and xenobiotics, and additional HCO_3^- for buffering of H^+ ion in the duodenum. Bile acids are the major components of bile accounting for about one-half to two-thirds of the total solutes. Bile also contains water, electrolytes, cholesterol, phospholipids, hormones, protein, and bilirubin.

Bile components are synthesized, stored, and secreted from the hepatocytes into the biliary ductal system.[9] In the absence of neural or hormonal input (as in the fasting state), the gallbladder is relaxed, the terminal biliary ductal sphincter (sphincter of Oddi) is contracted, and bile is largely stored in the gallbladder. While stored in the gallbladder, water and large portions of the electrolytes are reabsorbed by the gallbladder mucosa, and the remaining constituents are thereby concentrated. During feeding, neural (ACh) and hormonal (CCK) mechanisms activate gallbladder contraction, biliary ductal sphincter relaxation, and emptying of bile into the

duodenum. Secretin and bile salts stimulate bile salt–independent and bile salt–dependent bile flow, respectively.[10]

Bile acids are synthesized from the cholesterol nucleus to which are attached a five- or eight-carbon side chain with a terminal carboxylic acid, and hydroxyl groups positioned at the C3, C7, or C12 carbon atom positions. The major primary bile salts are cholic acid and chenodeoxycholic acid in about equal molar quantities. When these primary bile acids are secreted into the lumen of intestine, a portion of each is dehydroxylated by intestinal bacteria to produce the secondary bile acids, deoxycholic acid and lithocholic acid.[8] Prior to secretion, bile acids are conjugated with taurine and/or glycine to form tauro- and glycoconjugated bile salts. Conjugation lowers the pK_a to well below the physiologic range of biliary and intestinal pH, and conjugated bile acids become ionized anions (referred to as bile salts) rather than undissociated bile acids. In the ionized form, they are less likely to be absorbed by the small intestine and so maintain a higher intraluminal concentration appropriate for emulsification, digestion, and absorption of lipids. Dogs and cats conjugate primarily with taurine. Dogs can convert to glycine conjugation if taurine is deficient, but cats cannot. Cats are obligate taurine conjugators, and have an essential dietary taurine requirement.[8]

Bile salts are amphipathic molecules with polar and nonpolar domains imparting two important functions. Bile salts have an initial detergent effect on fat particles in food permitting the breakup of fat globules into smaller sizes. This initial emulsification phase facilitates intraluminal hydrolytic digestion of lipids. Bile salts further assist in the absorption of fatty acids, monoglycerides, cholesterol, and other lipids through the formation of mixed micelles that serve to transfer digested lipids across the unstirred layer of the mucosa.

Following emulsification and micellarization of fat, most of the secreted bile salts are transported along the GI tract to the ileum where they are absorbed by ileal enterocytes and into the portal blood flow via Na^+–bile salt cotransporters.[8]

Colon

Electrolytes

The large intestine regulates the electrolyte and water composition of the feces. There are distinct differences in the mechanisms of electrolyte transport between the ascending and descending colon, but in general the canine and feline colon absorb water, sodium, and chloride while secreting potassium and HCO_3^-.[48] In the colon (but not in the small intestine), aldosterone stimulates synthesis of Na^+ channels, which leads to Na^+ retention and K^+ secretion. Bicarbonate secretion is another important feature of colonic electrolyte function that helps to neutralize acids produced by bacterial fermentation. Chloride–bicarbonate (Cl^-–HCO_3^-) exchange is the primary cellular mechanism responsible for bicarbonate secretion.

Mucus

A lubricant layer of mucus forms a crucial physiologic barrier between the colonic mucosa and the luminal environment. Mucus is a constantly changing mix of secretions and exfoliated epithelial cells, the chief determinants of which are high-molecular-weight glycoproteins or mucins. GI mucins are secreted from goblet cells as they ascend from their origin in the crypts to the colonic epithelium. Mucin secretion is dependent upon the close integration of the cystic fibrosis transmembrane regulator (CFTR), chloride secretion, and granule exocytosis. In addition to their physiologic role as a mucosal barrier, mucins may also have a pathologic role in the metastases of epithelial tumors and enhanced susceptibility to infection.[48]

Digestion

Hydrolysis

Hydrolytic digestion takes place both in the lumen and in the brush-border of the intestinal villus epithelium. Luminal digestion results largely from the effect of gastric (pepsin and lipase) and pancreatic (amylase, protease, and lipase) enzymes. Membrane digestion serves to further reduce the size of dextrins and disaccharides to monosaccharides, and small- and intermediate-size peptides to amino acids.

Carbohydrates

Starch and glycogen are the most important dietary carbohydrates. Luminal starch digestion begins in the stomach with some limited acid hydrolysis and ends in the small intestine with pancreatic amylase digestion. Amylase hydrolysis of starch yields α-limit dextrins, maltotriose, and maltose. Brush-border enzymes (maltase, isomaltase, lactase, sucrase) further hydrolyze these and other dietary sugars to yield monosaccharides. Glucose and galactose are actively absorbed by a Na^+-dependent carrier system, and fructose is transported by means of facilitated diffusion (Fig. 1-20).[49]

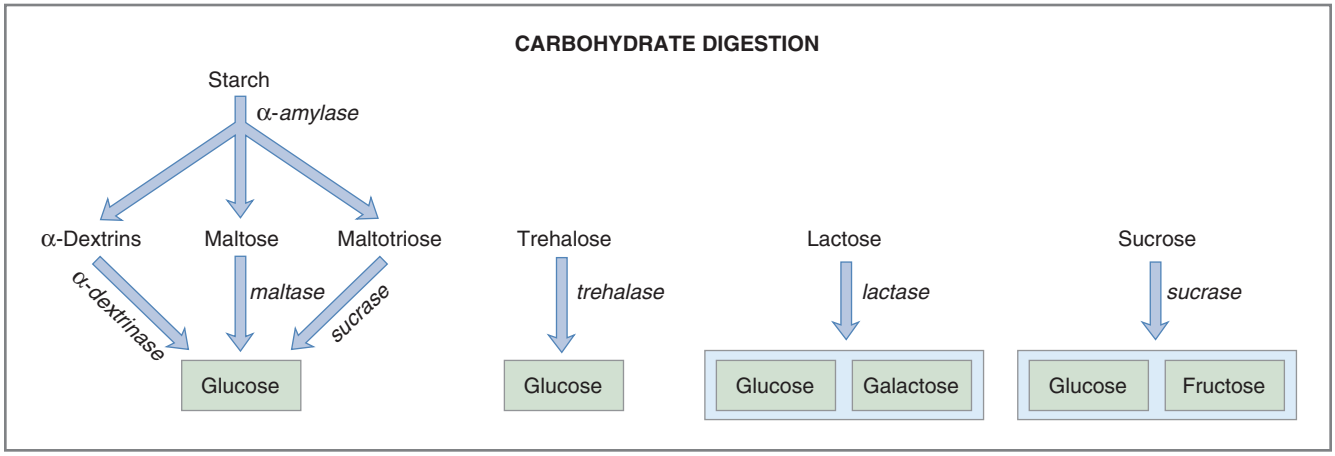

Figure 1-20 Carbohydrate digestion in the small intestine. (From Costanzo L (ed): *Physiology*, 4th ed. Philadelphia: Saunders, 2010.)

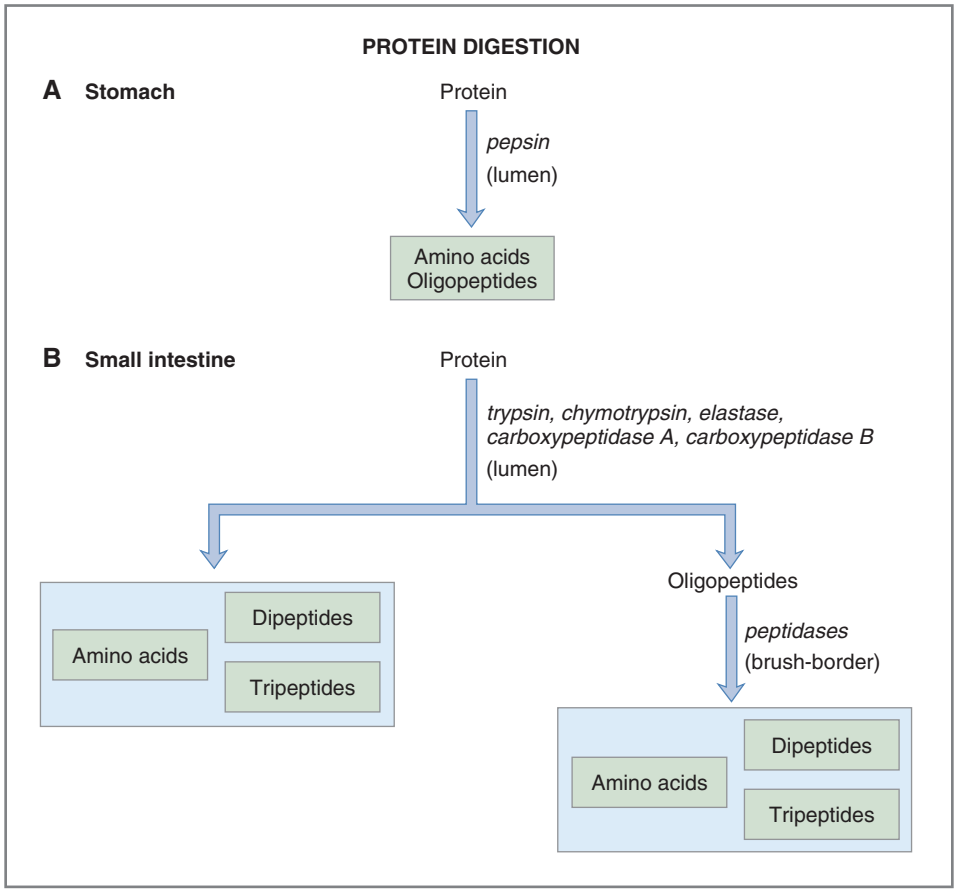

Figure 1-21 Protein digestion in the stomach and small intestine. (From Costanzo L (ed): *Physiology*, 4th ed. Philadelphia: Saunders, 2010.)

Protein

Intraluminal hydrolytic digestion of protein begins in the stomach with peptic digestion and ends in the small intestine with pancreatic protease digestion. Gastric pepsin is an endopeptidase that is secreted in response to a protein meal and low intragastric pH. Peptic activity terminates when gastric contents are mixed with bicarbonate in the small intestine. The presence of food in the small intestine provokes CCK release from the small intestine, which, in turn, stimulates the pancreas to secrete digestive enzymes. Trypsin, chymotrypsin, elastase, and carboxypeptidase are examples of pancreatic proteases, each having specific sites of proteolysis. Specific carrier systems exist for neutral, dibasic, and dicarboxylic amino acids, and some small- and intermediate-size peptides are readily absorbed intact across the enterocyte membrane (see also Figs. 1-19 and 1-21).[50]

Triglyceride

Triglyceride is the major dietary lipid, along with cholesterol, phospholipids, and fat-soluble vitamins. The digestion of dietary lipids begins in the stomach with the action of lingual and gastric lipases, and is completed in the small intestine with the actions of pancreatic lipase, cholesterol ester hydrolase, and phospholipase A_2. Lipid digestion and absorption is more complicated because of lipid solubility characteristics, and involves emulsification of fat by bile salts, hydrolysis of fat by pancreatic lipase and colipase, solubilization of fatty acids and monoglycerides into mixed micelles, absorption, reesterification, chylomicron formation, and transport into the intestinal lymphatics or portal circulation (Fig. 1-22).[51]

Fermentation

The colon contains the largest concentration of bacteria in the GI tract. The colonic microflora plays an important role in nutrition primarily via the production of short-chain fatty acids (SCFAs). Major fiber fermentation substrates include cellulose, hemicellulose, and pectin, substrates that typically are not digested by pancreatic or intestinal amylases. Acetate, propionate, and butyrate account for more than 85% of formed SCFAs, and they accumulate in concentrations up to 150 mmol/L in the canine and feline colon. SCFAs are rapidly absorbed by the colonic mucosa, are readily metabolized by colonic epithelial cells, and have various physiologic effects. Among their physiologic effects, SCFAs promote differentiation and proliferation of colonocytes, stimulate absorption of water and electrolytes, provide 10% to 14% of an animal's overall energy requirements, and influence or modify motility of the GI tract.[52]

Absorption

Intestine

The small intestine is primarily absorptive in function. Water, solutes, glucose and other monosaccharides, amino acids and small peptides, free fatty acids and glycerol, minerals and vitamins, bile salts, and other nutrients are absorbed from the lumen into villus epithelial cells (Table 1-4).[49-51]

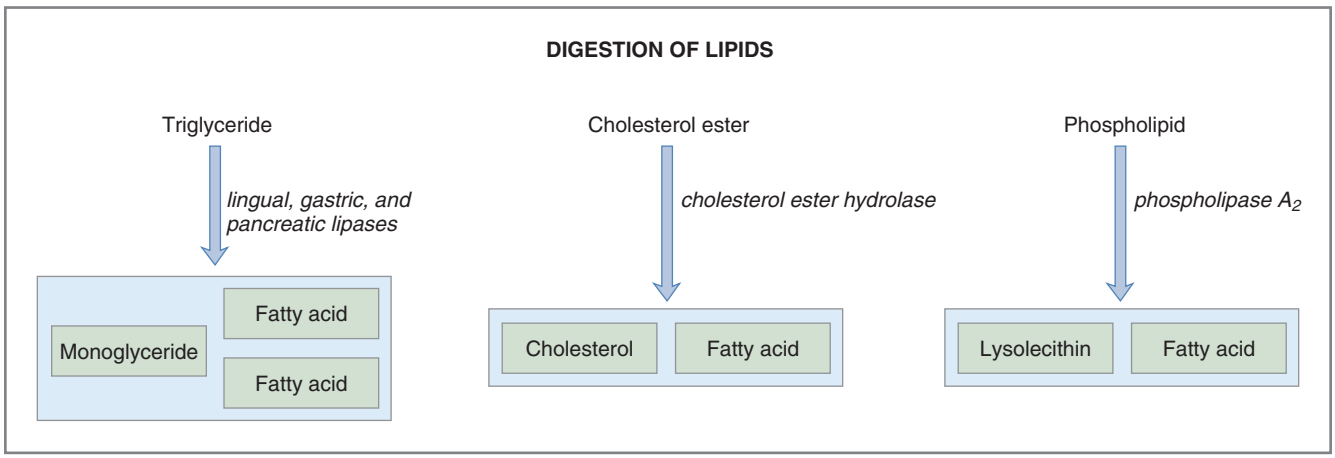

Figure 1-22 Lipid digestion in the small intestine. (From Costanzo L (ed): *Physiology*, 4th ed. Philadelphia: Saunders, 2010.)

Table 1-4 Summary of Small Intestinal Absorption

Nutrient	Digestion Product	Site of Absorption	Mechanism
Carbohydrates	Glucose	Small intestine	Na^+-glucose cotransport
	Galactose	Small intestine	Na^+-galactose cotransport
	Fructose	Small intestine	Facilitated diffusion
Proteins	Amino acids	Small intestine	Na^+-amino acid cotransport
	Dipeptides	Small intestine	H^+-dipeptide cotransport
	Tripeptides	Small intestine	H^+-tripeptide cotransport
Lipids	Fatty acids	Small intestine	Bile salts form mixed micelles
	Monoglycerides	Small intestine	Diffusion of monoglycerides, fatty acids, and glycerol
	Glycerol	Small intestine	Reesterification in the cell
Fat-soluble vitamins		Small intestine	Micelles form with bile salts
Water-soluble vitamins		Small intestine	Na^+-dependent cotransport
Cobalamin (B_{12})		Ileum	Intrinsic factor
Bile salts		Ileum	Na^+-bile salt cotransport
Ca^{2+}		Small intestine	Ca^{2+}-binding protein
Fe^{2+}	$Fe^{3+} \rightarrow Fe^{2+}$	Small intestine	Binds to apoferritin in the cell

Water and Solutes

Villus epithelial cells absorb Na^+, Cl^-, and H_2O, and this absorption is regulated by parasympathetic and sympathetic neurons (see Fig. 1-17). Vasoactive intestinal polypeptide and ACh-containing parasympathetic neurons inhibit fluid absorption from villus epithelial cells, while noradrenergic and opioid neurons stimulate fluid absorption from these same cells. The *jejunum* is the major site of Na^+ absorption in the small intestine. Na^+ is absorbed into jejunal enterocytes via several different Na^+-dependent cotransporters, including Na^+-monosaccharide cotransporters (Na^+-glucose and Na^+-galactose), Na^+–amino acid cotransporters, and Na^+–H^+ exchange. Cellular carbonic anhydrase is the source of protons for the Na^+–H^+ exchange. In the jejunum, there is a net absorption of $NaHCO_3$ (sodium bicarbonate), whereas in the ileum there is net absorption of NaCl. The *ileum* contains a unique Cl^-–HCO_3^- exchange mechanism, resulting in a net absorption of NaCl in the ileum.[53]

Cotransport

Sugars such as glucose and galactose are absorbed across the small intestinal brush-border membrane via carriers that couple their movements to that of sodium (Na^+). Coupling to Na^+ permits organic solutes to be transported against concentration gradients running opposite to that for Na^+. Organic solutes are ultimately transported from enterocyte to blood via basolateral membrane carriers. Some oligopeptides are absorbed intact along with single amino acids by a similar proton-coupled mechanism. This absorptive process is indirectly coupled to Na^+ transport, as protons are derived from Na^+–H^+ exchange, which acidifies the unstirred layer adjacent to the brush-border membrane. The Na^+ gradient, therefore, is the driving force for sugar, amino acid, oligopeptide, and vitamin absorption.[49,50]

Monosaccharides

Glucose and galactose are actively absorbed across the enterocyte epithelium via the sodium-glucose cotransporter protein, SGLT 1. Fructose absorption does not involve an energy-requiring step or a cotransporter in the apical membrane. All monosaccharides are subsequently transported from the enterocyte into the portal capillaries via facilitated diffusion (glucose transporter [GLUT] 2; Fig. 1-23).[49]

Amino Acids

Acidic, neutral, basic, and imino amino acids are actively transported into the enterocytes by specific carrier proteins coupled to Na^+ transport. Separate H^+-dependent cotransporters transport dipeptides and tripeptides from the intestinal lumen into the enterocyte, utilizing an H^+ ion gradient created by a Na^+–H^+ exchanger in

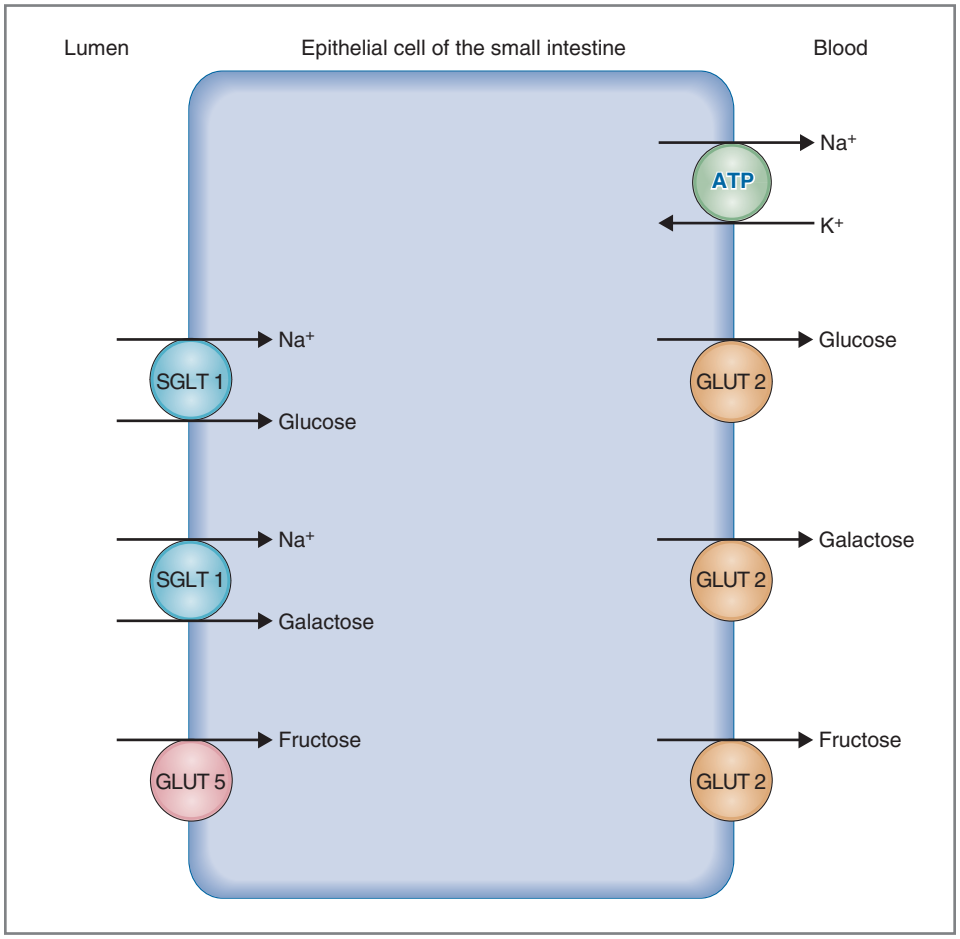

Figure 1-23 Carbohydrate absorption in the small intestine. GLUT 2, glucose transporter protein 2; GLUT 5, glucose transporter protein 5; SGLT 1, sodium/glucose cotransporter 1. (From Costanzo L (ed): *Physiology*, 4th ed. Philadelphia: Saunders, 2010.)

the apical membrane. Peptides are hydrolyzed within the cell, and all amino acids are subsequently transported from the cell to the portal circulation via facilitated diffusion (Fig. 1-24).[50]

Lipids

Mixed micelles of monoglycerides, lysolecithin, cholesterol, and free fatty acids are absorbed by mid-jejunal enterocytes. Bile salts are separated from the lipid fraction and reabsorbed further down the GI tract by ileal enterocytes. Within jejunal enterocytes, products of lipid digestion are reesterified with fatty acids to form triglycerides, phospholipids, and cholesterol ester. Reesterified lipids and apoproteins are subsequently incorporated into chylomicrons which are then transported primarily into intestinal lacteals, and secondarily into portal capillaries (Fig. 1-25).[51]

Water-Soluble Vitamins

The water-soluble vitamins (B_1, B_2, B_6, B_{12}, C, folic acid, nicotinic acid, and pantothenate) are absorbed by a Na^+-dependent cotransport mechanism. The exception is the absorption of vitamin B_{12} (cobalamin), which, instead, depends upon intraluminal binding to R proteins and intrinsic factor before presentation to, and absorption from, the ileal brush-border.

Fat-Soluble Vitamins

Fat-soluble vitamins (A, D, E, and K) are emulsified and micellarized by bile salts in the small intestine, separated from bile salts, absorbed into enterocytes, and incorporated into chylomicrons along with cholesterol, lipoproteins, and triglycerides, before being distributed into the lymphatic circulation.

Calcium

Vitamin D (1,25-dihydroxycholecalciferol) promotes Ca^{2+} absorption by inducing the synthesis of vitamin D–dependent Ca^{2+}-binding protein (calbindin D-28K) in intestinal epithelial cells.[54]

Iron

Iron is absorbed across the apical membrane of intestinal epithelial cells as free iron or as heme iron. Free iron and iron derived from heme are bound to apoferritin and transported across the basolateral membrane into the portal circulation. In the circulation, iron is bound to transferrin and stored in the liver and bone marrow.[54]

Colon

Solutes

The mechanisms of absorption in the large intestine are in many ways similar to those of the small intestine, but with several important differences (Table 1-5).[48] Active nutrient (glucose, amino acid, monoglyceride) absorption is prominent in the small intestine, but there is no evidence of active glucose or amino acid absorption in the colon except during the early neonatal period. Sodium absorption also differs in the colon. Glucose- and amino acid-stimulated sodium transport is a well-established property of the small intestine,

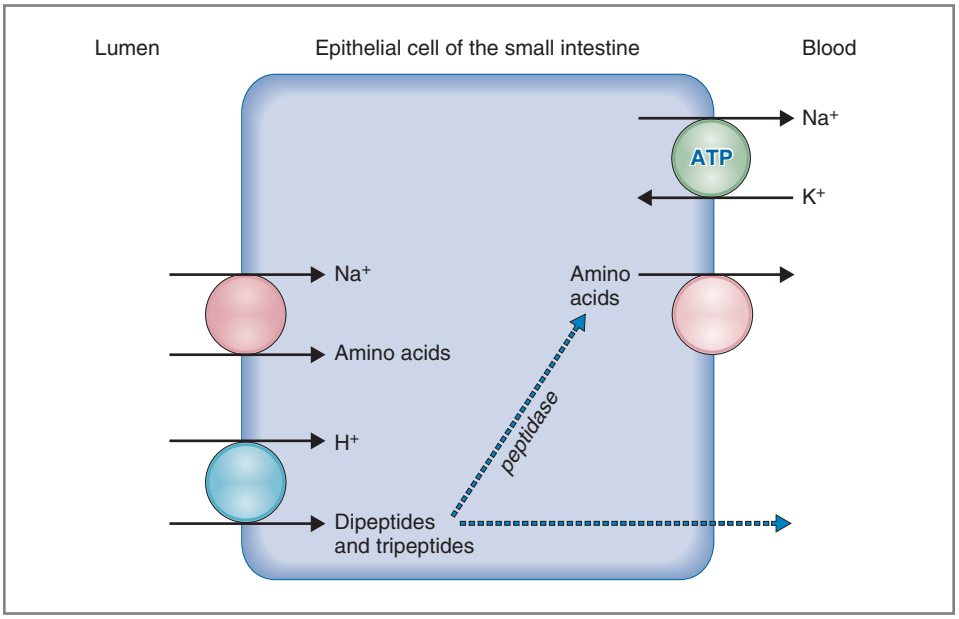

Figure 1-24 Protein absorption in the small intestine. (From Costanzo L (ed): *Physiology*, 4th ed. Philadelphia: Saunders, 2010.)

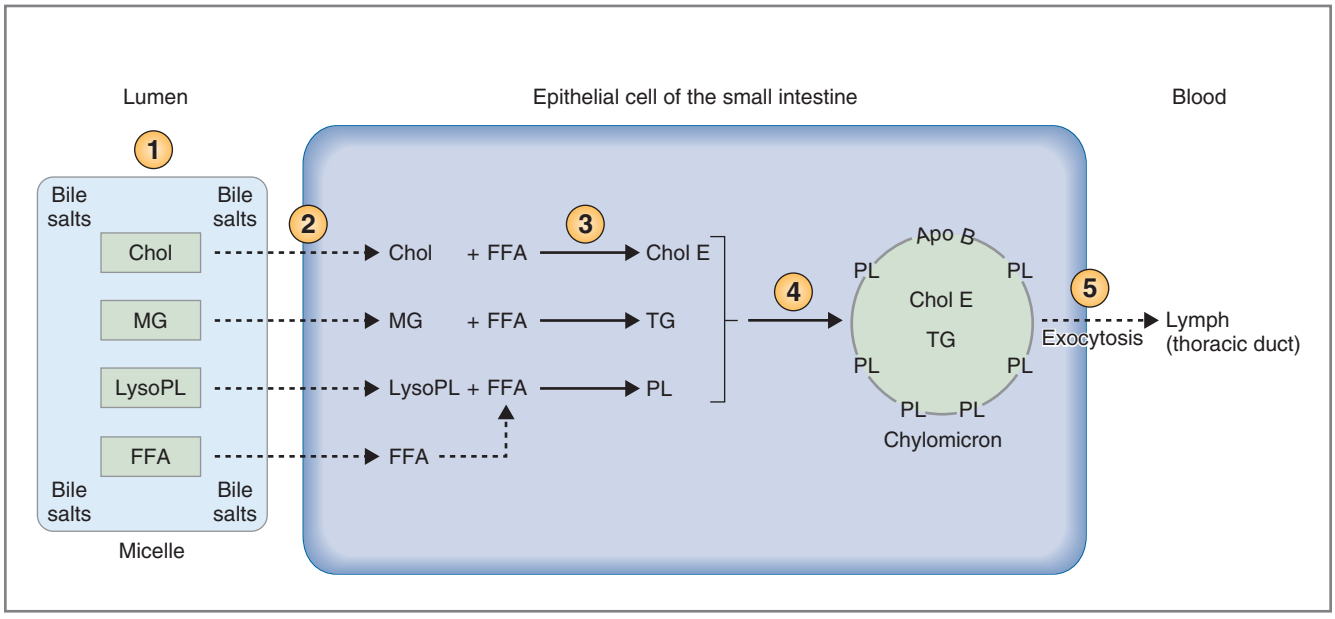

Figure 1-25 Lipid absorption in the small intestine. Apo B, apoprotein B; Chol, cholesterol; FFA, free fatty acids; LysoPL, lysophospholipids; MG, monoglyceride; PL, phospholipids. (From Costanzo L (ed): *Physiology*, 4th ed. Philadelphia: Saunders, 2010.)

so much so that oral glucose-electrolyte solutions have been used to reduce the morbidity of infectious diarrheal diseases of the small intestine. In contrast, glucose-coupled sodium transport does not take place in the colon; sodium transport in the colon instead relies upon electrogenic transport. The large intestine also differs in its response to mineralocorticoids. Aldosterone markedly increases sodium transport in the colon, but has only a modest effect in the small intestine.[48]

Ammonia

Ammonia is an important by-product of amino acid metabolism. The GI tract is the most important source of ammonia, which derives mostly from the colon through the action of bacterial urease on endogenous urea or dietary amines. Ammonia produced by colonic bacteria enters the portal circulation and is transported to the liver for urea cycle transformation.

Short-Chain Fatty Acids

SCFAs (acetate, propionate, butyrate) produced by microbial fermentation in the large intestine are absorbed by mechanisms governing weak electrolyte movement. In the un-ionized form, SCFAs are lipid soluble and can rapidly diffuse across the cell membrane (Fig. 1-26). In the ionized form, however, they are water soluble, and most are too large to traverse the pathways for small ions. SCFAs may account for up to 15% of the metabolic fuel of the canine and feline colon.[52]

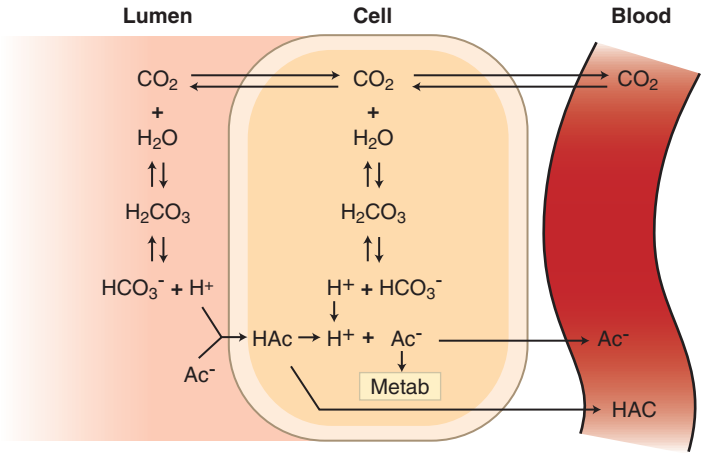

Figure 1-26 Short-chain fatty acid absorption in the colon.

Table 1-5 Differences in the Biologic Properties of the Small and Large Intestines

Biology	Small Intestine	Large Intestine
Villus projections (villi)	Present	Absent
Brush-border microvilli	Prominent	Sparse
Goblet cells	Sparse	Abundant
Endocrine cells	>20 cells	3 cell types
Crypt → epithelial migration	Rapid	Slow
Amino acid absorption	Present	Absent
Glucose absorption	Present	Absent
Lipid absorption	Present	Absent
Vitamin absorption	Present	Absent
Glucose/Na^+ absorption	Present	Absent
SCFA production/ absorption	Minimal	Prominent

SCFA, small-chain fatty acid.

Gallbladder

During fasting, water and electrolytes are reabsorbed from the lumen of the gallbladder. The organic components of bile (e.g., proteins, lipids, phospholipids, cholesterol, and mucus) are not absorbed and instead become concentrated during isotonic fluid removal. Dehydration of gallbladder bile during prolonged fasting may lead to gallbladder dysmotility, biliary stagnation, and supersaturation.

Blood Flow

The splanchnic vasculature constitutes the largest regional circulation derived from cardiac output. More than a quarter of the output from the left ventricle flows through the splanchnic vessels. The major function of the splanchnic circulation is to support the broad range of activities associated with the digestive system: motility, secretion, digestion, absorption, and metabolism. In addition, the splanchnic circulation serves as a storage site for a large volume of blood that can be mobilized during exercise.

The splanchnic circulation is more complicated, both anatomically and functionally, than most other regional circulations. The coronary circulation, for example, serves one major function—that is, support of myocardial contractility. In perfusing the digestive system, the splanchnic circulation subserves motility from the esophagus to the colon; fluid secretion from the GI tract, pancreas, and liver; hydrolytic digestion in the stomach and intestine; fermentative digestion in the colon; absorption in the intestine, colon, and gallbladder; and metabolic activity in the liver.

The splanchnic circulation is arranged both in parallel and in series. Its three major arteries—the celiac, superior mesenteric, and inferior mesenteric—form an extensive anastomosing network that is directed to the stomach, small and large bowel, spleen, pancreas, and liver. The hepatic branch of the celiac artery supplies the liver with 25% of its blood flow. From the other abdominal viscera, blood is taken up by the main portal vein and constitutes the remaining 75% of hepatic perfusion. Splanchnic circulation terminates with the hepatic veins, which return nearly all of the splanchnic blood flow to the caudal vena cava.

The highest tissue blood flows (2 to 4 mL of blood flow per gram of tissue) are found in the mucosa of hollow organs during secretion, digestion, and absorption. The next highest tissue blood flows are in solid organs, for example, the pancreas, at 0.5 mL of blood flow per gram of tissue. The lowest tissue blood flows are in the muscular outer coat of hollow organs at rest (0.1 mL of blood flow per gram of tissue).[16,55]

Branches of the splanchnic arteries give rise to smaller branches that penetrate the surface and muscular coat of the organ, and eventually enter an extensive submucosal network of small arteries. From this network the mucosal arterioles carry blood to the dense mucosal capillary beds. The submucosal vascular arrangement guarantees circulatory communication between segments of the gut and leads to great overlap in the distribution of blood by adjacent arterial branches. This anatomical organization helps to protect against a total loss of blood flow to a segment of gut if its major arterial branch is occluded by a thrombus or embolus.

Splanchnic blood flow is regulated by general hemodynamic principles (i.e., cardiac output, systemic arterial pressure, fluidity of the blood, and blood volume), the autonomic nervous system, neurohumoral substances, local metabolism, and local vascular properties.[16,55]

Bacteriology

The microflora of the GI tract constitutes a complex ecosystem of aerobic and anaerobic bacteria in dynamic equilibrium with viruses, protozoa, fungi, and GI epithelial cells. The diverse metabolic functions of the GI microflora include carbohydrate fermentation and

absorption, trophic effects, suppression of pathogenic bacteria, stimulation of the innate immune response, and prevention of carcinogenesis and allergenicity.[48] In general, there is a progressive colonization and successional ecology of the GI tract from the stomach to intestine and colon.[48] The flora is sparse in the stomach, relatively more populated in the upper small intestine, and of increasing complexity and volume in the ileum and colon. Bacteria are found in both the lumen and attached to the mucosa, but they do not normally penetrate the bowel wall. Bacteria make up most of the flora in the colon and up to 60% of the dry mass of feces. Somewhere between 300 and 1000 different species live in the gut, with most estimates at about 500 (see Chapter 2).

The colon contains the largest concentration of bacteria in the gastrointestinal tract, up to 10^{11} organisms per gram of feces.[48] The colonic microflora play an important role in the nutrition of the animal primarily via the production of SCFAs.[56] Major fiber fermentation substrates include cellulose, hemicellulose, and pectin, substrates that typically are not digested by pancreatic or intestinal amylases. Acetate, propionate, and butyrate account for more than 85% of formed SCFAs, and they accumulate in concentrations up to 150 mmol/L in the colon of dogs.[57] SCFAs are rapidly absorbed by the colonic mucosa, are readily metabolized by colonic epithelial cells, and have various physiologic effects. Among their physiologic effects, SCFAs promote differentiation and proliferation of colonocytes,[58] stimulate absorption of water and electrolytes,[59] provide 7% to 10% of an animal's overall energy requirements,[57] and influence or modify motility of the gastrointestinal tract.[60]

The GI flora is influenced by many factors, including host species, breed, developmental stage, dietary history, environmental conditions, geographic locale, colonic motility patterns, disease, and medication history.[48] A more detailed discussion of the GI microflora may be found in Chapter 2.

Immune Surveillance

The GI tract contains a diverse array of immune cells, including T and B lymphocytes, plasma cells, macrophages, dendritic cells, antigen-presenting cells, mast cells, eosinophils, and neutrophils.[61-68] The normal histology of the canine and feline GI tract is affected by many variables such as age of the animal,[69,70] dietary history, and medication history and has been the subject of considerable controversy. The World Small Animal Veterinary Association (WSAVA) GI Standardization Group used an evidence-based medicine approach[71] to establish a reference range for immunocytes in the GI tract of dogs and cats. Most of the studies employed microscopic evaluation of hematoxylin and eosin (H&E)-stained tissues,[72-79] whereas others used immunohistochemistry (IHC) to label and count leukocyte populations.[80-91] Details of these studies have been published in the GI Standardization Group's archives,[92] but summaries of studies in each anatomic area follow.

Gastric Body Mucosa

Two studies have characterized the leukocyte subpopulations within the superficial region of the normal canine gastric fundic mucosa.[85,91] In one of these studies,[91] a "mucosal unit" was defined as a 250-μm length of mucosa, in which $CD3^+$ intraepithelial lymphocytes (mean, 0.93; range, 0 to 2), $CD3^+$ lamina propria lymphocytes (mean, 4.2; range, 0.5 to 13), lamina propria eosinophils (mean, 0.45; range, 0 to 2), and lamina propria plasma cells (mean, 1.59; range, 0 to 5.83) were enumerated. Biopsy samples were derived from eight dogs, in which considerable interanimal variation in cell counts was noted.

Gastric Antral Mucosa

The leukocyte subpopulations within the superficial region of the normal canine antral mucosa have been characterized in two studies.[85,91] In one study,[90] a "mucosal unit" was defined as a 250-μm length of mucosa, in which $CD3^+$ intraepithelial lymphocytes (mean, 4.4; range, 1.5 to 8), $CD3^+$ lamina propria lymphocytes (mean, 10.7; range, 2.5 to 16.5), lamina propria eosinophils (mean, 2.7; range, 0 to 6), and lamina propria plasma cells (mean, 6.8; range, 0.5 to 15.5) were enumerated. Biopsy samples were derived from eight dogs in that study, in which considerable interanimal variation in cell counts was noted.

Duodenal Mucosa

Several studies have evaluated the normal canine and feline duodenal mucosa using H&E and immunohistochemical staining.[87,91-93] The normal villus length for an adult dog is 722 ± 170 μm, the normal crypt depth is 1279 ± 203 μm, and the normal villus to crypt ratio is 0.68 ± 0.30.[79,92,94] Normal dogs have a mean number of 3.6 ± 3.56 goblet cells per stretch of 100 villous enterocytes, and 9.3 ± 3.09 goblet cells per stretch of 100 cryptal enterocytes.[87] Villous intraepithelial lymphocytes are less numerous in the dog (20.6 ± 9.5 per 100 enterocytes) than in the cat (47.8 ± 11.7 per 100 enterocytes), but the number of cryptal intraepithelial lymphocytes in the dog (5.2 ± 2.33 per 100 enterocytes) is similar to that in the cat (4.6 ± 1.7 per 100 enterocytes).[87,91,92] In the dog, the total leukocyte count is greater in the cryptal lamina propria (156.3 ± 24.91 per 10,000 μm^2) than in the lamina propria of the base (128.3 ± 26.64 per 10,000 μm^2) or tip (100.7 ± 43.89 per 10,000 μm^2) of the villus.[87] Similarly, there are more eosinophils in the canine cryptal lamina propria (9.8 ± 7.51 per 10,000 μm^2) than in the lamina propria of the villus base (3.7 ± 3.52 per 10,000 μm^2) or tip (3.8 ± 6.06 per 10,000 μm^2).[87] In cats, a population of globular leukocytes sometimes is recognized within the intestinal epithelium. These cells have distinctive eosinophilic granules within the cytoplasm and express the molecule perforin as shown by IHC labeling with cross-reactive antisera.[95] This observation suggests that the cells are granular lymphocytes with cytotoxic function. In general, these cells do not appear to increase in number in feline inflammatory enteropathy, but neoplasia of this lineage is documented.[90]

Colonic Mucosa

In the colonic mucosa, there are, on average, 7.7 ± 3.7 intraepithelial lymphocytes per stretch of 100 colonocytes in the normal canine basal crypt epithelium.[87] In the lamina propria between the basal crypts of the canine colon there are approximately 5.5 ± 4.29 plasma cells and 3.8 ± 3.72 eosinophils per 10,000 μm.[87,88,96] Some studies have assessed the number of goblet cells in normal canine colonic cryptal epithelium (25.6 ± 7.32 per 100 colonocytes).[87,88,97] The GI Standardization Group recognized that measurement of goblet cells in colonic epithelium is not straightforward and that the number of such cells may be artifactually decreased by discharge of mucus during the biopsy process.

Along the length of the GI tract, immune cells are found in the epithelium, lamina propria, and submucosa. Appropriate interactions between these different cell types are essential in generating either immune responsiveness or tolerance to the large array of luminal antigens.[98,99] Differences abound along the GI tract, but some generalizations may be made. $CD8^+$ T cells are found primarily in the epithelium; fewer $CD8^+$ T cells are found in the lamina propria or submucosa. Most intraepithelial lymphocytes (IELs)

are $CD3^+/CD8^+$, a phenotype consistent with suppressor-cytotoxic functions. Lamina propria T cells on the other hand are predominantly of the $CD4^+$ helper phenotype. IgA-containing plasma cells are more prominent than IgG- or IgM-containing plasma cells in the lamina propria. In the healthy GI mucosa, a balance would appear to be maintained between helper and suppressor T-cell populations, which allows specific antigen responsiveness while avoiding hyperreactivity.[62,63,100] A more detailed discussion of gastrointestinal immunity may be found in Chapters 3 (Immunology) and 4 (Inflammation).

Liver Metabolism

The liver is involved in many aspects of intermediary metabolism.[7,8,10,13]

Carbohydrate Metabolism

The liver is at the center of carbohydrate metabolism through its role in maintaining normoglycemia. Carbohydrate stored in the liver as glycogen is hydrolyzed to glucose via glycogenolysis during periods of hypoglycemia. When the glycogen available is insufficient, glucose is produced from amino acids by gluconeogenesis. Glucose is also produced from glycerol and intermediates of glycolysis, such as lactic and pyruvic acids. With inadequate glucose in the diet, blood glucose is maintained at the expense of body proteins. Body lipid stores are also depleted during starvation, although lipids do not participate in the maintenance of blood glucose other than by serving as an alternate source of energy, as glucose cannot be synthesized from fatty acids.

Protein Metabolism

The liver is an important site of protein metabolism. Amino acids and proteins absorbed from the intestine or produced in the body are delivered to the liver. The liver deaminates amino acids and converts them to carbohydrates and lipids. Deamination produces α-keto acids, which can be metabolized for energy or used for synthesis of monosaccharides and fatty acids. The liver synthesizes amino acids from intermediates of carbohydrate and lipid metabolism by amination and transamination. Examples of amino acid transaminations include the following:

- Alanine + α-ketoglutarate ↔ pyruvate + glutamate
- Aspartate + α-ketoglutarate ↔ oxaloacetate + glutamate

The liver synthesizes many proteins, including albumin and fibrinogen, most α-globulins, and some of the β-globulins. Prothrombin and clotting factors V, VII, VIII, IX, and X are produced in the liver, as well as ceruloplasmin, ferritin, and many serum enzymes.

Lipid Metabolism

The liver is involved in the intermediary metabolism of lipids, most importantly triglyceride synthesis and fatty acid oxidation, as well as digestion and absorption from the GI tract, and cholesterol metabolism outlined below:

- Intestine → Cholesterol in Chylomicrons → Apoprotein B48 → Liver
- Muscle, Connective Tissue → Cholesterol in High-Density Lipoproteins (HDLs) → Liver
- Liver → Cholesterol in Very-Low-Density Lipoproteins (VLDLs) → Serum and Bile
- Blood → Cholesterol in Low-Density Lipoproteins (LDLs) → Apoprotein B100 → Liver

Nucleic Acid Metabolism

The urea cycle and the biosynthesis of pyrimidine nucleotides are the most important roles of the liver in nucleic acid metabolism. Ammonia is an important product of amino acid metabolism. The GI tract is the most important source, primarily the colon, through the action of bacterial urease on endogenous urea that diffuses to the intestine and on degraded dietary amines. Ammonia produced by the colonic bacteria enters the portal vein and is transported to the liver to be transformed by the urea cycle in the following stoichiometry:

- 2 NH_3 (ammonia) + CO_2 + 3 ATP + H_2O → urea + 2 ADP (adenosine diphosphate) + 4 P_i (phosphate inhibitor) + AMP (adenosine monophosphate) + 2 H

Coagulation Factors

The liver synthesizes plasma clotting factors I (fibrinogen), II (prothrombin), V, VII, VIII, IX, and X. Factors II, VII, IX, and X are vitamin K–dependent clotting factors.

Bile Secretion

The liver secretes a slightly alkaline isosmotic solution of bile containing bile salts, bilirubin, phospholipids, cholesterol, electrolytes, and water. Bile secretion serves many useful purposes, not the least of which is bile-salt generation and delivery for emulsification and micellarization of dietary fat. Bile salts are synthesized from cholesterol, conjugated to amino acids, secreted into the biliary tract, stored in the gallbladder, and subsequently delivered to the small intestine postfeeding. Intestinal bacteria may transform some of the primary bile acids into secondary bile acids. Ileal reabsorption of bile salts permits enterohepatic recirculation, liver reuptake, reconjugation, and resecretion.

Porphyrin Metabolism

Porphyrins are intermediates of the heme biosynthetic pathway. Porphyrins are found in hemoglobin, myoglobin, cytochromes, catalase, and peroxidase enzyme. The liver also serves as an excretory route for the porphyrins.

Metal Metabolism

The liver stores iron, which can be toxic in excessive amounts (hemochromatosis). The amount of iron in the body is largely determined by regulation of its absorption in the upper small intestine. Iron is stored intracellularly as ferritin in a number of tissues, with the liver having a large storage capacity. When the capacity of the liver is exceeded, iron accumulates as hemosiderin. The liver incorporates copper into specific copper proteins such as cytochrome c oxidase, mitochondrial monoamine oxidase, and ceruloplasmin. Mobilization of copper from hepatocytes takes place by at least two mechanisms: ceruloplasmin and bile secretion. Cholestatic liver disease is associated with secondary copper retention, which may then induce hepatocyte injury.

Vitamin Metabolism

The liver produces bile for absorption of fat-soluble vitamins (A, D, E, K), and the liver is an important site for vitamin storage. Vitamin A is stored in both Kupffer cells and hepatocytes. Approximately 95% of total body vitamin A is stored in the liver. Water-soluble vitamins, except for vitamin B_{12} (cobalamin), are readily absorbed from the small intestine. These vitamins are used primarily as coenzymes in various metabolic reactions. Large amounts of all water-soluble vitamins except vitamin C are stored in the liver.

Glutathione Metabolism

Glutathione (GSH) is synthesized in most if not all mammalian cells. The liver is particularly active and has relatively high levels of GSH. GSH performs a variety of physiologic and metabolic functions, including thiol transfer reactions which protect cell membranes and proteins; thiol-disulfide reactions involved in protein synthesis, protein degradation, and catalysis; reducing capacity; detoxification of hydrogen peroxide, organic peroxides, free radicals, and foreign compounds; and metabolism of various endogenous compounds.

Xenobiotic Metabolism

Numerous foreign compounds, including drugs, are so hydrophobic that they would remain in the body indefinitely were it not for hepatic biotransformation.

Hormone Metabolism

Natural and synthetic hormones are metabolized in the liver. The liver metabolizes mineralocorticoids (aldosterone), glucocorticoids (i.e., cortisol, corticosterone), and sex steroids (i.e., androgens, estrogens, progesterone).

Immune Surveillance

The "reticuloendothelial" system in the liver removes microbes, endotoxins, enterotoxins, and exotoxins from the portal circulation following their absorption from the intestine.

Neural, Endocrine, and Paracrine Activation

The many functions of the GI tract are integrated through the coordination of neural, endocrine, and paracrine mechanisms of activation (see Fig. 1-1; Fig. 1-27; Table 1-6). These functions include contraction and relaxation of smooth muscle; secretion of enzymes for digestion; secretion of fluids and electrolytes; nutrient absorption; and mucosal growth.

Endocrine Regulation

A GI hormone is classically defined as a substance that (a) is found in GI endocrine cells, (b) is released by physiologic stimuli, (e.g., feeding), (c) circulates in blood, (d) binds to a cell receptor at a distant site, and (e) evokes a biologic response.[101,102] However, the characterization of an event as the physiologic result of a hormonal action may be exceedingly difficult. It is now clear that many biologic substances previously classified as GI hormones are neither confined to the GI tract nor are solely blood-borne. For example, some of the peptides localized in gut endocrine cells (e.g., cholecystokinin, SP, neurotensin, and somatostatin) may be found in gut neurons and act as neurocrine substances.[103] As enteric neuropeptides, these substances may evoke similar or different biologic responses. Some of these same peptides are also located outside the enteric nervous system in vagal afferent fibers or CNS neurons. Thus, some GI hormones may also function as enteric or brain neuropeptides. A further complication is that some gut endocrine

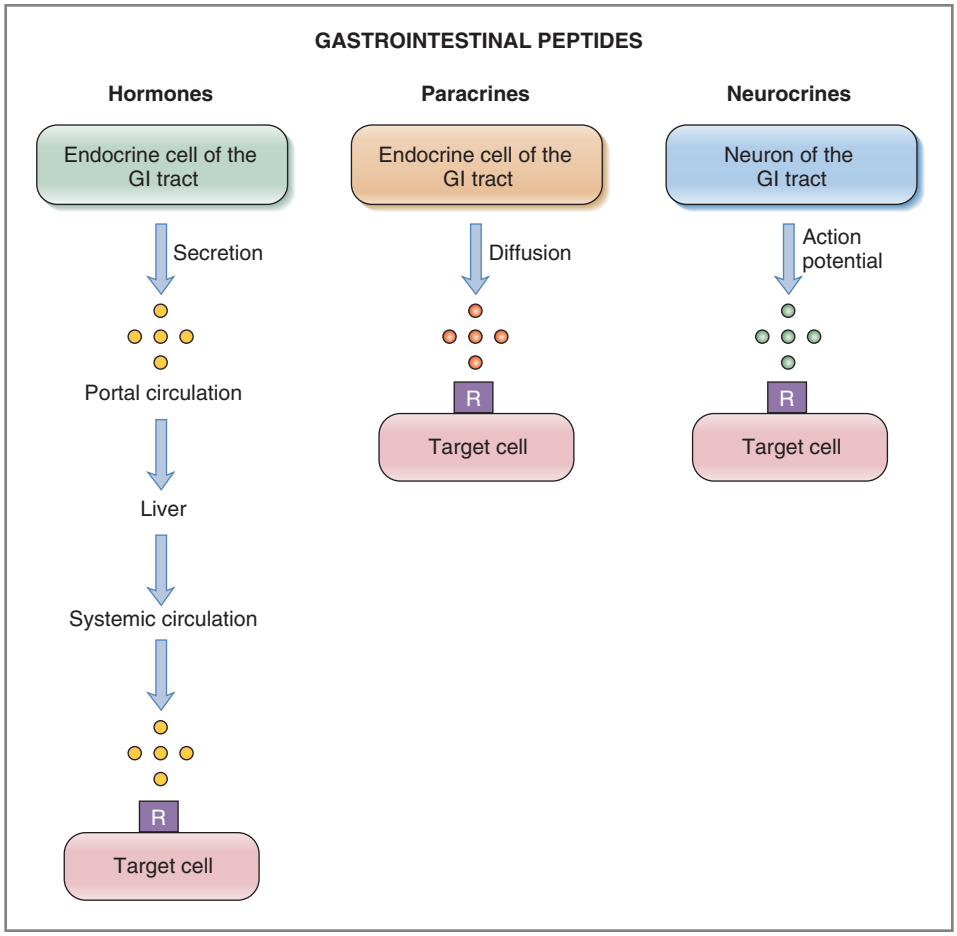

Figure 1-27 Classification of gastrointestinal peptides as hormones, paracrines, or neurocrines. (From Costanzo L (ed): *Physiology*, 4th ed. Philadelphia: Saunders, 2010.)

Table 1-6 Overview of Endocrine, Neural, and Paracrine Regulation in the Gastrointestinal Tract

Substance	Physiologic Release	Site of Action	Effect
GI Hormones			
Gastrin	Intragastric peptides, gastric distention	Gastric parietal and chief cells	H^+ and pepsinogen secretion
		Pancreatic acinar cells	Enzyme secretion
		Stomach, duodenum, pancreas	Growth
Cholecystokinin	Duodenal fatty acids, amino acids, H^+	Gallbladder	Contraction
		Sphincter of Oddi	Relaxation
		Pancreas	Enzyme secretion and growth
		Stomach	Inhibition of gastric emptying
Secretin	Duodenal H^+, fatty acids	Pancreatic duct cells	HCO_3^- and water secretion
		Biliary epithelium, duodenum	HCO_3^- and water secretion
Enteroglucagon			
Oxyntomodulin	Ileal/colonic glucose and lipid	Gastric parietal cells	Inhibits H^+ secretion
GLP-1		Pancreatic islet (β) cells	Stimulates insulin secretion (incretin during euglycemia)
GLP-2	Duodenal fatty acids	Stomach	Inhibits gastric emptying ("ileal brake")
	Ileal fatty acids	Small intestine, colon	Inhibits gastric emptying (ileal brake) and secretion
	Carbohydrates, lipids, SCFA		Crypt cell proliferation, suppression of apoptosis
			Reduces gut permeability and bacterial translocation
Gastric inhibitory polypeptide	Fatty acids, glucose, amino acids	Duodenum, jejunum, ileum	Inhibits gastric and intestinal motility; Stimulates insulin secretion (incretin during euglycemia)
Somatostatin	Lipids, protein, and bile	Stomach, intestine, pancreas	Inhibits gastric, intestinal, and pancreatic secretion
Motilin	H^+ and lipids	Stomach, duodenum, jejunum	Increases GES pressure, stimulates propulsive motility
			Stimulates gastric, pancreatic, and biliary secretion
Pancreatic polypeptide	Protein, cholinergic reflexes	Pancreas	Inhibits pancreatic enzyme and fluid secretion
Peptide YY	H^+ and lipids	Ileum and colon	Ileal brake, proliferation of gut mucosa
		Stomach and pancreas	Inhibits secretion (H^+, pancreatic enzyme)
5-Hydroxytryptamine	H^+	Intestine and colon	Stimulates motility and secretion
Ghrelin	Dietary protein	Pituitary	Stimulates growth hormone secretion
Enteric Neuropeptides			
Substance P	Luminal distention, H^+, hyperosmolarity	Stomach, intestine, colon	Sphincteric contractions, intestinal peristalsis
		Pancreas	Stimulates pancreatic enzyme secretion
Vasoactive intestinal polypeptide	Vagal stimulation	Stomach, intestine, colon	Increased blood flow, stimulation of fluid secretion
		Stomach, intestine, colon	Relaxation of smooth muscle
		Pancreas	Stimulates fluid and bicarbonate secretion
Opioids	Intestinal distention	Stomach, intestine, colon	Inhibits longitudinal smooth muscle contraction
			Stimulates circular smooth muscle contraction
			Inhibits water and electrolyte secretion
Bombesins (GRP and (neuromedin B)	Vagal stimulation	Stomach	Stimulates gastric acid secretion
		Pancreas	Stimulates pancreatic enzyme secretion
		Gallbladder	Stimulates gallbladder contraction
Somatostatin	Lipids and protein	Stomach, intestine, pancreas	Descending inhibitory reflex of peristalsis
Gastrin/CCK	Intestinal distention	Ileum and colon	Ileal and colonic contractions
Neuropeptide Y	Intestinal distention	Intestine and colon	Inhibits intestinal motility
5-Hydroxytryptamine	H^+ and hypertonic solutions	Stomach, intestine, colon	Regulates migrating myoelectric complex
Paracrine Mediators			
Histamine	Vagal stimulation	Stomach	Stimulates gastric acid secretion
Somatostatin	Lipids and proteins	Stomach	Inhibits gastrin secretion
		Pancreas	Regulates insulin and glucagon secretion
Prostaglandins	H^+, gastric distention	Stomach	Stimulates bicarbonate and glycoprotein secretion
			Stimulates epithelial cell renewal and blood flow
			Inhibits prostanoid receptors

CCK, cholecystokinin; GES, gastroesophageal sphincter; GLP-1, glucagon-like peptide-1; GLP-2, glucagons-like peptide-2; GRP, gastrin-releasing peptide; SCFA, small-chain fatty acid.

cells may release peptides into the extracellular fluid from which they diffuse to, and directly act on, neighboring cells. Consequently, a GI peptide may evoke a biologic response through a paracrine mechanism of activation that operates independently of, or in parallel to, an endocrine mechanism of activation. Somatostatin, for example, stimulates biologic responses through endocrine, paracrine, and neurocrine mechanisms—endocrine regulation of gastric acid secretion, paracrine regulation of antral gastrin secretion, and neurocrine regulation of smooth muscle contraction.

Gastrin-Cholecystokinin Family

The GI hormones[101,102,104] and related peptides have been divided into structurally homologous families. The first family consists of gastrin and CCK. Gastrin and CCK share five basic characteristics: (a) partial sequence homology; (b) similar biologic activities; (c) heterogeneity—each hormone exists in different molecular forms; (d) ubiquity—each hormone is synthesized in different cell types; and (e) differential principality—different molecular forms predominate in different tissues and cells.[101,104]

Gastrin exists in several molecular forms—G-34, G-17, and G-14—gastrin peptides that contain 34, 17, and 14 amino acids, respectively. G-34, also known as "big gastrin," is the most abundant form of gastrin in serum. G-17, known as "little gastrin," is less abundant than G-34 in serum but is more potent in stimulating gastric acid secretion. "Mini gastrin" (G-14) has little biologic effect. Endocrine cells (G cells) in the gastric antrum and duodenum secrete gastrin in response to protein meals and, to a lesser extent, gastric distention.[101,104] The most important biologic action of gastrin is the stimulation of gastric acid secretion by gastric oxyntic (parietal) cells. A substantial fraction of the gastric acid secretory response to protein meals is, in fact, mediated by gastrin. However, interactions between gastrin, ACh (neurocrine stimulant), and histamine (paracrine stimulant) determine the final gastric acid secretory output.[105] Most evidence suggests that the gastrin effect occurs through the binding of gastrin to CCK_B receptors on oxyntic cells. Other important biologic actions of gastrin include stimulation of gastric pepsinogen secretion, gastric mucosal blood flow, antral motility, and pancreatic enzyme secretion, and of pancreatic, gastric and duodenal growth.[101,104,106] Pancreatic islet cells (delta cells) are a site of gastrin synthesis and secretion in fetal and neonatal animals.[106] Malignant transformation of these islet cells in adult animals results in functional gastrinomas. All but one of the gastrinomas that have been reported to date in the dog or cat have been of pancreatic origin.

CCK also exists in several molecular forms: CCK-63, CCK-58, CCK-39, CCK-33, CCK-12, CCK-8, and CCK-5. The predominant forms in serum are CCK-33, CCK-39, and CCK-58 and probably account for most of the GI hormone responses.[101,102,104] CCK-8 is the predominant form found in neurons and probably accounts for most of the enteric and CNS neuropeptide responses. Endocrine cells (I cells) in the duodenum and jejunum secrete CCK in response to intraduodenal fatty acids, amino acids, and H^+ ion.[101,102,104] As a GI hormone, CCK evokes several important biologic responses, most importantly, contraction of the gallbladder and stimulation of pancreatic enzyme secretion. Although CCK receptors have been demonstrated on both gallbladder smooth muscle cells and pancreatic acinar cells, it is now clear that CCK evokes gallbladder contraction and pancreatic enzyme secretion through activation of pre-synaptic cholinergic neurons at both sites.[104,106]

Other important endocrine actions of CCK include augmentation of pancreatic fluid secretion in the presence of secretin, relaxation of the sphincter of Oddi, inhibition of the gastric emptying of liquids, and stimulation of pancreatic growth.[101,104] CCK has two important biologic actions as an enteric or brain neuropeptide (see "Enteric Neuropeptides" below).

Secretin-Enteroglucagon-Gastric Inhibitory Polypeptide Family

A second structurally homologous GI hormone family consists of secretin, enteroglucagon, gastric inhibitory polypeptide (GIP), as well as the enteric neuropeptides VIP and peptide histidine-isoleucine (PHI). All of these substances share considerable sequence homology.

Like gastrin and CCK, secretin exists in several molecular forms: 27–, 28–, 30–, and 71–amino-acid polypeptides.[107] Acidification of the duodenum and jejunum by gastric H^+ is the most important stimulus for secretin secretion by endocrine cells (S cells) in the small intestine.[101,104] Intraduodenal lipid may also stimulate secretin release in some species. The most important biologic action of secretin is secretion of a bicarbonate-rich pancreatic fluid from pancreatic ductal cells.[106,107] Pancreatic bicarbonate is important in neutralizing gastric acid delivered to the small intestine and in creating an alkaline environment that is close to the pH optimum of pancreatic lipase and co-lipase. Less important biologic actions of secretin are stimulation of secretion of bile bicarbonate and pancreatic enzymes.[101,106] The latter effect is observed only in the presence of CCK. Secretin has also been identified in brain neurons, but a functional role for secretin in these neurons has not yet been elucidated.

Enteroglucagon and pancreatic glucagon arise from the same gene precursor through posttranslational processing. Several molecular forms of enteroglucagon have been characterized, including enteroglucagon or oxyntomodulin, a 37–amino-acid peptide; glicentin, a 69–amino acid, C-terminal extended form of oxyntomodulin; glucagon-like peptide (GLP)-1; intervening peptide-2; and GLP-2. Endocrine cells (L cells) in the terminal ileum and colon secrete enteroglucagon(s) in response to intraluminal glucose and lipid. The most important GI action of the enteroglucagons is the inhibition of gastric acid secretion.[101,104] GLP peptides are also involved in the regulation of insulin secretion and glycemic control. GLP-1 is reported to stimulate proinsulin expression, and to delay intestinal glucose absorption through inhibition of gastric emptying,[108] thus acting as an incretin hormone during euglycemia to lower blood glucose. GLP-2 is a 33–amino-acid peptide hormone released from intestinal endocrine cells following nutrient ingestion.[109] It exerts trophic effects on the small- and large-bowel epithelium via stimulation of cell proliferation and inhibition of apoptosis. GLP-2 also upregulates intestinal glucose transporter activity, and reduces gastric motility and gastric secretion.[110]

GIP is a 54–amino-acid peptide that exists in a single molecular form.[111] It is secreted by endocrine cells of the proximal small intestine in response to intraduodenal glucose, fatty acids and amino acids. Two important biologic actions of GIP are inhibition of gastric acid secretion and stimulation of intestinal fluid secretion. The third, and likely most important, biologic action of GIP is the stimulation of pancreatic insulin release during hyperglycemia. It has been suggested that GIP and GLP-1 function as incretins and are the substances responsible for increased glucose disposal and enhanced insulin responses during intestinal absorption of glucose.[101,104,111]

Somatostatin

Somatostatin, or somatotropin release-inhibiting factor, was originally isolated from the hypothalamus and found to inhibit GH and thyrotropin release from the pituitary. Somatostatin was

subsequently found in gut endocrine cells and gut neurons and shown to have endocrine, neurocrine, and paracrine biologic effects. Two molecular forms of somatostatin have been identified in gut endocrine cells: somatostatin-14 (SS-14) and somatostatin-28 (SS-28). Endocrine cells (D cells) throughout the GI tract secrete somatostatin in response to protein, lipid and bile. As a GI hormone, somatostatin inhibits gastric acid and pepsin secretion, pancreatic enzyme and fluid secretion, gallbladder contraction, and intestinal amino acid and glucose absorption.[101,104] In addition to its role as a GI hormone, somatostatin also functions as an enteric neuropeptide (e.g., inhibition of intestinal motility) and as a paracrine substance (e.g., inhibition of gastrin secretion).

Motilin

Motilin is a 22–amino acid peptide found in endocrine cells of the proximal small intestine. Motilin secretion is stimulated by H^+ and lipid during the fed state, but motilin secretion appears to be most important in the interdigestive (fasting) state. During fasting, motilin is released episodically into the serum and initiates phase III of the MMC.[112] The MMC is a motility pattern that empties the stomach and small intestine of indigestible solids that accumulate during feeding. The cyclic release of motilin from the small intestinal mucosa during fasting is also thought to coordinate gastric, pancreatic, and biliary secretions with phase III of the MMC.[113]

Neurotensin

Neurotensin is a 13–amino-acid peptide, isolated from dog ileal and jejunal mucosal endocrine cells (N cells), for which no definitive endocrine function has been established. Intraluminal lipid stimulates neurotensin release from these endocrine cells. Neurotensin has been shown to inhibit gastric emptying and to stimulate pancreatic and biliary secretion. One of the most likely potential roles of neurotensin is that of a physiologic enterogastrone that mediates inhibition of acid secretion after fat ingestion.[101,104]

Pancreatic Polypeptide

Pancreatic polypeptide (PP) is a 36–amino-acid peptide that shares sequence homology with the enteric neuropeptide known as neuropeptide Y (NPY). PP is found exclusively in pancreatic islet cells (F cells). PP release is stimulated by protein meals and by cholinergic reflexes. The most important biologic action of PP is the inhibition of pancreatic enzyme and fluid secretion.[101,104] Islet cell PP secretion likely autoregulates acinar and ductal cell secretions because of the islet–acinar portal venous system. Other possible endocrine functions of PP include relaxation of gallbladder smooth muscle, mild stimulation of gastric acid secretion, and initiation of the MMC along with motilin.[113]

Peptide YY

Peptide YY is a 36–amino-acid peptide with structural similarities to PP and to NPY. Peptide YY may function as a physiologic enterogastrone similar to neurotensin in inhibiting pancreatic and gastric secretions.[101,104]

5-Hydroxytryptamine

5-Hydroxytryptamine (5-HT or serotonin) is found in endocrine cells (e.g., enterochromaffin cells) and enteric neurons throughout the GI tract of most animal species.[1,2,4] In some species, 5-HT is also found in intestinal mucosal mast cells, pancreatic islet cells, and bronchial endocrine cells. 5-HT secreted by enterochromaffin cells may act through an endocrine or paracrine mechanism to stimulate GI smooth muscle contraction and intestinal electrolyte secretion.[102]

Ghrelin

Ghrelin is a 28–amino-acid octanoylated peptide found most abundantly in endocrine cells of the stomach.[114,115] It stimulates pituitary GH secretion. Ghrelin administration also has been shown to stimulate appetite, body growth, and fat deposition. The postprandial gastric expression of ghrelin suggests a GI–hypothalamic–pituitary axis that influences GH secretion, body growth, and appetite that is responsive to nutritional and caloric intakes. Ghrelin and leptin may be the "yin and yang" of a system that relays peripheral information to the brain and directs the body in the appropriate maintenance of energy reserves and nutritional intake.

Enteric Neuropeptides

A substance may be defined as an enteric neuropeptide if (a) it can be demonstrated histochemically in enteric neurons, (b) mechanisms for its biosynthesis exist in enteric neurons, (c) it is concentrated in nerve terminals, (d) it is released from nerve terminals by depolarizing stimuli through a calcium-dependent mechanism, and (e) mechanisms for the breakdown, reuptake, or removal of the substance exist.[103]

Tachykinins

The tachykinin family is represented by SP, substance K, neuromedin K, physalaemin, kassinin, and eledoisin. SP is probably the most important enteric neuropeptide of this group. SP is distributed in enteric neurons throughout the GI tract and pancreas, and it is released from these neurons in response to luminal distention or depolarization. SP has three important biologic actions as an enteric neuropeptide.[103] First, it causes contraction of GI smooth muscle through an indirect effect of mediating cholinergic transmission and a direct effect on smooth muscle during the peristaltic reflex. Second, SP is located in primary sensory afferent fibers and may be important, along with calcitonin gene-related peptide, in pain input to the CNS. Finally, SP neurons stimulate pancreatic enzyme secretion.

Vasoactive Intestinal Polypeptide/Peptide Histidine-Isoleucine

The classic enteric neuropeptides VIP and PHI share sequence homology with one another and with the GI hormones secretin, enteroglucagon, and GIP. VIP and PHI have many similar biologic activities and are derived from the same biosynthetic precursor. VIP and PHI are released by vagal stimulation and have four important biologic actions[103]: (a) stimulation of pancreatic fluid and bicarbonate secretion, (b) stimulation of salivary and intestinal fluid secretion, (c) increasing intestinal blood flow, and (d) relaxation of GI smooth muscle. This last property of VIP/PHI is felt to be important in descending intestinal inhibition (along with somatostatin) and in sphincter relaxation.

Opioids

Opioid neurons are distributed throughout the GI tract. Methionine-enkephalin, leucine-enkephalin, and dynorphin are the most representative members of the opioid enteric neuropeptide family.[103] At least three different types of binding sites for these opioid peptides can be distinguished in the gut (μ, δ, and κ) but there may be others (ε and σ). The binding sites for these opioids are located on other neurons, smooth muscle cells, and epithelial cells. Opioid binding results in (a) inhibition of contraction of longitudinal smooth

muscle through inhibition of ACh release from myenteric plexus neurons, (b) direct stimulation of circular smooth muscle contraction, and (c) inhibition of intestinal water and electrolyte secretion through inhibition of submucosal plexus neurons. These effects account for the potent antidiarrheal properties of morphine and other opiate alkaloids.[103]

Bombesins

The bombesins are so-named because of their original isolation from the skin of the frog genus *Bombina*. The mammalian bombesins that have been identified as enteric neuropeptides are GRP and neuromedin B. GRP is released by vagal stimulation, and it stimulates gastrin release from antral G cells. Thus, GRP acts a cotransmitter (along with ACh) to stimulate gastrin release.[103] GRP also stimulates pancreatic acinar cell enzyme secretion.[103,106]

Somatostatin

In addition to its role as a GI hormone, somatostatin (SS-14) has been identified as an enteric neuropeptide in neurons throughout the GI tract. Somatostatin inhibits ACh release from myenteric plexus neurons and may be involved in the descending inhibitory reflex of peristalsis.[103] Somatostatin neurons in the submucous plexus have a mucosal projection suggesting a further role for neuronal somatostatin in the control of mucosal function.

Gastrin-Cholecystokinin

CCK-8 is an important enteric neuropeptide in the ileum and colon, particularly in the cat. Intraluminal distention activates CCK-8–containing neurons, which then stimulate the release of ACh from myenteric plexus neurons. CCK-8 thus acts as an excitatory transmitter in stimulating the peristaltic reflex in ileum and colon.[101,103] Brain CCK-8 neurons are involved in mediating the satiety response following feeding.

Pancreatic Polypeptides

A 36-amino-acid peptide, NPY shares structural similarities with the GI hormones PP and peptide YY. Neurons containing NPY decrease ACh release from myenteric plexus neurons and hence inhibit small intestinal smooth muscle contraction.[103]

5-Hydroxytryptamine

In addition to its role as an endocrine/paracrine substance of the GI tract, 5-HT is also found in enteric neurons where it is believed to regulate the migrating myoelectrical complex and the intestinal peristaltic reflex.[58]

Paracrine Substances

A substance may be defined as having a paracrine mechanism of activation if (a) the substance is found within an effector cell, (b) receptors for the substance exist on an adjacent paracrine target cell, (c) the effector cell and paracrine target cell are in close proximity, and (d) the substance when applied to the paracrine target cell evokes a biologic response.[101,102] Histamine, somatostatin, adenosine, and prostaglandins have been shown to satisfy these criteria.

Histamine

Histamine is formed from the decarboxylation of histidine in enterochromaffin-like cells found throughout the GI tract of the dog. In the dog, gastric mucosal histamine stores appear fully accounted for by mast cells, there being no evidence to indicate histamine is stored in endocrine cells.[105] Histamine released from mast cells diffuses into the interstitial milieu and is believed to bind parietal cell H_2 receptors to stimulate H^+ secretion.[105]

Somatostatin

As a paracrine substance, somatostatin has an important role in the inhibition of gastrin release. Somatostatin cells in the gastric antrum have long cytoplasmic processes that terminate adjacent to antral G cells. Paracrine release of somatostatin by these somatostatin cells is postulated to mediate the negative feedback inhibition of H^+ on gastrin release.[116] Somatostatin released from pancreatic islet cells (D cells) may also autoregulate pancreatic insulin and glucagon secretion through a local paracrine mechanism.[117]

Prostaglandins

Prostaglandins are long-chain fatty acids that are distributed throughout the GI tract. The role of prostaglandins as paracrine substances is perhaps best understood in the gastric mucosa, where they bind to inhibitory prostanoid receptors on gastric oxyntic cells. These receptors are coupled to inhibitory G proteins and subsequent inhibition of adenylate cyclase and H^+ secretion.[118] A "cytoprotective effect" of prostaglandins, separate from the direct inhibition of acid inhibition, has also been implied. Gastric prostaglandins, for example, stimulate mucosal bicarbonate and glycoprotein secretion, epithelial cell renewal, and mucosal blood flow. These effects are all central to the barrier properties of the gastric mucosa.[119]

CHAPTER 2

Gastrointestinal Microbiota

Jan S. Suchodolski

The intestinal microbiota is the collection of all live microorganisms that inhabit the gastrointestinal (GI) tract. The word *microflora* is often used synonymously, but *microbiota* (from *bios*, Greek: life) is the technically correct term. The intestinal microbiota plays an important role in GI health and disease, yet our understanding of the composition, dynamics, and functionality of the intestinal ecosystem remains rudimentary. The total microbial load in the intestine is estimated to be 10^{12} to 10^{14} organisms, approximately 10 times the number of body cells. It is estimated that the intestine harbors several thousand bacterial strains.[1,2] This mutually interacting system comprising the host cells and the resident microbes is termed the *intestinal microbiome*. The microbiota can be influenced by exogenous factors such as diet and antibiotic administration, but it is usually resilient to these changes and returns rapidly to its pretreatment state. Therefore long-term treatment strategies for modulating the microbiota are necessary. New molecular tools have improved our understanding of microbial diversity in the intestine. Although the major phylogenetic lineages are similar, the microbiota differs substantially at the level of species and strain in each individual animal of the same species. Yet despite these differences, the metabolic end products in the intestine are very similar between individuals. New metagenomic approaches suggest the presence of a "core microbiome," where the function of the intestinal ecosystem is independent of the presence of specific bacterial species or strains. For better understanding of microbial–host interactions in health and disease, future work must focus on the intestinal microbiome as one entity, evaluating its phylogenetic composition as well as metabolic functions.

Methods for Characterization of the Intestinal Microbiota

Practical Considerations

Methods for characterization of the intestinal microbiota are based on cultivation techniques or molecular tools (Fig. 2-1). The selection of the best approach depends on the study problem (e.g., detection of specific pathogens in clinical specimens, or general characterization of the intestinal ecosystem), the cost, and the availability of technologies. Each method has strengths but also limitations (outlined below). For general ecologic surveys of microbial communities, molecular high-throughput sequencing techniques yield the most information as they allow in-depth identification of microorganisms. For screening of specific pathogens, culture techniques and species specific polymerase chain reaction (PCR) assays may be most useful. Both of these methods are sensitive to sample handling and processing. Detailed instructions for sample collection and shipping for each particular assay should be acquired before sample submission as many laboratories use their own in-house culture or PCR assays. In the case of molecular methods, there is usually no standardization of DNA extraction or PCR protocols among laboratories, and such factors impact on the sensitivity and specificity of the assays. Improper DNA extraction, especially from fecal samples, may result in the presence of residual PCR inhibitors that cause false negative results. Because of the high sensitivity of PCR assays (theoretically a single target copy can be amplified), any DNA contamination can lead to false-positive results. A laboratory should be chosen that has expertise in molecular analysis, and that has validated each assay in the target specimen.

Bacterial Culture

Traditional evaluation of the composition of the canine and feline intestinal microbiota has been obtained using culture techniques. Bacterial culture is useful for assessing the viability of organisms, determination of an active infection, and antibiotic susceptibility testing in clinical specimens. Individual isolates can be typed for epidemiologic surveys of specific strains and their virulence factors. Culture is also valuable for understanding the metabolic properties of individual microbes. The value of bacterial culture is greatest when a clinical sample is evaluated for the presence of specific pathogens (e.g., *Salmonella*, *Campylobacter jejuni*).

Several limitations are associated with culture methods, especially if they are used to survey for the presence of unknown microorganisms in intestinal samples. Bacterial culture underestimates total bacterial numbers in the intestine, as microscopic counts (especially when using fluorescent dyes) are typically higher than the total viable counts obtained from culture. Although the majority of intestinal bacteria cannot be cultured, this does not necessarily mean that they are uncultivable, but rather, that insufficient information is currently available about their optimal growth requirements. Furthermore, many microbes depend on mutualistic interactions with other bacteria and the host, hindering their successful isolation in vitro. While recent advances have increased the cultivable fraction,[3] it is estimated that less than 10% of intestinal bacteria can be cultured, and an even smaller fraction can be correctly classified. Therefore studies of the intestinal ecosystem may

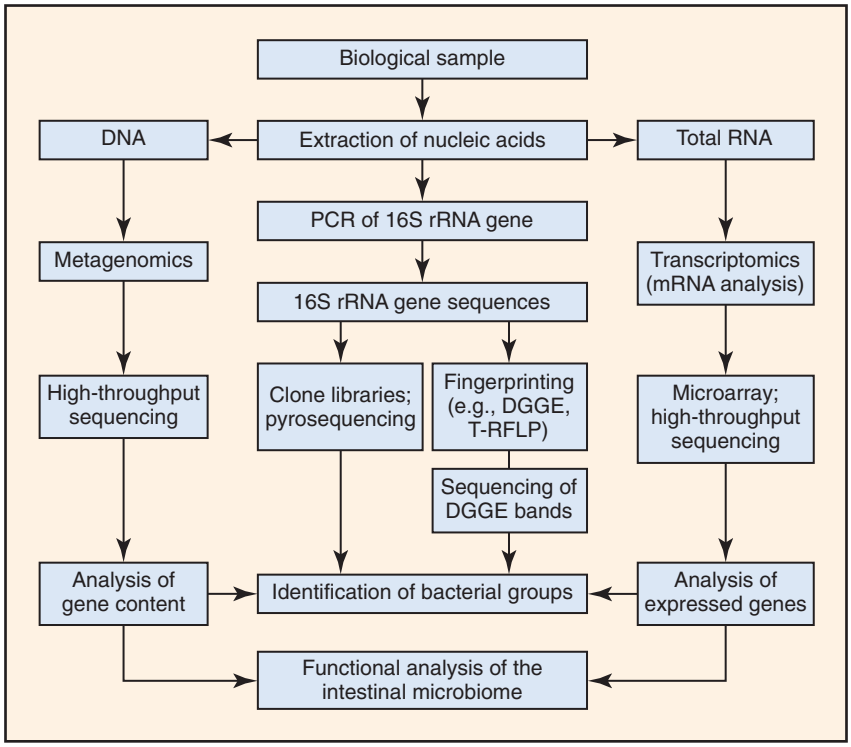

Figure 2-1 Molecular methods for characterization of the intestinal microbiome. PCR amplification of the 16S rRNA (ribosomal RNA) gene allows either direct identification of bacterial phylotypes or the creation of a molecular fingerprint representing the bacterial diversity in a sample. New metagenomic and transcriptomic approaches, based on high-throughput sequencing of DNA or messenger RNA (mRNA) without prior amplification of a specific gene, yield an overview over the gene content of the sample and therefore the functional properties of the intestinal microbiome.

exhibit bias toward the minor cultivable portion of the gut microbiota. The analytical sensitivity of bacterial culture depends on the organism and its growth requirements. Bacterial culture is associated with difficulties in handling, storing, and shipping of clinical specimens. Ideally, samples should be processed immediately to preserve anaerobic species. Many selective culture media lack sufficient specificity, and often organisms other than the target are enumerated.[4] Phenotypic and biochemical identification systems often fail to accurately classify many microorganisms, requiring DNA sequencing of isolates.

Molecular Techniques

Because bacterial culture underestimates microbial diversity, the use of molecular tools has now become the standard approach in microbial ecology.[5-7] The principle of these methods is that DNA or RNA is extracted from intestinal samples, and a specific gene is amplified with universal primers that target conserved regions (located up- and downstream of variable regions within the gene).[8] This approach allows in theory the amplification of DNA from all known and unknown bacterial species in a sample (see Fig. 2-1). The mixture of sequences can then be separated by subcloning and identified by sequencing, or they can be separated by methods that yield a "fingerprint" of the bacterial community.[8,9] The 16S ribosomal RNA (rRNA) gene is most commonly targeted as more than 1.6 million unique sequences are available in public databases (Ribosomal Database Project; http://rdp.cme.msu.edu/). Other more rarely used genomic targets include the 16S to 23S internal transcribed spacer (ITS) region or the chaperonin (cpn60) sequences.[10] If the sequence for a particular phylotype is known, specific PCR assays can be designed for its detection. Real-time PCR assays (with universal-, group-, or species-specific primers) can be used for quantitative analysis. Novel techniques analyze total genomic DNA or messenger RNA (mRNA) without prior amplification of specific genes and yield information about the gene content (metagenomics) or the expressed genes (transcriptomics) of the intestinal microbiome.

Molecular Fingerprinting

Molecular fingerprinting techniques are used for simultaneous analysis and comparison of microbial communities in multiple samples. These techniques provide information on microbial changes over time and in response to treatment. Available techniques include denaturing gradient gel electrophoresis (DGGE), temperature gradient gel electrophoresis (TGGE), and terminal restriction fragment length polymorphism (T-RFLP). The goal is to separate the mixture of PCR amplicons that were generated with broad range primers (universal or group specific) to yield a "fingerprint" of the bacterial community. This is achieved as each bacterial phylotype has a unique nucleotide composition (i.e., guanine+cytosine content). These differences in nucleotide composition result in unique melting behaviors of PCR amplicons. Each PCR amplicon reaches a specific melting point in a different position in a polyacrylamide gel, where it will denature and slow its migration. This banding pattern illustrates the bacterial diversity in the sample (Fig. 2-2). In DGGE, a gel containing a linear gradient of DNA denaturants is used, whereas in TGGE a temperature gradient is used for separation. Bands of interest can be excised and sequenced. DGGE and TGGE are inexpensive and rapidly performed. However, because DGGE/TGGE bands are usually short, only limited resolution of PCR amplicons can be achieved, and many bacterial phylotypes will have similar or

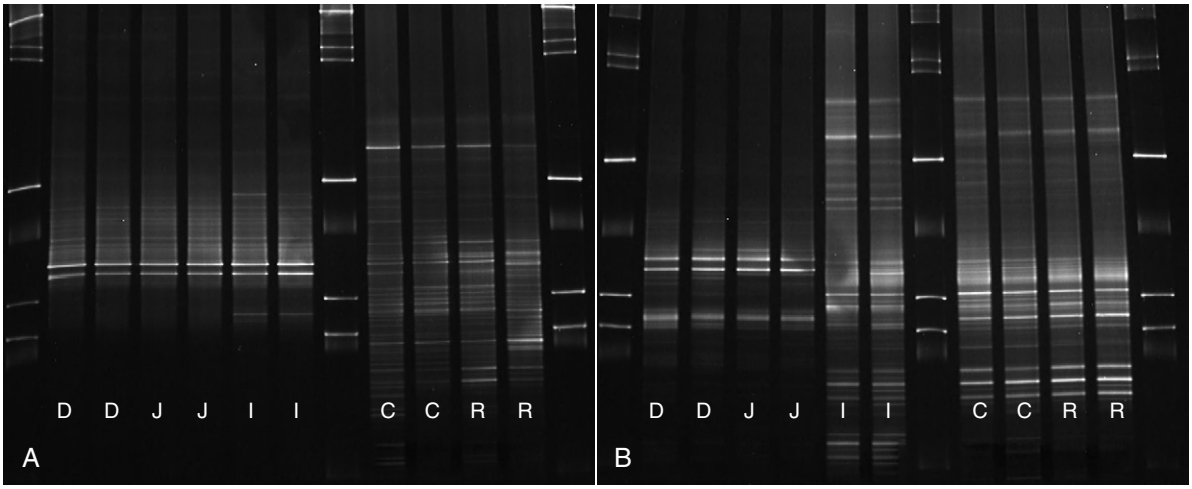

Figure 2-2 Denaturing gradient gel electrophoresis (DGGE) as an example for the use of molecular fingerprinting for profiling and comparison of microbial diversity between intestinal samples. This figure illustrates the differences in bacterial diversity in the various segments of the canine GI tract and the differences in bacterial communities between individual dogs (samples analyzed in duplicate). (C, colon; D, duodenum; I, ileum; J, jejunum; unlabeled lanes represent gel markers).

the same melting behaviors. Therefore, these techniques yield typically only 20 to 40 bands, capturing only changes in the predominant bacterial groups. The use of T-RFLP allows profiling, but also quantification of microbial communities. Bacteria are amplified in PCR assays containing a fluorescent labeled primer. The PCR products are then fragmented by size with sequence specific restriction enzymes. The fragments are separated by capillary electrophoresis with subsequent quantitative measurement of the fluorescence.

Identification of Bacterial Groups

The amplification of the 16S rRNA gene with universal primers that target conserved regions allows amplification of theoretically all bacteria present in the sample. For identification of individual bacterial phylotypes, PCR amplicons must be separated and sequenced. A commonly used method is the construction of 16S rRNA gene clone libraries.[6,7,10] The PCR amplicons are separated by ligation into plasmid vectors with subsequent transformation into *Escherichia coli* cells. These cells are plated on culture medium and grown overnight. Each cell forms a colony containing one plasmid with the original amplified 16S rRNA gene sequence. This plasmid can then be purified and sequenced. Although this approach is informative, it is laborious and not well suited for analysis of large sample numbers. Recently, new high-throughput sequencing platforms have been introduced that allow automated separation of PCR amplicons without the need for subcloning. These platforms (e.g., 454-pyrosequencing, Illumina) allow several thousand sequences to be analyzed within a few hours, yielding a deep coverage of the microbiota.[2,11] However, because of the high bacterial diversity in the intestine, groups of low abundance (especially pathogens of interest) may constitute such a low proportion of the total bacteria, that they still escape identification. Therefore, for the detection of particular groups of interest (i.e., *Bifidobacterium* spp.), the use of group specific PCR primers is recommended.

Techniques based on the 16S rRNA gene also have limitations. Bias is inherent during DNA extraction, primer selection, PCR amplification, and sequence analysis. Some commonly used primers and PCR protocols underestimate the presence of specific bacterial groups, especially those with a high guanine+cytosine content (e.g., *Bifidobacterium* spp.),[7] and some researchers use either a primer mix or group-specific primers for more accurate amplification.[11]

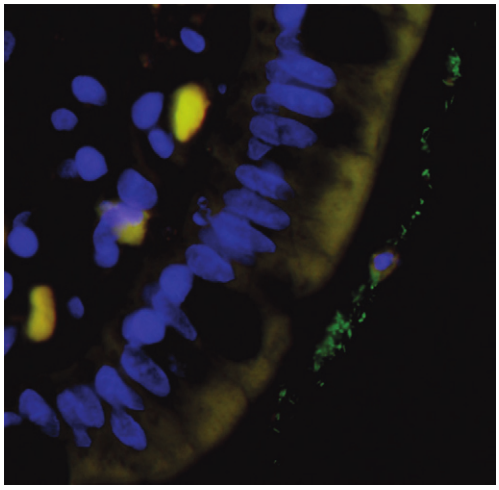

Figure 2-3 Fluorescent in-situ hybridization (FISH). The use of fluorescence-labeled FISH probes allows quantification and visualization of bacteria in relation to the epithelial mucosa (i.e., mucosa-adherent or invasive). This figure shows normal intestinal epithelium. Bacteria (*green*) are located in the mucus adherent to the epithelial cells. (Green, eubacterial probe labeled with 6-FAM; blue, nuclei of epithelial cells labeled with DAPI.) (Courtesy of Kenneth W. Simpson, Cornell University.)

Quantification of Bacterial Groups

Commonly used methods include quantitative real-time PCR assays,[10,12] fluorescent in-situ hybridization (FISH),[13] RNA dot blot hybridization,[14,15] and flow cytometry of fluorescent-labeled probes. Universal-, group-, or species-specific primers can be utilized. FISH allows for quantification of bacterial groups (Fig. 2-3), and this method also permits visualization of the location of bacteria in relation to the epithelium (i.e., intracellular, adherent, or invasive).

There is an inherent bias in use of the 16S rRNA gene for the purpose of absolute quantification. The 16S rRNA genes of bacteria

are organized into "operons" that vary in number from 1 to 15 among individual phylotypes. The operon number may also change during the growth phase and altered activity of cells.[16,17] Consequently, molecular results should be related to absolute cell counts with caution. It is more appropriate to express quantitative results as relative proportions to either total bacteria or to other bacterial groups.

Metagenomics and Transcriptomics

Analysis of 16S rRNA genes has provided new information about the phylogenetic diversity of the intestinal microbiota. However, to understand the impact of the microbiota on GI health it is necessary to (a) identify members of the intestinal ecosystem, and (b) explore the functionality of the microbial community. Metagenomics and transcriptomics are emerging fields in microbiology that are based on high-throughput sequencing techniques or the use of microarrays (see Fig. 2-1). In metagenomics, DNA extracted from a sample is sequenced without prior amplification of specific genes. This results in a snapshot of the gene pool and functional potential of the microbiome. For example, metagenomic approaches have revealed the existence of a "core microbiome" in the intestine, because despite obvious differences in bacterial composition between individuals, these individuals share common microbial genes and metabolic pathways.[18] In transcriptomics, mRNA is analyzed to provide a measure of gene expression within the intestinal microbiome. These techniques are expected to yield more in-depth understanding of microbial-host interactions in health and disease.

The Intestinal Ecosystem in Dogs and Cats

As a result of anatomical and physical differences, each intestinal compartment constitutes a unique ecosystem where microorganisms have their own niche and provide specialized functions by utilizing host nutrients and in return providing metabolites for host uptake (Table 2-1). Molecular studies reveal that each dog and cat has a unique microbial profile.[6,19] The microbiota is similar at higher phylogenetic level between individual animals of the same species, but it differs substantially at the level of species and strain, with typically only 5% to 20% overlap in bacterial species between individual animals. Bacterial counts and diversity increase along the GI tract and may vary between the intestinal lumen and the mucosa.[19,20] Bacterial counts vary between the fed and fasting state. The oral cavity is an important part of the intestinal ecosystem, because bacteria are constantly swallowed and they may be able to colonize parts of the intestine. The composition of the oral microbiota is complex. In one study, 84 different cultivable phylotypes were identified in the oral cavity of dogs, with the major groups being *Actinomyces*, *Porphyromonas*, *Fusobacterium*, *Neisseria*, and *Streptococcus* spp.[21] Oral bacterial counts can reach up to 10^7 colony-forming units per gram (CFU/g). The stomach harbors 10^1 to 10^6 CFU/g, while bacterial counts in the duodenum and jejunum of dogs and cats range from 10^2 to 10^9 CFU/g. This is considerably higher than found in the human duodenum ($<10^5$ CFU/g). Cats appear to have higher counts of anaerobic bacteria in the small intestine compared with dogs.[22] The ileum is a zone of transition between the small and large bowel and contains a more diverse microbiota and higher bacterial numbers (10^7 CFU/mL of contents) than the proximal small intestine. Colonic bacterial counts range between 10^9 and 10^{11} CFU/g of intestinal content. The predominant bacterial groups cultured from the canine and feline intestine include *Bacteroides*, *Clostridium*, *Lactobacillus*, *Bifidobacterium* spp., and Enterobacteriaceae (Table 2-2).

Because the vast majority of intestinal bacteria are not cultivable, molecular analysis (typically based on characterization of 16S rRNA) has expanded knowledge of diversity within the mammalian gut.[2,7] Several thousand individual phylotypes are estimated to inhabit the human colon.[1] There are approximately up to 900 bacterial phylotypes in the canine jejunum.[2] Despite this vast diversity, only 12 of the 55 known major phylogenetic lineages have been observed in the mammalian GI tract (see Table 2-2). The phyla *Firmicutes*, *Bacteroidetes*, *Proteobacteria*, *Actinobacteria*, *Spirochaetes*, and *Fusobacteria* constitute almost 99% of all gut microbiota in dogs and cats. The remaining 1% is represented by the phyla *Tenericutes*, *Verrucomicrobia*, *TM7*, *Cyanobacteria*, *Chloroflexi*, and a few unclassified bacterial lineages. The relative proportions of these groups vary along the GI tract (see Table 2-2). Generally, proportions of aerobic bacteria or facultative anaerobic bacteria are higher in the proximal intestine, while anaerobes predominate in the colon. In the stomach, mucosa-adherent *Helicobacter* spp. predominate, followed by various lactic acid bacteria (e.g., *Lactobacillus* and *Streptococcus* spp.) and *Clostridium* spp. The proximal small intestine is more diverse than the stomach and harbors approximately 10 different bacterial phyla, with Clostridia, *Lactobacillales*, and *Proteobacteria* dominating.[2] *Proteobacteria* and *Spirochaetes* are present in higher proportion in the proximal GI tract and typically represent <1% of sequences in the large intestine of healthy animals. *Firmicutes* is the major group represented in fecal samples (ranging

Table 2-1 Examples of Biochemical Reactions Performed by the Intestinal Microbiota

Microbial Activity	Products	Representatives
Decarboxylation, deamination of amino acids	Ammonia	*Clostridium* spp., *Peptostreptococcus* spp., *Peptococcus* spp.
Deconjugation/dehydroxylation of bile acids	Secondary bile acids (cholate/deoxycholate)	*Clostridium hiranonis*, *Lactobacillus* spp.
Vitamin synthesis	Vitamins K_2, B_{12}, biotin, folate	*Enterococcus* spp., *Pseudomonas* spp., *Sphingomonas* spp., *Lactobacillus* spp.
Carbohydrate fermentation	Lactate, propionate, acetate, butyrate	*Clostridium* cluster XIVa, *Prevotella* spp., *Faecalibacterium* spp., *Bifidobacterium* spp.
Amino acid fermentation	Hydrogen, methane, amines, phenols, ammonia (NH_3), organic acids, hydrogen sulfite	Sulfate-reducing bacteria (SRB), *Desulfovibrio* spp., *Clostridium* spp., *Peptostreptococcus* spp.

Staphylococcus spp.	5.2-5.3	*Desulfovibrio* spp.	N/A

Results were obtained either by bacterial culture,[1,7] 16S rRNA gene sequencing,[36,48] sequencing of the cpn60 gene,[8] or FISH.[23]

between 30% to 95% of 16S rRNA gene sequences in various studies), followed by *Bacteroides*, *Actinobacteria*, and *Fusobacteria*. *Firmicutes* are a heterogenous bacterial phylum. They are represented mainly by the *Clostridiales* and Erysipelotrichaceae. Within those orders, *Clostridium* spp., *Ruminococcus* spp., *Faecalibacterium* spp., *Dorea* spp., and *Turicibacter* spp. are the major groups. Based on phylogenetic analysis, the *Clostridiales* are comprised of at least 70 different species (Table 2-3), which are organized into phylogenetically distinct *Clostridium* clusters. These clusters differ in abundance in different parts of the intestine. Clusters XIVa and IV encompass many important short-chain fatty acid-producing bacteria (see Table 2-3) and predominate in the ileum and colon of both cats and dogs. Cluster XI and I (*Clostridium perfringens* group) are the second most abundant groups in the small and large intestine of dogs and cats.[6,7]

Presence of a Core Microbiome and Functional Redundancy

There are marked differences in the composition of the microbiota between individuals, and even between monozygotic twins. However, the metabolic end products are similar between individuals. Additionally, although some environmental influences lead to significant changes in bacterial groups, these changes are not immediately associated with any obvious changes in gut function in healthy animals. New metagenomic studies have evaluated the gene content of the intestinal microbiota and suggest that the intestine harbors a "core microbiome," because despite observed differences

Table 2-3 Most Abundant Representative of the Various *Clostridium* Clusters in Canine and Feline Fecal Samples

Cluster I
Clostridium perfringens
Clostridium colicanis
Clostridium disporicum

Cluster IV
Faecalibacterium spp.
Clostridium methylpentosum
Ruminococcus spp.

Cluster XI
Clostridium hiranonis
Clostridium bartlettii
Clostridium lituseburense
Clostridium sordellii
Clostridium glycolicum
Peptostreptococcus spp.

Cluster XIVa
Dorea spp.
Roseburia/Ruminococcus group
Clostridium saccharolyticum
Clostridium celerecrescens
Clostridium symbiosum
Clostridium bolteae
Clostridium oroticum
Clostridium methoxybenzovorans
Clostridium algidixylanolyticum
Clostridium hathewayi
Clostridium amygdalinum
Lachnospiraceae

Cluster XVIII
Clostridium cocleatum
Clostridium ramosum

The order *Clostridiales* is the most abundant and most diverse group in the large intestine of dogs and cats, is comprised of at least 70 known species, and constitutes approximately one-third of total colonic bacteria.

in bacterial phylotypes among individuals, the microbiome of each individual appears to have similar gene content and therefore similar functions.[18] Furthermore, a functional redundancy exists in the GI tract. Several members of the community can perform similar functions, and if one group is displaced because of perturbations (e.g., antibiotic therapy), other members of the community are able to maintain a stable ecosystem. These findings highlight the need to evaluate the intestinal microbiome as an entity, including phylogenetic relationships and metabolic functions (i.e., metagenome, transcriptome, and metabolome).

Other Members of the Intestinal Ecosystem

Besides bacteria, the GI tract harbors fungi, archaea, protozoa, and viruses (including bacteriophages). Recent molecular studies have provided information about the diversity of these microorganisms, but their interactions, their influences on the host, and their role in health and disease remain unclear.

Fungi

Specific fungal organisms (e.g., *Histoplasma capsulatum*) are associated with GI disease, but the role of fungal organisms in the intestinal ecosystem has not been studied extensively. Identification and characterization of fungi is technically challenging. Special staining techniques (e.g., Gomori methenamine silver, Gridley fungus, and periodic acid-Schiff stains) improve the detection sensitivity on histologic sections or fecal smears, but do not allow identification of the organisms.[23] Fungal culture is technically challenging, and serologic tests and immunoassays for the detection of fungal antibodies and antigens are only available for specific pathogens.

The significance of fungi for the GI health of dogs and cats remains unclear. Yeasts and molds have been cultured from the intestine of 25% of healthy Beagles, with mean counts of 10^1 CFU/g jejunal content and 10^5 CFU/g of feces.[20,24,25] A higher prevalence of fungal DNA (76% of dogs) was reported in the proximal small intestine in healthy dogs and dogs with chronic enteropathies using a panfungal PCR assay.[26] A total of 51 different phylotypes were identified in the duodenum of 135 healthy and diseased dogs, with the majority of dogs harboring only one phylotype.[26] Fungi were more frequently adherent to the intestinal mucosa than in the luminal content.[26,27] Recent unpublished data from the author's laboratory obtained using panfungal PCR primers followed by 454-pyrosequencing revealed four fungal phyla in canine and feline fecal samples, with the majority of sequences belonging to Ascomycota (>90%) and *Neocallimastigomycota* (>5%). Saccharomycetaceae were the predominating fungal group in fecal samples of dogs and cats (Table 2-4). All 19 animals evaluated harbored fungal organisms, and multiple species (median, 40; range, 10 to 98) were observed in each sample. Each animal had a unique fungal profile.

Table 2-4 Most Prevalent Fungal Genera Identified in Canine Fecal Samples

Fungal Genus	Mean % of Fungal Population	% of Dogs (n = 19)
Catenulostroma	11.4	94.7
Candida	11.6	94.7
Penicillium	2.8	89.5
Aureobasidium	2.9	84.2
Myrothecium	5.6	78.9
Bipolaris	4.2	78.9
Keissleriella	1.0	73.7
Teratosphaeria	1.1	73.7
Phoma	2.7	73.7
Phomatospora	6.0	73.7
Cochliobolus	7.1	68.4
Cladosporium	5.5	57.9
Pyrenophora	1.6	57.9
Aspergillus	1.3	57.9
Hypocrea	1.2	47.4
Phaeosphaeria	2.4	47.4
Shiraia	1.1	47.4
Saccharomyces	0.8	47.4
Pleiochaeta	0.1	42.1
Engyodontium	0.5	42.1
Nomuraea	0.2	31.6
Alternaria	0.7	31.6
Trematosphaeria	0.3	31.6
Dendryphion	0.3	31.6
Helicoön	0.1	31.6
Sporisorium	0.2	31.6
Fusarium	0.1	31.6
other	27	N/A

Fecal samples from 19 dogs living in various environments were analyzed by fungal tag-encoded FLX amplicon pyrosequencing (fTEFAP). Fungi were present in all 19 samples. Multiple species (median, 40; range, 10 to 98) were observed in each sample, but each dog harbored a unique fungal profile.

Archaea

Archaea are single-celled microorganisms with structure similar to bacteria. They are evolutionarily distinct from bacteria and eukaryotes and form the third domain of life. Archaea are obligate anaerobes living in environments low in oxygen (e.g., water, soil). Archaea are commensal in the intestine of ruminants and have recently been described in the human intestine, with *Methanobacteriales* most commonly reported.[28,29] Recent 16S rRNA gene-based studies in the author's laboratory revealed two distinct archaeal phyla in the intestine of dogs and cats: *Crenarchaeota* and *Euryarchaeota*. Similar to man, Methanobacteria were the most abundant class of archaea.

The role of archaea in GI health and disease remains unclear. Methanogens are associated with periodontal disease in man.[30] They are considered commensal in the GI tract, but they may contribute to pathogenicity through mutualistic interactions with other microbes.[31] One major function of methanogens is the scavenging of various fermentation products produced by other microbes (e.g., CO_2, H_2, alcohols, and acetic acid), resulting in the production of methane and CO_2. The reduction of hydrogen promotes an environment that favors the growth of polysaccharide fermenting bacteria, leading to a higher energy utilization of the diet. For example, higher numbers of methanogenic archaea have been observed in obese people.[29] It has also been hypothesized that reduction in hydrogen concentrations results in lower production of hydrogen sulfite by sulfate reducing bacteria, thus reducing damage to epithelial cells.

Viruses

Knowledge of viral communities in the GI tract of dogs and cats is limited to a few families (including rotavirus, coronavirus, and parvovirus). Recent human studies revealed that the viral community in the GI tract is as diverse as the bacterial, with several hundred different phylotypes.[32] The vast majority of these are bacteriophages. It is likely that a similar viral community is present in the intestine of dogs and cats. It remains technically challenging to characterize the viral community because of their heterogeneity (i.e., DNA

viruses, RNA viruses, single-stranded DNA [ssDNA] viruses). Consequently, a universal approach as used for bacteria and fungi is not feasible. New metagenomic approaches show the most promise for the characterization of intestinal viruses.

Dynamics of the Intestinal Microbiota

Host genetics substantially influence the overall composition of the intestinal microbiota. Environmental factors such as antibiotic administration and dietary changes cause shifts in microbial groups, but these changes are individualized for each animal.[2,33] The qualitative microbial composition is stable over long periods of time, but the proportions of individual bacterial groups may have substantial day-to-day variation. The small intestinal microbiota has greater temporal variation compared with the more diverse large intestine.[25]

Changes in Intestinal Microbiota During Life Stages

The intestine harbors permanently colonizing microorganisms that are acquired at birth and remain largely stable over life. Passing microbes (i.e., swallowed) are present only transiently in the GI tract. Within hours after birth, the sterile intestine becomes colonized by bacteria present in the birth canal, milk, and surrounding environment.[34] Shifts in relative proportions of bacteria occur during postnatal development. In one study, bacterial counts in the small intestine were highest in one-day-old puppies and decreased significantly thereafter. They remained stable at approximately 10^7 CFU/g over the observation period of 42 days.[34] Aerobes predominate in the first weeks of life, but the proportion of anaerobes gradually increases with age, mostly because of an increase in *Bacteroidetes*. The major shifts in microbial populations correlate with dietary changes (i.e., suckling and transition to solid food) and the physiologic development of the host's ability to metabolize dietary substrates (e.g., development of intestinal brush-border enzymes) in the first weeks after birth.[34,35] The microbiota increases in diversity in the first few months of life and remains remarkably stable during adulthood. More pronounced changes are observed in older animals (i.e., dogs older than 11 years), especially in the large intestine.[20] These changes are most likely caused by the changing structure and function of the GI tract with increasing age. Older dogs have more *Clostridium perfringens* and *Streptococcus* spp., and fewer *Bacteroides*, *Bifidobacterium*, and *Lactobacillus* spp.[20] DGGE fingerprinting profiles also cluster according to age, and levels of *Bacteroides* are significantly lower in older dogs.[33]

Mechanisms Regulating the Intestinal Microbiota

Several physiologic mechanisms regulate bacterial colonization in the intestine. Gastric acid, bile, and pancreatic enzymes inactivate most ingested microorganisms. Intestinal motility is an important regulator of bacterial counts in the intestine, as microbes that are not able to adhere to the epithelium will be quickly eliminated. In contrast, higher numbers of bacteria are present in the large intestine as a consequence of stagnant flow of luminal content and the abundance of nutrients. The ileocolic valve together with normal intestinal motility prevents retrograde migration of bacteria from the large into the small intestine.[36] Any changes in these control mechanisms may lead to alterations to community composition or total bacterial count. For example, atrophic gastritis or acid suppressant therapy leads to an increase in duodenal bacterial counts in man.[37] Similarly, dogs with experimentally induced exocrine pancreatic insufficiency (EPI) have increased bacterial number in the proximal small intestine.[38] Anatomical malformations (e.g., strictures, surgically created blind loops) associated with altered motility are a common site of bacterial overgrowth in man.

Role of Microbiota in Immunity, Host Defense, and Energy Regulation

A balanced intestinal ecosystem primes and stimulates the immune system, aids in defense against intestinal pathogens, and provides nutritional benefits to the host. Animals can live well when raised under germ-free conditions. However, morphologic and immunologic differences between germ-free and conventionally raised animals suggest that that the commensal microbiota is a significant contributor to the development and maintenance of gut physiology and immune function.[39] Germ-free animals have an altered mucosal architecture (i.e., thinner lamina propria) and reduced turnover of epithelial cells compared with conventionally raised animals.[39] The underdeveloped immune system is rapidly restored upon introducing bacteria into germ-free mice.[40] Bacteria communicate with the host via Toll-like receptors (TLRs) and dendritic cells. The resident intestinal microbiota is a crucial part of the intestinal barrier that protects the host from invading pathogens. This mechanism is called *colonization resistance*. Proposed defenses include the competition for oxygen, nutrients, and mucosal adhesion sites, and the creation of a physiologically restrictive environment for nonresident bacterial species (e.g., secretion of antimicrobials, alterations in pH, and hydrogen sulfide production).[41] Other crucial parts of the intestinal barrier are the intestinal epithelial cells, protective mucus, and the gut-associated lymphoid tissue (GALT). The increase in diversity of the colonizing microbiota at weaning strengthens the colonization resistance against pathogens. Furthermore, the resident microbiota drives maturation of the intestinal immune system. Younger animals with underdeveloped microbial diversity and immature GALT are dependent on protective colostral antibodies and milk components. Younger animals are typically more susceptible to invading pathogens (e.g., *Campylobacter* spp.). Studies of murine models have suggested that the pattern of microbial colonization in early life may impact on host physiology and colonizing resistance far into adulthood.[42]

Bacteria in the large and small intestine can differ in their contribution to GI health. The large intestinal microbiota is mainly beneficial to the host. Clostridiaceae, *Dorea* spp., Lachnospiraceae, *Ruminococcus* spp., *Faecalibacterium* spp., and *Roseburia* spp. are the predominant bacteria in the colon. The majority of colonic bacteria are anaerobic and their main functions are to produce energy from undigested food and to help in the competitive exclusion of potential pathogens. The slower flow of ingesta and the increased time and availability of nutrients favors microbial diversity in the colon. Bacteria within this ecosystem have developed cooperative strategies to transform the complexity of nutrients to their own and the host's benefit. Colonic bacteria provide digestive enzymes that allow utilization of complex carbohydrates. For example, 8% of the genome of *Bifidobacterium longum* is comprised of genes needed for carbohydrate metabolism.[43] Microbes metabolize sloughed epithelial cells, endogenous mucus, and nondigested substrates that have passed through the small intestine. The latter are predominantly complex carbohydrates, including starch and dietary fiber such as cellulose, pectin, and inulin. The fermentation of these substrates results mainly in the production of short-chain fatty acids (e.g., acetate, propionate, and butyrate) that provide energy for bacterial metabolism and for epithelial cell growth. Up to 7% of the metabolic energy of dogs, and to a lesser extent in cats, is produced by

microbial fermentation.[44] Peptides, amino acids, and intermediate products of microbial metabolism such as ethanol, lactic acid, and succinic acid are further metabolized into short-chain fatty acids. Some members of the *Clostridium* cluster XIVa also utilize lactate for butyrate production, thus preventing lactate accumulation in the human colon. However, colonic microbial metabolism of some substrates, mainly proteins, may also yield toxic intermediates with negative effects on epithelial cells.

Small intestinal bacteria have a more delicate relationship with the host. As a result of increased intestinal motility, they are predominantly adherent to the mucosa. These organisms are an important stimulator of mucosal immunity. Subtle changes in this balance may impact on the health of the host. The predominantly facultative anaerobic bacteria may compete with the host for nutrients and may produce deleterious metabolites. In pigs, up to 6% of dietary energy may be lost to the host as a result of bacterial uptake in the small intestine.[45] Small intestinal microbiota, especially *Lactobacillus* spp. and *Clostridium* spp. (*C. hiranonis* and *C. scindens*) deconjugate bile acids, impairing fat absorption and producing secondary bile acids that may damage the epithelium.[46] Other abnormal functions may be dehydroxylation of fatty acids, destruction of brush-border enzymes, damage of carrier proteins, and competition for nutrients (e.g., cobalamin).

Gastrointestinal Microbiota in Disease

The close contact between microbiota and host has significant impact on GI health. Colonization with transient pathogens, overgrowth of resident opportunistic commensals, or altered communication between the intestinal innate immune system and the commensal microbiota may result in GI disease. Invasion of specific pathogens (i.e., *Salmonella*, enterotoxigenic *C. perfringens*, *Campylobacter jejuni*, and others) may profoundly disturb the structure of the GI mucosa. Enteric pathogens can penetrate into the submucosa and Peyer's patches, or produce exo- or enterotoxins that alter enterocyte function. Enterotoxins often stimulate mucosal fluid secretion, while villus effacement and loss of surface area diminishes mucosal absorptive capacity, resulting in diarrhea. Dysfunction of the mucosal barrier can lead to increased intestinal permeability and clinically significant bacterial translocation.[47]

Several GI diseases are associated with nonspecific alterations in the microbiota. Small intestinal bacterial overgrowth or antibiotic-responsive diarrhea (also known as tylosin-responsive diarrhea) is suspected to be caused by an intestinal dysbiosis.[48] Rapid diet changes or dietary indiscretion, changes in the architecture of the intestine, or changes in intestinal motility (e.g., surgical creation of intestinal loops, short bowel syndrome, and resection of the ileocolic valve) are also associated with alterations in the intestinal ecosystem. EPI is associated with an increase in bacterial counts in the canine small intestine, which often is reversible upon pancreatic enzyme supplementation.[38] Such alterations may lead to various mechanisms that will negatively impact the function of the GI tract. Examples are an altered intestinal barrier with increased intestinal permeability, and direct damage to the intestinal brush-border and enterocytes leading to nutrient and vitamin malabsorption. Overgrowth of specific bacterial groups may lead to increased competition for nutrients and vitamins and increased deconjugation of bile acids and creation of potentially deleterious metabolites.

The commensal intestinal microbiota is also thought to play an integral part in the pathogenesis of inflammatory bowel disease (IBD) in man, dogs, and cats.[1,13,49] In man, the microbiota is implicated because inflammation is present in gut compartments with the highest bacterial counts and the diversion of the fecal stream or antibiotic therapy improves clinical signs. In murine models of IBD, inflammation develops only in the presence of bacteria. The cause–effect relationship between microbial alterations and inflammation is not well determined. It is suspected that intestinal inflammation causes a shift toward Gram-negative bacteria (e.g., *Proteobacteria*) that may perpetuate the disease in genetically susceptible individuals. New hypotheses also suggest that intestinal inflammation may trigger alterations in the immune system, which, in turn, diminish the colonization resistance of the resident microbiota, resulting in an overgrowth of pathogens.[50] One current hypothesis implicates an abnormal interaction between commensal bacteria and the intestinal immune system in genetically predisposed individuals.[51] For example, a subset of people with Crohn's disease may not be able to effectively clear commensal or pathogenic bacteria, resulting in overcompensating antibacterial effector T cells that may, in turn, cause tissue damage.[51] People with Crohn's disease have a decrease in the bacterial phyla *Firmicutes* and *Bacteroidetes*, and an increase in *Proteobacteria* and *Actinobacteria*.[1] In most studies of human IBD, a reduction in the diversity of *Clostridium* clusters XIVa and IV (e.g., *Lachnospiraceae*, *Ruminococcaceae*, *Faecalibacterium prausnitzii* and *Clostridium coccoides* subgroups) was identified, suggesting that these bacterial groups, which are mainly producers of short-chain fatty acids, may play an important role in maintenance of GI health. Alterations in microbial composition have also been recently reported in dogs and cats with IBD.[13,49] Similar to people, dogs and cats with idiopathic IBD had significantly more Proteobacteria and reductions in *Clostridium* clusters XIVa and IV in their duodenum compared with healthy animals.[13,49,52] Boxer dogs with histiocytic ulcerative colitis respond to therapy with fluoroquinolones, and in this disease there is an association between the presence of adherent and invasive *Escherichia coli* (AIEC) and inflammation.[53] These AIEC isolates share similarities to those obtained from ileal tissues of people with Crohn's disease.[53]

Modulating the Intestinal Microbiota

Members of *Clostridium* clusters XIVa and IV (e.g., *Dorea* spp., *Lachnospiraceae*, *Ruminococcus* spp., *Faecalibacterium* spp., and *Roseburia* spp.) are consistently depleted in people with IBD and acute colitis,[51] suggesting that these organisms are important in maintaining intestinal homeostasis. This observation emphasizes the need to distinguish the presence of beneficial clostridial groups from opportunistic commensals such as *C. perfringens* and *Clostridium difficile*. Changes in proposed beneficial bacterial groups such as *Bifidobacterium* spp. have also been observed in GI disease, although to a lesser extent. Modulating the intestinal microbial ecosystem is therefore a rational therapeutic approach in animals with GI disease. Clinical experience shows that dietary changes or antibiotic administration often leads to an improvement in GI signs. However, the exact mechanism remains elusive. Antibiotics can eliminate specific pathogens or can, as is also proposed for diets, lead to more general modulations of the intestinal microbiota. This potentially results in a reduced burden of stimulating antigens or the creation of an environment within the GI tract (e.g., changes in osmolarity and pH) that allows for more effective utilization of ingesta.

Because of vast interindividual differences in the intestinal microbiota, it is difficult to define what constitutes a normal and balanced intestinal ecosystem. Dietary manipulation, the administration of antibiotics or pre- and/or probiotics are commonly used modulating strategies. It is important to note that although such interventions may cause shifts in the composition of the intestinal microbiota, these

changes are largely individualized for each animal. Bacterial groups of a higher phylogenetic level (i.e., order or family) may show a synchronized response to the environmental influence, but these changes are rarely associated with one specific bacterial species or bacterial strain that is consistently altered in every individual. As a consequence of the complexity of the microbiota, the vast majority of bacterial groups within the ecosystem remain typically unaffected by diet or nutraceuticals.[33,54] This complicates the prediction as to which animal may benefit most from a selected strategy. Probiotics can lead to a transient increase in the administered target species, but this has an insignificant impact on the composition of the total microbial ecosystem. Furthermore, probiotics are typically eliminated from the intestine within a few days after ending administration. Therefore administration of high doses over prolonged periods of time is usually required. Prebiotics are typically complex carbohydrates that are added to diets to enhance the growth of endogenous microorganisms; including *Bifidobacterium* spp. Increases in bacterial groups that utilize these nutrients have been demonstrated.[55] Such changes are again typically very minor within the entire ecosystem, as the administered prebiotics fulfill only some of the nutrient requirements for their target bacteria, but other essential nutrients remain at growth-limiting amounts. At this point, the significance of altering a rather minor proportion of the ecosystem remains unclear. It is also now well recognized that the microbiota is generally resilient to change and returns rapidly to its pretreatment state within a few days. Consequently, long-term modulation is needed to maintain a desired ecosystem. Antibiotic usage has a more pronounced effect and may disrupt the microbial ecosystem for prolonged periods of time (weeks to months). In one study evaluating the fecal microbiota of healthy people, approximately 30% of all bacterial taxa were affected, some of them for up to six months.[11] Similarly, administration of tylosin for 14 days led to significant modifications in the jejunal microbiota of dogs, with some bacterial groups depressed for more than 14 days.[2] However, highly individualized responses for some bacterial groups were observed in each animal.

Based on these findings, it remains challenging to provide a universal algorithm for modulation of the microbiota. Every animal may require individualized management consisting of combinations of dietary modification, antibiotics, and pro- or prebiotics. Therefore, therapeutic modulation is currently based on empirical approaches with improvement of clinical signs as the most useful outcome measure. New molecular tools such as metagenomics and transcriptomics will be useful for elucidating how such modulatory strategies affect the gene content within the intestinal microbiome. This may help to customize treatment strategies for individual animals and conditions.

CHAPTER 3

Gastrointestinal Immunology

Oliver A. Garden

Introduction

Gastrointestinal (GI) or gut-associated lymphoid tissue (GALT) is part of the mucosal immune system and comprises up to 70% of total body lymphoid tissue. Despite exposure to a vast array of exogenous antigens, the GI immune system is able to discriminate innocuous antigens from pathogens, deploying an array of protective mechanisms to prevent damaging immune responses.

Gastrointestinal Immunoanatomy: Inductive and Effector Sites

The GI immune system is compartmentalized into (a) afferent or inductive sites, where antigen-presenting cells (APCs) prime naive T and B cells to initiate the immune response, either by processing and presenting local antigens or by migration from the lamina propria (LP), an important site of antigen sampling, and (b) efferent or effector sites, where antibody and T-cell–mediated responses are mounted after extravasation, retention, and further differentiation of the lymphocytes. The afferent arm of the GI immune system comprises Peyer patches (PPs), isolated lymphoid follicles (ILFs), and mesenteric lymph nodes (MLNs), while the efferent arm comprises lymphocytes located in the LP and epithelium; cryptopatches, loosely organized clusters of approximately 1000 cells located at the base of the intestinal crypts, have also been described in the mouse. Cryptopatches were originally thought to be sites of extrathymic intraepithelial lymphocyte (IEL) development, but more recent studies suggest that they are precursors of ILFs. Additional species-specific accumulations of lymphocytes include the rare T-cell–dominated "lymphocyte-filled villi" of rats and man, colonic "lymphoglandular complexes" of pigs, and the "continuous ileal PP" of ruminants, pigs, and dogs, which appears to be a primary lymphoid organ responsible for B-cell development.[1-3] Located throughout the small intestine, PPs comprise at least three aggregated lymphoid follicles with an overlying follicle-associated epithelium (FAE) containing microfold (M) cells, specialized epithelial cells that transport antigens from the lumen to the underlying lymphoid tissue. This process, called *transcytosis*, is mediated by mechanisms that include endocytosis of clathrin-coated vesicles, actin-dependent phagocytosis, and fluid-phase pinocytosis or macropinocytosis. M cells express a receptor for secretory (s) immunoglobulin (Ig) A on their apical surface, which facilitates the transcytosis of IgA-coated bacteria to the underlying APC-rich dome region of the PP. M cells lack a rigid internal cytoskeleton and are easily deformed by lymphoid cells migrating into the epithelium; this flexibility allows the creation of a pocket beneath the M cells, from which lymphoid cells can enter and leave without breaching the M-cell membrane. These pockets are thought to represent specialized extensions of the germinal centers of the underlying follicles, and contain equal proportions of memory T and B cells. The subepithelial dome region is rich in $CD11b^-$ and $CD11b^+$ $CD8\alpha^-$ dendritic cells (DCs), potent APCs that capture antigens transported across the M cells. The FAE expresses the chemokines CCL20, CXCL16, and CCL9, creating a micromilieu that attracts the underlying DCs. Following antigen uptake, the DCs either migrate directly to the adjacent interfollicular T-cell zones of the PPs, or pass to the MLNs where they may interact with naive T cells (Fig. 3-1).

The latest literature describes the GALT as including PPs, ILFs, and the appendix, while MLNs are now considered to lie outside the GALT as they do not directly sample luminal antigens. Similarly, the effector sites are not considered *bona fide* lymphoid tissue on the basis of established terminology.

What Is Known in Dogs and Cats?

PPs are recognized in both the dog and cat. There are approximately 20 PPs in the dog, spanning the whole of the small intestine and ranging in size from a few millimeters to 4 cm.[4] The single ileal PP in the dog differs from those of the duodenum and jejunum, with large follicles, a small dome and very little interfollicular tissue.[2,3] The ileal PP has fewer T cells than the proximal PPs, consistent with its putative role in B-cell ontogeny.[2,3] Pinpoint-sized collections of lymphoid follicles resembling PPs are occasionally present in the stomach, colon, and rectum of the dog.[4] Lymphocytes in the paracortical and interfollicular areas of PPs are predominantly $CD4^+$, while B cells in the dome region of canine PPs express IgA or IgG.[2,3] Lymphoid follicles are present throughout the intestine and are the predominant type of aggregated lymphoid tissue in the canine colon and rectum. They comprise isolated follicles of 0.5 to 3 mm that occupy the LP and submucosa, and serve a similar function to the follicles within PPs.[4]

The intestinal LP of the dog contains plasma cells, T cells, and putative DCs.[4-6] Plasma cells are predominantly IgA^+ and are concentrated within the crypt regions in the small intestine and deep LP in the colon; fewer of them are found within the villi and superficial LP of the colon and there is a progressive decline in the density of IgA^+ plasma cells from the duodenum to the ileum.[6-9] In contrast, $CD4^+$ and $CD8^+$ T cells present within the canine LP are concentrated toward the tips of the villi, with no apparent differences in proximal to distal small intestinal distribution.[6,10] The ratio of

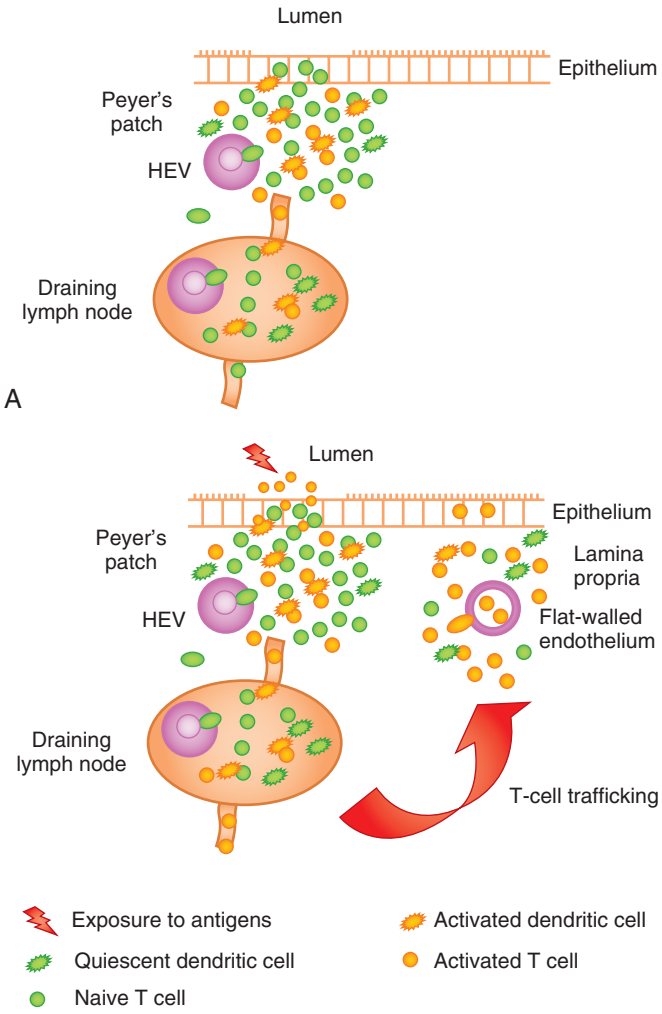

Figure 3-1 Gastrointestinal immunoanatomy: inductive and effector sites. **(A)** Naive T cells continuously migrate from the bloodstream into the inductive sites of the GI immune system, traversing the high-endothelial venules (HEVs) in a multistep extravasation cascade. The lymphocytes then migrate through the tissue in search of their cognate antigens. If these antigens are not found, the T cells leave the lymphoid tissue by means of the efferent lymphatics, to be carried back to the bloodstream via the thoracic duct. From there the cells can continue their journey to other secondary lymphoid organs. **(B)** However, if cognate antigens are encountered, the naive lymphocytes are activated and are imprinted with a preference to home back to the tissues in which they were primed by the resident dendritic cells (DCs), mediated in the case of the GI immune system by upregulation of $\alpha_4\beta_7$ and CCR9 expression by the T cells. Thus, on returning to the systemic circulation via the efferent lymphatics, they preferentially home back to the intestinal lamina propria (LP) to execute their effector functions, this time gaining access to the tissue via the normal flat-walled endothelium of postcapillary venules. Naive B cells also undergo recirculation in a similar manner. The GI immune system is constantly exposed to a plethora of luminal antigens, sampled by M cells and DCs that extend dendrites between the enterocytes; a certain low-level paracellular leak of antigens into the GI mucosa is also thought to occur. Given this constant antigenic exposure, it is not surprising that the majority of LP T cells have an activated or memory phenotype, though recent studies have suggested that constitutive migration of naive $CD4^+$ and $CD8^+$ T cells into the small intestinal LP may also occur. An overly aggressive immune response to luminal antigens, particularly the microbial flora, is thought to underlie inflammatory bowel disease. (Images reproduced with permission from the contributing author.)

$CD4^+$:$CD8^+$ T cells is approximately 60:40 in the LP and 15:85 in the epithelium.[10] Subtractive analysis suggests that a population of $CD3^+CD4^-CD8^-$ cells exists in the canine villus epithelium, thought to represent γδ T cells.[10] Immunohistochemical studies have suggested that αβ and γδ IELs are present in approximately equal numbers in the canine duodenum, jejunum, and ileum.[11] Up to 20 IELs per 100 enterocytes have been counted in each region of the small intestine.[6,11] A more recent flow cytometric study has suggested that αβ IELs outnumber γδ by up to 2:1 in the proximal small intestine and by up to 5:1 in the colon, perhaps reflecting the greater sensitivity of this technique.[12] The distribution of T cells is similar in the feline LP[13,14]; however, IELs in cats are more numerous, with more in the villus than crypt epithelium and a rising count from the duodenum (50 IELs/100 enterocytes) to ileum (80 IELs/100 enterocytes).[14] The majority of feline IELs are $CD8^+$ (up to 50%), with fewer $CD4^+$ cells (up to 10% to 15%) and a sizable population of $CD3^+CD4^-CD8^-$ cells (thought to be $\gamma\delta^+$).[13,14] IgA^+ plasma cells predominate in the small intestine, with increasing numbers around the crypts; however, in contrast to the dog, there is a trend for the number of IgA^+ cells to increase from the duodenum to ileum.[14] IgG^+ plasma cells are more numerous in the feline colon, with fewer IgA^+ and IgM^+ cells.[15] A small number of IgM^+ IELs may be observed in cats,[14] but these are not documented in other species and their significance remains unclear.

A significant number of lymphoid cells within the canine LP are $CD45R^+$, raising speculation that a proportion of the T cells found within this compartment are naive, in contrast with the predominantly effector/memory T-cell phenotype observed in the murine and human LP.[6] A recent study demonstrated that the LP of random source cats has more $CD4^+$ T cells expressing the activation marker CD25 (the interleukin [IL]-2 receptor α chain) than that of specific pathogen-free cats, suggesting that exposure to luminal antigens increases the number of activated/memory T cells within this compartment, in common with other species.[16] Examination of expression of class II molecules of the major histocompatibility complex (MHC) in the canine small intestine reveals a web of subepithelial dendritic-like cells in the villus LP.[10,17] However, the strongest MHC class II expression occurs within the PPs and some expression of this antigen is also apparent within the epithelium, particularly within the ileum.[10,17] A similar pattern of LP MHC class II expression has been documented in the cat, although epithelial labeling was negative in one study[13] and weak and restricted to PPs in another.[14]

Innate and Adaptive Arms of the Gastrointestinal Immune System

Overview

Box 3-1 summarizes the defense mechanisms of the GI tract, including both nonimmune and immune-mediated components.

Pattern Recognition Receptors and the Epithelium

There is increasing recognition of the importance of the innate immune system to GI homeostasis and the pathogenesis of inflammatory bowel disease (IBD). Macrophages, neutrophils, dendritic cells, and intestinal epithelial cells are all able to recognize pathogen-associated molecular patterns (PAMPs) on the surface of a wide variety of microbes by means of pattern recognition receptors (PRRs). Characterized by extracellular leucine-rich repeat domains and the activation of signaling pathways that converge on nuclear factor-kappa B (NF-κB), the Toll-like receptors (TLRs) have emerged as preeminent PRRs of the innate immune system and play

Box 3-1 Defense Mechanisms of the Gastrointestinal Tract

Physical/Biochemical/Microbial
- Normal motility, gastric and pancreatic juices; proteolysis (e.g., lysozyme)
- Cellular proliferation, epithelial barrier (e.g., dynamic tight junctions, mucus[1], trefoil peptides[2], glycocalyx)
- Natural microbial flora (i.e., biofilm)

Innate Immunity
- Complement, defensins,[3] Toll-like receptors (TLRs)[4]
- Intracellular pattern recognition receptors (e.g., nucleotide-binding, oligomerization domain 2 [NOD2])[5]
- Autophagy[6]
- Mast cells, macrophages, neutrophils

Adaptive Immunity
- IgA, IgG, IgM, IgE; dendritic cells, T cells, B cells, plasma cells

Notes:
1. See reference 18 for further information.
2. Members of the trefoil family are characterized by the possession of at least one copy of the trefoil motif, a 40-amino-acid domain that contains three conserved disulfides.[19] Trefoil peptides are synthesized by mucin-secreting GI epithelial cells, including goblet cells, and function to stabilize the mucus barrier. Upregulated at sites of mucosal injury, they also promote angiogenesis and stimulate epithelial cells to migrate into the denuded area of mucosa. Deficient expression of trefoil peptides is thought to predispose to intestinal inflammation and malignancy.
3. Defensins are antimicrobial peptides of two structurally different families (α and β) expressed by Paneth cells in the small intestine (α-defensins) and epithelial and plasma cells in the colon (β-defensins; Paneth cells are rare in the colon). They form micropores in the phospholipid bilayer of bacterial membranes, thus causing loss of structural integrity. Defective synthesis of defensins is thought to contribute to the pathogenesis of Crohn's disease.
4. See next section for information on this important family of pattern recognition receptors.
5. NOD2 is a prototypical NOD-like receptor (NLR) expressed by monocytes, macrophages, dendritic cells, and Paneth cells; it acts as an intracellular microbial sensor whose ligand is muramyl dipeptide, a peptidoglycan motif common to both Gram-positive and Gram-negative bacteria. NOD2 polymorphisms are associated with Crohn's disease, thought to be caused by a decrease in the negative regulation of TLR responses occurring in the normal GI tract, and thus a pathologic increase in responses to the normal flora.
6. "Autophagy" (more specifically: macroautophagy) is a process characterized by the formation of double-membrane cytosolic vesicles (autophagosomes) that deliver their cargo to the lysosome for degradation. The autophagosome is formed by a dynamic process of membrane expansion, rather than budding off from preexisting organelles. Autophagy is important in the maintenance of cellular homeostasis, complementing the ubiquitin-proteasome system in the clearance of proteins; it may also eliminate damaged or surplus organelles. By sequestering invasive microbes, autophagy is thought to play a role in intestinal defense, and abnormalities in autophagy have been associated with Crohn's disease.

an important role in the GI tract. Thus, TLR signaling triggered by commensal bacteria contributes to the maintenance of intestinal epithelial barrier function. Moreover, TLR-9 signaling via exposure to unmethylated CpG motifs (common in bacterial DNA), plays a role in the inhibition of colonic inflammation in a murine model of IBD and is thought to mediate the antiinflammatory effects of probiotics in this system. Several protective strategies have evolved to ensure that inappropriate TLR signaling does not occur in health; for example, expression of TLRs 2 and 4 is confined to crypt enterocytes and the LP in man, niches that would not normally be colonized by commensal flora. Similarly, TLR-5 expression is confined to the basolateral membranes of murine intestinal epithelial cells, ensuring that activation only occurs upon breach of the epithelial barrier by bacteria bearing the TLR-5 ligand, flagellin. In contrast, TLR-3 is mostly expressed by mature epithelial cells facing the lumen, since its ligand (viral double-stranded RNA [dsRNA]) is not normally a component of the GI microflora and would therefore warrant an inflammatory response if detected. The intestinal epithelium is thus increasingly recognized as a sentinel for the GALT, interrogating the composition of the microbial flora and helping to orchestrate appropriate immune responses in health. It is a source of a wide range of cytokines that can promote the recruitment and activation of immune cells, including tumor necrosis factor (TNF)-α; transforming growth factor (TGF)-β; IL-1, IL-6, IL-7, IL-8, and IL-10; monokine induced by interferon (IFN)-γ (MIG); IFN-inducible T-cell-α chemoattractant (ITAC); macrophage inflammatory protein (MIP)-3α; CXCL-9, -10, and -11; and fractalkine. A triad of cytokines produced by the intestinal epithelium (thymic stromal lymphopoietin [TSLP], IL-25 [IL-17E], and IL-33) promotes the development of T-helper type 2 (Th2) responses and serve immunoregulatory properties. These latter may be direct, for example, TSLP-mediated inhibition of IL-12/23p40 expression by GALT DCs and facilitation of the peripheral induction of regulatory T cells (Tregs), or indirect, for example, IL-25- and IL-33-mediated downregulation of IFN-γ and IL-17A by the reciprocal induction of Th2 cytokines.

To date, TLRs 2 to 5, 7, and 9 have been cloned in the dog, and peripheral blood mononuclear cells are known to express TLRs 2 and 4.[20-22] The complete sequences of TLRs 4 and 9 have been cloned in the cat,[20] but only partial sequences have been cloned for TLRs 1 to 3 and 5 to 8.[23] Real-time polymerase chain reaction (PCR) assays have been developed for detection of messenger RNA (mRNA) encoding TLRs 1 to 9, and these have shown mRNA encoding TLRs 2 to 5 and 7 to 9 within feline T and B cells.[23] Immunohistochemistry and immunogold electron microscopy have provided evidence for the expression of TLR-4 (the receptor for lipopolysaccharide [LPS]) by macrophages in the canine lung, small intestine, liver, and spleen; epithelial cells within the lung, small intestine, cornea, and renal tubules were also labeled by this cross-reactive antibody.[24] Primary colonic epithelial cells in the dog express mRNA encoding the nucleotide-binding oligomerization domain 2 (NOD2) and TLRs 2 and 4, and IL-7 and IL-8 responses can be elicited by exposure of these cells to the respective ligands, peptidoglycan (TLR-2) and LPS.[25] A recent study has also suggested that TLRs 2, 4, and 9 (all responsive to bacterial products) are upregulated in canine IBD; furthermore, respective mRNA transcript abundance showed no change with therapy despite clinical improvement, raising the intriguing possibility of a primary defect representing a genetic predisposition, as described in human IBD.[26] This important group of PRRs is likely to remain the focus of continuing research.

Lymphocyte Trafficking, Activation, and Gastrointestinal Imprinting

Naive T cells continuously migrate from the bloodstream into the inductive sites of the GALT, traversing the high-endothelial venules (HEVs) in a multistep extravasation cascade involving (a) tethering and rolling mediated by sialomucins and selectins (e.g., peripheral lymph node addressin [PNAd] expressed by HEVs interacting with L-selectin [CD62L] expressed by naive T cells); (b) activation, firm adhesion, and transmigration, mediated by chemokines, integrins, and Ig superfamily members (e.g., intercellular cell adhesion molecule-1 [ICAM-1] and mucosal addressin cell adhesion

molecule-1 [MAdCAM-1] expressed by HEVs respectively interacting with leukocyte function antigen-1 [LFA-1] and the integrin $\alpha_4\beta_7$ expressed by naive T cells); and (c) chemotaxis mediated by chemokines (e.g., CCL19 and CCL21 produced by stromal cells and presented on the luminal face of HEVs, interacting with CCR7 expressed by naive T cells). The lymphocytes then migrate through the tissue parenchyma in search of cognate antigen. If these antigens are not found, the T cells leave the lymphoid tissue via the efferent lymphatics, to be carried back to the bloodstream via the thoracic duct; from there, the cells can continue their journey to other secondary lymphoid organs. However, if cognate antigens are encountered, the naive lymphocytes are activated and are imprinted with a preference to home back to the tissues in which they were primed by the resident DCs, mediated in the case of the GI immune system by upregulation of $\alpha_4\beta_7$ and CCR9 expression by the T cells. Thus, on returning to the systemic circulation via the efferent lymphatics, these T cells preferentially home back to the intestinal LP to execute their effector functions, this time gaining access to the tissue via the normal endothelium of postcapillary venules (see Fig. 3-1). To an extent, they may also re-enter the PPs and MLNs by means of $\alpha_4\beta_7$–MAdCAM-1 interactions. The vitamin A metabolite, retinoic acid (RA), appears to be implicated in imprinting intestinal tropism (high-level $\alpha_4\beta_7$ and CCR9 expression) onto activated $CD4^+$ and $CD8^+$ T cells. DCs from MLNs and PPs express the enzymes catalyzing the production of RA from retinol, thus equipping them with the molecular machinery required for imprinting. CCL25 expressed by the small intestinal epithelium and presented on the surface of HEVs is also important in mediating the chemotaxis of $CCR9^+$ T cells into the LP and towards the epithelium. Naive B cells undergo recirculation in a similar manner; however, CXCL13 presented by HEVs adjacent to or within the lymphoid follicles interacts with CXCR5 expressed by naive B cells, which are, in turn, attracted to the mantle zone by CXCL13 deposited on the dendrites of follicular DCs. B cells undergo priming just outside the lymphoid follicles by interactions with cognate T cells and APCs, before reentering the follicles and migrating to the germinal centers. The B cells may then leave the follicles as memory/effector cells. During inflammation, the recirculation routes of lymphocytes may be broadened, thus helping to explain the extraintestinal manifestations of certain GI infections and IBD. In contrast to the conventional view that naive T cells migrate only to lymphoid tissues, failing to gain access to extralymphoid sites, recent studies show constitutive migration of naive $CD4^+$ and $CD8^+$ T cells into the small intestinal LP. However, the majority of cells in this compartment show an activated or memory phenotype.

The polymeric Ig receptor (pIgR) is expressed on the basolateral surface of intestinal epithelial cells and mediates endocytosis and transcytosis of J chain–linked dimeric IgA or pentameric IgM (Fig. 3-2). The ectodomain of the pIgR, termed the *secretory component* (SC), is cleaved at the junction with the membrane-spanning region and binds covalently to one of the sIgA molecules in each dimer, affording protection against proteolysis; it associates with the IgM molecules in a noncovalent manner, remaining in dynamic equilibrium with free SC in the local microenvironment. There are two potential routes of transmission of locally produced and serum-derived IgG into the intestinal lumen. The first is passive, involving the paracellular diffusion of IgG, whereas the second involves the neonatal Fc receptor (FcRn), which is an MHC class I–related molecule that binds to the Fc domain of IgG. The FcRn is important in neonatal life as it mediates transfer of colostral IgG across the intestinal epithelium. Expression of FcRn is downregulated at the time of weaning in rodents, but continues into adulthood in man. Little is known about the FcRn expression in other species, although FcRn was recently characterized in piglets.

FcRn is expressed by placental syncytiotrophoblasts, endothelial cells, pulmonary and mammary epithelial cells, renal podocytes, hepatocytes, monocytes, macrophages, dendritic cells, and neutrophils. The receptor is thought to have an important role in GI immune surveillance as it shuttles IgG from the basolateral to apical membrane of enterocytes, where IgG binds bacterial antigens. The IgG-antigen then undergoes transcytosis back to the basolateral membrane where there is stimulation of local and systemic immune responses. FcRn can thus act as an immunologic sensor for activity within the lumen of the human GI tract, but it is not known whether there is a similar role for FcRn in dogs and cats. Similar antibody shuttling from the basolateral to the apical membrane of enterocytes and back has been described for IgE in the context of food allergy or the presence of parasites, but this involves the CD23 molecule.

Mucosal Ig in the dog and cat is thought to derive from serum transudation (IgG) and local production by resident plasma cells (IgA and IgM; and IgG in the colon).[5,27,28] A canine small intestinal explant culture system has confirmed that IgA is synthesized by local plasma cells.[29] Canine serum IgA is dimeric and largely synthesized by GI lymphoid tissues,[30] but there is a lack of correlation with duodenal secretory IgA, suggesting that measurement of serum IgA concentration is a poor correlate of GI mucosal immunity.[31] Similarly, salivary IgA concentration also correlates poorly with duodenal IgA concentration.[31] The value of measuring fecal IgA is controversial, one study suggesting that it may reflect mucosal secretory IgA concentration[32] and another concluding that it is of limited value.[33] This discrepancy may in part relate to the reagents used in the IgA detection system employed in some investigations.[33] Quantitative reverse transcriptase (RT) PCR has revealed the presence of mRNA encoding the α chain, pIgR, and J chain in the canine duodenal mucosa, suggesting that dogs employ a similar mechanism of IgA transcytosis to that of other species, but differences in expression were not found when tissues from animals with and without chronic diarrhea were compared.[34] Four different allelic variants of the canine *IGHA* gene are reported,[35,36] but the functional significance of this finding is unclear. Feline IgA has been studied as a human allergen,[37,38] but little is known about epithelial transcytosis of this molecule.

Immune Privilege and Oral Tolerance

Overview of Mechanisms

The conventional paradigm of immune privilege as a form of protection from immune responses that is conferred by anatomical sequestration has been revised in recent years. There is now increasing recognition of the part played by active immunologic mechanisms at these sites (e.g., apoptosis of autoreactive T cells mediated by Fas-FasL interactions) and modern immunology has adopted a broader, more inclusive concept of this phenomenon, which now embraces all sites harnessing regulatory mechanisms to suppress pathologic immune responses against local antigens. Thus, the GI tract may be considered as a site of immune privilege resulting from the complex interactions between the microflora, dietary antigens, and GI immune system. Tolerance of dietary and GI microbial antigens (oral tolerance), defined experimentally by the inability to elicit systemic immune responses to antigens sampled by the oral route, is achieved following interactions between the intestinal barrier and epithelial tight junctions, phagocytes, tolerogenic DCs, and Tregs. Breakdown in these mechanisms is thought to underlie

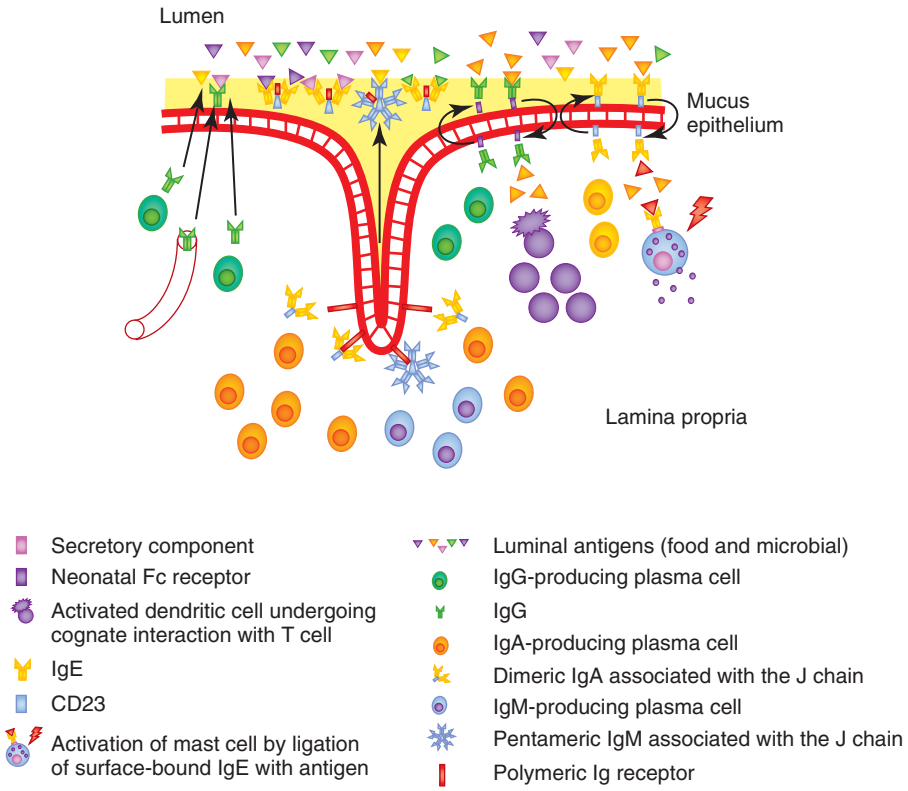

Figure 3-2 An overview of gastrointestinal immunoglobulins. The predominant gastrointestinal immunoglobulin (Ig) is IgA, produced as a dimer associated with the J chain; IgM is also produced by mucosal plasma cells in association with the J chain, in the form of a pentamer. In addition, the J chain is synthesized by a proportion (70% to 90%) of IgG-producing plasma cells, but does not combine with this isotype and thus undergoes intracellular degradation. IgA and IgM molecules are transported across the epithelium by means of the polymeric Ig receptor (pIgR), expressed on the basolateral surface of secretory epithelial cells. At the apical surface, the extracellular ligand-binding region of pIgR, known as the secretory component (SC), is cleaved and released in the free form or as a component of secretory IgA or IgM. SC has intrinsic antimicrobial properties and protects secretory IgA (sIgA) and sIgM from proteolytic degradation. Expression of the pIgR is regulated by microbial products via Toll-like receptor signaling and host factors, such as proinflammatory cytokines. Locally produced and plasma-derived IgG makes its way into the lumen via paracellular pathways and by active shuttling mediated by the neonatal Fc receptor; antigen molecules captured at the luminal surface may then be transported into the mucosa, where they may be sampled by local dendritic cells (DCs), leading to their activation and interaction with cognate T cells either in situ or following DC migration to the mesenteric lymph nodes. A similar cycling of IgE mediated by CD23 also occurs in allergic states, leading to the degranulation of mast cells and a local type I hypersensitivity response. Ig molecules act as a first line of defense, mediating immune exclusion of antigens in the mucus layer. IgA is also thought to bind antigens in the lamina propria, "excreting" them into the lumen, and has an antimicrobial action within the epithelium. (Image reproduced with permission from the contributing author.)

IBD. Tregs playing a role in the immunologic homeostasis of the GI tract include those characterized by constitutive expression of the CD25 and the transcription factor FoxP3 ($CD4^+CD25^+FoxP3^+$), and others characterized by the synthesis of immunomodulatory cytokines, such as IL-10 (Tr1) and TGF-β (Th3). These distinctions are not absolute and cells with overlapping characteristics are described in murine models. The mechanisms responsible for the induction of oral tolerance are believed to be dependent on the feeding protocol used. High doses of oral antigen favor clonal deletion or functional quiescence (anergy) of T cells and low doses favor the induction of Tregs. However, Tregs have been elicited by both low- and high-dose protocols, and the different mechanisms are not mutually exclusive. Oral tolerance suppresses experimental autoimmune diseases following feeding of incriminated antigens. Experimental autoimmune encephalomyelitis, arthritis, and type 1 diabetes mellitus have been prevented or ameliorated in this way. These observations have underpinned clinical trials that have assessed the efficacy of this approach in human patients with type 1 diabetes mellitus, multiple sclerosis, rheumatoid arthritis, and uveitis, but the outcomes of these trials have been variable and somewhat disappointing. Tregs have been identified in dogs[39-43] and in cats in the context of feline immunodeficiency virus infection,[44-48] but little is known about the role of these cells in the canine and feline GI tract. Oral tolerance is readily induced in the dog, a recent study demonstrating that the ingestion of ovalbumin ameliorated conjunctivitis, clinicopathologic markers of asthma, and serum titers of ovalbumin-specific IgE and IgG elicited by ocular and airway provocation of presensitized beagles.[49]

Microbiota and Dysbiosis

The full complexity of the GI microbiota and its profound influence on local and systemic immune responses is now well recognized (see Chapter 2). The majority of bacterial species populating the GI tract cannot be cultured, leading in the past to gross underestimates of the number of organisms and the composition of this population. The total microbial load of the human GI tract (10^{13} to 10^{14} microorganisms) contains more than 100 times as many genes (the "microbiome") as the human genome. People may thus be considered "metaorganisms" with a vast, integrated community of prokaryotic symbionts, commensals, and pathobionts,

which in health remains finely balanced. Absolute numbers of organisms vary from 10^{11} cells/g content in the ascending colon to 10^7 to 10^8 cells/g in the distal ileum and 10^2 to 10^3 cells/g in the proximal ileum and jejunum. Anaerobes are several orders of magnitude more abundant than aerobes and eukaryotic fungal organisms have also been identified as components of the microbiota. More than 99% of the human GI microbiota comprises species within four bacterial phyla (*Firmicutes*, *Bacteroidetes*, *Proteobacteria*, and *Actinobacteria*). Most members of the microbial community are indigenous and stable (autochthonous), but some (e.g., the majority of pathogens) may be transient (allochthonous). General functions of the microbiota in health include the following: (a) the provision of short-chain fatty acids as an energy source and the synthesis of vitamins; (b) the maintenance of local and systemic immune regulation by effects on both the innate and adaptive immune system, including the induction of Tregs; (c) stimulatory and cytoprotective effects on the epithelium, helping to preserve the barrier function of the GI tract; and (d) the competitive exclusion of pathogens. Disturbances in the composition of the microbiota (dysbiosis) that favor pathobionts at the expense of symbionts and commensals are thought to promote intestinal inflammation, leading to IBD in individuals with an appropriate genetic background. Factors that are thought to contribute to dysbiosis include host genetic factors (e.g., mutations in the *NOD2* gene), lifestyle issues (e.g., psychological or physical stress and a poor diet), and medical practices (e.g., excessive antibiotic use and overly stringent sanitation). Whether dysbiosis directly causes disease or merely represents an epiphenomenon of an altered intestinal microenvironment remains unclear, but several lines of evidence point to its pathogenic significance. For example, most studies of human IBD show decreased microbial diversity in active disease, associated with increased relative abundance of the *Enterobacteriaceae* and decreased representation of the *Firmicutes*, with selectively diminished *Clostridium* spp. Some patients with Crohn disease have decreased numbers of *Faecalibacterium prausnitzii*, and the same organism is known to increase the synthesis of IL-10 by human peripheral blood mononuclear cells in culture, decrease the activation of NF-κB and the synthesis of IL-8 by Caco-2 cells, and ameliorate the severity of trinitrobenzene sulfonic acid–induced colitis in mice.

The GI microbiota of dogs and cats in health and disease has now been examined (Fig. 3-3). Interactions of the duodenal microflora with the underlying mucosa were recently investigated in a cohort of 17 client-owned cats with IBD, making comparisons with 10 healthy colony cats.[50] The number of mucosa-associated *Enterobacteriaceae* as determined by fluorescence in-situ hybridization (FISH) with probes to 16S rDNA was higher in cats with GI disease than healthy cats. Furthermore, total numbers of mucosal bacteria were strongly associated with changes in mucosal architecture and the density of macrophage and T-cell infiltrates.[50] The number of *Enterobacteriaceae*, *E. coli*, and *Clostridium* spp. correlated with abnormalities in mucosal architecture, upregulation of mRNA encoding IL-1, IL-8, and IL-12, and severity of clinical signs, raising the possibility that the bacteria contributed to the pathogenesis of IBD in these cats.[50] FISH was also used to explore the fecal microflora in 11 individually housed colony cats with IBD, making comparisons with 34 healthy colony cats. Total bacteria, *Bifidobacterium* spp. and *Bacteroides* spp. were all more abundant in the healthy cats, whereas *Desulfovibrio* spp. (which produce toxic sulfide moieties that may elicit mucosal inflammation) were more abundant in the colitic cats, supporting the notion of dysbiosis in IBD and raising the possibility that bacterial metabolites may directly injure the feline intestinal mucosa.[51]

Similar studies have also been performed in the dog. The first suggestion that the enteric flora could be implicated in the pathogenesis of chronic intestinal inflammation in the dog came with the association of adherent and invasive *E. coli* with histiocytic ulcerative colitis in Boxers,[52] a disease that was previously thought to represent an unregulated, idiopathic immune-mediated response. Moreover, antibiotic therapy was effective in eliciting remission of disease and was associated with the eradication of invasive intramucosal *E. coli*, supporting the notion that the bacteria were involved in its pathogenesis. The microbiota of the duodenum in 10 dogs with IBD was defined by means of 16S ribosomal RNA (rRNA) gene sequencing of brush samples collected during diagnostic endoscopy, making comparisons to nine healthy control dogs.[53] Species richness was significantly lower in dogs with IBD, and was enriched in sequences from the families *Enterobacteriaceae* (the majority classified as *E. coli*–type sequences) and *Clostridiaceae*. Moreover, there was a positive correlation between the number of clones belonging to the family *Clostridiaceae* and clinical severity score, and a trend between the number of clones belonging to the family *Enterobacteriaceae* and histopathologic severity.[53] These data suggest that imbalances of the intestinal microbial community may occur in canine IBD; however, remaining questions include the following: (a) What is the impact of breed on determinations of microbial diversity? (b) What are the specific organisms associated with IBD versus other intestinal diseases? and (c) What is the primary or secondary pathogenic significance of dysbiosis in canine IBD?

Increasing awareness of the role of dysbiosis in the pathogenesis of intestinal and extraintestinal diseases has driven a globally concerted effort to manipulate the GI microflora for therapeutic gain, by means of antibiotics, prebiotics, probiotics, and synbiotics (mixtures of pre- and probiotics). Among these strategies, probiotics have attracted considerable commercial interest in human and veterinary medicine, despite often sparse research substantiating their benefit. Proposed mechanisms of probiosis include remodeling of microbial communities and suppression of pathogens; upregulation of antiinflammatory factors such as TGF-β and IL-10 produced by mononuclear cells; downregulation of proinflammatory factors such as TNF-α and IL-8 produced by epithelial cells; promotion of tolerogenic DCs and induction of Tregs; and preservation of intestinal barrier function. Human GI diseases in which probiotics have elicited beneficial responses include acute gastroenteritis, antibiotic-associated diarrhea and colitis, IBD, irritable bowel syndrome, and necrotizing enterocolitis. Various organisms with potential probiotic qualities (e.g., species specificity, nonpathogenicity, resistance to digestion by gastric acid and intestinal enzymes, and ability to adhere to the intestinal epithelium and influence host immune responses) have been identified in dogs[54-58] and cats,[59-61] offering promise in the treatment of GI diseases in these species.[62] For example, a probiotic cocktail of *Lactobacillus acidophilus* (strains NCC2628 and NCC2766) and *Lactobacillus johnsonii* (NCC2767), originally derived from fecal isolates of dogs without GI signs, was able to increase tissue mRNA and supernatant protein concentration of IL-10, and to decrease the ratio of TNF-α/IL-10, IFN-γ/IL-10, and IL-12p40/IL-10 tissue mRNA in duodenal biopsies derived from dogs with chronic enteropathies, when cultured with the probiotic cocktail in vitro for 20 hours.[63] However, the same cocktail yielded less-convincing results when administered to dogs with food-responsive diarrhea alongside an elimination diet for 4 weeks. Followup biopsies failed to show an increase in regulatory cytokine mRNA in the dogs treated with probiotics, but the influence of the probiotic might already have occurred by the time the follow up biopsies were collected.[64] Both the probiotic and placebo

Figure 3-3 Granulomatous colitis of Boxer dogs is characterized by a mucosally invasive microflora. Granulomatous colitis (GC) of Boxer dogs, also known as histiocytic ulcerative colitis, typically affects individuals younger than 5 years of age and is characterized by hemorrhagic, mucoid diarrhea, anemia, hypoalbuminemia, weight loss, and thickening and ulceration of the colon with loss of epithelium and goblet cells and the accumulation of periodic acid-Schiff (PAS)–stained macrophages. It has features in common with ulcerative colitis, including its macroscopic appearance, regional distribution, and immunopathology; Crohn's disease, including its predominantly granulomatous nature, the presence of bacteria within macrophages, and the clinical response to fluoroquinolones; and Whipple disease, including the accumulation of PAS-positive macrophages. Recent years have seen significant advances in our understanding of this disease, which is thought to involve adherent and invasive *Escherichia coli*. One of the tools used to explore this disease and others in veterinary gastroenterology is fluorescent in-situ hybridization (FISH) with probes to conserved and variable regions of the ribosomal 16S subunit. **(A)** The eubacterial probe *EUB-338* (GCTGCCTCCCGTAGGAGT) has been applied to examine the distribution of bacteria within colonic biopsies from Boxer dogs with GC. Bacteria within the normal colon, identified by means of epifluorescence microscopy using the probe cyanine (Cy) 3-*EUB-338* (*red; arrows*), are confined to the surface mucus layer and colonic glands; nuclei are stained blue in this section by means of 4′,6-diamidino-2-phenylindole (DAPI) (×400). **(B)** In GC of Boxer dogs, clusters of bacteria hybridizing with Cy3-*EUB-388* (*red*) are scattered throughout the upper third of the mucosa, clumps of small coccobacilli (1 to 3 μm) most commonly observed in areas in which goblet cells and glands are replaced by a cellular infiltrate (×400). **(C)** Bacteria may often be found within cells, identified here with Cy3-*EUB-338* (*red*) and fluorescein isothiocyanate (FITC)–antivimentin (*green*), labeling nuclei with DAPI (*blue*; n = nucleus) (×600). **(D)** Gram staining reveals that the invasive bacteria are Gram-negative coccobacilli within macrophages (*arrows*) (×1000). Further studies, including culture of affected mucosa, 16S sequencing, and FISH with specific probes, suggested that the bacteria incriminated in GC of Boxer dogs are adherent and invasive *E. coli* resembling the *E. coli* associated with Crohn's disease. (The work illustrated in this figure was performed in the laboratory of Dr. K. Simpson, College of Veterinary Medicine, Cornell University; the images have been reproduced from *Infection and Immunity* 74:4778, 2006 with permission from the American Society for Microbiology.)

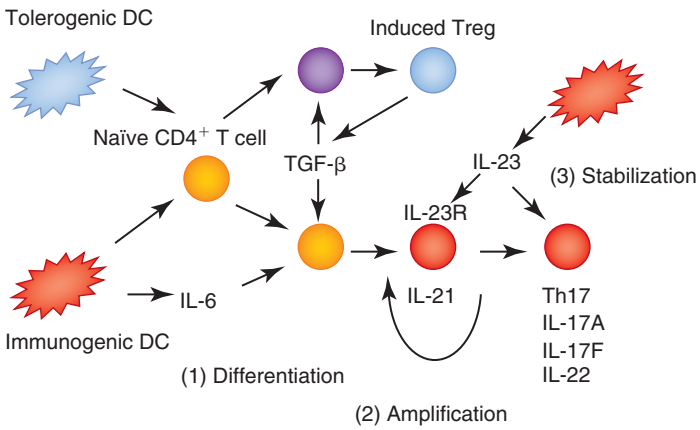

Figure 3-4 Steps in the differentiation of Th17 cells. (1) The activation of naive T cells in the presence of TGF-β and IL-6 initiates the Th17 differentiation pathway; more recently, TGF-β in combination with IL-21 was also shown to induce the differentiation of Th17 cells. The cellular source of these cytokines remains controversial: although IL-6 is produced by activated antigen-presenting cells (e.g., dendritic cells; DCs) on engagement of specific pathogen-recognition receptors (e.g., Toll-like receptors) and IL-21 may be produced by natural killer (NK) and NK T cells in the absence of IL-6, the source of TGF-β could be either Tregs present in the same microenvironment (as illustrated) or the DCs stimulating Th17 differentiation. (2) IL-21 is an important cytokine produced by Th17 cells themselves, amplifying their generation in an autocrine manner and inducing the expression of the IL-23 receptor. IL-23 expands and stabilizes Th17 cells, which express IL-17A, IL-17F, and IL-22, in addition to IL-21. Signal transducer and activator of transcription (STAT) 3 plays a critical role in Th17 differentiation, as IL-6, IL-21, and IL-23 all depend on this factor for intracellular signaling. In contrast to other lymphoid sites, the gastrointestinal immune system is able to support the constitutive differentiation of Th17 cells. Thus, $CD103^-$ ($\alpha_E\beta_7^-$) and $CD103^+$ ($\alpha_E\beta_7^+$) DC subsets in the intestine and mesenteric lymph nodes direct the differentiation of Th17 cells and Tregs respectively, attributed to the ability of $CD103^-$ DCs to produce large amounts of IL-6 but small amounts of TGF-β, and vice versa for $CD103^+$ DCs. While the differentiation of Th17 cells and Tregs is generally thought to proceed in a reciprocal fashion, parallel differentiation in the GI tract may occur.[217] Both Th1 and Th17 cells are implicated in Crohn's disease, but Th17 cells have not yet been explored in dogs and cats. (Image reproduced with permission from the contributing author.)

groups showed a decrease in the number of colony-forming units of *Enterobacteriaceae* per milliliter of fecal material after 4 weeks, concordant with other studies in dogs implicating this family of bacteria in the pathogenesis of chronic enteropathies.[64] Furthermore, a recent study failed to demonstrate any benefit of the immune-enhancing probiotic *Enterococcus faecium* strain SF68 in dogs with chronic, naturally acquired, subclinical giardiasis, in contrast to its ability to decrease giardial cyst shedding and antigen load in rodents.[65] This probiotic has yielded variable results in cats, appearing to ameliorate the morbidity associated with chronic felid herpesvirus-1 infection in experimental, group-housed cats in one study,[61] but failing to alter immune parameters (other than increasing the percentage of peripheral $CD4^+$ lymphocytes) in another.[60] Fewer studies of probiotics have been performed in cats than dogs, but *L. acidophilus* strain DSM13241 has shown promising results in healthy adult cats, increasing the number of beneficial *Lactobacillus* spp. and decreasing the numbers of *Clostridium* spp. and *Enterococcus faecalis* in feces. Furthermore, phagocytic activity of peripheral granulocytes was increased and plasma endotoxin concentration and erythrocyte osmotic fragility were decreased in cats receiving this probiotics.[59] A number of studies have also shown the potential benefit of prebiotics based on the fructan sources inulin and fructooligosaccharides[66] on the intestinal microflora and selected metabolic and immunologic parameters of dogs[67-72] and cats.[73]

Inflammatory Pathomechanisms

In genetically predisposed individuals, tolerance of dietary antigens may break down and lead to the development of Th2-mediated food allergies, characterized by the excessive production of IgE.[74-76] Similarly, defective tolerance of the intestinal microflora contributes to the pathogenesis of IBD, including human Crohn disease (a transmural granulomatous ileocolitis that may be segmental, but which often involves the terminal ileum) and ulcerative colitis (a superficial ulcerative disease of the colon and rectum, with lamina propria infiltration by neutrophils and microabscessation). Crohn disease is generally thought to be driven by Th1 inflammation and ulcerative colitis by Th2, but increasing awareness of the role played by IL-23 and Th17 cytokines in GI homeostasis and inflammation has led to a revision of this simplified viewpoint. IL-23 is a heterodimeric cytokine belonging to the IL-12 family and comprising the subunits IL-12p40 and IL-23p19. IL-23 is an essential component of the mucosal protective immune response, particularly against bacterial infection, but when high concentrations are maintained for extended periods, the associated chronic inflammation may contribute to the pathogenesis of IBD. Produced by DCs in response to microbial stimulation, IL-23 plays a role in the expansion and maintenance of Th17 cells, a novel population of $CD4^+$ T cells whose differentiation is dependent on the presence of IL-6 and TGF-β (Fig. 3-4). The LP is enriched in Th17 cells, which are thought to play both tissue-protective and proinflammatory roles in the GI tract. Th17 cells are somewhat heterogeneous and show a degree of phenotypic plasticity and are capable of producing a range of cytokines including IL-17A, IL-17F, IL-21 and IL-22. IL-17A is thought to mediate a protective role during acute intestinal inflammation (e.g., by stimulating the expression of enterocyte claudin proteins, thereby leading to the formation of tight junctions and augmenting epithelial barrier function), while IL-17F appears to play a pathogenic, proinflammatory role (e.g., $IL\text{-}17F^{-/-}$ mice show reduced susceptibility to dextran sulphate sodium [DSS]-induced colitis compared with wild-type mice). IL-21 amplifies the induction of Th17 cells in an autocrine manner and pathophysiologic functions of IL-21 in the GI tract include the following: (a) enhancement of IFN-γ synthesis by Th1 and natural killer (NK) cells; (b) stimulation of fibroblast synthesis of matrix metalloproteinases (MMPs), which promote tissue damage by cleaving components of the extracellular matrix; (c) enhancement of epithelial synthesis of macrophage

inflammatory protein-3α (CCL20), a chemoattractant that draws T cells into the lamina propria; and (d) mediation of conventional T-cell resistance to the suppressive influence of Tregs. IL-22 is a member of the IL-10 family and has both pro- and antiinflammatory functions in the GI tract. The IL-22 receptor complex is expressed by nonhemopoietic cells (e.g., epithelial cells of the intestine, skin, and lungs) and is thought to have a role in the promotion of innate tissue defenses. This cytokine is also synthesized by DCs, which are thought to be its principal cellular source during the early phase of infection with attaching and effacing bacterial pathogens. IL-22 targets intestinal epithelial cells, inducing their expression of antimicrobial peptides such as members of the RegIII family; S100A8 and S100A9, components of the heterodimeric protein calprotectin; and β-defensin, a cysteine-rich cationic protein. It also increases the proliferation and migration of enterocytes and helps to restore goblet cells, thus enhancing mucus production, all suggesting a role in restitution of the epithelial barrier. However, IL-22 may also have a proinflammatory role in certain contexts, in vitro studies demonstrating that it increases the expression of IL-8 and TNF-α by enterocytes, and proinflammatory cytokines, chemokines, and MMPs by colonic myofibroblasts. Hence, its role in chronic intestinal inflammation remains unclear. Indeed, it is hard to reconcile its antiinflammatory properties in the murine DSS and T-cell receptor $(TCR)^{-/-}$ models of colitis with its high level of expression in murine T-cell transfer colitis and active Crohn disease. Further work needs to be undertaken to define its role in IBD more clearly and to ensure that therapies targeting IL-22 in chronic disease do not result in enhanced susceptibility to mucosal infections.

Oral tolerance has been demonstrated in the dog[49] and similar pathomechanisms to those of human IBD are believed to occur in canine patients with this disease.[77] Although little mechanistic information is currently available in companion animals, several studies have characterized the cells and cytokines expressed within the canine and feline GI tract in both healthy animals and those with IBD (Fig. 3-5).[4,5,78] An immunohistochemical study revealed increased numbers of LP T and B cells, and glandular epithelial T cells, in colonic biopsies of dogs with IBD when compared with sections from control dogs without GI signs.[79] Similarly, increased densities of IgG^+, $IgG3^+$, and $IgG4^+$ plasma cells, T cells, MHC class II^+ cells, and macrophages were observed in the colonic LP of Boxer dogs with histiocytic ulcerative colitis (HUC) when compared with colonic tissue from control animals and nonlesional colon; furthermore, there were fewer goblet cells within the epithelium of HUC patients and increased intensity of MHC class II expression by enterocytes.[80] An immunohistochemical study of duodenal biopsies from dogs with IBD revealed increased densities of LP IgG^+ plasma cells, T cells, macrophages and neutrophils, and increased intraepithelial $CD3^+$ T cells.[81] More subtle changes, limited to the epithelium, were detected in dogs with "nonspecific dietary sensitivity," which showed increased proportions of $CD45^+$ and $CD4^+$ cells, but decreased proportions of $CD8^+$ IELs in the duodenum and increased proportions of $CD45^+$ and $CD3^+$ IELs in the colon.[82] In both regions of the intestine, LP populations were not altered in the dogs with nonspecific dietary sensitivity.[82] Studies interrogating the cytokines expressed by the GI mucosa have yielded variable results: semiquantitative RT-PCR assays of mucosal biopsy homogenates have suggested increased expression of mRNA encoding IL-2, IL-5, IL-12p40, TNF-α, and TGF-β in the duodenum of German Shepherd dogs with IBD or antibiotic-responsive diarrhea (formerly "small intestinal bacterial overgrowth")[83] and increased expression of mRNA encoding IL-2 and TNF-α in the colon of dogs with idiopathic lymphoplasmacytic colitis.[84] However, a more recent quantitative (real-time) RT-PCR approach failed to demonstrate differences in the abundance of transcripts encoding IL-2, IL-4, IL-5, IL-6, IL-10, IL-12, IL-18, IFN-γ, TNF-α, and TGF-β in the duodenum of German Shepherd dogs and other breeds with chronic enteropathies compared with control dogs without diarrhea.[85] Comparable studies have been performed in the cat, revealing a subtle IBD phenotype characterized

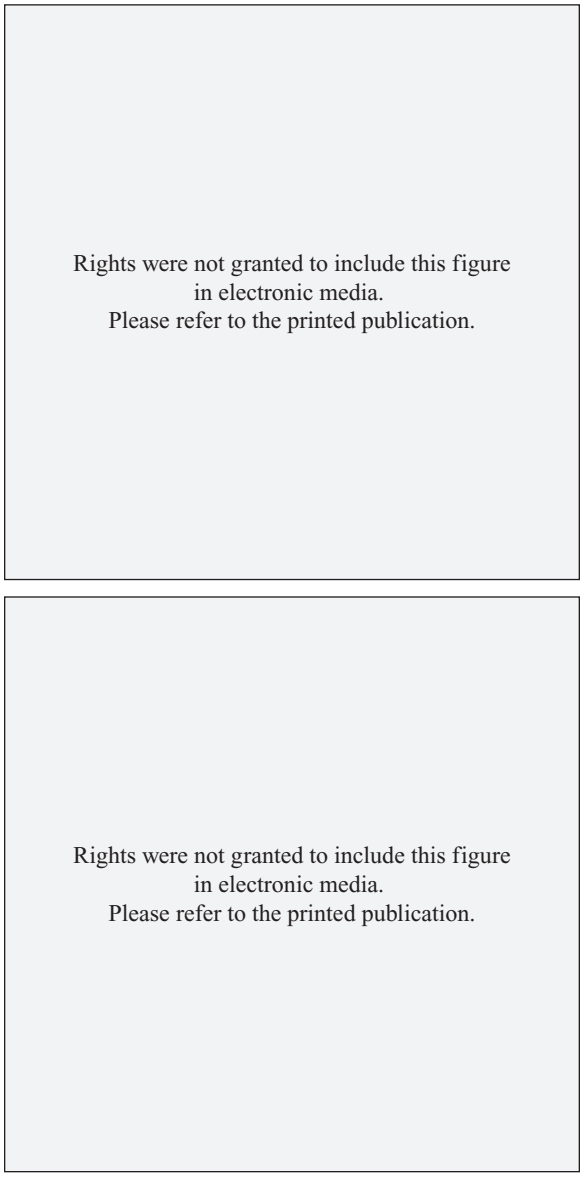

Figure 3-5 "Physiologic inflammation" in the healthy canine small intestine. Expression of mRNA encoding **(A)** IFN-γ and **(B)** IL-10 within the jejunal mucosa of a healthy Irish Setter (i) and Beagle (ii), as detected by in-situ hybridization, is shown. Positive labeling, represented in black, is apparent in the lamina propria (LP) of both breeds, although Beagles tend to show more pronounced labeling for both cytokine mRNA species in this study.[78] Epithelial labeling is also apparent, most clearly observed in the current sections for IL-10 in the Beagle, although other sections in the same study also showed epithelial expression of IFN-γ in both Beagles and Irish Setters.[78] This study and others suggest that healthy canine intestinal mucosa is characterized by the expression of a mixture of both pro- and antiinflammatory cytokines, some of which may be derived from the epithelium, in common with observations made in other species. (Images derived from Garden OA et al., *Vet Immunol Immunopathol* 70:1, 1999 and reproduced with permission from Elsevier.)

by increased density of LP MHC class II$^+$ cells (DCs and macrophages) and more pronounced MHC class II expression by duodenal enterocytes.[86] There were no differences in the LP densities of IgA$^+$ and IgG$^+$ plasma cells, or CD3$^+$ T cells, in the duodenum of enteropathic and control animals.[86] Quantitative RT-PCR revealed greater abundance of mRNA encoding IL-6, IL-10, IL-12p40, TNF-α, and TGF-β in the duodenum of cats with IBD, suggesting a complex phenotype involving the concurrent upregulation of proinflammatory and immunoregulatory cytokines.[87]

In summary, a unifying model of IBD in dogs and cats remains elusive, but recent studies provide some intriguing new clues, including the likely role of the intestinal flora. P-glycoprotein overexpression may also be implicated in the development of steroid-refractory canine IBD[88] and ciclosporin may be a useful immunosuppressive drug in these patients.[89] Significant progress has been made in recent years and the future is likely to yield exciting developments in this dynamic field of clinical research, leading to a greater understanding of the pathogenesis of chronic enteropathies in small animals and in turn novel therapeutic strategies.

CHAPTER 4

Gastrointestinal Inflammation

Michael J. Day

The fundamental biology of the acute and chronic inflammatory responses is well described in numerous texts.[1,2] Acute inflammation occurs within hours to days of exposure to an inciting trigger and is characterized by changes such as vasodilation, tissue edema and protein exudation, neutrophilic exocytosis, and the release of a wide range of cell-derived preformed or newly synthesized inflammatory mediators. By contrast, the chronic inflammatory response generally occurs subsequent to this acute reaction (over weeks to months) or may have a distinct inciting trigger. Chronic inflammation involves tissue infiltration by mononuclear inflammatory cells (macrophages with formation of multinucleate giant cells, lymphocytes, and plasma cells) with production of a separate range of proinflammatory mediators, cytokines and chemokines. The chronic inflammatory response may incorporate aspects of tissue necrosis and remodeling involving stromal growth factors, matrix metalloproteinases and their inhibitors, and progress to the formation of granulation tissue and organized fibrosis.

These various inflammatory processes may all be recognized in the gastrointestinal tract at all levels from the oral to anorectal mucosa. Alimentary inflammation may be recognized clinically or perendoscopically, but definitive characterization of the inflammatory response requires mucosal biopsy and microscopic assessment of tissue changes. Gastrointestinal inflammation is generally categorized according to the identity of the dominant infiltrating population as neutrophilic, granulomatous, pyogranulomatous, eosinophilic, or lymphoplasmacytic. However, in reality there is a broad spectrum of inflammatory change and mixed inflammatory reactions are often observed. For example, significant elevation in the number of mucosal eosinophils may often accompany lymphoplasmacytic reactions, or foci of neutrophilic inflammation may occur within an otherwise chronic mononuclear cell infiltrate.

The challenge of interpretation of alimentary inflammation is compounded by the intrinsic relationship between the immune and inflammatory responses in these mucosal tissues. The gastrointestinal mucosae are normally populated by large numbers of leukocytes involved in the provision of innate and adaptive immune surveillance.[11,12,15,51] These cells may be diffusely present throughout the lamina propria or marshalled into organized lymphoid structures and their function is described elsewhere in Chapter 3. These immune populations are designed to respond to the plethora of antigenic substances that naturally pass over the mucosal surface, although the outcome of such responses may be immunologic tolerance rather than activation of protective immunity. Many of these lymphoid responses are therefore regarded as physiologic rather than pathologic, so a major complication in interpreting gastrointestinal inflammation is distinguishing between cellular proliferation occurring to maintain homeostasis *versus* proliferation indicating a true inflammatory reaction.

It remains the case that our assessment of alimentary inflammation is largely made by subjective evaluation of a hematoxylin and eosin (H&E)-stained section of biopsy tissue. As is discussed in Chapter 29, this observational process is fraught with potential pitfalls, largely relating to lack of standardized criteria, which define changes consistent with inflammation and distinguish these from baseline physiological infiltration. To that end, the World Small Animal Veterinary Association (WSAVA) Gastrointestinal Standardization Group recently proposed histologic guidelines by which gastrointestinal inflammatory responses may be interpreted in a more standardized fashion.[10]

In the research laboratory, it has become possible to more rigorously define alimentary inflammatory processes by the application of immunohistochemical phenotyping of mucosal leukocyte subpopulations and enumeration of these per unit area of mucosa. Flow cytometric analysis of disaggregated mucosal biopsies has also been employed for the phenotypic characterization of intraepithelial and lamina propria leukocytes.[45,55] Additionally, immunohistochemical, biochemical or molecular tools have been used to characterize the local tissue production of proinflammatory mediators including cytokines, chemokines, and matrix metalloproteinases. Preliminary studies now report the role of "pattern recognition receptors" (PRRs) expressed by antigen-presenting cells (APCs) in the initial interaction between pathogens and the alimentary immune system. For example, cultured canine colonic epithelial cells express both membrane (Toll-like receptors 2 and 4) and intracytoplasmic (nucleotide-binding oligomerization domain [NOD]2) PRRs, and when stimulated by appropriate ligands (lipopolysaccharide or peptidoglycan) display upregulation of genes encoding the cytokines interleukin (IL)-7 and IL-8.[50] These PRRs are also naturally expressed within the canine intestinal mucosa.[24,28] Despite these advances, there remains much to learn about canine and feline alimentary inflammation. For example, the interaction between an array of neuropeptides and the intestinal immune and inflammatory processes remains to be investigated. Dogs and cats appear to lack Paneth cells of the basal crypt region of the intestine that in other species have a major role in the production of assorted bacteriocidal toxins (lysozyme, defensins) and may act to protect the adjacent crypt epithelia. Whether these species have an alternative source of these key inflammatory mediators is also unknown. The application of immunohistochemical and molecular techniques to the study of canine and feline gastrointestinal inflammatory disease are

described using selected clinical examples in the sections that follow.

Oral Inflammation

The oral cavity is an anatomical site predisposed to continual inflammatory change by factors such as high antigenic exposure (to food or microbial flora), physiologic microtrauma related to prehension and mastication of food, and the range of dental pathology to which small companion animals appear susceptible. Underlying systemic pathology (e.g., uremia) may also contribute to the likelihood of clinical expression of oral inflammation.

One of the most severe and clinically challenging examples of oral inflammatory disease is feline chronic gingivostomatitis. This disorder likely has multifactorial etiopathogenesis involving dental disease, feline calicivirus infection, oral bacterial infection, and the exuberant mucosal immune response to assorted antigenic materials. The histopathologic appearance is of a severe, predominantly plasmacytic inflammatory reaction with the presence of distinctive large plasma cells (Mott cells) containing an accumulation of immunoglobulin protein as cytoplasmic Russell bodies (Fig. 4-1). Other cell types may also be part of this mucosal infiltrate, particularly lymphocytes and eosinophils.

Recent immunohistochemical investigations have characterized the normal baseline resident leukocytes in the feline oral mucosa[20] and defined how these alter in this chronic inflammatory process. The mucosal infiltrates in cats with chronic gingivostomatitis are dominated by immunoglobulin (Ig) G plasma cells and recently emigrated myelomonocytic cells expressing the marker MAC387. There are also appreciable numbers of $CD3^+$ T lymphocytes, and of these, $CD8^+$ cells dominate over $CD4^+$ T cells with a median CD4-to-CD8 ratio of 0.22. Surprisingly few IgM or IgA plasma cells, and sparse mast cells, are present in these lesions. APCs expressing class II molecules of the major histocompatibility complex (MHC) are also present, principally forming a subepithelial and perivascular network.[19] This reaction has been functionally categorized as a mixed T-helper 1 (Th1) and Th2 immune response by analysis of tissue cytokine gene expression,[22] and affected cats are also known to have alterations in salivary immunoglobulin concentrations (elevated IgG and IgM with decreased IgA).[21]

Gastric Inflammation

The etiopathogenesis of gastritis has been relatively poorly studied in small companion animals. It is clear that the gastric mucosa has a normal complement of resident leukocytes that maintain immune surveillance and that "gastric lymphoid aggregates" within the lamina propria are a normal feature of the histology of this organ. The follicular microarchitecture and immunophenotype of lymphoid cells within these aggregates has been characterized in the normal dog.[25] As is discussed in Chapter 56, gastritis may be primary in nature, or may occur in association with an inflammatory response in the intestinal tract. Gastritis may have a defined etiology identified from history or clinical examination (e.g., irritant gastritis) or may be classed as idiopathic in nature.

The specific characterization of gastric inflammation relies on examination of biopsy tissue, which is most often collected endoscopically. A thorough histologic examination of the gastric mucosa necessitates collection of biopsy samples from both the fundic and antral-pyloric regions, as lesional change may be recognized in either or both of these sites. The distinct microarchitecture of these anatomical locations means that histologic patterns of inflammatory change may differ, and for this reason the WSAVA Gastrointestinal Standardization Group (see previous discussion) defined specific criteria related to the assessment of inflammatory change in the gastric fundus and antrum.[10]

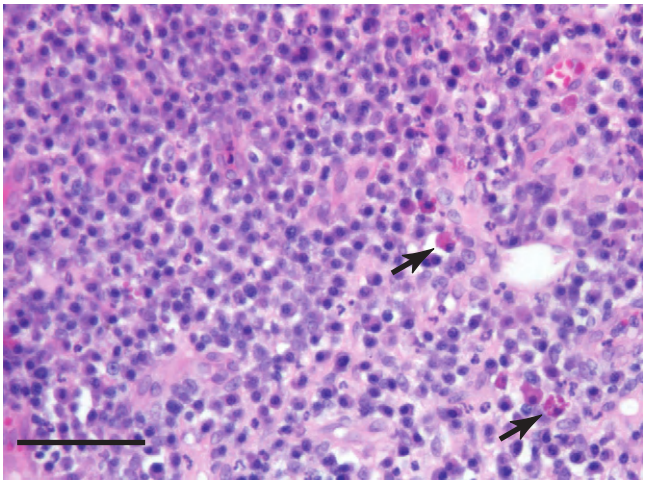

Figure 4-1 Feline gingivostomatitis. Biopsy of gingival mucosa showing an intense inflammatory infiltration dominated by plasma cells. Examples of Mott cells containing cytoplasmic Russell bodies are arrowed. H&E, Bar = 100 μm.

All forms of acute and chronic inflammatory change may be recognized within the gastric mucosa, although lymphoplasmacytic or mixed lymphoplasmacytic and eosinophilic inflammation is probably more commonly noted than neutrophilic, granulomatous, pyogranulomatous, or pure eosinophilic gastritis.[49] Leukocyte infiltration of the lamina propria may be accompanied by microarchitectural disturbances involving the surface epithelium (subtle degenerative change through to ulceration), deep epithelium (degenerative change within the fundus or hyperplasia within the antrum) or glandular tissue ("mucosal atrophy" characterized by fibrosis or "glandular nesting").

Lymphoplasmacytic inflammation is characterized by infiltration of these cell types into the lamina propria and is often accompanied by distinct increases in the number of intraepithelial lymphocytes (IELs) within both surface and deep epithelial structures (Fig. 4-2). In the fundic mucosa, lymphocytes also often infiltrate and apparently disrupt the glandular tissue. It is likely that the majority of these epitheliotropic lymphocytes are $CD3^+$ T cells and probably $CD8^+$ cytotoxic cells, although immunohistochemical characterization has not been widely reported. In humans, this histologic pattern characterizes the autoimmune disease "atrophic gastritis," and although the similarity has been noted, there is no proposal at this time that the canine or feline reaction pattern represents an equivalent disorder. Another distinctive feature of gastric inflammation (particularly lymphoplasmacytic gastritis) in dogs and cats is hyperplasia of the gastric lymphoid aggregates, which may sometimes be extreme and occupy up to 50% of the tissue area of any one biopsy.[35]

One of the most contentious areas in small animal gastroenterology is the debate concerning the role of *Helicobacter* spp. in the induction of gastritis.[37] These distinctive bacteria are frequently noted associated with the surface epithelium and gastric pits of canine and feline tissue biopsies with entirely normal microarchitecture (Fig. 4-3); however, there have been clinical and experimental research studies that have proposed them as an etiologic factor in gastric mucosal inflammation and lymphoid aggregate hyperplasia.[36,41,44] By contrast, other experimental infection studies have not

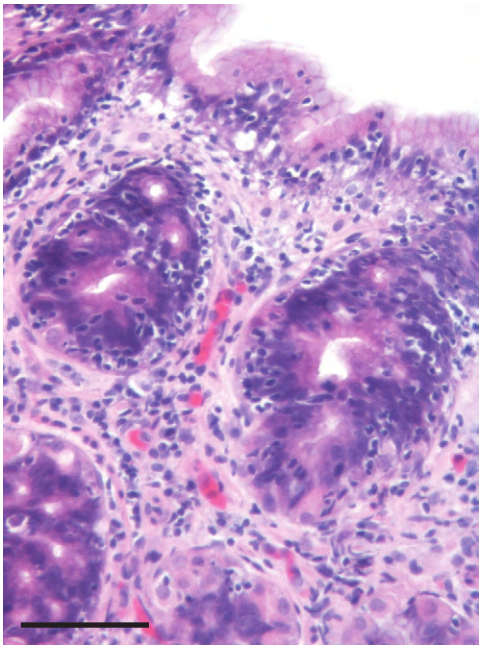

Figure 4-2 Lymphoplasmacytic gastritis. Biopsy of superficial fundic mucosa from a dog with lymphoplasmacytic gastritis. There is mild to moderate infiltration of the lamina propria by a mixed population of lymphocytes and plasma cells. Prominent lymphocytic infiltration of the superficial and glandular epithelium is also seen. H&E, Bar = 200 μm.

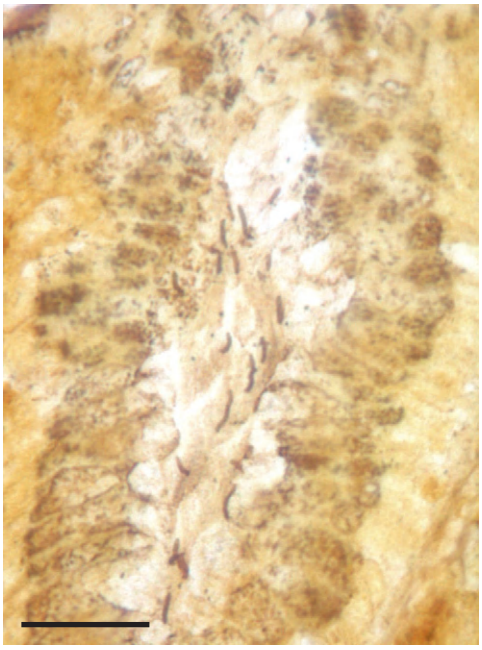

Figure 4-3 Gastric *Helicobacter*. Biopsy of normal canine gastric mucosa showing numerous elongate, spiral-shaped bacteria within the lumen of this gastric pit. There is no association with an inflammatory response in this case. Warthin Starry silver stain, Bar = 50 μm.

shown an association between infection and gastric pathology.[43] A recent investigation of 30 dogs with lymphoplasmacytic gastritis identified *Helicobacter* in 77%, but there was no correlation between infection and the severity of inflammatory change. The same study quantified cytokine gene expression within these mucosal biopsies and identified a Th1-skewed profile with expression of IL-1β, IL-8, IL-10, transforming growth factor (TGF)-β, and interferon (IFN)-γ, but lack of IL-4 transcription. Expression of IL-10 and IFN-γ was most closely associated with the presence of lymphoplasmacytic infiltration.[53] There remains little definitive evidence that *Helicobacter* have a significant role in the development of canine and feline gastritis.

Small Intestinal Inflammation

Small intestinal inflammation in dogs and cats may involve any level of this structure (duodenum, jejunum, or ileum) or may be a diffuse change that can also affect the stomach and colon concurrently. As above, inflammatory change in this organ is generally assessed by microscopic examination of tissue biopsies and these are most often collected endoscopically. For this reason, in many patients only the duodenal mucosa is assessed, despite the fact that it is possible to collect perendoscopic tissue samples from the ileum. Recent investigations have examined the correlation between duodenal and ileal pathology within the same patient, and suggested that duodenal samples may not be an adequate reflection of pathologic change that may be occurring in the distal small intestine.

Small intestinal inflammation in these species is most often lymphoplasmacytic or mixed lymphoplasmacytic and eosinophilic in nature, but eosinophilic, neutrophilic, or pyogranulomatous enteritis is also recognized.[23,31,54] Inflammatory infiltration of the villus or pericryptal lamina propria and elevation in the number of IELs is generally accompanied by a range of microarchitectural changes. These are described in greater detail elsewhere (see Chapter 29), but include villus stunting and fusion, epithelial degeneration to ulceration, cryptal dilation, distortion or crypt abscessation, or mucosal fibrosis.

The nature of the inflammatory infiltration provides guidance on the possible etiology of the intestinal disease. Superficial neutrophilic enteritis is most consistent with an infectious causation whereas eosinophilic enteritis is generally interpreted to suggest parasitic infestation or disease involving a type I hypersensitivity reaction (dietary hypersensitivity). Pyogranulomatous inflammation may trigger a search for particular classes of pathogen or discrete microgranulomata may be associated with blockage of lacteal outflow and the development of lymphangiectasia. Lymphoplasmacytic inflammation (Fig. 4-4) is the hallmark of idiopathic inflammatory bowel disease (IBD), but may also occur in dietary hypersensitivity or in dogs with antibiotic responsive diarrhea (ARD; also small intestinal bacterial overgrowth, SIBO). In the cat, lymphoplasmacytic inflammation of the small intestine may be associated with similar inflammatory disease of the liver and pancreas (colloquially "triaditis").[6]

The recognition of small intestinal inflammation, and particularly lymphoplasmacytic inflammation, is problematic. This relates to the concept discussed above—that the normal small intestinal mucosa is an immunologically active site populated by significant numbers of lymphocytes, plasma cells, and APC that are involved in mediating either tolerogenic or immunogenic responses to luminal antigen. Because of this, it can often be difficult to distinguish between a physiologically reactive mucosa and one undergoing inflammatory change, particularly in the absence of clear evidence of morphologic abnormality. Many clinicians are frustrated by biopsy reports detailing "normal mucosa" in animals with clinical and endoscopic evidence of inflammatory disease. The application of the WSAVA Gastrointestinal Standardization Group criteria for the characterization of duodenal intestinal inflammation[10] may go some

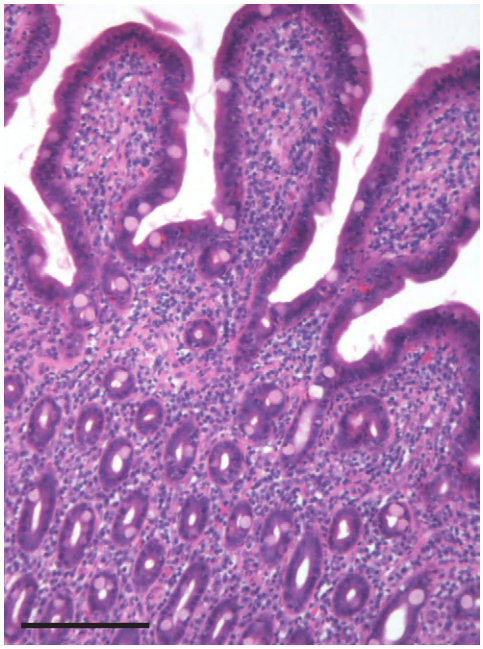

Figure 4-4 Lymphoplasmacytic enteritis. Biopsy from a dog with lymphoplasmacytic enteritis of moderate severity. There is mild to moderate villus stunting without significant epithelial damage. There is prominent infiltration of the villous and pericryptal lamina propria by a mixed population of lymphocytes and plasma cells. The crypts are cut in cross-section as a consequence of the orientation of the biopsy, but are more widely separated than normal by the inflammatory infiltration. H&E, Bar = 500 μm.

way toward providing a more consistent approach to microscopic diagnosis.

At the research level, many recent advances have been made in further understanding the nature of lymphoplasmacytic inflammation in the small intestine of the dog and cat. Even where H&E-stained sections of tissue biopsies may appear morphologically normal, immunohistochemical evaluation of cellular subpopulations has revealed subtle changes. The lamina propria of dogs with IBD is characterized by an elevation in IgG plasma cells, $CD4^+$ T lymphocytes bearing the αβ T-cell receptor (TCR) and myelomonocytic cells expressing MHC class II or MAC387. Additionally, there is an elevation in intraepithelial T cells and a reduction in mucosal mast cells in canine IBD. By contrast, in dogs with ARD the dominant changes are an elevation in IgA plasma cells and $CD4^+$ T cells.[13] Such findings are not always consistent between different studies; for example, one investigation failed to demonstrate increases in villus T cells, IgA, and IgG plasma cells in dogs with IBD, and in fact showed that the number of villus T cells was lower in dogs with IBD than in healthy animals.[32]

Assessment of functional aspects of the immune and inflammatory response by measurement of cytokine gene expression has proven more challenging in these canine diseases. Early investigations using conventional reverse transcriptase polymerase chain reaction (RT-PCR) technology suggested a mixed Th1 and Th2 cytokine profile in both canine enteropathies,[16] but subsequent studies employing more sensitive real-time RT-PCR failed to distinguish between samples from clinically normal and diseased dogs.[39] Genes encoding some types of nuclear transcriptional receptors are upregulated in some dogs with inflammatory enteropathy.[17] Expression of the epithelial drug efflux pump protein P-glycoprotein has been examined in the mucosa of dogs with IBD. Those animals that make a clinical response to prednisolone therapy have low baseline expression of P-glycoprotein, and this is seen to be upregulated in biopsies from these dogs taken posttreatment.[3] Expression of candidate genes involved in postinflammatory repair processes has also been examined in dogs with inflammatory enteropathies. In the duodenum of dogs with food-responsive diarrhea or IBD there is upregulation of messenger RNA (mRNA) expression encoding the growth hormone receptor and insulin-like growth factors-1 and -2.[46]

Recent studies also have evaluated systemic markers of inflammation in dogs with IBD (both small and large intestinal). Assessment of a range of serum acute-phase proteins (C-reactive protein, haptoglobin, α_1-acid glycoprotein, and serum amyloid A) revealed elevation of C-reactive protein in patients with IBD,[33] although this was not replicated in a second study.[5] Similarly, an association between canine IBD and the presence of serum perinuclear antineutrophil cytoplasmic antibody (pANCA) has been demonstrated.[4,5] Measurement of serum neutrophil elastase concentration also is being examined as a potential marker for intestinal inflammation in the dog.[47]

Similar investigations have occurred with samples from cats with idiopathic IBD. In this instance there were no significant differences between normal and diseased cats with respect to the numbers of lamina propria IgG or IgA plasma cells, $CD3^+$, $CD4^+$, or $CD8^+$ T cells or leukocytes expressing the MAC387 antigen. The most striking distinction was marked elevation in MHC class II expression in diseased cats—particularly by enterocytes.[52] A unique difference between the small intestine of dogs and cats is the constitutive expression of MHC class II by canine enterocytes versus induced expression of this molecule in inflammatory or neoplastic disease of the cat. Also in contrast to the dog, studies of cytokine gene expression by real-time RT-PCR in small intestinal biopsies from cats with lymphoplasmacytic inflammation revealed elevations in transcription of genes encoding IL-6, IL-10, IL-12p40, tumor necrosis factor (TNF)-α and TGF-β. These findings are consistent with a mixed Th1-proinflammatory and immunoregulatory phenotype.[38]

A recent investigation directly addressed the hypothesis that feline IBD involves an interaction between luminal flora and the mucosal immune system. Using fluorescence in-situ hybridization (FISH) to identify and localize various bacterial species within lesional mucosa (n = 17 cats with IBD vs. n = 10 healthy cats), clear associations have been found between bacterial load and location (particularly numbers of *Enterobacteriaceae*, *Escherichia coli*, and *Clostridium* spp.) and clinical signs, histopathologic severity of mucosal lesions, numbers of T cells and macrophages infiltrating the lamina propria, and cytokine gene expression (IL-1, IL-8, and IL-12).[29]

Colonic Inflammation

Colitis in small companion animals may be primary or one part of a diffuse gastrointestinal inflammatory disease. The major microarchitectural changes accompanying colonic inflammation have been defined by the WSAVA Gastrointestinal Standardization Group and include surface epithelial degeneration to ulceration, crypt hyperplasia, dilation, and distortion, and mucosal atrophy and fibrosis.[10] Colitis is most frequently lymphoplasmacytic in nature, but eosinophilic, neutrophilic and pyogranuzlomatous forms are also seen (Fig. 4-5).

Some studies have further investigated the immunologic features of lymphoplasmacytic colitis in the dog. Mucosal biopsies from dogs with lymphoplasmacytic colitis have been reported to have more $CD3^+$ T cells and IgA and IgG plasma cells than those from the colonic mucosa of healthy dogs.[30] However, these findings are inconsistent as another group has reported elevated numbers of mucosal

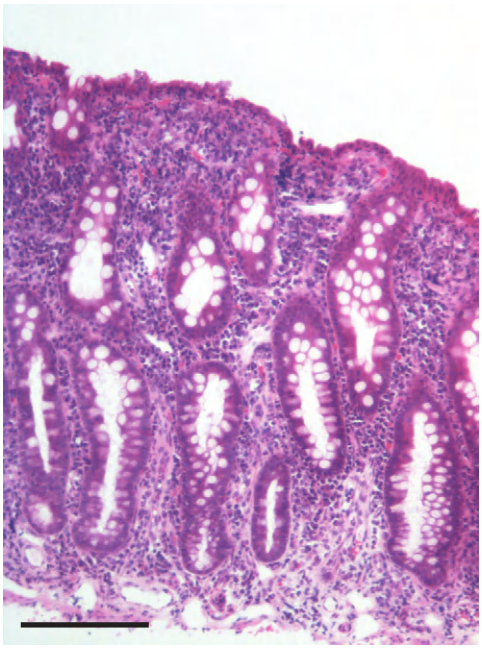

Figure 4-5 Lymphoplasmacytic colitis. Biopsy from a dog with lymphoplasmacytic colitis of moderate severity. The surface epithelium is attenuated and devoid of goblet cells. The crypts are mildly dilated and distorted and there is infiltration of the lamina propria by a mixed population of lymphocytes and plasma cells. The inflammatory infiltrate extends from the superficial lamina propria to the level of the muscularis mucosa. H&E, Bar = 500 μm.

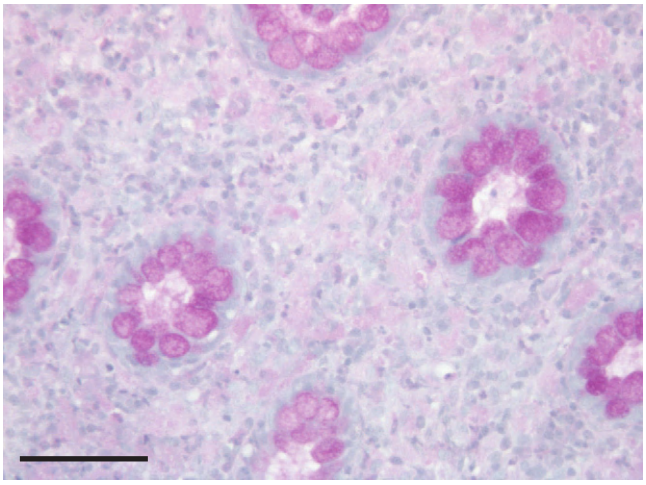

Figure 4-6 Histiocytic ulcerative colitis. Biopsy from the colon of a 3-year-old, female Boxer dog with severe granulomatous inflammation of the mucosa. The section is stained by periodic acid-Schiff, which stains goblet cells in residual crypts and the cytoplasm of macrophages within the lamina propria. PAS, Bar = 100 μm.

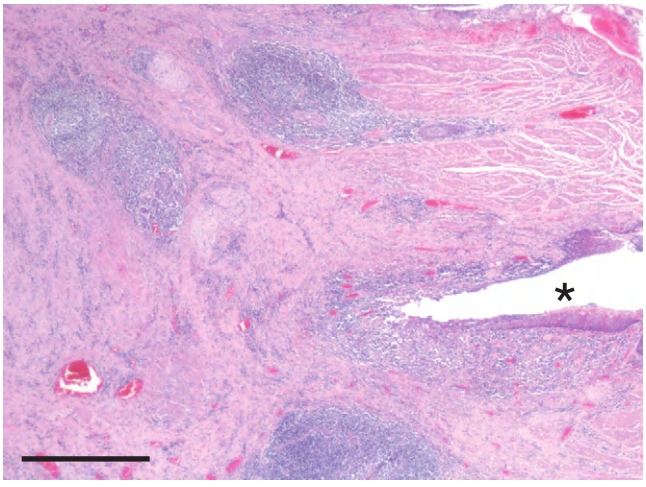

Figure 4-7 Anal furunculosis. Surgical resection of a region of perianal ulceration and sinus tract formation in a 6-year-old, neutered female, German Shepherd dog. Normal perianal structure is replaced by an extensive zone of fibrosis containing series of perivascular lymphoplasmacytic aggregates. At one margin of the image is the termination of a sinus tract (*asterisk*) extending from the perianal surface. This tract is partially lined by degenerate squamous epithelium and there is an intense local mononuclear inflammatory response. H&E, Bar = 1 mm.

T and B cells, but no increase in total plasma cells.[48] Colonic lavage fluids collected from dogs with lymphoplasmacytic colitis have been shown to contain an increased concentration of IgG and nitrite. The latter is a metabolite of nitric oxide, a key inflammatory mediator.[18] Molecular studies have shown upregulation of expression of genes encoding Th1 and proinflammatory cytokines (IL-2, TNF-α) in the mucosa of dogs with lymphoplasmacytic colitis.[40]

Canine pyogranulomatous colitis may be related to specific etiologic agents such as *Histoplasma*. One specific form of canine colitis, histiocytic ulcerative colitis (HUC), has attracted much interest because of the distinct breed association for the disorder (Boxer dogs). Characterized by granulomatous colitis with distinctive macrophages filled with periodic acid-Schiff (PAS)–positive material, this disease was for many years considered to be an idiopathic immune-mediated disorder (Fig. 4-6). Immunohistochemical characterization of lesional colon revealed the presence of infiltrating IgG plasma cells (of the IgG3 and IgG4 subclasses), $CD3^+$ T lymphocytes, $MAC387^+$ myelomonocytic cells, and MHC class II^+ macrophages. There was additional elevation of MHC class II expression by enterocytes.[14] More recent studies have defined HUC as an infectious, rather than immune-mediated, disorder. The clinical responsiveness of these patients to appropriate antimicrobial therapy[7,25] correlates well with the identification of lesion-associated *E. coli* bacteria by FISH.[42]

Rectoanal Inflammation

The most investigated example of inflammatory disease affecting this portion of the canine gastrointestinal tract is anal furunculosis. This enigmatic disorder has long intrigued investigators due to the strong breed predisposition for the German Shepherd dog. This association in a breed also susceptible to the enteropathies described previously, led to early suggestions that a mucosal immunodeficiency might account for the occurrence of this range of disorders. Despite many biochemical and, more recently, molecular studies of the IgA secretion pathway in this breed, there is still little clear evidence for an inherited immunodeficiency related to mucosal IgA production. However, a genetic association between anal furunculosis and a particular allele of an MHC class II gene has been shown.[34]

The inflammatory lesion in canine anal furunculosis is distinctive. Microscopically, there are complex, deep-running sinus tracts (which very rarely fistulate) with a central core of neutrophilic inflammation lined by an intense lymphoplasmacytic infiltration (Fig. 4-7). These tracts often run through extensive zones of fibrosis,

within which may be scattered ectopic (inflammatory) lymphoid follicles.[9] Immunohistochemical characterization of these infiltrates has demonstrated large numbers of IgG, IgM, and IgA plasma cells together with a significant population of $CD3^+$ T lymphocytes.[8] At the functional level, there is molecular evidence for activation of cytokine genes (encoding IL-1, IL-2, IL-6, TNF-α, and IFN-γ) compatible with a proinflammatory and Th1 immune response,[27] and expression of matrix metalloproteinases[26] (MMP-9 and MMP-13) that are likely involved in the tissue remodeling and fibrosis that is a feature of the lesions. These collective observations have led to the hypothesis that inappropriate T-cell activation underlies the pathology of anal furunculosis—and this would certainly be borne out given the dramatic success of systemic cyclosporine therapy in the medical management of this disease. What remains to be definitively shown is the pathogenesis by which these lesions develop. There is little evidence to support the theory that the initiating lesion is anal sacculitis, but histologic and serologic examination does suggest that dermal furunculosis (deep staphylococcal pyoderma) of the haired perianal skin may progress to severe perianal furunculosis.[9]

CHAPTER 5

Cellular Growth/Neoplasia

Alexandra Sahora and Chand Khanna

The balance between cell growth and death is essential in maintaining tissue and organ homeostasis, even in simple biologic systems. This is of particular importance in specialized organs of high cell turnover such as the gastrointestinal (GI) tract of larger mammals. Several mechanisms of control have evolved within these organs to maintain this balance, including regulators of cell-cycle progression, proliferation, and death. These regulators are influenced by both local (paracrine and autocrine) and systemic (endocrine) signals.[1] Derangements in any of these control mechanisms can result in a disruption of the balance between proliferation and death, often leading to abnormal proliferation and potentially to cancer. The effectiveness of the control mechanisms is evidenced by the relatively infrequent development of cancer of the GI tract despite the extraordinary and diverse requirements for cellular turnover and differentiation of this tissue. This chapter reviews the pathways and processes that control cell growth and proliferation, with specific focus on those that when dysregulated result in cancer of the GI tract.

Overview of Normal Cell Growth and Proliferation

For most cell types, regulation of cell division and replication is a highly conserved continuum with cells traversing through the stages of interphase, mitosis, and cytokinesis (Fig. 5-1). Interphase is defined as the period prior to cell division where the cell grows and replicates its chromosomes in preparation for division by mitosis. For somatic cells, cellular replication is accomplished during mitosis and cytokinesis. The result of mitosis is the generation of two daughter cells (cytokinesis) each with a diploid (2n) genetic constitution. For germline cells that are committed to cellular reproduction, cells exit interphase and enter meiosis. In meiosis, chromosomal numbers within a nucleus are halved (1n) after two cell divisions. Following cytokinesis, two haploid germ cells are available for reproduction.[2]

Interphase

During interphase, cells undergo DNA duplication and a period of extensive RNA, protein, and lipid synthesis. This stage is composed of three signal dependent phases: growth-1 (G_1), synthesis (S), and growth-2 (G_2), that is then followed by mitosis (M) (see Fig. 5-1). Cells that have reached terminal differentiation or the nonreplicating phase, exit from the cycle toward the end of the G_1 phase and arrest in a phase called G_0. Several mechanisms control cell growth and proliferation during the transitions between G_1 and S and between G_2 and M in the cell cycle (also termed *checkpoints*). The key players that are involved in the regulation of these transitions are cyclins and cyclin-dependent kinases (CDKs).[3]

Cyclins and Cyclin-Dependent Kinases

The entry of cells from the phase of mitosis to G_1 involves the presence of progrowth external factors and appropriate internal mitogenic signals. Under circumstances that favor proliferation, the cell cycle progresses as CDKs associate with small intracellular regulatory subunits called cyclins. Cyclins, unlike CDK proteins, have variable expression patterns depending on the cell-cycle phase, acting as a primary level of control for CDK activation. For instance, expression of cyclins A and B is highest at the S/G_2 phase transition, whereas expression of cyclins D and E are highest at G_1/S.[4]

Prior to becoming functional, the cyclin–CDK complexes must become phosphorylated by cyclin-activating kinases (CAKs). This process is site-dependent, meaning that phosphorylation may result in either suppression or activation of the complex, depending on the specific phosphorylated residue.[5] Once activated, the cyclin–CDK complexes can then exert their regulatory control via the phosphorylation of target proteins.

During G_1, cyclin D activates either CDK4 or CDK6, resulting in a functional cyclin–CDK complex. When activated, this complex results in the phosphorylation of several target proteins, including the retinoblastoma protein (Rb).[6] Once the Rb is phosphorylated, the transcription factor E2F is liberated and enables not only the transcription of a variety of genes but also the induction of cyclin E. Cyclin E, in association with CDK2, maintains the Rb in a phosphorylated state. It is the phosphorylation of the Rb that is considered the quintessential final guardian of the transition from G_1 to S phase, and is the critical point at which a cell will move into S phase or into G_0, otherwise known as the *restriction point*. Elevated levels of phosphorylated Rb allow for the accumulation of free E2F, which increases the level of cyclin A and enables the cell to progress into DNA synthesis, or S phase. Cyclin A then plays a critical role in S phase as it interacts with CDK2 and CDK1 while cyclins D and E are concurrently degraded. CDK2 and CDK1 are key for the transition through S phase into M phase, or mitosis. In particular, CDK1, in association with cyclins A and B, is required for the phosphorylation of cytoskeletal proteins necessary for mitosis.[3,7]

In addition to the cell-cycle dependent expression of cyclins, and the regulatory control of the CAKs, the cell cycle is also regulated by the activity of antagonistic cyclin-dependent kinase inhibitors

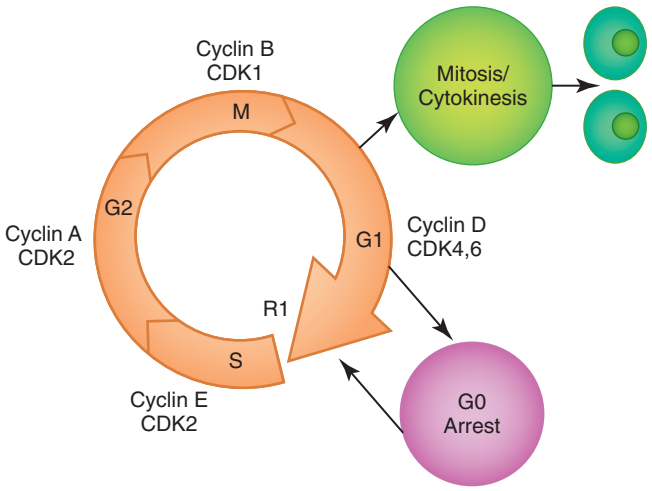

Figure 5-1 The cell cycle. The cell cycle consists of four phases: M (mitosis), G_1 (protein synthesis to prepare for S phase), S (synthesis), and G_2 (protein synthesis to prepare for mitosis). Movement through the cell cycle is tightly regulated by cyclins and cyclin-dependent kinases (CDKs). Retinoblastoma protein (RB) in its active phosphorylated state prevents movement of cells from G_1 to S phase (restriction point; R1) controlling individual cell division. Cells may move out of the cell cycle and arrest (G_0). Following mitosis, the division of cells yielding two progeny results from cytokinesis.

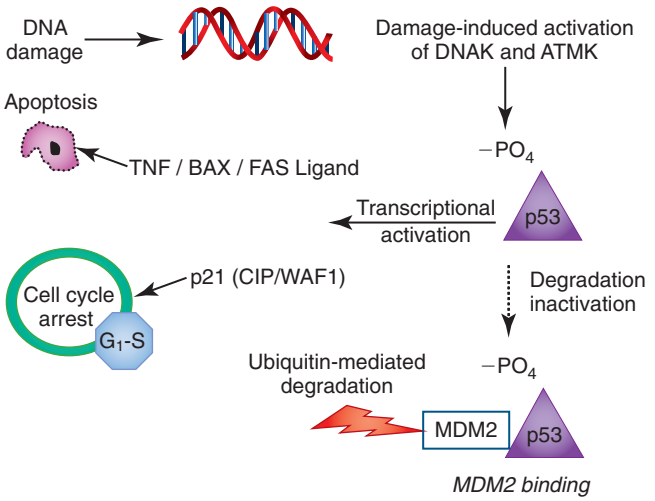

Figure 5-2 p53 regulation and function. In response to DNA damage, the DNA-kinase (DNAK) or ATM kinase (ATMK) phosphorylate p53. This activation step allows p53 to act as a transcriptional activator of genes involved in cell-cycle arrest (p21) and apoptosis (tumor necrosis factor, bax, or Fas ligand). p53 also transcriptionally activates the expression of MDM2, which binds p53, resulting in p53 inactivation and then targets p53 for degradation.

(CDKIs). These proteins block progression of the cell from G_1 to S phase by binding cyclin–CDK complexes and blocking the activation of downstream proteins. Three types of CDKIs are recognized and include the INK4 family, CIP, and KIP.[8] The INK4 family of CDKIs exhibits high specificity for CDK4 and CDK6 complexes, preventing the association of these proteins with cyclin D. CIP (WAF1/p21) is regarded as a general CDK inhibitor, whereas KIP (p27) functions via activation of transforming growth factor (TGF)-β that subsequently prevents the activation of cyclin E/CDK2 and arrests the cell in G_1.[9]

Ligands and Transmembrane Receptors

The internal regulation of the cell cycle is modulated by external and extracellular environmental cues. There are four recognized pathways that play a part in conveying these extracellular messages into the cell: tyrosine phosphorylation; serine and threonine phosphorylation; generation of signaling nucleotides via G-protein-coupled receptors; and production of calcium phosphoinositol through stimulation of phospholipase C.[10] Signaling through these pathways provides a connection between the cell cycle and the environment in which a cell resides. In the presence of growth factors, cells may more easily transition between cellular checkpoints, and in some cases will by influenced toward cellular survival rather than death (discussed below in "Overview of Cellular Death and Apoptosis: The Response to DNA Damage").[11]

Mitosis and Cytokinesis

Once a cell has committed to replicate and surpasses the checkpoints at G_1/S and then G_2/M, it enters mitosis. Mitosis is characterized by cellular DNA replication and segregation, organized in four different phases.[2] Prophase, the first phase of mitosis, involves the replication of chromosomes (4n) and the division of chromosomes into two sister chromatids. These chromatids are joined by a central centromere. In the cytoplasm, centrioles and asters develop and then align at either pole of the nucleus. The nuclear membrane disintegrates at the end of prophase while the centromeres form spindle fibers that will become the organizational scaffolds for chromosomal assembly. In metaphase, the chromosomes are aligned via centriole-spindle fiber interactions on the middle of the spindle, or the metaphase plate. Once aligned, the centromeres split and individual chromatids are segregated to either centriole by the regressing spindle fibers (anaphase). The final phase of mitosis, or telophase, involves the reappearance of the nuclear envelope around each centriole and its associated chromatids. The shared cytoplasm between these two new nuclei is then split (cytokinesis). The maintenance of DNA ploidy, or normal diploid genotype, is critical in mitosis. Aneuploidy, or aberrations in the normal 2n chromosomal number, often resulting from dysregulated mitosis, is a frequent change noted in cancer.[10,12]

Overview of Cellular Death and Apoptosis: The Response to DNA Damage

Exposure to cellular stressors, hypoxia, and toxins can result in damage or changes in the genetic material (DNA) of a cell. In a preserved checks-and-balances system, these changes are identified by a cell and result in its arrest within the cell cycle, most often at a cellular checkpoint. During cellular arrest the damaged DNA is surveyed and repaired. If the damage is determined to be extreme or nonrepairable the cell undergoes controlled cell death (apoptosis). This process of arrest, survey, repair, or death ensures high-quality, mutation-free replication needed for optimal organ homeostasis. Cell-cycle control genes function at each of the cell-cycle cellular checkpoints in a nonmutually exclusive manner. The best-characterized checkpoint gene is the tumor-suppressor gene p53 (Fig. 5-2).[13] The activation of p53 relies upon phosphorylation by either DNA-dependent protein kinase or by ATM kinase in response to cellular damage. Once phosphorylated, p53 functions as a transcriptional activator of multiple cell-cycle regulator genes, including p21 (CIP1/WAF1).[14,15] p53 mediates cell death in part by downregulating the expression of the oncogene bcl2, an inhibitor of apoptosis, which shifts the balance toward cell death. Accumulations in

proapoptotic signals, such as bax, tissue necrosis factor, Fas ligand, and the activation of other oncogenes, also promote cellular apoptosis through p53 regulation.

p53 is also modulated by a variety of proteins to ensure proper function. The gene MDM2 (mouse double minute 2 oncogene) functions as an antagonist to p53.[16] MDM2 can target p53 for degradation by binding the protein and tagging for proteosome-mediated degradation. Conversely, p53 also has a defined binding site in the MDM2 internal promoter that competitively binds free p53. Significant MDM2-p53 binding results in decreased circulating p53, suppressing p53 transcriptional activity.[17] The collective result is that the p53 available for phosphorylation and subsequent transcription of proapoptotic/proarrest proteins drops, favoring cell survival.

The "Cancer Genes": Oncogenes and Tumor-Suppressor Genes

When mutated, certain genes confer malignant characteristics across multiple tumor types. Many of these "cancer genes" have functions related to control of the cell cycle or apoptosis. Two broad categories of cancer genes are known to exist. Oncogenes represent normal genes (protooncogenes) that undergo "gain-of-function" in cancer that contribute to cell proliferation or reduced cell death. Conversely tumor-suppressor genes normally restrain cell proliferation or promote appropriate cell death and undergo "loss-of-function" in cancer.[18]

Oncogenes

Studies of RNA tumor viruses (retroviruses) provided the first evidence that genetic factors play a role in the development of cancer. Rous demonstrated that a retrovirus, now known as avian leukosis virus, was capable of producing lymphoid tumors in chickens.[19] Retroviral sequences that are responsible for transforming properties are called *viral oncogenes* (v-onc). The names of these genes are derived from the tumors in which they were first described (e.g., v-ras from rat sarcoma virus). Subsequently, viral oncogenes were shown to have cellular homologues called *cellular oncogenes* (c-onc).[20] The term *protooncogene* was later used to describe cellular oncogenes that do not have transforming potential to form tumors in their native state but which can be altered to lead to malignancy. Most protooncogenes are complex genes involved in the control of cell growth and proliferation. These genes, when transcribed, represent a variety of proteins, including signaling growth factors, growth factor receptors, protein kinases, signal transducers, and nuclear proteins and transcription factors. Abnormal function/expression of any of these proteins can result in changes that lead to aberrant proliferation.

Growth factors act through transmembrane receptors on the cell surface and trigger the intracellular cascades that ultimately result in cellular proliferation. Overexpression of a growth factor and the abnormal expression of a growth factor by a cell that typically does not produce it represent two ways in which a cellular environment can contribute toward carcinogenesis. Examples of growth factors that are typically expressed by tumor cells are epidermal growth factor (EGF) and fibroblast growth factor (FGF).[21]

The growth factor receptor can be another target for change. Several receptor proteins are formed for protooncogenes. Overexpression or disturbances (mutation) in the structure of these proteins can result in aberrant regulation of signal transduction that may tip the scale toward tumorigenesis.

Protein kinases function in signal transduction on the inner side of the cell membrane. These proteins transmit signals through cytoplasmic intermediaries through phosphate group transfer. Structural changes in these genes and proteins lead to increased kinase activity that can have profound effects on signal transduction pathways.

Signal transduction through the cell involves a variety of second messengers, such as guanosine triphosphate (GTP), adenosine triphosphate (ATP), and intracellular calcium. If mutated, the genes that transcribe these proteins may alter the response of these second messengers to inhibitory or activation signals. A common signal transducer that is altered in malignancies is GTP. GTP is converted to guanosine diphosphate (GDP) via the guanosine triphosphatase (GTPase) activity of G proteins as part of the signaling cascade. This cascade is modulated by the expression of the ras family of genes, where the resultant proteins police GTPase and GTP binding activity. When mutated, the ras oncogene allows for continual expression of GTP, reduced numbers of the CDKI p21 (CIP), and reduced GTPase activity. These changes together favor tumor formation.[22]

Alterations in the level and activity of intranuclear transcription factors may allow for aberrant gene expression and induce a malignant phenotype. An example of a key nuclear oncogene is that of the myc family and in particular c-myc. c-myc plays a significant role in modulating cellular proliferation, differentiation, and apoptosis amongst other functions. Mutations in c-myc are frequently encountered across tumor types, including those in the GI tract.[23]

In general, oncogenes require mutation of only one allele in order for phenotypic change to occur. This is known as a dominant gain-of-function. The conversion from protooncogene, the normal phenotype, to oncogene, the mutated form, can involve a variety of mechanisms, commonly relying upon abnormal gene amplification. Other mechanisms of mutation include chromosomal translocation, point/frameshift mutations, and viral insertions.[24]

Table 5-1 lists the oncogenes associated with the development of GI cancer. The oncogene β-catenin (and alternations in the Wnt [wingless]–β-catenin pathway) has been specifically incriminated in the development of GI cancers. This pathway involves the regulation of cytoplasmic free β-catenin and conformational changes in the APC–axin–GSK-3B complex. Nuclear translocation of this β-catenin and subsequent interactions with nuclear proteins result in the active transcription of a variety of genes including c-myc, cyclin D_1, MMP-7, and ITF-2, most of which are progrowth proteins that have been implicated in cancer development.[25]

Tumor-Suppressor Genes

Tumor-suppressor genes differ from oncogenes in that both alleles encoding a gene must be converted in order for a phenotype to be seen. Maintenance of a single allele is sufficient for protein expression to maintain cellular phenotype. When tumor-suppressor genes are mutated, the result is a loss of inhibitory function and the promotion of cellular growth and proliferation.[26] Two common tumor-suppressor genes that have been studied extensively and implicated in a variety of human and animal tumors include the Rb and the p53 tumor-suppressor genes.

As illustrated previously, the Rb plays a crucial role in the decision of a cell to proceed from G_1 to S phase.[6] Disruption of the Rb or other proteins that work in concert with the Rb can lead to unwanted cellular proliferation. Observations of the familial inheritance patterns of certain cancers, like that of the inherited form of retinoblastoma led to the formation of Knudson's two-hit model. This hypothesis suggests that two separate mutations must occur in a tumor-suppressor gene prior to tumor development. Mutations or dysregulation in the Rb pathway are common in many different forms of cancer in both man and animals.[27-33] The inherited form of retinoblastoma results from a germline mutation in one allele of a

Table 5-1 Cancer Genes and Gastrointestinal Cancers

Gene Class	Specific Examples	Normal Function	Abnormal Function	Association with Human Gastrointestinal Cancers
Oncogenes	β-Catenin in the canonical Wnt pathway	Pathway that regulates cellular growth and proliferation	Increased nuclear β-catenin activity	Attributed to the development of multiple GI cancers
	c-myc	Nuclear transcription factor involved in cellular growth, proliferation, and apoptotic pathways	Overexpression of c-myc favors cellular proliferation and growth by inducing cyclins and CDKs	Colorectal cancer
	ras	Oncogenes that encode for proteins similar to the G proteins	Alterations in the cell cycle that favor cell proliferation by specifically keeping p21/CIP/WAF1 inactivated	Attributed to the development of multiple GI cancers
Tumor-suppressor genes	p53	Key gene that controls cell-cycle progression, regulation of genetic expression, and responses to DNA damage	p53 inactivation either by mutation or overexpression of MDM2 oncogene favors cellular growth and proliferation	Attributed to the development of multiple GI cancers
	Rb	Critical component of regulation of the cell cycle, particularly at the G_1/S phase	Rb mutations result in abnormal cellular growth and proliferation	Familial/somatic retinoblastoma Attributed to the development of multiple GI cancers
	APC	Tumor-suppressor gene regulating multiple pathways for cellular growth and proliferation	Mutations in both alleles resulting in dysregulation of growth signals	Colorectal cancer and familial adenomatous polyposis (FAP) coli Intestinal cancer Hepatic cancer
	Smad4 (DPC-4)	Functions through the TGF-β signaling pathway that negatively regulates epithelial cell growth	Biallelic mutation results in disruption of the TGF-β pathway	Pancreatic cancer Familial juvenile polyposis Colorectal cancer
DNA mismatch repair	hMSH2	High affinity for correcting single base mispairs and structural anomalies	Dysfunctions enable the accumulation of mutations that may confer growth advantages that result in malignancy	Hereditary nonpolyposis colorectal cancer (HNPCC) syndromes
	hMLH1	Molecular coupling between recognition factors and downstream proteins that are key for excision and replacement of base pairs		Attributed to the development of multiple GI cancers
Hormonal regulation via G-coupled-protein receptors and mitogen-activated protein kinase (MAPK)	Gastrin	Regulator of gastric acid secretion	Hypergastrinemia (especially with concurrent *Helicobacter pylori* infection)	Gastric cancer Colorectal cancer
			Achlorhydria (lack of gastrin)	Gastric cancer related to bacterial overgrowth
	Cholecystokinin (CCK)	Regulates contraction of the gall bladder and secretion of pancreatic enzymes	Elevations in CCK	Pancreatic cancer
	Neurotensin (NT)	Released in response to intraluminal fats	Elevations in NT	Attributed to the development of multiple GI cancers
	Gastrin-releasing peptide (GRP)	Stimulates release of multiple GI hormones	Elevations in GRP/mutations in GRP receptor	Gastric cancer Pancreatic cancer

APC, antigen-presenting cell; MLH, mutL homolog 1; MSH, malignant hyperthermia sensitivity; Rb, retinoblastoma protein.

gene that exists in all cells that derive from that altered cell. This loss is referred to as the *loss of heterozygosity* or *allelic deletion*. A secondary somatic mutation (second hit) occurs in the other normal allele of that same gene, resulting in the so-called two-hit knockout of tumor-suppressor function.[34] In the sporadic form of retinoblastoma, two distinct somatic mutations are needed in both the Rb alleles to eliminate tumor-suppressor function and lead to cancer development. Not surprisingly, the sporadic form of retinoblastoma occurs in older patients and is less commonly bilateral at presentation.

The tumor-suppressor gene p53, sometimes known as the "guardian of the genome," controls cellular arrest, apoptosis, and proliferation, and is essential in mitigating DNA damage. The policing activity of p53 prevents the accumulation of mutations that would favor genomic instability and subsequent malignancy.[14] Inactivation of p53 by mutation plays a critical role in tumorigenesis in many human and animal cancers.[35-39] For the most part, dysregulation of p53 protein is associated with its stabilization and overexpression in cancer tissues. Germline mutations that affect p53 also have been documented and associated with familial cancer risk (Li-Fraumeni syndrome).[40] The activity of p53 can also be affected by nonmutational means. Overexpression of the p53 inhibitor MDM2, a cellular oncogene, reduces the amount of active p53, shifting the cell balance away from apoptosis.[17]

Another key tumor-suppressor gene linked to the development of several GI neoplasms is Smad4 (DPC4). Smad4, a member of the Smad family, plays a critical role in the mediation of the TGF-β pathway by acting as signal transducer. Wild-type expression of this gene results in suppression of epithelial cell growth via regulation of transcription of target genes inside the nucleus.[10] Germline mutations in Smad4 have been implicated in the development of familial juvenile polyposis, a precancerous condition of the GI tract. Somatic mutations in this same tumor-suppressor gene have also been linked to the development of pancreatic and colorectal cancers.[41]

DNA Mismatch Repair and the Prevention of Mutations

DNA mismatch repair is a cellular process that monitors and corrects DNA replication errors and thereby limits mutation risk. In this process, mismatch correction recognition enzymes bind to the DNA at the site of mismatch. After identifying the marred region, additional enzymes excise the aberrant DNA. This step is then followed by DNA polymerase-mediated reconstruction of the strand and DNA ligase activity to seal the nicks. In people, many mismatch repair enzymes have been identified including the hMSH, hMLH, and hPMS families.[10] Of these enzymes, hMSH2 and hMSH1 are the most implicated in tumorigenesis when mutated. Germline or somatic mutations in either of these enzymes is correlated with the development of hereditary nonpolyposis colorectal cancer (HNPCC) syndromes in humans. Additionally, alterations in mismatch repair that confer tolerance to DNA mutations may also result in carcinogenesis by allowing mutations to exist without addressing them.[42]

Mechanisms of Oncogenesis: Transformation from Normal to Malignant State

Understanding of normal cell biology and the processes that lead to malignancy has increased dramatically in recent years. We now recognize that the transformation of a normal cell into a malignant cell requires molecular, biochemical, and cellular changes that incrementally contribute to the process. Furthermore, despite the wide diversity of cancer types, these acquired capabilities appear to be common to all types of cancer. An optimistic view of increasing simplicity in cancer biology is further endorsed by the fact that all normal cells—irrespective of origin and phenotype—carry similar molecular machineries that regulate cell proliferation, differentiation, aging, and cell death.

The continuum from a normal cellular phenotype to malignancy includes metaplasia (particularly in the GI tract), benign tumors, in-situ tumors, and cancer. Each step in this continuum is the result of genetic dysregulation (involving cancer-associated genes) within the tumor and in the surrounding tumor stroma. Metaplasia is defined as the conversion of a mature differentiated cell into another form of a mature cell type, often following injury or insult. Typically, this occurs secondary to a chronic disease such as inflammatory bowel disease (IBD).[43] These changes often result from mutations in committed adult tissue-specific stem cells or secondary to transdifferentiation of lineage-committed cells.[44] Although metaplasia involves alterations in genotype and phenotype, once the inciting stimulus is removed, the change can revert, leading to a normal phenotype. In contrast, phenotypic changes noted in benign tumors, in-situ tumors, and malignancy are irreversible.[45] Benign tumors may be locally invasive, but do not metastasize. Although in-situ tumors are true malignancies of the epithelium, these tumors have not gained the ability to penetrate through basement membranes. These tumors are small and are often the precursor to malignancy, where a tumor has the capability of explicit local invasion and metastasis.

The model of cancer progression that involves cancer cells moving through multiple stochastic events, leading from the normal state to malignancy is not equally applied to all cancer types. Cancers of the GI tract are well matched to this model where distinctive precancerous lesions have been identified within the continuum.[46] This stepwise association of genetic dysregulation coupled to a specific disease entity in this continuum has been best defined in human colon cancer by Vogelstein et al. and is affectionately referred to as the "Vogel-gram of multistep carcinogenesis."[47,48] In tumors where such precancerous lesions are not identified (e.g., osteosarcoma), a similarly complex set of genetic changes are nonetheless believed to be necessary.

In 2000, Hanahan and Weinberg proposed that the cancer phenotype is defined by five to six defining hallmarks.[49] These cancer hallmarks include (a) self-sufficient growth, (b) insensitivity to antigrowth signals, (c) evasion of programmed cell death (apoptosis), (d) limitless replicative potential, (e) sustained angiogenesis, and (f) tissue invasion and metastasis. One appealing feature of these hallmarks of cancer is that the complexity and diversity of genetic dysregulation known to exist in and between cancers can be unified by the phenotypic effects associated with these genetic events. Some genetic events may be responsible for the acquisition of one or more of the hallmarks, whereas other genetic events may contribute to part of a single hallmark. Each of the acquired capabilities described previously represent a dysregulation in a homeostatic mechanism. The process of metastasis requires angiogenesis and invasion, as such the traits of sustained angiogenesis, and tissue invasion and metastasis may be collectively considered to represent a single hallmark of metastasis.

The hallmark of autonomy in cellular growth allows cancer cells to be free from dependency on external mitogenic signals. This hallmark is often attained following genetic dysregulation of one or more of the cell-cycle control mechanisms. The ability to evade the attempts of the body to arrest abnormal proliferation is then required for the development of malignancy. The normal cell responds to cell–cell interactions, intracellular signals, and other environmental information when deciding whether to divide, differentiate, or die.

These intricate signals and clear cell–cell communications are key to maintaining the harmony of homeostasis. In the event of malignancy, cells no longer appropriately respond to signals for cytostasis and shirk the postmitotic state (G_0). A common pathway of eluding differentiation involves the oncogene c-myc, a nuclear transcription factor for cellular growth. In yet another example of cellular yin and yang, c-myc function is restrained by the MAD–MAX transcription factor complex. When c-myc associates with the protein MAX, the resultant effect is cellular growth and proliferation. However, if MAX is conjoined with a MAD transcription factor, the balance is shifted toward terminal differentiation. If a genetic alteration occurs, resulting in an exuberant dominance of c-myc expression, the scales are tipped and prevention of proliferation or arrest is not possible.[23]

Cancer cells must also gain the ability to avoid death, or apoptosis. The minimization of the number of cells that perish allows tumors to grow and invade locally, a hallmark of all types of benign or malignant tumors. As discussed previously, this often involves loss of the recessive p53 tumor-suppressor gene or aberrant overexpression of anti-p53 genes such as MDM2.[50] Failure of tumor cells to appropriately undergo apoptosis following DNA damage progressively contributes to the hallmarks of cancer by allowing growth disrupting mutations to persist in cells without death. An innate mechanism created to stop aberrant cellular proliferation exists in the chromosomes themselves. Aging somatic cells are allowed only a finite number of replications limited by their chromosomal ends (telomeres). Because of the inaccuracy of 5′ to 3′ DNA synthesis at the terminal regions of chromosomes, an average of 50 to 200 repeated noncoding DNA nucleotides are lost during each cell division, a phenomenon termed *telomere attrition*.[2] Once the telomeric region has been sufficiently compromised, the cell enters a period of senescence, defined by continued cell functioning but the loss of replicative capabilities. In time, the aged cell enters crisis, the terminal cell stage where morphologic alterations and chromosomal instability result in ultimate cell death.[51,52] By recruiting the enzyme, telomerase, cancer cells retaliate against this mechanism and maintain the lengths of their telomeres. In so doing, the cancer cell achieves immortality, unrestrained in the number of replications it can undergo.[53-55]

Once a tumor establishes itself, it must ensure the survival of its increasing mass. This is accomplished primarily via the recruitment of new blood vessels to bring essential nutrients, oxygen, and facilitate the elimination of waste products.[56] This process is known as *angiogenesis* or *vasculogenesis*. Just as a tumor may enlist the aid of neighboring normal cells to help it grow, it may also elicit normal cells to produce angiogenic signals. At least 20 angiogenic growth factors have been identified and described, including vascular endothelial growth factor (VEGF) and basic fibroblastic growth factor (bFGF). As with any controlled system, antiangiogenic substances also exist (e.g., angiostatin and thrombospondin).[57] In normal adult cells, the switch controlling angiogenesis favors antiangiogenic control. In cancer, the angiogenic signals prevail resulting in new blood vessel formation. Angiogenesis begins with the activation of the endothelial cells by binding of an angiogenic signal (e.g., VEGF) to a surface endothelial receptor. In concert with angiogenic stimulation, proteins called *matrix metalloproteinases* (MMPs) help the activated endothelial cells invade the extracellular matrix by breaking down the surrounding tissues.[58-60] The activated endothelial cells then mature, forming hollow networks that coalesce into blood vessels. The importance of new blood-vessel formation in neoplastic cells is not restricted to just feeding the primary tumor. Metastasis, or the spread of cancer cells to other areas of the body distant from the primary site, relies upon tumor emboli being able to access blood and lymphatic vessels. Metastases are not a direct extension of the primary tumor and are not dependent upon the route of spread (i.e., hematogenous versus lymphatic versus peritoneal seeding).[61] The process of metastasis is believed to occur through the completion of a series of stepwise events. For this process to occur, a cancer cell must leave the site of the primary tumor, pass through the tumor basement membrane, and then pass through or between endothelial cells to enter the circulation (extravasation). While in the circulation, tumor cells must be able to resist anoikis (programmed cell death associated with loss of cellular contact), evade immune recognition and physical stress, and eventually arrest at distant organs. At that distant site the cell must leave the circulation and survive in the hostile microenvironment of the foreign tissue. This distant site may be the eventual target organ for metastasis or may be a temporary site. In either case the cancer cell is thought to lie dormant for a protracted period of time before moving to its final location. Following dormancy, cells receive signals to proliferate, create new blood vessels (angiogenesis) or coopt existing blood vessels, and then successfully grow into a measurable metastatic lesion. It is likely that further progression is associated with the repetition of this process and the development of metastases from metastases; as such the steps outlined above continue not only after the detection of the primary tumor but also after the detection of metastases. The basic tenets of this model of metastasis have been intact for more than 40 years; however, a greater understanding of biologic principles associated with each metastasis process is emerging and has been reviewed.[62-64] The opportunity provided by this emerging understanding is the development of novel strategies for the management of metastases in pet animals.

Risk Factors Contributing to the Hallmarks of Gastrointestinal Cancers

We have reviewed the mechanisms of normal cell proliferation and apoptosis, the genes and pathways involved in these mechanisms that when dysregulated contribute to cancer, and the necessary and defining features (hallmarks) of the cancer phenotype. The factors that contribute to the dysregulation of gene and gene function are complex and include host genetics, environmental exposures, cellular aging, and the interplay among these factors. Some cancer risks contribute to cancer development in all organ systems, whereas others are organ and cell-type specific. The following sections review specific cancer risks that may contribute to the development of cancers of the GI tract.

Inflammation as a Precursor to Cancer

Chronic inflammation, particularly in the GI tract, can mediate changes that, if left unaddressed, can progress to cancer. In examples such as gastroesophageal reflux disease (GERD) and IBD, derangements in mucosal host defenses and dysregulation of immune responses result in chronic inflammatory changes. In human patients, these diseases have been shown to progress from reversible metaplastic disease through dysplasia to cancer.[65,66] Inflammatory mediators, cytokines, and reactive oxygen and nitrogen species are often elevated in these conditions. Signal transduction pathways are activated including the arachidonic acid–cyclooxygenase (COX) and the canonical Wnt pathways to promote cellular proliferation, mounting the risk of acquiring somatic mutations that may result in a malignant phenotype.[67] Additionally, oxidative stress may result in mismatch repair and p53 dysfunction allowing for higher numbers of mutations and the evasion of apoptosis.[68] With this selection toward mutability, long-term inflammation can easily expedite the

normally slow transition toward malignancy and facilitates tumorigenesis. Direct correlations between gastric infection with *Helicobacter pylori* and the development of gastritis that matures into gastric cancer are well established in both humans and animals.[69-71] The same pathophysiology may be involved in diseases such as esophageal osteosarcoma–fibrosarcoma secondary to *Spirocerca lupi* infestation in dogs. It is interesting to speculate that intestinal lymphoma may develop as a sequel to prolonged severe lymphocytic-plasmacytic IBD.[72,73] In dogs or cats, no direct correlations have been established between these disease states.

Chemical Carcinogenesis and Dietary Factors

The GI tract is exposed to a variety of factors that may act as carcinogens/procarcinogens, including dietary substances or by-products. Correlations between the consumption of certain compounds and the development of cancer are well documented in humans and animals.[74] Procarcinogens that are ingested are either activated or detoxified, typically through the liver, and can exert DNA damage that may result in a somatic mutation. When paired with other protumor factors, these mutations can result in malignancy.[10] Other connections between the fiber and fat content in foods are implicated in tumor regulation.[75]

Hormonal Control over Gastrointestinal Proliferation

GI hormones play a significant role in the proliferation and maintenance of GI tissues via tightly regulated G-protein-coupled receptors (GPCRs) and the downstream activation of mitogen-activated protein kinases (MAPKs).[76] The primary function of GI hormones is the endocrine control of secretion, absorption, motility, and digestion mediated through the GI tract. However, when dysregulated, these hormones and their associated GPCRs are integral to the development of neoplastic conditions in locations such as the stomach, colon, and pancreas.[77] The primary GI hormones that have been investigated in cancer development include gastrin, a hormone that is responsible for gastric acid secretion; cholecystokinin (CCK), a mediator of gallbladder and pancreatic function; neurotensin (NT), a hormone released in response to intraluminal fats; and gastrin-releasing peptide (GRP), the universal switch for GI hormone release. These hormones act synergistically with and antagonistically to each other and are also influenced by external factors. These intimate interactions ultimately maintain a delicate balance favoring homeostasis.[78]

Once disrupted, either via hormonal or receptor dysregulation, cellular proliferation is favored and the risk of malignancy increases. Cancers that originate in the stomach and colon are particularly sensitive to the abnormal expressions of gastrin and of gastrin receptors. In conditions that favor hypergastrinemia, such as infection with *H. pylori*, metaplastic changes are noted in the GI mucosa.[77] When chronic, these changes can become irreversible, resulting in the formation of carcinomas.[79] In conditions where gastrin is insufficiently produced, tumorigenesis is also possible as a sequel to bacterial overgrowth, inflammation, and the activation of pathways that shift toward abnormal cell growth (e.g., STAT3, interferon [IFN]-γ).[78]

Gastrointestinal Cancer Stem Cells

A recent hypothesis in solid and hematopoietic tumor cancer biology involves a specialized subset of tumor cells that are endowed with unique abilities to replicate. These progenitor cells, otherwise known as *cancer stem cells*, account for a very small population of the cells within a mass. These cells are believed to retain the tumorigenicity of a cancer and are responsible for the emergence of cellular heterogeneity within a cancer. In studies that examined the clonogenicity of several tumor types (i.e., leukemia, multiple myeloma, lung, and breast cancer), a range of 1 in 10,000 to 1 in 100 tumor cells was capable of producing new tumor colonies when transplanted to naive environments.[80,81] These percentages mimic the prevalence of normal stem cells within the body, and this suggests that only a small percentage of cancer cells are truly tumorigenic.[82] From the cancer stem cell hypothesis emerges the possibility that tissue-specific stem cells (e.g., GI stem cells) may be a receptive or permissive cellular target for the genetic events that lead to the cancer phenotype. The "stemness" of these cells may then contribute to their ability to act as cancer stem cells once transformed. GI stem cells have high replicating and differentiating capabilities that are required to maintain tissue homeostasis, as well as the ability to restore a multitude of cells within the GI system.[44] The implication that a finite group of cells controls the growth of a given tumor has widespread significance in cancer biology, diagnosis, and therapy. As with tissue and embryonic stem cells (i.e., bone marrow), cancer stem cells may be more chemoresistant than the remainder of the tumor population. Elevated expression of cell survival proteins as well as upregulation of transmembrane receptors that promote chemotherapy export (i.e., multidrug resistance genes) may all play a role in the invisibility of cancer stem cells.[83] By discovering targets that specifically lead to the destruction of the progenitor cells, treatment responses and remission times may be dramatically improved.[84,85]

CHAPTER 6

Abdominal Pain

Jean A. Hall

Definition

Abdominal pain is pain that originates from within the abdominal cavity. *Acute abdomen* is a term used to designate acute onset of abdominal pain, sepsis, or shock caused by abdominal disorders.

Pathophysiology and Mechanisms

Based on its origin, pain can be divided into visceral, somatic, and neuropathic. Abdominal pain is visceral in origin. Visceral pain differs from somatic pain in several ways.[1] First, visceral pain is not evoked in all visceral organs because peripheral receptors behave differently. Hepatic and renal parenchyma, for example, are not sensitive to pain; therefore activation of their receptors does not reach the level of consciousness. Second, visceral pain is not always associated with injury. Stimuli producing pain include distention, ischemia, and inflammation. Third, visceral pain is diffuse and poorly localized because there are fewer sensory visceral afferent fibers relative to afferent innervations of somatic tissues. Moreover, these visceral afferent fibers terminate diffusely in the spinal cord on neurons receiving input from both somatic and visceral receptors. Fourth, visceral pain is referred to the body wall because somatic (e.g., skin and muscle) and visceral afferents terminate on the same dorsal horn neurons in the spinal cord. This viscera–somatic convergence may give rise to referred pain in areas remote from the original lesion. Fifth, visceral pain is accompanied by motor and automatic reflexes such as nausea and vomiting. Visceral afferents travel together with afferents of the autonomic nervous system, and crosstalk occurs between nerves at local and central levels.[1] Thus sensory stimulation of the chemoreceptor trigger zone may initiate nausea and vomiting in addition to abdominal pain. Intense or long-lasting pain stimuli or inflammation can lead to plastic changes in the nervous system both in the periphery and at the spinal and supraspinal level. This results in enhanced visceral input, increased central neuronal activity and excitability, referred to as sensitization, and may ultimately lead to central plasticity, hyperexcitability, and pain memory.[1]

The visceral pain system consists of afferent peripheral fibers that synapse in the dorsal horn of the spinal cord and transmit information to a second order neuron, which than transmits information to the brain where information is further distributed to different supraspinal centers for processing.[1] Visceral afferent fibers are thinly myelinated Aδ-fibers or unmyelinated C-fibers with free nerve endings that respond to mechanical, thermal, and chemical stimulation. Visceral afferents converge with neurons in the dorsal root that receive input from superficial and deep somatic tissue as well as other viscera. Thus a group of neurons become hyperexcitable in an area of the dorsal horn as a result of a visceral pain signal. This is perceived as pain in somatic tissues innervated by afferents projecting to this same area in the dorsal horn. Afferent signals in second order neurons travel in spinothalamic tracts to reach thalamus and cortex. These neurons are subject to descending control from higher brain centers, which can be inhibitory or excitatory. Descending inhibition, via endogenous opioid release on afferent fibers in the spinal cord, appears to be the major way by which brain controls pain perception. The brain can also undergo cortical reorganization by enlarging and involving neighboring areas. Central sensitization results in allodynia (i.e., pain caused by a visceral stimulus that does not normally provoke pain), hyperalgesia (i.e., decreased pain threshold), and a significant increase in the size of the referred pain area together with hyperalgesia of muscle and skin.[1]

Differential Diagnosis

Abdominal pain is associated with a number of disorders (Table 6-1).[2,3] Differential diagnoses can be categorized based on disorders of body systems. These include disorders of the gastrointestinal system (stomach, small intestine, and large intestine), hepatobiliary system and pancreas, urologic system (renal, ureter, bladder, and urethra), hemolymphatic (spleen and lymph nodes), reproductive systems (prostate and testicles; uterus and ovaries), peritoneum and retroperitoneum, vascular and mesentery, and body wall including skin and subcutaneous tissues.

Extraabdominal disorders should also be considered because they may be mistakenly interpreted as causing abdominal pain. Skeletal or thoracolumbar pain from intervertebral disk disease, diskospondylitis, spinal neoplasia, sublumbar or retroperitoneal abscesses, fractures, and pelvic trauma can mimic abdominal pain. Other extraabdominal sources of pain include meningitis, polymyositis, steatitis, heavy metal toxicities, and black widow or brown recluse spider envenomation.[4] Poor abdominal palpation technique in a normal dog or cat also can elicit abdominal rigidity that may be erroneously interpreted as abdominal pain.

*Common.

Evaluation of the Patient

History

A complete and detailed history should be obtained as for any other serious disease process. The history should start with the presenting complaint (abdominal pain) and include a chronologic description of progression of illness. When was the patient last normal? The focus should be on the previous six months, but be sure to include all previous medical conditions. Ask about clinical signs involving other body systems, for example, vomiting, diarrhea, appetite, fecal consistency, polyuria, polydipsia, urination behavior, coughing, and sneezing. Discuss current and previous medications, including routine medications like heartworm and flea and tick treatments. Ask about current diet as well as feeding behavior. Inquire about travel history and vaccination status. Ask about exposure to toxins, missing sewing thread and needles, chew toys, and the possibility of trauma.

Physical Examination

The initial physical examination is focused on the identification and treatment of immediately life-threatening problems (e.g., shock and gastric dilation volvulus [GDV] syndrome). This includes a quick assessment of cardiovascular, respiratory, and central nervous systems, and abdominal palpation to determine if GDV is present. If the patient is stable, a more thorough physical exam is performed. Abdominal palpation may reveal focal pain (e.g., caused by an intestinal foreign body), regional pain (e.g., caused by pyometra), or diffuse pain (e.g., caused by peritonitis).[2] Size of liver, spleen, kidneys, and bladder should be noted. Intestines and colon should be assessed for pain, thickening, gas, or a foreign body. The spine should be palpated for the presence of skeletal pain masquerading as abdominal pain. The abdominal wall should be inspected for traumatic wounds or bruising.

Digital rectal exam should be performed to assess fecal color and the size and morphology of the prostate gland. Peripheral lymph nodes should be inspected for signs of systemic disease. An oral examination should be performed to look for a linear foreign body wrapped around the base of the tongue.

Laboratory Evaluation and Tests

In addition to a thorough history and physical examination, the diagnostic workup for the patient with abdominal pain may include imaging, abdominal fluid analysis, clinical laboratory tests, and if needed, exploratory abdominal surgery (Fig. 6-1).[3] If the problem cannot be localized following thorough physical exam, abdominal imaging should be performed. If an obvious reason for surgery is identified on abdominal radiographs, then surgery should be performed after initial stabilization. If not, samples should be collected for a minimum data base (e.g., complete blood count, serum

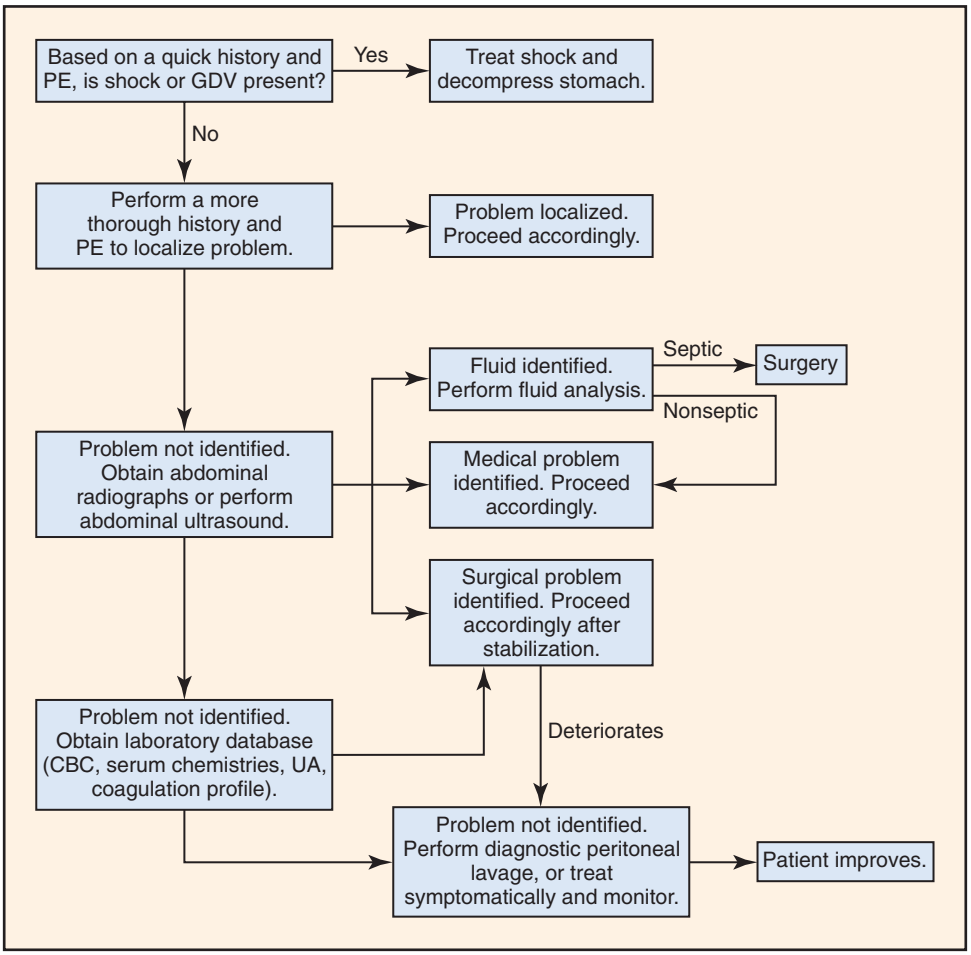

Figure 6-1 Diagnostic approach to the painful abdomen.[3]

chemistry, coagulation profile, urinalysis, fecal analysis). If abdominal pain persists and a cause has not been determined, abdominocentesis and diagnostic peritoneal lavage should be performed.

Radiography is a familiar and available modality for evaluating patients with painful abdomen.[5] If gastrointestinal (GI) perforation is suspected, an iodinated contrast agent should be used (e.g., diatrizoate sodium as a 30% solution at a dose of 2 to 20 mL/kg). Iodinated contrast agents decrease small intestinal transit time. Remember that some pain medications (e.g., opioids) prolong gastric emptying time.[6] Contrast procedures that are used to evaluate patients with urologic disorders include positive contrast cystography, urethrography, and excretory urography. Ultrasound is widely available and can support radiographic findings.[7] In addition, ultrasound may be helpful for collecting peritoneal or retroperitoneal fluid, as well as for aspirating or biopsying various abdominal structures. Radiographs should be obtained before performing diagnostic peritoneal lavage. Computed tomography (CT) and magnetic resonance imaging (MRI) may aid in identification of underlying conditions.

Abdominal paracentesis (i.e., percutaneous removal of abdominal fluid for diagnostic purposes) provides a rapid, easy, and safe method of diagnosing disease associated with abdominal effusion.[8] This can be performed by simple- or four-quadrant abdominal paracentesis. Four-quadrant abdominal paracentesis is performed by dividing the abdomen into four quadrants by bisecting the linea alba through the umbilicus. Each site is prepared aseptically and all four sites are aspirated in sequence until 5 to 10 mL of fluid is collected. Ultrasound guidance of the needle is used if fluid is not easily retrieved. Diagnostic peritoneal lavage is indicated when the other techniques have failed to provide a diagnostic sample. A dialysis catheter or other catheter with numerous side holes provides more opportunities for retrieval of a fluid sample; it is directed into the abdominal cavity just caudal to the umbilicus. (The animal is encouraged to empty its urinary bladder, a surgical preparation is performed, and local anesthetic instilled.) Warm 0.9% sodium chloride (20 to 22 mL/kg) is infused and the animal is gently rolled from side to side to disperse the fluid prior to aspiration and fluid collection. Fluid should be collected for cytologic analysis, chemical analysis, and culture.

Abdominal fluid can be classified as a pure transudate, modified transudate, or exudate (see Chapter 8), depending on the fluid's total nucleated cell count and protein concentration.[9] Modified transudates and exudates are further classified as neoplastic, inflammatory (nonseptic), hemorrhagic, or septic. Chemical analyses may include blood urea nitrogen (BUN), creatinine, amylase, lipase, glucose, potassium, or bilirubin. In many cases, comparison of abdominal fluid content with that of serum can support or even make a definitive diagnosis.[9] Abdominal fluid creatinine concentration greater than two times serum creatinine concentration, and abdominal fluid (potassium) greater than 1.4 times (dogs) or 1.9 times (cats) serum (potassium) suggests uroabdomen. Lipase and amylase concentrations greater than that of serum suggest pancreatitis. Abdominal fluid (bilirubin) that is greater than serum concentrations indicates bile peritonitis.

Treatment and Management

General Principles

Abdominal pain is approached on the basis of the severity of clinical signs. Initially the patient must be treated for shock and stabilized. Subsequent diagnostic steps are used to determine whether surgery or medical therapy is more appropriate.

Stabilization should be the primary objective in dogs or cats with shock and abdominal pain. Ventilation and/or perfusion abnormalities should be managed by providing oxygen therapy and intravenous fluids. If possible, diagnostic blood and urine samples should be collected prior to fluid therapy for later submission, if indicated. Choice of fluids and rate of administration are based on underlying clinical disorders (see Chapter 48). The goal is to restore heart rate, capillary refill time, mucous membrane color, blood pressure, urine output, bicarbonate or base excess, and lactate to normal.[2]

Treating abdominal pain does not necessarily compromise timely diagnosis or treatment of a surgical abdomen.[10] A literature review of studies published from 1996 through 2007 on the timing and frequency of assessment, and on the use of patient-controlled analgesia for nonsurgical pain in inpatients on medical wards showed that opioid administration has a negligible impact on successful clinical management of acute abdominal pain.[10]

Medical

Conditions treated medically include gastroenteritis (bacterial, viral, and toxic causes), pancreatitis, nonseptic cystitis, pyelonephritis, acute prostatitis, and cholecystitis. Medical treatment should be directed at the underlying disorder as well as supportive of normal body functions. Pain management should be a part of medical therapy. Analgesic agents should be administered to all patients, whether medical or surgical, in which immediate relief of abdominal pain cannot be accomplished.[4] Opioid agents (e.g., morphine) may induce vomiting and thus may not be as appropriate as other drugs. Phenothiazine tranquilizers should not be used in pain management. Suggested drugs include butorphanol at 0.1 mg/kg intravenously (cats) and 0.2 to 0.4 mg/kg intramuscularly, intravenously, subcutaneously every 2 to 4 hours (dogs); buprenorphine 0.005 to 0.02 mg/kg intramuscularly, intravenously, or subcutaneously every 6 to 12 hours (dogs) and 0.01 to 0.03 mg/kg intramuscularly every 12 hours (cats); fentanyl at 3 µg/kg intravenous bolus followed by 1 to 5 µg/kg/h given intravenously by constant rate infusion (dogs and cats); or hydromorphone at 0.1 to 0.2 mg/kg intramuscularly, intravenously, or subcutaneously (dogs and cats).

Early antibiotic therapy within one hour of recognition of severe sepsis improves survival in humans.[2] Therefore if septic peritonitis is suspected based on abdominal fluid cytology (the presence of phagocytosed bacteria), empirical antibiotic therapy should be initiated according to Gram staining characteristics of the bacteria. Additional therapeutics that should be considered include antiemetic agents (see Chapter 35).[4]

Surgical

Patients with a diagnosed surgical condition, evidence of sepsis, evidence of free abdominal gas, intractable hemorrhage, or who fail to stabilize with aggressive medical therapy are candidates for emergency surgery.[11] If medical therapy is ineffective, the animal's condition is deteriorating or does not improve after two to five days of therapy, or if severe abdominal pain persists, it is appropriate to recommend exploratory surgery.[3] The owner should be advised that a nonsurgical problem may be found or that a definitive diagnosis might not be possible, in which case biopsies should be taken from multiple organ systems.[3] Examples of conditions requiring surgical intervention include gastrointestinal obstruction, gastric rupture, and GDV; urinary obstruction, calculi, and ruptured bladder; pyometra, uterine torsion, and prostatic abscess; hepatic abscess, obstruction of the common bile duct, and ruptured gallbladder; pancreatic abscess; splenic torsion; abdominal hernia with

strangulated viscera; penetrating abdominal wound; ruptured abdominal neoplasia; and septic peritonitis. Anesthesia and abdominal surgery offer the opportunity to initiate nutritional support through early enteral feeding via esophagostomy, gastrostomy, or jejunostomy feeding tubes (see Chapter 33).[2]

CHAPTER 7

Anorexia

Kathryn E. Michel

Definition

Anorexia is the lack or loss of appetite for food. It is a common and nonspecific finding in sick or injured patients and a frequent reason people seek medical attention for their pets. Anorexia can be partial or complete, depending on its underlying cause and severity. Resolution of this condition can be relatively simple in patients if its etiology is readily treatable. However, when anorexia is due to a chronic or incurable condition (which occurs with certain gastrointestinal diseases), management of anorexia becomes more challenging and more critical because of the negative consequences of long-term inadequate food intake.

Pathophysiology and Mechanisms

Control of Food Intake

Regulation of initiation, maintenance, and termination of food intake is complex and involves integration of numerous internal and external stimuli by different areas of the central nervous system (CNS). In addition to signals for hunger and satiety, there are other factors influencing initiation and maintenance of food intake. Understanding these various stimuli will help clinicians assess which factors may be involved when evaluating anorexic patients.

Sensory Signals

Sensory signals affecting feeding behavior fall into two categories: orosensory and postingestive. When one thinks of orosensory stimuli, the concept of flavor immediately comes to mind; however, olfaction and perception of physical attributes of a food (e.g., temperature, texture, consistency) contribute to the relative appeal of that food. Sense of smell is more highly developed in dogs and cats than in humans; consequently, it is likely to have a greater role in influencing food intake in these species. Warming food often enhances its aroma, and this may explain why dogs and cats prefer foods that are warmed to approximately their body temperature. Food acceptance drops off sharply, however, when the food is perceptibly warmer than normal body temperature.[1]

Although olfaction is involved in initiation of food intake and contributes to what is perceived as the flavor of food, the way foods taste is important for maintaining food consumption. Dogs and cats are believed to be able to taste salty, bitter, acidic, and meaty (*umami*) flavors. Dogs, but not cats, can also taste sweet flavors.[2] Increasing fat and protein content of foods generally improves palatability for dogs and cats, as will adding natural sweeteners for dogs. Cats, on the other hand, seem to have a preference for slightly acidic flavors. Texture and consistency of a food can be an important aspect of palatability for companion animals. Dogs and cats generally dislike sticky or powdery foods, while increasing moisture content correlates with enhanced appeal. However, individuals can develop strong preferences for a particulate texture or kibble shape and refuse foods of higher moisture content.

Postingestive sensory signals come from the gastrointestinal tract and prompt termination of a meal. Mechanoreceptors located in the stomach, for example, detect gastric distention and provide feedback signals to the brain via vagal stimulation.

Metabolic Signals

There are several orexigenic factors that are produced in the CNS; however, neuropeptide Y (NPY) plays the central role in regulating appetite in the hypothalamus. A variety of signals that influence NPY production will increase or decrease food intake.[3] Decreased circulating insulin concentration can increase NPY levels while postprandial elevations in serum insulin concentration decreases NPY. Leptin, a peptide secreted by adipocytes, plays a key role in maintaining energy balance. Leptin levels increase as fat reserves increase, which reduces NPY production. The polyphagic effect of glucocorticoids is believed to be due to these substances increasing NPY while there is evidence that certain cytokines have the opposite effect on NPY production.

Digestion and absorption of nutrients from a meal also trigger release of factors that feedback to the CNS. Cholecystokinin release by the gut in response to arrival of fat and certain amino acids in the duodenum suppresses food consumption. Peptide YY is another factor believed to inhibit food intake; it is released by the gut after food ingestion.

Environmental Signals and Learned Behavior

Although food itself and the physiologic response to ingestion of a meal are major factors influencing food intake, the environment in which food is offered may override any preexisting positive or negative sensory and metabolic signals. Companion animals usually become accustomed to some kind of routine associated with meals. Timing and location of meals, ambient noise level, type of feeding bowls, the person offering the food, and positive or negative associations of these environmental cues can influence patient appetite. Past experiences have some degree of impact on what types of food an animal find acceptable. Although cats in particular tend to be

neophilic in their food preferences, individual animals may develop fixed food preferences with partiality to particular flavors or textures.[4]

Differential Diagnosis

Any condition or circumstance interfering with initiation of food intake or triggering negative stimuli during food consumption can lead to anorexia. Inciting causes can include pathologic conditions, drug therapy, and alterations in the patient's diet, environment, and psychological status.

Reduced food intake is common in patients with organ failure, neoplasia, and conditions producing inflammation or hyperthermia. Underlying mechanism can be one or more circulating factors that act on appetite and satiety centers in the brain, including certain cytokines (e.g., tumor necrosis factor [TNF]-α, interleukin [IL]-1, interferon) or substances that would normally be metabolized by affected organs (e.g., uremic toxins). Chronic pain may directly cause negative stimuli that discourage food ingestion or may generate factors that trigger a reduction in appetite. Gastrointestinal tract diseases are often associated with anorexia. The cause of reduced food consumption may be pain or discomfort in conjunction with the act of eating (e.g., severe periodontal disease, stomatitis, dysphagia, pancreatitis, gastroenteritis). Another significant negative stimulus for food intake is nausea, a frequent clinical sign in gastrointestinal disorders including gastroenteritis, inflammatory bowel disease, pancreatitis, and hepatic diseases. Anorexia is a frequent consequence of conditions leading to hypokalemia and gastrointestinal ileus.

Anorexia may be iatrogenic in some patients. Factors that disrupt a patient's normal routine (e.g., stress of hospitalization and treatment, change in diet or feeding management) can interfere with learned feeding behaviors. Many pharmaceutical agents affect appetite through the same mechanisms at work in gastrointestinal disorders (Box 7-1). Nausea and vomiting are common side effects of many classes of drugs, including antibiotics, cardiac glycosides, and chemotherapeutic agents. Nonsteroidal antiinflammatory drugs, corticosteroids, and chemotherapeutic agents can cause gastrointestinal tract pathology. Adynamic ileus is a side effect of some analgesic agents, particularly the narcotic analgesic agents.

One consequence of a patient experiencing noxious stimuli when it eats is that it may come to associate pain, nausea, or indisposition with the diet being fed or even with the act of eating. This phenomenon is called *learned food aversion* and can be a contributing factor in development and persistence of anorexia for many companion animals.

Box 7-1 Medications Causing Anorexia in Cats and Dogs

- Antibiotics (including amoxicillin, ampicillin, cephalexin, chloramphenicol, erythromycin, tetracycline, trimethoprim/sulfadiazine)
- Cardiac glycosides
- Nonsteroidal antiinflammatory drugs
- Corticosteroids
- Chemotherapeutic agents (including cisplatin, doxorubicin, methotrexate)
- Narcotic analgesic agents
- Chelating agents (penicillamine)

Evaluation of the Patient

Because anorexia is nonspecific and associated with a broad spectrum of conditions, the diagnostic plan is initially predicated on the medical history and physical examination. There are two specific aspects of the history and physical examination, however, that should receive special attention: the patient's dietary history and the assessment of body condition.

History

Historical findings in anorexic patients are variable and depend upon the underlying condition. Key information is obtained by conducting a thorough dietary history, including magnitude and duration of the patient's reduction in food intake, details of the patient's normal diet with attention to feeding management plus recent changes that may have occurred, a description of normal feeding behavior and whether this has altered, and any other aspects of the patient's household environment that can affect the patient's routine, psychological status, or access to food (e.g., move to a new residence, changes in the household makeup) (Box 7-2).

To assess the patient's food intake for adequacy of calories and essential nutrients, it is necessary to obtain a detailed account of what the pet is consuming. To acquire this information, the pet's caregiver may have to keep a food diary for a few days, documenting the types and amounts of foods the patient consumes, including commercial pet foods, home-prepared diets, table foods and scraps, treats, and dietary supplements. Many people will try a variety of pet foods and offer table foods when they perceive their pet has a decreased appetite or shows disinterest in its usual diet. This dietary change is usually unsuccessful, although it sometimes produces an overall improvement in meeting calorie needs, but at the expense of complete and balanced nutrient intake.

The patient's maintenance energy requirement (MER) can be estimated from an accounting of its "normal" diet and food intake. If this information is not available, MER can be calculated using body weight and surface area (Box 7-3). Comparing patient's MER with an estimate of its current energy intake based on dietary history will reveal the magnitude of the caloric deficit. Patients receiving significant amounts of their calories (>25%) from foods other than complete and balanced pet foods should have an assessment of the overall nutritional adequacy of the diet (Box 7-4). Although short-term intake (1 to 2 weeks) of an unbalanced diet

Box 7-2 Conducting a Dietary History

- What is the pet normally fed?
- What is the pet currently being fed?
- Be certain to inquire about specific varieties and amounts of:
  - commercial pet foods
  - home-prepared diets
  - table foods or scraps
  - treats
  - dietary supplements
- Who lives in the household and have there been any recent changes including people and other pets?
- How is the pet fed and have there been any recent changes including:
  - who feeds the pet
  - timing
  - free choice versus meals
- What is the pet's feeding behavior

Box 7-3 Calculating Maintenance Energy Requirement (MER) for Dogs and Cats

1. Calculate resting energy requirement (RER) using one of the following equations:
   - $RER = 70WT_{kg}^{0.75}$
   - $RER = 30WT_{kg} + 70$*
2. MER is a multiple of RER based on the pet's level of physical activity.
   - Adult dogs: MER = 1.2 to 2.0 × RER
   - Adult cats: MER = 1.0 to 1.5 × RER

*Only for animals weighing between 2 and 30 kg.

Box 7-4 Assessing the Nutrient Adequacy of a Diet for a Dog or a Cat*

- What is the protein source? Ideally the protein source should be of animal origin (especially for cats) and lean rather than fatty.
- What is the fat source?
- What is the carbohydrate source? Cooked cereal grains provide one of the more digestible forms of carbohydrate.
- Is there a source of macrominerals (particularly calcium)?
- Is there a source of vitamins and trace elements?

*This checklist provides a quick overall assessment of the nutritional adequacy of a diet but does not ensure that it is nutritionally complete and balanced.

is unlikely to lead to significant nutrient deficiencies, some patients can become depleted in certain essential nutrients in a matter of weeks, depending upon the underlying disease. Expert nutritional advice should be sought for a patient who is eating an unbalanced diet and is anticipated to continue to do so for longer than a few weeks.

In addition to allowing an assessment of caloric and nutritional adequacy of the patient's food intake, dietary history should reveal any changes in that individual's household environment, including overall feeding management. This information will help differentiate between anorexia resulting from external factors that have caused psychological stress, fear, or competition with another animal versus anorexia secondary to an underlying physical condition (Fig. 7-1).

Obtaining information about the patient's normal feeding behavior and how it has changed can help pinpoint causes of anorexia. Patients with a normal or increased interest in food but reluctance to eat or that abruptly stop eating may be experiencing pain or dysfunction associated with prehending or swallowing. In contrast, patients with systemic diseases often show little, if any, interest in food.

Physical Examination

Careful examination of the oral cavity and cranial nerve function will help to identify decreased food intake due to sensory abnormalities or conditions leading to pain or dysfunction associated with eating and swallowing. Ideally the examination should include

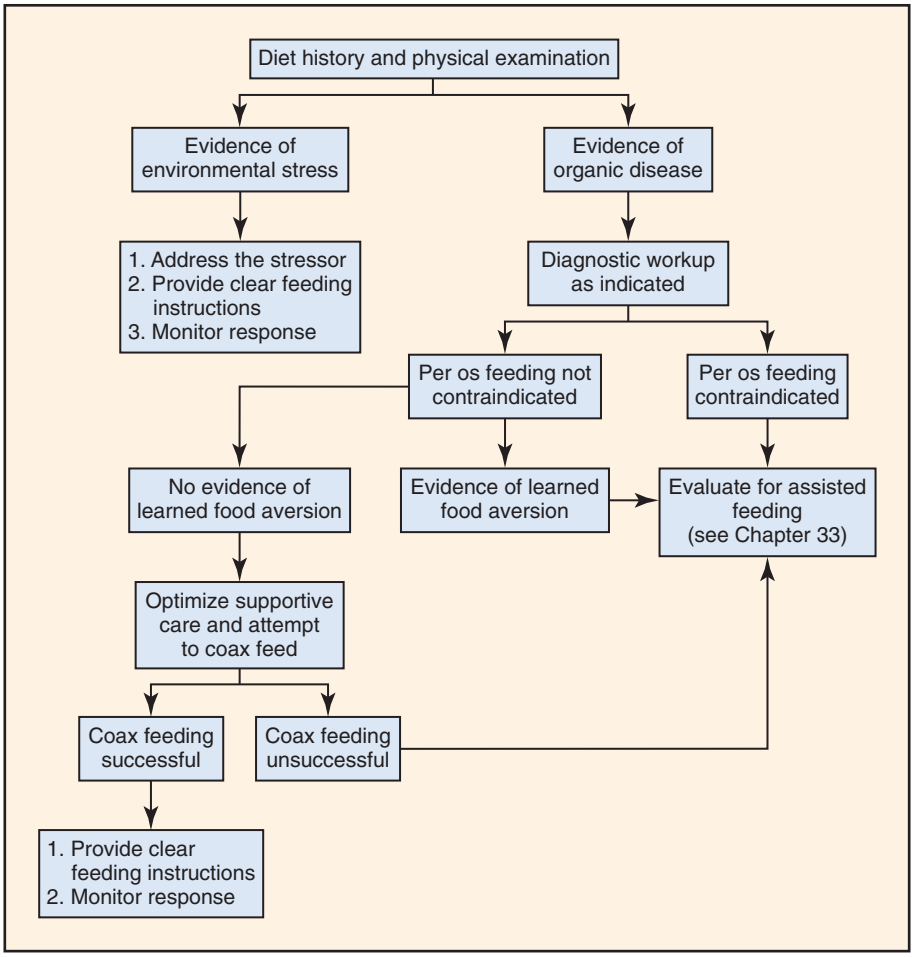

Figure 7-1 Algorithm for basic approach to anorexia.

observation of prehension, mastication, formation of a bolus, and swallowing.

The impact of anorexia on a patient's nutritional status can be assessed in part by evaluating its body condition. Body condition should be evaluated in terms of both the patient's energy reserves (body fat) and lean body mass (muscle mass). When weight loss is a consequence of simple starvation, metabolic adaptations occur that spare the catabolism of endogenous proteins and lean tissue. However, when weight loss is a result of a reduction in food intake secondary to a pathologic condition, a catabolic state ensues with the magnitude tending to mirror the severity of underlying disease processes. In such circumstances a disproportionate amount of weight loss is a consequence of breakdown of lean body mass. Thus it is common to see patients with significant muscle wasting despite excessive body fat. Simply assigning a body condition score based on body silhouette and palpation of adipose tissue is insufficient because patients that are significantly protein-depleted and therefore at risk for nutritionally associated complications will be overlooked.

Diagnostic Tests

Diagnostic workup of anorexic patients usually includes hematology, serum biochemistry, urinalysis, and fecal parasitologic examinations. Feline leukemia virus (FeLV) and feline immunodeficiency virus (FIV) status should be determined in cats. Based on the patient's signalment, history, physical examination, and results of the preliminary laboratory tests, further diagnostic testing and imaging may be indicated.

Treatment and Management

General Principles

Anorexia is usually secondary to some underlying condition; therefore the principal goals of therapy are to diagnose and address primary problems. Every effort should be made to optimize the patient's overall comfort and well-being through supportive care, as this will improve likelihood of adequate voluntary food consumption (see Fig. 7-1).

Attention should be given first to ensuring the patient is properly hydrated and has normal electrolyte concentrations. Hypokalemia is common in inappetent patients and can produce gastrointestinal ileus. Consideration should be given to intravenous administration of vitamin B complex. B vitamins are water soluble and are rapidly eliminated from the body. Patients with poor food intake or who are consuming an unbalanced diet may become deficient in one or more of the B vitamins, which can produce anorexia.

One should also address conditions causing discomfort or distress. Efforts should be made to normalize body temperature as febrile patients are unlikely to eat, and hypothermia causes poor gut perfusion. Effective pain management will improve a patient's comfort, although this must be balanced with the fact that some pain medications may reduce appetite either by decreasing gut motility or causing gastrointestinal tract pathology. It is essential to recognize and treat nausea by addressing underlying etiology or administering antiemetic drugs (see Chapters 23 and 35). It should also be remembered that drugs being given to a patient to treat the primary complaint may be affecting appetite. Adjusting the dosage or switching to another route of administration or a different drug may improve the patient's food intake.

Optimizing environment and timing of meals can be important. One should try to maintain the patient's normal routine and minimize stressful conditions at mealtimes. For example, treatments or procedures that frighten or otherwise upset the patient should not be scheduled to coincide with feeding times. If the patient is hospitalized, offering food in a location other than a busy hospital ward may improve food acceptance.

Box 7-5 Tips for Coax Feeding a Dog or a Cat

- Minimize stress at mealtimes.
- Approximate the patient's routine feeding management as much as possible.
- Recognize the signs of food aversion.
- Try to choose complete and balanced, and energy dense foods that are appropriate for the patient's medical condition.
- When medically appropriate, choose foods which with the patient is familiar.
- Try novel foods if the patient seems averse to its typical diet.
- Warm the food slightly.
- Offer modest portions of fresh foods frequently.
- Offer one food item at a time.
- Do not leave food with the patient for extended periods of time.
- Give clear feeding instructions that include the specific diet to be fed, portion size, and meal frequency.

Dietary

Enteral or parenteral nutrition may be needed in anorexic patients with concurrent conditions in which it is anticipated that voluntary food intake will be insufficient during initial stages of treatment or where feeding is contraindicated (see Chapter 33). Patients who are judged able to achieve adequate voluntary intake are candidates for coax feeding.

Coax feeding is not force feeding. With few exceptions, companion animals will experience stress and resist when food is forcibly placed in their mouths. It is rare that a force-fed patient achieves sufficient food intake, and this type of maneuver can put it at risk of both aspiration pneumonia and development of learned food aversion. The goal of coax feeding is to persuade the patient to consume adequate amounts of food on a voluntarily basis.

Several strategies can be employed for successful coax feeding (Box 7-5). First, assess whether the patient is showing signs of learned food aversion. Observe the patient's behavior when food is offered. Does the patient show interest or does it turn its head, back off, or actively try to push the food away? If food is placed in or near the patient's mouth does it show signs of nausea (e.g., salivation or swallowing)? If the patient does not appear averse to food, then different types of food can be used to tempt it. There are several considerations to bear in mind when choosing a food for coax feeding. The goal is to find a complete and balanced diet that will be suitable for nutritional management of any concurrent conditions and of which the patient will consume sufficient amounts to meet its caloric needs. Ideally, the diet will be energy dense so as to minimize the quantity the patient needs to consume. Sometimes the only food that a patient will accept is one which is not nutritionally complete or which is not entirely appropriate given the patient's underlying disease. Depending upon circumstances, this may be innocuous in the short-term. In other cases, however, it may worsen the patient's condition or lead to new problems.

Finding a diet the patient accepts often involves empirically trying a variety of foods. Knowing what the patient typically ate before becoming ill can aid in making choices (e.g., if it is clear that an individual previously only ate a dry commercial diet or had a

Table 7-1 Appetite Stimulants

Drug	Dosage	Side effects
Benzodiazepine derivatives		Sedation, idiosyncratic hepatic necrosis, effects wane with time when used in sick animals
Diazepam	0.2 mg/kg intravenously (cats)	
Oxazepam	2.5 mg/cat PO (cats)	
Cyproheptadine	2-4 mg/cat PO q12-24h 0.2 mg/kg PO q12h (dog)	Can cause excitability, aggression, and vomiting
Mirtazapine	3.75-7.5 mg/dog, daily PO; 1.9 mg/cat q24h to 72h	Serotonin antagonist; should not be administered to patients receiving monoamine oxidase (MAO) inhibitors
Megestrol acetate	0.25-0.5 mg/kg q24h PO for 3-5 days, then q48-72h (cats)	Polyuria-polydipsia, diabetes mellitus, adrenocortical suppression, hepatotoxicity

fixed preference for a certain flavoring). A patient may develop an aversion to the type of food it used to eat; in such cases the patient may find a novel food more appealing. Knowledge of attributes of food that enhance palatability for dogs and cats (i.e., aroma, moisture, fat, protein, sweetness, acidity, and mouth feel) should be employed when making a food selection.

When a food is offered for the first time, the portion should be modest and the food should be fresh and at room temperature or slightly warmer. Avoid leaving food with the patient for extended periods of time (particularly moist foods that will dry out and lose their appeal). Offering multiple varieties of food simultaneously can make it difficult to discern which foods the patient prefers, will make keeping track of the patient's calorie intake more complicated, and could increase the risk of developing a learned food aversion.

If an acceptable food is found, the next steps are to estimate how much of that food the patient should consume on a daily basis to meet its energy needs and translate that into clear feeding instructions for nursing staff and pet owners when it is discharged from the hospital. If the patient appears to be developing a food aversion or if repeated attempts at coax feeding fail, assisted feeding should be considered to prevent further deterioration of the patient's nutritional status.

Medical

Several drug classifications (benzodiazepines, 5-hydroxytryptamine [5-HT_2] antagonists, tricyclic antidepressants, progesterone derivatives) are believed to have appetite-stimulant properties (Table 7-1). None of these drugs is without side effects, and none will be efficacious if the underlying condition is not addressed and the patient's comfort and well-being has not been optimized through appropriate supportive care. Even under best conditions, appetite stimulants are often ineffective, and the effects will be short term when they do work. Appetite stimulants are most likely to be successful in patients who may have developed a food aversion during an illness from which they have recovered. Most patients in which coax feed fails should be evaluated as candidates for assisted feeding.

CHAPTER 8

Ascites

Caroline Mansfield

Definition

Ascites is defined as fluid accumulation within the peritoneal cavity. Although any peritoneal fluid accumulation could be classified as ascites, the term is more often used to refer to pure and modified transudates. Pure transudates are clear, colorless fluids, with low nucleated cell count (< 1.0 to 1.5 × 10^9 cells/L or <1000 to 1500 cells/μL), specific gravity ≤1.013 to 1.018, and total protein <2.5 g/dL (<25 g/L). Modified transudates may be clear, straw colored, or cloudy in appearance. The protein count of a modified transudate is slightly higher (2.5 to 5.0 g/dL or 25 to 50 g/L) as is the total nucleated cell count (<5.0 to 7.0 × 10^9 cells /L or 5000 to 7000 cells/μL) and specific gravity (>1.013 to 1.018).[1] Exudates are viscous and/or serosanguineous in appearance, have a high protein content (>5.0 g/dL) and cellularity (>10,000 cells/μL), and have a relatively high specific gravity (>1.018). Ascites generally indicates serious disease and warrants prompt investigation.

Pathophysiology and Mechanisms

Ascites forms because of disruption of Starling forces in local capillary beds, with diffusion of fluid across the serosa into the peritoneal cavity. Under normal circumstances, portal pressure gradient decreases (from 6.5 to 13 cm H_2O to 3 to 3.5 cm H_2O) as it progresses from the hepatic triads through to the sinusoids, central vein, hepatic veins, and the caudal vena cava.[2] The changing pressure gradient pushes fluid from sinusoids into protein-rich perisinusoidal spaces (spaces of Disse) which are covered by a thin membrane.[3,4] The balance between oncotic and hydrostatic pressures is maintained by lymphatic system (much of it located in the diaphragm) returning tissue fluid to the vascular system.[5,6]

Portal hypertension is a sustained increase in blood pressure of portal vasculature. Portal hypertension can be caused by capillarization of hepatic sinusoidal endothelium, increased portal blood volume, or increased resistance to normal flow.[3,6,7] Diseases that lead to *portal hypertension* are divided anatomically into prehepatic, intrahepatic (presinusoidal, sinusoidal, or postsinusoidal), and posthepatic causes.[7-9] Ascites in *posthepatic* and *sinusoidal* or *postsinusoidal intrahepatic* portal hypertension develops when sinusoidal pressure increases so that fluid leaving sinusoids exceeds the capacity of lymphatics to return it to circulation.[8] The fluid that leaves the surface of the liver has percolated through the spaces of Disse where hepatic lymph has a high protein content, resulting in formation of a modified transudate.[6,10,11] Acquired portosystemic shunts do not develop in *posthepatic portal hypertension* because caval pressure also increases significantly.[7,8]

Ascites caused by *presinusoidal intrahepatic* and *prehepatic portal hypertension* is uncommon because the rate of fluid production rarely exceeds rate of lymphatic absorption.[6,7,9] When accumulation exceeds absorption, a pure transudate develops because there is transudation of intestinal lymph which has a much lower protein content than hepatic lymph.[9,12]

Regardless of cause or anatomic site of portal hypertension, the renin–angiotensin–aldosterone system (RAAS) contributes to ascites formation.[13] Circulating blood volume may be initially increased by development of extrahepatic portosystemic shunts and shunting of blood to systemic circulation.[14-16] When *portal hypertension* exceeds this capacity, there may be a decrease in circulating intravascular blood volume detected by volume receptors,[3,8,13,17] and the RAAS becomes activated. Decreased renal prostaglandins and natriuretic factor result in water and sodium retention.[6,7,18] Further increases in blood volume perpetuates the tendency toward ascites formation.[19-22] If portal pressures are already elevated, altered renal sodium handling may be a precipitating (rather than a perpetuating) factor for ascites formation.[23-25]

Increases in capillary hydrostatic pressure resulting from intravenous fluid overload or reduced cardiac output may occasionally be severe enough to induce ascites, although pulmonary edema is often the predominant clinical sign particularly in cats.[1] Vasculitis is another potential cause of fluid accumulation in abdominal and thoracic body cavities.

Decreases in plasma colloidal osmotic (oncotic) pressure represent another disruption to Starling forces. This circumstance arises when serum albumin decreases to <10 to 15 g/L (1.0 to 1.5 g/dL) and is often accompanied by fluid accumulation in pleural space and subcutaneous tissues. Fluid that develops in this instance is a pure transudate.

Differential Diagnosis

Posthepatic portal hypertension occurs when there is obstruction of flow from hepatic veins and caudal vena cava to the right side of the heart. Pericardial disease (e.g., pericardial effusion or pericarditis causing cardiac tamponade) is the most common cause in dogs.[26-28] Other possible causes include right-sided cardiac disease (e.g., intracardiac masses, tricuspid valve insufficiency, cor triatrium dexter, pulmonic stenosis) and pulmonary hypertension (e.g., primary or caused by chronic respiratory disease, left-sided congestive heart

failure, pulmonary thromboembolism and dirofilariasis).[29-33] Obstruction of the caudal vena cava because of congenital abnormalities, thrombi formation, dirofilariasis ("caval syndrome"), neoplasia, or trauma may also occur.[34-37] Budd-Chiari–like syndrome refers to obstruction of hepatic venous flow to the right atrium.[38] Posthepatic portal hypertension is uncommon in cats.[1]

Hepatic (sinusoidal or postsinusoidal) portal hypertension generally results from chronic hepatic disease that either increases resistance to portal blood flow or increases hepatic arterial blood flow. The most common cause of sinusoidal or postsinusoidal portal hypertension is diffuse parenchymal disease such as cirrhosis (an end-stage disease in breed-specific hepatopathies), drug-related hepatopathies, fibrosis, diffuse neoplasia, chronic diffuse hepatitis, and chronic cholangiohepatitis.[6,15,39,40] In rare cases, severe hepatocyte swelling due to vacuolar hepatopathy (e.g., hepatic lipidosis) may cause portal hypertension, but rarely does it cause fluid accumulation.[1]

Prehepatic or presinusoidal hepatic portal hypertension results from intraluminal occlusion of the portal vein (thrombosis, neoplasia), abnormal developmental anomalies of the portal vein (stenosis, atresia, hypoplasia) or extraluminal compression of the portal vein by neoplasia or other abdominal masses.[41-44] It may also develop as a consequence of surgical ligation of a congenital portosystemic shunt.[1] Congenital arterioportal fistula is a direct communication between a portal venous branch and a hepatic arterial branch, representing another presinusoidal portal hypertension.[45,46]

Hypoalbuminemia is another cause of ascites formation, when serum albumin concentration falls below 1.5 g/L. Albumin may be decreased because of excessive losses, decreased production, or protein-calorie malnutrition. Albumin is a small protein (molecular weight 66,000 daltons) easily lost in severe *glomerular* disease (*protein-losing nephropathy*), as well as *protein-losing enteropathy* and severe exudative cutaneous lesions. Albumin may decrease in other exudative process such as septic or neoplastic peritonitis. The liver is the major site of albumin synthesis and is capable of producing adequate albumin at 33% of maximal capacity.[47] That factor, in addition to the relatively long circulating half-life of albumin (8 to 9 days) means that hepatic disease must be both chronic and severe to cause clinically important hypoalbuminemia.[6,47,48] End-stage acquired hepatic disease, and congenital portosystemic shunting both cause substantially decreased albumin production.[42] Decreased nutritional intake alone is seldom sufficient to cause albumin to decrease to such an important degree, but starvation will contribute to the severity of hypoalbuminemia associated with other causes.

Evaluation of the Patient

History

History is highly dependent upon underlying disease. Congenital diseases would be more likely in young animals, while some breeds are predisposed to specific hepatopathies, congenital portosystemic shunts, portovascular anomalies, or hepatic fibrosis.[46,49,50] Owners may present their animal for "weight gain" caused by abdominal distention. If ascites is caused by primary hepatic disease, the animal may display neurobehavioral signs ranging from changes in temperament to seizures and coma caused by hepatic encephalopathy. Other signs of hepatic dysfunction may be present such as anesthetic or sedative intolerance, dermatoses, polyuria/polydipsia, melena, acholic feces, vomiting, diarrhea, weakness, and lethargy.[47,51] Determination of toxin and drug exposure is important.

Dyspnea, exercise intolerance, and syncope may be present if concurrent pleural effusion is present. Dyspnea could still be a manifestation of ascites if abdominal fluid volume impedes diaphragmatic muscle contractility.[52] Heartworm prophylaxis status should be established in animals from heartworm endemic areas. Losses of albumin through exudative processes are fairly self-evident, but clinical signs associated with loss through glomeruli or intestines may be less obvious. Small bowel diarrhea may be present or absent even in severe small-intestine disease if the large intestine retains sufficient capacity to absorb excess fecal water. Establishment of intestinal parasitic prophylaxis may also be important, especially in young puppies or kittens.

Physical Examination

Expected physical examination findings are also dependent on underlying disease processes. In general, ascites can be detected only when a large volume of fluid is present. This large volume often precludes thorough abdominal palpation and assessment of organ size. Animals with profound abdominal distention may have loss of dorsal musculature and body condition. Assessment of mucous membrane color is often useful and may demonstrate anemia (Chapter 16) or icterus (Chapter 18). Prolonged capillary refill time or skin tenting may be present with dehydration, and rarely there may be signs of a bleeding diathesis because of coagulopathy (Chapter 9). Digital rectal examination may provide evidence of melena, acholic feces, or hematochezia. Abdominal pain may be present with gastrointestinal ulceration or perforation.

Concurrent pleural effusion may be present with posthepatic portal hypertension because of right-sided cardiac disease or pulmonary hypertension. Relevant clinical signs may include tachypnea, muffled heart and lung sounds, jugular distention, cardiac murmur, pulsus paradoxus, and abnormal adventitious lung sounds.

Laboratory Evaluation and Tests

Figure 8-1 outlines an algorithmic approach to diagnostic evaluation of ascites. The first step in diagnostic evaluation is abdominal fluid analysis to allow differentiation of pure and modified transudates, septic and nonseptic exudates, blood, and chyle. Abdominocentesis is readily performed in conscious animals and should be performed in a sterile manner with needle insertion at the level of the umbilicus, just lateral to midline. Peritoneal lavage is rarely required in cases of ascites. If there is a suspicion of concurrent pleural effusion, then thoracocentesis may be performed in preference to abdominocentesis as both a palliative and diagnostic tool.

Ascitic fluid is first characterized according to appearance, specific gravity, total protein, and cellularity. Table 8-1 outlines the basic differences between fluid types. Fluid analysis should include cytologic and chemical evaluation. Additional fluid analysis could include Gram staining and culture (bacterial infection), measurement of blood urea nitrogen (BUN) and creatinine (renal failure), and triglyceride analysis (lymphatic transport disorders). Determination of serum-ascites albumin gradient may be used to differentiate between transudative and exudative processes. A serum-ascites albumin gradient >1.1 g/dL is usually indicative of portal hypertension but may not distinguish between hepatic and posthepatic portal hypertension.[53] Ascitic fluid amino acid profiles (e.g., glutamate-to-glutamine ratio) may help to differentiate cirrhosis and other noncirrhotic causes of ascites.[54]

Interpretation of abdominal fluid characteristics should always be performed in conjunction with serum hematology, serum biochemistry, and urinalysis. Hematology usually shows only nonspecific changes in hepatic disease such as a microcytic anemia, or normocytic, normochromic nonregenerative anemia. Serum enzyme activities that reflect hepatocellular injury or repair such as alanine

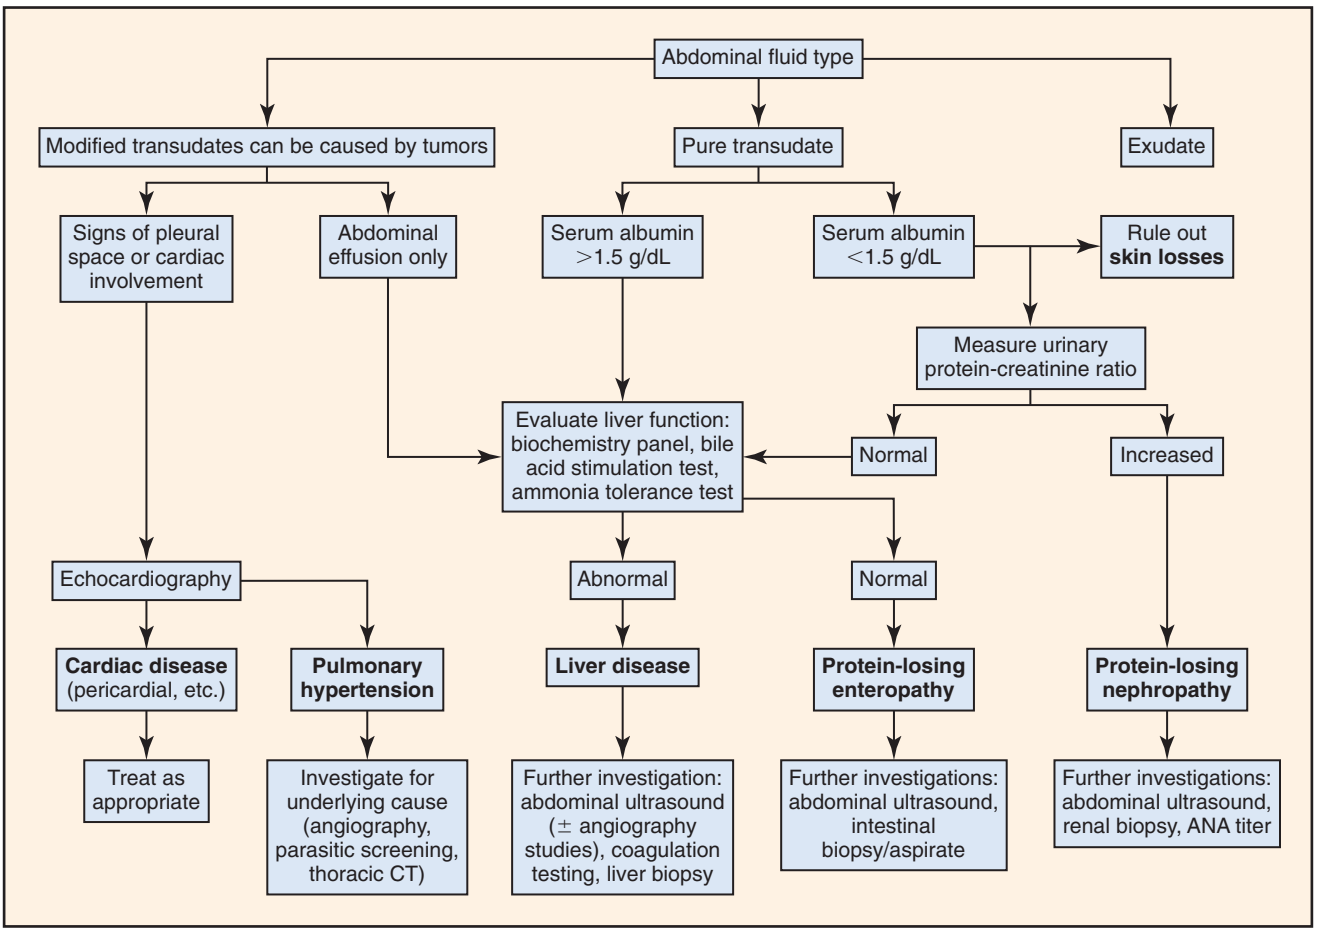

Figure 8-1 Algorithmic approach to diagnostic evaluation of ascites.

Table 8-1 Differentiation Among Fluid Types

Fluid Type	Appearance	Specific Gravity	Total Protein	Nucleated Cell Count	Cell Types
Pure transudate	Clear	≤1.013-1.018	<2.5 g/dL	1000-1500 cells/μL	Occasional mesothelial cells
Modified transudate	Straw-colored, slightly cloudy	>1.013-1.018	2.5-5.0 g/dL	<5000-7000 cells/μL	Mesothelial cells, nondegenerate neutrophils, macrophages, lymphocytes
Nonseptic exudate	Turbid to opaque, blood tinged	>1.018	>2.5 g/dL	>5000 cells/μL	Mesothelial cells, nondegenerate neutrophils, macrophages, lymphocytes, and occasionally neoplastic cells
Septic exudate	Turbid to opaque, blood tinged	>1.018	>2.5 g/dL	>5000 cells/μL	Degenerate neutrophils, intracellular bacteria
Blood	Cloudy and red (clear supernatant after centrifugation)	= Peripheral blood	= Peripheral blood	= Peripheral blood	= Peripheral blood
Bile	Clear to cloudy with green tinge	>1.018	>2.5 g/dL	>5000 cells/μL	Bilirubin crystals evident
Urine	Clear to slightly cloudy and pale yellow	Variable	Variable	>3000 cells/μL	May become septic
Chyle	Opaque and white-pink	Variable	20-70 g/dL	<10,000 cells/μL	Fluid triglyceride > serum triglyceride, large number of small lymphocytes

aminotransferase (ALT) and aspartate amino transferase (AST) are commonly increased in animals with primary hepatic disease, or hepatocellular swelling secondary to congestion (posthepatic portal hypertension).[55] Other serum hepatic enzyme activities may be more useful markers of cholestasis and drug induction. Alkaline phosphatase (ALP) is associated with the canalicular membrane and γ-glutamyltransferase (GGT) with the epithelial cells of the bile ducts.[55] ALP has a half-life of 66 hours in dogs and <6 hours in cats; therefore it is usually the last serum enzyme to return to normal in dogs.[55] In dogs ALP is induced by glucocorticoids (stress or hyperadrenocorticism) and exogenous drugs (phenobarbital or exogenous corticosteroids) while GGT is not affected.[55] There is no stress-induced induction of ALP in cats.[55] This fact plus the short circulating half-life means any increase in ALP in cats must be considered significant. Bone isoenzyme of ALP can be increased in young dogs and cats, as well as in animals with severe bone pathology, and may be increased with congenital portosystemic shunts.

Renal (protein-losing nephropathy [PLN]) and intestinal (protein-losing enteropathy [PLE]) protein losses must also be ruled out as causes of hypoalbuminemia. Hypoglycemia may occur in congenital or end-stage hepatic disease, when <20% hepatic function remains. The urea cycle detoxifies ammonia produced by the gut, and BUN is often decreased when there is decreased hepatic function. Urea is also affected by nonhepatic factors, and it is unusual for low urea to be the sole abnormality in hepatic disease. BUN may also be artifactually increased if there has been recent gastrointestinal hemorrhage. Serum cholesterol may be high if there is impaired excretion of cholesterol (bile duct obstruction, severe cholestasis), normal, or low if there is altered intestinal absorption and hepatic synthesis. Increases in serum bilirubin may be evident on biochemical testing before jaundice is clinically apparent. Differentiation of unconjugated versus conjugated bilirubin is usually of little benefit in companion animal medicine. Measurement of serum bile acids reflects hepatocellular function and efficiency or integrity of enterohepatic circulation with increases often seen before increases in serum bilirubin.[56,57] Ammonia tolerance testing may be performed if portosystemic shunting is suspected, but care must be taken not to precipitate hepatoencephalopathy in susceptible animals. Plasma samples should be analyzed within 20 minutes of collection.

Urinalysis findings may be nonspecific in dogs and cats with ascites. Dogs often have hyposthenuria (urine specific gravity <1.008), and ammonium biurate crystals may be detected in both dogs and cats with congenital portosystemic shunts. Urine protein-to-creatinine ratio determinations may be necessary to exclude PLN as a cause of hypoalbuminemia. In some instances it may be difficult to obtain a cystocentesis sample in an animal with large-volume ascites, and in such patients should be guided by ultrasound.

Coagulation factors should be assessed if liver dysfunction is suspected, particularly before liver sampling is performed. Platelet dysfunction may also result from severe liver disease, so assessment of platelet function via function analyzer or a buccal mucosal bleeding time is warranted. Pretreatment with injectable vitamin K and plasma may be appropriate before hepatic surgery or biopsy.

Conventional survey radiography is of little benefit in assessing abdominal pathology when there is a large-volume effusion. It may, however, be useful for assessing concurrent thoracic cavity disease and vena caval dimensions.[58] Abdominal ultrasound is more useful in investigation of ascites. In some cases, ultrasound may detect small amounts of fluid not detected clinically. Ultrasound of heart and caudal vena cava is the diagnostic test of choice for diagnosing pericardial disease, right-sided heart disease, pulmonary hypertension, and caudal vena caval obstruction. Ultrasonography may also detect extrahepatic and intrahepatic shunting vessels although the sensitivity for detection is less than 100%. Ultrasound evaluation of the liver and biliary tract may permit determination of hepatic parenchymal or cholestatic disease. In some instances, advanced imaging techniques such as scintigraphy or computed tomography (CT) angiography may be necessary, particularly for shunting vessels.[59]

Sampling of the liver for cytologic or histopathologic assessment is important in diagnosing hepatic disease, but there are some limitations in its diagnostic utility. Fine-needle aspiration (FNA) is a relatively easy and safe procedure and can be performed without ultrasound guidance in diseases causing marked hepatomegaly. There is a low risk of hemorrhage, but it is only diagnostic for exfoliative diseases such as lymphoma, lipidosis, glycogen deposition, and vacuolar hepatopathy, all of which are unlikely causes of ascites. Larger tissues samples may be obtained by needle biopsy (ultrasound guided) or tissue wedge (exploratory laparotomy or laparoscopy). This should be performed only if the patient is stable for a general anesthetic agent, has adequate hemostasis, and an adequate sample size can be obtained. If a correctable problem such as a congenital extrahepatic shunt is suspected, potential benefits of a surgical procedure outweigh the risks as long as the patient is medically stable. In general, multiple needle biopsies should be taken to maximize the likelihood of diagnosis, and subcapsular connective tissue should be excluded to avoid the misdiagnosis of fibrosis.

Treatment and Management

General Principles

Treatment of ascites is highly dependent on underlying etiology, and this should be pursued extensively before definitive treatment. Palliative treatment may be necessary, however, to improve respiration, and abdominocentesis may be performed.[60] Care should be taken not to remove too much fluid, as this may worsen hypovolemia and ascites and precipitate hepatic encephalopathy in animals with hepatic disease.[61] If there is concurrent pleural effusion, thoracocentesis is more likely to relieve respiratory distress than abdominocentesis. Furosemide is relatively ineffective as a sole agent in mobilizing ascitic fluid, and an aldosterone antagonist (e.g., spironolactone) may be more effective.[17,61-63] Combined use of a loop diuretic and a low-sodium diet is best in chronic cases, provided there is sufficient oral potassium intake. Hypokalemia and metabolic alkalosis are risk factors for development of hepatic encephalopathy.[17,64,65]

Cardiac Disease

Diuresis is ineffective and probably contraindicated for the mobilization of ascitic fluid caused by pericardial effusion. The preferred treatment of choice for pericardial effusion is pericardiocentesis, and this may be repeated a number of times in individual animals. Pericardiectomy (either via thoracotomy or thoracoscopy) may be necessary for management of recurrent effusions or to differentiate malignant from benign causes.[27,66] Pulmonic stenosis may be treated by balloon valvuloplasty whilst medical management is currently the only realistic option for tricuspid insufficiency.[67,68]

Respiratory Disease

Management of pulmonary hypertension is highly dependent on the underlying cause, and oxygen supplementation may be necessary in the short-term. Vasodilators such as pimobendan and sildenafil also may be beneficial.[69]

Hepatic Disease

Medical management of hepatic disease is aimed at treating underlying disease and managing associated clinical signs (ascites, gastrointestinal hemorrhage, and hepatoencephalopathy). The mainstay of medical management is dietary reduction of protein (in dogs), particularly aromatic amino acids, sufficient to reduce signs of hepatoencephalopathy but not to aggravate protein catabolism.[63] Supplementation of soluble fiber and various water- and fat-soluble vitamins may be beneficial, in addition to moderate sodium reduction.[63]

Treatment of concurrent complications includes lactulose and antibiotics for hepatoencephalopathy, proton-pump inhibitors for gastrointestinal ulceration, and mannitol for cerebral edema.[70]

Specific treatment of the underlying etiology can range from immunosuppressive therapy (e.g., prednisolone, azathioprine) to copper-chelating agents and antifibrotic drugs.[70] Nutraceutical management of liver disease (vitamins C and E, *S*-adenosyl-L-methionine, and silymarin) are receiving increasing attention as supplementary therapy in acquired hepatopathies, although evidence-based data are still lacking in most instances.[71] Ursodeoxycholic acid is also being increasingly used in treatment of cholestatic liver disease.

Surgical correction of symptomatic, single congenital portosystemic shunts is considered the treatment of choice, with a greater success rate seen with extrahepatic shunts using newer modalities such as cellophane banding or ameroid constrictors.[72,73] Although no one contests this statement when discussing the more classic young, symptomatic patient, there are an increasing number of older, asymptomatic patients or middle-aged asymptomatic patients that are fortuitously diagnosed when working up other problems—for these patients, surgery has not been shown to be needed. Intrahepatic shunts are more difficult to correct surgically. Surgical correction of multiple shunts because of portal hypertension is not indicated.

Protein-Losing Enteropathy

Treatment of PLE is dependent upon the underlying cause, such as inflammatory bowel disease, lymphangiectasia, parasitism, infectious disease, intussusception, and neoplasia. Enteral feeding is ideal, but short-term support may need to be provided in the form of total parenteral nutrition. Colloidal fluid support may also be necessary, although plasma transfusions alone does not provide sufficient albumin unless given at a dose approximating 20 mL/kg.[74]

Protein-Losing Nephropathy

Current recommendations for treatment of significant proteinuria are reduced dietary protein, fatty acid (omega-3) supplementation, low-dose aspirin to prevent thromboembolic disease and use of an angiotensin-converting enzyme inhibitor.[75] In some individual cases, uses of immunosuppressive or antihypertensive medication may also be warranted.[76]

CHAPTER 9

Coagulopathy

Mary Beth Callan

Definition

The hemostatic system (i.e., platelets, vascular endothelial cells, plasma coagulation factors) is a finely controlled mechanism that prevents excessive blood loss following vascular injury. Abnormalities in any part of the hemostatic system may result in bleeding. Hemostatic disorders may be classified as *primary* or *secondary*. Primary hemostasis refers to the platelet–vessel interaction; therefore primary hemostatic disorders include thrombocytopenia, thrombopathia, von Willebrand disease (vWD), and, rarely, vasculopathy. Secondary hemostasis refers to generation of thrombin and formation of a fibrin clot through a series of enzymatic reactions; therefore coagulopathies are secondary hemostatic disorders that typically result from deficiency of one or more plasma coagulation factors. In addition, enhanced fibrinolysis may result in a bleeding tendency.

Pathophysiology and Mechanisms

Following vascular injury, platelets adhere to exposed subendothelial collagen. Under conditions of high shear forces (in arterioles and microcirculation) plasma von Willebrand factor (vWF) is also needed to support platelet adhesion. Once activated, platelets aggregate (i.e., stick to one another via crosslinking by fibrinogen) to form an unstable platelet plug. Stabilization of the platelet plug with a fibrin clot occurs through blood coagulation. The liver is the major site of synthesis for blood coagulation factors that are secreted into circulation as inactive zymogens. Plasma coagulation factors (F) II, VII, IX, and X, as well as anticoagulant protein C and protein S, require vitamin K for carboxylation of their glutamic acid residues, allowing them to bind calcium ions essential to the coagulation process. FVII (extrinsic pathway) plays a pivotal role in the initiation of coagulation, combining with membrane protein tissue factor (TF) following vessel injury. Activated FVII and TF complex (FVIIa–TF) in the presence of calcium cleaves FIX (intrinsic pathway) and FX (common pathway) to their activated forms, ultimately leading to the generation of fibrin. Platelets exert a procoagulant effect with the platelet membrane phospholipid phosphatidylserine (PS) providing a catalytic surface for enzymatic activities known as tenase and prothrombinase, resulting in activation of FX and FII (prothrombin), respectively.

The liver plays a key role in regulating fibrinolysis, synthesizing both plasminogen and the major plasma inhibitor of plasmin, α_2-antiplasmin. Within the fibrinolytic system, plasminogen is converted to plasmin via tissue-type plasminogen activator (t-PA). Plasmin then degrades fibrin into soluble fibrin degradation products (FDPs). Therefore decreased production of plasminogen or α_2-antiplasmin because of severe hepatic dysfunction may cause thrombosis or excessive fibrinolysis and a bleeding tendency, respectively.[1] Patients with hepatic disease may have increased FDPs as a result of enhanced fibrinolysis or decreased hepatic clearance of FDPs from circulation.

Primary and secondary hemostatic disorders may be hereditary or acquired. In the context of hepatobiliary and gastrointestinal disease, there are two main considerations regarding hemostatic defects: (a) development of a hemostatic abnormality secondary to an underlying hepatobiliary or gastrointestinal disease, and (b) a hereditary or acquired hemostatic disorder causing gastrointestinal bleeding. Hepatic failure may cause coagulopathy because of impaired production of plasma coagulation factors. It has been estimated that greater than 70% of functional hepatic mass must be lost to cause clinically important decreases in clotting factors.[2] Consequently, patients with massive hepatocellular necrosis and end-stage chronic hepatic disease are more likely to have a coagulopathy. Severe bleeding may exacerbate hemostatic defects (e.g., secondary to disseminated intravascular coagulation [DIC]). Depending on the cause of the hepatopathy (e.g., infectious disease, neoplasia, heat stroke), DIC may occur and contribute to an acquired hemostatic disorder. A thrombopathia associated with hepatobiliary disease has been documented in dogs with mucosal surface bleeding having normal coagulation profiles and platelet counts but impaired whole-blood platelet aggregation in response to collagen and arachidonic acid.[3] Proposed mechanisms of such an acquired thrombopathia include altered arachidonic acid metabolism and prostaglandin synthesis, disruption of membrane release of calcium into the cell, and defective calcium-initiated platelet granule release.[3]

Extrahepatic biliary obstruction (EHBO) may cause vitamin K–dependent coagulopathy because of impaired absorption of this fat-soluble vitamin from the intestines. Intrahepatic cholestasis has been postulated to decreased vitamin K absorption in some cats with hepatic disease (e.g., cholangiohepatitis, hepatic lipidosis), with a correlation existing between increased serum alkaline phosphatase and coagulation abnormalities.[4] Other rare potential causes of a vitamin K-dependent coagulopathy include severe intestinal disease leading to impaired absorption of vitamin K and oral antibiotic therapy resulting in decreased synthesis of vitamin K by intestinal flora. One study of experimentally induced cholestasis (via ligation of the common bile duct) in dogs resulted in inhibition of adenosine

diphosphate (ADP) and collagen-induced platelet aggregation in vitro, with impaired platelet function attributed to elevated serum bile acids rather than bilirubin.[5]

Differential Diagnosis

Hemostatic disorders in patients with underlying hepatobiliary disease may be noted initially when performing a coagulation screen in preparation for hepatic biopsy or surgery. Alternatively, such patients may be presented for a bleeding, either spontaneous or following surgery or trauma, due to their underlying hepatobiliary disease. In patients presented for gastrointestinal hemorrhage, it may be challenging to determine if a hemostatic disorder has exacerbated mucosal bleeding caused by underlying gastrointestinal disease rather than either condition occurring alone.

Hepatobiliary or Gastrointestinal Disease Causing Hemostatic Disorder

Because severe hepatic dysfunction is required to impair production of blood coagulation factors, acute massive hepatocellular necrosis and cirrhosis are more likely than other hepatopathies to cause clinically significant hemostatic disorders. Toxin ingestion appears to be the most common cause of massive hepatocellular necrosis and subsequent coagulopathy. Chapter 61 discusses hepatotoxins that cause hemostatic disorders.

Coagulation abnormalities in dogs and cats with hepatic disease are common. Sixty-six percent to 93% of dogs[6-8] and 82% of cats[4] have at least one coagulation test abnormality, the most common being prolongation of the activated partial thromboplastin time (aPTT) in 75% of dogs and prothrombin time (PT) in 77% of cats evaluated. Histopathologic diagnoses reported in dogs with coagulation abnormalities include acute hepatitis with necrosis, chronic active hepatitis, cirrhosis, and diffuse hepatocellular carcinoma,[8] whereas diagnoses reported in cats include hepatic lipidosis, cholangiohepatitis, and lymphoma.[4] Approximately 45% of cats with severe hepatic lipidosis have abnormal coagulation profiles.[9] Despite the high prevalence of coagulation test abnormalities in dogs and cats with hepatobiliary disease, few have clinically evident bleeding tendencies.[4,7-9]

Vitamin K–dependent coagulopathies may develop in patients with EHBO, particularly if the obstruction is complete and of several days' duration. The most common causes of EHBO in dogs include necrotizing cholecystitis secondary to cholelithiasis, pancreatitis, and neoplasia.[10-12] The most common causes of feline EHBO fall into two groups: neoplasia of either biliary or pancreatic origin, and inflammatory diseases including pancreatitis, cholangiohepatitis, cholecystitis, and cholelithiasis.[13] The prevalence of coagulation test abnormalities in dogs and cats with extrahepatic biliary disease varies, potentially as a consequence of some patients having EHBOs that are partial or acute. In one retrospective study of cats with EHBO, eight of 18 (44%) cats had a prolonged PT whereas 10 of 18 (56%) had a prolonged aPTT; all cats with prolonged PT also had an aPTT prolongation.[13] However, in a retrospective study of cats with obstructive cholelithiasis, a normal coagulation profile was noted in all eight cats tested.[14] Similar differences have been noted in dogs with EHBO. Nine dogs undergoing choledochal tube stenting had normal PT and aPTT,[11] whereas prolongation of aPTT was associated with mortality among 57 dogs undergoing extrahepatic biliary surgery.[10] In this latter study, the retrospective nature precluded determination of the cause of prolonged aPTT, but DIC and systemic inflammatory response syndrome (SIRS) secondary to septic bile peritonitis and vitamin K malabsorption may have contributed to the coagulopathy.[10] Although coagulation profile results are variable amongst both dogs and cats with EHBO, bleeding is uncommonly observed in such patients with abnormal hemostatic profiles. However, there is a case report of excessive bleeding associated with vitamin K deficiency in a dog with an EHBO.[15]

Exocrine pancreatic insufficiency (EPI) may result in a vitamin K–dependent coagulopathy as a result of lipase deficiency preventing breakdown of dietary triglycerides into monoglycerides and fatty acids, a step in lipid digestion that is needed for adequate solubilization and absorption of fat soluble vitamins.[16]

Hemostatic Disorder Causing Gastrointestinal Bleeding

Primary hemostatic disorders are more likely than coagulopathies to cause gastrointestinal bleeding. Severe thrombocytopenia (platelet count <30,000/μL) is the most common primary hemostatic disorder causing mucosal surface bleeding. Differential diagnoses for severe thrombocytopenia include idiopathic thrombocytopenic purpura (ITP), secondary immune-mediated thrombocytopenia (associated with drugs, neoplasia, or infectious diseases), bone marrow suppression, or various infectious diseases (especially tick-borne diseases). ITP is the most common cause of severe thrombocytopenia in dogs but is rare in cats. vWD and thrombopathia are other primary hemostatic disorders that may cause gastrointestinal bleeding, either spontaneous or associated with underlying gastrointestinal disorders. Dogs and cats with hereditary thrombopathies may present with petechiae, ecchymoses, excessive bleeding following surgery or trauma, or bleeding from various mucosal surfaces including the gastrointestinal tract. Well-characterized canine hereditary thrombopathies include thrombasthenic thrombopathia (also referred to as Glanzmann thrombasthenia), an absence or deficiency of the platelet glycoprotein (GP) IIb/IIIa receptor for fibrinogen (documented in Otterhounds and Great Pyrenees[17]), Basset Hound thrombopathia (a platelet signal transduction defect resulting in abnormal cyclic adenosine monophosphate [cAMP] metabolism[18]), platelet δ-storage pool deficiency (caused by decreased dense granule ADP content, reported in the American Cocker Spaniel[19]), and platelet procoagulant deficiency (also referred to as Scott syndrome, which is a result of abnormal membrane PS exposure and described in the German Shepherd[20]). A thrombopathia caused by a platelet δ-storage pool deficiency has also been documented in blue smoke Persian cats with Chediak-Higashi syndrome.[21] Acquired platelet function defects may occur following ingestion of nonsteroidal anti-inflammatory drugs (NSAIDs) or in association with uremia, cholestatic hepatic disease, and dysproteinemias. In gastrointestinal bleeding following NSAID administration, the cause is more likely gastrointestinal ulceration than an acquired thrombopathia, although concurrent platelet dysfunction could exacerbate bleeding.

Coagulopathies are more often associated with cavity bleeding than mucosal surface bleeding, but secondary hemostatic defects should be considered in patients with gastrointestinal bleeding. Mild to moderate thrombocytopenia has been documented in dogs with anticoagulant rodenticide poisoning, but marked thrombocytopenia (<30,000/μL) has also been reported.[22] Melena, hematochezia, and other surface bleeding (e.g., epistaxis, hematuria, gingival bleeding) have been noted in dogs with anticoagulant rodenticide poisoning and normal platelet counts.[23] A hereditary vitamin K–dependent coagulopathy attributable to defective γ-glutamylcarboxylase has been reported in Devon Rex cats with spontaneous hemorrhage into the thoracic cavity, joint, and urinary bladder.[24,25] Hereditary FVII deficiency is typically considered an asymptomatic defect or a cause

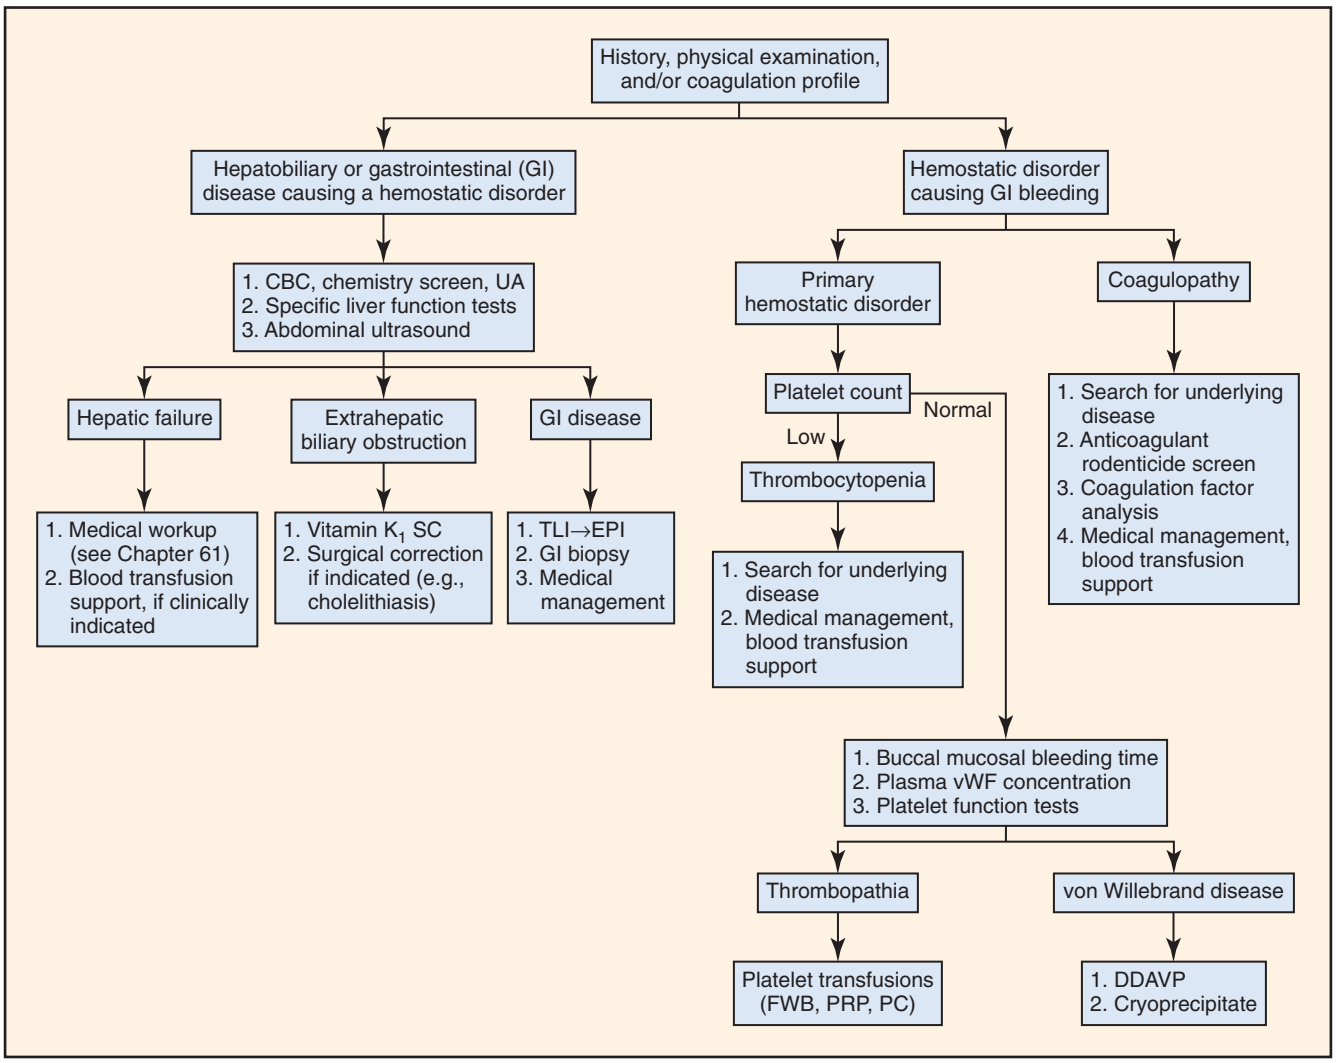

Figure 9-1 Algorithm for diagnostic and therapeutic approach to hemostatic disorders.

of minor bleeding, although severe bleeding has been reported, most often after surgery or trauma.[26] Hematochezia has been noted in FVII-deficient Beagles without other signs of colonic inflammation.[26] Of the intrinsic coagulopathies, hemophilia A (FVIII deficiency) or hemophilia B (FIX deficiency) may be more likely than others to cause bleeding within the gastrointestinal tract; severe gastrointestinal hemorrhage, potentially in association with coccidiosis, has been reported in hemophilic puppies.[27]

Evaluation of the Patient

History

The presence of a hemostatic abnormality should prompt questions about prior bleeding, such as excessive bleeding following neutering, other surgery, or trauma. A complete medication history is essential, as various drugs affect platelet function (e.g., aspirin) or platelet number (e.g., trimethoprim-sulfate–induced immune-mediated thrombocytopenia, or azathioprine-induced bone marrow suppression leading to decreased platelet production) and some potentially cause hepatoxicity (e.g., trimethoprim-sulfate and azathioprine). Similarly, toxin exposure could produce a severe coagulopathy (e.g., brodifacoum) or acute hepatocellular necrosis and resultant coagulopathy (e.g., aflatoxin).

Determining the presenting complaint, time that patient was last normal, progression of clinical signs, and systems review may provide key information for differentiating acquired and hereditary hemostatic disorders, as well as identifying the underlying cause of the gastrointestinal or hepatobiliary disease (Fig. 9-1). For example, in the case of young dog with a recent dietary indiscretion and an acute onset of vomiting, subsequent development of icterus and a coagulopathy may be more likely attributed to pancreatitis and an EHBO than to hepatic failure.

Physical Examination

The type of bleeding may help differentiate primary and secondary hemostatic disorders. As a general rule, primary hemostatic disorders are usually associated with petechia, ecchymosis, and mucosal surface bleeding (e.g., melena, epistaxis, gingival bleeding, hematuria), whereas coagulopathies typically produce cavitary bleeding (e.g., hematoma, hemarthrosis, hemoperitoneum, hemothorax). Melena is not necessarily indicative of a hemostatic disorder as gastrointestinal ulceration, neoplasia, and a variety of other disorders may produce melena. Interestingly, dogs with vWD do not typically present with spontaneous petechia and ecchymosis. Patients with primary and/or secondary hemostatic disorders may both present with excessive bleeding following surgery or trauma.

Icterus in patients with a coagulopathy is suggestive of hepatic disease or EHBO. However, hemolysis from immune-mediated hemolytic anemia or microangiopathic hemolytic anemia and concurrent DIC could also produce icterus and coagulopathy. Pallor may occur in patients secondary to blood loss. Although pallor is not necessarily helpful in identifying a patient's underlying disease process, it may indicate the need for additional oxygen-carrying support (i.e., a red blood cell [RBC] transfusion). Hepatomegaly may be indicative of an acute inflammatory process or infiltrative disease, whereas microhepatia is more suggestive of cirrhosis. Similarly, concurrent splenomegaly, lymphadenopathy, and/or an abdominal fluid wave may help narrow the list of differential diagnoses. Finally, a patient's body condition score may reflect the chronicity of the underlying disease.

Laboratory Evaluation and Tests

Initial hemostatic testing typically includes platelet count, PT, and aPTT. In emergencies, evaluation of a blood smear allows estimation of platelet numbers (e.g., 10 to 20 platelets per oil immersion field is considered adequate). The blood smear should be evaluated in conjunction with automated platelet counts because platelet clumping can cause spuriously decreased automated platelet counts. A bleeding tendency is not typically observed until the platelet count is <30,000 to 40,000/μL. However, platelet counts of 25,000 to 30,000/μL are associated with an autosomal recessive trait of congenital asymptomatic thrombocytopenia in Cavalier King Charles Spaniels.[28] The platelet count is interpreted in light of the complete blood cell count (CBC). Pancytopenia usually indicates a bone marrow aspirate or biopsy. Severe thrombocytopenia (<30,000 platelets/μL), regenerative anemia, and normal PT and aPTT in patients with melena or other surface bleeding may be suggestive of an immune-mediated thrombocytopenia; and, infectious disease screening and radiographic imaging (e.g., thoracic radiographs, abdominal ultrasound) may be indicated to rule out underlying disease. Thrombocytopenia plus prolongation of PT and aPTT would be suggestive of a consumptive coagulopathy, as potentially noted in patients with severe hemorrhage or DIC.

The PT assesses extrinsic and common coagulation pathways while aPTT assesses intrinsic and common pathways. Therefore prolonged PT plus normal aPTT isolates hemostatic defects to the extrinsic pathway (i.e., FVII deficiency), whereas prolonged aPTT plus normal PT indicates an intrinsic coagulopathy. The more commonly seen combination of prolonged PT and aPTT is caused by deficiency of multiple plasma coagulation factors or, less likely, a common pathway factor deficiency (i.e., FX, FII, fibrinogen). If a heritable single factor deficiency is suspected, plasma coagulation factor activity analysis should be performed (Comparative Coagulation Laboratory at Cornell University) to confirm the diagnosis and guide treatment. Anticoagulant rodenticide screening, hepatic function tests, and/or ultrasonographic imaging of the liver and biliary tract may be appropriate in patients with suspected multiple coagulation factor deficiencies.

If the platelet count, PT, and aPTT are normal, then a buccal mucosal bleeding time (BMBT) is used to test platelet function in patients with mucosal surface bleeding. The BMBT is specific for primary hemostatic defects, and reference values are less than 4 and less than 2 minutes for dogs and cats, respectively. Although the effect of anemia on BMBT in dogs and cats has not been evaluated, similar bleeding time tests in humans have been shown to be dependent on RBC number with prolonged bleeding times being corrected following RBC transfusion.[29] The same is expected to be true for dogs and cats although lower cut-offs for packed cell volume (PCV) affecting BMBT results have not yet been determined. Finding prolonged BMBT in a patient with a normal platelet count and PCV is suggestive of vWD, thrombopathia, or, rarely, vasculopathy. Because vWD occurs more commonly than thrombopathia in dogs (both occur rarely in cats), measurement of plasma vWF-to-antigen concentration is indicated in patients with prolonged BMBT before pursuing specific platelet function tests. As genetic mutations causing various hereditary thrombopathies are characterized, diagnosis of a thrombopathia will be greatly simplified as a small ethylenediaminetetraacetic acid (EDTA) blood sample can be submitted for DNA analysis. DNA testing is currently available through Auburn University for diagnosis of Glanzmann thrombasthenia in the Great Pyrenees, Otterhound, and Basset Hound thrombopathies. Screening for other platelet function defects typically requires onsite evaluation of the patient at a university and institution performing platelet aggregation studies.

Complete blood count (CBC), serum chemistry screen, and urinalysis may point toward hepatic failure or EHBO as the cause of a coagulopathy. Finding decreased serum concentrations of glucose, blood urea nitrogen (BUN), albumin, and cholesterol and increased concentration of bilirubin is suggestive of hepatic dysfunction, whereas elevation of serum alkaline phosphate (ALP), γ-glutamyltransferase (GGT), cholesterol, and bilirubin would be more suggestive of a EHBO. Specific hepatic function tests (e.g., blood ammonia, serum bile acid concentrations provided serum bilirubin is not elevated) can support a diagnosis of hepatic failure. Abdominal ultrasound is indicated to evaluate hepatic architecture (hepatic size is better evaluated by radiographs), the biliary tract, and surrounding structures, including the pancreas and duodenum.

The anticoagulant proteins antithrombin (AT) and protein C are synthesized by the liver and have been used to detect hepatobiliary disease and portosystemic shunting in dogs.[30] Dogs with hepatic failure (majority caused by ingestion of hepatotoxins) had substantially reduced plasma AT and protein C activities compared with dogs with chronic hepatitis or miscellaneous hepatobiliary disease (including neoplasia and vacuolar hepatopathy). Ninety-five percent and 85% of dogs with acute hepatic failure had decreased protein C and AT activities, respectively.[30] In dogs with portosystemic vascular anomalies, low protein C and AT activities were noted in 88% and 53% of dogs, respectively.[30] Interestingly, dogs with hepatobiliary disease and portosystemic vascular anomalies had low protein C activity more frequently than prolongation of either PT or aPTT.[30] Measurement of plasma protein C activity may be useful in assessing both hepatic function and perfusion. However, in contrast to decreased plasma coagulation factor activity, low AT and protein C activities may be associated with thrombotic disorders rather than a hemorrhagic tendency.

Treatment and Management

Hepatobiliary or Gastrointestinal Disease Causing Hemostatic Disorder

Identification and correction of underlying hepatobiliary or gastrointestinal disorders is necessary to resolve acquired hemostatic disorders. However, some underlying conditions (e.g., hepatic cirrhosis) cannot be reversed. Patients with hepatic dysfunction causing coagulopathy and bleeding may benefit from fresh-frozen plasma (FFP) (6 to 12 mL/kg intravenously q12h) as a way to improve hemostasis

prior to hepatic biopsy or in actively bleeding patients. Citrate is rapidly metabolized by the liver, but administration of large volumes of FFP or whole blood can cause ionized hypocalcemia secondary to impaired citrate metabolism in patients with severe hepatic dysfunction, particularly if anesthetized and hypothermic. It is prudent to determine blood type and perform a blood crossmatch for dogs transfused more than 4 days prior and for all cats in case the patient has significant bleeding following a hepatic biopsy. Packed red blood cells (PRBCs) (10 mL/kg intravenously initially, and then given to effect) can provide additional oxygen-carrying support. Alternatively, fresh whole blood (i.e., less than 8 hours old from the time of collection and stored at room temperature) (20 mL/kg intravenously) may be administered to provide plasma coagulation factors, RBCs, and platelets to patients thrombocytopenic from increased consumption.

Vitamin K_1, also called phytonadione, (1 mg/kg subcutaneously q24h) is indicated in patients with coagulopathy secondary to EHBO or potentially severe intestinal disease causing malabsorption of vitamin K. Administration of vitamin K typically corrects such coagulopathies within 24 hours because the liver continues producing coagulation factors in their inactive form despite the cholestasis. One may administer vitamin K to patients with hepatic dysfunction to optimize hepatic carboxylation of vitamin K–dependent factors. If a patient with a vitamin K–dependent coagulopathy presents with severe or life-threatening bleeding, FFP will improve hemostasis more rapidly than administering vitamin K alone.

Hemostatic Disorder Causing Gastrointestinal Bleeding

It is essential that underlying causes of acquired hemostatic disorders causing gastrointestinal bleeding be identified so as to institute specific treatment. For example, corticosteroids would be appropriate for a dog with melena caused by immune-mediated thrombocytopenia, whereas doxycycline would be indicated in a dog with melena and severe thrombocytopenia secondary to ehrlichiosis. Similarly, oral vitamin K would be the most appropriate treatment for a dog with anticoagulant rodenticide poisoning.

In patients with hereditary bleeding disorders causing gastrointestinal bleeding, the hemorrhagic tendency is a lifelong problem that may require intermittent blood transfusions to control bleeding. Although there are few indications for platelet transfusions in small animal medicine, patients with hereditary thrombopathies experiencing severe mucosal surface bleeding may require platelet transfusions. In such patients, fresh whole blood is typically administered to provide functional platelets and RBCs because they often develop blood loss anemia. Platelet-rich plasma and platelet concentrate are other options for transfusion support, although these products are not available in clinical practice. Administration of cryoprecipitate (1 unit/10 kg body weight intravenously, q8-12h), a plasma product containing a high concentration of vWF in addition to FVIII, fibrinogen, and fibronectin is recommended to control severe bleeding in vWD patients. Desmopressin (DDAVP) (1 µg/kg subcutaneously) is another option improving hemostasis in vWD dogs. DDAVP has also been shown to exert beneficial hemostatic effects in human patients with acquired and hereditary thrombopathias,[31] although similar data is not available for dogs and cats. Administration of FFP can be used to help control bleeding from any coagulopathy, and type-compatible RBC transfusion support should be available, regardless of the underlying cause of the gastrointestinal or other bleeding.

CHAPTER 10

Constipation

Robert J. Washabau

Definition

Reviews of idiopathic megacolon have emphasized the importance of considering an extensive list of differential diagnoses (e.g., neuromuscular, mechanical, inflammatory, metabolic/endocrine, pharmacologic, environmental, and behavioral causes) for the obstipated cat (Box 10-1; reviewed in reference 1). One review of published cases suggests that 96% of cases of obstipation are accounted for by idiopathic megacolon (62%), pelvic canal stenosis (23%), nerve injury (6%), or Manx sacral spinal cord deformity (5%).[2] A smaller number of cases are accounted for by complications of colopexy (1%), and colonic neoplasia (1%); colonic hypo- or aganglionosis was suspected in another 2% of cases. Inflammatory, pharmacologic, and environmental/behavioral causes were not cited as predisposing factors in any of the original case reports. Endocrine factors (e.g., obesity and hypothyroidism) were cited in several cases, but were not necessarily impugned as part of the pathogenesis of megacolon. It is important to consider an extensive list of differential diagnoses in an individual animal, but it should be kept in mind that most cases are idiopathic, orthopedic, or neurologic in origin. Behavioral (e.g., stress) and/or environmental (e.g., competition for the litter box) factors may play an important role in the development of the disorder, but haven't been very well characterized in retrospective or prospective studies.

Pathophysiology and Mechanisms

Megacolon develops through two pathologic mechanisms: *dilation* and *hypertrophy*. *Dilated megacolon* is the end stage of colonic dysfunction in idiopathic cases. Cats affected with idiopathic dilated megacolon have permanent loss of colonic structure and function. Medical therapy may be attempted in such cases, but most affected cats eventually require colectomy. *Hypertrophic megacolon*, on the other hand, develops as a consequence of obstructive lesions (e.g., malunion of pelvic fractures, tumors, foreign bodies). Hypertrophic megacolon may be reversible with early pelvic osteotomy or it may progress to irreversible dilated megacolon if appropriate therapy is not instituted.[3]

Constipation and *obstipation* are earlier manifestations of the same problem. Constipation is defined as infrequent, difficult, painful evacuation of feces but does not necessarily imply a permanent loss of function. Many cats experience one or two episodes of constipation without further progression. Intractable constipation that has become refractory to cure or control is referred to as *obstipation*. Obstipation implies a permanent loss of function. A cat is assumed to be obstipated only after several consecutive treatment failures. Recurring episodes of constipation or obstipation may culminate in the syndrome of *megacolon*.

The pathogenesis of idiopathic dilated megacolon involves functional disturbances of colonic smooth muscle. Megacolonic smooth muscle develops less isometric stress in response to neurotransmitter (acetylcholine, substance P, cholecystokinin), membrane depolarization (potassium chloride), or electrical field stimulation, when compared to healthy controls.[4,5] Differences have been observed in longitudinal and circular smooth muscle from descending and ascending colon. No significant abnormalities of smooth muscle cells or of myenteric neurons have been observed on histologic evaluation. Feline idiopathic megacolon is a generalized dysfunction of colonic smooth muscle, and treatments aimed at stimulating colonic smooth muscle contraction generally improve colonic motility. The lesion may begin in the descending colon and progress to involve the ascending colon over time.[6]

Differential Diagnosis

Neoplasia

In dogs, colonic tumors are more common than gastric or small intestinal tumors. The mean age of dogs affected with colonic neoplasia is variably reported between 7 and 11 years of age.[7] Most colonic tumors of dogs are malignant and include adenocarcinomas, lymphosarcomas, and gastrointestinal stromal tumors (leiomyosarcoma, neurofibrosarcoma, fibrosarcoma, and ganglioneuroma).[8-17] Leiomyosarcomas are the most common (91%) of the gastrointestinal stromal tumors.[10-13] Most colonic neoplasia develop in the descending colon and rectum, although leiomyosarcomas more frequently develop in the cecum.[10,12] Local tumor invasion apparently occurs at a slower rate with canine colonic neoplasia, and metastasis to distant sites is relatively uncommon. Benign colonic neoplasia (e.g., adenomas, adenomatous polyps, and leiomyomas) also occur, although they are less common than malignant tumors. Malignant transformation of adenomatous polyps to carcinoma in situ and invasive adenocarcinoma has been demonstrated in the dog just as it has in humans.[7,18,19] Extramedullary plasmacytomas are an uncommon tumor of the gastrointestinal tract, but many of these occur in the large intestine and rectum.[20,21] All of the aforementioned tumors are associated with signs of inflammation and obstruction (e.g., hematochezia, tenesmus, and dyschezia). Carcinoids (rare 5-hydroxytryptamine [5-HT] secreting tumors) are occasionally associated with diarrhea because of the effects of 5-HT on secretion and motility.

Box 10-1 Differential Diagnosis of Constipation in the Cat

Neuromuscular Dysfunction
Colonic smooth muscle: idiopathic megacolon, aging
Spinal cord disease: lumbosacral disease, cauda equine syndrome, sacral spinal cord deformities (Manx cat)
Hypogastric or pelvic nerve disorders: traumatic injury, malignancy, dysautonomia
Submucosal or myenteric plexus neuropathy: dysautonomia, aging

Mechanical Obstruction
Intraluminal: foreign material (bones, plant material, hair), neoplasia, rectal diverticula, perineal hernia, anorectal strictures
Intramural: neoplasia
Extraluminal: pelvic fractures, neoplasia

Inflammation
Perianal fistula, proctitis, anal sac abscess, anorectal foreign bodies, perianal bite wounds

Metabolic and Endocrine
Metabolic: dehydration, hypokalemia, hypercalcemia
Endocrine: hypothyroidism, obesity, nutritional secondary hyperparathyroidism

Pharmacologic
Opioid agonists, cholinergic antagonists, β agonists, diuretics, phenothiazines

Environmental and Behavioral
Soiled litter box, inactivity, hospitalization, change in environment

In cats, adenocarcinoma (46%) is the most common large intestinal tumor, followed by lymphosarcoma (41%) and mast cell tumors (9%).[22-24] The mean age of cats affected with colonic neoplasia is 12.5 years. The descending colon (39%) and the ileocolic sphincter (28%) are the most common sites of colonic neoplasia in the cat. Unlike colonic tumors in dogs, feline colonic tumors have a high rate (63%) of metastasis and, of course, metastasis is associated with decreased survival time. Metastatic sites include colonic lymph nodes, mesenteric lymph nodes, liver, spleen, bladder, urethra, omentum, mesocolon, lungs, duodenum, and peritoneum.

Intussusception

Intussusception is an invagination of one segment of the gastrointestinal tract into the lumen of an adjoining segment. The intussusceptum is the invaginated segment of the alimentary tract, whereas the intussuscipiens is the enveloping segment. Invagination may occur in an antegrade (aborad) or retrograde (orad) direction, but is most commonly in the antegrade direction. Any portion of the alimentary tract may be involved, but enterocolic intussusceptions account for almost two-thirds of published cases in dogs and cats. Enterocolic intussusceptions can be further divided into three types: cecocolic (or cecal inversion), with the inverted cecum forming the apex[25]; ileocolic, with the ileum forming the apex; and ileocecal, with the ileocecal junction forming the apex.[26] Of these three forms of enterocolic intussusception, the ileocolic intussusception is most frequently encountered in clinical practice. A number of conditions are reported to predispose to intussusception, including intestinal parasitism, viral enteritis, foreign bodies, and masses, but in dogs and cats most intussusceptions are idiopathic.[27-29]

Evaluation of the Patient

History

Constipation, obstipation, and megacolon may be observed in cats of any age, sex, or breed; however, most cases are observed in middle aged (mean = 5.8 years) male cats (70% male, 30% female) of Domestic Shorthair (46%), Domestic Longhair (15%), or Siamese (12%) breeding.[2] Affected cats are usually presented for reduced, absent, or painful defecation for a period of time ranging from days to weeks or months. Some cats are observed making multiple, unproductive attempts to defecate in the litter box, while other cats may sit in the litter box for prolonged periods of time without assuming a defecation posture. Dry, hardened feces are observed inside and outside of the litter box. Occasionally, chronically constipated cats have intermittent episodes of hematochezia or diarrhea caused by the mucosal irritant effect of fecal concretions. This may give the pet owner the erroneous impression that diarrhea is the primary problem. Prolonged inability to defecate may result in other systemic signs, including anorexia, lethargy, weight loss, and vomiting.

Physical Examination

Colonic impaction is a consistent physical examination finding in affected cats. Other findings will depend upon the severity and pathogenesis of constipation. Dehydration, weight loss, debilitation, abdominal pain, and mild to moderate mesenteric lymphadenopathy may be observed in cats with severe idiopathic megacolon. Colonic impaction may be so severe in such cases as to render it difficult to differentiate impaction from colonic, mesenteric, or other abdominal neoplasia. Cats with constipation as a consequence of dysautonomia may have other signs of autonomic nervous system failure, such as urinary and fecal incontinence, regurgitation because of megaesophagus, mydriasis, decreased lacrimation, prolapse of the nictitating membrane, and bradycardia. Digital rectal examination should be carefully performed with sedation or anesthesia in all cats. Pelvic fracture malunion may be detected on rectal examination in cats with pelvic trauma. Rectal examination might also identify other unusual causes of constipation, such as foreign bodies, rectal diverticula, stricture, inflammation, or neoplasia. Chronic tenesmus may be associated with perineal herniation in some cases. A complete neurologic examination with special emphasis on caudal spinal cord function should be performed to identify neurologic causes of constipation, for example, spinal cord injury, pelvic nerve trauma, and Manx sacral spinal cord deformity.

Laboratory Evaluation and Tests

Although most cases of obstipation and megacolon are unlikely to have significant changes in laboratory data (e.g., complete blood count, serum chemistry, urinalysis), nonetheless these tests should be performed in all cats presented for constipation. Metabolic causes of constipation, such as dehydration, hypokalemia, and hypercalcemia, may be detected in some cases. Basal serum T_4 concentration and other thyroid function tests should also be considered in cats with recurrent constipation and other signs consistent with hypothyroidism. Although hypothyroidism was documented in only one case of obstipation and megacolon, obstipation is a frequent clinical sign in kittens affected with congenital or juvenile-onset hypothyroidism.[2] Constipation could also theoretically develop following successful treatment of feline hyperthyroidism.

Abdominal radiography should be performed in all constipated cats to characterize the severity of colonic impaction, and to identify predisposing factors such as intraluminal radiopaque foreign material (e.g., bone chips), intraluminal or extraluminal mass lesions,

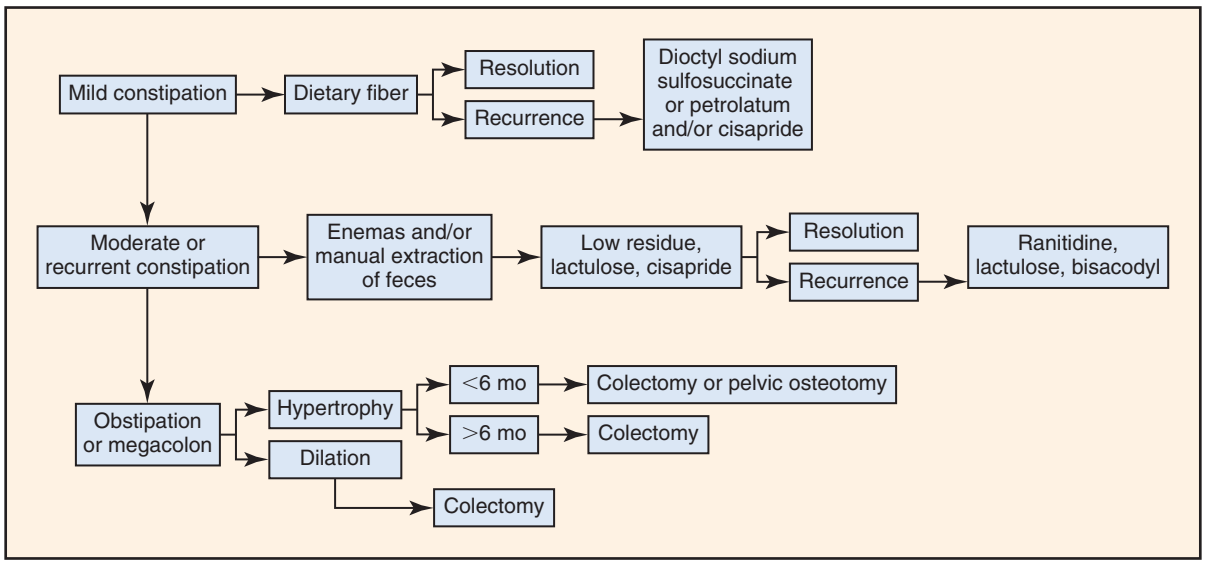

Figure 10-1 Medical management of cats affected with mild constipation, moderate or recurrent constipation, and obstipation or megacolon.

pelvic fractures, and spinal cord abnormalities. Radiographic findings of colonic impaction cannot be used to distinguish between constipation, obstipation, and megacolon in idiopathic cases. First or second episodes of constipation in some cats may be severe and generalized but may still resolve with appropriate treatment.

Ancillary studies may be indicated in some cases. Extraluminal mass lesions may be further evaluated by abdominal ultrasonography and guided biopsy, whereas intraluminal mass lesions are best evaluated by endoscopy. Colonoscopy may also be used to evaluate the colon and anorectum for suspected inflammatory lesions, strictures, sacculations, and diverticula. Barium enema contrast radiography may be used if colonoscopy is not possible. Both colonoscopy and barium enema contrast radiography will require general anesthesia and evacuation of impacted feces. Cerebrospinal fluid analysis, computed tomography (CT) or magnetic resonance imaging (MRI), and electrophysiologic studies should be considered in animals with evidence of neurologic impairment. Finally, colonic biopsy or anorectal manometry is necessary to diagnose suspected cases of aganglionic megacolon.

Treatment and Management

Specific therapeutic plans depend upon severity of constipation and underlying causes.[1] Medical therapy may not be necessary with first episodes of constipation. First episodes are often transient and resolve without therapy. Mild to moderate or recurrent episodes of constipation, on the other hand, usually require some medical intervention. These cases may be managed, often on an outpatient basis, with rehydration, dietary modification, water enemas, oral or suppository laxatives, and/or colonic prokinetic agents. Severe cases of constipation usually require brief periods of hospitalization to correct metabolic abnormalities and to evacuate impacted feces using water enemas, manual extraction of retained feces, or both. Followup therapy in such cases is directed at correcting predisposing factors and preventing recurrence. Subtotal colectomy will become necessary in cats suffering from obstipation or idiopathic dilated megacolon. These cats, by definition, are unresponsive to medical therapy. Pelvic osteotomy without colectomy may be sufficient for some cats suffering from pelvic canal stenosis and hypertrophic megacolon.[30]

Figure 10-1 is an algorithm for the therapeutic approach to the constipated, obstipated, and megacolonic cat.

Removal of Impacted Feces

Removal of impacted feces may be accomplished through the use of rectal suppositories, enemas, or manual extraction.

Rectal Suppositories

Numerous pediatric rectal suppositories are available for management of mild constipation. These include dioctyl sodium sulfosuccinate (emollient laxative), glycerin (lubricant laxative), and bisacodyl (stimulant laxative). Use of rectal suppositories requires a compliant pet and pet owner. Suppositories can be used alone or in conjunction with oral laxative therapy.

Enemas

Mild to moderate or recurrent episodes of constipation may require administration of enemas and/or manual extraction of impacted feces. Several types of enema solutions may be administered, such as warm tap water (5 to 10 mL/kg), warm isotonic saline (5 to 10 mL/kg), dioctyl sodium sulfosuccinate (5 to 10 mL/cat), mineral oil (5 to 10 mL/cat), or lactulose (5 to 10 mL/cat). Enema solutions should be administered slowly with a well-lubricated 10 to 12 Fr rubber catheter or feeding tube. Enemas containing sodium phosphate are contraindicated in cats because of their propensity for inducing severe hypernatremia, hyperphosphatemia, and hypocalcemia in this species.[31]

Manual Extraction

Cases unresponsive to enemas may require manual extraction of impacted feces. Cats should be adequately rehydrated and then anesthetized with an endotracheal tube in place to prevent aspiration should colonic manipulation induce vomiting. Water or saline is infused into the colon while the fecal mass is manually reduced by abdominal palpation. Sponge forceps may also be introduced rectally (with caution) to break down the fecal mass. It may be advisable to evacuate the fecal mass over a period of several days to reduce risks of prolonged anesthesia and perforation of a devitalized colon. If this approach fails, colotomy may be necessary to remove

the fecal mass. Laxative and/or prokinetic therapy may then be instituted once the fecal mass has been removed.

Laxative Therapy

Laxatives promote evacuation of the bowel through stimulation of fluid and electrolyte transport or increases in propulsive motility. They are classified as bulk-forming, emollient, lubricant, hyperosmotic, or stimulant laxatives according to their mechanism of action. There are literally hundreds of products available for treatment of constipation.

Bulk-Forming Laxatives

Most bulk-forming laxatives are dietary fiber supplements of poorly digestible polysaccharides and celluloses derived principally from cereal grains, wheat bran, and psyllium. Some constipated cats will respond to supplementation of the diet with one of these products, but many require adjunctive therapy (e.g., other types of laxatives or colonic prokinetic agents). Dietary fiber is preferable because it is well tolerated, more effective, and more physiologic than other laxatives. Fiber is a classified as a bulk-forming laxative, although it has many other properties. Beneficial effects of fiber in constipation include increased fecal water content, decreased intestinal transit time, and increased frequency of defecation.[32,33] Fiber-supplemented diets are available commercially, or the pet owner may wish to add psyllium (1 to 4 tsp. per meal), wheat bran (1 to 2 tbsp. per meal), or pumpkin (1 to 4 tbsp. per meal) to canned cat food. Cats should be well hydrated before commencing fiber supplementation to maximize therapeutic effect. Fiber supplementation is most beneficial in mildly constipated cats prior to development of obstipation and megacolon. In obstipated and megacolon cats, fiber may, in fact, be detrimental. Low-residue diets may be more beneficial in obstipated and megacolonic cats.

Emollient Laxatives

Emollient laxatives, or stool softeners, are anionic detergents that increase the miscibility of water and lipid in digesta, thereby enhancing lipid absorption and impairing water absorption. Dioctyl sodium sulfosuccinate and dioctyl calcium sulfosuccinate are examples of emollient laxatives available in oral and enema form. Anecdotal experience suggests that dioctyl sodium sulfosuccinate therapy may be most useful in animals with acute but not chronic constipation. As with bulk-forming laxatives, animals should be well-hydrated before emollient laxatives are administered. It should be noted that clinical efficacy has not been definitively established for the emollient laxatives. Dioctyl sodium sulfosuccinate, for example, inhibits water absorption in isolated colonic segments in vitro, but it may be impossible to achieve tissue concentrations great enough to inhibit colonic water absorption in vivo. Dioctyl sodium sulfosuccinate at a dosage of 30 mg/kg/day had no effect on fecal consistency in Beagle dogs.[34] Further studies are required to determine clinical efficacy and therapeutic role of dioctyl sodium sulfosuccinate in management of constipated cats.

Lubricant Laxatives

Mineral oil and white petrolatum are two major lubricant laxatives available for treatment of constipation. Lubricating properties of these agents impede colonic water absorption, as well as permit greater ease of fecal passage. These effects are usually moderate, however, and lubricants are generally beneficial only in mild cases of constipation. Mineral oil usage should probably be limited to rectal administration because of risk of aspiration pneumonia with oral administration, especially in depressed or debilitated cats.

Hyperosmotic Laxatives

This group of laxatives consists of poorly absorbed polysaccharides (e.g. lactose, lactulose), magnesium salts (e.g., magnesium citrate, magnesium hydroxide, magnesium sulfate), and polyethylene glycols. Lactose is not effective as a laxative agent in all cats.[35] Lactulose is the most effective agent in this group. The organic acids produced from lactulose fermentation stimulate colonic fluid secretion and propulsive motility. Lactulose administered at a dosage of 0.5 mL/kg body weight q8-12h fairly consistently produces soft feces in the cat. Many cats with recurrent or chronic constipation have been well managed with this regimen of lactulose. The dosage may have to be tapered in individual cases if flatulence and diarrhea become excessive. Magnesium salts are not currently recommended in the treatment of feline constipation and idiopathic megacolon. Some veterinarians have reported anecdotal successes with the polyethylene glycols.

Stimulant Laxatives

Stimulant laxatives (bisacodyl, phenolphthalein, castor oil, cascara, senna) are a diverse group of agents that have been classified according to their ability to stimulate propulsive motility. Bisacodyl, for example, stimulates nitric oxide–mediated epithelial cell secretion and myenteric neuronal depolarization.[36] Diarrhea results from the combined effect of increased mucosal secretion and colonic propulsion. Bisacodyl, at a dosage of 5 mg q24h PO, is the most effective stimulant laxative in the cat. It may be given individually or in combination with fiber supplementation for long-term management of constipation. Daily administration of bisacodyl should probably be avoided, however, because of injury to myenteric neurons with chronic usage.[36]

Colonic Prokinetic Agents

Stimulation of colonic smooth muscle contraction might improve colonic motility in cats affected with idiopathic dilated megacolon.[4,5,37] Unfortunately, many currently available gastrointestinal prokinetic agents have not proved useful in the therapy of feline constipation either because of significant side effects (e.g., bethanechol) or because the prokinetic effect is limited to the proximal gastrointestinal tract (e.g., metoclopramide, domperidone, erythromycin). The 5-HT_4 serotonergic agonists (e.g., cisapride, prucalopride, tegaserod, mosapride) appear to have the advantage of stimulating motility from the gastroesophageal sphincter to the descending colon with relatively few side effects. Cisapride, for example, increases gastroesophageal sphincter pressure, promotes gastric emptying, and enhances small intestinal and colonic propulsive motility.[38] Cisapride enhances colonic propulsive motility through activation of colonic neuronal or smooth muscle 5-HT receptors in a number of animal species.[39,40] In vitro studies show that cisapride stimulates feline colonic smooth muscle contraction,[5,40] although it has not yet been conclusively shown that cisapride stimulates feline colonic propulsive motility in vivo. A large body of anecdotal experience suggests that cisapride is effective in stimulating colonic propulsive motility in cats affected with mild to moderate idiopathic constipation; cats with long-standing obstipation and megacolon are unlikely to show much improvement with cisapride therapy. Cisapride was widely used in the management of canine and feline gastric emptying, intestinal transit, and colonic motility disorders throughout most of the 1990s.[38,41,42] Cisapride was withdrawn from the American, Canadian, and certain West European countries in July 2000 following reports of untoward cardiac side effects in human patients. Cisapride causes QT interval prolongation and slowing of cardiac repolarization via blockade of the rapid

component of the delayed rectifier potassium channel (I_{Kr}).[43] This effect may result in a fatal ventricular arrhythmia referred to as torsades de pointes. Similar effects have been characterized in canine cardiac Purkinje fibers,[44] but in vivo effects have not yet been reported in dogs or cats. Withdrawal of cisapride has created a clear need for new gastrointestinal (GI) prokinetic agents, although cisapride continues to be available from compounding pharmacies throughout the United States. Tegaserod and prucalopride have been used in the therapy of several of the GI motility disorders, but have limited availability around the world.[37]

Tegaserod is a potent partial nonbenzamide agonist at 5-HT_4 receptors and a weak agonist at 5-HT_{1D} receptors.[45,46] Tegaserod has definite prokinetic effects in the canine colon, but it has not yet been studied in the feline colon. Intravenous doses of tegaserod (0.03 to 0.3 mg/kg) accelerate colonic transit in dogs during the first hour after intravenous administration.[45] Tegaserod at doses of 3 to 6 mg/kg PO normalizes intestinal transit in opioid-induced bowel dysfunction in dogs,[47] and it may prove useful in other disorders of intestinal ileus or pseudoobstruction. Gastric effects of tegaserod have not been reported in dogs, so this drug may not prove as useful as cisapride in the treatment of delayed gastric emptying disorders. In vitro studies suggest that tegaserod does not prolong the QT interval or delay cardiac repolarization as has been occasionally reported with cisapride. Tegaserod was marketed under the trade name of Zelnorm in the United States in September 2002 for the treatment of constipation-predominant irritable bowel syndrome in women. As with cisapride, it was eventually removed from the American market because of untoward cardiac side effects.

Prucalopride is a potent 5-HT_4 receptor agonist that stimulates giant migrating contractions (GMCs) and defecation in dogs and cats.[48,49] Prucalopride also appears to stimulate gastric emptying in the dog.[50] In lidamidine-induced delayed gastric emptying in dogs, prucalopride (0.01 to 0.16 mg/kg) dose-dependently accelerates gastric emptying of dextrose solutions. Prucalopride has not yet been marketed in the United States or elsewhere.

Misoprostol is a prostaglandin E_1 analogue that reduces the incidence of nonsteroidal antiinflammatory drug-induced gastric injury. Main side effects of misoprostol therapy are abdominal discomfort, cramping, and diarrhea. Studies in dogs suggest that prostaglandins may initiate a giant migrating complex pattern and increase colonic propulsive activity.[51] In vitro studies of misoprostol show that it stimulates feline and canine colonic smooth muscle contraction.[52] Given its limited toxicity, misoprostol may be useful in cats (and dogs) with severe refractory constipation.

Ranitidine and nizatidine, classic histamine H_2 receptor antagonists, may also stimulate canine and feline colonic motility. These drugs stimulate contraction apparently through inhibition of tissue acetylcholinesterase and accumulation of acetylcholine at the motor endplate. It's not yet clear how effective these drugs are in vivo, although both drugs stimulate feline colonic smooth muscle contraction *in vitro*.[53] Cimetidine and famotidine, members of the same classification of drug, do not have this effect.

Surgical

Colectomy should be considered in cats that are refractory to medical therapy. Cats have a generally favorable prognosis for recovery following colectomy, although in some cases mild to moderate diarrhea may persist for weeks to months postoperatively.[54,55] Pelvic osteotomy without colectomy has been recommended for cats with pelvic fracture malunion and hypertrophic megacolon of less than 6 months' duration.[56] Pathologic hypertrophy may be reversible with early pelvic osteotomy in such cases. Some surgeons still prefer colectomy in this instance because of the technical difficulty of some pelvic osteotomies.

Prognosis

Many cats have one or two episodes of constipation without further recurrence, although others may progress to complete colonic failure. Cats with mild to moderate constipation generally respond to conservative medical management (e.g., dietary modification, emollient or hyperosmotic laxatives, colonic prokinetic agents). Early use of colonic prokinetic agents (in addition to one or more laxative agents) is likely to prevent the progression of constipation to obstipation and dilated megacolon in these cats. Some cats may become refractory to these therapies, however, as they progress through moderate or recurrent constipation to obstipation and dilated megacolon. These cats eventually require colectomy. Cats have a generally favorable prognosis for recovery following colectomy, although in some cases mild to moderate diarrhea may persist for 4 to 6 weeks postoperatively.

CHAPTER 11

Diarrhea

Stanley L. Marks

Definition

Diarrhea is an increase in the frequency, fluidity, or volume of feces[1] that is best characterized by duration (acute versus chronic), pathophysiologic mechanism, and anatomic location. Diarrhea is considered acute if it lasts for less than 14 days, and chronic when it persists for more than 14 days. Acute, self-limiting diarrhea is a relatively common problem in dogs and cats and usually requires minimal diagnostic testing and therapy. In contrast to most animals with acute diarrhea, chronic diarrhea can be particularly challenging to diagnose, because most animals will not respond to empirical therapies, necessitating a well-formulated and cost-effective diagnostic and therapeutic plan. Specific therapeutic modalities are based upon a definitive diagnosis or histologic characterization of intestinal biopsies.

Although diarrhea is the primary sign of intestinal dysfunction, there are a number of secondary clinical signs that may become the principal one for which the animal is presented, and it is noteworthy that diarrhea may or may not accompany these secondary clinical signs. These secondary signs include *abdominal distention*, *abdominal pain*, *borborygmus*, *dehydration*, *flatulence*, *halitosis*, *melena*, *hematochezia*, *polydipsia*, *polyphagia*, *tenesmus*, *vomiting*, and *weight loss*. Animals may present with alterations in appetite ranging from polyphagia to anorexia, and these same alterations in food intake can be recognized as a consequence of disease progression (e.g., inflammatory bowel disease, intestinal lymphangiectasia, and lymphoma). Weight loss is often associated with nutrient malabsorption of diffuse mucosal disease. Vomiting can be associated with a variety of gastrointestinal disorders and is relatively common in animals with inflammatory bowel disease (IBD). Colorectal disorders are often associated with tenesmus, dyschezia, and large bowel diarrhea characterized by hematochezia, increased mucus on feces, marked increase in defecation frequency, and a reduction in fecal volume.

Pathophysiology and Mechanisms

There are four major pathophysiologic mechanisms that can result in diarrhea, although more than one mechanism can contribute to diarrhea simultaneously.

Osmotic Diarrhea

Osmotic diarrhea is caused by unusually large amounts of poorly absorbable osmotically active solutes in the intestinal lumen. Osmotic diarrhea occurs with malabsorptive disorders where nutrients are maldigested or malabsorbed, remain within the intestinal lumen, and osmotically attract water. Exocrine pancreatic insufficiency is an example of an osmotic diarrheal disorder. Retention of nutrients can lead to alterations in intestinal microflora and fermentation of carbohydrates, further increasing numbers of osmotically active particles. The fecal water output in osmotic diarrhea is directly related to fecal output of the solute or solutes that are exerting an osmotic gradient across intestinal mucosa. Electrolyte absorption is unaffected by these osmotically active substances, and fecal water typically contains very little unabsorbed sodium or potassium.[2] This is the basis for the calculation of the "fecal osmotic gap." In this calculation, the difference between luminal osmolality (equal to body fluid osmolality, approximately 290 mOsm/kg, because the colon cannot maintain an osmotic gradient against plasma) and osmolality of luminal contents contributed by fecal electrolytes is estimated. The contribution of fecal electrolytes is calculated as twice the sum of sodium and potassium ions to account for the anions that accompany these cations. A fecal osmotic gap greater than 50 mOsm/kg suggests osmotic diarrhea.[2] One of the major hallmarks of osmotic diarrhea is that diarrhea resolves when the patient stops ingesting the poorly absorbable solute.

Secretory Diarrhea

Secretory diarrhea is caused by abnormal ion transport in intestinal epithelial cells. The most common cause of secretory diarrhea in dogs and cats are abnormal mediators resulting in changes in intracellular cyclic adenosine monophosphate (cAMP), cyclic guanosine monophosphate (cGMP), calcium, and/or protein kinases, which in turn cause a decrease in neutral sodium chloride absorption or an increase in chloride secretion.[3] Such mediators include endogenous enteric hormones or neuropeptides, inflammatory cell products, bacterial enterotoxins, laxatives, fatty acids, and bile acids (see Chapters 1 and 57 for more detail). Secretory diarrhea has two important distinguishing features; first, fecal osmolality can be accounted for by sodium, potassium, and their accompanying anions, and thus the osmotic gap is small; and second, the diarrhea usually persists despite fasting because the diarrhea is caused by abnormalities in ion transport that have nothing to do with food. Enteropathogenic *Escherichia coli* and IBD are examples of secretory diarrheas.

Increased Mucosal Permeability

Increased mucosal permeability causes loss of fluids, electrolytes, proteins, and red blood cells into the intestinal lumen. Erosive or ulcerative enteropathies, inflammatory (IBD), or neoplastic disorders (intestinal lymphoma) are common causes of alterations in mucosal permeability.

Deranged Motility

Experimental studies in dogs show that abnormal ileal and colonic motility patterns may contribute to clinical symptomatology of IBD.[4,5] The two major motor abnormalities in intestinal inflammation are suppression of phasic contractions, including migrating motor complexes, and stimulation of giant migrating contractions (GMCs), the powerful ultrapropulsive contractions that usually propagate uninterruptedly form the point of their origin in the small intestine to the terminal ileum and often into the colon.[4] Stimulation of GMCs in fasting and fed states produces ultrarapid transit of intestinal and pancreaticobiliary secretions and undigested food into the colon to increase its osmotic load with resultant diarrhea.[4] Platelet-activating factor (PAF) may be one of the inflammatory response mediators that stimulates GMCs,[5] and it is synthesized and released from several immunocytes, including polymorphonuclear (PMN) leukocytes, monocytes, macrophages, mast cells, and eosinophils.[5]

Differential Diagnosis

Box 11-1 lists differential diagnoses for acute and chronic diarrhea in dogs and cats, as well as those disorders that are potentially life-threatening. Many cases of chronic diarrhea can manifest initially as acute diarrhea. Localization of the disease process into "small bowel" versus "large bowel" has some limitations, as many diarrheal diseases with primary manifestations of one compartment (large bowel *or* small bowel) may have diffuse gastrointestinal (GI) involvement (large *and* small bowel). This point is underscored by a study in 40 dogs suggesting that routine collection of ileal biopsies is warranted in dogs with colonopathy, and that routinely sampling of duodenum and ileum increases the diagnostic yield compared to biopsy of one anatomic site.[6] Regardless, the initial differentiation into small and large bowel components helps to further clarify the medical investigation (see Figs. 11-1 and 11-2).

Evaluation of the Patient

Signalment

Awareness of the importance of the animal's signalment and breed predilections for GI disease can facilitate development of a differential diagnosis for the particular animal. A 3-year-old Yorkshire Terrier dog with a 2-month history of small intestinal diarrhea, weight loss, and progressive abdominal distention has a signalment and history suggestive of intestinal lymphangiectasia. Likewise, a young Boxer dog with a 3-month history of tenesmus, hematochezia, increased stool frequency, and mucoid stools could be consistent with histiocytic colitis. Tunnel vision should be avoided, however, as it is plausible that a Boxer dog could have diarrhea from any number of underlying causes.

History

History and physical examination often indicates the anatomic localization and severity of the disease process, and it helps prioritize differential diagnoses. History should ensure that systemic causes of diarrhea are not overlooked. A comprehensive history should also identify important predisposing factors (e.g., exposure to parasites, infectious agents, drugs, toxins). It is equally important to fully characterize the nature of diarrhea and appearance of feces (Table 11-1). For dogs with a history of tenesmus, it is pivotal to determine whether signs are secondary to colitis or to a discrete mass or polyp in the colorectal region. The latter is often associated with a change in the appearance of the stool ("ribbon-like," "pencil-thin") in the absence of a marked increase in frequency of bowel movements or increased fecal mucus as seen with colitis. Likewise, absence of clinical signs of diarrhea does not rule out severe underlying intestinal disease; dogs with protein-losing enteropathy (PLE) may have anorexia and weight loss without associated vomiting and diarrhea. Failure to consider the role of diet or dietary supplements in precipitating or alleviating the diarrhea can cause delayed diagnosis or improper dietary recommendations. Box 11-2 outlines specific questions that should be addressed.

Key: #, potentially life-threatening; *, typically associated with acute diarrhea; †, typically associated with chronic diarrhea; ‡, associated with acute or chronic diarrhea.

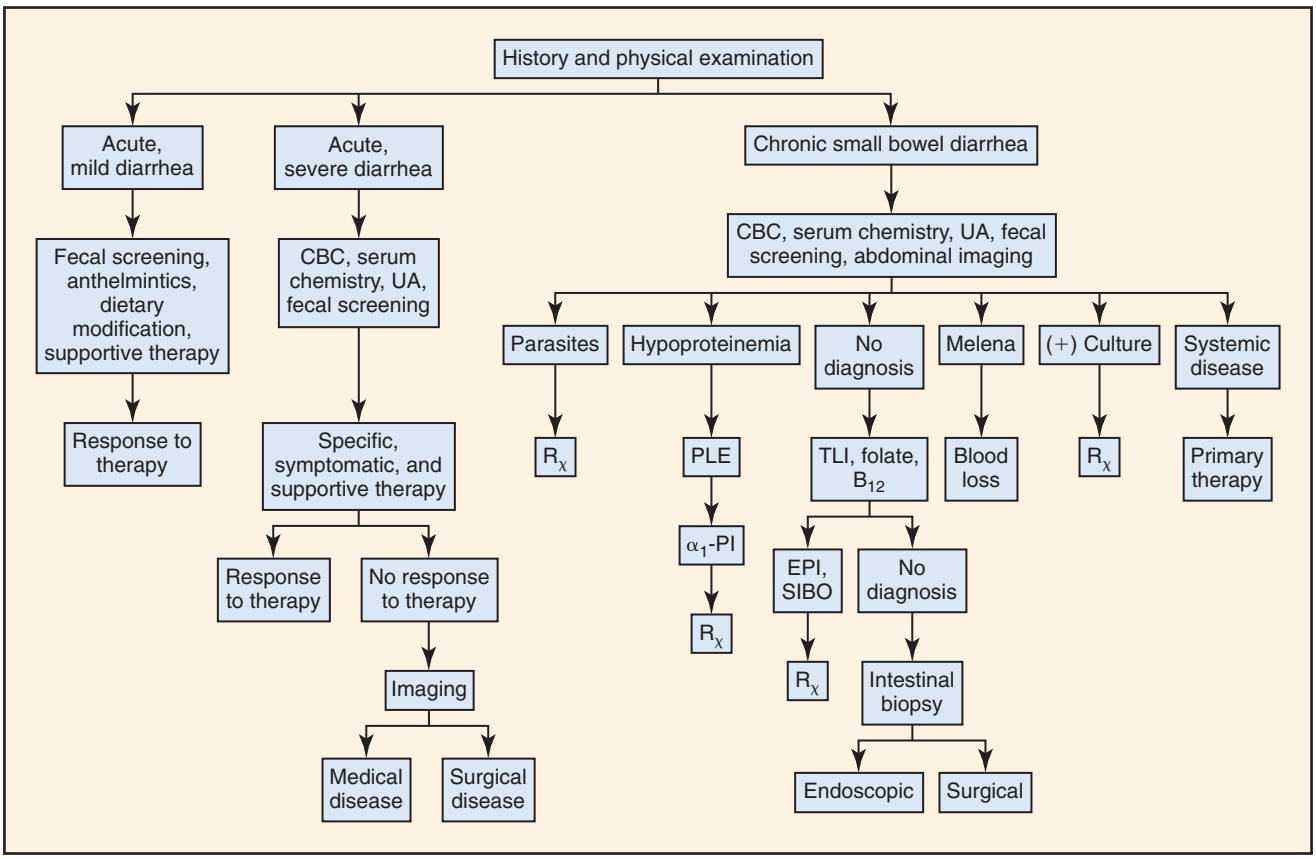

Figure 11-1 Medical workup for dogs and cats with diarrhea primarily of small bowel origin.

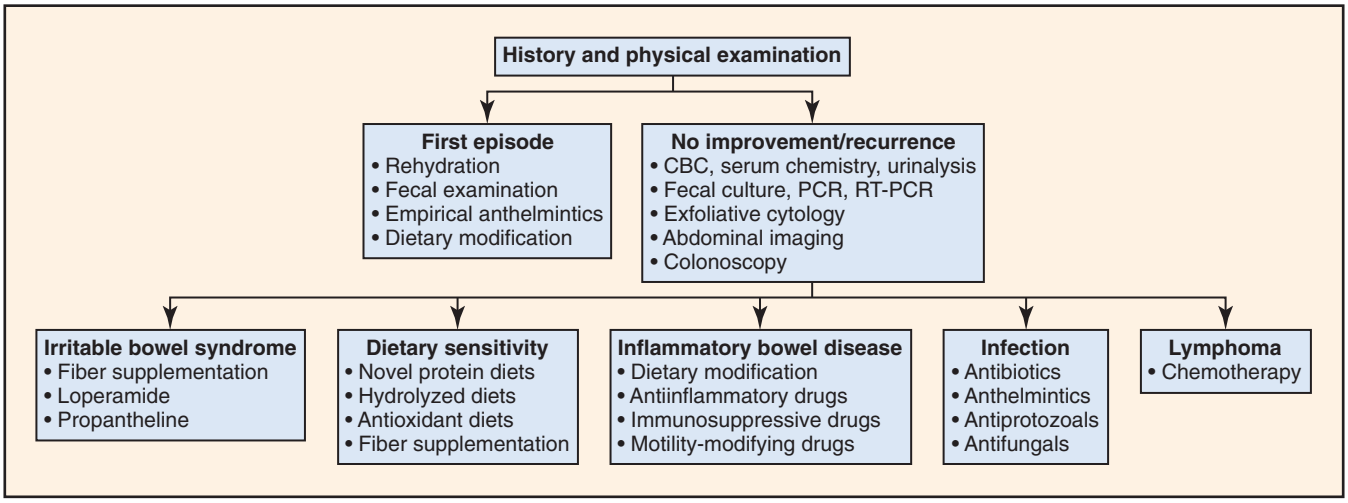

Figure 11-2 Medical workup for dogs and cats with diarrhea primarily of large bowel origin.

Physical Examination

A thorough physical examination helps determine severity and likely origin of the problem. Careful attention should be placed on physical appearance of the animal (emaciation or malnutrition suggestive of malassimilation from IBD, intestinal lymphoma, lymphangiectasia, or pancreatic insufficiency); detection of fever (infectious enteropathy or breakdown of the intestinal mucosal barrier); abdominal effusion and edema (secondary to protein losing enteropathies); and mucous membrane pallor (secondary to intestinal blood loss). Abdominal palpation is performed for detection of mass lesions, thickened bowel loops (neoplasia, intussusception, IBD, fungal enteropathies, mesenteric lymphadenopathy), or pain (bowel inflammation, pancreatitis, peritonitis, ischemia of bowel, and gas-associated bowel distention). In cats the thyroid region should be carefully palpated for thyroid nodules, and the kidneys and liver examined for changes in size and contour. Digital rectal palpation is important for detection of rectal masses or irregular thickening of rectal wall, colorectal strictures, and collection of feces for gross inspection and further evaluation. Digital rectal

Table 11-1 Differentiation of Small Versus Large Bowel Diarrhea*

Differentiation of small versus large bowel diarrhea based upon clinical signs and the physical appearance of feces.

Sign	Small Bowel	Large Bowel
Frequency of defecation	Normal to mildly increased	Markedly increased
Fecal volume	Normal to increased	Decreased
Fecal mucus	Usually absent	Often present
Fecal blood	Melena	Hematochezia
Tenesmus	Absent	Often present
Urgency	Absent	Often present
Vomiting	May be present	May be present
Steatorrhea	May be present	Absent
Dyschezia	Absent	Often present
Weight loss	Common	Uncommon

*Caution should be heeded with the oversimplistic attempts at compartmentalizing the diarrhea into a small bowel versus a large bowel compartment, as many diarrheal diseases can have diffuse involvement histologically.

Box 11-2 Questions that Should be Asked in Patients with Diarrhea

- What is the clinical course or onset of the diarrhea (congenital or acquired; abrupt or gradual in onset; continuous or intermittent)?
- What is the duration of signs?
- What are the physical characteristics of the diarrhea?
- Are there any alleviating or exacerbating factors for the diarrhea such as dietary changes, antibiotic administration, stress, recent travel, or recent kenneling?
- What is the animal's past medical history, and is this diarrhea episode a new problem or a recurrent one? If recurrent, how was the diarrhea managed previously, and what was the outcome?
- What is the animal's anthelmintic and vaccination history?
- Are any other pets in the household similarly affected?
- Is the diarrhea associated with any other systemic (e.g., polyuria/polydipsia) or gastrointestinal signs such as weight loss, vomiting, and anorexia?

palpation of the rectum in cats is usually performed under general anesthesia or deep sedation. Macroscopic examination of a fresh fecal specimen is essential for assessment of bulk, color, consistency, detection of blood and mucus, and detection of foreign material. Small bowel diarrhea is generally free of grossly visible mucus or red blood, but prominent steatorrhea may cause the feces to appear lighter in color. Acholic or pale feces can also be seen in association with extrahepatic bile duct obstruction causing a lack of the bile pigment stercobilin in the feces. Rapid intestinal transit time can be associated with yellow or green stools caused by incomplete metabolization of bilirubin.

Laboratory Evaluation and Tests

An important part of the workup is determining whether the animal has a self-limiting or potentially life-threatening problem. This distinction is pivotal as it determines the level of diagnostic testing and therapy needed and helps determine the likelihood of an animal having a self-limiting diarrhea that could be managed empirically, or an animal having a chronic disease that warrants hospitalization and a more comprehensive workup. This distinction is based on a comprehensive history, thorough physical examination, clinical experience and judgment, and awareness of the differential diagnoses for the diarrhea. Animals showing one or more of the following physical examination findings or signs at presentation warrant a more comprehensive workup and possible hospitalization: fever; abdominal pain; abdominal effusion; organomegaly; moderate to severe dehydration; severe lethargy; melena or hematochezia; mucous membrane pallor; jaundice or congestion; palpable abdominal mass or dilated loop of bowel; frequent vomiting; or other signs of systemic disease such as polyuria/polydipsia.

For animals with acute, mild diarrhea that appear relatively healthy on physical exam and are deemed likely to have a self-limiting gastroenteropathy, a minimum database consisting of centrifugation fecal flotation using zinc sulfate (specific gravity of 1.18 to 1.2) complemented with a fecal enzyme-linked immunosorbent assay (ELISA) or immunofluorescence test for *Giardia* is typically adequate for assessment of parasitic disease. In addition, measurement of hematocrit and total protein are helpful to assess hydration status. Fecal cytology in diarrheic dogs is a low-yield diagnostic test because finding of "safety pin"-shaped endospores consistent with *Clostridium perfringens* are of no diagnostic value. Their detection does not correlate with the presence of *C. perfringens* enterotoxin, the putative virulence factor associated with diarrhea.[7,8] Likewise, detecting "spiral-shaped" bacteria assuming the appearance of "seagulls" is insufficient for a diagnosis of *Campylobacter*-associated diarrhea because spiral-shaped bacteria resembling *Campylobacter* spp. are commonly identified in feces from healthy, nondiarrheic dogs and cats. Isolation of the microaerophilic organism utilizing selective culture media is a far more sensitive diagnostic tool compared with stained fecal smears.[9] In contrast to direct fecal cytology, exfoliative rectal cytology is a useful diagnostic test in dogs and cats with signs of colitis, and is best indicated for diagnosis of specific enteropathogens such as *Histoplasma* spp., *Pythium insidiosum*, or *Prototheca*,[10] or for colonic neoplasms such as lymphoma and carcinoma.

Animals with potentially life-threatening diarrhea or diarrhea that has not responded to conventional therapeutic approaches within 2 to 4 weeks warrant the time and effort required to make a specific diagnosis. The decision of whether to embark on an attempt to make a specific diagnosis usually depends on the nature of the problem, the availability of specific diagnostic facilities, and any client constraints (e.g., financial). For undiagnosed chronic or life-threatening diarrhea, the minimum database should include a complete blood count (CBC), a serum biochemistry profile, a urinalysis, a centrifugation fecal flotation using zinc sulfate, and a direct smear of saline admixed fresh feces for protozoa. A fecal ELISA for parvovirus in puppies should be considered based on signalment, vaccination history, clinical signs, and hematologic findings. The minimum database is performed to determine whether primary GI or metabolic/systemic disorders are associated with diarrhea. Baseline testing should also include specific tests for common disorders known to be likely in a particular animal (e.g., serum thyroxin testing in a 14-year-old cat with a history of chronic weight loss, diarrhea, and polyphagia).

Baseline Laboratory Tests

Complete Blood Count. The complete blood count may reveal an *eosinophilia* secondary to endoparasitism, eosinophilic enteritis, hypoadrenocorticism, or mast cell neoplasia. *Anemia* may result from enteric blood loss or from depressed erythropoiesis caused by systemic disease, chronic inflammation, or malnutrition. A

peripheral *neutrophilia* could reflect stress, inflammation, or infection. Finding a left shift with toxic neutrophils should warrant an aggressive workup for underlying causes (infection, immune disease, etc.). *Lymphopenia* is a relatively common finding in dogs with intestinal lymphangiectasia.

Serum Chemistry. The serum biochemistry panel should be scrutinized for elevations in *urea* and *creatinine* concentration from dehydration or renal disease. The *blood urea nitrogen (BUN)-to-creatinine* ratio can be discordantly elevated from dehydration (prerenal azotemia) or gastrointestinal bleeding. In addition, *panhypoproteinemia* and *hypocholesterolemia* can be recognized in animals with a protein-losing enteropathy from intestinal lymphangiectasia or other infiltrative bowel disorders. Electrolyte changes as a consequence of diarrhea should be carefully scrutinized, and corrected whenever warranted. *Hyperkalemia* and *hyponatremia* are typical electrolyte alterations commonly found in Addisonian dogs; however, these electrolyte changes have been documented in dogs with whipworm infestations and other enteropathies in the absence of Addison disease (pseudo-Addison disease). In addition, dogs with atypical Addison disease can manifest diarrhea in the absence of electrolyte changes. Elevated hepatic enzyme values should be interpreted cautiously in patients with gastrointestinal disease because drainage of bacteria or endotoxin via the portal circulation can precipitate a reactive hepatopathy with elevations of hepatocellular leakage enzymes. Serum thyroxine concentrations are typically included on serum biochemistry panels performed at reference laboratories, and routine measurement of serum T_4 is warranted in any diarrheic cat older than 8 years, independent of concurrent signs such as polyphagia and weight loss.

Feline Leukemia Virus and Feline Immunodeficiency Virus Serologic Screening. Serologic screening for feline leukemia virus (FeLV) and feline immunodeficiency virus (FIV) is warranted in diarrheic cats based upon habitat and housing environment. The enteritis sometimes caused by FeLV and FIV is incompletely understood, although it has long been recognized that FeLV can directly infect intestinal epithelial cells as well as gut-associated lymphoid tissue.[11]

Fecal Enteric Panel. The fecal enteric panel is a low-yield and expensive diagnostic test with misleading results if not performed judiciously in diarrheic dogs and cats. The clinical documentation of enteropathogenic bacteria causing diarrhea in dogs and cats is clouded by the presence of these organisms in apparently healthy animals. A fecal enteric panel consisting of a Gram-stained fecal smear, culture for *Salmonella* and *Campylobacter*, and ELISAs for immunodetection of *Clostridium difficile* toxins A and B and C. *perfringens* enterotoxin is an expensive test (approximately $120 in the author's laboratory) that should be reserved for diarrheic dogs and cats that are systemically ill (fever, severe lethargy, leukocytosis with or without a left shift and toxicity), have an acute onset of hemorrhagic diarrhea, or a recent onset of diarrhea following kenneling or attendance at a show. Lastly, fecal enteric panels should be proactively done when the zoonotic enteropathogens, *Campylobacter* or *Salmonella*, are considerations in diarrheic pets owned by people who are immunocompromised.

Diagnostic Imaging

Survey Abdominal Radiography. Survey abdominal radiographs are a relatively low-yield diagnostic procedure in most dogs and cats with chronic diarrhea, but are indicated in animals for detection of fluid–gas patterns suggestive of mechanical obstruction from foreign bodies, intussusceptions, or masses (see Chapter 26). Although many medical causes of GI disease result in mild to moderate intestinal wall thickening, measurements of wall thickness should not be attempted on survey radiography.

Upper Gastrointestinal Tract Contrast Radiography. Partial or complete mechanical gastrointestinal obstructions are the main indications for upper GI contrast radiography. The modality has been used for determination of gastrointestinal transit; however, disturbances in motility can be difficult to document using liquid barium, and the stress associated with hospitalization can alter gastric and intestinal transit times. Upper GI contrast radiography has also been used to evaluate mucosal abnormalities such as ulcers and filling defects; however, the procedure has limitations and subtle lesions are easily missed (see Chapter 26). The diagnostic yield of upper GI contrast radiography is frequently compromised as a consequence of improper patient preparation (inadequately fasted), too low a volume of barium administered, and insufficient radiographs at suitable time points.

Abdominal Ultrasonography. Abdominal ultrasonography is complementary to survey abdominal radiographs, and has largely replaced contrast radiography for the diagnosis of GI neoplasia, intussusception, and diffuse mural infiltrative disease (see Chapter 26). In addition, ultrasound-guided percutaneous biopsy or aspiration of masses or enlarged mesenteric lymph nodes is an effective diagnostic procedure. Both IBD and small-cell lymphoma of the bowel can have manifestations ranging from normal ultrasonographic appearance to generalized thickening of the intestinal wall with enlarged mesenteric lymph nodes. A loss of intestinal wall layering is more consistent with a diagnosis of lymphoma than IBD. A recent study revealed that cats showing a pattern of thickening of the muscularis propria on ultrasound exam were more likely to have lymphoma compared to cats with IBD and healthy controls.[12] In addition, cats with ultrasonographic evidence of moderate to marked mesenteric lymphadenopathy are more likely to have a diagnosis of intestinal lymphoma.[12]

Specialized Gastrointestinal Function Tests

Serum Trypsin-like Immunoreactivity. Steatorrhea and weight loss in the face of a normal to increased appetite is consistent with a malassimilation disorder such as exocrine pancreatic insufficiency (EPI). A genetic predisposition to development of pancreatic acinar atrophy has been reported in German Shepherd dogs and rough-coated Collies, although many other breeds, including mixed breeds, are affected. Pancreatic acinar atrophy predominantly affects dogs between 1 and 5 years of age, although it also may occur in older dogs. Pancreatic insufficiency is rare in cats, and occurs as a consequence of chronic, intermittent bouts of pancreatitis in this species. In contrast to most dogs with the disease, cats often have loss of both exocrine and endocrine pancreatic function, and are thus typically diabetic as well. The optimal test for the diagnosis of EPI in dogs and cats is a species-specific assay of trypsin-like immunoreactivity (TLI). Assay of fecal proteolytic activity (PA) using an azoprotein- or casein-based method can also be used, but it is not as sensitive as the TLI assay and is more impractical to perform. Microscopic examination of Sudan- and iodine-stained fecal smears for excessive fat droplets and undigested starch muscle is subjective, imprecise, and notoriously unreliable.

Serum Cobalamin and Folate. Measurement of serum vitamin B_{12} (cyanocobalamin) and folate concentrations are used to evaluate the absorptive function of the ileum and jejunum, respectively, and

are abnormally decreased in infiltrative bowel disorders such as IBD or lymphoma affecting these regions of bowel. A deficiency of cyanocobalamin can adversely affect DNA replication in the intestinal crypts, and affect the overall response of the animal to dietary and medical therapy. Cyanocobalamin is easily supplemented via parenteral (subcutaneous) injection on a weekly basis for 6 weeks, with periodic reevaluations of serum cyanocobalamin concentrations recommended thereafter. Measurement of serum cobalamin and folate concentrations are also commonly utilized to diagnose "small intestinal bacterial overgrowth" (SIBO) in dogs, although several studies highlight the relative insensitivity of this assay for this specific purpose.[13,14]

^{51}Cr-EDTA, Polyethylene Glycols, and Differential Sugar Absorption Studies. The integrity of the barrier function of the GI tract has been evaluated by permeability testing in several species, and many different marker molecules, including ^{51}chromium-labeled ethylenediaminetetraacetate[15] (^{51}Cr-EDTA), polyethylene glycols, and mono- and disaccharides have been evaluated.[16] Mannitol and lactulose are nonmetabolizable, hydrophilic, and lipophobic, with negligible affinity for the monosaccharide transport system, and are absorbed passively by nonmediated means. Recovery in urine is almost total and renal clearance is high. The simultaneous use of two allows a differential estimation of transcellular pathways through small-size channels, and paracellular pathways through large-size channels (tight junctions). Furthermore, the simultaneous use of these two sugars and the calculation of the ratio of the sugars makes the test independent of the degree of completion of the urine collection. Finally, it is known that intestinal permeability to mannitol is close to that of rhamnose and permeability to lactulose is similar to that of ^{51}Cr-EDTA.[17] GI permeability and mucosal function testing is used predominantly in the research arena, and not used very often in routine clinical practice.

Fecal α_1-Proteinase Inhibitor. PLE is a syndrome caused by a variety of gastrointestinal diseases causing enteric loss of albumin and globulin. Intestinal inflammation, infiltration, ulceration, blood loss, and primary or secondary lymphangiectasia are well-documented causes of PLE. If left untreated, the final outcome of PLE is panhypoproteinemia with decreased intravascular oncotic pressure and the development of abdominal and pleural effusion, peripheral edema, and death. Protein-losing enteropathy is uncommon in cats, and most cats with PLE are diagnosed with intestinal lymphoma or severe IBD. Serum albumin and total protein should be carefully evaluated in all patients with a history of weight loss, anorexia, vomiting, or diarrhea. Although PLE is typically associated with panhypoproteinemia, the absence of hypoglobulinemia does not preclude a diagnosis of PLE because chronic antigenic stimulation could increase the serum globulin concentration into the "normal" reference range. Additional abnormalities found on the serum biochemistry profile in association with PLE include hypocholesterolemia (secondary to malabsorption) and hypocalcemia. The causes for the hypocalcemia are multifactorial and include hypoalbuminemia (affects total calcium), decreased absorption of vitamin D, and malabsorption of magnesium.

Measurement of fecal α_1-proteinase inhibitor (α_1-PI) can be used to further support a diagnosis of PLE in animals with concurrent liver disease or protein-losing nephropathy (PLN), although this test is limited by logistical constraints in that samples must be shipped frozen, and there is currently only one laboratory that performs the ELISA at Texas A&M University.[18] α_1-PI is the same size as albumin and is lost in the intestinal tract and excreted via the feces where it can be measured as a marker for PLE. Three separate voided fecal specimens are collected into special volume-calibrated cups available from the laboratory. It is important that fecal specimens be naturally voided as digital extraction of the fecal specimen can result in microscopic blood loss and false elevations in fecal α_1-PI. Fecal specimens should be immediately frozen after collection and shipped on ice via overnight mail to the laboratory.

Intestinal Biopsy

Flexible Endoscopy and Biopsy. Endoscopic examination with mucosal biopsy is warranted for definitive diagnosis and to provide prognostic information for patients with chronic diarrhea once dietary, parasitic, systemic or metabolic disorders, and infectious diseases have been excluded (see Chapter 27). There are several inherent disadvantages of flexible endoscopy, including the inability to access the entire length of the gastrointestinal tract (unless enteroscopy is performed), and the inability to acquire deep biopsies involving the muscularis mucosa or submucosa consistently.

Rigid Proctoscopy and Biopsy. Rigid proctoscopy can be performed using a stainless steel or plastic Welch-Allyn sigmoidoscope, which consists of a hollow tube with an eyepiece on the proximal end, an insufflation bulb, and a cold light source with a fiber bundle for the transmission of light to the distal end. Sigmoidoscopy only allows direct examination of the rectum and descending colon; however, the procedure entails less risks, time, and cost than colonoscopy, and is able to diagnose the majority of large bowel disorders because of the diffuse nature of the disease. Flexible colonoscopy is indicated for evaluation of upper colonic disease, including cecal inversion, colonic neoplasia, and occult *Trichuris* infection, and is also warranted for examination and biopsy of the ileum (see Chapter 27).

Exploratory Celiotomy and Biopsy. Exploratory celiotomy allows direct visual inspection, palpation, and collection of multiple full-thickness intestinal mucosal specimens, which can facilitate the differentiation of IBD from intestinal lymphoma. In addition, procurement of biopsy specimens from the liver, mesenteric lymph nodes, and pancreas can be performed.

Treatment and Management of Acute, Self-Limiting Diarrhea

General Principles

Symptomatic therapy of the dog and cat with acute, self-limiting diarrhea typically involves empirical therapy because the causes for many of these diarrheal disorders are often undetermined. Principal goals of symptomatic therapy are restoration and maintenance of fluid and electrolyte balance, dietary modification, administration of broad-spectrum anthelminthics such as fenbendazole, and judicious use of antimicrobials when warranted. The unfounded recommendation of withholding food for 24 to 48 hours to facilitate "bowel rest" is completely unsubstantiated, and there is growing evidence that the benefits of early enteral nutritional support are far superior for promoting intestinal integrity, promoting weight gain, and improving patient outcome.[19]

Medical

Dietary Therapy

Dietary therapy consisting of either a highly digestible, moderately fat-restricted, low-residue intestinal formula or an elimination diet consisting of a novel, select protein source are typically used for animals with acute diarrhea. Fat delays gastric emptying, and

fat-restricted diets appear to be better tolerated in a variety of gastrointestinal diseases. Assimilation of dietary fat is a relatively complex process, and malabsorbed fatty acids are hydroxylated by intestinal and colonic bacteria. Hydroxy–fatty acids stimulate colonic water secretion and exacerbate diarrhea and fluid loss.[20] Fat malassimilation can also be associated with malabsorption of bile acids, resulting in deconjugation of unabsorbed bile acids and increased mucosal permeability and secretion.[21]

Antimicrobials

Use of antimicrobials as empirical therapy in the management of uncomplicated or noninfectious diarrhea is not recommended because of adverse effects of the antibiotics on the normal intestinal microflora (dysbiosis) and their tendency to promote resistant strains of bacteria. Antibiotics are indicated when specific bacterial or protozoan enteropathogens, such as *Campylobacter*, *Clostridium*, or *Giardia* are isolated from the feces. In addition, broad-spectrum bactericidal antibiotics should be considered in conditions associated with severe mucosal damage and a high risk of bacterial translocation with consequent bacteremia or endotoxemia. Lastly, antibiotics such as tylosin or metronidazole can be used to manage dogs with antibiotic-responsive diarrhea, a chronic disorder that is seen more commonly in large-breed dogs, and that is a diagnosis of exclusion.

Oral Protectants

Oral protectants such as kaolin-pectin, bismuth, activated charcoal, and barium are purported to act locally within the gut lumen to adsorb bacteria and toxins and to provide a protective coating on inflamed mucosal surfaces. Bismuth subsalicylate is the most useful of these agents because it has antienterotoxin, antibacterial, antisecretory, and antiinflammatory actions. Caution should be heeded with the use of salicylate-containing compounds in cats because of the prolonged elimination of this compound in cats. Bismuth dosed at 0.5 to 1 mL/kg BID for 2 to 3 days is safe in cats.

Fluids

Acute diarrhea may cause severe dehydration for which intravenous fluid therapy may be required (see Chapter 48).

Treatment and Management of Chronic Diarrhea

Medical

Dietary Therapy

Dietary management for dogs and cats with chronic diarrhea is dependent upon the underlying diagnosis. Elimination and hydrolyzed protein diets have proved to be effective for the management of dogs and cats with IBD involving the small and large bowel. Elimination diets contain single, novel protein sources, whereas hypoallergenic diets contain hydrolyzed protein sources that have been enzymatically hydrolyzed into polypeptides. Although more expensive and less palatable, hydrolyzed diets are particularly beneficial as elimination diets for the diagnosis and management of food hypersensitivity, when a patient appears to be allergic to multiple allergens, when a complicated dietary history makes it difficult to identify a "novel" protein, or when a patient has severe IBD.[22] The supplementation of *fermentable fiber* sources such as psyllium or oat bran may be necessary in patients with IBD involving the large intestine that show partial resolution of their clinical signs. The gelling and binding properties of fatty acids and deconjugated bile acids in fermentable fibers may be beneficial in certain gastrointestinal diseases. The use of fermentable fiber in preference to nonfermentable fiber is generally advocated because most soluble fibers generate butyrate, the principal source of energy for the colonocyte, and other short-chain fatty acids. Short-chain fatty acids may lower the colonic luminal pH, impeding the growth of pathogens.[23] The health benefits derived from dietary supplementation of *prebiotics* have yet to be fully recognized in dogs and cats with chronic diarrhea, although prebiotic administration has been shown to decrease the concentrations of fecal ammonia and amines and increased the numbers of bifidobacteria in dog feces.[24]

Fish oil is reported to be beneficial in ulcerative colitis and Crohn disease patients,[25] but the results are controversial. Only a few studies found significant decreases in rectal leukotriene (LT) B_4 concentrations; the others simply reported clinical improvement. There are no published studies in the veterinary literature to date demonstrating the efficacy of n-3 fatty acid supplementation in managing canine or feline patients with IBD. *Water-soluble vitamins* are often depleted by the fluid losses associated with diarrhea and *fat-soluble vitamin* loss can be significant in animals with steatorrhea. *Magnesium* deficiency has been documented in Yorkshire Terriers with severe IBD and lymphangiectasia,[26] and dogs that are severely hypomagnesemic warrant parenteral supplementation of magnesium sulfate administered at 1 mEq/kg/24h as a constant-rate infusion.[26] Magnesium can also be supplemented orally as magnesium hydroxide (milk of magnesia) at a dosage of 5 to 15 mL per dog q24h. Cats and dogs with severe IBD frequently have subnormal serum *cobalamin* concentrations. Cyanocobalamin should be supplemented parenterally (subcutaneously), and is empirically administered at a dose of 250 μg per cat or toy-breed dog up to 1000 μg per large- or giant-breed dog, at a dosing interval of once weekly for 6 consecutive weeks. Cyanocobalamin concentrations should be rechecked every 6 to 8 weeks, particularly in cats, given the shorter half-life of the vitamin in cats.

The goal of therapy for intestinal lymphangiectasia, a common cause of PLE, is to decrease the enteric loss of plasma protein, resolve associated intestinal or lymphatic inflammation, and control effusion or edema. *Marked dietary fat restriction* is one of the most important aspects in the management of dogs with intestinal lymphangiectasia. Diets that are highly digestible and that contain less than 20% fat calories on a metabolic equivalent basis are recommended.[27] The author recommends feeding of a premium commercial-based diet if possible; however, there are a small number of dogs with severe lymphangiectasia that will need further fat restriction than available in commercial diets, and home-cooked diets are warranted. These home-cooked diets should be made up by a veterinary nutritionist to ensure that the diets are complete and balanced. Dogs with concurrent IBD and lymphangiectasia are more challenging to manage from a dietary perspective because these animals need a novel, select protein source diet that is also markedly fat restricted and virtually no commercial diet fits these criteria. An alternative to consider is the use of hypoallergenic diets containing hydrolyzed protein sources and moderate amounts of dietary fat. Failure to respond favorably to these diets warrants a home-cooked diet that is more fat-restricted and contains a novel, select protein source. Administration of medium-chain triglycerides (MCTs) to enhance the caloric density of the diet is controversial because of unpleasant taste and potential for inducing diarrhea. MCTs are not transported entirely via the portal circulation to the liver and can exacerbate lymphangiectasia.

Antimicrobials

Metronidazole (Flagyl), an inhibitor of cell-mediated immunity,[28] has been frequently used as an adjunctive agent for the management of IBD. The dose of metronidazole is 10 to 15 mg/kg q12h.

Metronidazole tablets have a sharp, unpleasant, metallic taste when scored that can cause severe salivation. Side effects are rare, although metronidazole is associated with a peripheral neuropathy in humans and animals. Less-common side effects include inappetence, nausea, vomiting, seizures, and reversible neutropenia. Reversible genotoxicity in feline peripheral blood mononuclear cells has been observed in cats after only a single dose of metronidazole, but resolved within 6 days of discontinuing the metronidazole.[29]

Tylosin (Tylan) is a macrolide antibiotic that has been reported to be effective and safe in managing canine IBD and antibiotic-responsive diarrhea (ARD).[30] Although the drug's mechanism of action is unknown, it appears to be effective in some dogs refractory to other forms of therapy. The dose range is 20 to 30 mg/kg q12h.

Motility Modifiers

Motility modifiers are *only* indicated as a last resort if the diarrhea is intractable, other causes of diarrhea have been ruled out, the diarrhea is *not* due to an infectious cause, and the patient has failed to respond to appropriate conventional therapy (e.g., diet change, deworming, corticosteroids, antibiotics). The opiate and opioid narcotic analgesics such as loperamide (Imodium; 0.1 to 0.2 mg/kg q8-12h [dogs], q12h [cats] PO) are the most effective motility modifiers for managing diarrhea. Anticholinergic agents are contraindicated because they may cause generalized suppression of all motility and potentiate ileus.

Probiotics

Administration of probiotics to dogs and cats with IBD represents a novel alternative therapeutic modality that warrants further investigation. It has been demonstrated that colitis in both humans and mice is associated with increased levels of cytokines such as tumor necrosis factor (TNF)-α, interleukin (IL)-6, IL-12p70, and IL-23.[31,32] Thus a proper selection of probiotic strains for the treatment of IBD is crucial and should be based on the estimation of their capacity to induce antiinflammatory pattern of cytokines (IL-10^{high}, TGF-β^{high}, IL-12p70^{low}, IL-23^{low}, TNF-α^{low}). Apart from immunomodulatory effects, probiotics have a protective effect on the normal microflora of the human gut by their antimicrobial activities directed toward intestinal pathogens.[33]

Probiotics also have been used to facilitate eradication of intestinal parasites. A recent study documented the ability of the probiotic organism *Enterococcus faecium* SF68 (Forta-Flora, Nestle-Purina, St. Louis, MO) to antagonize *Giardia intestinalis* infection in mice.[34] Oral feeding of *E. faecium* strain SF68 starting 7 days before inoculation with *Giardia* trophozoites significantly increased production of specific anti-*Giardia* intestinal immunoglobulin (Ig) A and blood IgG. This humoral response was mirrored at the cellular level by an increased percentage of CD4(+) T cells in Peyer patches and spleens of SF68-fed mice. Improvement of specific immune responses in probiotic-fed mice was associated with a diminution in the number of active trophozoites in small intestine as well as decreased shedding of fecal *Giardia* antigens (GSA65 protein). A recent study evaluating efficacy of *E. faecium* SF68 in 20 adult dogs with chronic naturally acquired giardiasis failed to affect cyst shedding or antigen content and did not alter innate or adaptive immune responses.[35] Additional studies are warranted in dogs and cats to further assess the immunomodulatory effects of probiotics and to evaluate their safety. The latter issue is particularly important given the recent finding of increased intestinal adhesion of *Campylobacter jejuni* in an in vitro model of canine intestinal mucus following incubation with *E. faecium*.[36] It should be noted that this *E. faecium* strain is different from the *E. faecium* SF68 strain available commercially; moreover, there has been no clinical or anecdotal evidence of *Campylobacter*-associated diarrhea in dogs administered probiotics to date.

Despite the paucity of prospective, randomized, placebo-controlled clinical trials in dogs and cats, tremendous interest has been shown among commercial pet food companies who are marketing probiotics for use in these species. Unfortunately, most of the evidence surrounding the use of probiotics in puppies or adult dogs with stress colitis or ARD is anecdotal, with no prospective, randomized, placebo-controlled studies in these disorders published to date.

Immunomodulatory Therapy

Most dogs and cats with moderate to severe IBD (canine IBD disease activity index >6 to 8) will require adjuvant immunotherapy in combination with dietary management and antimicrobial therapy. It is important to understand that the therapy of IBD must be tailored according to each patient's response.

Oral Corticosteroids

Corticosteroids remain the cornerstone of medical therapy for IBD, despite the lack of published controlled clinical trials documenting their benefit in dogs and cats with IBD. The value of corticosteroids relates to their antiinflammatory and immunosuppressive properties, although they also increase intestinal sodium and water absorption in the small and large bowel, and regulate basal colonic electrolyte transport. The dosage and duration of therapy is based on severity and duration of clinical signs, severity and type of inflammation, clinical response, and tolerance to the drug. The initial dosage of prednisone for therapy of IBD in dogs is 1 to 2 mg/kg q12h, not to exceed a total dose of 50 mg q12h. Cats are typically administered prednisolone, and the drug is started at a dose of 5 mg per cat q12h. The drug is gradually tapered over a 6- to 10-week period once clinical remission is attained. Combination therapy with dietary therapy, azathioprine, or metronidazole is undertaken with the goal of attempting to reduce the dose of prednisone. Parenteral corticosteroid therapy is reserved for the initial management of cats and dogs with intractable vomiting or those with severe malassimilation.

Budesonide

Budesonide, an orally administered corticosteroid structurally related to 16-hydroxyprednisolone, has high topical antiinflammatory activity and low systemic activity because of its high affinity to the steroid receptor and rapid hepatic conversion to metabolites with minimal or no steroid activity. Despite the drug's theoretical benefits, budesonide is associated with significant suppression of the hypothalamic–pituitary–adrenal axis.[37] The drug is dosed at 1 mg once daily for cats and toy-breed dogs, up to 2 mg q12h for large- or giant-breed dogs.

Azathioprine

Azathioprine is an antimetabolite that is converted to 6-mercaptopurine in the liver and then to thioinosinic acid. The latter compound impairs purine biosynthesis and this biochemical reaction inhibits cellular proliferation and reduces natural killer cell cytotoxicity.[38] Onset of these immunologic effects is slow and can require several months for maximal effectiveness. The drug is most useful in dogs as adjunctive therapy in severe or refractory IBD. Azathioprine can also be used for its steroid-sparing effects when adverse effects of prednisone are unacceptably high. The dose for dogs is 50 mg/m^2 or 1 to 2 mg/kg q24h for 2 weeks, followed by

alternate-day administration, whereas cats should receive 0.3 mg/kg q48h. The most significant side effect of azathioprine is bone marrow suppression, particularly in cats. Other side effects include anorexia, pancreatitis, and hepatic dysfunction.

Chlorambucil

The alkylating agent chlorambucil is beneficial for managing refractory cases of IBD and T-cell (small-cell) lymphoma of the gastrointestinal tract, particularly in cats.[39] Hematologic monitoring is warranted every 3 to 4 weeks to assess for neutropenia. In dogs chlorambucil is administered at 1.5 mg/m^2 on alternate days.

Cyclosporine

Cyclosporine is effective in dogs with IBD that are refractory to prednisone immunotherapy.[40] The recommended dose of cyclosporine is 5 mg/kg q24h. Although extremely expensive, particularly for large-breed dogs, the drug overall is relatively well tolerated.

Sulfasalazine

The drug consists of sulfapyridine linked to mesalamine (previously called 5-aminosalicylic acid) by an azo bond that is cleaved by colonic bacteria with subsequent release of the active moiety of the drug, mesalamine. Sulfapyridine is almost completely absorbed in the colon, metabolized in the liver, and excreted in the urine. The mesalamine moiety is locally absorbed and inhibits the formation and degradation of inflammatory mediators, including leukotrienes, prostaglandins, thromboxane, platelet activating factor, histamine, and a number of cytokines.[41] Sulfasalazine is of no value in managing small bowel inflammation because colonic bacterial metabolism is needed to release the active moiety. The usual initial dose in dogs is 20 to 40 mg/kg q8h for 3 weeks, followed by a progressive tapering every 2 to 3 weeks of the dose frequency (q8h to q12h to q24h to q48h). The drug should be used with caution and at a lower dose (10 to 20 mg/kg q24h) in cats because of the salicylate portion of the drug. The most common side effects of sulfasalazine are anorexia, vomiting, cholestatic jaundice, allergic dermatitis, and keratoconjunctivitis sicca (KCS).

Colloids

Administration of colloids such as Dextran 70 or hetastarch are used to increase the plasma oncotic pressure in dogs with intestinal lymphangiectasia or other PLEs when severely hypoalbuminemic. Colloids are typically administered prior to surgery in an effort to minimize complications associated with low plasma colloidal oncotic pressure. Administration of fresh-frozen plasma is an expensive and less efficient means of increasing colloidal oncotic pressure in dogs that are severely hypoalbuminemic. Loop diuretics such as furosemide (1 to 2 mg/kg subcutaneously or PO) can be used to decrease abdominal or pleural effusions, although caution should be heeded in monitoring the patient's hydration status and serum potassium concentrations. Potassium-sparing diuretics such as spironolactone (2 to 4 mg/kg PO or IV) can be used together with furosemide to decrease the likelihood of hypokalemia arising.

CHAPTER 12

Dyschezia and Tenesmus

Albert E. Jergens

Definition

Dyschezia and tenesmus are clinical signs usually associated with colorectal disease. *Dyschezia* is the term applied to difficult or painful defecation, which is most commonly observed with anorectal disorders. *Tenesmus* is the clinical sign associated with straining to defecate (more common) or urinate (less common). Tenesmus is usually caused by large bowel disease, particularly colitis. Straining is usually evident as an animal maintaining a posture of defecation for an extended period, or as repeated, nonproductive attempts to defecate are observed. Tenesmus is often associated with other clinical signs of colonic disease including large bowel diarrhea (e.g., increased frequency of defecation, the production of scant fecal volume), hematochezia (fresh red blood on the feces), and/or excessive fecal mucus. Tenesmus is a clinical sign and not a disease; consequently, an underlying cause must be identified. In general, tenesmus and dyschezia are more commonly associated with colorectal disorders in dogs than in cats. Dysuria in cats with lower urinary tract disease may be misinterpreted as dyschezia and tenesmus.

Pathophysiology and Mechanisms

Inflammation of the colonic or rectal mucosa is the most common cause of tenesmus and dyschezia in dogs and cats.[1-4] Tenesmus may also occur with colonic, rectal, or anal obstruction, and constipation. Dyschezia is usually caused by diseases involving anal and perianal structures.[3,4] Severity of inflammation causing tenesmus or dyschezia is generally dictated by the magnitude of the host immune response. For example, mucosal inflammation of colonic inflammatory bowel disease (IBD) may be explained by (a) aberrant host responses to the colonic microbiota and (b) disturbances in colonic motility.[5] A generic inflammatory response involving infiltrating immune cells (e.g., B and T lymphocytes, macrophages), secretomotor neurons (e.g., vasoactive intestinal polypeptide, substance P), cytokines (both T-helper type 1 [Th]1 and Th2 derived), and various inflammatory mediators (e.g., leukotrienes, prostanoids, reactive oxygen species, and nitric oxide metabolites) drive the chronic inflammatory process.[5] Inflammation can cause suppression of normal colonic motility patterns, which may contribute to onset and severity of clinical signs. Other factors that may contribute to large bowel signs include previous therapies (especially antibiotics), bacterial fermentation (e.g., short-chain fatty acids [SCFA], lactate) products, altered composition of the colonic microbiota, and perturbed mucus secretion.

Other inflammatory conditions causing tenesmus and dyschezia can include helminths (*Trichuris* spp., *Ancylostoma* spp.), protozoa (*Giardia* spp., *Trichomonas* spp.), fungi (*Histoplasma* spp.), oomycetes (*Pythium* spp.), algae (*Prototheca* spp.), bacteria (*Campylobacter* spp., *Clostridia* spp., enteropathogenic/enterotoxigenic *Escherichia coli*), colorectal tumors, and rectal/anal strictures.[2] Mechanism for mucosal inflammation with these disorders varies and includes local mucosal irritation (e.g., nematode parasites), robust host immune responses (e.g., histoplasmosis, pythiosis), and direct mucosal association (e.g., adherent and invasive *E. coli* [AIEC] as seen with granulomatous colitis).

Constipation is another important cause of tenesmus and dyschezia in animals.[2] Constipation is defined as difficult, reduced, or painful evacuation of feces that occurs secondary to colonic hypomotility or dysmotility disorders, mechanical obstruction, or colorectal diseases. Dry, hardened feces are difficult to pass, and chronically constipated cats have intermittent episodes of tenesmus, hematochezia, or diarrhea due to the mucosal irritant effect of impacted feces. Fiber-responsive colitis is a unique large bowel diarrheal syndrome of dogs in which altered colonic motility causes clinical signs of excessive fecal mucus, hematochezia, and tenesmus.

Urogenital disease may occasionally cause tenesmus in some animals as nonbacterial (e.g., feline lower urinary tract disease [FLUTD], neoplasia, calculi) and bacterial-mediated inflammation involving the urinary bladder, urethra, and genital organs (e.g., prostate) is relatively common in dogs and cats.

Differential Diagnosis

Box 12-1 presents causes for tenesmus and dyschezia in companion animals. Although diseases affecting colon and rectum are the predominant source of clinical signs, it is important to exclude disturbances in other organs (e.g., urogenital disease) that can also cause tenesmus. Cats are notorious for stranguria associated with FLUTD, which can confound accurate assessment of ineffective straining associated with colorectal disease. A thorough patient history and observation of the animal's elimination process are essential for avoiding misdiagnosis.

Evaluation of the Patient

History

Always obtain a history pertaining to both urinary and gastrointestinal tracts in animals with tenesmus. A careful history and complete physical examination are required to determine which organs are affected and to assess potential severity of the dysfunction. Besides tenesmus, lower urinary tract disorders (especially cystitis or urethritis) often result in hematuria and pollakiuria, which are

Box 12-1 Causes for Tenesmus and Dyschezia in Dogs and Cats

Colorectal Disease
Constipation
Colitis-proctitis
Inflammatory bowel disease
Histoplasmosis
Clostridium enterotoxicosis
Protothecosis (rare)
Rectal stricture
Neoplasia or polyps
Foreign material
Fiber-responsive diarrhea

Perianal Disease
Anal sacculitis, impaction, or abscess
Anal sac neoplasia
Perianal fistula
Perianal hernia

Urogenital Disease
Cystitis–urethritis–vaginitis
Urinary bladder–urethra calculi
Prostatitis–prostatomegaly
Neoplasia of urethra, bladder, prostate, vagina

Other Causes
Caudal abdominal mass
Pelvic fracture–neoplasia

readily apparent to most clients. Normal urinary habits are most suggestive of tenesmus caused by colorectal disorders. Tenesmus preceding defecation usually indicates an obstructive lesion, whereas inflammatory disorders are often associated with persistent tenesmus following evacuation. A history of large bowel signs may be evident in patients with colonic disease alone and in animals having more extensive colorectal disease. Systemic signs of disease, such as anorexia, weight loss, vomiting or diarrhea, may be reported especially in animals having concurrent systemic disease or disorders involving other segments of the gastrointestinal tract. Animals are generally alert, active, and well-fleshed with normal appetites on presentation. The following historical concerns are of significance in animals with tenesmus and dyschezia:

- Is the diarrhea (if present) acute or chronic? Acute, self-limiting large bowel diarrhea is common and rarely requires an in-depth diagnostic evaluation.
- Are clinical signs static, progressive, or cyclical? Colorectal neoplasia may cause progressive signs whereas colonic IBD is characterized by a waxing/waning clinical course.
- Is there evidence of dietary, environmental, parasitic, or infectious causes for large bowel signs? Dietary and parasitic causes may constitute up to 50% of clinical cases dependent upon the geographic area.
- What type of diet is the animal being fed? Note recent dietary changes (this might incriminate responsible nutrients), the amount and frequency of feeding, and the administration of medications (e.g., antibiotics, narcotics, motility modifiers, laxatives) that might alter colonic function.
- Do clinical signs resolve when the animal is fed either an intact protein or hydrolysate elimination diet? This might suggest the presence of an adverse food reaction (i.e., dietary sensitivity or intolerance).
- A positive response to glucocorticoid therapy may indicate inflammatory or immune-mediated diseases, such as IBD or perianal fistula.
- Does the animal roam freely? If so, parasitic, toxic, and infectious causes for colorectal diseases may be more likely.
- Does the animal's travel history suggest an increased risk of disease with a regional incidence, such as histoplasmosis (Midwest United States) or intestinal parasites (Southern United States)?

Physical Examination

Physical examination provides important localizing information regarding potential cause(s) for dyschezia and tenesmus. The perineal region is carefully examined for perineal hernia, perianal fistula, abnormalities to the anal sacs (e.g., inflammation, rupture, tumor), or perianal masses. Abdominal palpation might yield a large turgid bladder (indicative of urinary obstruction), a fecal impacted colon (indicative of constipation), or prostatomegaly. Rectal examination is performed to rule out colonic stricture (rare); intraluminal masses (polyps or malignant tumors); abnormalities to the anal sacs, prostate, or urethra; and caudal abdominal cavity disorders (mass, pelvic fracture). Penis and vagina are also closely examined by the clinician for evidence of pain, masses, or calculi. Rectal evaluation permits the inspection of fresh feces for hematochezia or mucus and can provide valuable exfoliative specimens for cytological review. Some animals with exquisite rectal sensitivity because of inflammation, stricture, or mass lesion may require sedation or general anesthesia before rectal evaluation can be safely and adequately performed.

Laboratory Evaluation and Tests

Diagnostic strategies for colorectal disorders vary considerably depending on severity, chronicity of signs, presence of systemic illness, and historical or likely responses to therapy (Fig. 12-1). A laboratory database consisting of a complete blood count, biochemistry profile, and urinalysis should be performed in animals having tenesmus associated with systemic signs (e.g., anorexia, weight loss, dehydration). Other specific diagnostic tests include the following:

- *Fecal parasitic examination* (e.g., direct fecal smears and fecal flotation studies), which should be performed to evaluate for helminth or protozoal infections. Some parasites (e.g., *Trichuris vulpis* and *Giardia* spp.) may require serial fecal flotations. To identify *Giardia* cysts, a zinc sulfate flotation test is recommended. Direct saline fecal smears are used to detect motile trophozoites of *Giardia*, *Tritrichomonas*, *Balantidium*, or *Entamoeba*.
- *Fecal cytologic examination* involves evaluation of stained rectal/colonic mucosal scrapings under high power or oil immersion to identify etiologic agents or inflammatory cells. A flat conjunctival spatula (carefully advanced digitally) procures excellent quality specimens that are placed on a microscope slide, air-dried, and stained with Diff-Quik or Wright stain. Increased numbers of leukocytes indicate a possible inflammatory or infectious etiology. Finding fungal (*Histoplasma*) organisms or clostridial spores may suggest an infectious cause for gastrointestinal signs. Finding clostridial spores should be confirmed by culture and toxin assays.
- *Fecal bacteria cultures* are sometimes useful when infectious diarrhea is suspected. The major bacterial pathogens in dogs and cats include *Campylobacter jejuni*, *Salmonella* spp., pathogenic *E. coli*, and *Clostridia*. Fecal specimens for culture must be fresh, of adequate quantity (e.g., small, pea size amount of stool), and transported rapidly for inoculation into enrichment media. Results should always be interpreted in light of clinical signs and results

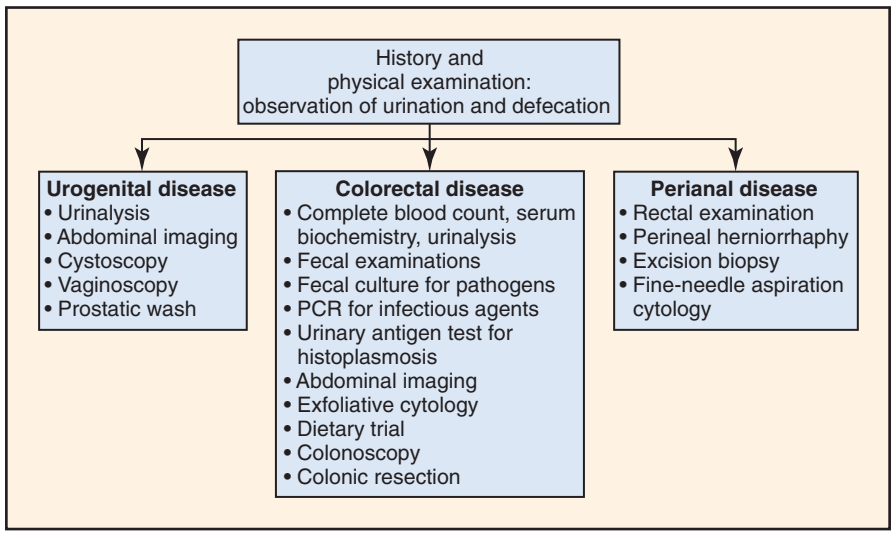

Figure 12-1 Diagnostic strategies for determining causes of tenesmus and dyschezia.

of laboratory tests. Fecal culture of a bacterial species is not necessarily definitive evidence for bacterial infection.

- *Molecular testing* using polymerase chain reaction (PCR) may be indicated for diagnosis of certain infectious agents, such as *Tritrichomonas foetus*, which may cause large bowel diarrhea in cats.[6]
- *Imaging* is infrequently diagnostic in animals with colorectal disease. Survey abdominal radiography may identify radiopaque foreign objects, fecal impaction, or extraluminal obstruction (e.g., pelvic canal stenosis, prostatomegaly, or lymphadenopathy). Pneumocolon may facilitate visualization of rectal masses. Ultrasonography is useful for confirming structural abnormalities to the genitourinary system causing tenesmus.
- *Fine-needle aspiration* of rectal or anal masses is useful for diagnosis of some perianal and rectal tumors. Excision biopsy is usually required for definitive diagnosis.
- *Colonoscopy with mucosal biopsy* often helps provide a definitive diagnosis of colonic mucosal disease.[7,8] Either flexible colonoscopy or rigid proctoscopy may be performed. Rigid proctoscopes are inexpensive and easy to use but only permit endoscopic evaluation of the distal colon and rectum. Flexible endoscopy is generally preferred as it enables evaluation of the entire colon, cecum, and the ileum. Proper patient preparation is critical for successful colonoscopy and facilitates procurement of diagnostically adequate specimens for histopathologic examination. Colonoscopy should only be performed after routine noninvasive diagnostic tests have failed to determine the cause for clinical signs. Simple proctoscopy may be sufficient in animals with isolated anorectal disease.

Treatment and Management

General Principles

Treatment of dyschezia and tenesmus depends predominantly on the cause. If genitourinary disease is the suspected cause of tenesmus, then specific therapy may include antibiotics for bacterial urinary tract and prostatic infection, surgical removal of calculi, drainage of prostatic cysts, and surgery or chemotherapy for genitourinary neoplasia. Tenesmus and dyschezia caused by colorectal or perianal disorders will also require specific medical or surgical intervention (Table 12-1).[1-4,9]

Table 12-1 Therapeutic Interventions for Tenesmus and Dyschezia

Causes for Tenesmus and Dyschezia	Therapeutic Interventions
Parasitic colitis	Anthelmintic or antiprotozoal therapy
IBD colitis	Elimination diet; immunosuppressive drugs; pre- and probiotic therapy
Colonic histoplasmosis	Antifungal drug therapy
Clostridial enterotoxicosis	Antibiotic therapy; fiber supplementation
Constipation	Correct underlying cause; medical therapy with dietary modification, enemas, laxatives, and prokinetic drugs; colectomy for megacolon
Rectal stricture	Balloon dilation of stricture
Neoplasia or polyps	Surgical excision of masses ± chemotherapy
Fiber-responsive diarrhea	Fiber supplementation
Anal sacculitis/impaction	Express contents ± antibiotic therapy
Anal sac neoplasia	Surgical excision ± chemotherapy
Cystitis or urethritis	Antibiotics based on urinary culture
Lower urinary calculi	Lithotripsy, cystotomy, hydropropulsion
Prostatomegaly or prostatitis	Neuter; antibiotics for prostatitis
Lower urinary neoplasia	Surgical excision ± chemotherapy

Medical

Tenesmus associated with acute, large bowel diarrhea is usually self-limiting. Dietary modification (see following discussion) will reduce signs and expedite clinical recovery in most instances. *Anthelmintics* should be administered if parasitic colitis is suspected. Fenbendazole and praziquantel have established efficacy against *Trichuris* spp. infection; treatment should be repeated at 3 weeks and again in 3 months to assure parasite eradication. Any coexisting intestinal infection (e.g., cryptosporidiosis, *Giardia* spp.) with *T. foetus* should be identified and treated if possible. Empirical therapy with fenbendazole is recommended and will improve signs but may not resolve

T. foetus infection. However, most cats (88%) will show spontaneous resolution of diarrhea within 2 years. *Antibiotics* are indicated for bacteria-mediated diarrhea causing tenesmus and when a specific enteropathogenic bacterial strain is identified through diagnostic (e.g., bacterial culture, PCR) testing. Metronidazole or tylosin may be used for treatment of acute or chronic *Clostridium perfringens* infection. Antibiotics also serve as adjunct therapy for anal sac impaction, anal sacculitis, and abscessation of the anal sacs following removal of contents.

Idiopathic IBD with colorectal involvement causing tenesmus is best treated using a combination of dietary and pharmacologic interventions. Drug therapy for IBD remains empirical but generally includes antiinflammatory (e.g., sulfasalazine, prednisone/prednisolone, budesonide), immunosuppressive (e.g., azathioprine, cyclosporine, chlorambucil), and select antimicrobial (e.g., metronidazole, tylosin) drugs. Histiocytic ulcerative colitis caused by adherent invasive *E. coli* (AIEC) is usually responsive to enrofloxacin therapy.[10]

Drug therapy for recurrent *constipation* is multifaceted and includes dietary modification, water enemas, oral laxatives, and colonic prokinetic agents in some combination.[2] Early use of drug therapy for episodes of constipation will prevent progression to obstipation or megacolon which eventually requires surgical intervention. *Malignant colorectal tumors*, including lymphomas, adenocarcinomas, and gastrointestinal stromal tumors, are associated with signs of inflammation (e.g., hematochezia, tenesmus) and obstruction in dogs. Benign colonic tumors, such as polyps, are generally restricted to the distal rectum. Depending upon tumor type, colorectal tumors are treated by surgical excision, chemotherapy, or antiinflammatory therapy in some combination.

Dietary therapy is an important treatment modality for canine and feline colitis caused by chronic immunologically mediated inflammation (e.g., idiopathic IBD) or adverse food reactions (e.g., food allergy, food intolerance). Both intact protein or hydrolysate elimination diets should be fed to reduce dietary sensitivities that occur secondary to impaired intestinal barrier function. Importantly, diets should also be highly digestible, low in fat content, lactose and gluten free, and should be fed for a sufficient time to elicit the desired clinical response. Dietary trials in cats are performed over a 7- to 10-day period; dogs with gastrointestinal signs caused by dietary ingredients are generally trialed for 3 to 4 weeks with an elimination diet to rule out adverse food reactions. Animals diagnosed with IBD will often require lifelong therapy with an elimination diet. Modification of the *n-3–to–n-6 fatty acid ratio* in the diet may further decrease mucosal inflammation and reduce tenesmus in animals.

Adjunct therapy for colitis also includes administration of *soluble fiber* (e.g., Metamucil, 1 to 3 tbsp. per meal), which serves to (a) normalize colonic motility patterns, (b) bind colonic irritants that may stimulate colonic secretions, and (c) produce beneficial SCFAs for colonic health, such as butyrate. Fiber-supplemented diets may be useful as primary therapy in certain forms of large bowel diarrhea in dogs.[11]

Surgical

Surgical therapy for treatment of tenesmus and dyschezia is required in animals with tumors affecting the colon and anorectum.[9] Complete surgical excision is indicated for colonic adenocarcinomas, cecal leiomyosarcomas, and obstructing lymphomas although complete surgical excision may not be possible for rectal carcinomas. Rectal tumors are generally excised by surgical eversion while benign rectal polyps may be removed endoscopically using a snare. Histopathology of the mucosa and submucosa is important for correct diagnosis and for defining the completeness of surgical removal. Cats diagnosed with severe recurrent obstipation or megacolon that is refractory to medical therapy will require subtotal colectomy to resolve clinical signs.[2]

Radiation and Endoscopy

Radiation therapy is uncommonly required for tenesmus seen with colonic disease but may be used to treat some rectal tumors that are inadequately excised. Balloon dilation via flexible endoscopy is the treatment of choice for benign rectal strictures causing obstruction, tenesmus, and dyschezia.[12] Multiple (two to three procedures) endoscopic balloon interventions may be required to adequately dilate the narrowed rectal lumen. Postprocedural glucocorticoid therapy is indicated to help prevent fibrosis and restricturing.

Alternative and Complementary

The alternative of n-3 and n-6 fatty acids in the diet to reduce production of key inflammatory mediators (e.g., leukotriene B_4) important in chronic inflammation was previously discussed (see Chapter 11). Other novel therapies for treatment of IBD have been proposed and include the administration of probiotics and prebiotics that modulate composition of the commensal microbiota to reduce gut inflammation. *Probiotics* are living microorganisms that, upon ingestion in sufficient numbers, impart health benefits beyond those of inherent basic nutrition. Lactobacilli and bifidobacteria have been the most commonly used human probiotics, but multistrain cocktails (e.g., VSL#3), *E. coli* Nissle 1917, and nonbacterial *Saccharomyces boulardii* have also been used for probiotic effect. Probiotic bacteria have measurable host benefits including ability to improve epithelial barrier function, modulate mucosal immune system, and alter intestinal flora.[13]

Prebiotics are nondigestible dietary carbohydrates—lactosucrose, fructooligosaccharides (FOS), psyllium, bran—that stimulate growth and metabolism of endogenous enteric protective bacteria upon consumption.[14] Beneficial effects of prebiotics are also associated with production of SCFA caused by fermentation by colonic bacteria. *Synbiotic therapy* (i.e., a combination of probiotics and prebiotics) is an emerging therapeutic modality. Increasing evidence supports a therapeutic role for probiotics, prebiotics, and synbiotics in gastrointestinal diseases of humans, including infectious diarrhea, *Helicobacter pylori* infection, irritable bowel syndrome, lactase deficiency, and IBD. Unfortunately, controlled clinical trials with these products in dogs and cats have not been performed, and future studies are needed to explore therapeutic efficacies and mechanisms of action of these mixtures in therapy of colonic inflammation causing tenesmus.

CHAPTER 13

Dysphagia and Gagging

Robert J. Washabau

Definition

The term *dysphagia* derives from the Greek roots *dys*, meaning "difficulty" or "disorder," and *phagia*, meaning "in eating." Broadly defined, *dysphagia* would apply to a large number of oropharyngeal disorders for which there is difficulty in eating. Thus the term could be used to describe problems associated with prehension of food or water, bolus formation, rostral-to-caudal contraction of pharyngeal constrictor musculature, dropping of food and/or water from the commissures of the mouth, and swallowing. Over time, *dysphagia* has become more strictly defined as difficulty in swallowing. *Gagging* or the *gag* reflex is an involuntary retching reflex stimulated by mechanical irritation of the posterior palate or pharynx. Dysphagia may provoke gagging, but gagging does not necessarily imply dysphagia. *Regurgitation* is a clinical sign more consistent with esophageal disease and should be differentiated from dysphagia, gagging, and vomiting (see Chapter 21). Regurgitation differs from vomiting in that it is characterized by passive retrograde evacuation of undigested food from the esophagus. *Vomiting* is characterized by coordinated activities of the gastrointestinal, musculoskeletal, and nervous systems culminating in the active evacuation of digested or partially digested food from the gastrointestinal tract (see Chapter 23).[1] Vomiting usually signifies disease caudal to the gastroesophageal sphincter. Signs referable to aspiration pneumonia, for example, *coughing* and *dyspnea*, may be the major presenting complaint in some animals. A good history will usually differentiate these signs from others (e.g., dysphagia, gagging) associated with oropharyngeal disorders.

Pathophysiology and Mechanisms

The oropharyngeal phase of swallowing is subdivided into three stages.[2-6] The first or *oral* stage begins with prehension of food with teeth and tongue and formation of the bolus at the base of the tongue. In the second or *pharyngeal* stage, rostral to caudal pharyngeal contractions propel the bolus from the base of the tongue to the cricopharyngeal or cranial esophageal sphincter opening. Mechanical stimulation of the caudal pharynx activates an afferent neural pathway that has its synapse in the brainstem, and which activates an efferent neural pathway back to the cricopharyngeus leading to inhibition and relaxation. The cricopharyngeus relaxes during the third or *cricopharyngeal* stage, and the bolus passes into the cranial esophageal body (Fig. 13-1). The cricopharyngeus subsequently contracts, pharyngeal muscles relax, and the oropharyngeal phase is repeated with successive swallows.

Abnormalities in any of the oropharyngeal stages can produce oropharyngeal dysphagia.[6] Oropharyngeal dysphagias are either morphologic or functional in origin. Morphologic disorders that interfere with oropharyngeal phase of swallowing include strictures, foreign bodies, and neoplastic, traumatic, and inflammatory processes of the oral cavity and pharynx. Most functional disorders consist of failure, spasticity, or incoordination of muscular contractions and are due to neuromuscular diseases.

Differential Diagnosis

Oropharyngeal Dysphagia

Three types of oropharyngeal dysphagia have been characterized in companion animal species: (a) *oral* stage dysphagias with prehension deficits mainly as a consequence of loss of tongue function; (b) *pharyngeal* stage dysphagias with transport deficits mainly as a consequence of loss of cranial and caudal pharyngeal constrictor function; and (c) *cricopharyngeal* stage dysphagias with cricopharyngeal opening or closure (achalasia or chalasia) deficits, or incoordination between pharyngeal contraction and cricopharyngeal sphincter relaxation.[6,7] Neuromuscular disease is the underlying pathogenesis of oropharyngeal dysphagia, but precise etiologies are rarely identified. Some cases have been associated with brainstem disease, peripheral neuropathy, myasthenia gravis, polymyositis, muscular dystrophy, and hypothyroidism. A unique form of oropharyngeal dysphagia bearing some resemblance to muscular dystrophy has been described in the Bouviers des Flandres breed (Table 13-1) [8,9]

Cricopharyngeal Achalasia

Cricopharyngeal achalasia is a neuromuscular disorder of young dogs characterized by hypertension of the cranial esophageal sphincter and inadequate relaxation of the sphincter with swallowing. Dysfunction of the inhibitory neuron mediating sphincteric relaxation has been postulated, but etiology, pathogenesis, and breed predisposition of this disorder are unknown.

Evaluation of the Patient

History

Dysphagia and gagging are the most important clinical signs with oropharyngeal disorders. Pet owners may also describe difficulties in drinking water or forming a solid bolus, excessive mandibular or head motion, persistent forceful ineffective swallowing efforts, dropping of food from the mouth, nasal discharge because of misdirection

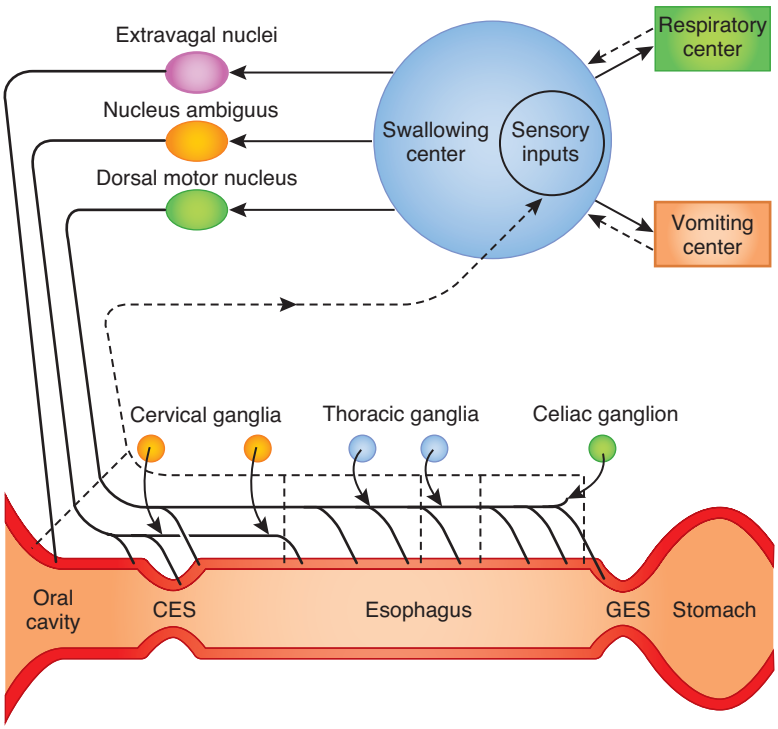

Figure 13-1 Neural regulation of swallowing in the dog and cat. (Reprinted with permission from Washabau RJ, Holt DE. Pathophysiology of gastrointestinal disease. In: Slatter D, ed. *Textbook of small animal surgery*, 3rd ed. Philadelphia, Saunders, 2003.)

Table 13-1 Known Breed Predispositions for Diseases of the Oropharynx Causing Dysphagia and Gagging

Condition	Breed
Oral neoplasia	Golden retriever, Weimaraner, Boxer, Cocker Spaniel
Oropharyngeal dysphagia	Bouvier des Flandres, Golden Retriever, Labrador Retriever
Oral eosinophilic granuloma	Siberian Husky

of food into the nasopharynx, excessive salivation, foaming from the mouth, coughing, failure to thrive, and reluctance to eat.[6,10] Regurgitation, a common sign of esophageal disease, is less frequently reported with oropharyngeal dysphagias.

Physical Examination

Physical examination findings are dependent upon the pathogenesis and severity of dysphagia. Many morphologic abnormalities (e.g., neoplasia, stricture, inflammation, foreign body) are fairly obvious on examination of the pharynx. Animals with oropharyngeal dysphagias, on the other hand, may have few morphologic abnormalities. Focal or generalized muscle atrophy and diminished or absent gag reflex may be the only abnormal findings in animals with neuromuscular disease.

Diagnostic Tests

Figure 13-2 depicts an approach to diagnosis of dysphagia and gagging associated with oropharyngeal disease. Diagnosis of a morphologic abnormality is usually straightforward and, except for tissue biopsy or culture, usually does not require any additional diagnostic testing. Survey radiography, ultrasound, computerized tomography, and magnetic resonance imaging (MRI) may be performed to assess for severity of local traumatic injury, or to assess for distant metastasis.[11] Diagnosis of oropharyngeal dysphagias is more difficult and may require use of videofluoroscopy[6,7] and/or electrophysiology.[2] If these techniques are not readily available in the private practice setting, cases should be referred to a specialty center.

Clinical Examination

Diagnosis of oropharyngeal dysphagia is usually made on the basis of clinical signs and by exclusion of other oropharyngeal pathology. Once an oropharyngeal dysphagia is suspected, it should be further classified into an oral, pharyngeal, or cricopharyngeal stage disorders.

Diagnosis

Videofluoroscopy is the diagnostic test of choice because it is impossible to further classify these disorders on the basis of physical examination or survey radiography. Videofluoroscopy findings of *oral* stage dysphagias are typified by weak tongue-thrust action, retention of contrast medium in the oropharynx, and loss of contrast medium from the mouth.[6,7] Aspiration pneumonia is not a typical finding in oral stage dysphagias. Videofluoroscopic findings consistent with a *pharyngeal* stage dysphagia include (a) incomplete pharyngeal contraction with adequate cricopharyngeal relaxation, (b) slow induction and slow progression of peristaltic-like contractions from the rostral to the caudal pharynx, and (c) laryngotracheal aspiration. Aspiration pneumonia is a typical finding in pharyngeal stage dysphagias. In *cricopharyngeal* stage dysphagia, the cricopharyngeus fails to relax (achalasia) or relaxes at an inappropriate time (incoordination) following pharyngeal contraction.

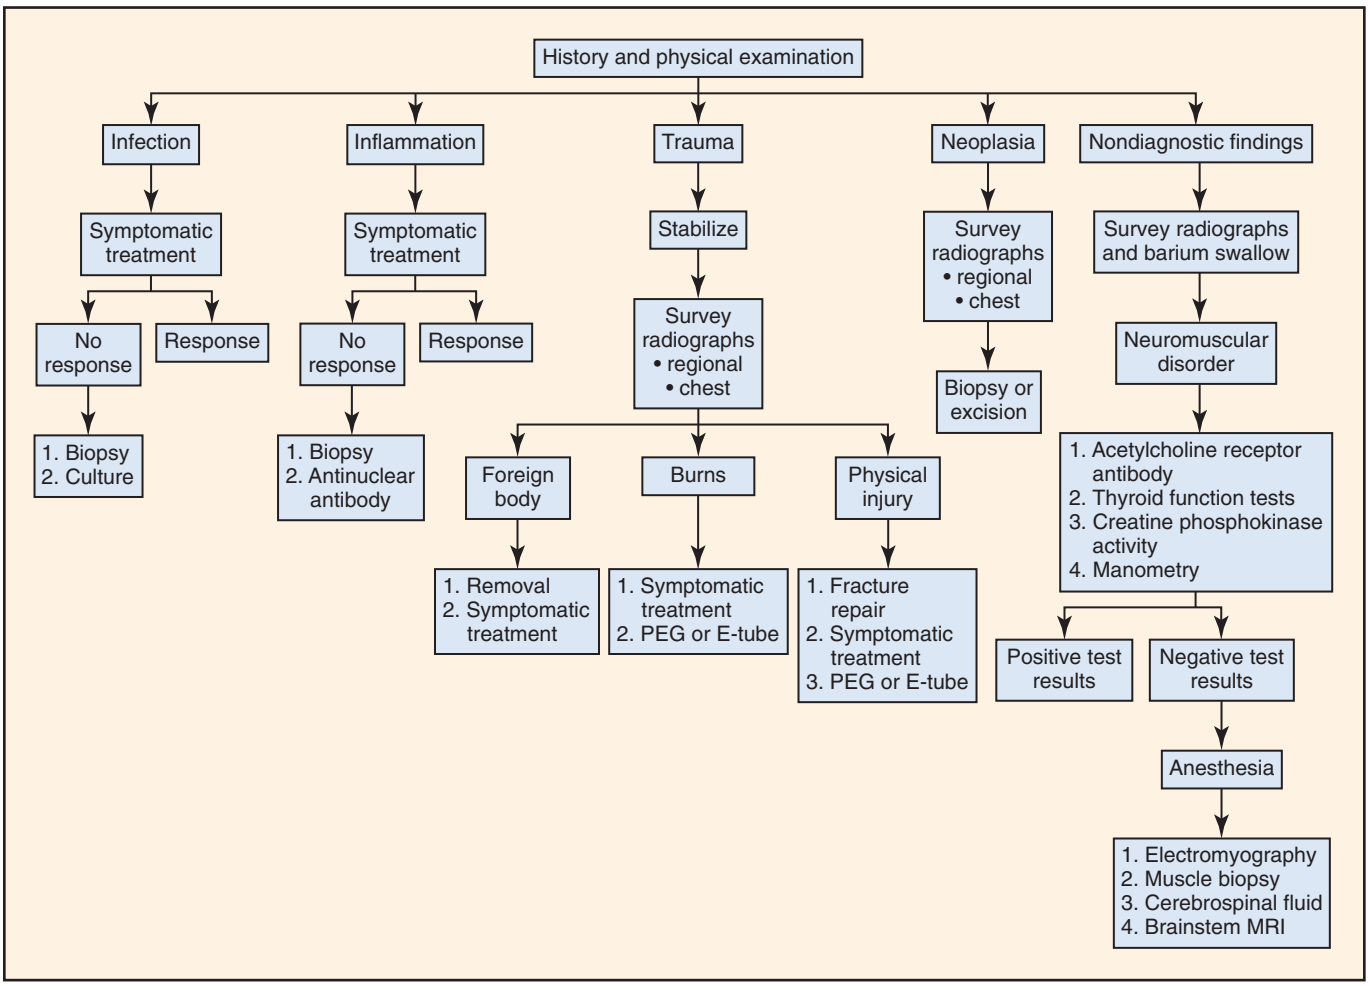

Figure 13-2 General diagnostic and therapeutic approach to dysphagia and gagging.

Electromyography may be useful in distinguishing oropharyngeal dysphagia from cricopharyngeal achalasia. Fibrillation and positive sharp waves observed in oropharyngeal musculature suggest that the disorder involves the structures of the oral cavity and pharynx instead of the cricopharyngeus.

Other diagnostic tests that may be warranted after an oropharyngeal dysphagia has been diagnosed are serology for nicotinic acetylcholine receptor antibody, antinuclear antibody, thyroid function test (e.g., thyroid-stimulating hormone [TSH] assay, TSH stimulation, serum thyroid hormones), serum creatine phosphokinase activity, muscle biopsy, and brainstem magnetic resonance imaging (see Fig. 13-2). Other oropharyngeal and esophageal pathologies are the major differential diagnoses for the oropharyngeal dysphagias.

Treatment and Management

General Principles

Except for cricopharyngeal achalasia, which is treated surgically by cricopharyngeal myotomy, oropharyngeal dysphagias are all treated medically. Cricopharyngeal myotomy appears to be of no benefit in oral and pharyngeal stage dysphagias; indeed, oropharyngeal dysphagias may be worsened by cricopharyngeal myotomy.

Medical

Medical therapy for oropharyngeal dysphagias is mostly supportive and consists of nutritional support (e.g., gastrostomy tube feeding) on a temporary or permanent basis. Elevated feedings and different food consistencies may be attempted, but these efforts are often of little clinical benefit. In early cases of myasthenia gravis, acetylcholinesterase inhibitors (e.g., pyridostigmine 0.5 to 3.0 mg/kg PO, BID-TID) may yield substantial clinical improvement.[12,13] Glucocorticoid therapy (prednisone 1.0 to 2.0 mg/kg PO, BID) will also improve clinical signs in many myasthenic and polymyositis patients, although many cases of canine myasthenia gravis appear to resolve spontaneously without immunosuppressive therapy.[14] Thyroid hormone replacement therapy (levothyroxine 22 µg/kg PO, BID) should be attempted in animals with documented hypothyroidism (see Fig. 13-2; Box 13-1).

Surgical

It is difficult to generalize based on the small number of cases that have been reported, but cricopharyngeal disorders are probably best treated with cricopharyngeal myotomy.[15] Most animals experience immediate relief following surgery.[16] Effective medical management has not been described for this disorder.

Box 13-1 Therapeutics for Oropharyngeal Disease

Broad Spectrum Antibiotics
- Aminoglycosides (gentamicin, amikacin), ampicillin, cephalosporins (cefoxitin, cephalexin, cephalothin), clindamycin, enrofloxacin, metronidazole

Chemical Diffusion Barriers
- Sucralfate 0.5 to 1.0 PO TID—should be given as oral suspension; much less effective when given as intact tablet

Gastric Acid Secretory Inhibitors
- Cimetidine 5 to 10 mg/kg PO or IV TID-QID
- Ranitidine 1 to 2 mg/kg PO or IV BID-TID
- Famotidine 0.1 to 0.5 mg/kg PO or IV BID
- Nizatidine 2.5 to 5 mg/kg PO QD
- Omeprazole 1-2 mg/kg PO q24h
- Pantoprazole 1 mg/kg IV
- Esomeprazole 1 mg/kg IV

Smooth Muscle Prokinetic Agents
- Metoclopramide 0.2 to 0.4 mg/kg PO, TID-QID
- Erythromycin 0.5 to 1.0 mg/kg PO, IV, BID-TID
- Bethanechol 5 to 15 mg/dog PO TID, 1.25 to 5 mg/cat PO TID

Glucocorticoids
- Prednisone 0.5 to 1.0 mg/kg SC or IM BID for esophageal strictures
- Prednisone 1.0 to 2.0 mg/kg PO BID for systemic lupus erythematosus and bullous pemphigoid

Thyroid Replacement Therapy
- Levothyroxine 22 µg/kg PO BID

Acetylcholinesterase Inhibitors
- Pyridostigmine 0.5 to 3.0 mg/kg PO BID-TID

CHAPTER 14

Fecal Incontinence

Nick Cave

Definition

Fecal incontinence is defined as the inability to retain feces in the colon and rectum leading to uncontrolled leakage of fecal material at times other than during conscious defecation. The recorded prevalence of fecal incontinence is 43 of 260,000 admissions to the University of Missouri and University of California Veterinary Medical Teaching Hospitals.[1] This is probably an underestimation of the true incidence of the disease. There is no sex predilection, but the majority of affected animals are 11 years of age or older. Although fecal incontinence in itself is not a significant cause of morbidity in cats and dogs, it can be a clinical sign associated with serious disease. It can be disastrous for a household pet irrespective of the underlying cause because it commonly leads to euthanasia.

Pathophysiology and Mechanisms

Similar to micturition, production and elimination of feces has a storage phase, a phase of awareness of the need to defecate, and the act of defecation. During each phase, there is coordination of four main anatomic structures: descending colon, rectum, internal anal sphincter (IAS), and external anal sphincter (EAS).

Storage Phase

During formation and storage of feces, distal colonic longitudinal contractions are inhibited by sympathetic activity. The main sympathetic supply to the distal colon and anorectum originates at L2-L5, synapses in mesenteric ganglia, and exits within the hypogastric nerve. Sympathetic stimuli via hypogastric and lumbar colonic nerves inhibit defecation in part by inhibiting colonic contractions. The site of inhibition appears to be in the caudal mesenteric and pelvic plexuses through synapses on parasympathetic motor neurons within vagal and pelvic nerves, respectively. The pelvic plexus lies lateral to the middle portion of the rectum.[2]

Fibers from lumbar colonic and hypogastric nerves also innervate the IAS leading to contraction.[3] Thus the internal anal sphincter is important in maintaining the resting pressure of the anal canal.[4,5] The region of increased tone extends from approximately the pelvic brim to the anus. Coordination of colonic contraction and sphincter relaxation occurs in the enteric nervous system, notably the pelvic plexus. Injury to the autonomic nerve fibers in the pelvic plexus may lead to fecal incontinence after resection of part of the distal colon or rectum. However, resection of the IAS does not necessarily completely interfere with fecal continence.[4]

Contraction of EAS under somatic control of the pudendal nerve (caudal rectal branch) can further raise pressure in the anal canal. In dogs it is likely that EAS and levator ani play an important role in maintenance of continence.

Awareness of the Need to Defecate

As feces form in the descending colon, occasional peristaltic waves push material distally into the rectum. In dogs, feces arriving from the colon are halted at the rectocolonic junction by sphincteric pressure, thus stool stops short of the rectocolonic junction instead of passing directly to the rectum.[6] Rectal tone is maintained mostly through sympathetic innervation.[7] Expansion of the rectal walls stimulates stretch receptors that send afferent signals through the pelvic nerve to ascending spinal cord tracts that ultimately lead to the frontal cortex. This leads to the awareness of the urge to defecate. Afferent fibers in the pudendal nerve convey the sensation to reinforce urge when fecal material extends to the level of the anus. A reflex arc is present whereby even slight distention of the rectum of humans or dogs results in relaxation of the IAS. This is the *rectosphincteric inhibition reflex*.[8] This arc is suppressed by upper motor neurons (UMNs) until the conscious decision is made to initiate defecation. Thus a disturbance of descending UMNs decreases inhibition. Contraction of the IAS is unlikely to be important in maintaining continence when pressure in the rectum becomes high, but may help guard against incontinence of small amounts of liquid stool. Additionally, reflex relaxation of the IAS in response to rectal distention allows for conscious "sampling" of the rectal contents and helps distinguish flatus from feces.

If the urge is not acted upon, material in the rectum is often returned to the colon where more water is absorbed. This is an act of conscious suppression that is reliant upon intact neural pathways from rectum to frontal cortex.

Defecation Phase

At the appropriate time, the impulse for defecation originates in the cerebral cortex and descends via motor tracts through the brainstem to the lower motor neurons of sacral, pelvic, and pudendal nerves leading to relaxation of the IAS. During normal defecation, there is relaxation of the rectum prior to colonic contraction, then migrating contractions of the colon pass aborally to the rectum. The IAS muscles continue to relax while large amplitude contractions of the colon migrate to the rectum.[4,9]

Migrating colonic contractions under control of the pelvic and sacral nerves advance fecal material into the rectum. The rectum

shortens as material is forced into the anal canal and peristaltic waves propel feces out of the rectum. Relaxation of the IAS is achieved by inhibitory reflexes carried predominantly by pelvic and sacral nerves to the mesenteric plexuses.[10] This inhibitory reflex is absent in animals with a congenital absence of distal colonic ganglionic neurons (Hirschsprung disease) causing failure to relax and functional colonic obstruction.[11] Vagal nerve function may compensate for denervation of the pelvic nerve leading to recovery of defecation reflexes after several weeks [12] Finally, somatic inhibition of skeletal muscle of the EAS via the pudendal nerve permits defecation into the animal's environment.

Overall coordination of defecation involves parasympathetic nervous system (via the vagus and pelvic nerves), sympathetic nervous system (via the hypogastric nerve), and somatic nervous system (via the pudendal nerve). Fecal incontinence can occur because of failure of storage (reservoir incontinence), failure of UMN control (UMN incontinence), or failure of IAS and EAS contraction (sphincter incontinence). Box 14-1 and Figure 14-1 outline causes of fecal incontinence.

Box 14-1 Causes of Fecal Incontinence

- Anorectal disease
  - Lacerations
  - Neoplasia
  - Perianal fistula
  - Surgical trauma
  - Anal sac removal
  - Perineal hernia repair
  - Perianal fistula excision
- Colorectal disease
  - Inflammatory disease–proctitis, colitis
  - Neoplasia
  - Constipation
  - Diarrhea
- Myopathies and neuromuscular junctionopathies
  - Trauma
  - Myopathy
  - Myasthenia gravis
- Peripheral neuropathies
  - Trauma
  - Drug-induced (e.g., vincristine)
  - Polyneuropathy
  - Dysautonomia
  - Chronic tenesmus
  - Diabetes mellitus
- Spinal cord disease
  - Congenital vertebral malformations (e.g., Manx syndrome)
  - Trauma
  - Neoplasia
  - Vascular compromise
- Intervertebral disk herniation
- Arachnoid cyst
- Instability
- Lumbosacral stenosis
  - Hemorrhage
  - Diskospondylitis
  - Infectious myelitis (e.g., *Neospora caninum*, distemper)
  - Degenerative myelopathy
- Prostatic disease
- Adverse behavior
- Cognitive dysfunction

Reservoir Incontinence

A reservoir mechanism is essential for continence, because the maximum period of sustained voluntary contraction of striated anal sphincter muscles is brief. Reservoir incontinence results from a failure of the large bowel to accommodate to the colorectal content. Animals with reservoir incontinence are usually aware of feces in the rectum and are able to sense imminent defecation. Reservoir incontinence is most often characterized by frequent, conscious defecation, but not by inadvertent anal dribbling. Adequacy of large bowel reservoir function is affected by colorectal irritability, capacity, compliance, and motility, and volume of feces. Causes of reservoir incontinence include acute or chronic proctitis, rectoanal neoplasia, and diffuse colitis.

Sphincter Incontinence

Failure of tonic anorectal and anal sphincter tone can occur due to trauma to the pudendal nerve, as part of cauda equina syndrome, or as part of more generalized degenerative or inflammatory neuropathies such as degenerative myelopathy of German Shepherds. Neurogenic sphincter incontinence is most commonly associated with lower motor neuron dysfunction, as seen with lumbosacral disease. Animals with lumbosacral disease often have decreased anal tone, decreased anal and rectal sensation, and loss of the rectosphincteric reflex. In a study of 69 surgically treated cases of degenerative lumbosacral stenosis in dogs, four (6%) had fecal incontinence prior to surgery, and of those only one improved without surgical correction.[13] Following dorsal decompressive laminectomy, a further four developed fecal incontinence. Although rare in cats, lumbosacral disease is occasionally seen and has been associated with fecal incontinence.[14] Perianal surgical procedures can result in damage to the EAS or its innervations leading to incontinence.[15-17]

Aging has a gradual and progressive effect on anal function. Effects of aging in human colon and anal sphincter include thinning of the external anal sphincter, weakening of muscular contraction, and increased latency of pudendal nerve firing.[18] This may be relevant to geriatric dogs and cats.

Upper Motor Neuron Incontinence

Loss of fecal continence secondary to spinal cord disease is usually associated with a severe compressive lesion. Some dogs may present with only mild proprioceptive deficits and normal spinal reflexes.[15,19] Lesions of the UMNs associated with fecal incontinence have been located in thoracic, cervical, and rarely central portions of the central nervous system (CNS). Lesions can be diffuse, but are most commonly a result of focal disease of which arachnoid cysts are the most frequently reported.[15,20] In many cases, fecal incontinence is reported to develop prior to development of gait defects in the pelvic limbs. Most described lesions were located in the dorsal or dorsolateral aspects of the spinal cord where ascending sensory tracts are located, thus disrupting ascending signals from rectal stretch receptors leading to defecation as soon as fecal material is advanced into the rectum.

Differential Diagnosis

Fecal incontinence can occur with both neurologic and nonneurologic disorders (see Box 14-1). It is important to differentiate true incontinence from behavioral problems. House soiling is a common cause for presentation and is more common than true fecal incontinence.[21,22] In a study of behavioral problems in old dogs, 10 dogs were presented with house soiling as the primary complaint, but only one was truly because of incontinence.[22] Once

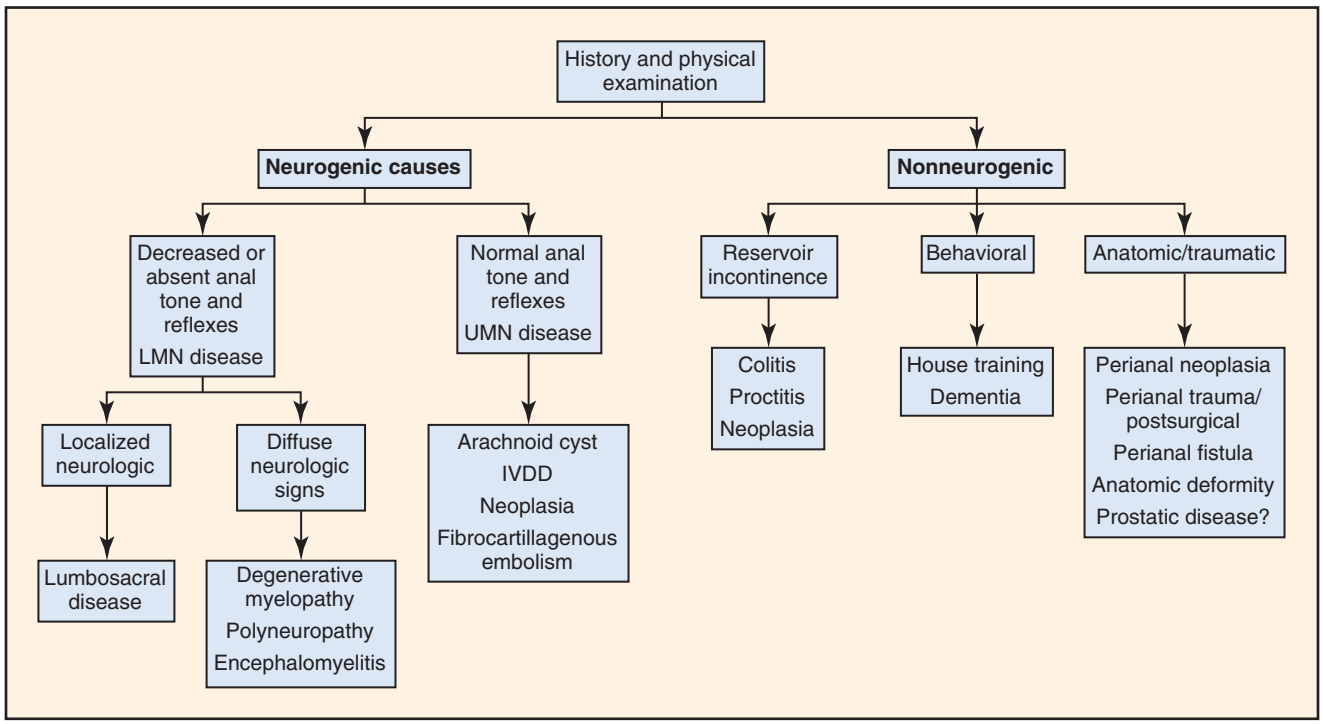

Figure 14-1 Algorithm for the investigation of fecal incontinence.

it is established that incontinence is present, nonneurologic and neurogenic causes should be differentiated. Common examples of conditions associated with neurogenic sphincter incontinence include diseases involving cauda equina (e.g., intervertebral disk disease, neoplasia, congenital malformations such as Manx deformity in cats).[13,15,19,20,23,24] Lesions of the UMN are commonly caused by arachnoid cyst formation. Sporadic cases have been described from more diffuse neurologic disease, such as dysautonomia, and diffuse inflammatory disease, such as meningoencephalitis of unknown origin, distemper encephalitis, and disseminated malignant histiocytosis.[25,26]

Conditions associated with nonneurogenic sphincter incontinence include perianal fistula, perianal neoplasia, prostatic disease, traumatic injury to the sphincter, and iatrogenic damage during perianal surgery such as anal sac removal or surgery for anal furunculosis.[16,27] Transient sphincter failure has been reported following traumatic lavage of the anal sac.

Evaluation of the Patient

History

Onset can be sudden leading to acute presentation, or gradual over weeks to months with slow progression of abnormal defecation prior to presentation. In some cases, animals have had abnormal patterns of defecation for years prior to evaluation.[15] Questions specific to the presenting problem should attempt to elucidate the following:

- The act of defecation—The owner's description of the animal's act of defecation should be carefully scrutinized. Does the animal consciously defecate (i.e., adopt a posture appropriate to defecation) and, if it does posture to defecate, whether the time and place it has chosen is appropriate? Failure to make any attempt at conscious defecation suggests a severe anorectal sensory derangement. These animals usually have a history of unconscious anal dribbling often occurring at times of increased abdominal or rectal pressures such as during coughing or physical exertion. Alternatively, is the defecation associated with tenesmus, urgency, or even dyschezia? In a house-trained animal, conscious defecation at inappropriate times or places, without the associated distress and urgency of reservoir incontinence, is more suggestive of a behavioral problem or a confused state. In a young animal, inappropriate defecation may be simply caused by a failure of house training. Dogs with UMN lesions associated with fecal incontinence may retain the ability to defecate normally at appropriate times, yet remain unaware of inappropriate defecation at other times, such as while walking, sitting, or sleeping.[19]
- Frequency of incontinence—This might range from very occasional episodes associated with colitis or adverse behavior to almost continuous and associated with functional failure of the anal sphincters.
- Fecal quality—Ascertain for diarrhea, constipation, hematochezia, and fecal mucus.

More general questioning should elucidate:

- Micturition—Is there any abnormality such as urinary incontinence or dysuria? If fecal incontinence is caused by neurologic disease, there may be simultaneous urinary incontinence.
- Gait and neurologic abnormalities—Is there a history of lameness, which might be associated with difficulty walking outside or posturing? Is there any other evidence of neurologic disease such as peripheral neuropathies, spinal ataxia, or brain disease such as senile cognitive dysfunction?
- Previous history of pelvic trauma or difficulty whelping.
- Drug or toxin exposure that might cause peripheral neuropathy.
- Environmental changes that could exacerbate adverse behavior or cognitive dysfunction.

Physical Examination

Thorough physical examination is indicated in all animals presenting with fecal incontinence. Particular attention should be paid to visual inspection of the anal area looking for dermatologic disease (e.g., fistula formation), resting anal tone, and tail carriage. Anal reflexes are usually assessed at this time (see "Neurologic Examination" below). This must be followed by careful digital examination of the anorectum to palpate for the presence, quality, and appearance of feces; the density or texture of the rectal mucosa; the presence of anorectal masses; and extraintestinal structures such as the prostate and urethra.[27] At this time anal tone is assessed, although qualitative assessments of anal tone are poorly correlated with more objective measures of anal sphincter function. This is partly because a denervated external anal sphincter does not readily atrophy, and partly because UMN lesions will often result in normal anal tone.[15] Abdominal palpation assesses colorectal content, bladder tone, and ease of bladder expression. The skin of the hind limbs should be carefully examined for areas of self-trauma, which may be suggestive of paresthesias, and the dorsal lumbosacral skin and musculature should be palpated for evidence of hyperesthesias. Hind-limb paresthesia and hyperesthesia are both suggestive of cauda equina syndrome.

Testing for the presence of lumbosacral (LS) pain should be performed by tail elevation and manipulation to produce lordosis and extension of the hip. Pain consistent with lumbosacral or lumbar spinal disease will occur in the absence of pain on abduction or rotation of the hip joints.[28] Coexistence of degenerative coxofemoral and lumbosacral diseases increase the difficulty in making a clinical diagnosis of LS disease.

Neurologic Examination

All animals with fecal incontinence should be subjected to neurologic examination. In neurogenic causes of incontinence, it is important to determine if incontinence is caused by an UMN or lower motor neuron (LMN) lesion. Neurologic examination demands observation of gait, cranial nerves, postural reactions, myotactic reflexes, and reflexes specific to defecation. Anal reflex is evaluated by pricking or pinching the perianal skin and looking for contraction of the anal sphincter. Rectal-inflation reflex is induced by inflating with 15 to 30 mL of air a Foley catheter that has been placed in the caudal extremity of the rectum. This induces anal contraction in both dogs and humans. Pudendal–anal reflex is evaluated by applying digital pressure to the penis while observing for anal contraction. All three reflexes assess sacral spinal segments, motor neurons in the pudendal nerves, and the external anal sphincter. Anal and pudendal-anal reflexes test perineal nerve afferents, whereas it is likely that the "rectal–inflation reflex" tests pelvic or S3 and C1 nerve afferents. These reflexes are usually preserved in animals with suprasacral spinal transverse myelopathies, whereas conscious perception of perineal and anorectal sensation (induced by the inflated Foley catheter) is not. Thus the history of fecal incontinence with normal perineal and anal reflexes is consistent with an UMN lesion cranial to the L3 spinal cord segments.[15] Lumbosacral disease may be associated with depressed cranial tibial, ischiatic, and withdrawal reflexes, and normal to exaggerated patellar reflexes.[28]

Laboratory Evaluation and Tests

Proctoscopy with biopsy is indicated if reservoir incontinence is suspected. Radiography may reveal diseases of the vertebral column responsible for incontinence. Myelography, epidurography, discography, and computed tomography (CT) scanning are of value in the diagnosis of deforming lesions affecting the spinal cord, including cauda equina. Electrodiagnostic evaluation of the incontinent animal greatly facilitates diagnosis. Electromyographic examination of muscles of continence may reveal denervation or myopathy. Clinical assessment of the pudendal–anal reflex can be made more objective by electrophysiologic evaluation of the reflex. The cerebrospinal fluid (CSF) examination may include a CSF distemper titer to assist diagnosis of canine distemper.

Treatment and Management

General Principles

Therapy of fecal incontinence is more likely to be successful following identification and treatment of the underlying cause. For instance, resolution of incontinence may follow successful treatment of diarrhea. Alternatively, behavior modification will be required to eliminate behavioral house soiling.[21] Successful surgical decompression of spinal lesions such as intervertebral disk herniations, and arachnoid cysts can restore fecal continence, even when the incontinence has been present for months.[13,15] Restoration of IAS tone after denervation may be a result of intrinsic myogenic properties of the sphincter.[3] However, complete recover of function is uncommon, and prognosis for LMN incontinence is generally guarded to poor.

Some patients may be managed by a dedicated pet owner with the use of daily warm water enemas. Alternatively, defecation may be induced by inflation of a rectal Foley catheter. This technique will not produce conscious defecation in animals with anorectal anesthesia but may produce involuntary rectal evacuation.[29] In animals with chronic posterior paralysis as a result of spinal cord damage, a minor stimulus to the hind limbs or perineum (e.g., light toe pinch or warm wash cloth) may stimulate appropriate elimination. Despite loss of rectal or anal function, unconscious passage of feces may still be precipitated by stimuli of colonic contractility. Exercise and eating are both prominent stimulants of colonic activity. Finally, application of diapers (nappies) may, if tolerated, enable persistence of an incontinent animal in the household.

Medical

The use of low-residue diets such as cottage cheese and rice reduces fecal volume by up to 85% if preceded by a poorly digestible diet. They also reduce frequency of defecation. Commercial premium diets often have a high digestibility, and several diets formulated for "intestinal disease" are reasonable empirical choices. Dietary fiber can increase fecal water content, increase fecal bulk, and thereby exacerbate fecal incontinence. However, nonfermentable fiber can also increase fecal firmness and increase segmental colonic contractions. In humans it may improve incontinence, especially when fecal quality is poor.[30] Addition of a mixed fermentable fiber such as psyllium (Metamucil) can be used on a trial basis. Dose is empirical and should be based on fiber content of the existing diet, but could range from 2% to 8% on a dry matter basis (1 rounded teaspoon of Metamucil contains 5 g of fiber). A reasonable approach is to initially introduce a highly digestible commercial dry diet that contains a source of fermentable fiber of between 2% and 8% on a dry-matter basis. If the animal is already consuming such a diet, or if there is little response, then the judicious addition of supplementary fiber can be attempted. This should be performed on a trial basis, as simple increase of fecal bulk that occurs with dietary fiber may be counterproductive.

Drug treatment is frequently instigated in hope of slowing colonic transit. Opioids such as loperamide increase segmental contractions and inhibit longitudinal colonic contractions and may be useful in the management of fecal incontinence when fecal water content is high. However, even in humans efficacy of loperamide

for managing fecal incontinence is inconclusive, and its efficacy has not been proved in dogs or cats.[31] Loperamide may be given for prolonged periods with little development of tolerance to their effects. A suggested dosage for loperamide is 0.1 to 0.2 mg/kg PO, given every 8 hours initially and to effect thereafter. Another pharmacologic approach is to attempt to increase anal tone. Phenylephrine gel (30%) causes contraction of the IAS, but has not been shown to be effective in humans.[32] Perhaps more promising are the recent studies in humans reporting the efficacy of injections into the anal submucosa of a gel of stabilized nonanimal hyaluronic acid with dextranomer gel (Zuidex), normally used for increasing urethral tone in urinary incontinence.[33] Although only half of patients appear to respond (defined as a 50% reduction in frequency of defecation), those that do respond experience 12 months of improvement after a single treatment of four 1-mL submucosal injections.

Surgical

Surgical techniques have been developed to improve or restore fecal continence in dogs. Such techniques are reserved for when identification and management of an underlying cause is either not possible or has not restored continence, and when medical therapy has failed. Sling techniques designed to increase pressure on the terminal rectum to reduce leakage have been published, including the use of a silicone elastomer sling.[34] A return to continence was reported in five of six dogs in one study, and only mild fibrosis was associated with the implant. In other techniques, reconstruction of a muscular sphincter using regional skeletal muscle flaps have shown promise in dogs rendered experimentally incontinent.[35,36] However, such techniques rely on either exogenous electrical stimulation or persistence of normal pudendal nerve function. Artificial sphincters using inflatable cuffs have also been used experimentally but there are no published reports of their clinical use.[37]

Conclusion

Fecal incontinence in dogs and cats can be devastating because of difficulties in management, and euthanasia is a high risk. Initial history should allow differentiation among patients with prostatic, neurologic, and neuromuscular disease. Any patient presenting with fecal incontinence should have a thorough neurologic assessment to determine if the cause is a result of LMN or UMN disease. If the neurologic assessment shows normal anal tone, reflex, and sensation, an UMN lesion may be present in which case a spinal magnetic resonance imaging is required to determine specific lesion location. If the lesion is focal in nature, it may be amenable to surgery. Surgical intervention may reverse signs of UMN fecal incontinence even when clinical signs have been present for many months to years. Thus diagnosis of UMN fecal incontinence has a better prognostic outlook with surgical intervention than does LMN fecal incontinence. Long-term management may need to be multifaceted and include dietary manipulation, behavioral management, and, potentially, drugs. Injection of stabilized nonanimal hyaluronic acid with dextranomer gel into rectal submucosa warrants investigation.

CHAPTER 15

Gastrointestinal Gas: Eructation, Borborygmus, and Flatulence

Nick Cave

Definition

Eructation is defined as the expulsion of gastrointestinal gas from the oral cavity; whereas *flatulence* is defined as the expulsion of gas from the anorectal canal. *Borborygmus* is the term used to describe the rumbling noise of gas as it is propagated through the gastrointestinal tract. All three can be normal manifestations of gastrointestinal tract function, but may be presented as problems because of frequency, intensity, or odor. Flatulence is common in pet dogs, for example, and nearly 40% of pet owners would alter the diet if that strategy prevented flatulence.[1]

Pathophysiology and Mechanisms

Gastrointestinal gas is derived from four sources: (a) aerophagia, (b) luminal chemical reactions, (c) bacterial fermentation, and (d) diffusion from circulation into the lumen. The majority of intestinal gas is composed of nitrogen, oxygen, hydrogen, methane, and carbon dioxide, all of which are odorless. Most intestinal nitrogen and oxygen is derived from ingested air. The predominant gases in flatus are CO_2, H_2, and N_2, with lesser quantities of CH_4 and H_2S.[2] Odiferous compounds identified in canine flatus include carboxylic acids, phenols, ammonia, hydrogen sulfide, indole, skatole, mercaptans, volatile amines, ketones, alcohols, and short-chain fatty acids, which together comprise less than 1% of intestinal gas.[3]

Aerophagia and Eructation

Some air is inevitably swallowed during normal feeding, although individual dogs and cats differ in volumes of swallowed air. Variables affecting the volume of air swallowed have not been defined but likely involve the size of the food bolus, rate of ingestion, physical characteristics of food, and head and neck posture during eating. In the stomach, gas bubbles coalesce and accumulate in the dorsal fundus and cardia, which activates stretch receptors in the wall of the gastric cardia.[4] Afferent vagal fibres arising from the cardia of the stomach induce transient relaxations of the gastroesophageal sphincter (GES).[5] These are relatively prolonged relaxations of the GES that have a pattern distinctly different from swallow-induced gastroesophageal sphincter relaxation. This reflex, induced by gastric gas, has been termed the *belch* or *eructation reflex*. As gas is refluxed through the relaxed GES postprandially, reflux of gastric contents and acid may occur simultaneously.[6]

Disease processes that disrupt stretch receptors, sensory vagal afferents, or vagal inhibition of the GES may impede sphincteric response to gastric gaseous distention. Development of gastric dilation–volvulus syndrome in dogs is believed to depend upon such defects. Indeed, gastric volvulus has been reported in dogs with a prior history of eructation, borborygmus, and flatuluence.[7] When chronic gastric bloating is a prominent sign, excessive aerophagia and defective eructation should be considered as underlying mechanisms. Aerophagia during eating may account for large amounts of intestinal gas, although dogs described as "greedy eaters" by their owners are not reported to have an increased incidence of flatulence.[1]

Aerophagia and gastric gaseous distention can also occur secondary to respiratory tract disease. Dyspnea resulting from brachycephalic airway disease can culminate in excessive aerophagia and gastric distention.[8]

Intestinal Gas Transit and Borborygmus

Gas that is present in the small and large intestine can originate from aerophagia or be endogenously formed. Intestinal CO_2 is mostly formed from the reaction between bicarbonate (HCO_3^-) and gastric acid producing water and CO_2 in the upper small intestine. For each mole of H^+ neutralized by pancreatic HCO_3^-, 1 mole of CO_2 is produced. In the 3 hours following a meal a dog may produce 6 mEq H^+, which will result in production of 134 mL CO_2.[9] Most of the CO_2 diffuses into circulation but some remains within the luminal contents. The remaining gases are produced from microbial fermentation, predominantly in the distal small intestine and colon.

Gas is moved along the intestine independently of solids and liquids, and gas transit is more effective in the erect than supine position illustrating active propulsion of gas.[10] Rate of gas passage is influenced by dietary fat, but not by dietary moisture content.[11] Intestinal gas can be rapidly propelled aborally in normal dogs such that infusion of air at 2 mL/min does not produce obvious abdominal discomfort.[12] In humans, up to 30 mL/min can be infused jejunally without discomfort.[11] Gas is actively propelled by a sustained contraction proximal to the gas but it is still not known if intestinal

gas induces classical peristaltic waves responsible for movement of liquid and solid ingesta.[13] Consumption of solid food, but not water, increases volume and rate of transit of gas through the gastrointestinal tract.[11] Duodenal lipid has the most profound inhibitory effect on gas transit times; fiber slows intestinal gas transit, as well as increases volume of gas produced from fermentation.[14]

Physical exercise is known to reduce the retention of gastrointestinal gas.[15] Although not directly studied in dogs, flatulence is reported less frequently by owners of dogs that exercise frequently than by owners of sedentary dogs.[1]

Borborygmus can result from excessive intestinal gas or altered gastrointestinal motility. Patients with irritable bowel syndrome develop intestinal gas retention and pain in response to gas loads that are otherwise well tolerated by normal individuals.[16] In those patients, proximal intestinal gas rather than large intestinal gas is responsible for clinical symptoms.[16]

Flatulence

Ingested atmospheric gases form the largest component of flatulence, but odiferous compounds resulting from microbial fermentation of luminal content are the most notable to pet owners. Flatulence that occurs within 2 hours of feeding is more likely related to rapid transport of aerophagic gases following feeding.[3,17] Fermentative by-products accumulate at other times and are not necessarily related to feeding. Malodor is strongly correlated with presence of hydrogen sulphide, although production of hydrogen sulphide is highly variable amongst animals fed the same diet.[3] Sulphur gases are produced by sulphate-reducing bacteria such as the genera *Desulfotomaculum*, *Desulfobacter*, *Desulfomonas*, and *Desulfobulbus*, and differences in sulphur gas production between animals likely represents differences in these microflora.[18] Sources of sulphur for fermentation include endogenously derived amino acids in mucin, sulphate in cruciferous vegetables and nuts, and poorly digestible sulphated polysaccharides such as the gelling agent carrageenan.

In addition to inhibiting gas transit, fermentable fibers are a significant substrate for luminal production of intestinal gases. In normal humans fiber intake increases the number of daily flatus emissions.[11,19] Thus normal humans high-fiber diets increase gas production by colonic flora and inhibit gas transit leading to gas retention, notable borborygmus, abdominal pain, and flatulence.[11] Ingestion of a "fiber-free" diet for 48 hours significantly reduces the total volume of flatus. Highly purified, highly fermentable fibers will increase flatus volumes more so than nonfermentable fiber, as well as altering the composition of flatus. For example, xylan and pectin diets induce much higher volumes of flatus, including hydrogen, carbon dioxide, and methane content than cellulose or corn bran diets.[20] Intestinal and/or microbial adaptation to changes in fiber content may take several days and flatus volumes may not stabilize until 2 to 5 days postfeeding.[20] Significant differences in intestinal microflora exist between individual dogs and cats, and some of that difference may even be related to breed.[21]

Methane production varies greatly between individuals, and is dependent upon diet, fiber content, and specific methanogenic bacteria.[22] Physiologic concentrations of methane slow ileal transit by augmenting ileal circular muscle contractions.[12] Consequently, inflammatory bowel disease (IBD) patients in whom methane is produced almost universally suffer from constipation and ileal discomfort.[12] Induction of nonpropulsive segmental contractions by methane may trigger dysmotility and discomfort in dogs and cats. Consequently, it is prudent to consider this side effect when supplementing fiber in the diet.

Box 15-1 Causes of Excessive Eructation, Borborygmus, and Flatulence

- Aerophagia with normal gastrointestinal motility
  - Behavioral (obsessive compulsive disorder)
  - Prandial aerophagia
  - Dyspnea
  - Postanesthetic complications
- Motility disorders
  - Megaesophagus
  - Irritable bowel syndrome
  - Foreign body
  - Neoplasia
  - Intussusception
  - Peritonitis
  - Adhesions
  - Postgastric dilation-volvulus syndrome
  - Electrolyte disturbances–K^+, Ca^{2+}
  - Autonomic neuropathy
  - Postoperative ileus
- Dietary causes
  - Indiscretion
  - Metabolic adverse reaction to food (e.g., lactose intolerance)
  - Food hypersensitivity
  - Excessive fermentation (e.g., excessive fermentable fiber, carrageenans, sulfates)
- Inflammatory intestinal disease
  - Idiopathic inflammatory bowel diseases
  - Intestinal parasitism
  - Postviral enteritis (e.g., parvoviral enteritis)
- Microbial
  - Antibiotic therapy
  - Small intestinal bacterial overgrowth?
- Metabolic disorders (Addison disease, uremia, diabetes mellitus, hypothyroidism)

Differential Diagnosis

Box 15-1 outlines known and suggested causes of excessive eructation, borborygmus, and flatulence in dogs and cats. Dietary indiscretion is likely the most important cause of acute onset of signs. In other clinical cases, gaseous signs may be harbingers of more serious intestinal disease. With concurrent abdominal pain and abdominal distention, intestinal dysmotility (e.g., irritable bowel syndrome) should be suspected.

Evaluation of the Patient

For animals presenting with signs of eructation, borborygmus, or flatulence, the initial evaluation of the patient is primarily concerned with distinguishing between patients with transient, self-limiting, or benign conditions and those more serious underlying conditions (Fig. 15-1).

History

It is important to determine the temporal association between eructation, borborygmus, or flatulence, and potential inciting events. Such events include eating, dietary change, dietary indiscretion, exercise, stress, repetitive behavior, and drug therapy. The nature of the flatulence can give some information as to the potential cause. Odorless flatus is more likely to be associated with aerophagia, whereas offensive odors are more likely to be a result of colonic

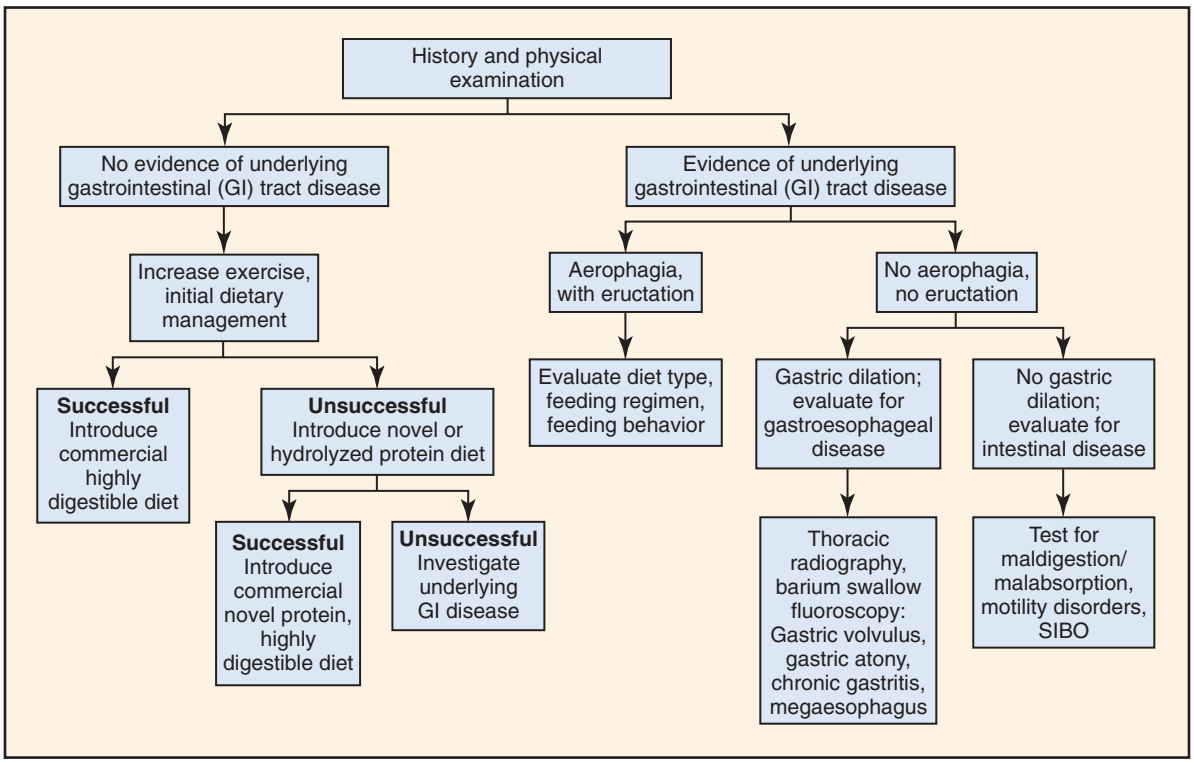

Figure 15-1 Algorithm for eructation, borborygmus, and flatulence.

bacterial fermentation following intestinal maldigestion or malabsorption.

An extensive dietary history is essential. In addition to dietary change, attention should be paid to the dietary composition as well. Diets with a high concentration of fermentable fiber or hydrolysis-resistant starch are more likely to be associated with excessive gas production. Moist, meat-based diets that contain little or no plant material may still contain considerable concentrations of gelling agents such as guar gum and carrageenan that can lead to gas production and malodorous flatulence. Dairy products can cause excess gas production in animals with lactase deficiency. Frequency of feeding and amount and timing of exercise may be important variables in some animals.

Other historical findings of importance include the presence of concurrent signs such as abdominal pain, abdominal distention, vomiting, regurgitation, hypersalivation, diarrhea, melena, and weight loss that might suggest more serious gastrointestinal disease. Abdominal pain may be manifested as a hunched posture with or without stiff gait, unsettled behavior, or the adoption of a praying position. Intermittent abdominal pain is common in dogs with irritable bowel syndrome, and may result from bowel distention by excessive intestinal gas, motility disorders which disrupt passage of gas through the bowel, or increased visceral sensitivity to bowel distention.

Prior medical history should be sought for gastric dilation–volvulus syndrome, and prior or current drug therapy, especially oral antibiotics. Extraintestinal causes of gastrointestinal gas accumulation include behavioral aerophagia, hypothyroidism, cough, and dyspnea.

Physical Examination

The presence of borborygmus, gastric tympany, intestinal gaseous distention, and the elicitation of flatulence during palpation are the most common physical examination findings in affected animals. Other physical examination findings are usually unremarkable unless concomitant gastrointestinal disease is present.

Laboratory Evaluation and Tests

Severe eructation in the absence of other localizing signs is usually consistent with excessive aerophagia or gastroesophageal dysmotility. Thoracic and abdominal radiographs may be required to evaluate the degree and distribution of gas accumulation, as well as the positioning of the gastrointestinal tract. Thoracic radiography is indicated to help rule out megaesophagus, gastric dilation-volvulus, hiatal hernia, and intestinal foreign bodies. Further evaluation of gastroesophageal dysmotility may require continuous imaging such as barium-swallow fluoroscopy (see Chapter 26). When supported by concurrent supportive clinical signs, thyroid function testing is indicated.

Borborygmus and flatulence warrant further investigation if there is suspicion for underlying gastrointestinal disease, or if the signs are nonresponsive to symptomatic management. Investigation into the presence and causes of maldigestion and malabsorption is strongly indicated when malodorous flatulence accompanies diarrhea or weight loss. Tests for maldigestion and malabsorption might include serum trypsinogen–like immunoreactivity, postprandial breath hydrogen measurement, serum B_{12} and folate, culture of duodenal fluid, fecal parasitic and microbial analysis, and intestinal biopsy (see Chapter 25).

Treatment and Management

General Principles

In the absence of a primary diagnosis, the symptomatic management of borborygmus and flatulence should begin with a change to a highly digestible, low-fat diet. As with any dietary variable, there is

no absolute value that constitutes "high" or "low," and they remain relative terms. Importantly, an attempt should be made to introduce a diet that has a *greater* digestibility and a *lower* fat content than the current or implicated diet. Empirical choices would be novel protein diets with less than 20% of calories as fat. Hydrolyzed protein diets have a high-protein digestibility, and most contain highly digestible carbohydrate sources as well. However fat content of some "intestinal diets" may be greater than ideal. Diets with fermentable fiber sources (gums, carrageenan, pectins, resistant starches, etc.) in greater concentrations than the current diet should be avoided. Crude fiber contents of less than 3% should suffice.

As an alternative approach, the owner can prepare a homemade diet comprised of highly digestible protein and carbohydrate sources appropriately balanced with vitamins and minerals. Suitable home-prepared diets for managing acute gastroenteritis or dietary indiscretion in dogs and cats include cottage cheese (1% milk fat) and boiled white rice, or chicken and rice. Cottage cheese and boiled white rice (1:1) provides 33% protein, 6% fat, and 61% carbohydrate as a percentage of calories. It contains 1 kcal/g as fed. Consequently, it is an ideal macronutrient profile, with an easy energy density to calculate in feedings. For short-term purposes, nutrient-balancing of the diet is unnecessary, and these diets can be safely fed to a well-nourished animal for at least 7 days without concern.

The possibility of food hypersensitivity reactions should be considered in any patient with chronic flatulence or borborygmus, and novel or hydrolyzed protein diets should be considered. A short-term trial of a highly digestible, low-fat diet should be considered prior to a trial with a novel protein diet. If the initial dietary change is unsuccessful, a home-prepared or commercial novel or hydrolyzed protein diet could be considered.

Flatulence is reported less frequently by owners of dogs that exercise frequently than by owners of more sedentary dogs.[1] It is not known, however, if the timing of exercise relative to meals is important, nor what amount of exercise is required. It would seem prudent to recommend an increase in daily exercise for dogs, and to encourage physical activity in cats for whom flatulence is problematic.

A study of flatulence in dogs revealed a decrease in frequency of flatus in dogs fed twice compared with once per day.[17] In another study, owners of dogs fed more than once per day did not report flatulence in their dogs more frequently than owners fed once daily.[1] Thus increasing the frequency of feeding may, in some dogs or cats, decrease flatulence, but at best the effect is mild.

Symptomatic therapy for eructation is focused on reducing aerophagia. Avoiding situations that provoke anxiety may be helpful. Feeding multiple small meals may reduce the gastric distention secondary to aerophagia.

In the rare event that dietary manipulation and regular exercise are not successful in eliminating signs, the patient should be evaluated for the presence of organic or functional gastrointestinal disease such as described for small intestinal diarrhea (see Chapter 11). Alternatively, symptomatic pharmacologic management can be tried.

Medical

When an underlying condition such as chronic gastritis or exocrine pancreatic insufficiency is present, medical therapy should be directed toward the underlying condition.

Simethicone is a nonabsorbable, surface-active, antifoaming agent that has been suggested for management of borborygmus, gaseous colic, and flatulence in human beings (25 to 200 mg per dose, q6h), although there is no consistent evidence to support its efficacy in humans and none in dogs or cats.[23]

A supplement incorporating 320 mg activated charcoal, 2.5 mg of an extract from the plant *Yucca schidigera*, and 17 mg of zinc (as zinc acetate dihydride) reduced the hydrogen sulphide content of flatus in dogs by 86%.[24] Of the three components, activated charcoal had the greatest single effect, which is consistent with some studies of its efficacy in humans at reducing odorous flatulence.[25]

In cases where objectionable flatulence is not responsive to dietary manipulation, empirical antibiotic therapy has been used with success in some cases.[26] Reasonable empirical choices are those predicted to be effective against colonic microflora such as metronidazole and tylosin. The nonabsorbable neomycin is another reasonable choice. It is the author's opinion that the empirical use of antibiotics for the sole problem of flatulence is difficult to justify.

Surgical

In large-breed dogs at risk for gastric dilation-volvulus syndrome, recurrent or chronic bloating warrants consideration of prophylactic gastropexy. In some dogs, borborygmus and eructation can indicate the presence of a chronic volvulus, for which gastropexy can resolve the majority of clinical signs.[1]

Surgical therapy for underlying causes of aerophagia may involve relief of chronic upper airway obstruction such as surgical correction of stenotic nares, everted laryngeal saccules, and elongated soft palate.

CHAPTER 16

Hemorrhage (Gastrointestinal)

Michael D. Willard

Definition

Gastrointestinal (GI) hemorrhage can be occult or it can be heralded by significant blood loss via the oral cavity or anorectum. *Hematemesis* refers to conditions associated with the vomiting of blood (Fig. 16-1). *Hematochezia* refers to frank red or reddish-brown blood pigments in the feces, while *melena* refers to black, tarry feces (Fig. 16-2). Melena requires significant blood loss in a relatively short period of time, and the blood must remain in the stomach and/or small intestine long enough to be at least partially digested before passage in the feces. Many patients have melena and hematemesis concurrently, but some patients may only have one of these signs. Other patients may be dying of severe GI hemorrhage, but may not have obvious melena.

Pathophysiology and Mechanisms

Blood may enter the gastrointestinal tract because of disruption in blood vessel or mucosal integrity (e.g., ulcers and erosions), coagulopathy, or ingestion of blood that sometimes occurs with hemoptysis or external sources (e.g., food).

Pathophysiology of hematochezia is relatively straightforward: either there is a bleeding mucosal lesion (i.e., polyp, tumor, inflammation, trauma, congestion, parasites) or there is coagulopathy. Bleeding associated with hematochezia typically occurs in the most distal segments of the GI tract (i.e., colonic), which is why blood appears as undigested pigment in feces. Dogs affected with severe intestinal hypermotility (e.g., parvoviral enteritis) occasionally will have hematochezia associated with upper GI tract bleeding because the blood does not reside in the small intestine long enough to undergo digestion. Mucosal congestion (e.g., ileocolic intussusception) is rarely sufficient to cause hematochezia.

Hematemesis and melena can have similar causes, all principally upper GI in location. Gastric ulceration or erosion is one of the more commonly sought causes of upper GI hemorrhage.[1] Gastric ulceration or erosion has many causes, including poor gastric mucosal blood flow, interference with normal prostaglandin metabolism, excessive gastric acidity, and direct damage to the mucosa (e.g., chemicals, foreign objects).[2]

Direct damage to gastric mucosa may be caused by drugs (e.g., aspirin and other nonsteroidal antiinflammatory drugs [NSAIDs]), various ingested toxic substances (chemicals, plants), tumors, and even mucosal trauma associated with repeated, vigorous vomiting. Cats are infrequently affected with gastric ulceration or erosion, but have the same possible causes as dogs.[3] *Helicobacter* spp. do not appear to be a major cause of gastric ulceration or erosion in dogs or cats as they do in humans, even though numerous organisms can be found in ulcerative tissue.[4] Despite long-standing beliefs, renal failure does not appear to be a common or important cause of gastric ulceration/erosion.[5]

Intestinal ulceration/erosion is much less common than gastric ulceration/erosion. Disruption of intestinal mucosa is primarily caused by infiltrative disease (e.g., neoplastic or inflammatory) or inability to neutralize gastric acidity (e.g., paraneoplastic effects of mast cell tumors and gastrinomas). It can also be associated with many of the NSAIDs (e.g., flunixin).[6] Hookworms can be surprisingly severe, even in older patients in endemic or unsanitary environments; monthly preventatives do not necessarily eliminate ancylostomiasis.

Differential Diagnosis

Anemia

Anemia can cause obvious clinical signs or may be discovered serendipitously during routine blood testing. Anemia has three major causes: hemolysis, hemorrhage, and bone marrow disease. Anemia occurring in conjunction with hypoalbuminemia is suggestive of blood loss, particularly from the GI tract. Anemia resulting from GI hemorrhage may be regenerative or nonregenerative, depending upon chronicity of the condition, but classically is more often associated with hypoalbuminemia (not necessarily hypoproteinemia or panhypoproteinemia). Chronic GI hemorrhage presents typically as a poorly regenerative, iron deficiency–type anemia (microcytic and hypochromic) with moderate to severe hypoalbuminemia.[7] However, GI blood loss must be substantial and of sufficient chronicity to produce these specific changes; most animals with GI hemorrhage do not have this type of anemia. Hemorrhage sufficient to cause anemia often occurs in the absence of hematemesis, hematochezia, and melena.

Hematemesis

The most common causes of gastric ulceration or erosion in dogs are drug-induced (e.g., NSAIDs, dexamethasone, and other glucocorticoids[8]), stress (e.g., hypovolemic shock, systemic inflammatory response syndrome, excessive physical exertion), cancer disruption of the gastric mucosa, adrenal insufficiency, and hepatic failure.[1,2,9]

Dual or multiple risk factors (e.g., NSAIDs plus dexamethasone or NSAIDs plus poor mucosal perfusion) increase the likelihood of

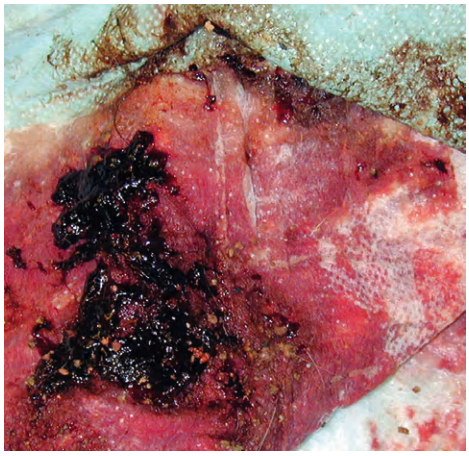

Figure 16-1 Hematemesis in a cat with perforating duodenal ulcer. Red, black, and brown pigments are all consistent with gastrointestinal hemorrhage.

Figure 16-2 Black, tarry feces (i.e., melena) from a thrombocytopenic dog. As the material is smeared across the paper, the obvious red color shows that it is actually blood.

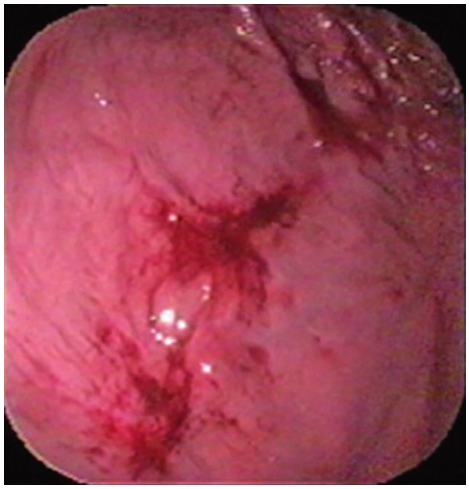

Figure 16-3 Endoscopic image of a dog's stomach. This dog had gastric bleeding as a result of erosions caused by submaximal stress (sled dog racing). The dog was asymptomatic and was racing without any signs of fatigue or illness.

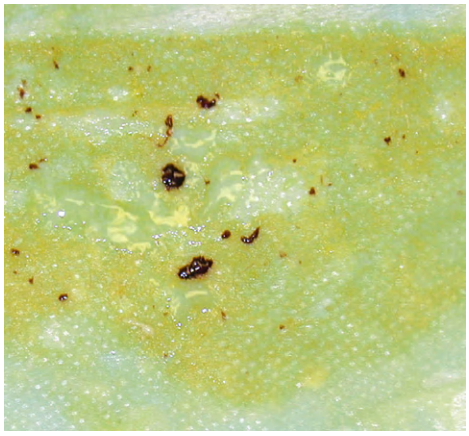

Figure 16-4 Vomitus from a dog with pancreatitis. Most of the material is bilious, but there are several spots of blood present. (Compare with Fig. 16-1.)

gastric ulceration or erosion.[1,10] Cyclooxygenase (COX)-2 selective inhibitors (e.g., carprofen, etodolac, deracoxib, meloxicam) have been developed to minimize the ulcerogenic effect of NSAIDs in the GI tract. Although these newer NSAIDs lessen the risk of gastric ulceration or erosion, they do not completely eliminate it. Many dogs have developed gastric ulceration or erosion following use of these putatively safer NSAIDs.[11,12] Some NSAIDs are especially well known for their ulcerogenic potential in dogs, including naproxen and flunixin meglumine.[6] It should be noted that gastric ulceration or erosion is not excluded by an absence of hematemesis or anemia. Dogs with substantial gastric bleeding because of stress-related gastric ulceration or erosion can appear clinically normal and function at a high level (Fig. 16-3).[2] Furthermore, there appears to be little relationship between bleeding and perforation as they do not necessarily arise from the same pathogenesis.

Cats are infrequently diagnosed with gastric ulceration and erosion. Lymphoma and other tumors appear to be the most important causes of gastric ulceration in this species, but there are very few published studies in cats to confirm or deny this opinion.[3]

It should be confirmed that "hematemesis" is not just reddish tinged gastric fluid caused by food digestion in the stomach. True hematemesis may range from minimal to copious amounts of blood. If there are simply a few spots or "flecks" of blood (Fig. 16-4), gastric mucosal trauma as a consequence of vigorous vomiting is a major differential (Fig. 16-5). If copious, there are numerous possible causes, and a methodical approach is best (Fig. 16-6). If history, physical examination, and routine blood tests do not give clues as to the cause of hematemesis, the basic approach should be to first eliminate coagulopathy, search for evidence of upper GI mucosal disease, and, finally, respiratory tract disease with ingestion of blood following hemoptysis.

Hematochezia

In a patient with hematochezia (Fig. 16-7),[13] one should consider consistency of the feces and whether rectal bleeding occurs independently of defecation. Rectal bleeding in the absence of defecation is strongly suggestive of anal sac disease. If the feces are otherwise normal, focal rectal disease (e.g., polyps, tumors, and fungal infections like pythiosis) is especially likely. Finding blood consistently confined to one side or area of the feces also suggests a rectal lesion. If stools are soft and clearly abnormal, then generalized colitis of any cause (e.g., inflammatory bowel disease [IBD], fungi,

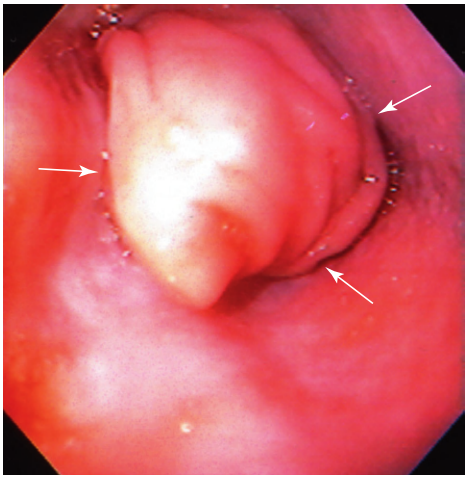

Figure 16-5 Gastric protrusion into the esophagus during vomiting. Vigorous vomiting can cause minor gastric mucosal injury, leading to hematemesis as shown in Figure 16-4.

bacteria, whipworms, and hookworms) are important differentials. Intussusceptions are an uncommon, but important cause of hematochezia. Acute ileocolic intussusceptions are often associated with scant bloody feces, but chronic ileocolic intussusceptions often cause diarrhea without bleeding. Cecocolic intussusceptions are rare causes of hematochezia that often represent a diagnostic challenge. Vascular malformations in the colonic mucosa are another rare cause of hematochezia.

Melena

Melena can be problematic because it is often misdiagnosed.[13] Dark green feces can appear melenic, and oral administration of bismuth compounds (e.g., Pepto-Bismol) consistently produces dark black feces. If melena is confirmed, the next determination is whether melena is part of an acute presentation such as hemorrhagic or parvoviral gastroenteritis. Causes of melena are the same as those that cause hematemesis, with some additional differential diagnoses (e.g., intestinal tumors, hookworms) that are sufficiently aborad that they cannot cause hematemesis.

Evaluation of the Patient

History

Presence of blood pigments in vomitus or feces is readily perceived by most pet owners with the exception of a "coffee-grounds" appearance of hematemesis which many do not recognize as digested blood. Anorexia may be the only other primary sign of gastric disease in some animals. Ataxia or weakness may be seen as a sign of anemia secondary to GI hemorrhage. Ascites or edema secondary to hypoalbuminemia are rarely reported or observed.

Documentation of NSAID usage (including the newer COX-2 drugs) is important and may be surprisingly difficult to elicit from the history. History should determine if dexamethasone or other glucocorticoids have been used. Anorexia or vomiting following shock or excessive exertion may be consistent with "stress" ulceration.

Hematochezia must be accurately described regarding its distribution on or in the feces as well as the consistency of the feces (normal, constipation, or diarrhea). Melena must be distinguished from the "dark" feces of other causes.

Physical Examination

GI hemorrhage is seldom reliably diagnosed at physical examination. Pale mucus membranes or weak thready pulses may provide clues to significant gastrointestinal blood loss. Gastric ulceration, perforation, and peritonitis should be suspected in patients manifesting abdominal pain, hyperthermia, hypothermia, or scleral injection. Cutaneous mast cell tumors can induce gastric ulceration, and they can perfectly mimic lipomas on physical examination.

Laboratory Evaluation and Tests

Most animals with GI hemorrhage are not obviously anemic on *complete blood counts* (CBC). Finding a microcytic, hypochromic anemia would be typical for iron deficiency seen with chronic, severe GI blood loss.[7] Increased RDW (red blood cell distribution width) is more sensitive than decreased MCV (mean corpuscular volume), but scanning blood smears for microcytes is the best way to screen for iron-deficiency anemia. Most anemias caused by GI blood loss are not microcytic, hypochromic. These anemias may be regenerative or nonregenerative, and concurrent hypoalbuminemia is typical. Hemoconcentration may be seen instead of anemia in some GI hemorrhagic disorders. Hemoconcentration in dogs with normal serum protein concentrations and acute hematemesis or hematochezia is very suggestive of hemorrhagic gastroenteritis syndrome.

Leukocytosis and neutrophilia may be observed in animals with perforated gastric ulcer, peritonitis, bacterial and fungal enteritis, nonspecific IBD, neoplasia, pancreatitis, and gastrointestinal foreign body. Leukopenia and neutropenia are more typical findings in young puppies affected with parvoviral enteritis. Eosinophilia is occasionally observed in animals with intestinal parasitism, food allergy, mastocytosis, and hypoadrenocorticism. Buffy coat smears may be useful in identifying circulating mast cells in animals affected with systemic mastocytosis. Adrenocorticotropic hormone (ACTH) stimulation should be considered as part of the further medical investigation of eosinophilia if there is no evidence for parasitism, allergy, or mastocytosis. Thrombocytopenia should be verified by a second platelet count. Gastrointestinal hemorrhage secondary to thrombocytopenia results most often from tick-borne rickettsial infection (Rocky Mountain spotted fever [RMSF], ehrlichiosis), immune thrombocytopenia, and systemic lupus erythematosus. Further medical investigation of thrombocytopenia should consist of RMSF and *Ehrlichia* serologies, antiplatelet antibody, antinuclear antibody, and bone marrow aspirate.

Serum chemistry is crucial to look for evidence of hepatic disease (e.g., increased alanine aminotransferase [ALT], hyperbilirubinemia, hypocholesterolemia, hypoalbuminemia, hypoglycemia, hyperammonemia, increased serum bile acid concentrations), hypoadrenocorticism (e.g., hyponatremia, hyperkalemia, lack of stress response in severely ill patient), and paraneoplastic syndromes (e.g., hypercalcemia associated with lymphosarcoma).

Fecal examinations are necessary to document hookworm and whipworm infestations. Mature dogs can have prepatent hookworm infections severe enough to kill them if they receive a massive exposure from a heavily contaminated environment.

Abdominal ultrasound is valuable in assessing stomach, intestine, colon, liver, and other abdominal organs. Ultrasound is a specific but insensitive test for GI ulceration, hepatic disease, and abdominal neoplasia.[14] Severe hepatic disease and GI ulcers may not be found in routine ultrasound studies. This is especially true of gastric lesions because of gastric gas, ingesta, and motility, which make mucosal detection more difficult. Nonetheless, ultrasound is recommended as it is far more sensitive than radiography. If ultrasound provides

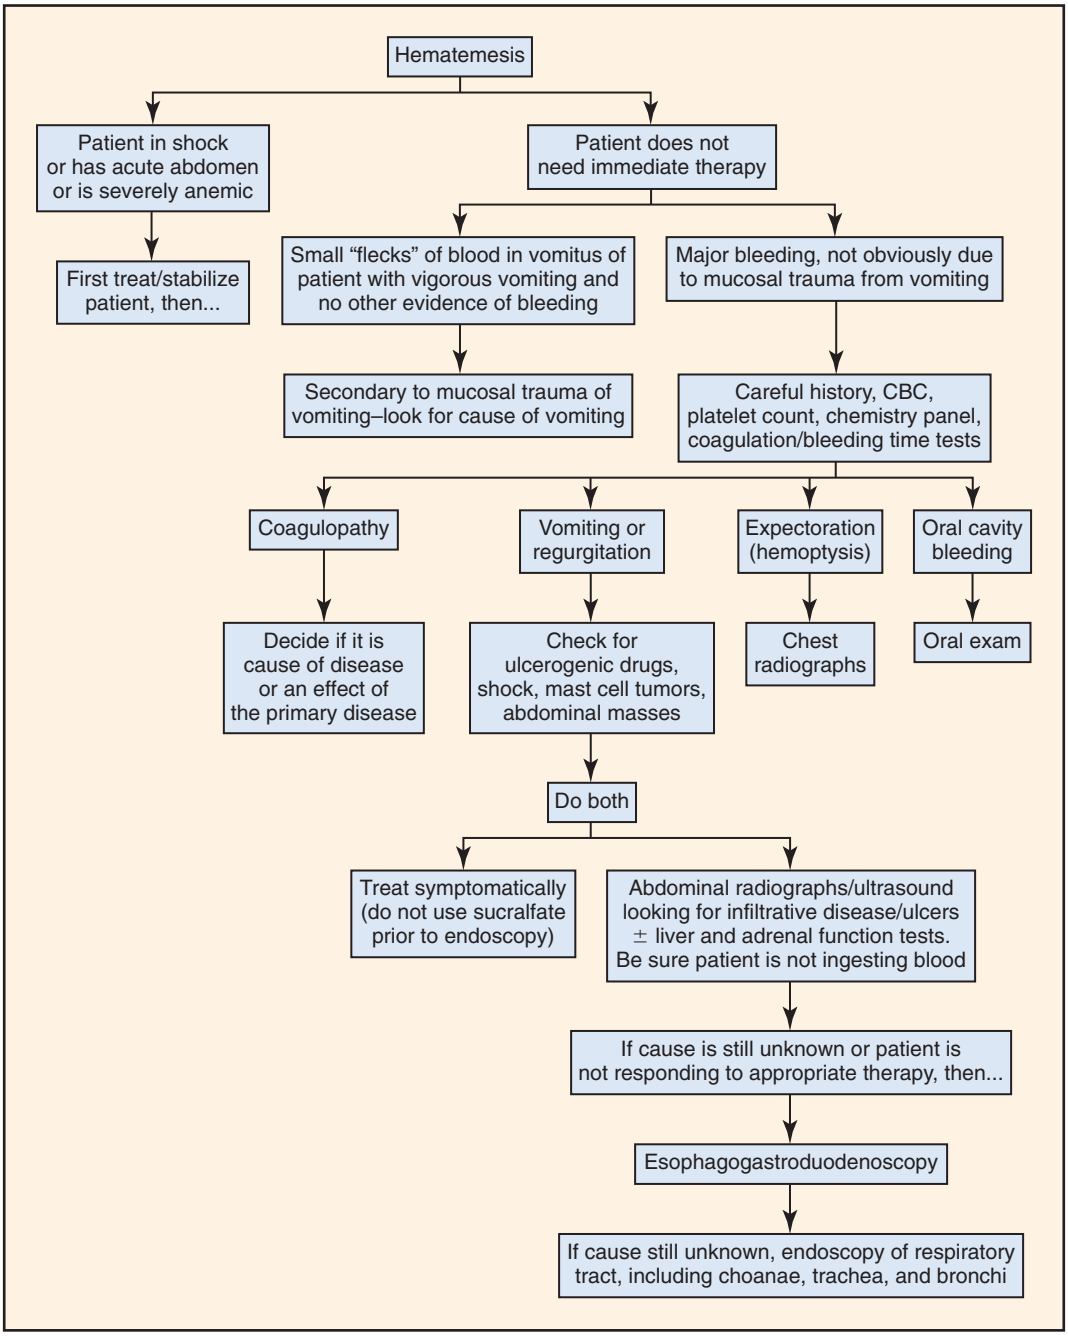

Figure 16-6 General diagnostic and therapeutic approach to hematemesis. CBC, Complete blood count. (Adapted from Nelson and Couto, *Small animal internal medicine*, ed 4, St Louis, 2009, Mosby.)

evidence of a disease with a high mortality rate (e.g., abdominal lymphoma), the pet owners may not wish to proceed with additional testing.

Additional diagnostic tests may be necessary depending upon the outcome of the initial medical investigation. If a definitive diagnosis is not immediately forthcoming, an assessment of coagulation (e.g., prothrombin time, partial thromboplastin time, buccal mucosal bleeding time, von Willebrand factor VIII antigen, fibrin degradation products) should be performed before more invasive and expensive tests are conducted. One or more of these tests will be abnormal with congenital or acquired liver disease, coagulation factor deficiency, disseminated intravascular coagulation, thrombocytopenia, thrombocytopathia, anticoagulant rodenticide toxicity, and hyperviscosity syndrome.

Treatment and Management

General Principles

Emphasis should be placed on finding the cause of GI hemorrhage rather than to simply start nonspecific therapy. Medical therapy is often ineffective if the underlying cause of gastric ulceration is not eliminated. Conversely, gastric ulcers will often spontaneously resolve once the cause is removed. If the cause is untreatable (e.g., nonresectable, scirrhous gastric carcinoma), administration of

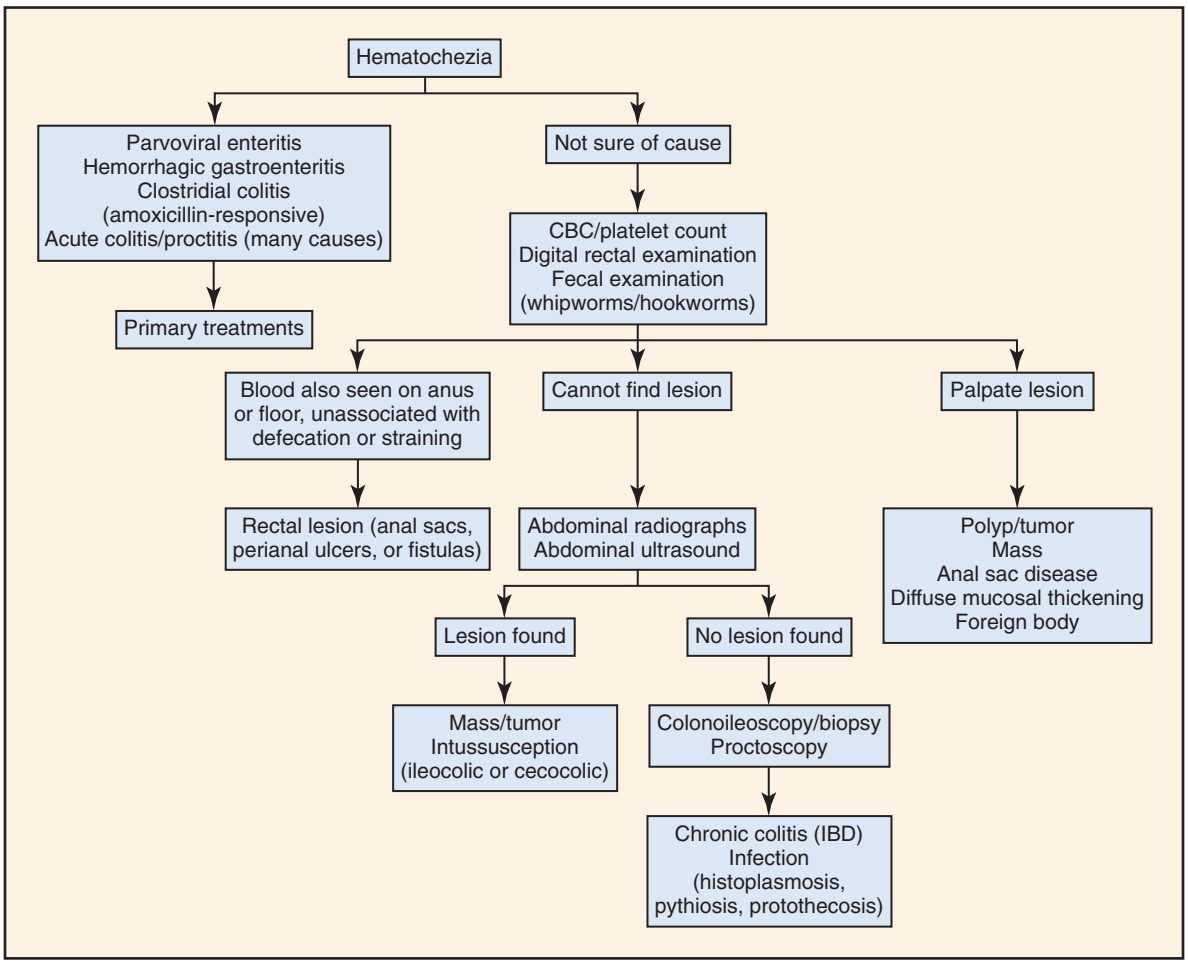

Figure 16-7 Diagnostic approach to hematochezia. CBC, Complete blood count; IBD, inflammatory bowel disease.

symptomatic and supportive therapies may be little more than palliative.

Medical

The *histamine-2 (H_2)-receptor antagonists* competitively inhibit binding of histamine to gastric parietal cell histamine H_2-receptors. They do not completely eliminate gastric acid secretion but substantially decrease it such that gastric ulcer can resolve. Cimetidine has the most side effects while famotidine has the fewest side effects and is the most potent H_2-receptor antagonist. Nizatidine and ranitidine are intermediate in strength, and both have gastric prokinetic effects. H_2-receptor antagonists are generally ineffective in preventing gastric ulcer caused by NSAIDs and steroids,[15,16] but may be helpful in preventing lesions caused by vigorous physical exercise (e.g., racing sled dogs).

The *proton-pump inhibitors (PPIs)* noncompetitively block the H^+-K^+ adenosine triphosphatase (ATPase) and more effectively suppress gastric acid secretion than H_2-receptor antagonists. They typically take 2 to 5 days to achieve maximal efficacy when administered orally but have significant acid suppression activity as soon as they are begun. Omeprazole, lansoprazole, pantoprazole, esomeprazole, rabeprazole, and dexlansoprazole are PPIs that are clinically available, although there is limited experience in dogs and cats with all but omeprazole. Omeprazole may cause diarrhea in some patients. The PPIs prevented gastric lesions caused by aspirin in some studies,[15] but not others.[17] PPIs lessen the incidence and severity of gastric ulcer caused by submaximal exertion in racing sled dogs.

Sucralfate is the sulfated form of sucrose combined with aluminum hydroxide. In the presence of acid, it binds to eroded surfaces offering mechanical protection, stimulating prostaglandin synthesis, and binding to epidermal growth factor. Sucralfate can bind to various other drugs potentially delaying or decreasing their absorption. It can be used in combination with H_2-receptor antagonists, but there is no evidence that this combination is more effective than single-agent therapy. Sucralfate is given orally (which can be problematic in vomiting animals), and it can attach to erosions and ulcers. (Because of its binding properties, sucralfate may prevent the endoscopist from directly viewing ulcerative lesions.) It is not necessarily effective in the prevention of gastric ulcer.[17]

Misoprostol is a prostaglandin E_1 analogue designed to prevent NSAID-induced gastric ulcer in people. It may not be as effective in dogs as has been reported in humans, but it does decrease the frequency of gastric ulcer[18] and helps some patients that do not tolerate NSAIDs well. It is not very effective in preventing steroid-induced gastric hemorrhage or that associated with spinal surgery.[16,17,19] Misoprostol can be used to treat existing ulcers, but it can cause diarrhea, abdominal cramping, and abortion due to its prostaglandin activity. It also tends to be more expensive than the H_2-receptor antagonists or sucralfate.

Surgical

If the underlying pathogenesis is identified and eliminated, most ulcers can be resolved medically, and most patients have evidence of improvement within 5 to 7 days of therapy. Focal lesions that cannot be resolved with medical management or those that pose a substantial risk of exsanguination should be surgically resected.

It is often advantageous to perform gastroduodenoscopy to determine the location and number of bleeding lesions prior to performing surgery. It can be difficult to locate bleeding mucosal lesions when examining gastric mucosa through a gastrotomy incision, and surgery may be unproductive if lesions are unresectable (e.g., widespread gastric erosions). Even when lesions are noted endoscopically prior to surgery, intraoperative endoscopy may be necessary to find all of them. Pyloric ulcers can be especially difficult to locate endoscopically, because of difficulty in carefully examining this area.

Endoscopic electrocautery or injection of clotting agents may be used in select cases. These techniques should not be performed unless the endoscopist has been trained in their use as they have the potential to hurt the patient as well as the equipment. In general, these techniques are done to stop bleeding to allow stabilization prior to surgery.

CHAPTER 17

Hepatoencephalopathy

Jill Maddison

Definition

Hepatic encephalopathy (HE) refers to a complex of neurologic abnormalities that occur in man and animals as a result of marked hepatic insufficiency.

Pathophysiology and Mechanisms

In the dog and cat HE most commonly results from a single congenital portosystemic shunt (PSS) that bypasses portal circulation and allows mesenteric blood to enter directly the caudal vena cava. Acquired portosystemic shunting also occurs in dogs as a consequence of portal hypertension (e.g., cirrhosis, arteriovenous fistula, hepatoportal fibrosis). HE has also been well documented in cats.

Anatomy

There are various shunt types. Intrahepatic shunts occur most commonly in large breeds (e.g., Doberman Pinschers, Labrador Retrievers, Golden Retrievers, Old English Sheepdogs, Irish Wolfhounds). In contrast, extrahepatic shunts predominate in smaller breeds (e.g., Yorkshire Terriers, Maltese Terriers, Miniature Schnauzers). Extrahepatic shunts predominate in cats although intrahepatic shunts have also been reported.

Pathophysiology

The basis for the neurologic dysfunction that occurs in HE is incompletely understood. The encephalopathy occurring in acute or chronic hepatic failure is usually reversible with amelioration of the underlying hepatic disease. This potential for structural and functional reversal of the neurological abnormalities in HE is consistent with a metabolic encephalopathy.

HE is a complex pathophysiologic state that is probably multifactorial in origin.[1] It is generally accepted that gut-derived substances of bacterial and protein metabolism are important in the pathogenesis. Evidence for this includes the observation that reduction of gut bacterial flora or dietary protein often result in improvement of neurologic function without altering underlying hepatic disease.

Although ammonia has long been implicated as being the most likely neurotoxin involved in HE, actual mechanisms are not well understood despite decades of research. Evidence is accumulating that brain glutamatergic system and astrocytic (glial) function is significantly deranged in HE as a result of their role in detoxifying ammonia.[2,3] Other theories proposed in the past (e.g., alteration in monoamine or catecholamine neurotransmitters because of perturbed aromatic amino acid metabolism, alteration in amino acid neurotransmitters, increased brain γ-aminobutyric acid [GABA], increased cerebral levels of an endogenous benzodiazepine-like substance) have little support today.

There are several observations that provide support for a central role for ammonia in the pathogenesis of HE.[4] Encephalopathy can be precipitated in cirrhotic patients by ingestion of ammonia-generating substances (e.g., protein, urea, ammonium salts). Congenital hyperammonemia caused by urea cycle disorders causes HE and coma in children and dogs. In addition, therapy decreasing intestinal production and absorption of ammonia (e.g., low-protein diet, lactulose administration, reduction of gut bacteria by antibiotics) usually results in improvement of clinical signs. Also of interest is the observation that metabolic derangements that increase movement of ammonia across cell membranes or increase ammonia production can precipitate HE in susceptible patients. Such derangements include alkalosis (which facilitates brain uptake of ammonia by increasing the concentration of ammonia base) and profound hypokalemia (which potentiates alkalosis and increases renal ammonia production).

Further evidence of the role of ammonia includes studies where administration of sodium benzoate to human patients with chronic HE-induced clinical and electroencephalogram (EEG) improvements paralleled reductions in blood ammonia. Sodium benzoate decreases blood ammonia concentrations by promoting its excretion in the form of hippurate. Other treatments that enhance ammonia excretion (e.g., L-dopa, which increases renal blood flow and hence renal ammonia excretion) have also been reported to ameliorate HE in human patients.

However, although blood ammonia concentrations are increased in most patients with HE, correlation between blood ammonia and degree of HE is poor, and some patients are encephalopathic without hyperammonemia. In addition, some medications may influence severity of HE without altering blood ammonia concentrations. Conversely, treatment of human patients with a monoamine oxidase inhibitor decreased blood ammonia concentrations, but failed to improve the encephalopathy.

That glutamate plays a central role in HE is suggested by the finding that there are many alterations of brain glutamate in various models of HE, and virtually all aspects of the glutamate system are

altered (e.g., synthesis, metabolism intercellular trafficking, function and expression of glutamate transporters and receptors).[2] Many of these functions occur in astrocytes (glial cells), cells that are consistently altered histopathologically in HE.

Differential Diagnosis

Clinical signs of HE may often be confused with those of primary gastrointestinal or neurologic disease. However, finding both gastrointestinal and neurologic dysfunction in a young dog or cat should alert clinicians to the possibility of HE. Lead toxicity also causes gastrointestinal and neurologic signs in young animals; however, neurologic dysfunction associated with lead poisoning in dogs is generally more hyperkinetic resulting in seizures and hysteria. In contrast, dogs and cats with HE typically present depressed, apathetic, and disorientated.

Other disorders that may have some clinical signs similar to HE and should be considered where appropriate include urinary tract infection (cystic calculi), intestinal parasitism, primary gastrointestinal disease, hypoglycemias, toxoplasmosis, hydrocephalus, acute ethylene glycol toxicity, rabies, central nervous system (CNS) neoplasia, canine distemper, storage disease, thiamine deficiency, and drug intoxication.

Evaluation of the Patient

History

Clinical signs are usually noticed in dogs and cats younger than 1 year of age, but patients can present at any age. Typical clinical signs in the dog include episodic lethargy and depression with periods of disorientation, aimless wandering, compulsive pacing, head pressing against walls, amaurotic blindness, and/or coma. Occasionally, seizures may be the presenting complaint in dogs. Neurologic signs can be related to a meal in approximately 25% of cases.

Episodes of anorexia and gastrointestinal signs such as vomiting are common in dogs. Other key features of clinical history may include dramatic but temporary resolution of clinical signs with antimicrobial therapy plus prolonged recovery from sedation or anesthesia. Polyuria and polydipsia occur in approximately one-third of dogs with HE. The mechanism has not been elucidated but may be related to central or primary (psychogenic) neuronal stimulation of the thirst center as a manifestation of HE, alterations in portal vein osmoreceptors, or a renal concentrating defect.

Clinical presentation of cats with HE is similar to dogs but has some unique aspects. Hypersalivation is the most frequently reported clinical abnormality in cats with HE but is rarely reported in dogs. Seizures also appear to occur more frequently in cats than dogs with HE. Seizures occurred in approximately 50% of feline cases reported in the literature. In contrast, seizures are not a particularly common feature of canine HE. Inappropriate aggression is also relatively frequently in cats compared to dogs. In contrast, compulsive behavior (head pressing, circling, aimless wandering) is observed more frequently in dogs than cats. Neurologic signs such as disorientation, ataxia, and stupor are frequently observed in both species. Figure 17-1 outlines the diagnostic approach to patients with signs of encephalopathy. Gastrointestinal abnormalities such as vomiting, diarrhea, and anorexia are reported less frequently in cats than dogs. Polyuria and polydipsia are also less frequently reported in cats than dogs. Risk factors that may precipitate HE in susceptible patients include alkalosis, hypokalemia (which may result from profuse vomiting or diarrhea or from excessive diuretic therapy with furosemide or other loop diuretics), anesthetics and sedatives (attributed to both increased cerebral sensitivity to the drugs and to impaired drug elimination; benzodiazepines are relatively safe), gastrointestinal hemorrhage (a common precipitating cause of HE is gastroduodenal ulceration which is common in patients with hepatic disease), transfusion of stored blood (it may contain high concentrations of ammonia), constipation (it increases colonic absorption of neurotoxic products of bacterial protein digestion), and methionine administration.

Physical Examination

Dogs with congenital PSS are usually small or unthrifty, but this is less common in cats. The liver in patients with congenital PSS is usually small and may not be palpable even in thin patients. In patients with acquired HE (acute or chronic) physical examination may reveal a small liver or hepatomegaly and/or jaundice. In all types of HE, physical signs related to hypoalbuminemia may develop (e.g., ascites, pleural effusion, subcutaneous edema). The kidneys may be enlarged. In contrast to dogs, cats with congenital PSS are often well grown and in good body condition.

Laboratory Evaluation and Tests

Nonspecific clinicopathologic changes frequently observed in dogs and cats with HE include hypoalbuminemia and mild to moderate elevations in serum alanine aminotransferase (ALT) and alkaline phosphatase (ALP). However, ALT and ALP may be occasionally in the reference range, especially in cats. Subnormal plasma urea concentrations are often detected. Increased hepatic enzymes and hypoalbuminemia occur less consistently in cats with HE compared to dogs. A small proportion of dogs are hypoglycemic, which may contribute to clinical signs of weakness and seizures.

The majority of affected animals will have fasting hyperammonemia, and all will exhibit intolerance to orally or rectally administered ammonium chloride. Fasting and/or postprandial serum bile acids are invariably increased in dogs but may be normal in cats. An interesting hematologic finding in many dogs with congenital PSS is microcytosis not usually associated with anemia. This hematologic abnormality also has been reported in up to 54% of cats.

Approximately 50% of dogs will have ammonium biurate crystalluria. Occasionally ammonium biurate calculi form and cause signs of urinary tract disease including hematuria and recurrent urethral obstruction. Ammonium biurate crystalluria appears to be less frequent in cats.

Plain abdominal radiographs of dogs with HE show a small liver and often renomegaly. This has been reported less frequently in cats. The increase in the size of the renal shadow in dogs is often marked (i.e., up to greater than four times the length of the second lumbar vertebra). The etiology of this enlargement has not been determined. It may be related to altered splanchnic blood flow or to increased metabolic activity of the kidney in the presence of hyperammonemia. Finding a small liver and enlarged kidneys on plain radiographs of a young dog is highly suggestive of a portacaval shunt. Portacaval shunts are usually confirmed by hepatic ultrasonography, visualization at surgery, operative mesenteric venography, cranial mesenteric angiography, transabdominal splenoportography, celiac arteriography, and/or quantitative hepatic scintigraphy.

No specific gross pathologic findings are characteristic of HE (apart from identification of portacaval shunts). Microscopic findings in the CNS include mild vacuolation of glial cells

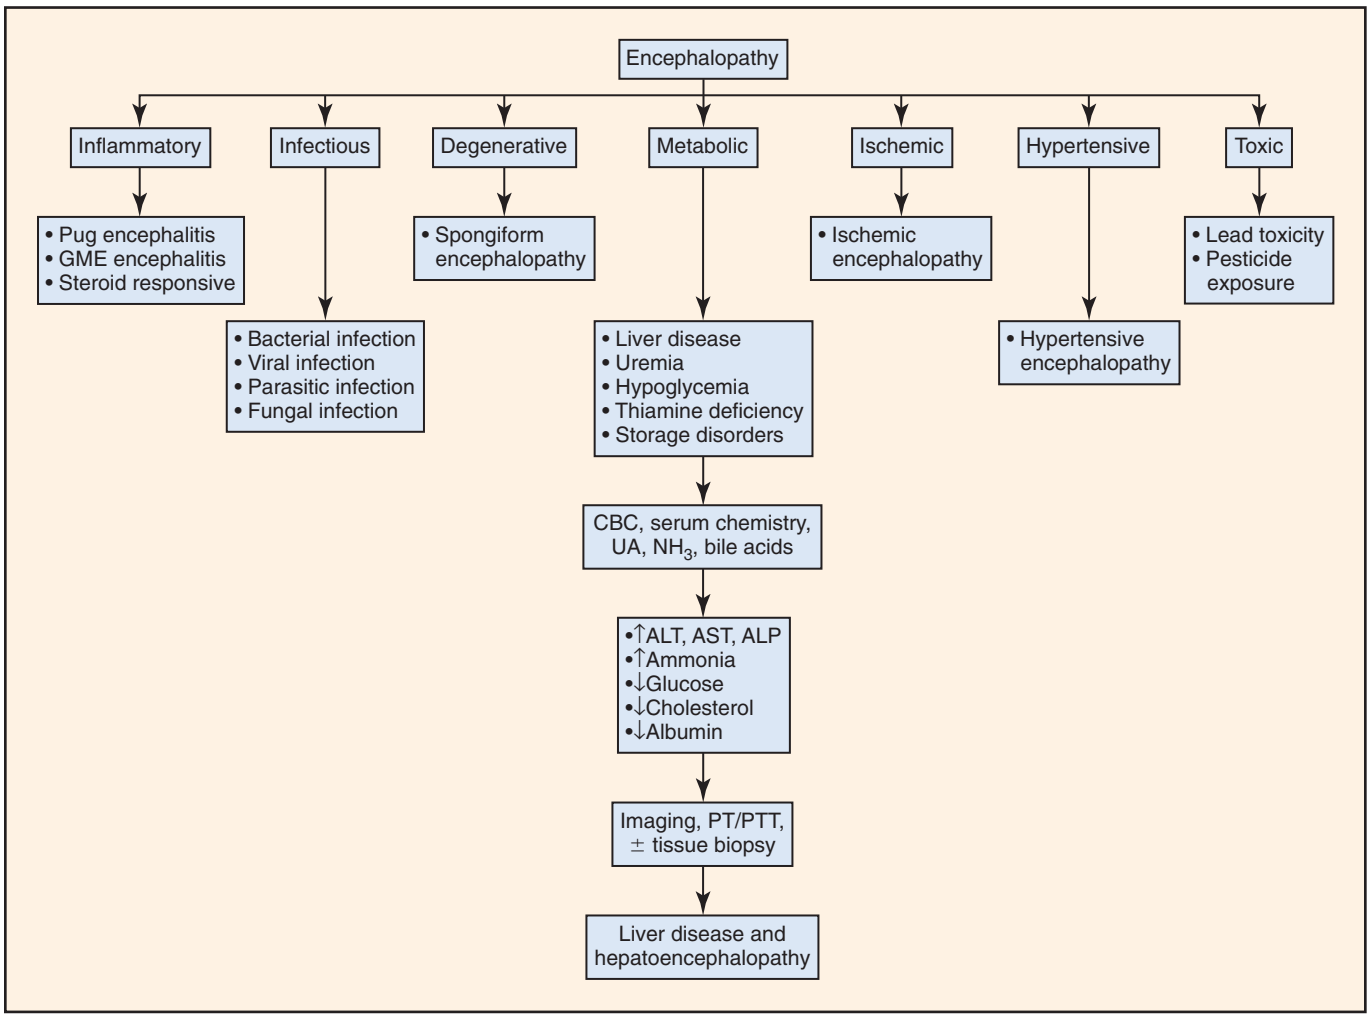

Figure 17-1 Diagnostic approach to patients with signs of hepatoencephalopathy. ALP, Alkaline phosphatase; ALT, alanine aminotransferase; AST, aspartate aminotransferase; CBC, complete blood count; GME, granulomatous meningoencephalomyelitis; PT, prothrombin time; PTT, partial thromboplastin time; UA, urinalysis.

and cerebral edema in severely affected cases (usually acute). In acquired HE, pathologic findings depend on the primary hepatic condition.

Treatment and Management

General Principles

Ideally treatment of any disorder is based on understanding pathogenesis of the clinical signs and abnormalities. Surgical correction of congenital PSS is an example of rational treatment that directly addresses the specific anatomical abnormality causing HE.

However, not all animals with HE have a surgically correctable problem. For example, acute hepatic failure, acquired PSS secondary to chronic hepatic disease, and multiple congenital shunts are not amenable to surgical correction. Surgical correction of single congenital PSS is not always possible because of lack of access to appropriate surgical expertise or economic factors. In addition, patients may need medical management prior to undergoing surgical correction to optimize their condition for surgery. In all of these instances, medical management may be instituted. However, medical management of HE is at best empirical because the pathogenesis of HE is uncertain.

Medical

Medical management may be attempted if surgical correction is not feasible. However, such treatment is palliative and commonly results in temporary alleviation of clinical signs. Medical treatment will not ameliorate portacaval shunting (either congenital or acquired), hence the liver will continue to be deprived of portal blood. As a result there may be continued hepatic atrophy and progressive failure of hepatic function, particularly protein synthesis. In acute hepatic failure, recovery of hepatic function is possible if the patient survives. However, acute hepatic failure carries a poor prognosis, and the treatment of choice in human medicine is hepatic transplantation.

The most successful medical treatment for HE is based on reducing gut bacterial protein metabolism. This is achieved by limiting or altering dietary protein intake and suppressing urease-producing gut bacteria. In addition, limiting absorption of ammonia from the colon may be beneficial.

Diet

The aim is to feed the highest level of protein that the animal will tolerate. Severe protein restriction in a patient with hepatic disease will exacerbate a negative nitrogen balance and lead to further breakdown of lean muscle protein, which aggravates hyperammonemia and may precipitate HE. Also because many affected dogs are large breeds (e.g., Labrador Retriever), excessively restricting dietary protein may lead to developmental orthopedic problems. In such cases rather than recommending typical prescription diets designed for dogs with hepatic disease, it may be preferable to use less-protein-restricted diets (e.g., products designed for dermatologic or gastrointestinal problems), some of which just meet nutritional requirements for growing dogs without being as excessive as most growth diets are. The other advantage of these diets is that the main protein source is often highly processed soy, which has been shown to be beneficial in dogs with HE. Some diets also contain appropriate amounts of calcium and appropriate ratio of calcium to phosphorus.

All patients with hepatic disease should be given enough protein to maintain a positive nitrogen balance, which is unfortunately difficult to quantify in clinical patients. In general, patients with hepatic disease should at least be fed 4 to 5 g protein/100 kcal. Only in cases where HE cannot be acceptably managed with medical therapy alone should protein levels be decreased further and then to no lower than 3 g protein/100 kcal for a short period of time. It is advisable to restrict protein only as needed to ameliorate HE signs and to use antibiotic therapy and lactulose to permit the maximum dietary protein intake possible without precipitating HE.

The source of dietary protein should be considered and have a high biologic value and digestibility. Amino acids from poor quality sources are deaminated at a higher rate yielding more ammonia. Poor quality proteins also undergo greater amounts of intestinal bacterial breakdown. The high content of heme and other nonprotein nitrogenous compounds in red meat makes it highly ammoniagenic; it should be avoided. Studies in human medicine suggest that dairy proteins are better tolerated than meat proteins in chronic HE and are associated with lower blood ammonia concentrations. Consequently, cottage cheese is suitable for dogs and cats as it has a high biologic value and is easily digested.

Recent attention in human medicine has focused on benefits of vegetable proteins compared with animal proteins. Vegetable protein diets appear to improve nitrogen balance, which is particularly important in patients with muscle wasting and cachexia who are at risk of worsening HE if dietary protein is increased. Fiber in the vegetables is beneficial in controlling glucose intolerance and decreasing production of neurotoxic substances in the gut. Commercial or homemade diets based on vegetable proteins may prove beneficial in management of chronic HE in dogs and cats if difficulties with palatability can be overcome.

Drugs

Antimicrobial Agents. Bacterial protein metabolism can also be reduced by use of antibiotics that lessen intestinal bacterial concentrations. Neomycin (10-20 mg/kg PO q6 to 12h) has been used for many years in human and veterinary medicine. Occasional problems associated with ototoxicity, bacterial resistance, and malabsorption have been reported in humans. As a result, neomycin is usually used in humans to treat acute exacerbations of HE rather than for chronic therapy, and this recommendation is reasonable for veterinary patients as well.

Metronidazole has also been used successfully in both human and veterinary medicine to reduce gut flora. Acute CNS dysfunction has been reported in dogs associated with relatively high doses of metronidazole; therefore, a conservative dose not exceeding 30 mg/kg/day is used in patients with HE. Metronidazole treatment should also primarily be used if possible to treat acute exacerbations of encephalopathy rather than as chronic therapy. Other antimicrobial agents that have been used to ameliorate acute signs of HE include ampicillin and vancomycin.

Lactulose. Lactulose (1-4-β-galactosidofructose) is a synthetic disaccharide that is neither hydrolyzed nor absorbed by the small intestine. Although its mode of action is uncertain, it is beneficial in patients with HE caused by PSS and for reducing ammonia absorption from the gut. Daily protein intake can often be increased while lactulose treatment continues without mental deterioration.

The therapeutic effect of lactulose cannot be attributed only to its cathartic effect because sorbitol, which also induces an osmotic diarrhea but without altering stool pH, has little effect on clinical signs of HE in humans. Other possible modes of action of lactulose include (a) an effect of lowered colonic pH on bacterial flora, (b) decreased ammonia absorption from the colon as a result of reduced relative concentration of ammonia (NH_3) (to which the colonic mucosa is more permeable than NH_{4+}), and (c) increased bacterial assimilation of ammonia or decreased ammonia generation by bacteria.

The therapeutic goal is to administer sufficient lactulose to cause passage of two to three soft stools per day. The precise dose rate has not been determined for dogs, but is approximately 2.5 to 25 mL given two or three times daily. Cats usually require 2.5 to 5.0 mL two or three times daily. Lactulose may also be administered as an enema in acute hepatic coma.

Recent studies in humans have suggested that another disaccharide, lactitol (β-galactosidosorbitol), is as effective as lactulose in controlling HE and is associated with fewer adverse effects (e.g., flatulence). The use of lactitol has not been reported in veterinary medicine but it may be considered as an alternative if lactulose-induced flatulence is unacceptable to the owner.

Surgical

Both intra- and extrahepatic PSS can potentially be successfully ligated by experienced surgeons. Single extrahepatic shunts are amenable to surgical correction but the difficulty with surgical correction of intrahepatic shunts lies with their relative inaccessibility.

Complete attenuation of the shunt is often impossible because of unacceptable increases in portal vein pressure. However, long-term amelioration of clinical signs is usually achieved in 85% of canine cases. Good to excellent clinical results can be expected in the majority of dogs regardless of whether the shunt is completely or partially occluded. In contrast, in a study of surgical management of feline portosystemic shunts, all four cats whose shunts were only partially ligated relapsed clinically several months after surgery. Clinical outcome has been reported to be significantly worse in dogs older than 2 years at the time of surgery.

An uncommon postsurgical sequelae in both dogs and cats is the development of intractable seizures and neurologic deficits (e.g., blindness). There are reports of successful management of this problem including use of propofol infusion.[5] However, in many cases management is unsuccessful; mortality is high and irreversible brain damage common in survivors. The pathogenesis of the seizures has not been determined.

CHAPTER 18

Icterus

Robert G. Sherding

Definition

The term *icterus* is used interchangeably with *jaundice* to refer to yellow discoloration of skin, mucous membranes, and sclerae caused by an accumulation of bilirubin pigment in plasma (hyperbilirubinemia) and tissues. Icterus generally becomes visible when serum bilirubin concentration exceeds 2 to 3 mg/dL (35 to 50 µmol/L), or greater than five- to 10-fold above reference range. Unlike other nonspecific clinical signs of hepatobiliary disease (e.g., inappetence, lethargy, weight loss, vomiting, diarrhea, and dehydration), icterus correlates with hyperbilirubinemia and is therefore a highly specific clinical sign consistent with decreased excretion of bilirubin in association with hepatobiliary disease or increased formation in association with severe hemolysis. Despite excellent specificity, icterus and hyperbilirubinemia are relatively insensitive indicators, found only in moderate to severe hepatic insufficiency and overall in less than 50% of dogs and cats with hepatic disease.[1]

Pathophysiology and Mechanisms

Bilirubin is an end product of hemoglobin metabolism. Icterus occurs when bilirubin formation exceeds hepatobiliary excretion. Three pathophysiologic mechanisms of hyperbilirubinemia and icterus are termed (a) *prehepatic*, which results from accelerated red blood cell destruction (hemolysis) and increased bilirubin production; (b) *hepatic*, which is caused by intrinsic hepatocellular disease and reduced hepatocyte uptake, conjugation, and secretion of bilirubin; and (c) *posthepatic*, which is caused by extrahepatic cholestasis and disruption of bile flow through the extrahepatic biliary system (Fig. 18-1).[1,2] This mechanistic classification helps to explain how different categories of disease can cause hyperbilirubinemia and icterus, although all three mechanisms may be operative in any individual.

Normal Bilirubin Metabolism

Bilirubin is a yellow pigment derived mainly from the degradation of red blood cell hemoglobin (see Fig. 18-1A). Under normal conditions approximately 80% of bilirubin comes from erythrocyte hemoglobin, while the remaining 20% is derived from the breakdown of other heme-containing proteins, such as myoglobin, P450 cytochromes, peroxidase, and catalase.[2] In macrophages of the mononuclear phagocytic system of the spleen, liver, and bone marrow, heme from senescent erythrocytes is cleaved by microsomal heme oxygenase to yield iron and biliverdin, a green pigment, which is then reduced to bilirubin, a yellow pigment, by biliverdin reductase. Daily production of bilirubin in adult mammals is approximately 3 to 5 mg/kg.[3] Unconjugated bilirubin, also called free bilirubin or indirect-reacting bilirubin, is insoluble in plasma. As it is released into the circulation it is tightly bound to albumin for transport to the liver, which completes the *prehepatic phase* of bilirubin metabolism.[2]

In the *hepatic phase*, bilirubin metabolism depends upon hepatocyte uptake, conjugation, and secretion, followed by posthepatic excretion in bile (see Fig. 18-1A).[2] Unconjugated bilirubin is removed from circulation by the liver (uptake), which involves dissociation from albumin at the sinusoid-hepatocyte interface and transport across the cell membrane by a carrier protein. Uptake capacity of hepatocytes greatly exceeds excretory capacity.[4] Once inside the hepatocyte, bilirubin is bound to ligandin, a cytosolic transporter protein that regulates the rate of bilirubin uptake.[2] Within the hepatocyte glucuronyl transferase catalyzes conjugation of bilirubin with glucuronic acid to form water-soluble bilirubin diglucuronide.[5] Conjugated bilirubin, also called water-soluble or direct-reacting bilirubin, is then secreted into the bile canaliculi which is both an energy-dependent process and rate-limiting step in the transfer of bilirubin from plasma to bile.[2] In the *posthepatic phase*, conjugated bilirubin is then transported with bile through the extrahepatic bile duct system, stored in the gallbladder, and excreted into the intestines through the common bile duct. In dogs, intestines and kidneys can also conjugate and excrete a small amount of bilirubin.[6]

Conjugated bilirubin that enters the intestinal tract with bile is poorly absorbed and passes largely into the large intestine where colonic bacteria convert it to colorless derivatives called urobilinogens.[2] A small portion of bilirubin within the intestine is deconjugated by enteric bacteria, reabsorbed by enterocytes, and returned to the liver by the enterohepatic portal venous circulation. The majority of intestinal urobilinogen is oxidized and passed in the feces as stercobilin, a pigment that imparts the normal brown color to feces. Normally, a small amount of intestinal urobilinogen (10% to 20%) is reabsorbed into the enterohepatic circulation and handled once again by the liver, except for approximately 1% to 5% of absorbed urobilinogen that is excreted into urine by the kidneys.[7]

Prehepatic Icterus

Icterus is characterized as *prehepatic* when the primary abnormality is overproduction of bilirubin resulting from hemolysis (see Fig. 18-1B). Accelerated erythrocyte destruction increases formation of

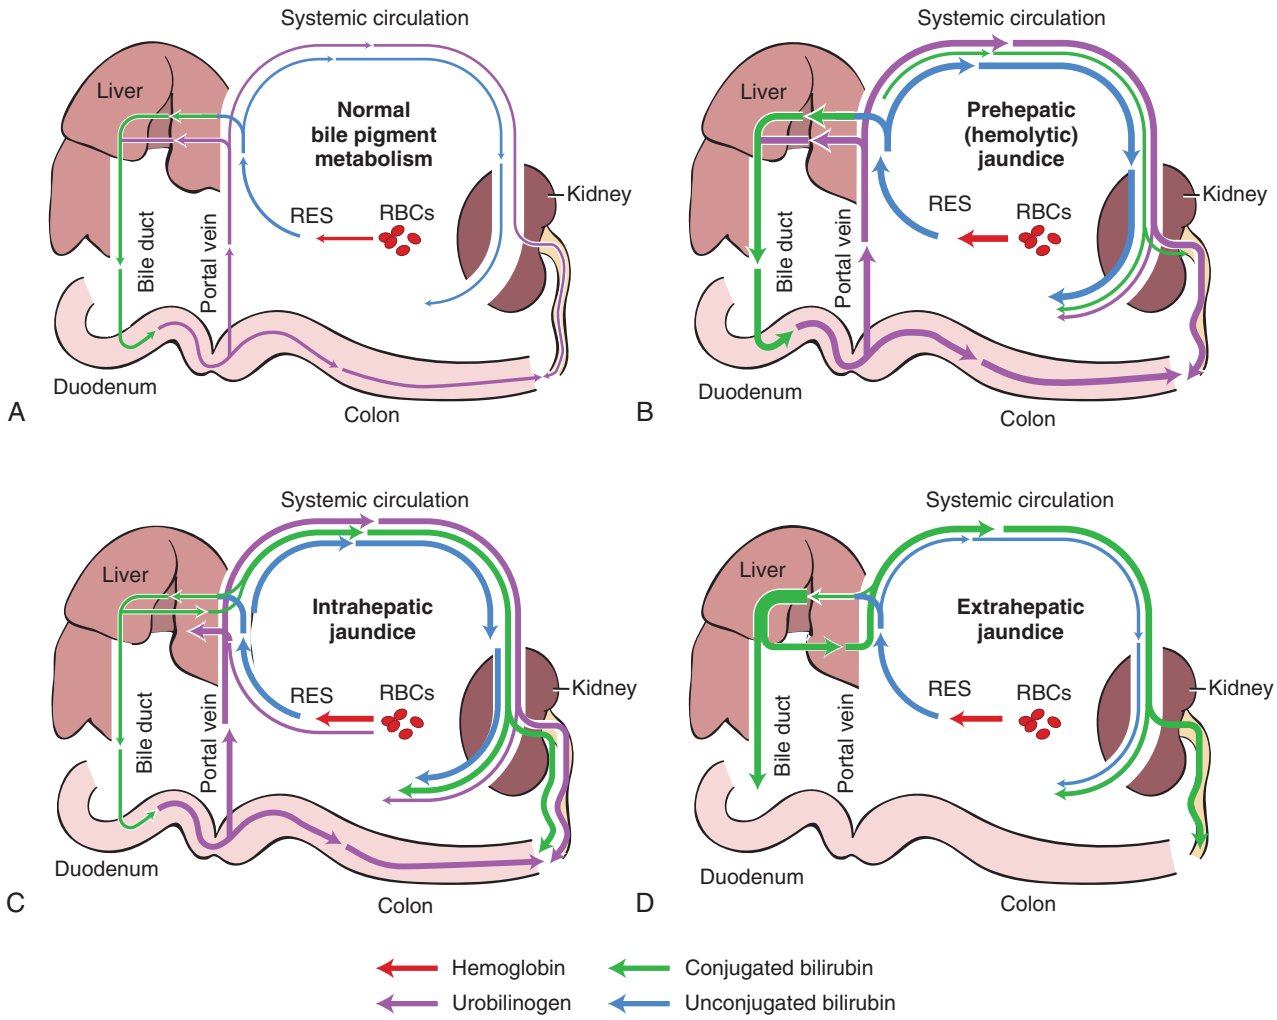

Figure 18-1 Diagrams comparing the formation, excretion, and enterohepatic circulation of bilirubin and other bile pigments in **(A)** the normal animal; **B,** *prehepatic* icterus associated with hemolysis and overproduction of bilirubin; **C,** *intrahepatic* icterus associated with hepatocellular disease and intrahepatic cholestasis; and **D,** *posthepatic* icterus associated with extrahepatic bile duct obstruction. bilirubin from heme. If this bilirubinemia overwhelms the liver's functional capacity for uptake, conjugation, and secretion, bilirubin is refluxed from the liver into the circulation resulting in hyperbilirubinemia and icterus.[2] The hemolytic event must be acute and severe to overwhelm the large reserve capacity of the normal liver. Severe hemolytic events can be complicated by anemic hypoxia of the liver, which can secondarily compromise hepatic function and contribute to intrahepatic cholestasis. Icterus and bilirubinemia associated with severe hemolysis are typically a mixture of unconjugated and conjugated bilirubin fractions resulting from combination of overproduction of bilirubin and intrahepatic cholestasis.[8] Increased excretion of conjugated bilirubin into the intestinal tract increases urobilinogen formation, which results in increased urobilinogen in urine and increased stercobilins in feces, which imparts a dark orange–brown color to the feces.[1]

Hepatic Icterus

Icterus is characterized as *hepatic* when the primary abnormality is intrahepatic cholestasis associated with hepatocellular injury, necrosis, or dysfunction (see Fig. 18-1C). Moderate to severe hepatic disease can impair various steps in handling of bilirubin particularly at the level of the canaliculi and intrahepatic bile ductules. Intrahepatic cholestasis and icterus develop most readily with hepatic parenchymal lesions that affect the periportal region of the liver lobule because bile flows from the centrilobular region toward the intrahepatic bile ductules in the portal triad.[3,9] Intrahepatic cholestasis causes reflux of conjugated bilirubin into the circulation. Unconjugated bilirubin also refluxes into circulation because increased bilirubin accumulation within hepatocytes interferes with the conjugation process. In cholestatic hepatic disease, concurrent retention of bile acids may further damage hepatocytes. Hyperbilirubinemia that occurs in most diseases of the liver is a mixture of conjugated and unconjugated bilirubin in varying proportions.[8] Some of the circulating conjugated bilirubin is excreted by kidneys and is detected in urine along with urobilinogen.

Posthepatic Icterus

Icterus is characterized as *posthepatic* when the primary abnormality is impaired excretion of bilirubin caused by extrahepatic biliary disease that interrupts or obstructs the flow of bile (see Fig. 18-1D). Extrahepatic cholestasis primarily causes reflux of conjugated bilirubin into the circulation, but bile retention also interferes with

conjugation and injures hepatocytes which can cause secondary unconjugated bilirubinemia. Thus posthepatic icterus is characterized by mixed hyperbilirubinemia with the conjugated fraction predominating. Some of the circulating conjugated bilirubin is excreted by the kidney and detected in urine; however, urobilinogen is absent in urine because obstructive extrahepatic biliary disease prevents delivery of precursor bilirubin into the intestine. In complete bile duct obstruction, failure of bile to enter the intestinal tract can result in pale gray–colored acholic feces.[1,10]

Differential Diagnosis

In dogs and cats, hyperbilirubinemia and icterus can be associated with many diseases that cause either hemolysis or intra- or extrahepatic cholestasis (Box 18-1). Figure 18-2 outlines an algorithmic approach for differential diagnosis of icterus. The first step is to consider prehepatic (hemolytic) icterus, which is usually indicated by the presence of moderate to severe anemia (hematocrit <20%) and evidence of red blood cell (RBC) regeneration (polychromasia, anisocytosis, and reticulocytosis) in the absence of blood loss.[11] The cause of hemolysis may be suggested by other hematologic findings such as autoagglutination, spherocytosis, Heinz bodies, RBC parasites, or RBC fragments (schistocytes). In icteric patients without clinical and hematologic evidence of severe hemolysis, diagnostic evaluation should focus next on identifying a primary hepatobiliary disease that can cause either intra- or extrahepatic cholestasis. Ultrasonography is especially useful for evaluating the liver, gallbladder, and bile ducts. Posthepatic icterus is unlikely if ultrasonography fails to reveal evidence of obstruction (bile duct distention), rupture (bile peritonitis), or other disease (e.g., cholelithiasis, gallbladder mucocele) in the extrahepatic biliary tract. Ultrasonography also helps to identify pancreatic or duodenal masses that could be obstructing the common bile duct. Once prehepatic hemolysis and posthepatic disruption of bile flow are excluded, diagnostic evaluation should focus on intrinsic hepatic parenchymal diseases that can cause icterus. Hepatic biopsy is required in many such cases.

Box 18-1 Differential Diagnosis of Icterus and Hyperbilirubinemia

Prehepatic (Hemolytic) Icterus
- Immune-mediated hemolytic anemia
- RBC infections
  - *Babesia* spp., hemotropic *Mycoplasma* spp., *Cytauxzoon felis*
- RBC oxidative injury by toxins and drugs (Heinz body anemia)
  - Acetaminophen, onion, garlic, zinc, vitamin K, benzocaine and other local anesthetics (cats), propylene glycol, naphthalene (mothballs)
- Envenomation (spiders, snakes, bees)
- Hypophosphatemia (insulin therapy, refeeding syndrome)
- Hereditary RBC defects
  - Pyruvate kinase deficiency, phosphofructokinase deficiency, stomatocytosis
- Microangiopathic RBC fragmentation
  - DIC, vasculitis, hemangiosarcoma, splenic torsion, heat stroke, heartworm postcaval syndrome
- Incompatible blood transfusion
- Neonatal isoerythrolysis

Hepatic (Hepatocellular) Icterus
- Adverse drug reactions (many)
- Hepatotoxins (many)
- Infectious hepatitis (many causes)
- Noninfectious chronic hepatitis
- Cirrhosis
- Breed-specific copper hepatopathies
- Cholangitis/cholangiohepatitis
- Feline hepatic lipidosis
- Hepatic neoplasia (primary, metastatic)
- Cholestasis of sepsis

Posthepatic (Obstructive) Icterus
- Cholelithiasis, choledocholithiasis
- Bile duct inflammation, stricture, or cyst
- Biliary fluke infestation (*Platynosomum concinnum*, *Amphimerus pseudofelineus*)
- Biliary neoplasia
- Gallbladder disease (cholecystitis, mucocele)
- Pancreatic disease (carcinoma, abscess, pancreatitis)
- Duodenal disease (neoplasia, foreign body, duodenitis)
- Bile duct or gallbladder rupture (bile peritonitis)

DIC, Disseminated intravascular coagulation; RBC, red blood cell.

Evaluation of the Patient

Icterus is sometimes noticed by an observant pet owner and quite readily detected on physical examination. Following a complete history and physical examination, initial diagnostic evaluation of the icteric patient should include a complete blood count (CBC), serum chemistry, urinalysis, and diagnostic imaging of the abdomen, especially ultrasonography. This minimum database usually enables classification of icterus as prehepatic, hepatic, or posthepatic in origin (see Fig. 18-2). Hepatic cytology and biopsy are often indicated for further evaluation of hepatic parenchymal disease. In most icteric patients coagulation status should also be evaluated. Abdominocentesis and fluid analysis are indicated in patients with abdominal effusion, especially if gallbladder or bile duct rupture is suspected. Laparoscopic or surgical intervention is usually the most effective way to confirm, characterize, and decompress posthepatic biliary obstruction.

History

Icterus is an important clinical sign of hemolysis and hepatobiliary disease in dogs and cats. Some owners may report changes in the color of urine or feces. Severe bilirubinuria can cause orange or green discoloration of urine (pigmenturia), whereas intravascular hemolysis can cause dark red or brown urine (hemoglobinuria).[1] Feces may appear dark orange–brown or green with increased excretion of bile pigments into the intestinal tract. Prolonged absence of bile pigments in the intestines in complete bile duct obstruction can result in pale gray–colored acholic feces.[10]

Other clinical manifestations of hepatobiliary disease can include inappetence, lethargy, weight loss, vomiting, diarrhea, polyuria-polydipsia, hepatic encephalopathy, abnormal bleeding tendencies, and abdominal distention related to hepatomegaly or ascites.[1,12] Genetic and breed predispositions for specific diseases (e.g., copper hepatopathy) should be also considered (see Chapters 61 and 62). Owners should be questioned about potential for exposure to infectious agents, hepatotoxins (e.g., xylitol, aflatoxin-contaminated dog food, amanita mushrooms, Microcystis blue-green algae, sago, or cycad palm), or medications that might cause hepatotoxicity (e.g., nonsteroidal antiinflammatory drugs, phenobarbital, and many others) (see Chapter 61).

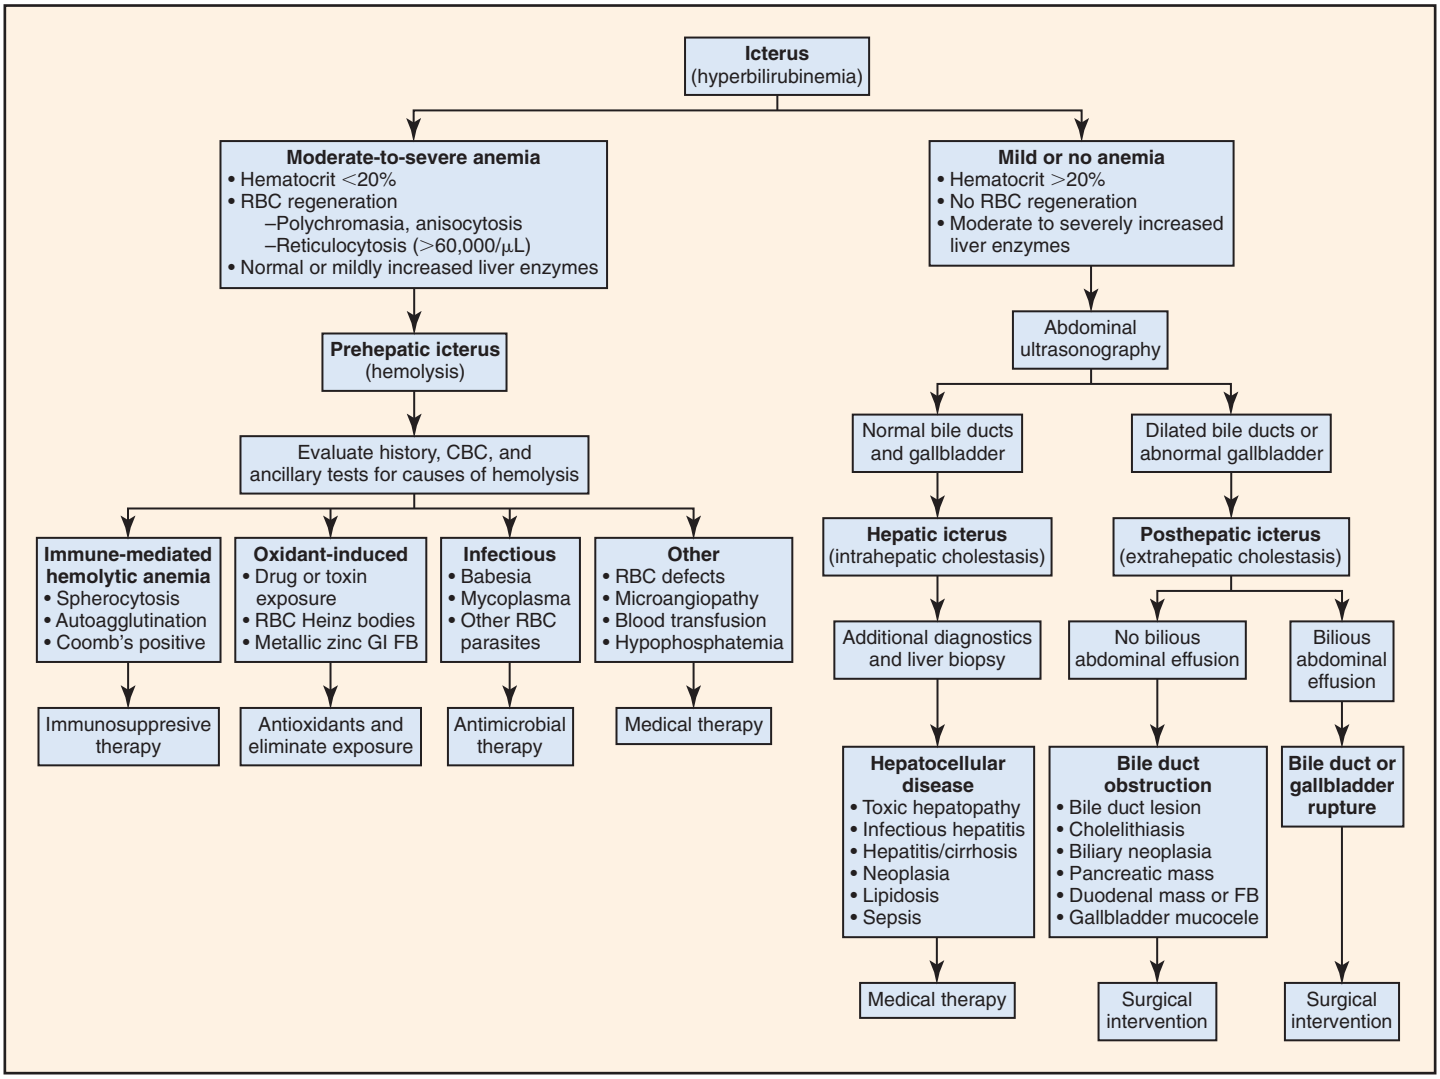

Figure 18-2 Algorithmic approach for the differential diagnosis of icterus in the dog and cat. CBC, Complete blood count; FB, foreign body; GI, gastrointestinal; RBC, red blood cell.

Patients with hemolytic icterus typically have a history of exercise intolerance, lethargy, weakness, and pallor of mucous membranes.[11] When hemolysis is suspected, history should ascertain potential for recent exposure to blood transfusions, oxidant substances, vector-borne hemotropic RBC parasites, venomous snakes and insects, zinc ingested with metallic objects, or zinc oxide sun protectants (see Box 18-1).[11] Breed predispositions to hereditary RBC defects should be taken into account. Signs that could indicate an underlying cause of microangiopathic hemolytic anemia should also be considered. Insulin therapy in ketoacidotic diabetic patients or intensive hyperalimentation can precipitate hypophosphatemic hemolysis when serum phosphorus is less than 1.5 mg/dL.[11]

Physical Examination

The clinical sign of icterus is recognized as yellow discoloration of the skin, oral mucous membranes, and sclerae caused by an accumulation of bilirubin in the tissues. Icterus generally becomes visible when serum bilirubin concentration exceeds 2 to 3 mg/dL. By comparison icteric plasma and bilirubinuria are seen at serum bilirubin concentrations of 1 to 2 mg/dL.[4] Intensity and distribution of tissue bilirubin is determined by (a) total serum bilirubin concentration; (b) proportion of conjugated versus unconjugated bilirubin; (c) background tissue color, which is affected by perfusion, hematocrit, and melanin pigment; and (d) tissue composition.[9] Ambient lighting can also affect the examiner's ability to detect icterus. Water-soluble conjugated bilirubin accumulates preferentially in tissues such as skin and sclerae.[9]

Additional physical findings in hepatobiliary disease can include hepatomegaly, hepatic masses, cranial abdominal pain, or abdominal effusion (ascites or biliary rupture).[12] In prehepatic icterus, the physical examination findings are attributable to severe hemolytic anemia and include mucous membrane pallor, depressed mentation, weakness or collapse, tachypnea, tachycardia, anemic murmur, and splenomegaly.[11]

Laboratory Evaluation and Tests

The CBC usually identifies prehepatic hemolytic icterus. Serum chemistry confirms hyperbilirubinemia and assesses other parameters that can be affected by hepatobiliary disease, including liver enzyme activities, albumin, cholesterol, blood urea nitrogen, and glucose. The urinalysis detects bilirubinuria and urobilinogen. Additional diagnostic tests, such as serum pancreatic-specific lipase, tests for specific infectious diseases, bile culture, and abdominal fluid analysis, are sometimes indicated.

Hematology

Once hyperbilirubinemia is confirmed, the next step is to determine if there is hemolysis. To induce icterus, hemolysis must be severe enough to cause moderate to severe anemia. A hematocrit less than 20% and evidence of RBC regeneration (polychromasia, anisocytosis, and reticulocytosis) in the absence of blood loss are indications to further evaluate for causes of hemolysis.[11] Red discoloration of plasma or serum (hemoglobinemia) can be seen in patients with intravascular hemolysis.

Cause of hemolysis is often suggested by history, physical examination, and other hematologic findings, but ancillary testing may be needed. The presence of autoagglutination, spherocytosis, or a positive direct Coombs test suggests immune-mediated hemolysis.[11] Finding numerous Heinz bodies indicates RBC injury from oxidant drugs or toxins (see Box 18-1). Red blood cell parasites, such as *Babesia* spp., hemotropic *Mycoplasma* spp., or *Cytauxzoon felis*, can sometimes be identified on stained blood smears, but specific immunodiagnostic or polymerase chain reaction (PCR) diagnoses are often required.[11] The presence of numerous RBC fragments (schistocytes) should prompt coagulation testing for disseminated intravascular coagulopathy (DIC) and further evaluation for other causes of microangiopathic hemolytic anemia. Additional evaluations in unexplained hemolytic anemia should include measurement of serum phosphorus for hypophosphatemic hemolysis and abdominal radiography to identify metallic gastrointestinal objects that might contain zinc. Genetic tests are available for some of the rare breed-specific hereditary RBC defects that can cause hemolytic icterus.[11]

Serum Bilirubin

Serum bilirubin concentration must usually exceed 2 to 3 mg/dL (35 to 50 µmol/L) before skin and mucous membranes become noticeably icteric. Although important as a laboratory finding, magnitude of the hyperbilirubinemia does not necessarily have prognostic significance nor does it help to distinguish between prehepatic, hepatic, and posthepatic causes of icterus.[1,8,13] Dry reagent and spectrophotometric methods are used to measure bilirubin. Serum bilirubin concentrations measured spectrophotometrically can be falsely elevated by up to 1 to 2 mg/dL in specimens that are severely lipemic or hemolyzed.[4] Fortunately, newer serum chemistry analyzers are less subject to this interference. Bilirubin is stable for 7 days in specimens refrigerated away from light at 4°C (39.2°F), but exposure to bright light can decrease bilirubin by 50% per hour.

Fractionation of total serum bilirubin into unconjugated (indirect-reacting) and conjugated (direct-reacting) forms in the van den Bergh reaction has little diagnostic value in dogs and cats and is no longer recommended.[1,8,13] Hematocrit and hematologic findings are more reliable for differentiating hemolytic and hepatobiliary icterus.[1] Ratios of bilirubin fractions in all three categories of icterus are unpredictable and do not readily discriminate between hemolytic, hepatic, and obstructive icterus.[1,8,13,14] Studies in dogs show that increased RBC turnover and decreased bilirubin clearance occur together in both hemolytic and hepatobiliary diseases.[8,14] Acute hemolysis is usually accompanied by secondary intrahepatic cholestasis, presumably resulting from hypoxia and oxidative stress.[8,13] This results in a mixed elevation in both unconjugated and conjugated bilirubin in hemolytic icterus. Dogs and cats with primary cholestatic hepatobiliary disease also develop mixed hyperbilirubinemia. Conjugated bilirubin that accumulates in canaliculi and hepatocytes is refluxed back into circulation while at the same time impaired conjugation increases circulating unconjugated bilirubin. This is coupled to increased erythrocyte turnover and a two- to fivefold increase in bilirubin production because of shortened erythrocyte survival time in the circulation. This may be related to instability of erythrocyte membranes in animals with hepatobiliary disease, and in some cases hypersplenism related to portal hypertension.[8,14]

Accumulation of biliprotein complexes in plasma can have variable reactivity on fractionation test procedures. In prolonged cholestasis and icterus, up to 90% of conjugated bilirubin can form irreversible covalent bonds to albumin as biliproteins.[15] The proportion of this tightly bound biliprotein is dependent on the duration and severity of cholestasis. Biliproteins are not filtered by the kidney and do not contribute to bilirubinuria. Disappearance of biliproteins from the circulation depends on the half-life of albumin (10 to 14 days), which can cause persistence of hyperbilirubinemia and icterus long after resolution of the underlying hepatobiliary disease.[15]

Urine Bilirubin and Urobilinogen

Conjugated bilirubin can be excreted by kidneys and detected qualitatively in urine using reagent strips (urine "dipsticks") or tablets (Ictotest; Ames).[1,16] Water-soluble conjugated bilirubin is more reactive than free bilirubin with these reagents. Bilirubinuria usually represents residual conjugated bilirubin that has been filtered by the kidneys but not reabsorbed by renal tubules. Bilirubin is unstable in urine at room temperature or with exposure to light, so urine should be evaluated within 30 minutes of collection or refrigerated at 2°C to 8°C (35.6°F to 46.4°F) in dark conditions.[16] The relative concentration of bilirubin in the urine increases with increasing urine specific gravity, yielding a more positive dipstick reaction than in dilute urine samples. A small amount of bilirubin is normally found in concentrated urine from healthy dogs, especially males, because dogs have a low renal threshold for bilirubin and because canine kidney can convert heme to bilirubin followed by conjugation and excretion.[6,16,17] Heme degradation and bilirubin conjugation by kidney is upregulated in dogs with intravascular hemolysis and hemoglobinuria. Bilirubin is not normally detectable in feline urine, so bilirubinuria in a cat is indicative of conjugated hyperbilirubinemia and hepatobiliary disease.[18]

Urobilinogen is a product of bilirubin degradation by intestinal bacteria. Approximately 20% of intestinal urobilinogen is absorbed into the enterohepatic circulation, and most of this is reexcreted by the liver except for a small amount of absorbed urobilinogen that is excreted in urine through glomerular filtration and tubular secretion.[7] In the past, urobilinogen in the urine has been used as evidence of an intact enterohepatic circulation and to rule out complete extrahepatic bile duct obstruction in icteric patients. However, formation of urobilinogen and its excretion in urine are affected by many other factors including the amount of conjugated bilirubin entering the intestine, activity of intestinal bacteria, intestinal transit time, and various urinary factors. Therefore, qualitative dipstick determination of urine urobilinogen is an unreliable marker of bilirubin metabolism and is not considered diagnostically useful.[1] Causes of spuriously low or negative urine urobilinogen results include abnormal intestinal transit (diarrhea), decreased intestinal bacterial activity (antibiotics), renal insufficiency, dilute urine, acidic urine, urine exposed to light, and urine samples left standing at room temperature.[1] Gastrointestinal hemorrhage can cause false positives, which can be misleading in animals with bile duct obstruction.

Other Serum Chemistry Parameters

In addition to hyperbilirubinemia, increased serum hepatic enzyme activities are expected in most patients with icterus. Increased serum alanine aminotransferase (ALT) and aspartate aminotransferase

(AST) activities reflect changes in hepatocyte membrane permeability, whereas increased serum alkaline phosphatase (ALP) and γ-glutamyltransferase (GGT) activities are a response to cholestasis. In general, hepatic enzymes are expected to be moderately to severely increased in hepatobiliary icterus and normal or only mildly increased in hemolysis, except when severe hemolytic events are complicated by intrahepatic cholestasis from anemic hypoxia, oxidative stress, and systemic inflammatory response. Generally, both ALP and GGT increase to comparable levels in cholestatic hepatic disease except in cats. Cats with idiopathic hepatic lipidosis may have increased ALP and a discordant GGT that remains normal or only minimally increased. Depending on disease and stage of progression, other biochemical abnormalities in cholestatic hepatic disease can include hypoalbuminemia, decreased blood urea nitrogen (BUN), hypercholesterolemia, and electrolyte abnormalities. Pre- and postprandial serum bile acid determinations are more sensitive than serum bilirubin for evaluating liver function in nonicteric dogs and cats. Serum bile acid testing is unnecessary in icteric patients without hemolysis because hyperbilirubinemia provides similar information.[1] The reader is referred to Chapters 25 and 61 for additional information on laboratory diagnostics in hepatic disease.

Other Laboratory Evaluations

Coagulation tests (e.g., activated partial thromboplastin time [aPTT], prothrombin time [PT], protein-induced vitamin K absence [PIVKA], thromboelastography) should be considered because coagulation abnormalities are common in icteric patients, especially with vitamin K–responsive coagulopathy in hepatobiliary icterus, and hypercoagulability or DIC in hemolytic icterus.[1,3] Pancreatic-specific lipase immunoassay (PLI) is indicated when pancreatitis is suspected as a cause of bile duct obstruction and in cats with cholangitis. It may be appropriate to evaluate for extrahepatic sepsis as a cause of functional cholestasis and to test for specific infectious diseases that can involve the liver or cause secondary hemolytic anemia. Older cats with evidence of liver disease should have baseline serum thyroxine concentration determinations to screen for underlying hyperthyroidism. Fluid analysis is important in icteric patients with abdominal effusion to identify neoplastic cells or evidence of gallbladder or bile duct rupture (bile peritonitis), such as the presence of bilirubin crystals or a higher bilirubin concentration in fluid than serum. Bacterial cultures of bile or hepatic specimens also can be helpful.[19]

Diagnostic Imaging

Diagnostic imaging procedures that are most often used for initial evaluation of the icteric patient are abdominal radiography and ultrasonography. Survey abdominal radiography can be used to evaluate liver size, identify abdominal masses or effusions, and detect calcified choleliths that might be a cause of extrahepatic biliary obstruction. In unexplained hemolytic icterus, abdominal radiographs are indicated for diagnosis of metallic objects in the gastrointestinal (GI) tract that could be a cause of zinc toxicosis.

Abdominal ultrasonography is a valuable noninvasive diagnostic tool for differentiating posthepatic biliary obstruction from intrahepatic parenchymal disease. Ultrasonography can be used to evaluate the hepatic parenchyma, bile ducts, and gallbladder, and to identify abdominal effusion (bile peritonitis).[12] Biliary obstruction, bile sludging, gallbladder mucocele, and cholelithiasis are readily identified with ultrasound.[20-26] Hepatic neoplasms, cysts, and abscesses are also usually easily detected. Ultrasonographic findings may also suggest parenchymal abnormalities such as lipidosis, cholangitis, cirrhosis, and lymphoma, or indicate portal hypertension.[12] Ultrasonography can also detect abnormalities in adjacent organs and structures such as the pancreas (carcinoma, pancreatitis), duodenum (neoplasia or foreign body obstructing the duodenal papilla), spleen, kidneys, and lymph nodes. Ultrasound-guided cytology specimens can be collected from any abnormal organ or structure in the abdomen, especially the liver, extrahepatic biliary system, and pancreas in icteric patients. Hepatobiliary nuclear scintigraphy is useful for diagnosing bile duct obstruction, but specialized facilities are needed.[27,28] Computed tomography (CT) and other advanced imaging techniques may be appropriate in some cases.

Hepatic Biopsy

Hepatic biopsy is the single most informative test in hepatic parenchymal disease and is usually required for definitive diagnosis of diseases such as hepatitis, cirrhosis, cholangitis, lipidosis, and neoplasia. Biopsy methods can include fine-needle aspiration (for cytology and culture); percutaneous needle biopsy ("blind" or ultrasound-guided); forceps biopsy by laparoscopy; or excisional biopsy by laparotomy. These procedures are described in Chapters 27, 28, and 61.

Treatment and Management

The appropriate treatment of the icteric patient depends on identifying and treating the underlying cause. In general, prehepatic and hepatic causes of icterus are treated medically, whereas some forms of posthepatic icterus may require surgical intervention.

General Principles

Although icterus is indicative of serious underlying hemolytic or hepatobiliary disease, increased concentrations of bilirubin in plasma, tissues, and urine are not considered to be detrimental in dogs and cats except in rare cases of extreme hyperbilirubinemia (>30 mg/dL) where bilirubin has the potential to injure the kidney or brain (kernicterus). Treatment is therefore directed at eliminating the cause of hyperbilirubinemia in most cases while allowing icterus to resolve on its own. Once the cause of hemolysis is identified and eliminated in patients with prehepatic icterus, erythrocyte turnover returns to normal, the accelerated or premature production of bilirubin ceases, and icterus resolves rapidly. In dogs and cats with hepatic icterus caused by intrinsic disease of the liver, treatment involves (a) specific medical therapy directed at underlying hepatic disease, (b) nonspecific adjunctive therapy with hepatoprotectant medications (see Chapter 46), and (c) therapy to prevent or control the complications of hepatic failure. Treatment of posthepatic icterus caused by extrahepatic bile duct obstruction often, but not always, requires surgical intervention to reestablish bile flow.

Medical

Treatment of hemolytic icterus depends on the inciting cause. In hemolytic crises induced by incompatible blood transfusions, medications, toxins, or envenomation, the hemolysis and icterus are usually self-limiting with supportive care and prevention of further exposure to the inciting factor. In patients with zinc toxicosis, metallic gastrointestinal foreign bodies that contain zinc are removed endoscopically or surgically. When hemolytic icterus is associated with specific erythrocytic infections, such as *Babesia* spp. or hemotropic *Mycoplasma* spp., treatment is aimed at eliminating the infection with appropriate antimicrobial agents. Treatment of icteric cats infected by *C. felis* is not usually successful. Immune-mediated hemolytic anemia is treated with corticosteroids and other

immunosuppressive agents that control immune destruction of erythrocytes, such as azathioprine, cyclosporine, mycophenolate mofetil, or leflunomide, and measures are taken to prevent thromboembolic complications.[11]

Treatments for specific hepatic diseases are described in Sections V and VI. In addition, nonspecific adjunctive medical therapy may be appropriate in cholestatic hepatic diseases. Ursodiol (ursodeoxycholic acid) is proposed to enhance bile flow and improve bile acid composition and water content of bile. The canalicular transport systems for excretion of bilirubin and bile acids are functionally different; however, bile acid excretion enhances bile flow which increases the maximum canalicular transport capacity for bilirubin.[29] This may justify use of ursodiol in nonobstructive icterus to enhance bilirubin excretion while reducing cholestatic hepatocellular injury caused by accumulation of hydrophobic bile acids. In addition, nutraceutical drugs (e.g., vitamin E [α-tocopherol], S-adenosylmethionine [SAMe], and Silybin) with hepatoprotective and antioxidant properties may be appropriate for icteric patients. Finally, medical therapy to prevent or control the complications of hepatic failure is used as needed (see Chapters 46 and 61). This can include nutritional support therapy and treatment for hepatic encephalopathy (diet, antibiotics, lactulose), ascites (diuretics), or gastrointestinal ulceration (proton pump inhibitors for acid control).

Surgical

Most patients with posthepatic obstructive icterus require surgical intervention to decompress the biliary obstruction and restore bile flow.[21,22,25,30-32] This often requires biliary diversion procedures such as cholecystoenterostomy. Choledochal stenting for decompression of extrahepatic biliary obstruction can also be effective.[33,34] When icterus is attributed to disease of the gallbladder (e.g., cholelithiasis, cholecystitis, gallbladder mucocele) treatment usually requires surgical gallbladder removal (cholecystectomy).[20,23,24,35-37] Icteric patients with bilious peritoneal effusion require abdominal surgery to identify and repair the ruptured gallbladder or bile duct and treat bile peritontis.[38]

CHAPTER 19

Polyphagia and Hyperphagia

Dorothy Laflamme

Definition

Polyphagia and hyperphagia are synonyms that refer to excessive food intake or overeating. Polyphagia may be considered pathologic (i.e., secondary to disease) whereas hyperphagia may be physiologic. Both reflect disturbances in normal appetite control. Differentiation and identification of the underlying cause is critical to proper treatment, controlling food intake, and managing body weight.

Appetite Control

Control over food intake and energy balance is regulated by multiple, redundant pathways. Hunger, or the drive to eat, is the dominant effect that is inhibited by various satiety signals. Neuronal and hormonal signals provide feedback to the brainstem and hypothalamic center that controls appetite.[1,2] Gastric and duodenal distention trigger inhibitory signals via the vagus nerve, reducing the desire for food. Gastrointestinal hormones (e.g., cholecystokinin, peptide YY) initiate a cascade effect that among other changes inhibits appetite. In addition hormones (e.g., insulin, glucagon-like peptide) suppress appetite, whereas insulin deficiency contributes to excessive food intake. These effects can be observed in patients with insulinoma and diabetes mellitus.

Gut hormones that promote food intake include ghrelin, which is stimulated by hypoglycemia. Multiple peripheral signals combine to stimulate release of hypothalamic orexigenic neuropeptides, neuropeptide Y, and agouti-related peptide, which promote food intake as well as decrease energy expenditure. Acting at the same hypothalamic neuroreceptor, melanocortins (α-melanocyte-stimulating hormone [MSH]) inhibit food intake and increase energy expenditure via stimulation of thyroid hormone and sympathetic nervous activity.[1,2] Glucocorticoids inhibit action of melanocortins and enhance appetite-stimulating effects of agouti-related peptide. Such polyphagia can be recognized in patients with hyperadrenocorticism.

Chronic regulation of energy intake is driven, in part, by adipose-derived substances such as leptin and adiponectin. The ultimate control over chronic regulation of energy balance and body weight is not fully known.

Disease and drugs can interfere with normal regulatory pathways, contributing to pathologic polyphagia. In addition, environmental and sensory factors can disrupt or override physiologic controls of appetite. Emerging research indicates that sensory properties of food and other pleasant factors involved with food intake stimulate parts of the forebrain recognized as "reward centers."[1-3]

Although the hypothalamus is the primary site for modulating hunger and satiety, the orbitofrontal cortex of the brain plays a key role in processing interacting sensory inputs including sight, smell, taste, and texture of food.[4,5] The forebrain, including the orbitofrontal cortex and nucleus accumbens, appears able to drive food intake despite a lack of hunger or physiologic need for food. Dopamine and opioid receptor pathways in the forebrain drive the desire for food reward, and ingestion of palatable food increases expression of opioid peptides.[3,4] Signals from this reward center can override satiety factors and stimulate food consumption.

Sensory-specific satiety is a decrease in appetite for a particular food rather than for food in general,[5] and is controlled by the orbitofrontal cortex. Recognition of sensory-specific satiety helps explain increased intake that often follows introduction of new foods or new flavors. Dogs and cats, like humans, tend to overeat when presented with a variety of foods.[6] After a time intake will decrease toward or even below energy needs, probably due to sensory-specific satiety as well as physiologic controls of energy balance. However, if novel foods are frequently introduced this stabilization does not take place, and the animal continues to gain weight.[7]

Stress and boredom are additional external factors that can increase food intake. Stress may stimulate appetite via increased release of endogenous corticosteroids or other orexigenic peptides.[8] The role of boredom is less understood but may increase appetite via forebrain mechanisms. Alternate, nonfood stimuli of the reward center may be helpful in managing this type of hyperphagia.

Differential Diagnosis

There are numerous causes of polyphagia and hyperphagia (Box 19-1). Polyphagia may be associated with weight loss, maintenance or gain, whereas physiologic hyperphagia is almost always associated with weight gain.

Evaluation of the Patient

History

Some common causes of hyperphagia can be identified on the patient's history. Pregnancy, lactation, outdoor housing in cold weather, or increases in exercise easily explain increased intake. Cold weather can increase energy requirements significantly. Neutering can cause an increase in food intake with associated weight gain. If no evidence exists to indicate pathologic polyphagia, a detailed dietary history may indicate physiologic or reward-driven hyperphagia (Fig. 19-1).

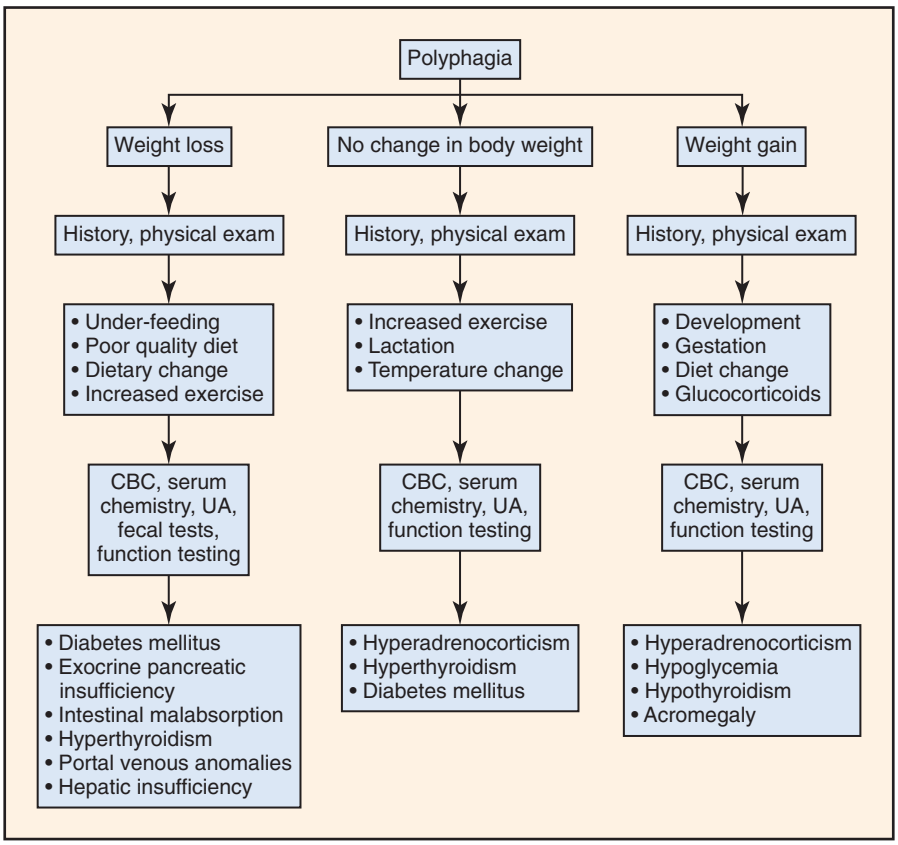

Figure 19-1 Diagnostic approach for the patient with polyphagia as the primary clinical sign. CBC, Complete blood count; UA, urinalysis.

Box 19-1 Common Causes of Hyperphagia and Polyphagia

Hyperphagia	Polyphagia
Cold weather	Diabetes mellitus
Exercise	Hyperadrenocorticism
Pregnancy or lactation	Hyperthyroidism
Neutering	Malabsorption syndromes
Reward driven	Exocrine pancreatic insufficiency
Stress	Drug induced
	Insulinoma
	Central nervous system diseases

Medical history should detect any recent changes in body weight. Polyphagia with weight loss is typically associated with diseases that decrease nutrient digestion and absorption or increase metabolism. Weight gain is common with drug-induced polyphagia (e.g., glucocorticoids) and conditions that increase food intake without altering energy metabolism. Other historical information critical in differentiation of polyphagia include evidence of drug use, polyuria/polydipsia, lethargy, diarrhea, and abnormal behavior (Table 19-1). Drugs recognized to induce polyphagia and weight gain include corticosteroids, anticonvulsants, some antihistamines and antidepressants.

Physical Examination

Physical examination may be normal or simply reflect abnormal body condition. Body weight change may not become manifested until late in the disease progression but is an important

Table 19-1 Differential Diagnoses for Polyphagia

Polyphagia and	Rule Out	Expect Weight
Polydipsia/polyuria	Diabetes mellitus	Loss
	Hyperthyroidism	Loss
	Acromegaly	Loss early/gain late
	Hyperadrenocorticism	Gain
	Sudden acquired retinal degeneration syndrome	Gain
Diarrhea	Exocrine pancreatic insufficiency	Loss
	Inflammatory bowel disease	Loss
	Malabsorption disorders	Loss
	Lymphangiectasia	Loss
	Intestinal parasites	Loss
	Hyperthyroidism	Loss
Ataxia	Central nervous mass lesion	Gain
	Insulinoma	Gain (loss in cats)
Vomiting or regurgitation	Megaesophagus	Loss
	Inflammatory bowel disease	Loss
	Antibiotic-responsive enteropathies	Loss

differentiating sign if present (see Fig. 19-1). Weight gain is common in physiologic hyperphagia, drug-induced polyphagia, and hyperadrenocorticism. Weight loss, especially with atrophy of lean body mass, suggests maldigestion or malabsorption of nutrients, compromised metabolism, or increased metabolic rate. Muscle wasting despite weight gain is suggestive of hyperadrenocorticism. Additional abnormalities may indicate specific underlying conditions. Abdominal palpation in animals with gastrointestinal disease may identify thickened bowel loops, abdominal effusions, masses, or abdominal pain.

Hyperthyroid cats usually have a palpable thyroid nodule and may have cardiac arrhythmias or a heart murmur. A potbellied appearance, symmetric alopecia, hyperpigmentation, and hepatomegaly are suggestive of canine hyperadrenocorticism. Acromegaly in cats and dogs is associated with broadened facial and body features plus prognathism. However, the insidious onset of these changes can make them difficult to recognize until very pronounced.

Central nervous system diseases causing polyphagia may cause ataxia or proprioceptive deficits. A complete neurologic examination should be performed to localize the lesion. Secondary neural signs may occur in patients with hypoglycemia due to insulinoma or hepatic encephalopathy (which rarely can cause polyphagia).

Laboratory Evaluation and Tests

If medical history and physical examination do not confirm a cause for polyphagia, diagnostic testing should be pursued based on clinical signs and weight loss or gain. In animals with polyphagia and weight loss but without other evidence of disease, fecal examination or empirical treatment with metronidazole or fenbendazole may first be attempted to treat presumed intestinal parasitism.

Initial laboratory testing should include hematology, serum biochemistry panel, and complete urinalysis. If gastrointestinal disease is suspected, eosinophilia may suggest undiagnosed intestinal parasites. Lymphocytopenia could be consistent with lymphangiectasia, as can be panhypoproteinemia (see Chapter 57). Chronic diarrhea, weight loss, and hypoproteinemia in the face of polyphagia are most consistent with small intestinal disease (see Chapter 57). Additional tests may be necessary to identify an underlying gastrointestinal cause of polyphagia. For example, intestinal biopsy can often diagnose inflammatory bowel disease or lymphangiectasia. Serum trypsin–like immunoreactivity is sensitive and specific for exocrine pancreatic insufficiency (see Chapter 60).

Endocrine causes of polyphagia can be differentiated on the basis on body weight changes and laboratory values. Hyperthyroidism and diabetes mellitus cause weight loss, while hyperadrenocorticism and insulinomas cause weight gain. Hyperthyroidism commonly produces a stress leukogram, elevations in hepatic enzyme activities, and high basal serum total thyroxine concentrations. Cats with mild hyperthyroidism may have total thyroxine (T_4) concentrations within the normal range, so repeated testing or measurement of serum free T_4 may be needed. Elevated fasting glucose plus polyuria, glucosuria, polyphagia, and weight loss strongly suggests diabetes mellitus. If preliminary findings suggest hyperadrenocorticism, increases in serum alkaline phosphatase, alanine transaminase, cholesterol, triglycerides, and mildly increased blood glucose might be observed. Glucosuria is uncommon but proteinuria common in dogs with hyperadrenocorticism. Specific testing for hyperadrenocorticism includes adrenocorticotropic hormone (ACTH) stimulation, low-dose dexamethasone suppression, and urine cortisol–creatinine tests. However, all of these tests can give false positives. Hypoglycemia with polyphagia is suggestive of insulinoma. Simultaneous, serial insulin and glucose measures or an amended insulin-to-glucose ratio test are used to confirm insulinoma.

Treatment and Management

Treatment varies with underlying disease. Correction of underlying pathology should resolve polyphagia. If underlying pathology cannot be determined or if a patient has drug-induced polyphagia but the drugs cannot be stopped, then weight management will depend on managing caloric intake.

Feeding a low-calorie, high-fiber diet in multiple small meals daily may aid in this regard. Dietary fiber promotes satiety via several routes, including gastric distention through physical bulk and water adsorption; delayed gastric emptying; reduced rate of intestinal transit; and slowed glucose absorption. This latter effect reduces postprandial fluctuations in glucose and insulin and their effects on hypothalamic satiety centers. High-protein diets also are recognized to enhance satiety, so they may be of value in polyphagic patients.[9]

In patients with physiologic hyperphagia and weight gain, client education is needed to alter feeding and behavioral conditions. Palatable foods upregulate expression of hunger signals while blunting the response to satiety signals and activating the "reward" system. Frequent changes in diet (e.g., new flavors, adding flavoring agents or table scraps or other encouragements) contribute to overeating; therefore, these practices should be halted. High-fiber, high-protein, and low-calorie diets can be used to aid satiety while reducing caloric intake and body weight.

CHAPTER 20

Polyuria and Polydipsia

David J. Polzin

Definition

Polyuria (PU) is defined as excessive urine production and is confirmed by demonstrating that daily urine production exceeds the upper limit of normal. In dogs, daily urine volume should normally not exceed approximately 50 mL/kg/day.[1] Normal daily urine volume is lower in cats. Frequency of voiding is not incl uded in the definition of PU and may be normal or increased in patients with PU. It is essential that PU not be confused with pollakiuria, the frequent voiding of small quantities of urine.

Polydipsia (PD) is consumption of water in excess of the upper limit of normal daily intake. Normal water intake in dogs is usually less than 60 mL/kg/day with an upper limit of 100 mL/kg/day.[1] Because water consumption is easier to measure, it is often used to confirm PD. However, environmental and behavioral factors (e.g., ambient temperature, activity of the animal) may markedly alter water consumption in dogs and should be considered in interpreting these measurements.[2] Normal values for water intake are likely substantially less in cats, but a well-defined cutoff value has not been established.

Diagnosis of PU or PD should ideally be confirmed by measuring water intake and/or urine production rate. Because water intake is more easily and accurately measured than urine output, confirmation of PU or PD is often made by measuring daily water intake. Although PD is usually a reliable surrogate for confirming PU or PD, increased water loss via nonurinary pathways (e.g., diarrhea) may be associated with PD absent PU.

Polyuric patients should have reduced urine specific gravity values; therefore, urine concentration is often used as a surrogate for confirming PU. Patients that persistently produce urine less concentrated than expected (i.e., <1.030 for dogs and <1.035 for cats) should be evaluated for a possible pathologic defect in urine-concentrating ability.[3] In dogs, urine samples obtained in the morning immediately upon arising are typically the most concentrated and thus provide a more reliable estimate of urine concentrating ability.[4] Urinalysis should be performed to determine urine concentration in any patient in which the owner reports increases in water intake or urination, regardless of whether the actual measured water intake exceeds the upper limit for PD. Patients with documented PD that have concentrated urine should be evaluated for nonurinary water losses.

Pathophysiology and Mechanism

General Mechanisms Affecting Water Intake and Urine Volume

Urine concentration and water consumption (thirst) are controlled by interactions between kidneys, pituitary gland, and hypothalamus. Plasma osmolality (primarily sodium concentration) is the primary parameter monitored by this control system. Ingestion of a water load decreases plasma osmolality, while water loss from the body (by any route) increases plasma osmolality. Alterations in plasma osmolality are sensed by receptor cells (i.e., osmoreceptors) in the hypothalamus that affect water intake (via thirst) and excretion (via antidiuretic hormone acting on the kidneys). This system maintains plasma osmolality within a very narrow range.

The normal response to a water load is suppression of antidiuretic hormone (ADH) and thirst. In the absence of ADH, the renal collecting tubules are impermeable to reabsorption of water. In this setting, hypoosmotic tubular fluid leaving the loop of Henle does not equilibrate with renal medullary interstitium resulting in dilute urine, thus allowing elimination of the water load. When PU or PD results from excessive water consumption, plasma osmolality and sodium concentration tend to trend toward the lower end of the normal range.

Correction of a water deficit requires intake and retention of exogenous water. This occurs through increasing thirst and release of ADH in response to an increase in plasma osmolality. Thirst is the primary defense against hyperosmolality. In response to ADH, further loss of water by kidneys is minimized by transient insertion of water-permeable channels (i.e., aquaporin-2) into membranes of renal collecting tubules, thus allowing water to move along its osmotic gradient from lumen of collecting tubules into the hypertonic medullary interstitium producing concentrated urine. When PU or PD results from a defect in urine concentrating ability, plasma osmolality and sodium concentration may trend toward the higher end of the normal range.

In contrast, isoosmotic fluid loss (e.g., many gastrointestinal and urinary fluid losses) typically reduces effective circulating volume without altering plasma osmolality. This decline in effective circulating volume is termed *volume depletion* rather than dehydration. With volume depletion, both sodium and water retention are needed to correct the volume deficit. Sensors and response system

for maintaining effective circulating volume are predominantly focused on modifying renal sodium handling; fluid volume is regulated because water is retained or excreted with sodium.[5] Factors active in this process include the renin–angiotensin–aldosterone system, atrial natriuretic peptide (ANP), ADH, and activation of thirst.

Water Balance and Polyuria and Polydipsia

In the steady state, water intake must equal water output. Water intake includes ingested water, water obtained from food, and water generated endogenously through oxidation of carbohydrates, proteins, and fat. Water output is the sum of urine volume and "insensible losses," which includes water contained in stool as well as evaporative losses from the skin and respiratory tract. These insensible losses typically account for approximately 20 to 25 mL/kg/day; however, they may increase with diarrhea, tachypnea, or increased ambient temperature.[6] When insensible losses increase, water intake may increase without a coincident increase in urine volume.

Urine volume is related to water intake, obligatory solute excretion, and urine-concentrating ability. If water consumption increases or the quantity of solute to be excreted increases (e.g., diabetes mellitus or administration of mannitol), urine volume will increase. Furthermore, as capacity to concentrate urine declines, volume of urine required to excrete the same solute load will increase. For example, if maximum urine concentration is 600 mOsm/L, it will require 500 mL to excrete a solute load of 300 mOsm. However, if the maximum urine concentration is 300 mOsm/L, it will require 1 L to excrete 300 mOsm. This resultant increase in urine volume requires a compensatory increase in water intake.

General Mechanisms Promoting Primary Polyuria

Ability to conserve or excrete water requires (a) the ability to manufacture and appropriately secrete ADH, (b) maintenance of an appropriately hypertonic renal medulla (i.e., functional renal countercurrent mechanism), and (c) ability of kidneys to respond appropriately to ADH when present. Disruption of any of these processes may cause PU. In addition, an excess of nonreabsorbable solute in the glomerular filtrate and renal tubules (e.g., glucosuria in diabetes mellitus or with mannitol infusion) may also impair the urine-concentrating mechanism. In osmotic diuresis, medullary blood flow is enhanced by an unknown mechanism. This results sequentially in decreased renal papillary osmolality and an elevation in both urine volume and sodium excretion, primarily because of a fall in water reabsorption in the descending limb of the loop of Henle and sodium reabsorption in the ascending limb of the loop of Henle. PU may also occur when the thirst center in the anterior hypothalamus is stimulated resulting in PD. Thus, PU may result from four mechanisms: (a) inadequate production of functional ADH (i.e., central diabetes insipidus), (b) lack of appropriate renal response to ADH (i.e., nephrogenic diabetes insipidus), (c) osmotic diuresis, or (d) primary PD. In the first three of these mechanisms, PU is primary and PD is secondary or compensatory. In the last, PD is primary and the PU occurs as a secondary compensation to eliminate excess water consumed. Combinations of these various mechanisms may occur together in the same patient.

Differential Diagnosis

Table 20-1 summarizes various recognized causes of PU and PD. Many of the causes of PU or PD present with other clinical signs or laboratory abnormalities, which readily facilitate their diagnosis (Table 20-2). In most instances, the cause for PU or PD can be determined from information gathered from history, physical examination, a complete blood count, serum chemistry profile, and urinalysis. The most common causes of PU and PD in dogs include renal disease, hyperadrenocorticism, and diabetes mellitus, whereas the most common causes of PU in cats include renal disease, hyperthyroidism, and diabetes mellitus. Gastrointestinal disease and gastrointestinal leiomyosarcoma have been linked to PU and PD.[7-9] Figure 20-1 is an algorithmic approach to diagnosis.

Evaluation of the Patient

History

Before searching for a cause, the presence of PU or PD should be confirmed. A thorough history of the patient's drinking and urinating habits should be obtained. In particular, PU must be differentiated from pollakiuria (i.e., an abnormal increase in the frequency of urination). Patients with PU void large volumes of urine with relatively normal to moderately increased frequency of urination. In contrast, patients with pollakiuria void small quantities of urine at increased frequency. In addition, pollakiuria is often associated with other signs of lower urinary tract disease such as dysuria and stranguria. In rare instances, patients may simultaneously have both PU and pollakiuria. When PU and pollakiuria occur together, they may be of different origins (e.g., PU caused by diabetes mellitus and pollakiuria caused by concurrent urinary tract infection) or emanate from the same condition (e.g., urinary tract infection affecting the kidney causing PU and the bladder causing pollakiuria). Quantifying daily water intake will help support or refute the presence of PD. PU and PD may be confirmed by measuring 24-hour water intake or urine output; however, a 3- to 5-day collection period is recommended to increase reliability. In dogs, daily water consumption in excess of 100 mL/kg confirms PD. Normal water intake for cats is substantially less, but a precise upper limit has not been established. Alternatively, measuring urinary specific gravity may provide evidence of adequate urine-concentrating ability (dogs, 1.030; cats, 1.035), thus providing evidence against PU or PD. However, urine specific gravity values persistently below 1.030 in dogs or 1.035 in cats should be pursued as possible evidence of a defect in urine-concentrating ability, even when daily water intake does not confirm PU or PD.

A complete drug and diet history should be obtained to rule out the possibility of iatrogenic causes for PU or PD. Drugs that may promote PU or PD include diuretics, systemic or topical corticosteroids, and some anticonvulsant medications (e.g., phenobarbital, phenytoin). Diets designed for urolith dissolution or prophylaxis typically promote increased water intake and urine volume because of their high salt and low-protein content. Canned and high-salt diets may be associated with an increase in urine production while dogs and cats consuming dry diets may consume more water because they receive little dietary water; however, their urine volume is typically normal.

Onset, duration, and magnitude of change in water intake and urine volume as well as presence or absence of other clinical signs are of great value in delineating the causation of PU or PD. The patient's species, age, sex (including neutered versus intact), and breed may also provide clues to possible causes for PU or PD. Patients with PU or PD often, but not always, present with clinical signs providing clues to the underlying causes responsible for PU or PD (see Table 20-2). Conditions that may be characterized by PU or PD alone include mild kidney disease (e.g., stages I and II chronic kidney disease [CKD]), pyelonephritis, hyperadrenocorticism, hypercalcemia, leptospirosis, central diabetes insipidus,

Table 20-1 Ruleouts for Polyuria and Polydipsia in Dogs and Cats

Ruleout for PU and PD	Additional Tests Supporting Diagnosis
Renal disease	Glomerular filtration rate (GFR) measurement (creatinine or iothalamate clearance), imaging (ultrasound, radiographs)
Pyelonephritis	Urine culture, renal imaging (ultrasound, excretory urography), pyelocentesis (culture, cytology)
Leptospirosis	Serology and/or polymerase chain reaction (PCR)
Chronic partial urinary obstruction	Urinary tract imaging (ultrasound, contrast radiography)
Renal glucosuria or Fanconi disease	Fractional urinary excretion studies (urine amino acids, bicarbonate, glucose, magnesium, phosphate, potassium, sodium)
Primary nephrogenic diabetes insipidus	Failure to respond to ADH (usually an exclusion diagnosis, typically a congenital disorder)
Postobstructive diuresis	Evidence of recent urinary obstruction, serial declines in serum creatinine and urea nitrogen concentrations
Renal medullary solute washout	Seek underlying cause, response to gradual partial water deprivation
Diabetes mellitus	Serum fructosamine concentration
Hyperadrenocorticism	Adrenocorticotropic hormone (ACTH) response test or low-dose dexamethasone suppression test
Hyperthyroidism (cats)	Free thyroxine (T_4) by equilibrium dialysis, thyroid scan
Hypoadrenocorticism	ACTH response test
Primary hyperaldosteronism	Plasma aldosterone, plasma aldosterone-to-renin ratio, oral fludrocortisone suppression test (urinary aldosterone-to-creatinine ratio)
Central diabetes insipidus	ADH response test, water-deprivation test, imaging (magnetic resonance imaging [MRI] or computed tomography [CT])
Acromegaly	Feline plasma growth hormone concentration (± available), insulin-like growth factor-I concentrations, MRI or CT of the pituitary fossa
Pheochromocytoma	Blood pressure, abdominal ultrasound, urine catecholamine concentrations
Hypercalcemia	Blood ionized calcium concentration
Hypokalemia (marked)	
Hyponatremia (marked)	
Hepatic failure	Fasting and postprandial serum bile acids, imaging (ultrasound, radiographs)
Portosystemic shunt	Fasting and postprandial serum bile acids, imaging (abdominal ultrasound, portography, rectal scintigraphy)
Leiomyosarcoma	Imaging, endoscopy, biopsy
Gastrointestinal disease	Imaging, endoscopy, biopsy
Pyometra	Imaging (ultrasound, radiographs)
Polycythemia	
Pericardial effusion	Echocardiogram
Psychogenic (primary) PD	Multiple urine specific gravity determinations, ADH response test, water-deprivation testing
Paraneoplastic	Imaging (radiographs, ultrasound, CT or MR)
Sudden acquired retinal degeneration syndrome (SARDS)	Retinal examination, electroretinogram
Iatrogenic	

ACTH, Adrenocorticotropic hormone; ADH, anti-diuretic hormone; CT, computerized tomography; GFR, glomerular filtration rate; MRI, magnetic resonance imaging; PCR, polymerase chain reaction; PD, polydipsia; PU, polyuria; SARDS, sudden acquired retinal degeneration syndrome; T_4, thyroxine.

primary (psychogenic) PD, and renal tubular dysfunctions (e.g., primary renal glucosuria, Fanconi syndrome, nephrogenic diabetes insipidus). Note that some diseases may first manifest as only PU or PD, so absence of overt clinical signs do not rule out causes for PU or PD. For example, many dogs with hyperadrenocorticism-associated PU or PD do not present with typical cutaneous lesions.

Physical Examination

A thorough physical examination including assessment of neurologic status, retinal examination, and determination of blood pressure may facilitate identification of the cause for PU or PD. In many patients, physical examination can provide important clues that guide the diagnostic search for underlying causes for PU or PD (see Table 20-2). In addition, assessment of hydration and circulating volume status of the patient is essential to interpretation of renal function and urine specific gravity (urine concentrating ability).

Laboratory Evaluation and Tests

Urinalysis

Urinalysis can provide evidence of a urine-concentrating defect and may also help delineate the cause of PU or PD. Determining the urine specific gravity on several occasions helps define what is typical for this patient. Because urine is most likely to be maximally concentrated first thing in the morning in dogs, urine samples should be obtained at this time if possible.[4]

Urine specific gravity values above 1.030 in dogs and 1.035 in cats are generally inconsistent with PU or PD, although it does not exclude the possibility of intermittent PU or PD. In patients with dehydration or extracellular fluid volume contraction, urine should be adequately concentrated unless ADH activity is inappropriately low, the kidneys are unable to respond to ADH, or an osmotic diuresis is present. Patients with PU or PD will most often have urine specific gravity values between 1.001 and 1.025. The presence of osmotically active substances such as glucose,

Table 20-2 Medical History and Physical Examination Findings Providing Clues to Possible Causes for Polyuria and Polydipsia

Clinical Finding	Possible Ruleouts
Weight loss	Kidney disease, diabetes mellitus, hyperthyroidism, pyelonephritis, malignancy-induced hypercalcemia, hypoadrenocorticism, hepatic disease, pyometra
Polyphagia	Diabetes mellitus, hyperthyroidism, hyperadrenocorticism, acromegaly
Decreased appetite	Kidney disease, pyelonephritis, malignancy-induced hypercalcemia, hepatic disease, hypoadrenocorticism
Vomiting	Kidney disease, hypoadrenocorticism, pyelonephritis, hepatic failure, hypercalcemia, hypokalemia, hyperthyroidism, diabetes mellitus, consumption of excess water
Malaise and/or weakness	Kidney disease, hypoadrenocorticism, pyometra, hypercalcemia, diabetes mellitus, hepatic disease, hypokalemia, hyperadrenocorticism
Behavioral or central nervous system (CNS) signs (seizures, ataxia, stupor, blindness)	Hepatic failure, primary PD, central diabetes insipidus, hyperadrenocorticism, acromegaly, sudden acquired retinal degeneration syndrome (SARDS)
Marked PU or PD	Primary PD, central diabetes insipidus, congenital nephrogenic diabetes insipidus
Middle-aged female, recent estrus	Pyometra
Bilateral alopecia, skin disease	Hyperadrenocorticism or other endocrinologic disorders
Abdominal distention	Hepatic failure, hyperadrenocorticism, pyometra, nephrotic syndrome, bladder enlargement caused by PU
Hepatomegaly	Hyperadrenocorticism, diabetes mellitus, hepatic disease
Small kidneys	Chronic or congenital kidney disease
Hypertension, hypertensive retinopathy	Chronic kidney disease (CKD), hyperthyroidism, diabetes mellitus, hyperadrenocorticism
Uremic breath, uremic stomatitis	Kidney disease
Thyroid or neck mass	Hyperthyroidism, hyperparathyroidism, CKD
Heart murmur	Hyperthyroidism, CKD, acromegaly
Panting, tachypnea	Hyperadrenocorticism, hyperthyroidism, mediastinal mass (lymphoma), pheochromocytoma

CKD, Chronic kidney disease; CNS, central nervous system; PD, polydipsia; PU, polyuria; SARDS, sudden acquired retinal degeneration syndrome.

mannitol, or radiocontrast agents is often associated with urine specific gravity values at the higher end of this range and sometimes above 1.025.

Urinalysis may also provide evidence of the underlying cause for PU or PD. Urine chemistries may reveal evidence of glucosuria, bilirubinuria, or proteinuria. Urine sediment examination may reveal evidence of white blood cells, bacteria, crystals, or casts.

The Minimum Database and Additional Testing

A minimum database consisting of medical history, physical examination, urinalysis, serum chemistry profile, and a complete blood count should be routinely performed on patients with PU or PD. In middle-aged to older cats, a thyroxine (T_4) test should also be considered part of the minimum database. In many instances, this minimum database is sufficient to identify likely causes for PU or PD and further diagnostic tests may be pursued based on these findings (see Tables 20-1 and 20-2).

In both dogs and cats where the minimum database fails to localize the cause of PU or PD, a urine culture should be performed to rule out pyelonephritis. In dogs where the initial database fails to identify the cause for PU or PD, a leptospirosis titer or polymerase chain reaction (PCR) should be included (if locally endemic), and a screening test for hyperadrenocorticism should be considered for middle-aged to older dogs.

Water Deprivation and Antidiuretic Hormone Response Testing

Water deprivation is not indicated as part of the minimum database for patients with PU or PD and should generally be reserved for use only when all other reasonable diagnostic ruleouts have been excluded. As a general rule, water should not be withheld from patients with PU or PD of undetermined origin. When indicated, water deprivation testing should be performed under close supervision because patients with profound PU or PD may dehydrate rapidly (i.e., over several hours). It should never be performed by withdrawing water from the patient overnight. Mechanics of performing water deprivation are described elsewhere.[1,6]

Water deprivation is primarily indicated for differentiating primary PD from central diabetes insipidus (or, rarely, congenital nephrogenic diabetes insipidus) in patients with profound PU or PD and dilute urine. Urine specific gravity values persistently below 1.005 are suggestive of central diabetes insipidus, primary nephrogenic diabetes insipidus (congenital), or primary PD. Occasionally, patients with hyperadrenocorticism or hepatic failure may have urine specific gravity values in this range. It is recommended that water deprivation testing be reserved for patients suspected to have primary PD (see Fig. 20-1). Serum sodium concentration may help differentiate primary PD from primary PU in that the serum sodium concentrations often trend toward the low end of the normal range with primary PD (i.e., dilution induced by drinking of electrolyte-free water). In contrast, serum sodium typically trends from the midrange to high end of the normal range in patients with primary PU and secondary PD.

The goal of water deprivation testing is to stimulate maximum release of endogenous ADH to determine if normal concentration mechanisms are functioning. It is contraindicated in dehydrated patients and azotemic patients. Patients with primary PD should have the capacity to produce concentrated urine when water intake is withheld. However, results of this test may be clouded by

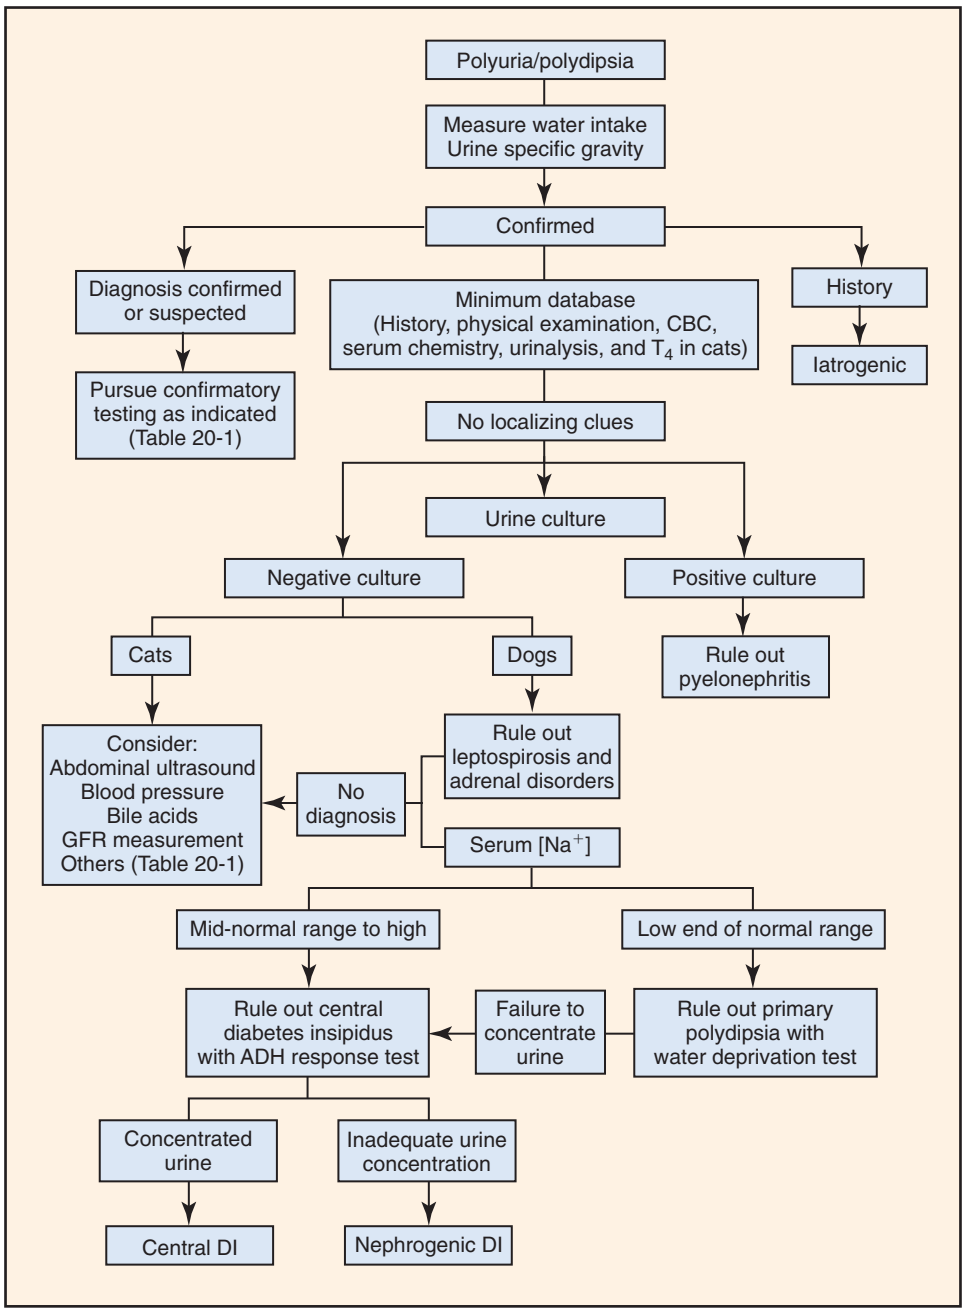

Figure 20-1 Algorithm demonstrating the diagnostic sequence recommended for establishing the diagnosis of PU and/or PD in dogs and cats. Tables 20-1 and 20-2 provide supplemental information useful in applying the algorithm to patients. ADH, Anti-diuretic hormone; CBC, complete blood count; DI, diabetes insipidus; GFR, glomerular filtration rate; T_4, thyroxine.

long-standing PU or PD where washout of renal medullary solute may limit the degree of urine concentration.

At the end of the water-deprivation test, water should be provided and an ADH analogue (e.g., desmopressin [DDAVP]) administered. If the patient has central diabetes insipidus, water deprivation should not result in urine concentration, but the urine should become concentrated after administration of ADH. However, as with primary PD, renal medullary washout may result in a less-robust increase in urine concentration.

An alternative to water-deprivation testing is to provide an ADH analogue to the patient for several days to determine if the urine becomes concentrated. If the urine becomes concentrated, the results suggest central diabetes insipidus. However, they do not completely exclude primary PD. A small risk with this approach is that exogenous administration of ADH will limit the ability to excrete water, and water intoxication may develop if the patient has primary PD and continues to drink excessively,.

Treatment and Management

General Principles

Polyuria and PD are often among the earliest clinical signs revealing presence of disease responsible for PU or PD (see Table 20-1). As such, treatment or management of PU or PD is usually directed at the primary disease responsible for PU or PD. For example, PU or PD caused by feline hyperthyroidism is managed by correcting

the hyperthyroid state. However, it may be impossible to eliminate the primary disease or defect in urine concentrating ability for some causes of PU or PD. For example, urine concentrating capacity cannot be restored for patients with chronic renal disease. In such instances, symptomatic treatment for PU or PD or its consequences may be desirable. Complications of PU or PD that may prompt consideration of symptomatic relief of PU or PD may include inappropriate voiding, nocturia, PU-associated litter box issues, or urinary incontinence.

Serious medical consequences are rare in patients with PU or PD if free access to water is available and the patient is willing and able to drink. Until the mechanism of PU has been established, owners should be discouraged from limiting access to water. In patients where PU or PD is driven by primary PU, dehydration and serious systemic consequences may develop when access to water is limited. If the patient is vomiting or other conditions limiting oral intake are present, fluids may need to be administered parenterally. Administration of parenteral fluids may also be required when dehydration persists despite ongoing PD.

Medical

Although medical therapy for PU or PD is generally directed at the underlying cause, in some conditions the primary cause for PU or PD cannot be eliminated and a defect in urine concentrating ability persists. In patients with limited urine concentrating ability, quantity of urine produced is largely determined by quantity of solute excreted in the urine. This is because solute excretion can only be increased by increasing urine concentration or increasing volume of water in which the solute is dissolved. However, by reducing the quantity of solute to be excreted, the magnitude of PU or PD can be diminished. This reduction in solute may be accomplished either by reducing the quantity of solute resulting from dietary intake or by reducing the quantity of sodium delivered to the distal nephron by enhancing proximal renal reabsorption of sodium. Potential benefits of such therapy may be to reduce magnitude of PU as well as its clinical consequences (e.g., nocturia, inappropriate voiding, litter box issues, urinary incontinence, PD).

Principal solutes present in urine are urea and sodium (salt). In patients with chronic renal disease, the magnitude of PU or PD may be reduced by feeding a diet containing reduced quantities of protein (the metabolic precursor of urea) and salt. However, this approach to management of PU or PD is only likely to be effective in patients where at least part of the mechanism of PU or PD is solute diuresis. Such patients typically have urine specific gravity values that are isosthenuric (1.008 to 1.012) or greater. In patients with congenital nephrogenic diabetes insipidus, magnitude of PU may be reduced by administration of thiazide diuretics, which induces a small degree of volume contraction. This in turn promotes enhanced proximal renal tubular reabsorption of sodium and water.

CHAPTER 21

Regurgitation

Robert J. Washabau

Definition

Regurgitation is the most important clinical sign of esophageal disease and should be differentiated from *dysphagia* and *gagging* of more proximal gastrointestinal disorders, and from vomiting of more distal gastrointestinal disorders. Regurgitation differs from *vomiting* in that it is characterized by the passive retrograde evacuation of undigested food from the esophagus. *Vomiting* is characterized by coordinated activities of the gastrointestinal, musculoskeletal, and nervous systems culminating in active evacuation of digested or partially digested food from the gastrointestinal tract.[1] *Vomiting* usually signifies disease caudal to the gastroesophageal sphincter. Severity of clinical signs with esophageal disease is dependent upon the pathogenesis of the disease. For example, animals with vascular ring anomaly may have severe regurgitation, but the appetite is usually excellent because of secondary malnutrition. On the other hand, animals with inflammatory esophageal disease may have *anorexia*, *dysphagia*, *odynophagia* (pain on swallowing), and *salivation* without much evidence of regurgitation. The latter group clearly presents a diagnostic challenge because of the differing clinical signs. For example, signs referable to aspiration pneumonia, *coughing* and *dyspnea*, may be the major presenting complaint in some animals. A good history usually elicits the other signs of esophageal disease in those patients.

Pathophysiology and Mechanisms

Transport of ingested liquids and solids from oral cavity to stomach is the major function of the esophagus. Anatomic structures that permit this function are striated muscle of the cranial esophageal sphincter (cricopharyngeus), striated and smooth muscle of the esophageal body, and smooth muscle of the caudal esophageal (gastroesophageal) sphincter. An important species difference between dogs and cats is in the musculature of the esophageal body. The full length of the canine esophageal body is composed of striated muscle, whereas the distal one-third to one-half of the feline esophageal body is composed of smooth muscle. Striated muscle of the cranial esophageal sphincter and esophageal body is innervated by somatic branches (glossopharyngeal, pharyngeal, and recurrent laryngeal) of the vagus nerve arising from the brainstem nucleus ambiguus. Smooth muscle of the esophageal body and caudal esophageal sphincter is innervated by autonomic branches (esophageal) of the vagus nerve arising from the dorsal motor nucleus of the vagus (see Figure 13-1).[2]

Anatomic and physiologic differences in canine and feline esophagus have been highlighted in several previous studies.[3-6] During fasting elevated pressures of the cranial and caudal esophageal sphincters prevent movement of food and chyme into the esophageal body from the oral cavity and stomach, respectively. When an animal swallows the cranial esophageal sphincter relaxes to permit movement of liquids and solids into the proximal esophageal body. Swallowing also initiates a wave of peristaltic contractions (primary peristalsis) in the esophagus that transports food into the distal esophageal body. Primary peristaltic contractions are reinforced by a secondary wave of contraction (secondary peristalsis) physiologically mediated by intraluminal distention. The caudal esophageal sphincter relaxes in advance of the propagated pressure wave to permit food to empty into the stomach. Once the bolus of food has passed into the stomach, the caudal esophageal sphincter resumes its high resting pressure.

Inflammation (esophagitis, gastroesophageal reflux, esophageal fistulae), *hypomotility* (idiopathic megaesophagus, dysautonomia, diverticula), and *obstruction* (stricture, hiatal hernia, neoplasia, intussusception, foreign bodies, vascular ring anomalies) are the major pathophysiologic processes involving the esophagus of dogs and cats.[7] With mild esophagitis and hypomotility lesions, the esophagus may undergo healing without further complication. In more severe cases the esophagus may respond with extensive fibrosis, muscular hypertrophy, esophageal narrowing, and/or loss of neural regulation (i.e., flaccidity). Luminal flow is directly related to the fourth power of esophageal radius so that even small diminutions result in significant reductions in esophageal transit.

Differential Diagnosis

Esophagitis

Esophagitis is an acute or chronic inflammatory disorder of esophageal mucosa that occasionally involves underlying submucosa and muscularis. It most often results from chemical injury from swallowed substances, esophageal foreign bodies, or gastroesophageal reflux. Esophageal mucosa has several important barrier mechanisms to withstand caustic substances, including stratified squamous epithelium with tight intracellular junctions, mucus gel, and surface bicarbonate ions. Disruption of these barrier mechanisms results in inflammation, erosion, and/or ulceration of the underlying structures.[8]

Gastroesophageal Reflux

Gastroesophageal reflux is a disorder of the caudal esophageal sphincter permitting reflux of gastrointestinal fluids or ingesta into the esophagus. Varying degrees of esophagitis result from prolonged contact of gastric acid, pepsin, trypsin, bile salts, and duodenal

bicarbonate with esophageal mucosa. The frequency of reflux and composition of the refluxed material determines the severity of the esophagitis. Gastric acid alone produces a mild esophagitis, whereas combinations of acid and pepsin or trypsin, bicarbonate, and bile salts produce a severe esophagitis.[9]

Esophageal Fistulae

An esophageal fistula is an abnormal communication between the esophagus and adjacent structures. Most esophageal fistulae involve the lungs or airway structures (e.g., esophagopulmonary, esophagobronchial, or esophagotracheal fistulae). Occasionally, esophageal fistulae expand into the pleural space or cervical tissues.

Idiopathic Megaesophagus

Idiopathic megaesophagus is the most common cause of regurgitation in the dog.[10] Aside from dysautonomia, megaesophagus is a rare finding in the domestic cat. The disorder is characterized by esophageal hypomotility and dilation, progressive regurgitation, and loss of body condition. Several forms of the syndrome have been described, including congenital, acquired secondary, and acquired idiopathic megaesophagus.

Dysautonomia

Dysautonomia is a generalized autonomic neuropathy that was originally reported in cats in the United Kingdom, but that has now been documented in dogs and cats throughout Western Europe and the United States.[11,12] Clinical signs reflect a generalized autonomic dysfunction but megaesophagus, esophageal hypomotility, and regurgitation are fairly consistent findings. Pathologically, degenerative lesions are found in autonomic ganglia, intermediate gray columns of the spinal cord, and some sympathetic axons. No definitive etiology has ever been established despite an intensive search for genetic, toxic, nutritional, and infectious etiologic agents.

Esophageal Diverticula

Esophageal diverticula are circumscribed sacculations in the esophageal wall that interfere with normal esophageal motility patterns. Both congenital and acquired forms have been described. Congenital diverticula have been attributed to abnormalities in embryologic development that permit herniation of mucosa through a defect in the muscularis. Acquired diverticula are subdivided into either traction or pulsion forms, depending upon pathogenesis. Traction diverticula tend to develop in the cranial and midesophageal body and result from periesophageal inflammation and fibrosis. Adhesions to adjacent tissue (e.g. lung, bronchus, lymph node) distort the esophageal lumen and create sacculations. Abscess development from grass awn migration is a common cause of traction diverticula in the western United States. Pulsion diverticula develop in association with increases in intraluminal esophageal pressure, abnormal regional esophageal motility, or when normal peristalsis is obstructed by a stenotic lesion.[13]

Esophageal Stricture

Esophageal stricture is an abnormal narrowing of the esophageal lumen. The most important etiologies of stricture are chemical injury from swallowed substances, esophageal foreign bodies, esophageal surgery, and intraluminal or extraluminal mass lesions (neoplasia or abscesses). Anesthesia, poor patient preparation, and poor patient positioning during anesthesia place some animals at risk for gastroesophageal reflux, esophagitis, and subsequent stricture formation.[14] Cats appear to be particularly susceptible to doxycycline-associated esophagitis and esophageal stricture.[15]

Hiatal Hernia

Two types of hiatal hernia have been recognized in the dog and cat: (a) sliding hiatal hernia, in which the abdominal segment of the esophagus and parts of the stomach are displaced cranially through the esophageal hiatus; and (b) paraesophageal hiatal hernia, in which the abdominal segment of the esophagus and caudal esophageal sphincter remain in a fixed position but a portion of the stomach herniates into the mediastinum alongside the thoracic esophagus. Sliding hiatal hernia is the most common form and may occur as a congenital or acquired lesion in the dog and cat.

Esophageal Neoplasia

Esophageal cancer accounts for less than 0.5% of all cancers in the dog and cat.[13] Tumors of the esophagus may be of primary esophageal, periesophageal, or metastatic origin. The most common primary esophageal tumors in the dog are osteosarcomas and fibrosarcomas, particularly in areas of *Spirocerca lupi* endemicity. *Spirocerca* esophageal granulomas may undergo metaplastic or neoplastic transformation to fibrosarcomas and osteogenic sarcomas. Squamous cell carcinoma is the most common primary esophageal tumor in the cat. Less commonly reported primary esophageal tumors of the dog and cat include leiomyo(sarco)mas, scirrhous carcinomas, melanomas, and adenocarcinomas. Metastatic lesions appear to be the most common esophageal tumors in dogs and cats and include thyroid, pulmonary, and gastric carcinomas.

Esophageal Foreign Bodies

Esophageal foreign bodies are a frequent clinical problem in dogs and cats. The most common esophageal foreign bodies found in dogs are bones, bone fragments, and monetary coins, whereas play objects are more commonly found in cats. Many foreign bodies are regurgitated or transported into the distal gastrointestinal tract, but others remain lodged in the esophageal body. Those that are too large to pass through the esophagus cause mechanical obstruction. The severity of esophageal damage is dependent upon foreign body size, angularity or sharp points, and the duration of obstruction.[16]

Vascular Ring Anomalies

Vascular ring anomalies are congenital malformations of major arteries of the heart that, because of altered anatomic relationships, entrap the esophagus and trachea. Persistent right aortic arch, persistent right or left subclavian arteries, persistent right dorsal aorta, double aortic arch, left aortic arch and right ligamentum arteriosum, and aberrant intercostal arteries have been described in both dogs and cats.[13] Persistent right aortic arch is the most common vascular ring anomaly found in dogs and cats.

Gastroesophageal Intussusception

Gastroesophageal intussusception is a rare condition of young dogs (most younger than 3 months of age) resulting from invagination of stomach into the esophagus, with or without other abdominal organs (e.g., spleen, duodenum, pancreas, omentum).[17] Many affected animals have preexisting esophageal disease, most importantly idiopathic megaesophagus. The role of idiopathic megaesophagus in the pathogenesis of gastroesophageal intussusception is not well understood, but it may be that the greatly enlarged capacity of a dilated esophagus accommodates invagination of the stomach through the diaphragmatic hiatus. Gastroesophageal intussusception is a true gastrointestinal emergency that may culminate in death if untreated.

Evaluation of the Patient

History

A careful history is useful in differentiating clinical signs of esophageal disease from oral, pharyngeal, and gastric disease, and in planning diagnostic tests needed in evaluation of the patient. Signs consistent with esophageal disease include regurgitation, odynophagia (painful swallowing), dysphagia (difficulty in swallowing), multiple swallowing attempts, excessive salivation (particularly with inflammatory disorders), and changes in appetite (ravenous appetite with motility disorders or reduced appetite with inflammatory disorders).

Physical Examination

Physical examination findings may be minimal in some animals with primary esophageal disease. Severe regurgitation and malnutrition may result in mild to moderate cachexia. Fever and pulmonary crackles or wheezes occur in association with aspiration pneumonia. An occasional foreign body or esophageal dilation may be detected during examination. Physical examination is important from the standpoint of excluding other gastrointestinal or systemic disease.

Laboratory Evaluation and Tests

Figure 21-1 outlines an approach to diagnosis of regurgitation associated esophageal disease. Initial laboratory testing should include routine hematology, serum biochemistry, urinalysis, and fecal parasitologic examination. This database will be useful in excluding systemic or metabolic disease as a cause of secondary esophageal signs. In the absence of systemic or metabolic disease, hypoproteinemia (associated with malnutrition) and leukocytosis (associated with esophageal inflammation or aspiration pneumonia) are the only laboratory abnormalities that are sometimes encountered. Hyponatremia and hyperkalemia may be evident in animals with Addison's disease and secondary megaesophagus.

Survey radiography, contrast radiography, fluoroscopy, and esophageal endoscopy are diagnostic methods currently available in modern veterinary practice. Survey radiography of the neck and thorax should be performed in all animals suspected of having

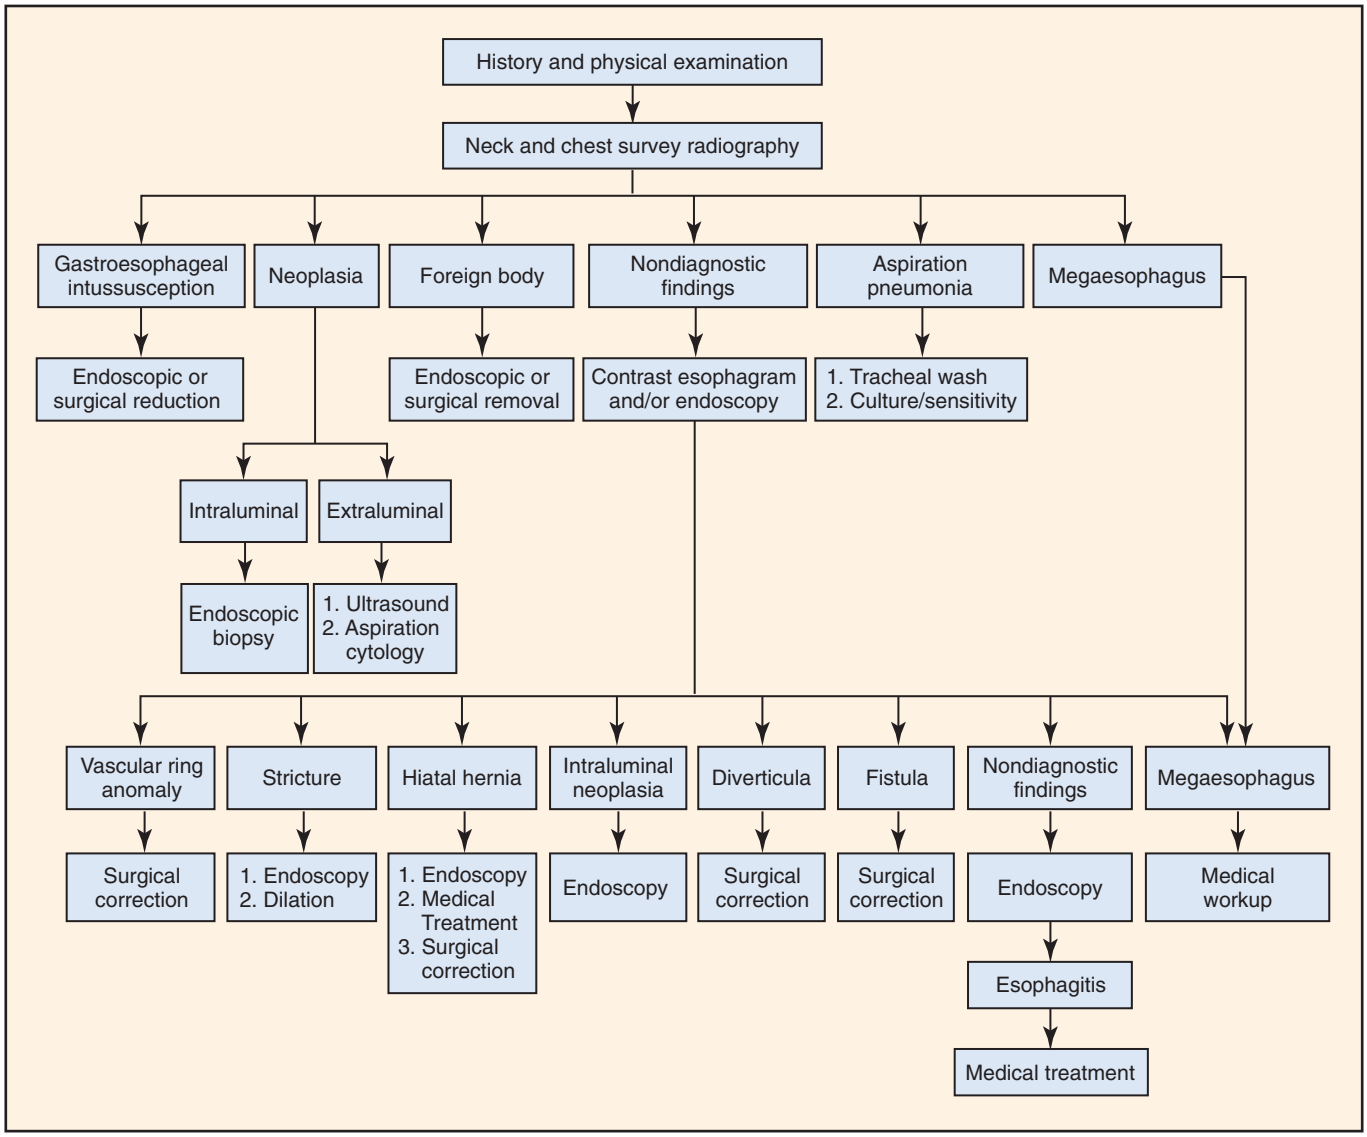

Figure 21-1 General diagnostic and therapeutic approach to regurgitation.

esophageal disease. Definitive diagnosis or evidence in support of a diagnosis may be obtained with survey radiographs in many cases, including esophageal foreign body, megaesophagus, neoplasia, hiatal hernia, and gastroesophageal intussusception. Thoracic radiographs will also identify some of the complications of esophageal disease, including aspiration pneumonia, pleural effusion, mediastinitis, and pneumothorax.

Contrast radiography and fluoroscopy can be performed to identify esophageal lesions or to confirm a tentative diagnosis. Disorders not readily diagnosed by survey radiography (e.g., radiolucent foreign body, esophagobronchial fistula, esophagitis, diverticula, and stricture) may be more readily diagnosed by contrast radiography. Dynamic contrast studies (i.e., videofluoroscopy) should be used instead of static barium radiographs whenever possible. In addition to structural information, dynamic studies will provide some information about esophageal motility. Contrast studies may be performed using barium paste (80% to 100% weight/volume), barium suspension (30% weight/volume), barium-coated meals, or iodinated contrast agents. The choice of a specific contrast agent depends upon which esophageal disease is suspected.

Esophageal endoscopy has become a very useful tool in diagnosis and treatment of esophageal disease. Usually performed after survey radiographic assessment, endoscopy and biopsy are particularly useful in diagnosing esophageal stricture, esophagitis, intraluminal mass, foreign body, and diverticula.[18] Endoscopy may also be used therapeutically to remove foreign bodies, to dilate esophageal strictures, or to place gastrostomy feeding tubes.

Ultrasonography has proved useful in diagnosis of periesophageal masses or other mediastinal disease. Esophageal manometry is useful for diagnosing cricopharyngeal achalasia, generalized esophageal motility disorders, and caudal esophageal sphincter incompetence, but the technique is currently only performed at major referral centers and university teaching hospitals. Nuclear scintigraphy and esophageal pH monitoring have also been used to diagnose esophageal motility disorders and gastroesophageal reflux, respectively.

Treatment and Management

General Principles

Animals with inflammatory conditions of the esophagus may be managed on an outpatient basis. Oral food intake should be withheld for 2 to 3 days in cases of mild esophagitis. Animals with more severe esophagitis (e.g., complete anorexia, dehydration, aspiration pneumonia) may require hospitalization. Food and water should be withheld in such cases, and animals may need additional nutritional maintenance either by enteral or total parenteral nutrition.

Medical (Drugs and Diet)

Because dietary fat delays gastric emptying and reduces caudal esophageal sphincter pressure, animals should be fed fat-restricted diets. Pet owners should also avoid late-night feedings because this would tend to reduce caudal esophageal sphincter pressure during sleep. In addition to nutritional considerations, rational medical therapy for this disorder includes diffusion barriers (e.g., sucralfate), gastric acid secretory inhibitors (e.g., cimetidine, ranitidine, famotidine, or omeprazole), and prokinetic agents (e.g., metoclopramide). Diffusion barriers are perhaps the most important medical therapy in gastroesophageal reflux. Sucralfate (0.5 to 1.0 g PO, TID) protects against mucosal damage from gastroesophageal reflux and promotes healing of existing esophagitis. Refractory cases of gastroesophageal reflux should also be medicated with acid secretory inhibitors and/or prokinetic agents. The H_2 histamine receptor antagonists such as cimetidine (5 to 10 mg/kg PO or IV, TID-QID), ranitidine (1.0 to 2.0 mg/kg PO or IV, BID-TID), and famotidine (0.1 to 0.5/mg/kg PO or IV, BID) inhibit gastric acid secretion and reduce the amount of acid reflux. Omeprazole (1 to 2 mg/kg PO, QD), an H^+,K^+-adenosine triphosphatase (ATPase) inhibitor, pantoprazole (1 mg/kg IV), lansoprazole (1 mg/kg IV), esomeprazole (1 mg/kg IV) could also be used to inhibit gastric acid secretion. Metoclopramide (0.2 to 0.4 mg/kg PO, TID-QID) and erythromycin (0.5 to 1.0 mg/kg PO, BID-TID) may be useful in treating gastroesophageal reflux because they increase caudal esophageal sphincter pressure. Serotonin (5-HT_4) agonists like cisapride also increase tone in the caudal esophageal sphincter, but cisapride has since been withdrawn from several international markets.[13]

Surgical

Surgical excision and repair provide the most successful outcomes in animals with esophagobronchial fistula, esophageal diverticula, vascular ring anomalies, some esophageal neoplasia, gastroesophageal intussusception, and hiatal herniae. Surgical cardiomyotomy (myotomy of the caudal esophageal sphincter) has been recommended in the past as a therapeutic measure in the belief that canine megaesophagus is similar to human achalasia. Because most studies have reported normal caudal esophageal sphincter tone and appropriate relaxation with swallowing, cardiomyotomy cannot be recommended for treatment of this disorder. Indeed, animals treated with myotomy generally have had poorer outcomes than untreated animals.

Nonsurgical

Esophageal strictures are best managed with mechanical dilation. Dilation may be achieved with balloon dilation catheters or bougienage tubes. Balloon dilations are safer and more effective in applying radial forces to expand the stricture site. Anecdotal opinion suggests that balloon dilations may be safer and more effective in applying radial forces to expand the stricture site. One recent study suggests that bougienage may be applied with increased risk of esophageal pathology or perforation (see Chapter 55).[14,19]

CHAPTER 22

Salivation

Robert Furman and Brook A. Niemiec

Definition

True ptyalism is an increase in production of saliva by one or more salivary glands. Pseudoptyalism is the inability of the patient to swallow normal amounts of saliva due to a disease process. There are many causes of ptyalism and pseudoptyalism, including oral trauma, oral cavity disease, toxin ingestion, salivary gland disorders, neoplasia, gastrointestinal tract disorders, metabolic and systemic disease, infectious diseases, neurologic disease, developmental anomalies, and behavioral responses. Excessive salivation is considered a normal finding in some dog breeds (e.g., Saint Bernard, Dogue de Bordeaux, and Mastiff).

Pathophysiology and Mechanisms

Excessive salivation is a common clinical finding in patients with disease of the oral cavity, and is usually as a consequence of pain, inflammation, and obstruction (see Chapter 54). Trauma patients, such as those with mandibular fracture, have concurrent disruption in the normal mechanisms of swallowing. Ingested toxins may have both direct noxious effects on saliva production and indirect effects through inflammation of mucosal surfaces. Primary salivary gland disorders (e.g., necrosis, inflammation, cancer) usually provoke an increase in secretion of saliva, although some salivary disorders may be associated with a decrease in saliva production. Neoplasia affecting structures of the oral cavity, oropharynx, and esophagus will interfere with normal swallowing mechanisms resulting in pseudoptyalism. True ptyalism is a common clinical sign with gastrointestinal, metabolic, and systemic disease, and involves activation of humoral and neural pathways for nausea and vomiting (see Chapter 23). Many of the infectious diseases, including viral, bacterial, rickettsial, and protozoal infections, can have direct or indirect effects on saliva production. Central nervous system disorders either increase salivation (e.g., meningitis) or interfere with normal swallowing function (e.g., trigeminal neuropathy).

Differential Diagnosis

The DAMNIT system of disease classification can be used to systematically consider the most important differential diagnoses for ptyalism[1-11] and pseudoptyalism:

- **D,** *Degenerative, Drug-Induced, and Developmental*—Some drug-induced disorders of ptyalism result from ingestion of unpleasant tasting medications (e.g., metronidazole in cats), whereas others (e.g., erythromycin in dogs) activate the humoral pathway for nausea, salivation, and vomiting. Developmental anomalies such as lip folds and malocclusions will often be accompanied by pseudoptyalism.
- **A,** *Anatomic, Allergic, Autoimmune*—Generalized idiopathic megaesophagus and gastric dilation/volvulus syndrome have documented distal effects on normal swallowing function resulting in pseudoptyalism. Some of the autoimmune disorders, such as pemphigus vulgaris, involve the mucous membranes as well as the skin resulting in both true ptyalism and pseudoptyalism.
- **M,** *Metabolic, Mechanical*—Any of the metabolic disorders (e.g., renal, hepatic, endocrine) may be accompanied by humoral activation of nausea, salivation, and vomiting. True fever and hyperthermic reactions directly stimulate panting, salivary secretion, and evaporative cooling. Bony fragments and other foreign bodies lodged in the soft palate, oropharynx, and proximal esophagus directly stimulate salivary secretion.
- **N,** *Nutritional, Neoplastic, Neurologic*—Incubation of pancreatic enzyme supplements in the food of dogs with exocrine pancreatic insufficiency may induce a severe inflammatory response of the oral cavity and true ptyalism. Cancers of the oral cavity, particularly squamous cell carcinomas in cats, induce true and pseudoptyalism (Fig. 22-1). Central nervous system disorders such as facial paralysis, seizure disorders, vestibular disease, and cranial nerve lesions may interfere with normal swallowing function. An unusual form of phenobarbital-responsive ptyalism has been reported in the dog that has been analogized to limbic epilepsy. Although poorly understood, behavioral responses or reactions may interfere with normal swallowing function (Fig. 22-2).
- **I,** *Inflammatory, Infectious, Immune-Mediated*—Caudal stomatitis in cats (see Fig. 22-3) and chronic ulcerative paradental stomatitis in dogs (Figs. 22-4 and 22-5) are important causes of true ptyalism. Severe untreated oral, esophageal, and gastric inflammation may progress to erosion and ulceration inducing both true and pseudoptyalism. Viral infections (e.g., rabies, pseudorabies, calicivirus, and herpes viruses), bacterial infections (e.g., tetanus, botulism, *Bordetella*), and periodontal disease (Fig. 22-6) may be associated with voluminous aqueous or mixed aqueous-mucoid salivary secretions. Almost any disease of the salivary gland (e.g., sialocele, foreign body, abscessation, trauma, necrosis, neoplasia, hyperplasia,

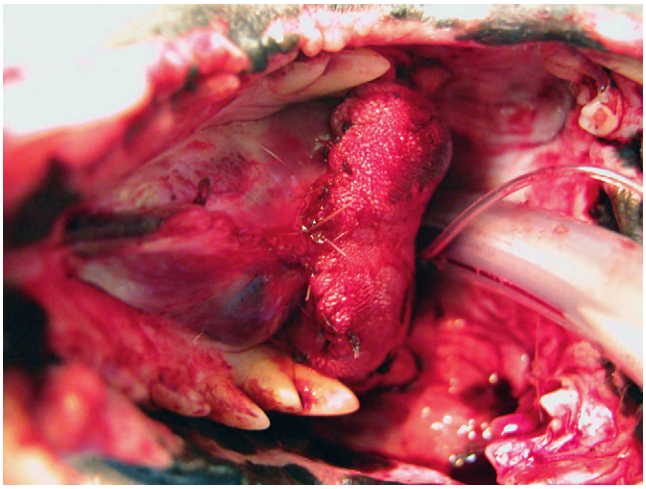

Figure 22-7 Postglossectomy image of the patient in Figure 22-1.

necrotizing sialometaplasia) is associated with moderate to severe true ptyalism.

- **T,** *Traumatic, Toxic*—Mandibular and maxillary fractures, temporomandibular joint luxation, and traumatic and electrical injuries stimulate salivary secretion from one or more of the salivary glands. Postmaxillectomy, mandibulectomy, and glossectomy patients (Fig. 22-7) all have predictable true and pseudoptyalism. Excessive salivation will regress with soft tissue and bony healing. Organophosphates, toxic mushrooms, caustic material, and insect bites are all associated with true ptyalism.

Evaluation of the Patient

History

Obtaining a thorough history will be essential to diagnosing the cause of true or pseudoptyalism. Important questions should include:

1. What is the age of the patient?
   Common causes for younger patients include foreign body or toxin ingestion, as well as burn injuries. Younger pets are also more likely to be affected by a viral infection or congenital abnormality. Older pets are more likely to be affected with metabolic, immune-mediated, and neoplastic diseases.
2. Is the condition acute, subacute, or chronic?
   Acute onset is more likely caused by viral infections, toxin exposures, and oral trauma. A more gradual onset is usually a result of severe periodontal disease, neoplasia, or metabolic disorders.
3. Are there concurrent clinical signs with particular reference to the gastrointestinal and respiratory tracts?
   Is the patient showing clinical signs of vomiting, coughing, gagging, or regurgitation? Vomiting associated with ptyalism generally has a gastrointestinal, neurologic, or metabolic origin. Idiopathic megaesophagus should be suspected in cases where regurgitation is reported. Gagging and coughing may be associated with foreign bodies or neoplasia of the oral cavity or oropharynx.
4. Does the animal have difficulty with prehension, mastication, bolus formation, or swallowing of water or food?
   Oral pain may interfere with feeding behavior because of the animal's reluctance to mobilize the structures of swallowing. Temporomandibular joint luxations and mandibular fractures can result in malocclusions that prevent closure of the mouth. Difficult swallowing (dysphagia) can result from any number of painful or neurologic disorders (see Chapters 13 and 54).
5. Is there any known exposure to toxins?
   Work around the household, including new carpeting, painting, construction, or carpet cleaning, should be queried. The use of flea and tick products or other chemicals should also be questioned.
6. Is the patient currently being treated with any other medications?
   A thorough inventory of medications and supplements should be developed, particularly complementary and alternative therapies.
7. Has there been any recent surgery or other nonsurgical trauma?
   Animal fights, other injuries, and dental, oral, and gastrointestinal surgeries should be queried.

Physical Examination

Complete physical and oral exams should be performed on the patient (Fig. 22-8). Oral cavity should be noted and detailed, including missing teeth, oral masses, fractured teeth, severe inflammation, and periodontal disease. The tongue should be elevated to look for sublingual swelling. Lymph nodes and salivary glands should be palpated for irregularities and size. Range of motion of the mandible should be assessed while simultaneously noting crepitus or discomfort. Neurologic exam of the head and neck should be performed particularly if clinical signs of gagging and dysphagia, are described. Assessing color and consistency of saliva may help to narrow the list of differential diagnoses. Presence of blood or purulent material in saliva suggests infection, neoplasia, and trauma as more likely diagnoses. Some patients may have severe pain associated with inflammation, foreign body, infection, or cancer involving structures of the oral cavity, thereby preventing direct observation without analgesia, sedation, or anesthesia.

Laboratory Evaluation and Tests

Cytology and culture of the saliva are generally unrewarding because of the complex nature and mixed flora of the oral cavity.[7] A minimum database should be obtained, including complete blood count, serum chemistry, serum thyroid hormone concentrations, and urinalysis. The initial data base may identify need for further medical investigation including function tests or imaging studies. Lesions of the oral cavity should be surgically biopsied under general anesthesia and submitted for histopathology. It is important to obtain a biopsy sample that contains a good representation of the lesion. While the patient is under anesthesia, intraoral dental radiographs should be obtained to look for evidence of disease below the gum line. Advanced imaging of head and neck via magnetic resonance imaging (MRI) or computerized tomography (CT) may be needed to rule out complicated causes of ptyalism. Additional diagnostic tests may be required once oral and maxillofacial disorders have been excluded from the list of differential diagnoses. These may include thoracic and abdominal radiographs, abdominal ultrasound, and endoscopy.

Treatment and Management

Syndromes of hypersalivation are quite often secondary to disease processes unrelated to structures of the oral cavity and oropharynx. In these cases, treatment and management should address the underlying cause (outlined in Chapters 54 to 61).

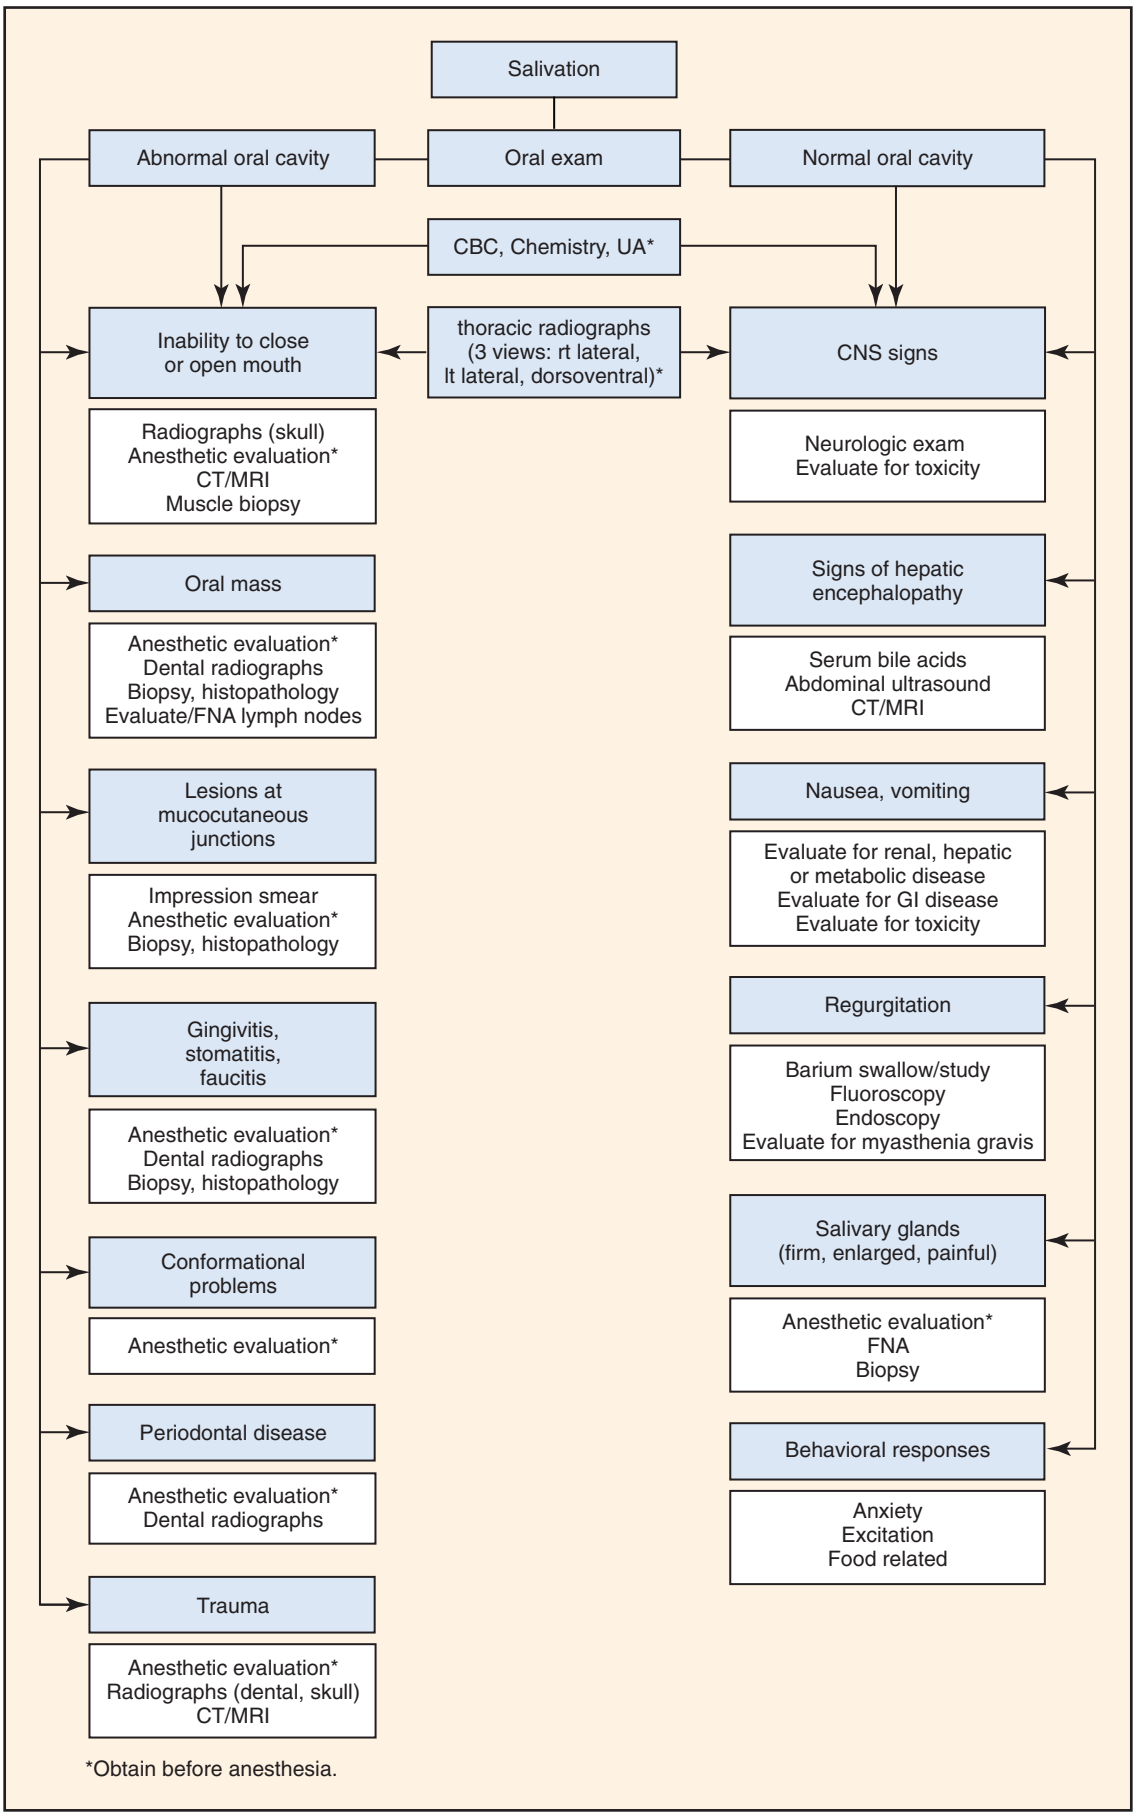

Figure 22-8 Algorithm for diagnosing salivation. CBC, complete blood count; chem, serum chemistry; CNS, central nervous system; CT, computed tomography; FNA, fine-needle aspiration; GI, gastiointestinal; MRI, magnetic resonance imaging; UA, urinalysis.

In cases where salivary glands are the primary cause of ptyalism, surgical removal of one or more of the affected glands is the treatment of choice.[8,9] Short-term treatment of hypersalivation may be achieved medically with the use of a muscarinic antagonist such as atropine or glycopyrrolate.[10] Cheiloplasty can be performed to help eliminate excessive drooling caused by lip malformation, mandibulectomy, glossectomy, or neurologic disorders of swallowing.[11]

CHAPTER 23

Vomiting

Robert J. Washabau

Definition

Vomiting or emesis is a complex reflex pathway that has evolved to protect animals from ingested toxins, but it holds greater importance because of the large number of medical conditions that may cause or be associated with it (Box 23-1).[1,2] Emesis may occur with such diverse conditions as systemic (septicemia, multiple organ failure), metabolic (uremia, liver failure), and endocrine (hyperthyroidism, hypoadrenocorticism) disease, as well as with inflammatory, infectious, neoplastic, obstructive, and toxicologic disorders of the gastrointestinal tract, pancreas, liver, and biliary tract. In each of these circumstances, vomiting is believed to be activated through a neural or humoral mechanism.[3,4]

Pathophysiology and Mechanisms

Physiology of Vomiting: Humoral and Neural Pathways

The first mechanistic studies of vomiting were carried out by Borison and Wang in the early 1950s.[3,4] Borison and Wang postulated a two-component model of vomiting involving activation of a humoral or neural pathway (Fig. 23-1). In the Borison–Wang model, vomiting was postulated to occur through activation of chemoreceptor trigger zone (CRTZ) by bloodborne substances (*humoral pathway*), or through activation of emetic center by vagosympathetic, CRTZ, nucleus tractus solitarius, vestibular, or cerebrocortical neurons (*neural pathway*). Through a complicated series of experiments, Borison and Wang showed that activation of CRTZ by circulating emetogenic substances (e.g. uremic toxins, cardiac glycosides, endotoxins, and apomorphine) could be abolished by CRTZ antagonism, but not by vagotomy, sympathectomy, or emetic center antagonism. At the same time, neural activation of emetic center by gastrointestinal disease (e.g., inflammation, infection, obstruction, toxicity, etc.) could be abolished by vagotomy, sympathectomy, and emetic center antagonism, but not by CRTZ antagonism. Thus, vomiting was most easily explained by two independent mechanisms—one mechanism involving an essentially neural pathway, the other mechanism operating through a humorally dependent pathway.[3,4] The Borison–Wang two-component model has helped to explain many of the vomiting disorders of animals and humans. The model is not without challenge. It has been suggested that there are parallel mechanisms for initiation of emesis in response to any stimulus, and it is the sum of the inputs that drives the emetic response.[5] In other words, emesis need not be simply an either/or response. The concept of a discrete emetic center has also been seriously challenged. Based on more recent electrophysiologic studies, a model of sequential activation of a series of effector nuclei (e.g., nucleus tractus solitarius, retrofacial nucleus, dorsal motor nucleus of the vagus) has been proposed that doesn't require a discrete emetic center.[5] Despite contemporary reexamination, there still is good agreement on two general patterns of emesis, one humoral and the other neural.

The essential component of the *humoral* pathway is the CRTZ located within the area postrema, which is sensitive to activation by bloodborne substances. The CRTZ is located anatomically outside of the blood–brain barrier and is readily perfused by substances in systemic circulation. Receptors within the CRTZ may be activated by many endogenous (e.g., uremic, hepatoencephalopathic, or endotoxins) or exogenously derived (e.g., digitalis glycosides, *cis*-platinum, apomorphine) bloodborne substances. Many pharmacologic approaches to antiemetic therapy have been based on receptor interactions at the CRTZ, emphasizing the *humoral* pathway of emesis.[1,4]

Although many antiemetic agents are based on CRTZ pharmacology, many spontaneous vomiting disorders result from activation of the *neural* pathway. Vomiting associated with primary gastrointestinal tract disease (e.g., inflammation, infection, malignancy, toxicity) results from activation of an afferent neural pathway, nucleus tractus solitarius neurons, and the emetic center. Efferent information transmitted back to the gastrointestinal tract stimulates motor correlates of vomiting (i.e., retrograde duodenal and gastric contractions, relaxation of the gastroesophageal sphincter, gastroesophageal reflux, opening of the proximal esophageal sphincter, evacuation of gastrointestinal contents).[6,7] A *neural* pathway can also be involved in vomiting associated with motion sickness. Although there are important species differences,[8-10] motion within the semicircular canals is transduced to vestibulocochlear neurons that ultimately synapse in the CRTZ (dog) or emetic center (cat). Finally, a *neural* pathway involving cerebrocortical neurons are very likely involved in vomiting disorders associated with anxiety or anticipation, but their importance in companion animals has not yet been established.

Pharmacology of Vomiting: Neurotransmitters and Receptors

Chemoreceptor Trigger Zone

Neurochemical studies have demonstrated several neurotransmitters (e.g., dopamine, norepinephrine, 5-hydroxytryptamine [5-HT], serotonin), acetylcholine, histamine, substance P, enkephalins), their respective receptors or binding sites (e.g., D_2 dopaminergic, α_2 adrenergic, 5-HT_3 serotonergic, M_1 cholinergic, H_1 and H_2 histaminergic, NK_1 neurokininergic, ENK_μ and ENK_δ enkephalinergic), and their respective synthetic or degradative enzymes (e.g., dihydroxyphenylalanine [DOPA] decarboxylase, dopamine

β-hydroxylase, 5-hydroxytryptophan decarboxylase, choline acetyltransferase, histidine decarboxylase, aminopeptidase N, enkephalinase) (Fig. 23-2).[11]

Some neurotransmitter-receptor signal transduction pathways are probably more important than others. For example, apomorphine (a D_2-dopamine receptor agonist) is a potent emetic agent in the dog, but it does not readily induce emesis in the cat.[12] This finding has two important implications: (a) CRTZ D_2-dopamine receptors may not be as important in mediating humoral emesis in the cat, and (b) D_2-dopamine receptor antagonists (e.g., metoclopramide) may not be effective antiemetic agents in the cat. Xylazine, an α_2-adrenergic agonist, is a more potent emetic agent in the cat than in the dog.[12,13] Xylazine's effect suggests that α_2-adrenergic antagonists may be more useful antiemetic agents than D_2-dopamine antagonists in the cat.[9] Cancer chemotherapy (e.g., *cis*-platinum, doxorubicin, cyclophosphamide) induced–emesis is mediated by activation of 5-HT_3 receptors in the CRTZ of the cat,[11,14-16] whereas visceral and vagal afferent 5-HT_3 receptors may be more importantly involved in the dog.[17] Antagonists of the 5-HT_3 receptor are efficacious in prevention of emesis associated with *cis*-platinum and other chemotherapy in cats[14-16] and dogs.[18] NK_1-receptor antagonists represent a unique new class of antiemetic agents that are based on substance P pharmacology at the CRTZ as well as the nucleus tractus solitarius. This group of antiemetic agents may have advantages over other antiemetic classifications in that they may inhibit vomiting through both pathways (humoral and neural).[19,20] Finally, although histamine and H_1- and H_2-histaminergic receptors have been demonstrated in the CRTZ of the dog, they have not yet been demonstrated in the cat. Histamine is a potent emetic agent in the dog, but the cat seems resistant to its emetic effects.[11,12] H_1-histaminergic antagonists (e.g., diphenhydramine, dimenhydrinate) are ineffective antiemetic agents for motion sickness in the cat.[10]

Emetic Center

Emetic center pharmacology is complicated; some experimental results may not be reflective of pharmacology at one site. At the present time 5-HT_{1A}, α_2-adrenergic, and NK_1 receptors are the only documented receptors involved in regulation of emesis at the level of the emetic center for which there are clinically available antiemetic agents. It has been shown that 5-HT_{1A}-receptor agonists (e.g., flesinoxan, 8-OH-DPAT, buspirone) suppress emesis associated with motion sickness in cats.[21] The emetic center α_2-receptor as well as the CRTZ α_2-receptor may be antagonized by a pure α_2-antagonist (e.g., yohimbine) or by mixed α_1/α_2 antagonists (e.g., prochlorperazine, chlorpromazine).[13] It is likely, however, that most of the antiemetic effect of the α-receptor antagonists results from antagonism at the level of the CRTZ.[21,22]

Vestibular Apparatus

Muscarinic M_1 receptors and acetylcholine have been demonstrated in the vestibular apparatus of the cat. Mixed M_1/M_2 antagonists (e.g., atropine) and pure M_1 antagonists (e.g., pirenzepine) inhibit motion sickness in the cat. It is not clear whether the antiemetic effect of these drugs is solely a result of M_1-receptor antagonism at the vestibular apparatus. Other sites (e.g., cerebral cortex, reticular formation, area postrema) of antagonism are possible.[11] More recently, NK_1 receptors have been shown to be involved in pathogenesis of motion sickness, and NK_1-receptor antagonists (e.g., maropitant) prevent motion sickness in both dogs and cats.[23,24]

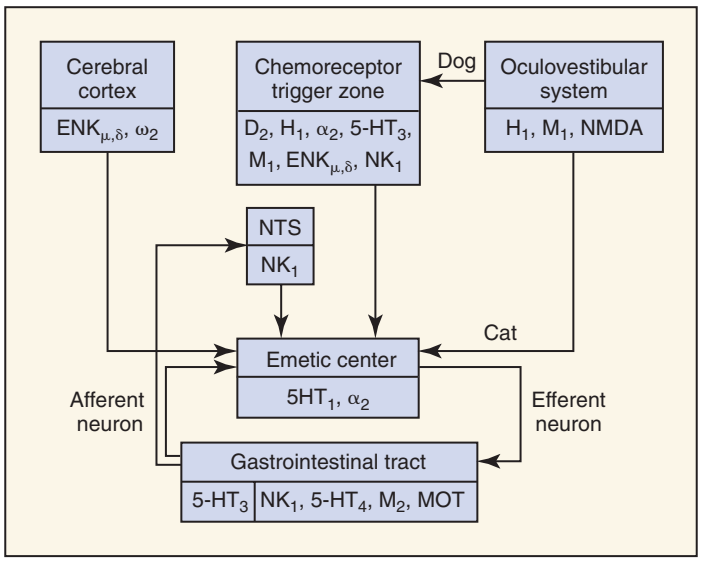

Figure 23-2 Pharmacology of vomiting—neurotransmitters and receptors. α_2, Alpha$_2$-adrenergic receptor; D_2, dopamine$_2$ receptor; ENK$_{\mu,\delta}$, enkephalin $_{\mu,\delta}$ receptor; H_1, histamine$_1$ receptor; 5-HT_{1A}, 5-hydroxytryptamine$_{1A}$ receptor; 5-HT_3, 5-hydroxytryptamine$_3$ receptor; 5-HT_4, 5-hydroxytryptamine$_4$ receptor; M_1, muscarinic$_1$ cholinergic receptor; M_2, muscarinic$_2$ cholinergic receptor; MOT, motilin receptor; NK_1, neurokinin$_1$ receptor; NMDA, N-methyl D-aspartate; NTS, nucleus tractus solitarius; ω_2, benzodiazepine ω_2 receptor.

Cerebral Cortex

Opioids, cannabinoids (e.g., nabilone) and benzodiazepines (e.g., diazepam, lorazepam) have been used to reduce anticipatory nausea and vomiting in human beings undergoing cytotoxic drug therapy. Cerebrocortical opioid and benzodiazepine receptors have been implicated but have not been well characterized pharmacologically. The importance of these receptors in pathogenesis of nausea and vomiting disorders in the dog and cat has not yet been established.[4,11,12]

Gut Afferents

There are a number of different mechanisms by which stimuli arising from the gastrointestinal tract activate the vomiting reflex. Ingested toxins, cell degeneration or necrosis, inflammation, luminal distention, chemotherapy, and radiation therapy all induce emesis. Of the many receptors found in the gastrointestinal tract, 5-HT_3 receptors likely play an important role in initiation of emesis.[11] It is now well established that cytotoxic drugs provoke 5-HT release from enterochromaffin cells in the gastrointestinal tract, which then activates 5-HT_3 receptors in afferent vagal fibers (dog)[17] or CRTZ (cat).[14,15] Vomiting induced by 5-HT release and 5-HT_3 receptor activation is abolished by pretreatment with 5-HT_3 antagonists (i.e., ondansetron, granisetron, tropisetron, dolasetron).[14,18] Metoclopramide is a weak antagonist of 5-HT_3 receptors but does not seem to be very effective in preventing chemotherapy-induced emesis.[25] It remains to be determined whether other gastrointestinal tract pathologies (e.g., inflammation, infection, malignancy, toxicity) are mediated via 5-HT_3 receptor activation.

Gut Efferents

Vagal efferent and myenteric neurons initiate complex excitation and inhibition of visceral smooth muscle (e.g., retrograde duodenal and gastric contractions, relaxation of the gastroesophageal sphincter, gastroesophageal reflux, opening of the cricoesophageal sphincter, and evacuation of gastrointestinal contents) that culminates in emesis. A number of receptors have been identified on myenteric neurons and gastrointestinal smooth muscle cells that regulate gastric emptying and/or intestinal transit. These include 5-HT_4 serotonergic (neuronal),[26] D_2-dopaminergic (neuronal),[27] M_2-cholinergic (smooth muscle),[28] and motilin (smooth muscle; dog only)[29] receptors. Cisapride and other 5-HT_4 agonists facilitate gastric emptying by activating presynaptic neuronal 5-HT_4 receptors.[20,26] Metoclopramide is a weak gastric prokinetic agent in the dog and cat and is believed to facilitate gastric emptying via agonism of 5-HT_4 serotonergic receptors[26] or via antagonism at D_2-dopamine receptors.[27] Canine gastric emptying is also regulated by motilin, a hormone that is released episodically from gastrointestinal endocrine cells. Motilin initiates phase III of the migrating myoelectric complex and facilitates gastric emptying during the fasting state. Low doses of erythromycin (0.5 to 1.0 mg/kg q8h PO, IV) stimulate motilin release and facilitate gastric emptying in the dog.[29-31] The role of motilin in regulation of feline gastric emptying is incompletely understood. Motilin-like macrolide antibiotics increase tone in feline caudal esophageal sphincter,[32] but their role in the regulation of gastric, intestinal, and colonic motility is incompletely understood.

Differential Diagnosis

Emesis may occur with such diverse conditions as systemic (e.g., septicemia, multiple organ failure), metabolic (e.g., uremia, liver failure), and endocrine disease (hyperthyroidism, hypoadrenocorticism), as well as disorders of the gastrointestinal tract (e.g., inflammatory bowel disease, gastrointestinal malignancy and obstruction, pancreatitis, and hepatobiliary disorders) (see Box 23-1).

Evaluation of the Patient

History

A complete and detailed history is the first step in establishing a correct diagnosis of a vomiting disorder. The patient's signalment will usually establish some level of probability for many of the differential diagnoses. For example, adrenocortical insufficiency would be an important differential diagnosis for a 2-year-old dog presented with an acute history of vomiting and muscular weakness, with or

without diarrhea. Similarly, acute onset of vomiting in an unvaccinated puppy should alert the veterinarian to the possibility of an infectious disease (e.g., parvoviral or distemper viral gastroenteritis). Chronic vomiting in an 11-year-old dog, on the other hand, would elicit a different set of differential diagnoses.

Following consideration of the patient's signalment, history taking should ascertain vaccination status, travel history, and any recent dietary changes. Previous medical problems, medication history, and possible ingestion of toxic substances or foreign bodies should also be ascertained. These pieces of information can be useful in formulating a list of differential diagnoses. Next, the veterinarian should be convinced that the pet owner is describing vomiting and not some other sign. Coughing associated with inflammatory disorders of the upper airway will often be described as vomiting by many pet owners. Gagging is also occasionally confused with vomiting. A careful history taking will usually discriminate coughing and gagging from vomiting. Pet owners will also often confuse regurgitation and dysphagia with vomiting. Regurgitation is the passive evacuation of ingested food from pharynx and/or esophagus; premonitory signs of retching and abdominal contractions seen with vomiting are not observed with regurgitation. The description of regurgitation by a pet owner would suggest a more proximal disorder of the pharynx or esophagus. Dysphagia or difficulty in swallowing would also suggest a more proximal disorder of the pharynx.

History taking should then elicit the duration, frequency, and time of vomiting episodes, as well as the relationship of vomiting to food and water consumption. Disorders of vomiting that are of short duration are usually self-limiting and not worthy of extensive investigation; chronic vomiting histories are more serious and certainly require a more detailed investigation. Frequent vomiting usually occurs as result of systemic, metabolic, or endocrine disorders or severe inflammatory disorders of the primary gastrointestinal tract. Vomiting that occurs in the immediate postprandial period is usually suggestive of overeating, excitement, or disorders of the esophageal body or esophageal hiatus (e.g., hiatal hernia). Conversely, vomiting of undigested or partially digested food 8 or more hours postprandially suggest a distal gastric (corpus, antrum, and pylorus) motility disorder or obstruction. Vomiting of water would be more suggestive of a proximal gastric (cardia, fundus) motility disorder. Vomiting during early morning hours often may result from gastroesophageal reflux.

Physical characteristics of the vomitus, including color, amount, odor, consistency, and presence or absence of blood or bile should be ascertained. Undigested food in the vomitus implies an esophageal etiology while digested food (chyme) implies a gastric or intestinal etiology for the vomiting. Blood in the vomitus implies disruption of gastrointestinal mucosa; blood may appear as frank red clots or as a dark brown "coffee grounds" material resulting from acid proteolysis. Bile in the vomitus usually suggests only that the pylorus has permitted bile reflux. However, bile salts increase permeability of the gastric mucosal barrier resulting in a syndrome of bile reflux gastritis. Bilious vomiting, therefore, might provide a clue to the pathogenesis of the disorder. A fecal odor has been described with lower intestinal (jejunoileal) obstruction.

Physical Examination

Examination of mouth and pharyngeal structures often provides important clues to the pathogenesis of vomiting (e.g., uremic breath or ulcers, icteric mucous membranes, severe pharyngitis or pharyngeal string foreign bodies). Physical examination finding of generalized lymphadenopathy suggest neoplasia or a systemic inflammatory disease as the pathogenesis of the vomiting. Hence, all lymph nodes should be carefully palpated to determine if they are enlarged or painful. Fever on physical examination would likewise suggest an inflammatory pathogenesis for the vomiting disorder. Extreme bradycardia or other rhythm disturbance detected upon cardiac auscultation might be an important sign of a metabolic disturbance such as adrenocortical insufficiency or septic shock. The abdomen should then be carefully palpated for effusion (e.g., peritonitis), masses (e.g., carcinomatosis or other malignancy), pain (e.g., peritonitis, pancreatitis, or nephritis), gaseous or fluid distention of the intestine (e.g., obstruction), kidney size and shape (e.g., end-stage fibrotic kidneys or nephritis), liver size (e.g., hepatitis), uterine distention (e.g., pyometra), and urinary bladder size (e.g., bladder obstruction). Rectal examination might also provide some evidence of pain or hematochezia (e.g., colitis), worms (e.g., hook or whipworms), or painful prostatomegaly (e.g., prostatitis or prostatic neoplasia). Finally, examination of the central nervous system should be considered, especially in animals in which the cause of vomiting is not so obvious. Some animals with intervertebral disk disease will experience nausea and vomiting because of pain.

Laboratory Evaluation and Tests

If a definitive diagnosis is not established from history and physical examination, additional diagnostic tests may be warranted, including complete blood count, serum chemistry, urinalysis, fecal parasitologic examination, and abdominal imaging. Peripheral eosinophilia in a complete blood count would suggest systemic mast cell disease, intestinal parasitism, or adrenocortical insufficiency. Leukopenia and neutropenia might be observed in the acute phase of a viral gastroenteritis. Leukocytosis might suggest an inflammatory disorder like acute pancreatitis. The serum chemistry will often help identify systemic, metabolic, and endocrine causes of vomiting. For example, (a) azotemia and hyperphosphatemia suggest that the vomiting has resulted from chronic renal failure; (b) hyperglycemia, acidosis, glucosuria, and ketonuria suggest diabetic ketoacidosis; (c) hyponatremia and hyperkalemia suggest adrenocortical insufficiency; (d) lipasemia suggests acute pancreatic necrosis; (e) increases in serum hepatic enzyme activities (alanine aminotransferase [ALT], aspartate aminotransferase [AST], alkaline phosphatase [ALP]) suggest primary hepatic disease; and (f) hypercalcemia suggests parathyroid or other malignancy. Urinalysis is useful in differentiating prerenal and primary renal azotemia while fecal examination may provide evidence of intestinal helminth infestation. Survey abdominal radiographs are indicated in the initial workup of a vomiting disorder. Abdominal radiographs provide useful information about the abdominal alimentary and extraalimentary structures. The decision to perform additional tests is based on response to empirical therapies and initial test results. Further tests might include adrenocorticotropic hormone (ACTH) stimulation, hepatic function tests, serum pancreatic enzymes, thoracic radiography, contrast radiography, abdominal ultrasonography,[33] computed tomography (CT)/magnetic resonance imaging (MRI), gastrointestinal endoscopy, laparoscopy, and laparotomy. Figure 23-3 is an algorithm for the medical investigation of vomiting disorders.

Treatment and Management

General Principles

Each vomiting patient is likely to have a unique clinical presentation; some are benign and require little in the way of intervention while others require extensive stabilization, therapy, and rehabilitation. Efforts should be made to identify and eliminate inciting agents; sustain blood and plasma volume; restore blood pressure;

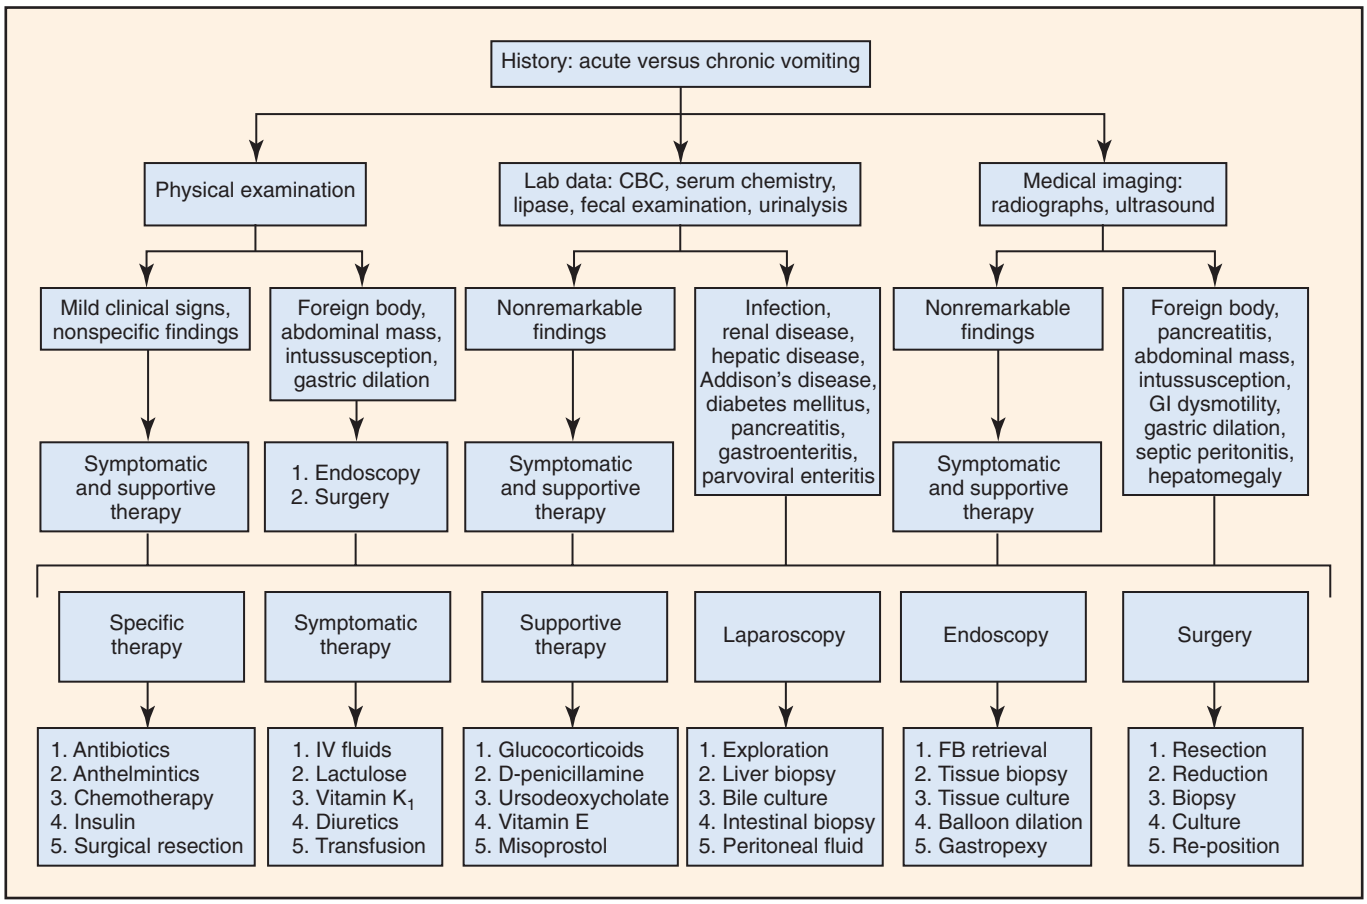

Figure 23-3 Diagnostic approach to vomiting disorders in dogs and cats. FB, Foieign body; IV, intravenous.

correct acid–base, electrolyte, and fluid deficits; and treat complications as they develop.

Nutrition

Short periods of fasting are appropriate to reduce severity and frequency of the central emetic response. Fasting in cats should be implemented only in those instances in which there is severe vomiting and risk of aspiration pneumonia. As obligate carnivores, cats develop fat mobilization and hepatic lipidosis during even short periods of starvation. With chronic vomiting disorders, esophagostomy, gastrostomy, and enterostomy tubes may be placed to facilitate nutrition in anorectic animals (see Chapter 33).

Fluids

Severe vomiting will likely result in serious fluid, electrolyte, and acid–base disturbances. The goal of fluid therapy is to restore volume and composition of body fluids to normal and, once this is achieved, to maintain external fluid and electrolyte balance so that input by treatment matches fluid losses (see Chapter 48). Electrolyte solutions can be divided into replacement and maintenance solutions. Replacement solutions provide 130 to 147 mEq/L of sodium, similar to values in extracellular fluid. Maintenance electrolyte solutions provide 40 to 77 mEq/L of sodium, about one-half or less of values in the extracellular fluid. Supplementation of replacement fluids may be required to correct acid–base imbalance and potassium deficits, particularly in animals suffering from vomiting and diarrhea. In the absence of cardiopulmonary disease, intravenous fluids can be safely administered to dogs and cats at 90 mL/kg/h. Animals with mild volume depletion can be treated with lower fluid rates (10-20 mL/kg/h, as needed).

Antiemetic Agents

Antiemetic therapy should be formulated on the basis of most likely underlying pathogenesis (i.e., neural or humoral pathway). The NK_1 neurokinin antagonists, α_2 adrenergic antagonists, 5-HT_3 serotonergic antagonists, and D_2 dopaminergic antagonists appear to be the most effective antiemetic agents in the dog and cat, although the D_2 dopaminergic antagonists appear to be less efficacious in the cat (Table 23-1). The reader is referred to Chapter 35 for more definitive outline of rational antiemetic therapy.

Anti-Secretory Agents

Histamine H_2 receptor antagonists and H^+,K^+-adenosine triphosphatase (ATPase) inhibitors are the best clinical examples of gastric acid secretory inhibitors. It may be difficult to impossible to determine pathogenesis of gastric injury in an individual animal. Most cases will likely result from the combined effects of acid injury and disruption of the gastric mucosal barrier. Acid suppression and restitution of the gastric mucosal defense mechanisms are the cornerstones of treatment (see Chapter 45).

Prokinetic Agents

Gastrointestinal prokinetic agents should be considered in patients that fail to respond to dietary and antiemetic therapy. Combination antiemetic and prokinetic therapy are particularly effective in refractory vomiting patients. The most effective prokinetic agents

Table 23-1 Antiemetic Classifications

Classification	Examples	Sites of Action	Dosage	Side Effects
α_2-Adrenergic antagonists	Prochlorperazine	CRTZ, emetic center	0.1 to 0.5 mg/kg q6-8h SQ, IM	Hypotension, sedation
	Chlorpromazine	CRTZ, emetic center	0.2 to 0.4 mg/kg q8h SQ	Hypotension, sedation
	Yohimbine	CRTZ, emetic center	0.25 to 0.5 mg/kg q12h SQ, IM	Hypotension, sedation
D_2-dopaminergic antagonists	Metoclopramide	CRTZ, GI smooth muscle	0.2 to 0.4 mg/kg q6h PO, SQ, IM, IV	Extrapyramidal signs
	Domperidone	CRTZ, GI smooth muscle	0.1 to 0.3 mg/kg q12h IM, IV	Extrapyramidal signs
	Prochlorperazine	CRTZ, emetic center	0.1 to 0.5 mg/kg q6-8h SQ, IM	Hypotension, sedation
	Chlorpromazine	CRTZ, emetic center	0.2 to 0.4 mg/kg q8h SQ, IV	Hypotension, sedation
H_1-histaminergic antagonists	Diphenhydramine	CRTZ	2 to 4 mg/kg q8h PO, IM	Sedation
	Dimenhydrinate	CRTZ	4 to 8 mg/kg q8h PO	Sedation
	Prochlorperazine	CRTZ, emetic center	0.1 to 0.5 mg/kg q6-8h SQ, IM	Hypotension, sedation
	Chlorpromazine	CRTZ, emetic center	0.2 to 0.4 mg/kg q8h SQ, IV	Hypotension, sedation
M_1-cholinergic antagonists	Pirenzepine	Vestibular apparatus, CRTZ	25 to 50 mg q24h PO	None reported
	Aminopentamide	Multiple CNS and PNS sites	0.01 to 0.03 mg/kg q8-12h PO, SQ	GI dysmotility
	Prochlorperazine	CRTZ, emetic center	0.1 to 0.5 mg/kg q6-8h SQ, IM	Hypotension, sedation
	Chlorpromazine	CRTZ, emetic center	0.2 to 0.4 mg/kg q8h SQ, IV	Hypotension, sedation
5-HT_3 serotonergic antagonists	Ondansetron	CRTZ, vagal afferent neurons	0.5 to 1.0 mg/kg q12h PO, IV	Sedation, head shaking
	Granisetron	CRTZ, vagal afferent neurons	0.1 to 0.5 mg/kg q12h PO, IV	Sedation, head shaking
	Tropisetron	CRTZ, vagal afferent neurons	0.5 to 3.0 mg/kg q12h PO	Sedation, head shaking
	Dolasetron	CRTZ, vagal afferent neurons	0.6 to 1.0 mg/kg q12h PO, IV	Sedation, head shaking
5-HT_4 serotonergic agonists	Cisapride	Myenteric neurons	0.1 to 0.5 mg/kg q8-12h PO	Cardiac arrhythmia
$ENK_{\mu,\delta}$-enkephalinergic	Butorphanol	CRTZ	0.2 to 0.4 mg/kg q12h IM	Sedation antagonists
NK_1 neurokinin antagonists	Maropitant	CRTZ, emetic center	1.0 mg kg q24h SQ	Injection irritant

CHAPTER 24

Weight Loss and Cachexia

Cynthia R. Ward

Healthy animals typically maintain their body weight within a remarkably stable range given the differing levels of caloric intake and energy expenditure that may occur daily. Significant, unintentional weight loss is usually a sign of disease. In patients who tend to mask early signs of disease, it may be the first clue of pathology. Loss of greater than 5% body weight should prompt diagnostic evaluation. Weight loss is considered a negative predictor in the outcome of many chronic diseases; therefore, it must be recognized and addressed.[1]

Definition

Weight Loss

Weight loss occurs when energy expenditures and caloric loss exceed caloric intake. The main controllers of these processes, appetite and metabolism, are regulated by an intricate network of neural and hormonal factors. These signals are primarily integrated in the arcuate nucleus of the hypothalamus, which maintains homeostatic control over food intake, levels of activity, and basal energy expenditure.[2] This area of the brain is relatively accessible to circulating signals and can respond to peripheral and central inputs. Peripherally secreted hormones, primarily insulin and leptin, give information relating to long-term energy stores in the body. Insulin, secreted by the pancreatic B cells, regulates storage of absorbed nutrients and acts as an adiposity signal to the brain.[3] Adiposity signals are cytokines produced and secreted by adipose tissue in proportion to the body fat content. Leptin secreted by adipocytes informs the brain of adipose energy reserves, and appetite is adjusted accordingly.[4] Signals relating to recent nutritional condition are provided by the vagal neural system that relates information about gastric distention and nutrients in the portal circulation.[5]

Enteroendocrine cells in the gut produce numerous hormones that are also integrated in the hypothalamus to control metabolism. These include satiety peptides cholecystokinin (CCK), glucagon-like peptide-1 (GLP-1), and oxyntomodulin that are produced in the small intestine in response to food in the gut lumen.[6-8] Peptide YY (produced in ileum and colon) and pancreatic polypeptide (produced by pancreatic cells) are released in response to feeding and signal satiety as well.[9-11] Ghrelin, produced primarily in the stomach, is secreted during fasting and stimulates appetite.[12]

When faced with a decrease in caloric intake, otherwise normal animals respond with a corresponding decrease in energy expenditure. Although body weight is lost, muscle protein is preserved while adipose tissue is broken down providing energy. The net result is fat loss over muscle loss. If adequate calories are later ingested, normal body weight and condition should be restored.

Cachexia

The terms *weight loss* and *cachexia* are often used interchangeably with cachexia usually referring to more severe weight loss that is associated with disease. Cachexia is technically different than simple weight loss, being a metabolic disorder of increased energy expenditure that cannot be resolved by merely providing extra calories.[13] It differs from simple weight loss in that the normal physiologic mechanisms supporting muscle preservation despite increased energy demands are lost.[14] Thus, protein and adipose tissue provide energy in the cachexic animal resulting in disproportionate muscle wasting in the animal. Cachexia occurs with severe debilitating disease, including malignancy, renal failure, heart failure, and chronic inflammatory diseases.[15] Cachexia is a significant predictor of mortality in human medicine.[16]

Although the pathogenesis of cachexia is not fully understood, cytokines have been implicated as major mediators.[17] Systemic inflammation from cell injury or activation of the immune system can trigger release of cytokines into circulation. Proinflammatory cytokines (e.g., interleukin [IL]- 1 and -2, interferon-γ, tumor necrosis factor [TNF]-α) are commonly implicated in the pathogenesis of cachexia.[18-20] These cytokines can activate proteolytic systems that cause hypercatabolism as well as activate tissue factors (e.g., IL-1, TNF-α) responsible for decreased protein synthesis and enhanced lipolysis.[20-22] The result of these processes is negative energy balance, muscle wasting, and weight loss. Other hormones implicated in cachexia are testosterone, insulin-like growth factor 1, myostatin, glucocorticoids, and catecholamines.[23-27]

Differential Diagnosis

The list of differential diagnoses for weight loss and cachexia is extensive. Major causes of weight loss include inadequate caloric ingestion, absorption, or digestion; caloric loss; increased metabolic rate; or cachexia. Inadequate calories available for ingestion occurs when animals are underfeeding or eat nutritionally incomplete diets. Dental pain, prehension or swallowing abnormalities, regurgitation, vomiting, or gastrointestinal obstructions can prevent adequate calories from being digested. Malabsorption, maldigestion, and diabetes mellitus are examples of weight loss as a result of an inability

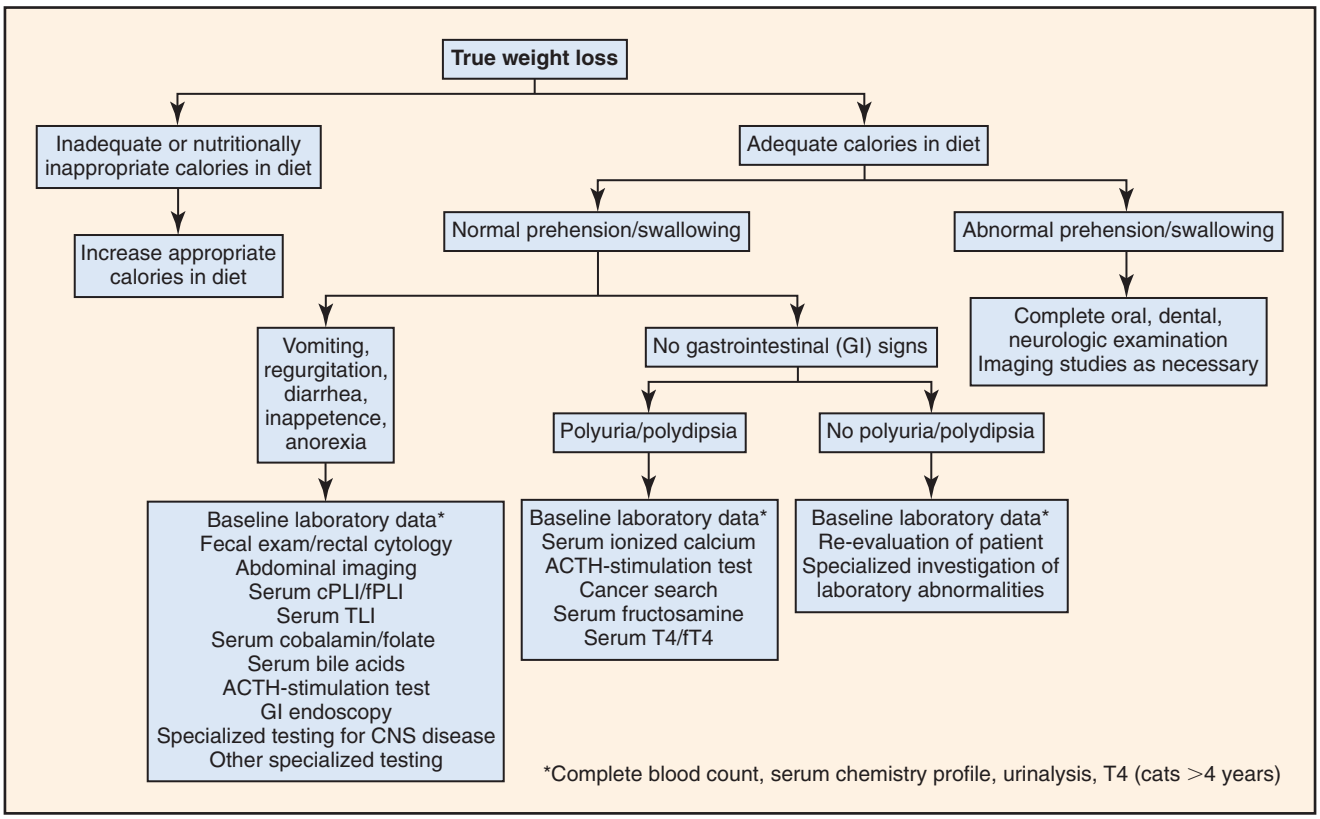

Figure 24-1 Algorithm for the diagnosis and treatment of weight loss. ACTH, Adrenocorticotropic hormone; CNS, central nervous system; cPLI, canine pancreatic-specific lipase; fPLI, feline pancreatic-specific lipase; TLI, trypsinogen-like immunoreactivity.

to absorb or process adequate calories. Caloric loss can occur from protein-losing diseases (e.g., protein-losing nephropathy, exudative skin lesions). Hyperthyroidism, extreme exercise, cold weather, lactation, and cachexia caused by chronic illness can produce weight loss from increased metabolism causing excess calorie usage.

Evaluation of the Patient

History

Weight loss may be the initial presenting complaint, part of other clinical signs, or unnoticed by the owner. A detailed history is important in patients with weight loss, and an algorithm for the diagnosis and treatment of weight loss is shown in Figure 24-1. Initially it is important to determine whether true weight loss has occurred because owners can be mistaken about weight changes in their pets. Medical records should be evaluated for previous weight measurements and compared to the current weight. These data should be compared to the current body condition of the animal. In addition to normal historical questioning, a detailed dietary history including type and amount of food given should be obtained to determine whether the animal is receiving sufficient calories to maintain its weight. Diets high in cellulose content and other indigestible material are examples of inappropriate calories in the diet. The practitioner should carefully question the owner about the animal's appetite and about other animals in the household who may be competing for food. Weight loss can occur in the face of a normal, increased, or decreased appetite. Malabsorption, maldigestion, hyperthyroidism, and diabetes mellitus are examples in which weight loss may occur with or without a decrease in appetite. The animal's ability to prehend and swallow food should be ascertained. Vomiting, regurgitation, and quantity and consistency of feces should be noted. The owner should be questioned about other clinical abnormalities in the animal. Environmental conditions, including any recent changes in weather or housing, should be noted to determine whether there is an impediment to the animal's ability to obtain sufficient food.

Physical Examination

To determine true weight loss, the animal must be weighed on an accurate and appropriate scale (e.g., pediatric scales should be used for small dogs and cats). If possible, the animal should be weighed on the same scale at each visit. Physical examination should include careful examination of the animal's body condition and hydration status. A body condition score should be recorded. Muscle mass should be noted as compared to fat. The mouth should be carefully examined for neural, oral, or dental disease that may produce avoidance of food because of pain or inability to prehend food. Nasal discharge can be important because some animals, especially cats, will not eat appropriately unless they can smell their food. Abdominal palpation should be thorough and all peripheral lymph nodes evaluated for signs of malignancy. A rectal examination with inspection of fecal matter should be performed in dogs.

Laboratory Evaluation and Tests

A complete blood count (CBC), serum biochemistry profile, total thyroxine (T_4) (cat), and urinalysis should be performed on animals exhibiting weight loss or cachexia unless the cause is obviously a lack of nutrition. Then a diagnostic plan is based on the history, physical examination, and clinical pathology data. This may include fecal examination, rectal cytology, abdominal/thoracic imaging,

infectious disease testing, biopsies of enlarged lymph nodes or masses, bone marrow examination if malignancy or disseminated histoplasmosis are suspected, or examination of the gastrointestinal (GI) tract. Cerebrospinal fluid analysis and central nervous system (CNS) imaging should be considered in difficult, unresolved cases of anorexia.

Treatment and Management

Because weight loss and cachexia are constitutional signs of disease, identification and successful treatment of underlying disease processes is necessary to resolve the clinical condition. Simple caloric replacement will not totally reverse weight loss in cachexic animals because they are hypermetabolic.

If the animal will eat normally, a dietary plan should be prepared to ensure sufficient caloric intake to support the animal's metabolic activity. Extra calories should be provided to compensate for weight loss. Calculation of caloric needs is outlined in Chapter 30. Feeding tube placement (Chapters 32 and 33) should be considered for animals with physical or behavioral impediments to food delivery to the stomach. Total or peripheral parenteral nutrition (Chapter 33) should be considered for animals with severe vomiting, pancreatitis, or other disease that prevents normal digestion. Appetite stimulants (e.g., cyproheptadine, mirtazapine) may be effective in hastening resolution of behaviorally induced inappetence.

CHAPTER 25

Laboratory Approach

STOMACH AND SMALL INTESTINE

Jan S. Suchodolski

Gastrointestinal (GI) diseases occur commonly in companion animals. Because of their nonspecific clinical signs, GI disorders pose a diagnostic challenge for the clinician. Collecting an initial database consisting of hematology, serum biochemistry, and urinalysis aids in determining extragastrointestinal causes of the observed clinical signs, and may be useful in the exclusion of systemic and metabolic disorders, the assessment of the severity of the disease, and of the hydration status of the patient. Assessing serum thyroxine (T_4) concentrations and feline leukemia virus (FeLV) and feline immunodeficiency virus (FIV) status are useful adjunct tests in cats with chronic GI disease.

Diagnostic imaging, especially a combination of ultrasonography and radiography, can be helpful for evaluation of patients for obstructions or neoplasia. Endoscopic examination and biopsy of the GI tract is currently regarded as the gold standard and yields information about macroscopic lesions and changes in histologic appearance of the mucosa; however, this approach is invasive. Furthermore, histologic interpretation of biopsy specimens can be highly variable among individual pathologists.[1]

Several specialized laboratory procedures are available for the diagnostic workup of patients with GI disease. Many of these tests can be either used as bedside diagnostics or can be performed by a reference laboratory. These tests include serum markers of GI function and inflammation and the evaluation of fecal samples for infectious agents. These tests are helpful for the diagnosis of GI disease and assessment of severity, and can be employed before proceeding to more invasive diagnostic procedures.

Detection of Bacterial Pathogens

Specific enteropathogens (e.g., *Clostridium perfringens*, *Clostridium difficile*, *Salmonella* spp., *Escherichia coli*, *Campylobacter* spp., or *Yersinia enterocolitica*) are associated with GI disease in dogs and cats. However, most of these enteropathogens are commensals in the GI tract and have been isolated at similar frequencies from diarrheic and nondiarrheic animals.[2] This complicates the clinical interpretation when presumptive enteropathogens are identified. Therefore adjunct laboratory testing for the presence of virulence genes (e.g., *E. coli* virulence factors), and/or toxins (e.g., *C. perfringens* and *C. difficile*) can be helpful in determining the clinical importance of isolated enteropathogens.

Various methods are available for the detection of enteropathogens, including bacterial culture, molecular tools (e.g., polymerase chain reaction [PCR]), or immunoassays (either antigen testing or serology). The analytical sensitivity of each method is influenced by how samples are collected, stored, and shipped. Detailed instructions for sample collection and submission should be obtained for each particular assay. It is important to note that there is generally a lack of standardization with regards to cultivation methods and PCR assays. In particular, DNA extraction and PCR protocols vary substantially among reference laboratories. These differences can have a substantial impact on the analytical sensitivity and specificity of bacterial culture and PCR assays.

Culture-dependent methods should be employed if a specific pathogen is suspected (e.g., *Salmonella* spp.). Isolating enteropathogens allows identification of an active infection by viable organisms, and also allows antibiotic susceptibility testing of the isolates. Individual isolates can be typed for epidemiologic surveys of specific strains and their virulence factors. In contrast, PCR detects DNA or RNA rather than the living cell. Although PCR tests are considered to have a higher sensitivity (in theory a single target copy can be amplified), the extraction of DNA from complex environments such as the intestine remains challenging. Improper DNA extraction from highly complex material, such as fecal samples, may result in residual PCR inhibitors and false-negative PCR results. As a result of the high sensitivity of PCR assays, DNA contamination is an important problem with the potential to lead to false-positive results. Therefore it is recommended that a laboratory with expertise in molecular analysis, which has validated the particular assay for the respective target organism, be selected.

Detection of *Helicobacter* spp.

A high prevalence of *Helicobacter*-like organisms (HLOs) has been reported in the stomach of dogs and cats, with up to 100% of healthy animals being positive in some studies.[3] HLOs are also highly prevalent in the intestine and can be found occasionally in the liver. *Helicobacter pylori*, the clinically most important *Helicobacter* species in man, is typically not isolated from companion animals and has been identified so far only in colony cats. The most commonly observed HLOs in pet cats and dogs are *Helicobacter felis*, *Helicobacter heilmannii*, *Helicobacter salomonis*, *Helicobacter bilis*, *Flexispira rappini*, *Helicobacter bizzozeronii*, and *Helicobacter baculiformis*. Animals usually harbor several different *Helicobacter* spp. The detection of

Helicobacter spp. is based on invasive or minimally invasive methodologies.

Minimally Invasive Methods

Minimally invasive methods allow the detection of *Helicobacter* spp., but do not allow assessment of concurrent GI disease associated with *Helicobacter* spp. Serologic tests have a relatively low sensitivity. Most commercial serologic assays test for immunoglobulin (Ig) G and IgM specific for the human pathogen *H. pylori*, and these assays therefore have little value in companion animals. Antibodies will circulate for several months after eradication of the organism and thus antibody tests have limited use for monitoring therapeutic success.[4] The ^{13}C-urea breath test is based on the detection of metabolic activity of *Helicobacter spp*. The organisms produce the enzyme urease, which catalyzes the metabolism of orally administered ^{13}C-urea. In turn, ^{13}C is released from the urea, incorporated into $^{13}CO_2$, and can be quantified in either breath or blood samples. This method is the diagnostic test of choice in humans and is also used to evaluate the success of treatment. A ^{13}C-urea breath and blood test has been evaluated for use in dogs, but is not offered commercially at this time.[5] Using PCR, *Helicobacter* DNA can also be detected in fecal samples, but the sensitivity of this approach is unclear in companion animals.[6]

Invasive Tests

Gastroscopy not only allows for the detection of *Helicobacter* spp. but also provides information about the presence of gastric lesions. Gastroscopy allows for direct visualization of the gastric mucosa. *Helicobacter* spp. have a typically patchy distribution in the mucosa, and it is recommended that biopsy specimens or impression smears be obtained from several areas of the stomach.[7] However, the cultivation of *Helicobacter* spp. from biopsy specimens is of low sensitivity. *Helicobacter* spp. can be detected in biopsies (Fig. 25-1) by means of histochemical stains (e.g., Warthin-Starry or modified-Steiner stains), immunohistochemistry, fluorescence in-situ hybridization (FISH), PCR, or commercially available rapid-urease tests.[8,9] It is important to note that the rapid-urease tests (e.g., CLOtest, Kimberly-Clark) may require up to 24-hour incubation before displaying a color change indicating a positive test result, especially if the patient has received acid-suppressing therapy. Brush cytology of the mucosa is a highly sensitive method for the detection of *Helicobacter* spp. The material obtained is spread across a microscope slide and stained with May-Grünwald-Giemsa, Gram, or Diff-Quick stain.[8]

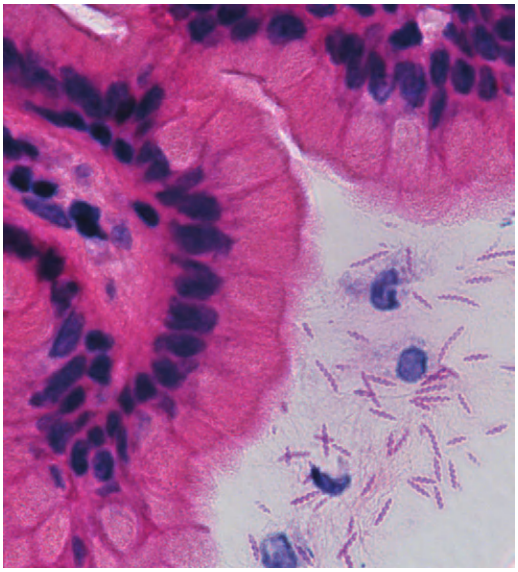

Figure 25-1 *Helicobacter* spp. adjacent to the gastric epithelium in a healthy dog. (Hematoxylin and eosin [H&E] stain; ×100.) (Picture courtesy of Dr. Jose Garcia-Mazcorro, GI Lab, Texas A&M University.)

Diagnosis of *Clostridium perfringens*–Associated Diarrhea

Bacterial culture for the isolation of C. *perfringens* has little diagnostic value as C. *perfringens* is a commensal that can be detected by PCR in up to 100% of dogs and cats.[10] The development of C. *perfringens*–associated diarrhea has been primarily related to the presence of various toxins, especially C. *perfringens* enterotoxin (CPE). A subset of C. *perfringens* organisms carries the gene coding for CPE. When sporulation occurs (this is poorly understood, but suspected triggers include dietary changes or antibiotic use), the enterotoxin is released in high quantities and may potentially cause changes in intestinal permeability leading to diarrhea. Enterotoxigenic C. *perfringens* can be detected by PCR assays that target the CPE gene; however, our recent unpublished studies reveal that 20% of healthy cats, 37% of healthy dogs, and 37% of diarrheic dogs and cats harbor the CPE gene. Similar results with no significant differences in the prevalence of enterotoxigenic C. *perfringens* between healthy and diarrheic dogs have been reported in the literature.[11] Furthermore, of those animals that carry enterotoxigenic C. *perfringens*, the expressed enterotoxin can only be detected in a small proportion of cases. Because of this, and because of the high rate of enterotoxigenic C. *perfringens* carriage in healthy animals, it is recommended that combined testing for the CPE gene by PCR and for the C. *perfringens* enterotoxin by fecal enzyme-linked immunosorbent assay ([ELISA]; e.g., C. *perfringens* enterotoxin test; Techlab, Blacksburg, Virginia) should be performed.[11] Other enterotoxin tests such as the reverse passive latex agglutination (RPLA) assay have a lower analytical sensitivity and are not recommended. Also, enumeration of C. *perfringens* endospores is not considered to be a reliable test for diagnosing C. *perfringens*–associated diarrhea in dogs. In one study, no association was established between C. *perfringens* endospore counts and the detection of CPE, and no difference was observed in the number of observed C. *perfringens* endospores between diarrheic and nondiarrheic dogs.[2]

Diagnosis of *Clostridium difficile*–Associated Diarrhea

Isolation rates for C. *difficile* range between 0% and 40%, and this organism has been isolated in similar frequencies from diarrheic and nondiarrheic dogs.[2,12] Approximately 50% of C. *difficile* organisms harbor toxin A and B genes. Consequently, the significance of detecting C. *difficile* organisms in dogs with diarrhea remains unclear. Currently the most accurate method for diagnosis of C. *difficile*–associated diarrhea is the detection of the organism (either by culture or by antigen testing for glutamate dehydrogenase) in combination with the detection of toxins A and B by ELISA.

The tissue culture cytotoxin-B assay detects the presence of toxin B and is considered the most sensitive (94% to 100%) and specific (99%) test for the diagnosis of C. *difficile*–associated diarrhea.[13] It is, however, technically challenging and requires a 2- to 3-day turnaround time. The latex particle agglutination (LPA) assay and RPLA assay have a high rate of false-positive and false-negative results and are not recommended. Various immunologic assays have

been developed that allow the detection of either toxin A or B or both toxins simultaneously. While most *C. difficile* strains contain toxin A (enterotoxin) and toxin B (cytotoxin), the occurrence of toxin A^-/toxin B^+ strains has been reported. Consequently, it is recommended to use immunoassays that target both toxins. Commercially available human ELISAs that measure both toxins (Premier ToxinA/B and the Techlab ToxinA/B) show a high sensitivity (93%) and specificity (95%) when testing cultured isolates of *C. difficile*. Both ELISAs show a lower sensitivity (27% to 33%) when canine fecal samples are tested directly for the presence of both toxins.[13] Although a positive toxin ELISA result is suggestive of *C. difficile*–associated diarrhea in animals with compatible clinical signs, confirming the presence of the organism improves the diagnostic accuracy. In man, it is recommended that up to three consecutive samples be tested if the first result is negative.

Detection of *Campylobacter* spp.

The normal GI tract harbors various spiral shaped bacteria, including *Campylobacter*, *Helicobacter*, *Spirochaetes*, and *Anaerobiospirillum*.[10] It is not possible to reliably distinguish these organisms on fecal smear examination. At least 14 different *Campylobacter* spp. have been identified in the GI tract of dogs and cats, and most animals harbor multiple species.[14,15] *Campylobacter upsaliensis* and *Campylobacter helveticus* have been reported as the most prevalent *Campylobacter* spp. in dogs and cats, respectively.[14,15] In contrast, *Campylobacter jejuni* and *Campylobacter coli*, the most commonly identified pathogens in man are infrequently isolated from dogs and cats, with prevalence rates ranging between 1% and 10% in most studies.[15,16] Because various *Campylobacter* spp. are part of the normal intestinal ecosystem, species-specific assays able to identify the potentially pathogenic and zoonotic *C. jejuni* or other *Campylobacter* spp. of interest must be used instead of broad-range culture or detection assays.

Salmonella spp.

Bacterial culture has typically a higher sensitivity for the detection of *Salmonella* spp. compared with PCR that is performed on DNA extracted directly from fecal samples. If fecal samples are initially enriched in tetrathionate broth for up to 24 hours before DNA extraction, PCR has a comparable sensitivity to culture.

Escherichia coli

E. coli is a normal inhabitant of the GI tract of dogs and cats.[10] However, diarrheic dogs more commonly harbor *E. coli* possessing specific virulence genes.[17] These include enteropathogenic *E. coli* (EPEC), enterotoxigenic *E. coli* (ETEC), verocytotoxin-producing *E. coli* (VTEC), enterohemorrhagic *E. coli* (EHEC), and enteroinvasive *E. coli* (EIEC). Consequently, molecular assays for the detection of these virulence genes must be employed to detect pathogenic strains of *E. coli*.

Recently, adherent and invasive *E. coli* (AIEC) strains were associated with the development of histiocytic ulcerative colitis in Boxer dogs, which responds to antimicrobial therapy.[18] The AIEC strains can be identified using FISH in mucosal biopsies.

Viral Enteritis

Parvovirus

The diagnosis of parvovirus infection requires a rapid result to initiate immediate treatment. Commonly used in-clinic immunoassays (e.g., SNAP Parvo Test, IDEXX Laboratories) have high positive and negative predictive values for the detection of canine parvovirus (CPV)-2 and can also detect feline panleukopenia virus.[19,20] New studies also show that these assays identify all three CPV types—2a, 2b, and 2c.[19] However, low virus loads may remain undetected with in-house immunoassays and PCR assays have been shown to have a superior analytical sensitivity.[21] Samples from animals that are suspected to have parvovirus infection, but have a negative SNAP test result, can be submitted to a reference laboratory for assessment by PCR or electron microscopy. A disadvantage of the in-house SNAP test is that it cannot differentiate vaccine strains from infectious strains of CPV-2.

Detection of Gastrointestinal Parasites in Feces

Fecal Examination Techniques

Testing for GI parasites is an important part of the diagnostic workup of patients with signs of GI disease. Successful identification of parasites is highly dependent on the quantity (2 to 5 g of feces is optimal) and quality (i.e., freshness) of feces obtained and the storage conditions of the sample. Additional factors determining success include the technique used (e.g., fecal smear, fecal flotation, antigen testing, or PCR) and the expertise of the examiner.

For in-house testing it is important to design a standard operating procedure to ensure that each procedure will be performed in a consistent, systematic, and reproducible manner. All fecal examination techniques have technical limitations. Therefore, negative results do not exclude the possibility of parasite infection, but may reflect low analytical sensitivity of the method used, absence of organisms in the aliquot examined, or intermittent shedding of organisms (e.g., *Giardia*).

Fecal examination techniques include direct fecal smears, fecal flotation with or without centrifugation, sedimentation techniques, antigen testing, and PCR assays. Generally, centrifugal flotation and antigen testing are considered to have the highest analytical sensitivity.

Direct fecal smears (wet mounts; a small amount of feces is mixed with saline yielding a layer that is thin enough to read newsprint through) may be useful for recovery of motile trophozoites (e.g., *Giardia* and *Tritrichomonas foetus*), but should only be performed on very fresh fecal samples (<10 minutes). Adding a drop of Lugol iodine may improve the detection of trophozoites. Additional slides can be prepared and stained (e.g., Diff-Quik) for cytologic examination (e.g., presence of neutrophils, bacterial spores). A disadvantage of direct smears is that only a low sample volume can be analyzed, resulting in a low sensitivity for the detection of intestinal parasites.

Fecal flotation techniques allow the separation of parasites from fecal debris because of the difference in specific gravity of parasite forms (Fig. 25-2). If the flotation solution has a higher specific gravity than the parasite form (e.g., eggs, oocysts, cysts), these will rise to the surface and can be identified (Table 25-1). Because flotation techniques allow the concentration of parasites, a higher sample volume (1 to 5 g) can be analyzed, improving the analytical sensitivity. Fecal flotation should be prepared on fresh feces (<2 hours). Flotation can be performed either as a passive separation technique (e.g., commercial kits including Fecalyzer, Ovassay) or as a centrifugation technique with either a fixed rotor or a swinging bucket rotor. Centrifugation techniques show a consistently higher recovery compared with passive techniques and are currently recommended for routine use in practice. In one study, a direct smear technique failed to identify whipworm eggs 93% of the time.[22] A passive flotation technique (e.g., Ovassay) yielded false-negative results in 30% of samples, while the centrifugation technique using Sheather's Sugar Solution yielded false-negative results in only 5%

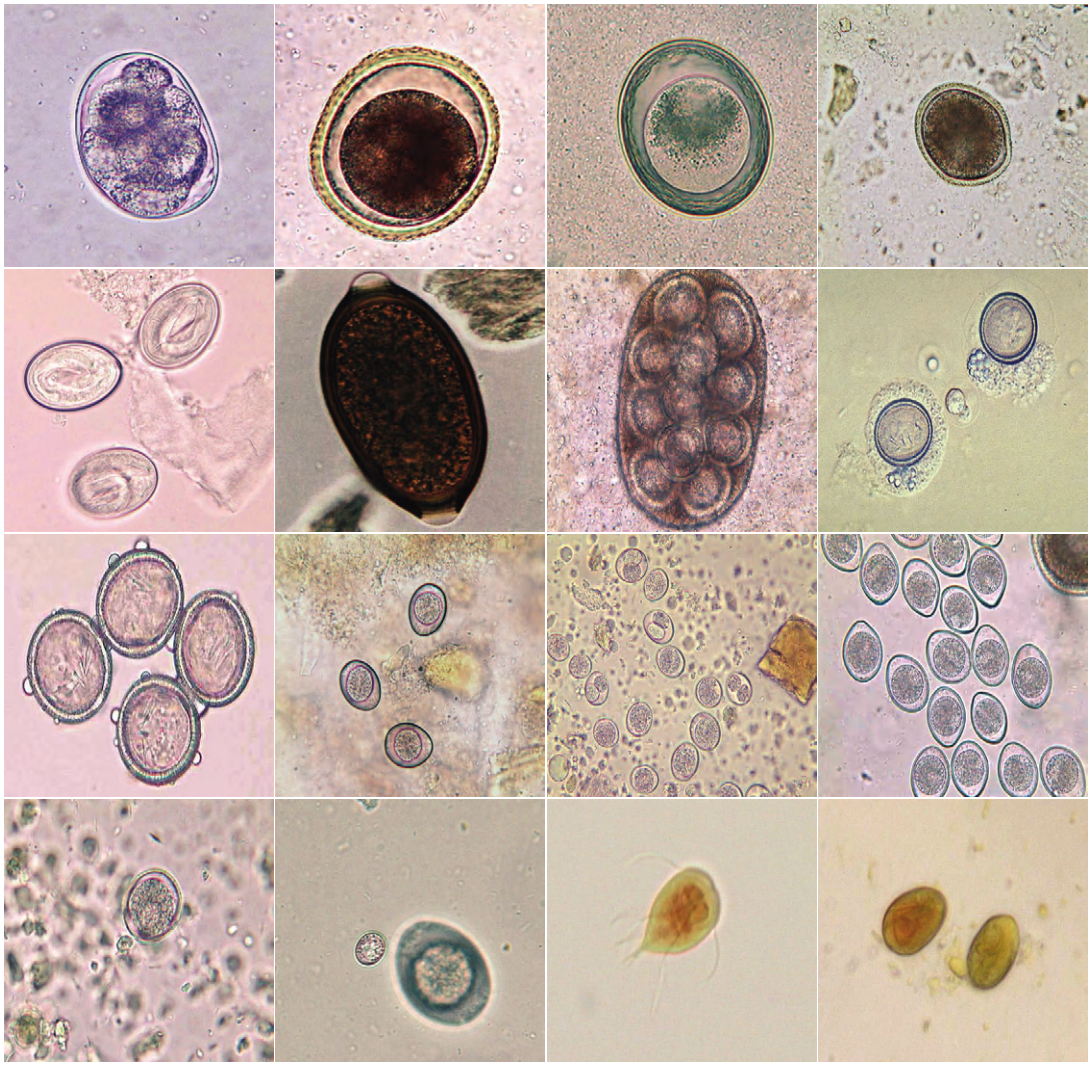

Figure 25-2 Commonly observed parasite eggs, oocysts, and trophozoites in fecal samples. Row 1, left to right: *Ancylostoma caninum* egg, *Toxocara canis* egg, *Toxascaris leonina* egg, *Toxocara cati* egg. Row 3, left to right: *Taenia* spp. eggs, nonsporulated oocysts of *Isospora canis*, nonsporulated oocysts of *Isospora ohioensis*, nonsporulated oocysts of *Isospora felis*. Row 4, left to right: nonsporulated oocysts of *Isospora rivolta*, *Toxoplasma gondii* unsporulated oocysts compared with *Isospora felis* in the background, *Giardia* spp. trophozoite, *Giardia* spp. cysts (iodine stain). (All photos courtesy of Dr. Byron L. Blagburn, College of Veterinary Medicine, Auburn University.)

of the samples examined.[22] Similar results were also observed for other parasite types. The recovery of parasites using commercially available passive flotation kits (e.g., Ovassay) can be improved if the flotation solution is applied for at least 20 minutes.

Box 25-1 summarizes the standard procedure for the centrifugal flotation technique. The specific gravity of the flotation solution plays a critical role in the identification of parasites. The higher the specific gravity of the parasite egg, the higher must be the specific gravity of the flotation solution to allow the ova to rise to the surface. For example, eggs of *Physaloptera* spp. (specific gravity 1.14) and *Taenia* spp. (specific gravity 1.23) have a higher specific gravity than the commonly used $ZnSO_4$ solutions (specific gravity 1.18), thus they will likely remain undetected. Table 25-2 lists the specific gravity of commonly used flotation solutions, and Table 25-1 lists the specific gravity of common parasite eggs. A specific gravity hydrometer may be used to measure the correct specific gravity of the solution. The use of a micrometer to measure the size of cysts and eggs may help identify parasites (see Table 25-1). The use of centrifugation and Sheather's Sugar Solution (specific gravity 1.27; commercially available from Jorgensen Laboratories) is currently recommended as the most efficient method for the recovery of the most common parasite eggs and oocysts.[23]

Diagnosis of Parasites of the Esophagus and Stomach During Fecal Examination

Spirocerca lupi eggs are barrel shaped and elongated with parallel sides (Fig. 25-3). Compared with other parasite eggs they are small (see Table 25-1), typically measuring 20 to 37 × 11 to 18 μm, and contain a larva when laid. The current gold standard for the detection of *S. lupi* is esophageal endoscopy and is required for differentiation between neoplastic and nonneoplastic *S. lupi* nodules.[25] Thoracic radiography is up to 86% sensitive if signs of thoracic vertebrae spondylitis, an undulating aortic border, and a caudal mediastinal mass are included.[24] The reported sensitivity for the

Table 25-1 Characteristics of Important Gastrointestinal Parasites

Parasite	Host	Diagnosis	Size of Reproductive Product (in μm)	Specific Gravity
Nematodes				
Ancylostoma caninum	Dogs	Flotation	70 × 45	1.06
Ancylostoma braziliense	Dogs and cats	Flotation	70 × 45	1.06
Uncinaria stenocephala	Dogs and cats	Flotation	80 × 45	1.06
Ancylostoma tubaeforme	Cats	Flotation	70 × 45	1.06
Toxocara canis	Dogs	Flotation	85 × 75	1.09

Table 25-2 Specific Gravities of Flotation Solutions

Solution	Specific Gravity*	Preparation in Water
Water	1.00	N/A
Sodium chloride	1.18	350 g per 1 L
Magnesium sulfate	1.20	450 g per 1 L†
Zinc sulfate	1.18	331 g per 1 L
Sodium nitrate	1.18	338 g per 1 L
Sheather's sucrose¶	1.27	454 g per 355 mL w/ 6 mL formaldehyde†

*Verify specific gravity with hydrometer.
†Water must be heated to get substance into solution.
¶Recommended flotation solution.

Figure 25-3 *Spirocerca lupi* egg containing a larva. The eggs are small and barrel-shaped. The reported sensitivity for the detection of eggs in feces is low and was highest (67%) when using a centrifugal flotation technique with $NaNO_3$ (specific gravity 1.22). Endoscopy is the recommended method for the detection of *Spirocerca lupi* (×400). (Picture courtesy of Dr. Jevan Christie, University of Pretoria, South Africa.)

Box 25-1 Procedure for Fecal Examination Using a Centrifugation Technique

1. Two to 5 g of feces (preferably abnormal stool) are mixed with 10 mL of flotation solution.
2. This emulsion is poured through a tea strainer or a cheese cloth into a fecal cup. Straining is important to remove the heavy fecal matter.
3. The emulsion is poured into a 15-mL conical centrifugation tube. The amount of flotation solution to be added depends on the rotor used (swinging bucket or fixed angle).

- *Swinging bucket rotor:* flotation solution is added to create a slightly positive meniscus (but do not overfill the tube to avoid spilling of parasite eggs).
  - Cover slip is placed on top of the tube *before* centrifugation.
  - Tube is centrifuged for 5 minutes at 280 g (1200 rpm).
  - The tube (with coverslip) is removed and let stand for 10 minutes.
- *Fixed angle rotor:* the tube is filled only ¾ full with flotation solution.
  - Tube is centrifuged for 5 minutes at 280 g (1200 rpm).
  - After centrifugation, more flotation solution is carefully added with a pipette down the side of the tube until the positive meniscus is created on top of the tube.
  - The coverslip is now placed on top of the tube and let stand for 10 minutes.

4. The coverslip is removed after 10 minutes and placed on a glass slide. The entire glass slide should be systematically scanned using ×10 magnification (i.e., 100 diameters). The ×40 magnification can be used for identification and measurement of parasites. It is important to standardize the procedure (including microscopic examination) for consistent results.

detection of eggs in feces is low and was highest (reaching 67%) using a centrifugal flotation technique with $NaNO_3$ (specific gravity 1.22).[25]

Stomach worms can cause vomiting, anorexia, melena, and anemia. The small stomach worm of cats (*Ollulanus tricuspis*; size 0.7 to 0.9 cm) can be detected during microscopic examination of vomitus or gastric lavage solution. *O. tricuspis* is sometimes also observed in dogs. Eggs of the large stomach worm of dogs and cats (*Physaloptera* spp.) have a high specific gravity (see Table 25-1) and are therefore difficult to detect in fecal smears or by fecal flotation using standard flotation solutions. However, as a result of the size and appearance of the worms (1 to 6 cm in length, cream to white colored, often coiled), they can be sometimes visualized in vomitus or during endoscopic examination.

Diagnosis of Parasites of the Small and Large Intestine

Giardia spp.

A centrifugation technique using Sheather's Sugar Solution is currently considered the best method for performing routine fecal flotation in practice; however, the sugar solution may distort or even destroy *Giardia* cysts, making them more difficult to diagnose for an inexperienced examiner. Therefore, the use of $ZnSO_4$ (specific gravity 1.18 to 1.2) may be a better method for diagnosis of *Giardia* spp. in practices that do not routinely analyze fecal samples. However, even the use of $ZnSO_4$ requires an experienced examiner and false negatives can occur. The in-clinic *Giardia* SNAP test

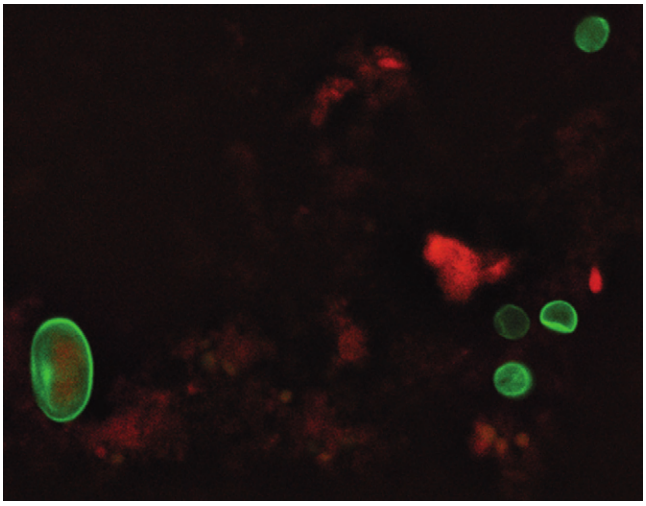

Figure 25-4 Immunofluorescence assay (IFA) for the simultaneous detection of *Giardia* and *Cryptosporidium* spp. in canine or feline fecal samples. The assay utilizes fluorochrome-labeled antibodies directed against *Giardia* (large green oval structure on the *left*) and *Cryptosporidium* (smaller green four round structures on the *right*). Fecal debris is stained red (×100). (Picture courtesy of Dr. Yasushi Minamoto, GI Lab, Texas A&M University.)

(IDEXX SNAP *Giardia* test) has a comparable sensitivity to $ZnSO_4$ centrifugation and ameliorates the need for identification of *Giardia* cysts based on morphology. However, false-negative results can occur and the combination of the SNAP *Giardia* test and $ZnSO_4$ centrifugation performed on the same sample may show the highest sensitivity.[23] *Giardia* cysts are shed intermittently and a single negative result on either or both of these tests does not rule out a *Giardia* infection. Therefore, the examination of three consecutive fecal samples over a period of 7 days (or pooled samples from consecutive defecations) examined using both $ZnSO_4$ and the *Giardia* SNAP test may achieve 94% accuracy.[26] It is important to note that the number of recovered cysts is typically independent of the clinical disease. Cysts are shed intermittently and it is not possible to draw conclusions about the severity of the disease.

The detection of *Giardia* antigen using a fluorochrome-labeled monoclonal antibody (immunofluorescence antibody test [IFA]; Merifluor *Cryptosporidium/Giardia* Direct Immunofluorescence Test Kit; Meridian Bioscience Inc, Cincinnati, Ohio) is often used as the gold standard for the diagnosis of a *Giardia* infection (Fig. 25-4).[27,28] A recent study compared IFA with $ZnSO_4$ flotation centrifugation, the in-clinic IDEXX SNAP *Giardia* test, and a commercial ELISA for *Giardia* antigen (*Giardia* II Test Direct ELISA; Techlab Inc, Blacksburg, Virginia). The authors found discordant results, suggesting that at the observed prevalence rates in a clinical setting (estimated prevalence rate: 4% to 10%), the in-house tests have poor positive predictive values but good negative predictive values.[27] This would suggest that when used in practice, these assays are helpful in ruling *out* giardiasis, but are incapable of ruling *in* the diagnosis.[27] These results also indicate that the in-house methods should not be used as screening tools in healthy animals, as false-positive results may occur, leading to an improper diagnosis and treatment.[27]

The use of a nested PCR assay for the detection of *Giardia* from fecal samples has been reported, and has shown good sensitivity for detecting *Giardia duodenalis* in cats.[29] The nested PCR allows determination of the genotype (also called assemblage) of the organisms, which is useful for epidemiologic studies.[29,28]

Three anterior flagellae and an undulating membrane that runs the length of the body can be seen. (Image reproduced with permission from www.fabcats.org; photo by Dr. A. Sparkes.)

Cryptosporidium spp.

Cryptosporidium oocysts can be isolated using centrifugal flotation with sucrose, but this technique showed a low sensitivity of 21.4% in one study.[30] The oocysts have a spheroid shape and because of their very small size (4 to 6 μm in diameter), they can easily be missed on fecal smears. An acid-fast stain will stain the oocysts red on fecal smears. The currently recommended test for detection of *Cryptosporidium* spp. is an IFA that will also simultaneously identify *Giardia* cysts (Merifluor *Cryptosporidium*/*Giardia* Direct Immunofluorescence Test Kit; Meridian Bioscience Inc, Cincinnati, Ohio). This test requires a fluorescence microscope and is offered by major reference laboratories. Figure 25-4 illustrates the size comparison between *Cryptosporidium* oocysts and *Giardia* cysts using the IFA.

A PCR test has been described, showing a higher analytical sensitivity for *Cryptosporidium parvum* in feline fecal samples compared with IFA.[31] In a study of dogs and cats with diarrhea, 24.3% were positive for *Cryptosporidium* on PCR, while only 2.7% were positive on IFA.[32] Commercially available in-clinic immunoassays have a low analytical sensitivity (42.9% to 71.4%) compared with IFA, but have been shown to have acceptable specificity (>96%) for detecting *Cryptosporidium* spp. in feline fecal samples.[30]

Canine Schistosomiasis

Canine schistosomiasis, also named bilharziasis, is caused by the trematode *Heterobilharzia americana*. Nutria, raccoons, and other vermin are the natural reservoirs for *H. americana*. Transmission is via penetration of the skin by cercariae in water sources containing the snail intermediate host. Clinical signs of infected dogs include lethargy, weight loss, hyporexia, vomiting, and diarrhea.[33] Diagnosis can be made on visualizing a granulomatous response to the migrating eggs in the hepatic or intestinal tissue at necropsy or histopathology. Parasite eggs can be demonstrated using saline fecal sedimentation (Fig. 25-5).[34] Canine schistosomiasis can also be diagnosed with an immunoassay detecting antigen in feces or urine that was originally developed for use in humans or by a fecal PCR assay specific for *H. americana*.[33]

Tritrichomonas foetus

T. foetus, a flagellated protozoan, has been identified as a pathogen in cats, causing diarrhea after both experimental and natural infection.[35] Trichomonads do not form cysts, but they reproduce by binary fission and are transmitted directly between hosts as trophozoites (Fig. 25-6). Pathogenic and nonpathogenic species of trichomonads can be found in the GI tract of dogs and cats. Diagnosis of a *T. foetus* infection can be made by the visualization of trophozoites on a direct fecal smear, by culture or PCR analysis of fecal material, or by observation of organisms in colonic mucosal biopsy specimens. The best results for all the detection methods are obtained if diarrheic stools are examined. Direct fecal smear examination has a low sensitivity (<14%) and low specificity (*T. foetus* can be misdiagnosed as *Giardia* spp. or the nonpathogenic *Pentatrichomonas hominis*). For the cultivation of organisms, the in-house culture system (In Pouch TF; Biomed Diagnostics, San Jose, California) should be inoculated with approximately 50 mg of freshly voided, loop or flush-collected feces, and then incubated at 25°C (77°F) for up to 12 days.[36] The pouch must be evaluated under a microscope every couple of days. *Giardia* spp. and *P. hominis* organisms do not survive in the culture media for longer than 24 hours and thus positive cultures are strongly suggestive of *T. foetus* infection.[36] The reported sensitivity for culture is 1000 *T. foetus* organisms per 50 mg of feces. *T. foetus* DNA can be amplified from fecal samples by PCR.[37] A nested PCR assay has been reported as the most sensitive method for detecting *T. foetus* in fecal samples (10 *T. foetus* organisms per 50 mg of feces).

Assessment of Gastrointestinal Function and Pathology

Gastrointestinal Permeability Testing

Various GI diseases can cause epithelial damage that will lead to an increase in intestinal permeability and subsequently to the translocation of antigens and/or pathogens through the intestinal mucosa. For the assessment of GI permeability exogenous nonmetabolizable markers, such as polyethylene glycol (PEG), mono- and

disaccharides, or radiolabeled substances are administered orally.[38-40] An increased recovery of those markers (e.g., lactulose, 51-chromium-labeled ethylenediaminetetraacetate [^{51}Cr-EDTA]) in serum or urine indicates an increase in GI permeability, while a decreased recovery of other markers indicates a decreased absorptive capacity of the marker (e.g., methylglucose).[39] Traditional probes such as ^{51}Cr-EDTA and PEG do not undergo metabolism or bacterial degradation in the GI tract and remain intact during their passage through the gut. Therefore the increased appearance of such probes in serum or urine indicates an increased permeability of the GI tract, but it is not helpful in localizing a specific site of the GI tract. In contrast, the various sugar probes are metabolized or undergo bacterial degradation in different parts of the GI tract. Therefore, a mixture of sugar probes can be used to help localize the site of increased GI permeability. For example, orally administered sucrose is too large to penetrate the intact gastric mucosa and is broken down by brush border enzymes upon entering the small intestine. Therefore, sucrose is typically not recovered in urine or serum of healthy animals with an intact gastric mucosa. However, an increase in the urine or serum concentration of sucrose is indicative of an increased gastric permeability suggestive of gastric mucosal damage. In contrast, the sugar probes lactulose and mannitol will survive the passage through the stomach and proximal small bowel, but will undergo bacterial degradation in the distal small intestine and colon. Therefore, changes in their recovery suggest an altered permeability in the small intestine. Sucralose is resistant to bacterial degradation in the colon and is also not absorbed in the GI tract. An increase in serum or urine sucralose can therefore be indicative of increased GI permeability in any part of the intestine. If sucralose is used in combination with other sugar probes, it can serve as a marker for large bowel permeability (i.e., increase in sucralose concentration but normal concentration of small intestinal sugar probes).

Rhamnose (R) and lactulose (L) are commonly used as markers for small intestinal permeability. The monosaccharide rhamnose crosses the epithelium passively through small pores in the intestinal cells (transcellular uptake). The disaccharide lactulose crosses the epithelium through larger pores located near the tight junctions of the intestinal cells (paracellular uptake). These larger pores occur less frequently than the smaller pores that allow penetration of monosaccharides. In animals with an intact intestinal epithelium, less lactulose in relation to rhamnose (expressed as lactulose/rhamnose [L/R] ratio) will cross the intestinal mucosa and can be recovered in serum or urine. Intestinal disorders cause a decrease in the total epithelial surface area in the intestine, causing a reduction in the transcellular pores and an increase in the permeability of the tight junctions. This results in an increase in the L/R recovery ratio. For the evaluation of small intestinal absorptive capacity, the monosaccharides xylose (X) and methylglucose (M) are commonly used, as they both are absorbed through a carrier-mediated transport. The two different markers are often measured together to assess intestinal damage, as xylose is absorbed by fructose carriers and methylglucose is absorbed by glucose carriers in the small intestine.[38,40]

Measurement of permeability may be helpful in disorders that are not accompanied by histopathologic changes in the GI mucosa. For example, increases in intestinal permeability have been reported in dogs with small intestinal bacterial overgrowth (SIBO), gluten-sensitive enteropathy, intestinal ischemia–reperfusion injury, nonsteroidal antiinflammatory drug–induced damage, and diet-responsive diarrhea.[41,42] However, intestinal permeability testing was not useful as an indicator of clinical disease activity in dogs with chronic enteropathies.[38] There is currently a lack of standardization for the various methods used for the assessment of intestinal permeability among laboratories. Furthermore, only few studies have been performed in clinical patients, and the interpretations of the results of GI permeability testing have not been well elucidated for routine clinical settings.

Evaluation of Intestinal Protein Loss

Protein-losing enteropathy (PLE) is defined as a heterogeneous group of diseases in which plasma proteins are lost into the GI lumen. Any GI disease, if severe enough, can lead to intestinal protein loss. Common causes for PLE include inflammatory enteropathies (e.g., inflammatory bowel disease [IBD]), infectious enteritis (bacterial, parasitic, or fungal enteritis), lymphangiectasia, intestinal neoplasia (e.g., lymphoma), intussusception, immunoproliferative disease, and small intestinal dysbiosis.[43] Although most animals with GI protein loss display panhypoproteinemia, it is not uncommon to encounter patients with hypoalbuminemia but without hypoglobulinemia. This is a result of an increased globulin production caused by concurrent or underlying disease (e.g., histoplasmosis, ehrlichiosis, chronic skin disease, immunoproliferative small intestinal disease in the Basenji). Therefore, it is crucial to determine serum albumin concentrations in addition to total plasma protein. Other causes of protein loss such as protein-losing nephropathy and hepatic insufficiency must be excluded.[43]

ELISAs for the measurement of fecal α_1-PI (α_1-proteinase inhibitor) have been validated for cats and dogs and are useful in assessing protein loss through the GI tract.[44,45] α_1-PI is a serum proteinase inhibitor, and is present in the lumen of the GI tract in trace amounts. α_1-PI has a similar molecular mass (approximately 60 kDa) to albumin. When GI disease is severe, α_1-PI is lost together with albumin into the lumen. Albumin is usually rapidly degraded by proteolytic enzymes, but α_1-PI is a proteinase inhibitor that is resistant to proteolytic enzymes and can be measured in feces as an intact molecule. α_1-PI serves as an indicator of loss of plasma proteins into the GI tract.

If intestinal protein loss is suspected in patients with concurrent renal or hepatic disease, the measurement of fecal α_1-PI concentration may help distinguish PLE from other causes of protein loss. Measurement of fecal α_1-PI can also be useful in animals with hypoalbuminemia that do not have signs of GI disease and where renal or hepatic causes of protein loss have been excluded. Fecal α_1-PI may be increased before protein loss is severe enough to lead to hypoalbuminemia. It should be noted that puppies and kittens younger than 1 year of age have significantly higher concentrations of fecal α_1-PI.

Other methods for the measurement of enteric protein loss involve determining the recovery of intravenously administered radioactively labeled substances (e.g., ^{51}Cr-albumin) in fecal samples.[46] Although considered the gold standard, those tests have the obvious disadvantage of the use of radioactivity.

Minimally Invasive Markers for Assessment of Gastric and Intestinal Inflammation and Damage

Serum Gastrin

A commercially available chemiluminescence immunoassay for use in humans (Immulite 2000, Siemens Diagnostics) has been validated for measurement of serum gastrin concentrations in dogs and cats.[47] Serum should immediately be separated from blood cells, frozen, and shipped on ice. The measurement of serum gastrin is useful in cats and dogs with unexplained gastric erosion or ulceration and mucosal hyperplasia. A several-fold and persistent increase (multiple consecutive samples should be evaluated after a 12- to

24-hour fast) in serum gastrin concentration in animals with concurrent clinical signs is suggestive of a gastrinoma. Normal fasting serum gastrin concentration makes gastrinoma unlikely. If serum gastrin is not markedly increased and a gastrinoma is suspected, a secretin stimulation test can be performed. However, it should be noted that, at least in dogs, the administration of a proton pump inhibitor can lead to massive increases of serum gastrin concentrations. Thus, such medication should be discontinued for at least 10 days before measurement of serum gastrin concentration,

Inflammatory Markers

Fecal calprotectin (also called calgranulin A/B or S100A8/A9) and calgranulin C (S100A12) have been reported to be increased in serum and/or plasma in human patients with various inflammatory disorders and are also sensitive and specific fecal markers for human IBD. Species specific assays for dogs have been developed and show promise for the assessment of intestinal inflammation in this species.[48,49] The clinical utility of these assays is under investigation. *N*-methylhistamine is a stable metabolite of histamine and has been used as a marker for mast cell activity and systemic release of histamine in human IBD. The use of *N*-methylhistamine in dogs and cats as a marker for GI disease is currently under investigation.

C-reactive protein (CRP) is a sensitive but nonspecific inflammatory marker and has been shown to correlate with the degree of experimentally induced damage to the gastric mucosa and with the clinical activity index in canine IBD.[50,51] New studies have evaluated the index of variability for CRP, suggesting that the use of population-based reference range is not appropriate for evaluating changes in CRP concentrations in individual patients (Ruaux CG, research abstract, ACVIM Forum 2010). Therefore, for assessment of the severity of GI disease, serial CRP measurements should be performed, and modest changes in serum CRP concentrations may indicate of the severity of GI disease.

Citrulline

Citrulline is an amino acid that is synthesized mostly by intestinal enterocytes and also to some degree by hepatocytes. Citrulline has been used as a marker of functional enterocyte metabolic mass. For example, human studies have demonstrated a correlation between fasting plasma citrulline concentrations and the functional length of the small intestine in patients with short bowel syndrome.[52] Plasma citrulline concentration has been shown to be significantly decreased in dogs with parvovirus enteritis, indicating that citrulline is a potential marker for spontaneous acute and severe intestinal failure.[53]

Occult Blood Testing

Fecal occult blood tests are used to detect blood in stools before visible melena occurs. Several assays are commercially available and are based on different test principles (e.g., guaiac or o-toluidine fecal occult blood tests). Their clinical use in dogs and cats is limited as they have poor sensitivity and specificity. Because the assay is not specific for a patient's hemoglobin, but can also react with any dietary hemoglobin, false-positive test results occur frequently. Therefore, to increase the specificity of occult blood testing, patients must ideally be on a meat-free diet for at least 3 days before fecal samples are collected.[54] However, it should be noted that the effect of diet is much smaller on tests based on o-toluidine when compared with those based on guaiac. Tests performed on three consecutive bowel movements may help to avoid false-negative results. Manual stool collection may cause iatrogenic blood contamination.

Miscellaneous Tests

An increased plasma L-lactate concentration (>6.0 mmol/L) has been shown to be a negative prognostic marker for postoperative survival time in dogs following gastric dilation volvulus.[55] Serum pepsinogen concentrations have been measured in humans to assess gastric inflammation and *H. pylori* infection. However, serum pepsinogen and serum gastric lipase concentrations were not useful in detecting gastric lesions in dogs or cats.[56]

Evaluation of Gastrointestinal Motility

The assessment of GI motility remains challenging, mostly because of the lack of practical and reproducible minimally invasive test procedures.[57] Scintigraphy is considered the gold standard for evaluation of gastric emptying but requires the use of a radioactive probe. Alternatively, radiopaque markers, such as barium-impregnated polyethylene spheres (BIPSs), have been introduced as an alternative. Both these markers have the disadvantage that, depending on their size, they only mimic emptying of either solid or liquid food.[58] Ultrasonography is a reliable and quantitative method for assessing the emptying time of liquids and solids when performed by an experienced ultrasonographer. A minimally invasive method to assess gastric emptying time in dogs and cats is the ^{13}C-octanoic acid breath test.[59] This test allows labeling of a complex meal with ^{13}C-octanoic acid, a medium-chain fatty acid that is absorbed in the duodenum. In liver ^{13}C is released and oxidized. A rise in $^{13}CO_2$ in the expiratory air or in blood indicates that gastric emptying has occurred.

The use of a wireless capsule (SmartPill), originally designed for use in humans, has been reported for assessment of GI motility in dogs.[60] The capsule measures 13 × 26 mm and is given orally to dogs. The capsule records pH, pressure, and temperature along its passage through the GI tract. These parameters allow calculation of gastric emptying time, small intestinal and/or colonic transit time, and also the total GI transit times. This system appears reproducible in dogs, and changes in GI motility in response to dietary modification and motility altering drugs have been demonstrated. Because of the size of the capsule, it leaves the stomach at the onset of the interdigestive migrating motor complexes (MMCs) after all liquids and solids have already been propelled into the small intestine. Because of the size of the capsule, this method cannot be used in cats and only in dogs of more than 15 kg body weight.

Assessment of Intestinal Function and Pathology

Serum Cobalamin and Folate

The uptake of cobalamin (vitamin B_{12}) and folate from the small intestine is dependent on several factors and can therefore be used as an indirect marker for the assessment of GI disease. Disorders that may affect serum cobalamin and/or folate concentrations include small intestinal inflammation, exocrine pancreatic insufficiency (EPI), and small intestinal dysbiosis (also referred to as small intestinal bacterial overgrowth [SIBO] or antibiotic-responsive diarrhea [ARD]). As a consequence of different sites of absorption, specific changes in serum cobalamin and folate concentrations can yield information on the localization and potentially the severity of intestinal disease (Table 25-3). Serum concentrations of cobalamin and folate should be assessed in any dog or cat with clinical signs of GI disease.

Cobalamin

Cobalamin is an essential, water-soluble vitamin and an important cofactor for many biochemical reactions. Canine and feline diets contain plentiful cobalamin, making a dietary insufficiency unlikely.

Table 25-3 Interpretation of Serum Cobalamin and Folate Concentrations in Dogs and Cats with Gastrointestinal Diseases

	Serum Folate	Serum Cobalamin
Increased	Dogs: small intestinal bacterial overgrowth Cats: clinical significance unknown Increased dietary intake of folic acid Vitamin supplementation	Clinical significance unknown in dogs and cats Recent parenteral administration (<4 weeks) of cobalamin
Decreased	Proximal or diffuse small intestinal disease (e.g., IBD, lymphoma, fungal disease)	Distal or diffuse small intestinal disease involving the ileum (e.g., IBD, lymphoma, fungal disease) Small intestinal bacterial overgrowth Exocrine pancreatic insufficiency Hereditary cobalamin malabsorption Low dietary intake (vegetarian diet)

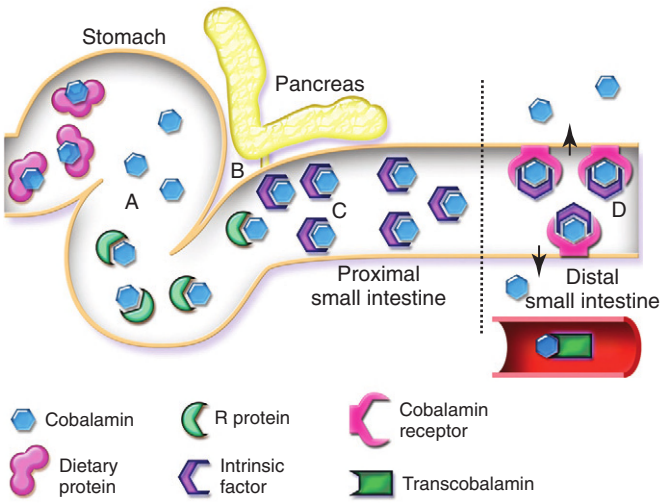

Figure 25-7 Absorption of dietary cobalamin. A, In the diet, cobalamin is bound to dietary protein. After digestion of these proteins in the stomach by pepsin and hydrochloric acid, cobalamin is released and immediately bound to R-protein, which is secreted in saliva and gastric juice. **B**, Pancreatic enzymes (i.e., trypsin and chymotrypsin) digest R-protein, again releasing cobalamin. **C**, Intrinsic factor, produced mostly in the pancreas in dogs and exclusively in the pancreas in cats binds to cobalamin and serves as a transporter to the distal small intestine (i.e., ileum). **D**, Cobalamin/intrinsic factor complexes are absorbed by specific receptors located in the ileal mucosa. (Reprinted from Suchodolski J, Steiner J. Laboratory assessment of gastrointestinal function. *Clin Tech Small Anim Pract* 18:207, 2003. With permission from Elsevier.)

However, patients that are fed an exclusively non-fortified vegetarian diet for longer periods may develop cobalamin deficiency unless supplementation occurs.

The physiologic mechanism of cobalamin absorption is complex and requires a functioning digestive system (Fig. 25-7). Dietary cobalamin is bound to animal-based protein. After digestion of these carrier proteins in the stomach, the cobalamin is immediately bound to R-protein, a cobalamin transporter secreted in saliva and gastric juice. Pancreatic enzymes (i.e., trypsin and chymotrypsin) digest the R-protein in the small intestine, and the free cobalamin is bound by intrinsic factor. The exocrine pancreas is a major source of intrinsic factor in dogs and appears to be the exclusive source of intrinsic factor in cats.[61] This is in contrast to humans where intrinsic factor is produced predominantly in the stomach. Intrinsic factor/cobalamin complexes are then absorbed by specific mucosal receptors located in the ileum.

Major disorders that interfere with cobalamin uptake are EPI, distal or diffuse small intestinal disease, and excess bacterial utilization of cobalamin in bacterial dysbiosis. Aberrations in the small intestinal microbiota may lead to increased competition for cobalamin resulting in decreased absorption by the host. Bacteria in the gut may compete with receptors located in the distal small intestine and prevent cobalamin uptake by enterocytes. *Bacteroides* spp. are the principal organisms involved because they can utilize cobalamin-intrinsic factor, whereas other bacteria can only bind free cobalamin, which is present in lower concentrations in the gut. The reported sensitivity of serum cobalamin for the diagnosis of SIBO is 25% to 55%.[62]

Any long-standing and severe intestinal disease (e.g., IBD, lymphoma, or fungal disease) affecting the ileum may also lead to damage of mucosal cobalamin receptors. This can cause cobalamin malabsorption with a subsequent depletion of body stores of cobalamin, and ultimately lead to a decreased serum cobalamin concentration.

Abnormalities of both vitamins are common in dogs and cats with EPI. Therefore, EPI should be ruled out in patients with GI signs and a decreased serum cobalamin concentration. Serum cobalamin must bind to intrinsic factor in order to be absorbed by receptors located in the distal ileum. Because the exocrine pancreas is the exclusive source of intrinsic factor in cats and the main source in dogs, EPI will lead to decreased secretion of intrinsic factor and, therefore, decreased uptake of cobalamin. Cats with EPI almost always have subnormal serum cobalamin concentrations. Similar subnormal cobalamin concentrations have been described in excess of 80% in dogs with EPI.[63]

The measurement of serum concentrations of cobalamin is only an indirect test for assessing cobalamin deficiency. Cobalamin deficiency leads to accumulation of serum or urine methylmalonic acid (MMA), the concentrations of which are often dramatically increased in patients with cobalamin deficiency and have been shown to decrease with cobalamin supplementation.[64] It has also been shown that some patients with low normal serum cobalamin concentrations have increased MMA concentrations, indicating cobalamin deficiency on a cellular level.[64] Therefore, cobalamin deficiency may even be present when serum cobalamin concentration is in the low end of the reference interval (<350 ng/L) and parenteral cobalamin supplementation should be considered in patients with compatible clinical signs. The measurement of MMA concentration is technically challenging and currently only available through few laboratories. Very young puppies (up to 13 weeks) have been shown to have lower serum cobalamin concentrations than adult dogs. Also, a hereditary form of cobalamin deficiency has

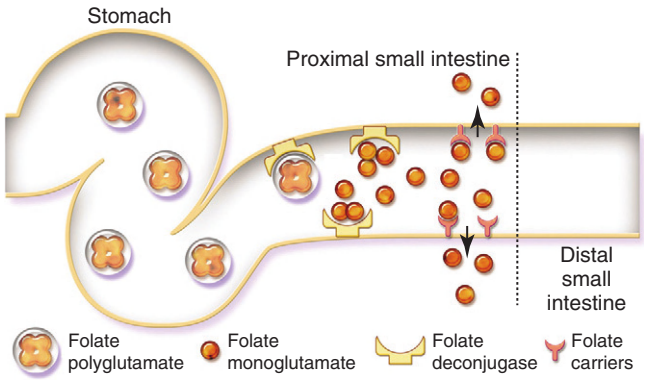

Figure 25-8 Absorption of folate. Dietary folate is usually present in the poorly absorbable polyglutamate form. Folate deconjugase, a brush-border enzyme secreted in the jejunum, removes all but one glutamate residue from the molecule. Specific carriers for folate monoglutamate in the proximal small intestine will promote folate uptake. Disease processes located in the proximal small intestine can lead to damage of folate carriers resulting in a decreased serum folate concentration. (Reprinted from Suchodolski J, Steiner J. Laboratory assessment of gastrointestinal function. *Clin Tech Small Anim Pract* 18:208, 2003. With permission from Elsevier.)

been reported in both dogs and cats, and affected animals present usually at a young age (6 to 12 weeks).[65]

Folate

Folate is a water-soluble vitamin that, similar to cobalamin, is abundant in canine and feline diets, making nutritional deficiency unlikely. Dietary folate is typically present in the poorly absorbable polyglutamate form. In the proximal small intestine, the brush-border enzyme folate deconjugase removes all but one glutamate residue from the molecule (Fig. 25-8). The uptake of folate monoglutamate occurs through specific carriers located in the proximal small intestine. Folate uptake is increased at a slightly acidic pH. Because erythrocytes contain high concentrations of folate hemolysis may lead to falsely increased serum folate concentrations.

In dogs increased serum folate concentrations can be indicative of small intestinal dysbiosis (SIBO/ARD). Resident bacteria in the distal small intestine (i.e., ileum) and in the large intestine can produce large quantities of folate. Because the carriers responsible for folate uptake are located exclusively in the proximal small intestine, folate produced in distal sections of the intestine cannot be absorbed. However, if folate-producing bacteria proliferate in the proximal small intestine, the bacterial folate can be absorbed by the host resulting in increased serum folate concentrations. The reported sensitivity of serum folate for the diagnosis of SIBO in dogs ranges from 50% to 66%, while no such data are available for cats.[62] Increases in serum folate concentrations are also often observed in dogs with EPI. Reduced pancreatic secretions, which normally help to suppress bacterial colonization in the small intestine, may lead to bacterial overgrowth in the small intestine. In contrast to dogs, cats with EPI often have a concurrent chronic enteropathy that may damage folate receptors in the proximal small intestine, leading to decreased serum folate concentrations.

Serum Cobalamin and Folate Concentrations in Patients with Small Intestinal Disease

Serum concentrations of cobalamin and folate are often abnormal in animals with EPI, and exocrine pancreatic function should be assessed in every animal with chronic GI disease. If serum trypsin-like immunoreactivity (TLI) is normal, then changes in serum cobalamin and folate are highly suggestive of small intestinal disease. The specific receptors for cobalamin and folate are located in different parts of the small intestine. Inflammatory disorders (e.g., IBD, lymphoma, fungal disease), especially if they are severe and chronic, may damage these receptors and can cause, depending on the localization of inflammation, subnormal serum concentrations of one or both vitamins.[66] A low serum folate concentration suggests proximal small intestinal disease, while low serum cobalamin suggests ileal disease. If both vitamins are decreased, this is indicative of a diffuse and potentially severe disease process.

Assessment of serum cobalamin and folate are helpful tools for the diagnosis of small intestinal dysbiosis (SIBO/ARD), although they have a poor sensitivity and specificity.[62] Serum cobalamin may be decreased and serum folate may be increased in animals with SIBO/ARD. If both vitamins are altered, then this is highly suggestive of small intestinal dysbiosis. However, changes may be evident only in chronic disease.

Assessment of Small Intestinal Dysbiosis

A definitive diagnosis of small intestinal dysbiosis is difficult to obtain. A tentative diagnosis can be made based on the combination of clinical signs, altered serum cobalamin and folate concentrations, and by a successful antibiotic therapeutic trial. However, other conditions, such as undetected intestinal pathogens, may also respond to antibiotic therapy, and an improvement after therapy does not necessarily confirm the presence of small intestinal dysbiosis. The measurement of serum cobalamin and folate concentrations is probably the most useful aid for the diagnosis of SIBO for the clinician, although both have a poor sensitivity and specificity for the diagnosis of SIBO.[62] Serum cobalamin may be decreased and serum folate may be increased; if both serum vitamin concentrations are altered this is considered highly suggestive of SIBO.

Quantitative cultures of duodenal juice have been considered the gold standard for SIBO. It is now well established that there is no correlation between bacterial counts and disease status, as in some studies healthy dogs had higher bacterial counts in the duodenum compared with dogs with suspected SIBO.[62] New studies have shown that each dog harbors a very unique small intestinal microbiota, making the determination of a normal or abnormal microbiota difficult.

Many other tests have been proposed for the evaluation of suspected small intestinal dysbiosis, including the measurement of serum unconjugated cholic acid (SUCA) concentration, the ^{13}C-xylose absorption test, the ^{13}C-bile acid absorption test, urinary indican test, or the hydrogen breath test. However, all of these tests are associated with a high degree of interindividual variation, making them unrewarding for the diagnosis of SIBO. Therefore, these tests have very limited clinical utility for the routine evaluation of patients with suspected SIBO.[62]

A recent study has shown an increased serum D-lactate concentration in cats with various GI diseases. The D-enantiomer of lactic acid is not normally found in any appreciable quantities in serum from mammals. The increase in serum D-lactate in cats with GI disease is possibly a result of derangements of the intestinal microbiota and increased bacterial production of D-lactate. Further studies are needed to evaluate the use of D-lactate as a marker for intestinal dysbiosis.[66]

PANCREAS

Romy M. HeiLmann and Jörg M. Steiner

Exocrine pancreatic disorders are common in clinical practice and pancreatitis is the most common disorder of the exocrine pancreas in both dogs and cats. Clinical diagnosis of pancreatitis can be challenging and it has been proposed that most cases of canine and feline pancreatitis remain undiagnosed. This is supported by necropsy studies showing that histopathologic evidence of pancreatic inflammation is very common in both species, even in patients without clinical signs.[1-3] Pancreatitis may be accompanied by relatively uncommon pancreatic complications such as pancreatic abscesses and pancreatic pseudocysts.

Exocrine pancreatic insufficiency (EPI) is the next most common disease of the exocrine pancreas in small animals, and it occurs more commonly in dogs than in cats. In the past few years feline EPI has been diagnosed with increasing frequency, likely because of increased awareness and the availability of better diagnostic tests. The diagnosis of EPI is usually uncomplicated when appropriate tests are utilized.

Uncommon diseases of the exocrine pancreas include pancreatic neoplasia (metastatic or, less commonly, primary neoplasia), pancreatic pseudobladder, pancreatolithiasis, and pancreatic parasites. Nodular hyperplasia of the pancreas is a common histopathologic finding, especially in older dogs and cats. This lesion is rarely associated with clinical disease; however, it can potentially interfere with the diagnostic evaluation of the pancreas and display findings that are usually associated with other pancreatic diseases (e.g., pancreatitis, neoplasia) (Table 25-4).

Pancreatitis

Signalment, History, and Risk Factors

Although dogs of any age, breed, or sex can develop pancreatitis, certain groups might be predisposed. Most dogs presented with pancreatitis are middle-aged to old (usually older than 5 years).[4,5] Several breeds have been reported or suspected to be at increased risk (e.g., Miniature Schnauzer, Yorkshire Terrier, Cocker Spaniel, Cavalier King Charles Spaniel, Collie, and Boxer) but none of these predispositions are consistent among studies.[3-6] Also, no clear sex predisposition has been identified.

Several pathologic conditions have been identified as potential risk factors for pancreatitis in dogs and, although a cause and effect relationship has not been established for most of them, their presence along with compatible clinical signs may raise the concern for pancreatitis. Many dogs with pancreatitis are overweight or obese, and endocrinopathies (e.g., hyperadrenocorticism, hypothyroidism, and diabetes mellitus) may be risk factors.[5] A history of drug administration (e.g., potassium bromide, phenobarbital, azathioprine, L-asparaginase, meglumine antimonite, and others) in conjunction with compatible findings should also raise a concern for pancreatitis.[7] Hypertriglyceridemia, when severe (higher than approximately 850 mg/dL), is reported as a risk factor for pancreatitis in Miniature Schnauzers.[8] This might also be true for dogs of other breeds that exhibit severe hypertriglyceridemia, but this has not yet been proven. Dietary factors (e.g., dietary indiscretion, consuming table scraps, ingestion of "unusual" food) and surgery at any time prior to diagnosis of pancreatitis have also been suggested as risk factors for pancreatitis in dogs.[6]

Similarly to dogs, cats of any age, breed, or sex can develop pancreatitis. Older cats appear to be more likely to develop chronic pancreatitis.[2,9-11] Domestic short hair and Siamese breeds have been reported to be at an increased risk in some studies, but this has not been confirmed by others.[2,9-11]

Clinical Signs and Physical Examination Findings

Dogs with pancreatitis can present with a wide variety of clinical signs, which can range from mild partial anorexia with no apparent gastrointestinal signs to cardiovascular shock and disseminated intravascular coagulation (DIC). There is no single clinical sign or combination of clinical signs that is pathognomonic for canine pancreatitis. Recent evidence suggests that pancreatitis can be subclinical in some cases, or be associated with only mild and nonspecific clinical signs such as anorexia and weakness.[1] In more typical cases, in addition to anorexia and weakness, dogs are presented with vomiting, diarrhea, and/or abdominal pain.[5,12] In particular, the combination of vomiting and cranial abdominal pain is considered suggestive (but not pathognomonic) of pancreatitis in dogs. Dehydration, abdominal pain, icterus, fever or hypothermia, bleeding diathesis, or ascites may be seen on physical examination.[5] Severe systemic complications (e.g., cardiovascular shock, DIC, or multiorgan failure) might occur in patients with severe pancreatitis.[12,13] It is important to note that additional clinical signs might occur as a consequence of concurrent diseases (e.g., polyuria/polydipsia in animals with diabetes mellitus).[5]

The most common clinical signs in cats with pancreatitis do not specifically indicate gastrointestinal (GI) disease and include complete or partial anorexia and lethargy.[9-11,14] Less common clinical signs include vomiting, weight loss, and diarrhea.[9-11,14] Abdominal pain is likely to be present in most cats with acute pancreatitis, but is often missed during routine physical examination. The most common physical examination findings include dehydration, pallor, and icterus.[9-11,14] Tachypnea and/or dyspnea, hypothermia/fever, tachycardia, signs of abdominal pain, and a palpable abdominal mass may also be noted.[9-11,14] Severe systemic complications (e.g., DIC, pulmonary thromboembolism, cardiovascular shock, and multiorgan failure) may occasionally be seen in cats with severe pancreatitis.

Routine Clinical Pathology[5,9-12,14,15]

Results of complete blood count (CBC), serum biochemistry profile, and urinalysis are nonspecific and thus not useful for the diagnosis of pancreatitis in dogs and cats. However, these tests should always be performed in animals with suspected pancreatitis because they are useful for the diagnosis or exclusion of other diseases, and also give important information about the general condition of the patient.

Often, especially in mild cases, the CBC, serum biochemistry profile, and urinalysis are normal. Possible hematologic findings in dogs and cats with pancreatitis include anemia or hemoconcentration, leukocytosis or leukopenia, and thrombocytopenia. Coagulopathies and DIC might be seen in some cases. Increases in hepatic enzyme activities and hyperbilirubinemia are common in both dogs and cats, and might erroneously direct the clinician to suspect primary liver disease. Azotemia is variably present and is most often associated with dehydration as a consequence of vomiting and/or diarrhea. Other possible findings include hypoalbuminemia, hypertriglyceridemia, hypercholesterolemia, and hyperglycemia. Electrolyte abnormalities are often present and

Table 25-4 Sensitivities and Specificities for Selected Diagnostic Modalities for the Diagnosis of Pancreatitis in Dogs and Cats*

	Sensitivity (%)	Specificity (%)	Comment
Dogs			
Pancreatic enzymes			
Serum amylase activity	18 to 69	~50	Low sensitivity and specificity. Both positive and negative results require verification with other diagnostics.
Serum lipase activity	14 to 73	~50	Low sensitivity and specificity. Both positive and negative results require verification with other diagnostics.
Serum TLI concentration	36 to 47	Relatively high	Low sensitivity. Normal concentrations do not exclude pancreatitis. Renal failure and intestinal disease might give false-positive results. High concentrations in the absence of renal or intestinal disease are suggestive of pancreatitis.
Serum PLI concentration	64 to 93	78 to 97	Highly sensitive and specific. Most accurate serum test for pancreatitis currently available.
Imaging methods			
Abdominal radiography	24	Low	Not useful for the diagnosis or exclusion of pancreatitis. Useful for the evaluation of other diseases.
Abdominal ultrasonography	68	Can be high	Relatively high sensitivity and specificity if stringent criteria are applied. Usefulness is highly operator- and equipment-dependent. Negative results do not rule out pancreatitis.
Pancreatic cytology	N/A	N/A	Must be performed under ultrasonographic guidance. Specificity is believed to be high, but pancreatic lesions might be missed if they are localized.
Pancreatic histopathology	Can be high	High	The gold standard for confirmation of pancreatitis. It is invasive and cannot be performed in severely compromised patients. Lesions are often highly localized so ruleout of pancreatitis is difficult.
Cats			
Pancreatic enzymes			
Serum amylase activity	Very low	Low	Not useful for the diagnosis of pancreatitis.
Serum lipase activity	Very low	Low	Not useful for the diagnosis of pancreatitis.
Serum TLI concentration	28 to 64	82	Low sensitivity. Normal concentrations do not exclude pancreatitis. Renal failure and intestinal disease might give false positive results. High concentrations in the absence of renal or intestinal disease are suggestive of pancreatitis.
Serum PLI concentration	54 to 100	82 to 91	Highly sensitive and specific. Most accurate serum test for pancreatitis currently available.
Imaging methods			
Abdominal radiography	Low	Low	Not useful for the diagnosis or exclusion of pancreatitis. Useful for the evaluation of other diseases.
Abdominal ultrasonography	11 to 67	73	Relatively high sensitivity and specificity if stringent criteria are applied. Usefulness is highly operator- and equipment-dependent. Negative results do not rule out pancreatitis.
Pancreatic cytology	N/A	N/A	Must be performed under ultrasonographic guidance. Specificity is believed to be high, but pancreatic lesions might be missed if they are localized.
Pancreatic histopathology	Can be high	High	The gold standard for confirmation of pancreatitis. It is invasive and cannot be performed in severely compromised patients. Lesions are often highly localized so ruleout of pancreatitis is difficult.

PLI, pancreatic lipase immunoreactivity; TLI, trypsin-like immunoreactivity.
*Based on references 1,2,5,10,11,15,18,23,26-28-36,40,46-49,51-54.

variable, with hypokalemia, hypochloremia, and hyponatremia being the most common. Hypocalcemia is more commonly seen in cats than in dogs, and is one of the most clinically important electrolyte disturbances in this species. Some cats with pancreatitis have hypocobalaminemia, which likely reflects concurrent intestinal disease.

Clinical Enzymology

Serum Pancreatic Lipase Immunoreactivity

There are many different lipases of various cellular origins (e.g., pancreatic, hepatic, gastric, and others) and all of them share the same function (i.e., hydrolysis of triglycerides). Therefore, depending on the assay conditions, many of the different lipases may

contribute to the total serum lipase activity measured by traditional activity assays for lipase. However, lipases of different cellular origins are encoded by different genes and thus have distinct amino acid sequences. Pancreatic lipase is exclusively expressed by pancreatic acinar cells and is structurally different from other lipases. Thus, immunoassays for the specific measurement of pancreatic lipase have been developed and validated for dogs and cats.[16,17] During pancreatitis pancreatic lipase leaks from acinar cells and enters the circulation in larger than normal quantities and can be detected by specific immunoassays for pancreatic lipase.

The immunoassays developed originally for pancreatic lipase were in-house tests that used polyclonal antibodies and had limited availability. Widely available commercial immunoassays (Spec cPL for dogs and Spec fPL for cats) that use monoclonal antibodies and show the same clinical performance as the original pancreatic lipase immunoreactivity (PLI) assays have been developed and have now replaced the original PLI immunoassays.[18,19]

Canine pancreatic lipase is believed to be exclusively of pancreatic origin.[20-22] An immunolocalization study suggested that canine pancreatic lipase is exclusively expressed by pancreatic acinar cells.[20] Another study in dogs with EPI showed a nearly total absence of serum canine pancreatic lipase immunoreactivity (cPLI) concentration.[21] In another study of a group of 31 dogs with a normal pancreas on histopathology, the specificity of Spec cPL was very high (96.8%).[22] In a recent multicenter study, in which dogs with clinical evidence of pancreatitis but without histopathologic confirmation of the disease were studied, the specificity of this assay was estimated to be at least 78%, when very conservative assumptions were applied.[23] Experimentally induced chronic renal failure and prednisone administration were not found to have any clinically significant effect on serum cPLI concentration.[24,25]

Serum cPLI concentration is also sensitive for the diagnosis of pancreatitis in dogs.[18,23,26,27] The reported sensitivity of cPLI for the diagnosis of canine pancreatitis is between 64% and 93%, depending on the severity of the disease in the patients studied. This is considerably higher than the sensitivity reported for serum canine trypsin-like immunoreactivity (cTLI) concentration (36.4% to 46.7%), serum amylase activity (18.2% to 73.3%), or serum lipase activity (13.6% to 69%), and is similar to or higher than that of abdominal ultrasound (67% to 68%) performed by a board-certified radiologist.[5,18,23,26-28] In a recent preliminary report of a multicenter study the sensitivity of this assay was estimated at 93%.[23] Because of its high sensitivity, normal serum cPLI concentrations make a diagnosis of clinically relevant pancreatitis very unlikely. However, it remains to be determined if, because of its high sensitivity, cPLI detects pancreatic pathology that is not clinically relevant. Based on the previously mentioned studies, serum cPLI concentration is the most sensitive and specific test currently available for pancreatitis in dogs.

Recently, a rapid point-of-care test for the estimation of pancreatic lipase in serum (SNAP cPL) was released. Studies evaluating the performance of this test are currently lacking, but would be expected to show a similar clinical performance to the serum Spec cPL assay. A positive test result should be followed up by laboratory measurement of serum Spec cPL concentration to confirm a diagnosis of pancreatitis and to serve as a baseline for monitoring the disease progress. A negative result makes a diagnosis of pancreatitis unlikely.

Studies in cats with both experimental and spontaneous pancreatitis have shown that serum feline pancreatic lipase immunoreactivity (fPLI) concentration is very sensitive for pancreatitis.[29-31] In one of these studies, fPLI was found to be 100% sensitive for moderate to severe spontaneous feline pancreatitis, and was superior to the sensitivities of serum feline trypsin-like immunoreactivity (fTLI) concentration (28%) or abdominal ultrasound (80%).[29] A preliminary report of a multicenter study reported the sensitivity of serum fPLI concentration as 78%.[31] Considering the overall sensitivities for pancreatitis reported for serum fPLI concentration (67% to 78%), fTLI (28% to 64%), and abdominal ultrasonography (11% to 67%), serum fPLI concentration currently appears to be the most sensitive test for the diagnosis of feline pancreatitis.[29,31-35] The specificity of serum fPLI concentration (82% to 91%) is reported to be superior to that of fTLI (82%) or abdominal ultrasound (73%).[15,29,31] Although further studies are needed to confirm these findings, serum fPLI concentration currently appears to be the most useful test for the diagnosis of feline pancreatitis. A point-of-care test for the estimation of Spec fPL (SNAP fPL) is also available, but studies evaluating this test have not been reported to date.

Serum Amylase and Lipase Activity

Serum amylase and lipase activities have long been considered markers for pancreatitis in dogs.[36,37] Although serum activities of these two enzymes increase during experimental canine pancreatitis, several studies have shown that these markers are not useful for the diagnosis of spontaneous canine pancreatitis because of their low sensitivity and specificity.[18,36-41] Many tissues other than the pancreas (e.g., gastric mucosa, hepatic parenchyma, and others) synthesize amylases and lipases. This has been confirmed in studies of dogs that would have been expected to have no or minimal serum lipase and amylase activities, namely, pancreatectomized dogs and dogs with EPI. Dogs in these studies retained significant serum lipase and amylase activities (often within the reference intervals), clearly indicating that tissues other than the pancreas account for a large portion of serum activities of these enzymes.[21,41] Furthermore, traditional catalytic assays are not able to differentiate amylases and lipases according to the tissue of origin leading to a low specificity of measurement of these enzyme activities for pancreatitis in dogs.[28,36]

In one study, approximately 50% of dogs with an increased serum activity of either amylase or lipase had no histopathologic evidence of pancreatitis.[36] The main nonpancreatic conditions associated with increased activities of these enzymes include renal, hepatic, intestinal, and neoplastic diseases, as well as corticosteroid administration (only for lipase activity). It has also been suggested that only increases of amylase and lipase activities of more than three to five times the upper limit of the reference range should be considered suggestive of pancreatitis in dogs, in order to increase the specificity of these assays.[42,43] However, even increases of this magnitude can result from nonpancreatic disorders.[28,36,43,44]

The sensitivity of serum amylase and lipase activities for spontaneous canine pancreatitis is low (32% to 73% for lipase activity and 41% to 69% for amylase activity) and is even lower when a cutoff value of three or five times the upper limit of the respective reference interval is used (14% for lipase activity and 18% for amylase activity in one study that used a cutoff of three times the upper limit of the reference range).[5,18,27] Thus, many dogs with pancreatitis may have normal serum activities of these enzymes and, therefore, normal serum amylase and/or lipase activities cannot rule out pancreatitis.[5,36] The low sensitivity of serum amylase and lipase activity assays is at least partially associated with the broad reference intervals for these assays, which are the result of extrapancreatic amylase and lipase activities. A new lipase assay (using the substrate 1,2-o-dilauryl-rac-glycero glutaric acid-[6′ methyl resorufin]-ester

[DGGR]) was speculated to be more useful for the initial evaluation of dogs suspected of having pancreatitis because of its higher sensitivity (93%) compared with traditional assays.[45] However, the specificity of this assay was low (53%), limiting its clinical usefulness.[45]

Serum lipase activity increases and serum amylase activity decreases in cats with experimentally induced acute pancreatitis.[30,46,47] Although well-designed clinical studies are lacking, serum lipase and amylase activities do not appear to be of any clinical value in the diagnosis of spontaneous feline pancreatitis.[10,32,48]

Trypsin-Like Immunoreactivity

TLI assays are species-specific immunoassays that measure trypsinogen and trypsin in serum. Trypsinogen is the inactive preform (or zymogen) of trypsin, a proteolytic enzyme synthesized exclusively by pancreatic acinar cells and normally secreted into the duodenum where it is activated, with only minimal amounts reaching the circulation. During pancreatitis, trypsinogen and prematurely activated trypsin enter the circulation in large quantities, and can be measured with the TLI assay.

Serum cTLI concentrations increase after experimental induction of pancreatitis in dogs, but decrease to concentrations within the reference interval as soon as 3 days after induction of pancreatitis in some dogs.[40] The sensitivity of serum cTLI for the diagnosis of spontaneous pancreatitis is low (36% to 47%), probably as a consequence of its short half-life.[18,27,28] In addition, although there is strong evidence that trypsinogen is exclusively of pancreatic origin,[41] it is believed that it is cleared by glomerular filtration, and serum cTLI concentration can be increased in dogs with renal failure.[28,40] This clearly affects the specificity of the test and complicates the interpretation of increased serum cTLI concentrations in azotemic dogs.

In cats with experimentally induced pancreatitis, serum fTLI concentration increases sharply after induction of pancreatitis, but returns below the cutoff value for pancreatitis within 48 hours.[30] fTLI has been evaluated for the diagnosis of spontaneous pancreatitis in cats and several cutoff values have been suggested.[33-35] When cutoff values allowing adequate specificity of the assay are used (i.e., 100 µg/L), the sensitivity of fTLI for the diagnosis of pancreatitis in cats is generally low (28% to 33%), with the highest reported sensitivity for this cutoff value being 64%.[33-35] In addition, the specificity of fTLI has been questioned, because mildly increased serum fTLI concentrations have been reported in cats with no demonstrable pancreatic disease, but other gastrointestinal disorders (e.g., IBD or gastrointestinal lymphoma) or azotemia.[15,33,35]

In the face of availability of better serum markers (cPLI and fPLI), cTLI and fTLI are currently considered to be of limited usefulness for the diagnosis of canine and feline pancreatitis, respectively.

Other Diagnostic Markers

Other diagnostic markers for pancreatitis have been developed and studied, but none can currently be recommended for the diagnosis of canine and feline pancreatitis in clinical practice, either because their diagnostic performance has not been sufficiently evaluated, or because they have a low sensitivity and/or specificity. In addition, the availability of most of these diagnostic tests is currently limited. Such tests include the determination of serum concentrations of phospholipase A_2, trypsin–α_1-antitrypsin complexes, and α_2-macroglobulin, determination of plasma and urine concentrations of trypsinogen activation peptide (TAP), and determination of lipase activity in peritoneal fluid.

Diagnostic Imaging

Abdominal Radiography

Conclusive diagnosis or exclusion of pancreatitis is not possible based on abdominal radiography alone.[5,9-11,34,43] In the majority of cases of canine and feline pancreatitis, abdominal radiographs are normal or show only nonspecific findings. Despite this, radiography remains a logical initial approach for patients suspected of having pancreatitis because it is relatively inexpensive and useful for the diagnosis and/or ruleout of other differential diagnoses.

In a group of 70 dogs with fatal acute pancreatitis, the sensitivity of abdominal radiography was low (24%).[5] Radiographic findings reported for dogs with pancreatitis include increased soft-tissue opacity and decreased serosal detail in the cranial right abdomen, indicating localized peritonitis.[5] Other findings include displacement of the stomach and/or duodenum and gaseous dilation of bowel loops adjacent to the pancreas.[5] Abdominal effusion or the presence of an abdominal mass might also be detected. Radiographic findings in cats with pancreatitis are similar to those in dogs.[10,11,34,49] In any case, radiography should always be followed by use of more sensitive and specific tests for the definitive diagnosis or exclusion of pancreatitis.

Abdominal Ultrasound

Abdominal ultrasound is considered the imaging method of choice for the diagnosis of pancreatitis in dogs and cats. However, the performance of ultrasonography in the diagnosis of pancreatitis is dependent on the experience of the ultrasonographer and the quality of the equipment used.

Abdominal ultrasound has been reported to have a relatively high sensitivity (68%) for severe acute pancreatitis in dogs, although with increasing quality of equipment the sensitivity might now have increased.[5] Abdominal ultrasound has been assessed mainly in dogs with fatal acute pancreatitis, in which lesions are usually pronounced, but its sensitivity would be expected to be lower in cases with mild or moderate pancreatitis.[5] A normal pancreas on ultrasound examination does not rule out pancreatitis in dogs.

Ultrasonographic findings in dogs with pancreatitis include hypoechoic areas within the pancreas (possibly indicating necrosis or fluid accumulation), increased echogenicity of the surrounding mesentery (a result of necrosis of the peripancreatic fat), enlargement and/or irregularity of the pancreas, dilation of the pancreatic or biliary duct, and abdominal effusion (Fig. 25-9).[5,50] On occasion, hyperechoic areas of the pancreas can be identified, possibly indicating the presence of pancreatic fibrosis. Cavitary lesions, a thickened duodenum, and biliary obstruction might also be noted.[50] If stringent criteria are applied, the specificity of abdominal ultrasonography for canine pancreatitis is considered to be relatively high, although other diseases of the pancreas (e.g., neoplasia, hyperplastic nodules, edema caused by portal hypertension or hypoalbuminemia) may display similar ultrasonographic findings and cannot be differentiated from pancreatitis in many cases.[51,52] In a recent study where ultrasonography was performed in 26 animals (both dogs and cats) with suspected gastrointestinal disease, six (23.1%) of the animals had ultrasonographic evidence consistent with pancreatitis, while histopathology revealed either a normal pancreas or pancreatic hyperplasia.[53] In the same study, there was only a 22% agreement between the ultrasound report and pancreatic histopathology in dogs.[53] These data raise concerns regarding the accuracy of ultrasonography in evaluating the canine pancreas and underscore the importance of not overinterpreting ultrasonographic findings. However, findings of this particular study should be evaluated with

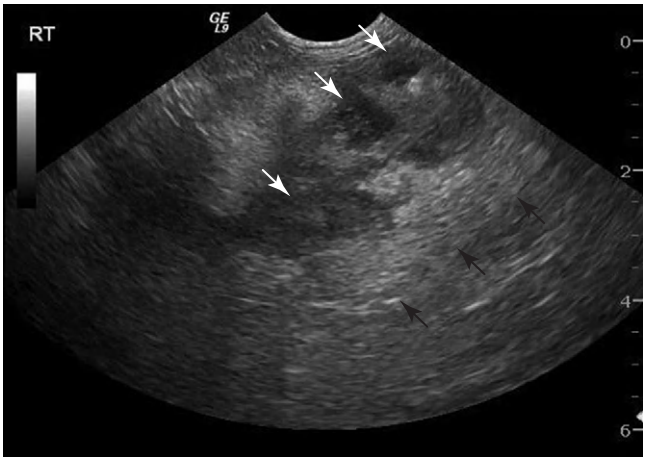

Figure 25-9 Ultrasonographic appearance of the pancreas of a dog with pancreatitis. The pancreas is enlarged and appears heterogeneous, with hypoechoic areas (*white arrows*) and hyperechoic surrounding fat (*black arrows*). These findings are highly suggestive of pancreatitis. (Courtesy of Dr. B. Young, Texas A&M University.)

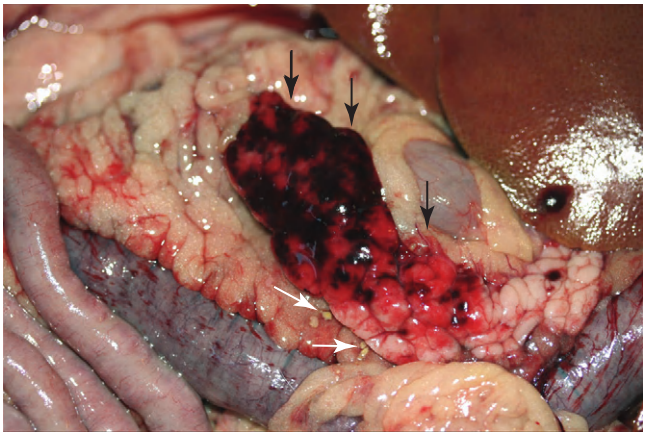

Figure 25-10 Gross appearance of the pancreas of a dog with acute pancreatitis. The pancreas appears severely hemorrhagic, necrotic, and edematous (*black arrows*). There is also peripancreatic fat necrosis (*white arrows*). Such appearance is highly suggestive of pancreatitis. (Courtesy of Dr. D. Ajithdoss, Texas A&M University.)

caution because localized pancreatic lesions suggestive of pancreatitis might have been missed on histopathology.

The reported sensitivity of abdominal ultrasonography for the diagnosis of feline pancreatitis is generally low (11% to 35%), with only one study reporting a sensitivity of 67%.[11,29,33,49] This high range of sensitivity likely reflects differences in the level of suspicion or the skills of the examiner, the equipment used, and the severity of lesions, and highlights the lack of standardized diagnostic criteria.[33,34,49] The generally low sensitivity of abdominal ultrasonography suggests that many cats with pancreatitis remain undiagnosed when the diagnosis is based solely on ultrasound examination.[11,33,49] The sensitivity of abdominal ultrasonography is believed to have increased since the reports cited previously because of advances in technology and an increasing level of awareness of the importance of feline pancreatitis, although this has not yet been confirmed. Abdominal ultrasonography has been thought to be relatively specific for the diagnosis of pancreatitis is cats but, similarly to dogs, other diseases (e.g., pancreatic neoplasia, edema) may be associated with similar findings.[54] In a recent study, there was an overall agreement of only 33% between the ultrasound report and pancreatic histopathology in cats, and some cats that had ultrasonographic evidence of pancreatitis had no evidence of pancreatitis on histopathology.[53] Ultrasonographic findings in cats with pancreatitis are similar to those described in dogs.[11,33,49,50,55] It is suggested that dilation of the pancreatic duct is suggestive of pancreatitis in cats, but recent studies have not confirmed this hypothesis.[56] In general, feline pancreatitis is often difficult to diagnose by abdominal ultrasound examination and it is important to note that a normal ultrasound examination does not rule out feline pancreatitis.[29,33]

Overall, abdominal ultrasonography is very useful for the diagnosis of pancreatitis in dogs and cats, especially when performed by an experienced ultrasonographer. Caution should be taken not to overinterpret ultrasonographic findings. Abdominal ultrasonography is also helpful in detecting possible concurrent abdominal disease in dogs and cats suspected of having pancreatitis. In addition, ultrasound-guided fine-needle aspiration is a useful tool for the confirmation of pancreatitis and some of its complications (e.g., pancreatic pseudocyst and pancreatic abscess), as well as the management of noninfectious fluid accumulations (e.g., pancreatic pseudocyst).[55]

Other Imaging Modalities

Contrast-enhanced computed tomography (CECT) is a valuable tool in the evaluation of human patients with suspected pancreatitis, but initial studies in dogs have not been promising.[57] The results of computed tomography (CT) performed in cats with histologically confirmed pancreatitis were also disappointing and this procedure currently cannot be recommended in diagnosis of feline pancreatitis.[29] Other imaging methods (e.g., endoscopic retrograde cholangiopancreatography [ERCP], endoscopic ultrasonography) have been used in healthy dogs and cats, in dogs with experimentally induced pancreatitis, and in dogs with gastrointestinal diseases, with varying results. However, as a consequence of the lack of standardized criteria for the diagnosis of pancreatitis, the complexity of these modalities, their limited availability, and the cost of the equipment, they cannot currently be recommended for the diagnosis of canine or feline pancreatitis.

Pathology

Direct visualization of the pancreas is possible during exploratory laparotomy or laparoscopy in live animals, or during necropsy. When certain gross lesions are present they are highly suggestive of pancreatitis and suggest preferred sites for biopsy.[10,18,49] Gross lesions suggestive of pancreatitis include peripancreatic fat necrosis, pancreatic hemorrhage and congestion, and a dull granular capsular surface (Fig. 25-10).[10,18,49] However, gross lesions may not always be apparent in dogs and cats with pancreatitis.[1,10,49]

At present, a definitive diagnosis of pancreatitis can only be made by histopathologic examination of the pancreas. Histopathology is also the only way to differentiate acute and chronic pancreatitis. Histopathologic scoring systems for the evaluation of severity of pancreatitis have been proposed for both dogs and cats.[1-3,58] However, histopathologic criteria for the classification of pancreatitis have not been universally standardized in veterinary medicine and substantial confusion exists regarding both classification and terminology of canine and feline pancreatitis, underlying the importance of developing a universally accepted multidisciplinary classification system as is available for human pancreatitis. Permanent histopathologic changes (e.g., fibrosis and acinar atrophy) are generally considered suggestive of chronic pancreatitis (Fig. 25-11).[1,43] The predominant cell type within an inflammatory infiltrate

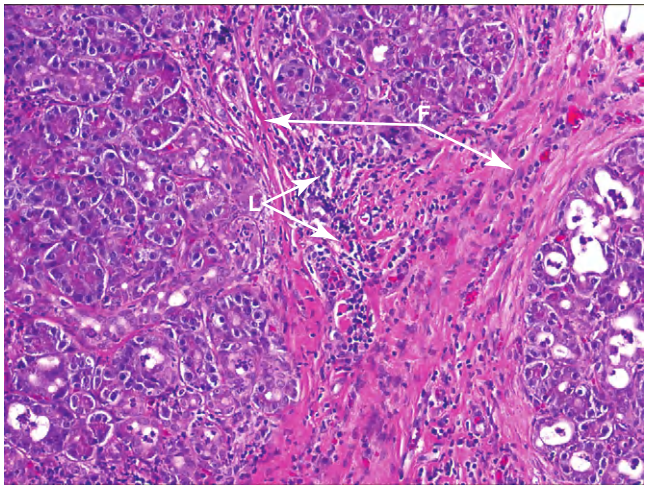

Figure 25-11 Histopathologic appearance of the pancreas of a cat with chronic pancreatitis. There is extensive fibrosis (*F*) and lymphocytic infiltration (*L*). Hematoxylin and eosin (H&E) stain; magnification ×200. (Courtesy of Dr. B. F. Porter, Texas A&M University.)

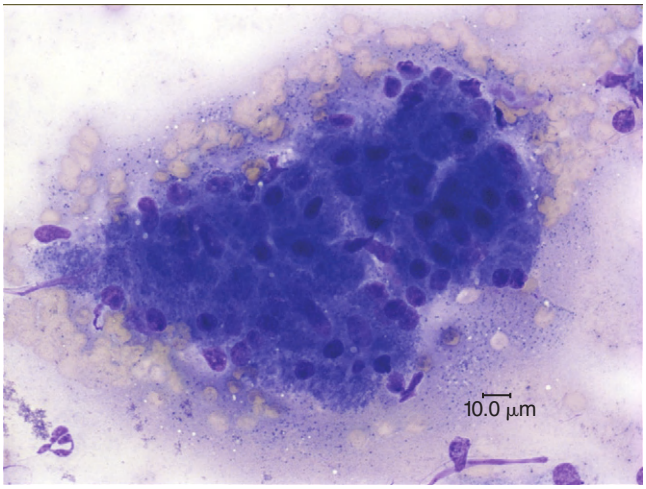

Figure 25-13 Cytologic appearance of a fine-needle aspirate from a normal canine pancreas. Acinar cells can be seen in the form of a multicellular cluster. Diff-Quik stain. (Courtesy of Dr. P. J. Armstrong, University of Minnesota.)

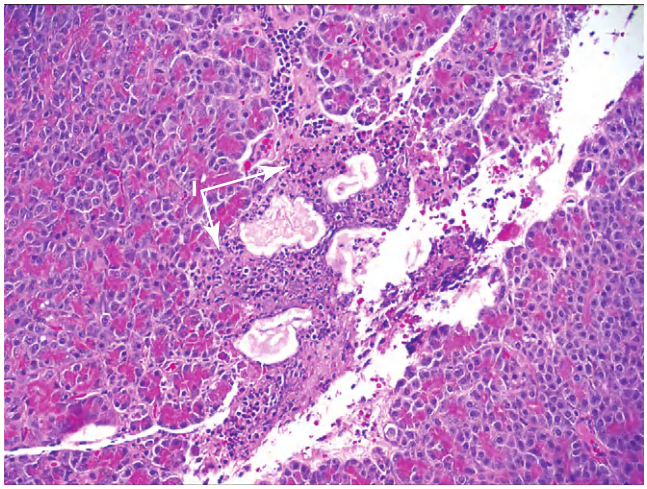

Figure 25-12 Histopathologic appearance of the pancreas of a cat with acute pancreatitis. There are areas of inflammatory infiltration (*I*) but there is no evidence of fibrosis or other permanent histopathologic changes. Hematoxylin and eosin stain; magnification ×200. (Courtesy of Dr. B. F. Porter, Texas A&M University.)

(neutrophils or lymphocytes) is often used to describe pancreatitis as suppurative or lymphocytic, and some authors consider that suppurative inflammation is compatible with acute disease and lymphocytic infiltration compatible with chronic disease (Fig. 25-12).[10,11] Some animals can show evidence of both suppurative and lymphocytic pancreatitis. Significant necrosis characterizes the pancreatitis as necrotizing.

Several limitations are associated with pancreatic histopathology as a definitive diagnostic tool for pancreatitis. First, determining the clinical significance of histopathologic findings may be challenging. In one study, 47 (64%) of 73 dogs that presented for necropsy for various reasons had microscopic evidence of pancreatitis.[1] Similarly, histopathologic lesions of pancreatitis were found in 67% of all cats examined, including 45% of healthy cats.[2] Currently, there are no standardized criteria that distinguish microscopic findings leading to clinical disease from those that do not, and it is possible that clinically insignificant pancreatic lesions could lead to a false diagnosis of pancreatitis. At the same time, exclusion of pancreatitis based on histopathology is difficult because inflammatory lesions of the pancreas are often highly localized and can easily be missed.[1,2,10,49] Consequently, multiple sections of the pancreas must be evaluated so as to increase the likelihood of finding microscopic lesions, although this is not always feasible in clinical practice. The absence of histopathologic features consistent with pancreatitis must be evaluated with caution, especially when only one section of the pancreas has been examined.[1,2] Finally, although pancreatic biopsy per se is considered safe, it requires invasive procedures that are expensive and potentially detrimental in patients with pancreatitis that are hemodynamically unstable.[53]

Because concurrent inflammation of the intestines and/or liver appears to be a common problem in cats and may also occur in dogs, intestinal and hepatic biopsies should be collected in patients (especially cats) suspected of having pancreatitis that are undergoing exploratory laparotomy. Likewise, cats with IBD and/or cholangitis that undergo laparotomy or laparoscopy should also have their pancreas evaluated.

Cytology

Fine-needle aspiration (FNA) of the pancreas and cytologic examination is minimally invasive, relatively safe, and can be used for the diagnosis of pancreatitis in both dogs and cats.[59] To date, no studies have evaluated the sensitivity and specificity of this diagnostic modality for the diagnosis of canine or feline pancreatitis, but the finding of inflammatory cells is considered specific for pancreatitis. Pancreatic acinar cells constitute the majority of the cells found in FNA smears from a normal pancreas (Fig. 25-13).[59] Acute pancreatitis is characterized by hypercellularity, and the presence of intact and degenerate neutrophils and degenerate pancreatic acinar cells (Fig. 25-14). In chronic pancreatitis, small numbers of lymphocytes and neutrophils are usually present, and the specimen is often characterized by low cellularity, possibly a result of replacement of the normal pancreatic tissue by fibrotic tissue.[59]

FNA cytology should be performed either under ultrasonographic guidance or during laparotomy.[59] It should be noted that, as for histopathology, highly localized lesions might be missed. Thus,

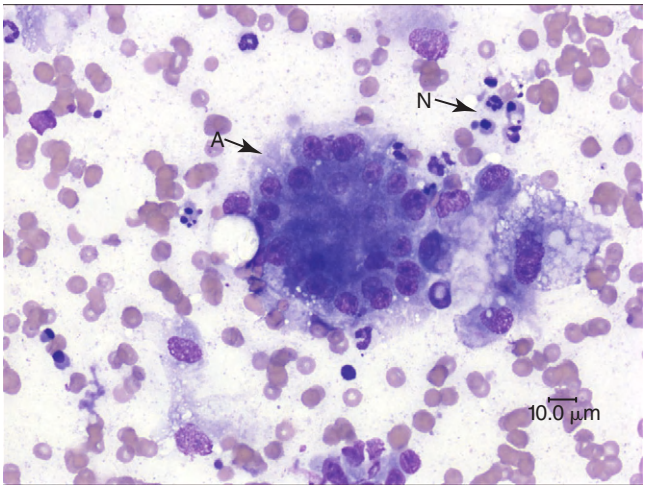

Figure 25-14 Cytologic appearance of a fine-needle aspirate from a canine pancreas with suspected pancreatitis. There is mild to moderate neutrophilic inflammation (*N*) with neutrophilic degeneration. A cluster of normal acinar cells (*A*) can also be seen. Diff-Quik stain. (Courtesy of Dr. P. J. Armstrong, University of Minnesota.)

negative results do not rule out pancreatitis. Although FNA cytology might also be useful in differentiating other conditions of the pancreas (e.g., neoplasia) from pancreatitis, it is not definitive.

Assessment and Prediction of the Severity of Pancreatitis

Assessment of the severity of human acute pancreatitis is based on the application of standardized severity scores.[60] Prediction of the severity of pancreatitis constitutes a very important component of the diagnosis of pancreatitis, because it allows prediction of the likelihood of complications and morbidity, and helps determine the optimal therapeutic plan before the patient enters a critical stage. It is based on a theory that states that the severity of an episode of pancreatitis is determined by events that occur within the first 24 to 48 hours of the episode.[61] These events are reflected through clinical, clinicopathologic, and imaging findings that can be used to predict the severity of the pancreatitis.[61]

In veterinary medicine, no well-established and universally accepted severity scoring systems for pancreatitis have been described. Serum PLI and TLI concentrations lack prognostic significance because they correlate poorly with histopathologic severity.[18] Currently, severity of canine and feline pancreatitis is determined based on clinical judgment, and typically a diagnosis of severe pancreatitis is made after the animal has entered a critical stage. In general, evidence of systemic complications (e.g., oliguria, azotemia, icterus, severely increased hepatic enzyme activities, hypocalcemia, hypoglycemia, severe hyperglycemia, leukocytosis, shock, or DIC) are considered as indicators of severe disease and a poor prognosis.[62-64] However, prediction of the severity of pancreatitis has not been studied sufficiently in dogs and cats. Markers that might prove useful in predicting the severity and/or outcome of an episode of pancreatitis are serum C-reactive protein concentrations, serum interleukin-6 concentrations, and plasma and urine TAP concentration, as well as the urine TAP-to-creatinine ratio.

Conclusions

No single diagnostic modality is 100% reliable for the diagnosis of canine or feline pancreatitis. Careful evaluation of the animal's history, physical examination, and routine clinical pathology findings, as well as the use of highly specific and sensitive tests (serum cPLI and fPLI concentration, abdominal ultrasonography, cytology, and/or histopathology), is crucial for an accurate diagnosis of pancreatitis. In clinical practice, a combination of serum cPLI or fPLI concentration, abdominal ultrasound, and in some cases FNA of the pancreas, currently constitutes the most practical and accurate approach for the diagnosis of both canine and feline pancreatitis.

Exocrine Pancreatic Insufficiency

Clinical Features

The classical presentation of dogs with EPI involves a chronic history of weight loss, a normal or increased appetite, and loose stools, usually characterized by passage of large volumes of semiformed feces. However, some dogs with EPI may present with a clinical history of periods of anorexia, absence of loose stools, occasional watery diarrhea, or vomiting. Other possible clinical signs include coprophagia, borborygmus, flatulence, abdominal discomfort, and a poor hair coat. In some cases, EPI may be subclinical and those cases can only be diagnosed with appropriate laboratory testing. Cats with EPI have a similar presentation to that of dogs. In cases where chronic pancreatitis is the cause of EPI, polyuria and polydipsia may be seen as a result of concurrent diabetes mellitus.

Trypsin-Like Immunoreactivity

Serum cTLI is the test of choice for the diagnosis of EPI in dogs. This test is highly sensitive and specific for the diagnosis of EPI, and a positive test (usually defined as <2.5 μg/L) in a dog with compatible clinical signs is sufficient to make a diagnosis.[65] A cTLI result well within the reference range is sufficient for excluding EPI, and a normal cTLI result should direct clinicians toward the investigation of other disorders as the cause of the observed clinical signs.[65] Single cTLI results within the equivocal range (usually between 2.5 and 5.7 μg/L) in dogs with clinical signs of gastrointestinal disease must be interpreted with caution.[66] In these patients, subsequent retesting of serum cTLI concentration shows either a normal concentration or progression to EPI.[66] Therefore, patients with cTLI results in the equivocal range should be investigated for chronic intestinal disease, with reevaluation of the cTLI a few weeks later. Some dogs with no clinical signs characteristic of EPI have repeatedly subnormal (<5.7 μg/L) cTLI concentrations.[66,67] These dogs have subclinical EPI and some are expected to develop clinical EPI in the future.[66,67] The time of progression from the subclinical to the clinical stage varies greatly, from a few months to years.[67] Thus, these patients should be closely monitored for the development of clinical signs of EPI, and cTLI testing should be repeated every 3 to 6 months.[66,67] Finally, because renal disease might increase serum cTLI concentrations and obscure a diagnosis of EPI, reevaluation of nondiagnostic serum cTLI concentrations in azotemic dogs suspected of having EPI is recommended. Similarly, concurrent inflammation might falsely increase the serum cTLI concentration.

EPI appears to be less common in cats than in dogs and the feline disease has been less-well investigated. Measurement of fTLI appears to be the most reliable test for the diagnosis of EPI in cats with a specificity of at least 85%.[68] The sensitivity of this assay for the diagnosis of feline EPI has not been evaluated. There are currently two assays that measure fTLI. A radioimmunoassay is available through the Gastrointestinal Laboratory at Texas A&M University, and an ELISA is available in Europe. Only the radioimmunoassay has been validated. Equivocal serum fTLI concentrations in azotemic cats suspected of having EPI should be reevaluated, because

renal disease might falsely increase serum fTLI concentration. The same is true for cats with concurrently increased serum fPLI concentrations indicating residual pancreatic inflammation.

Pancreatic Fecal Elastase

An ELISA for the measurement of pancreatic elastase in feces is commercially available and is marketed in Europe (Shebo Biotech, Germany) for the diagnosis of canine EPI.[69,70] A recent study reported false-positive results in 23.1% of cases,[71] and the sensitivity of this assay has not been sufficiently evaluated. Because of its poor positive predictive value, a positive test result must be verified by measurement of serum cTLI concentration. This test might also be useful for EPI cases that are caused by pancreatic duct obstruction; however, to date only one case has only been reported anecdotally.

Other Tests

Serum amylase and lipase activities have no value in the diagnosis of EPI in dogs or cats.[21,41,72] cPLI concentrations are low or undetectable in most dogs with EPI, but some overlap between healthy dogs and dogs with EPI exists, making this test inferior to cTLI for the diagnosis of EPI.[21] However, cPLI might be used to diagnose isolated pancreatic lipase deficiency, a rare form of EPI, where serum cTLI concentrations are expected to be normal.[73] Commercial assays for the measurement of serum PLI concentration (Spec cPL and Spec fPL) are not useful for the diagnosis of EPI in dogs and cats, respectively, because they have been optimized to detect changes in the higher ranges of their respective working ranges.

Measurement of fecal proteolytic activity has been used in the past for the diagnosis of EPI in dogs and cats, but is now only used for species for which a TLI assay is not available.[74,75] A plethora of other tests, including microscopic examination of feces and the bentiromide absorption (benzoyl-tyrosyl-paraaminobenzoic acid [BT-PABA]) test, have also been described for the diagnosis of EPI in the past. However, these tests often give false-positive and/or false-negative results and many of them are impractical, expensive, or of limited availability; thus none is recommended for the diagnosis of canine or feline EPI.

Histopathology

EPI is a functional and not a histopathologic diagnosis; thus histopathology is not indicated for the diagnosis of EPI. More than 90% of the pancreatic parenchyma must be destroyed before clinical signs of EPI develop, so it is almost impossible to make an accurate gross or histopathologic estimate of the extent of pancreatic atrophy. The only value in histopathology is determination of the underlying cause of EPI (pancreatic acinar atrophy or pancreatitis). However, in breeds of dog that are predisposed to EPI as a consequence of acinar atrophy (i.e., German Shepherd, rough-coated Collies, and Eurasian) histopathology is redundant.[76] Therefore, histopathology should only be used in atypical cases where the cause of EPI needs to be definitively determined.

LIVER

Dennis J. Meyer

The liver is mainly comprised of hepatocytes, sinusoidal cells, and biliary epithelium. Hepatocytes make up approximately 60% of the hepatic parenchyma with sinusoidal endothelial cells, hepatic stellate cells (formerly referred to as Ito cells), liver-associated lymphocytes, and Kupffer cells comprising the remainder (Fig. 25-15). The approximation of the gutter-like hemicanals on adjacent surfaces of neighboring hepatocytes form the intercellular space called the *canaliculus*, which is the beginning of the hepatobiliary system. The liver has two blood supplies. The hepatic artery and the portal vein comprise approximately 20% and 80%, respectively, of the total blood flow, which mixes as it enters the sinusoids. Multiple tests have been developed to assess liver function because of this cellular, biliary, and vascular complexity. In general, these tests aim to

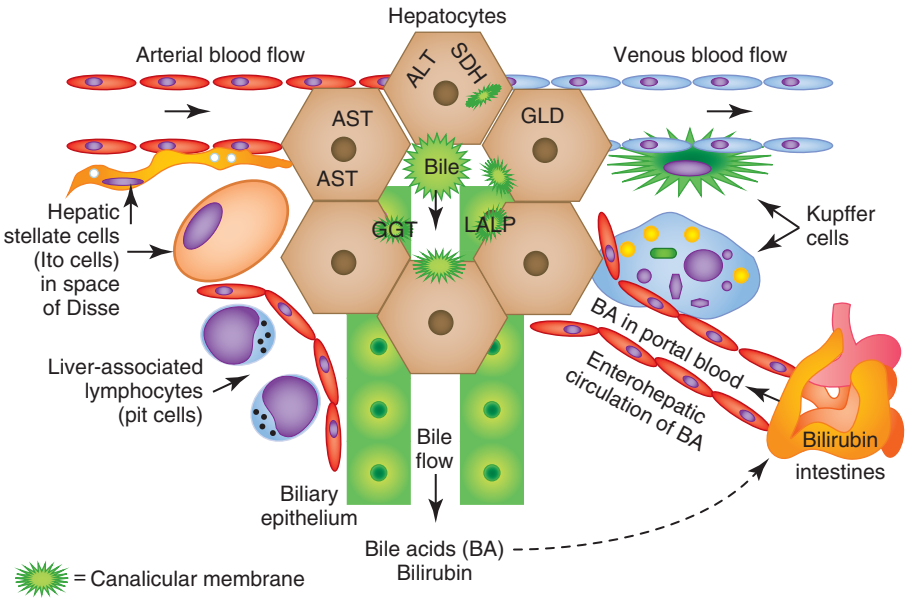

Figure 25-15 Hepatic function. This figure shows the complex cell constituency comprising the liver and the microanatomic relationships of these cells, the cellular location of liver enzymes, and the enterohepatic circulation of bile acids. evaluate hepatocyte membrane integrity and function, hepatobiliary function, the portal circulation, and the enterohepatic circulation. Because of the intimate anatomic and intertwining functional relationships of hepatic components, there is frequent overlap of findings with varied pathology of the liver, the portal circulation, or even extrahepatic disease.

When evaluating a patient with suspected hepatobiliary disease signalment, clinical history, and physical examination can help to formulate a list of reasonable differential diagnoses. Several hepatobiliary diseases have been reported to show breed predilections (Boxes 25-2 and 25-3).

Serum Hepatic Enzyme Activities

Alanine aminotransferase (EC 2.6.1.2; also known as alanine transferase, ALT), aspartate aminotransferase (EC 2.6.1.1; also known as aspartate transaminase, AST), glutamate dehydrogenase (EC 1.4.1.3; GLD, GLDH), alkaline phosphatase (EC 3.1.3.1; ALP), and γ-glutamyltransferase (EC 2.3.2.2; γ-glutamyl-peptide:amino acid, γ-glutamyl transferase, GGT) are the predominant hepatic enzyme activities that are relatively sensitive indicators of primary hepatic pathology. The interpretation of tests for liver disease is confounded by the effect of extrahepatic inflammatory diseases, especially those involving the pancreas or the intestines, on the liver, notably Kupffer cells, leading to abnormal results of liver tests and histopathologic changes sometimes referred to as nonspecific or reactive hepatitis. Endocrinopathies and induction of hepatic enzyme activities by medications can cause abnormal serum liver enzyme activities that mimic primary hepatic pathology (Box 25-4). Thus, the finding of abnormal serum hepatic enzyme activities should always prompt consideration of extrahepatic disorders in addition to primary liver pathology. In the aged dog (i.e., older than approximately 8 years of age), nodular regenerative hyperplasia of the liver is a common benign liver pathology that is associated with increases in liver enzyme activities, often with an ALP prominence, abnormal ultrasound findings, and varied histopathologic findings that may suggest vacuolar hepatopathy and/or chronic hepatitis.[1,2]

ALT is predominately located within the hepatocyte cytosol with minimal skeletal muscle activity. Following release from hepatocytes, it has a half-life of approximately 45 to 60 hours in the dog and 3.5 hours in the cat (Fig. 25-16 and Table 25-5).[3,4] AST has high activity in hepatic tissue and skeletal muscle. It has a half-life

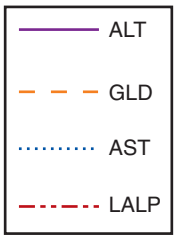

Figure 25-16 Time course of serum hepatic enzyme activities. This figure shows the approximate time course for serum enzyme activities following acute, severe hepatocellular injury with resolution in the dog. (Modified with permission from Meyer DJ, Harvey JW: *Veterinary Laboratory Medicine—Interpretation and Diagnosis*, 3rd ed. Philadelphia: Saunders, 2004.)

of approximately 12 hours in the dog and 1.5 hours in the cat.[4,5,6] Pathology involving hepatocytes in the dog results in the release of ALT and, if the insult is sufficiently severe, AST will also increase, but with a rise in AST activity that is less than that of ALT (see Fig. 25-16 and Table 25-5). In the cat, AST frequently increases concomitant with a rise in ALT activity. Resolution of hepatocellular pathology is indicated by normalization of serum AST activity, followed by normalization of ALT activity as determined by repeated sampling (see Fig. 25-16). A persistent increase in serum ALT activity for several weeks, especially if accompanied by a rise in AST, is one indication for a liver biopsy (Fig. 25-17). GLD is located within the mitochondria of hepatocytes. It has a half-life of approximately 18 hours in the dog.[7] A rise in GLD is interpreted in similar fashion to that of ALT and has a sensitivity that is similar to or better than ALT for the detection of liver pathology in the dog.[8,9] A variety of drugs cause mild increases in the serum ALT activity, presumably as a result of enzyme induction without causing liver pathology.[10,11]

A rise in ALP is generally caused by increased osteoblast activity, impaired bile flow, and/or drug induction. In the growing animal, ALP activities are higher than in adults as a result of increased bone

Table 25-5 Approximate Half-life of Serum Hepatic Enzyme Activities (Hours) for the Dog and Cat

Enzyme	Dog	Cat
ALT (alanine aminotransferase)	60	3.5
GLD (glutamate dehydrogenase)	18	Not determined
AST (aspartate aminotransferase)	12	1.5

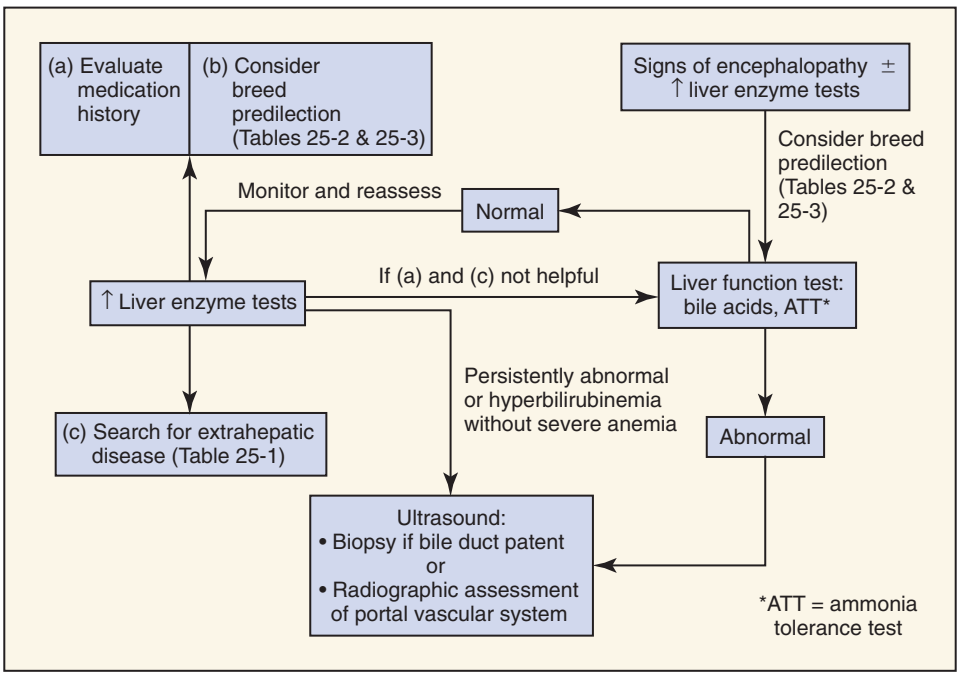

Figure 25-17 Diagnostic approach for abnormal liver tests. This figure outlines a diagnostic approach for the evaluation of abnormal liver tests and/or hepatic encephalopathy.

turnover, but they do decline with bone maturation. An increase in the total ALP activity because of an increase of bone ALP in the adult can be associated with osteomyelitis and osteosarcoma.[12] Bone ALP can be measured specifically to make that determination and follow the effect of treatment. Impaired bile flow caused by intrahepatic pathology or obstruction of the common bile duct stimulates the liver to increase ALP production and release into the circulation. Liver ALP has a half-life of approximately 66 hours in the dog and 6 hours in the cat.[4,13] A rise in ALP precedes a rise in bilirubin subsequent to impaired bile flow in the dog.

Drugs that stimulate the production of ALP include corticosteroids and anticonvulsants (e.g., phenobarbital, phenytoin, or primidone).[11,14] Endogenous or exogenous corticosteroids induce production of an ALP isoenzyme in the dog that is unique for this species. It has a half-life of approximately 74 hours.[4,13] Individual variation occurs as to the magnitude of increase, which can be dramatic in some dogs and is associated with severe microscopic hepatocellular ballooning degeneration (vacuolar change) and foci of neutrophilic inflammation.[15] The finding of an increased serum ALP activity with hepatocellular ballooning degeneration on biopsy, without a history of exogenous corticosteroid administration or laboratory findings of hyperadrenocorticism, should prompt consideration of nodular regenerative hyperplasia or chronic extrahepatic disease.[2,16] Hepatic ALP activity and the corticosteroid-induced ALP isoenzymes can be measured separately. However, the diagnostic reliability of these isoenzyme-specific assays is poor because of overlap in increases of these isoenzymes with primary liver pathology and increases secondary to corticosteroid and phenobarbital induction.[14,17-19] Phenobarbital causes an increase in predominantly liver and corticosteroid-induced ALP isoenzymes, but there is no unique phenobarbital-associated isoenzyme.[14]

The Scottish Terrier has a markedly higher serum alkaline phosphatase activity than other breeds, which rises further with age. However, the cause and clinical importance of this finding is unknown.[20,21]

Serum GGT activity is of hepatic origin; there is no bone GGT. Increased production of GGT by the liver and release into the circulation is stimulated by impaired bile flow or drug induction.[22,23] Drugs that cause a rise in serum GGT activity in the dog include phenobarbital and corticosteroids.[11,23,24]

Despite similar hepatobiliary tissue localization and a rise subsequent to increased enzyme production and release from the liver, there is not necessarily a concomitant rise in ALP and GGT activities subsequent to liver pathology or drugs that stimulate their hepatic production for reasons that are poorly understood. ALP, but not GGT, is increased following the administration of primidone or phenytoin to dogs.[11] In dogs with liver pathology, the frequency and magnitude of increase is generally greater for ALP than for GGT, and ALP has higher sensitivity but lower specificity than GGT as an indicator of liver disease.[25] In contrast, in cats the frequency and magnitude of increase is generally greater for GGT than for ALP and GGT has higher sensitivity but lower specificity than ALP for liver pathology.[26] However, a generally marked increase in ALP compared with GGT in feline hepatic lipidosis is notable.[27]

Tests Dependent on Liver Function

Albumin is produced by hepatocytes and has a half-life of approximately 8 days in the dog and probably slightly shorter in the cat.[28] Liver-related hypoalbuminemia is associated with portosystemic vascular anomalies and hepatic cirrhosis. Hypoalbuminemia because of protein-losing nephropathy or protein-losing enteropathy should be considered before ascribing hypoalbuminemia to decreased hepatic production. Albumin is a negative acute-phase protein and mild reductions (values remain within the reference interval) as a result of reduced synthesis are associated with chronic extrahepatic inflammation. There is often a concomitant mild rise in globulin concentration as a consequence of increased production of acute-phase proteins by the liver.[29]

The majority of coagulation factors are synthesized in the liver. The liver also plays a key role in the production of anticoagulant factors and the removal of activated clotting factors and products of fibrinolysis. Prothrombin time (PT) and activated partial thromboplastin time (aPTT) should be evaluated prior to procedures that compromise vessel integrity, notably liver biopsy, when hepatic pathology is suspected. aPTT and PT are both likely to be prolonged in severe, acute hepatic necrosis,[30] whereas only aPTT tends to be prolonged in dogs with congenital portosystemic vascular anomalies.[31,32] Also, in a model of chronic hepatic pathology, aPTT becomes abnormal earlier than PT.[33] Coagulation factors II, VII, IX, and X are dependent on vitamin K for activity. Vitamin K deficiency and the likelihood of hemorrhage are associated with bile duct obstruction and prolonged anorexia (e.g., in cats with hepatic lipidosis). Measurement of PIVKAs (protein induced by vitamin K absence or antagonists) appears to be more sensitive for the detection of vitamin K deficiency than the PT and aPTT assays.[34] When vitamin K deficiency is the cause of the abnormal coagulation tests, these return to reference values within 24 to 36 hours following the parenteral administration of vitamin K, but remain abnormal if the activity of other coagulation factors is reduced because of liver pathology.

Ammonia is produced in the intestinal tract and transported by the portal circulation to the liver where it is metabolized. One by-product is urea nitrogen, which enters the circulation and is excreted by the kidneys. Hyperammonemia is associated with portosystemic shunting because of portosystemic vascular anomalies that are either congenital or acquired secondary to cirrhosis. The finding of hyperammonemia supports the clinical suspicion of hepatic encephalopathy. Hyperammonemia also facilitates the development of ammonium biurate crystalluria, which is commonly associated with congenital portosystemic vascular anomalies. In one hospital setting, the measurement of the fasting plasma ammonia concentration was more sensitive and specific for the detection of portosystemic shunts in dogs than fasting plasma bile acid concentration.[35] Ammonia can be measured before and after the administration of ammonium chloride per os or per rectum. Ammonium chloride at 100 mg/kg and up to a maximum dose of 3 g is mixed in 20 to 100 mL of warm tap water to a concentration not to exceed 30 mg/mL and is administered orally or by orogastric intubation. Blood is collected into ammonia-free heparinized tubes and blood ammonia measured.[36] For the rectal route, a warm-water enema is given 12 hours prior to the administration of 2 mL/kg of a 5% ammonium chloride solution by a rectally placed catheter, and the blood ammonia is measured 20 and 40 minutes later.[37] A more than a two- to threefold increase in blood ammonia at any time point is considered abnormal.

Rare cases of hyperammonemia caused by an enzyme deficiency in the urea enzyme cycle in the dog have been reported.[38] Clinical signs of hepatic encephalopathy in these cases are associated with an abnormal ammonia tolerance test but a normal serum concentration of total bile acids. Measurement of the urea cycle enzymes in

liver tissue obtained by biopsy is needed for confirmation of the diagnosis.

As mentioned previously, blood urea nitrogen (BUN) is a by-product of ammonia metabolism. BUN is below the reference interval or inappropriately low compared with creatinine in most dogs and cats with congenital portosystemic vascular anomalies as a consequence of shunting of ammonia-rich portal blood directly into the systemic circulation.[39]

Bilirubin is derived from the metabolism of aged erythrocytes by macrophages and transported to the liver. This metabolite is referred to as unconjugated (indirect-reacting) bilirubin. Hepatocytes efficiently remove it from the sinusoidal blood and conjugate it with glucuronic acid; a process that is catalyzed by UGT1A1, an enzyme in the uridine diphosphate glucuronosyltransferase (UGT) family.[40,41] Some drugs impair the function of UGT1A1, resulting in an increase in unconjugated bilirubin in the circulation (unconjugated hyperbilirubinemia) without concomitant anemia or hepatic pathology.[42,43] Conjugated bilirubin is excreted by the canalicular membrane into the bile and carried to the intestinal tract where bacteria convert it to urobilinogens and stercobilin, the latter imparts the brown color to feces (see Fig. 25-15). Some of the colorless urobilinogen is passively reabsorbed and renally excreted. Measurement of urinary urobilinogen is an archaic test that was developed to determine patency of the bile duct and is now considered clinically useless. A variety of extrahepatic bacterial infections can release substances that impair canalicular membrane function, resulting in retention of conjugated bilirubin in the circulation (conjugated hyperbilirubinemia) (see Box 25-4). Because there is no physical biliary obstruction, it is considered a functional impairment of bile flow. Often there is only minimal concomitant change in liver enzyme activities or findings observed histologically.[44,45] Hyperbilirubinemia resolves with successful management of the extrahepatic infection.

Hyperbilirubinemia, an increase in the circulating total bilirubin concentration, leads to icterus (jaundice). The kinetics of bilirubin metabolism differ between the dog and man.[46] Conjugated, but not unconjugated bilirubin can appear in the urine (bilirubinuria) and a small amount of conjugated bilirubin can be detected in healthy dogs. Measurement of the unconjugated and conjugated fractions of serum bilirubin is generally not necessary or even helpful in determining the cause of hyperbilirubinemia. A rapid acceleration of erythrocyte destruction because of severe hemolytic disease resulting in hyperbilirubinemia (prehepatic icterus) is associated with anemia. Liver enzyme activities may also be abnormal in these patients because of the anemia-related, hypoxia-induced degeneration of hepatocytes, notably in the centrilobular region (zone 3) of the liver. Differentiation of hyperbilirubinemia because of intrahepatic pathology (hepatic icterus) versus obstruction of the bile duct (posthepatic icterus) is challenging. Ultrasound is used to assess bile duct patency and, if abnormalities are not detected, examination of a liver biopsy is often necessary.

Variable amounts of a second type of conjugated bilirubin can form with prolonged cholestasis.[47] Conjugated bilirubin can become irreversibly bound to albumin through a poorly understood mechanism. This type of bilirubin is referred to as biliprotein or δ-bilirubin. Instead of being rapidly eliminated (hours) in bile like the first form of conjugated bilirubin once the cholestatic process is resolved, δ-bilirubin is removed from the circulation at the rate of albumin degradation, which is approximately 6 to 8 days. If the majority of conjugated hyperbilirubinemia is in the form of biliprotein, icterus will be protracted (days to weeks) following successful management of the cholestatic process. Some chemistry analyzers can directly measure biliprotein.

Hepatocytes synthesize two primary bile acids from cholesterol, cholic acid and chenodeoxycholic acid, and conjugate them to glycine or taurine. Bile acids are secreted by the canalicular membrane into canaliculi for transport to the intestinal tract by the biliary system. Conjugated bile acids are efficiently absorbed (~95%) by the ileum into the portal circulation and transported back to the liver for efficient first-pass uptake (~60% to 80%) by hepatocytes primarily located in periportal region (see Fig. 25-15).[48,49] Conjugated bile acids are reexcreted into the biliary system for another enterohepatic journey during which they contribute the osmotic force that impels bile flow and provide surface-active detergent properties that facilitate intestinal absorption of lipids. This recycling of bile acids is referred to as an *enterohepatic circulation*. Small quantities of primary bile acids that are not reabsorbed in the ileum are dehydroxylated by anaerobic bacteria in the colon to form secondary bile acids. Some of these are absorbed into the portal venous circulation and recycled as well. Conjugated primary and secondary bile acids comprise the majority of the bile acid pool in the portal circulation. Uptake of bile acids by hepatocytes from the sinusoidal blood involves the sodium taurocholate cotransporting protein (NTCP) and the organic anion transporting protein (OATP), and bile acid transport into the bile at the canalicular domain is driven by the bile salt export pump (BSEP).[50-53]

Circulating total bile acid concentrations are usually measured after withholding food for 8 to 12 hours and again approximately 2 hours after a small meal of canned pet food in an attempt to stimulate contraction of the gallbladder and challenge the liver. To avoid lipemia, approximately 2 to 3 teaspoons are given to animals weighing less than 10 to 15 pounds and up to 2 to 3 tablespoons are given to larger animals. Postprandial gallbladder contraction is inconsistent or may occur during the fasting period, resulting in a fasted value that exceeds the postprandial value. However, both values are usually within the reference interval. Total bile acid concentrations increase in the circulation when pathology alters the enterohepatic circulation. Fasting and/or postprandial serum bile acid concentrations approximately greater than 15 μmol/L for the cat and 25 μmol/L for the dog are supportive of liver pathology or portosystemic vascular abnormality.[54-57] Bile acids can also be measured in the urine of dogs and cats.[58,59] Microscopic examination of a liver biopsy is required to characterize the liver pathology and determine its severity. Some of the highest values are found in congenital portosystemic vascular anomalies and cirrhosis. Maltese dogs can have high total bile acids without liver pathology for unknown reasons; the ammonia tolerance test in these dogs is normal. If the ammonia tolerance test is abnormal, a congenital portosystemic vascular anomaly is indicated. Small intestinal bacterial overgrowth (SIBO) can enhance the deconjugation of bile acids, which are less efficiently removed from the portal circulation resulting in an increase in the circulating total bile acid pool. An increase of a specific unconjugated bile acid, unconjugated cholic acid, has been associated with SIBO in dogs in one study, but the diagnostic value of this test was not verified in another study.[60,61]

Hypoglycemia caused by liver disease is often associated with congenital portosystemic vascular anomalies, especially in small breeds and in patients with acute severe hepatocellular necrosis.[30,62] Hypoglycemia is also associated with glycogen storage disease and primary hepatic neoplasia.[63,64,65,66]

Liver-related hypocholesterolemia is often associated with congenital portosystemic vascular anomalies.[62]

CHAPTER 26

Diagnostic Imaging of the Gastrointestinal Tract

RADIOGRAPHY

Kari L. Anderson and Daniel A. Feeney

Indications

With the exception of the esophagus, digestive tract organs share many common characteristics, including their location (peritoneal cavity), their afferent blood supply (i.e., celiac and cranial mesenteric arteries), portions of their efferent blood drainage (i.e., portal and hepatic veins) and a number of functions (e.g., motility, digestion, secretion, absorption, and excretion). These common characteristics must be considered in the approach to diagnosis. Clinical signs of gastrointestinal disease include vomiting, diarrhea, anorexia, abdominal pain, and weight loss. However it must be remembered that diseases of other organs, such as the pancreas, liver, kidneys, or adrenal glands can cause similar clinical signs. The diagnostic process is thus aimed at expeditiously including or excluding differential diagnoses using cost-effective diagnostics, including serum biochemical analysis and survey radiographs. In addition, these cost-effective diagnostics are generally available in primary care small animal practices, making them practical and applicable. Once initial diagnostic tests have been concluded, a more focused, but often more costly, diagnostic test, such as abdominal ultrasonography, endoscopy, or cytology, can be used to further localize the disease or make a specific diagnosis. This chapter describes an organized approach to the radiographic assessment of the gastrointestinal tract.

Technical Considerations

There are several reviews on specific radiographic techniques published elsewhere.[1-6] Several decisions need to be made before considering any imaging procedure, particularly those that are invasive or more costly. Specifically, what is the aim of the radiographic study? Is it to investigate organ geometry (i.e., size, shape, location, surface character, number or degree of organ involvement), organ opacity (i.e., gas, fluid, soft-tissue parenchyma, mineral, or metal), organ function (i.e., motility, breakdown, secretion, absorption, or excretion), organ leakage, organ obstruction, organ wall anatomy, organ wall thickness or pliability, etiology of dilation (segmental or diffuse), gas patterns, or effect of a diseased adjacent organ? Once the intent of the imaging procedure is established, it should then be determined whether survey radiographs alone are adequate to make the diagnosis or whether additional imaging procedures will be necessary. Horizontal beam or contrast procedures could be a necessary part of the additional medical workup. If a contrast procedure is indicated, the type of contrast medium should also be considered. Considerations for a contrast radiographic procedure should include the goal of the study (e.g., assessment of organ distention, motility, leakage, or foreign bodies), potential for body cavity or pulmonary contamination, options for contrast medium administration (i.e., oral, gastric, nasoesophageal, or nasogastric intubation), potential for air embolism from negative contrast medium, and the best choice for the contrast agent. Micropulverized barium sulfate suspensions are utilized in the assessment of motility and mucosal morphology, but can cause inflammation if the suspensions gain entry into the lungs or body cavities. Ionic iodinated oral preparations are associated with rapid propulsion, but are less useful for evaluating mucosal morphology, and side effects because of airway aspiration may be significant. Nonionic iodinated media are useful for the assessment of motility but not mucosal morphology, and fewer side effects have been reported if the media gains entry into lungs or body cavities. Another consideration is whether the positive contrast medium should be used as constituted or administered with food. In general, contrast agents should be administered without food for evaluation of mucosal morphology, detection of leakage, and timing of organ transit (e.g., stomach and small bowel) unless the goal is to assess the solid phase of gastrointestinal transit. Once these questions have been answered, other considerations related to the patient may be addressed.

Preprocedural Considerations

Patients with alimentary disease can be nauseous, weak, or dehydrated as well as having complications of alimentary tract disease, including aspiration pneumonia, sepsis, electrolyte and acid–base abnormalities, and abdominal distention. A balance between what is optimal for the patient and what is optimal for the imaging procedure should take these complications into account. Dyspnea and acute pain, for example, could be significant factors to consider in delaying the decision to perform an imaging procedure. Patient attitude and preparation are equally important patient parameters to take into account. Fractious patients may harm staff or themselves and must be adequately restrained or sedated. The authors prefer light phenothiazine sedation if sedation is needed.[7,8] Generally, no specific preparation is necessary for survey radiographs. In fact, unnecessary preparations or patient alterations may interfere with

image quality. For example, sedation may lead to slight accumulation of air in the esophagus that may be confused with megaesophagus. No specific preparation is required for an esophagram, but both the upper gastrointestinal (GI) series and the barium enema require cleansing enemas and/or cathartics, and, unless imaging is considered an emergency, food should be withheld for at least 18 to 24 hours.

Consideration should also be given to personnel safety. Appropriate radiation safety precautions must be taken for any radiographic procedure, including use of personnel shielding devices (e.g., aprons, gloves, eye shields, and/or thyroid shields). Appropriately placed personal body monitors must be used. Radiographic procedures should be planned such that manual restraint of the patient is minimized. Potential radiation exposure, including scatter and primary beam radiation, should also be minimized.

Positioning and Views

Standard Views

Standard, vertical–beam radiography (i.e., recumbent views taken with the patient on the x-ray table) with variable positioning can be used to characterize gas and fluid distribution within organs. The authors recommend right lateral and ventrodorsal (VD) recumbent views as a starting point for routine survey radiographs. The pylorus can appear like a ball-shaped foreign body in these views (Fig. 26-1).

Horizontal-Beam Views

The objective of horizontal-beam radiography (i.e., the x-ray beam is directed parallel to the x-ray table) is to use the influence of gravity on gastrointestinal fluid distribution to clarify findings suspected on routine survey radiographs. The most common uses of horizontal-beam radiography are (a) to position the patient such that any freely movable (free) fluid can be shifted away from the area of interest; (b) to position the patient such that free fluid can be serially quantified; (c) to position the patient to permit differentiation of free and trapped fluid, which is often associated with inflammatory and neoplastic conditions; and (d) to position the patient such that air observed in the abdominal cavity is freely movable or trapped within normal viscera. A horizontal fluid line indicates the presence of both air and fluid in the abdominal cavity (Fig. 26-2).

Esophagram

Contrast Media, Dose, and Route of Administration

If a perforation that potentially communicates with the lung or airways (e.g., bronchoesophageal or esophagopulmonary fistula) is suspected, a nonionic iodinated contrast agent (e.g., iohexol or iopamidol) or barium should be used. Alternatively, a half-strength water-soluble ionic iodinated contrast agent (e.g., oral Hypaque, or any angiographic or urographic iodinated contrast agent) can be used. If the study using an iodinated agent is negative, a study using liquid barium should follow, as some perforations cannot be identified using iodinated agents. Either type of contrast agent should be administered via buccal pouch infusion of 5 to 15 mL. If the goal of

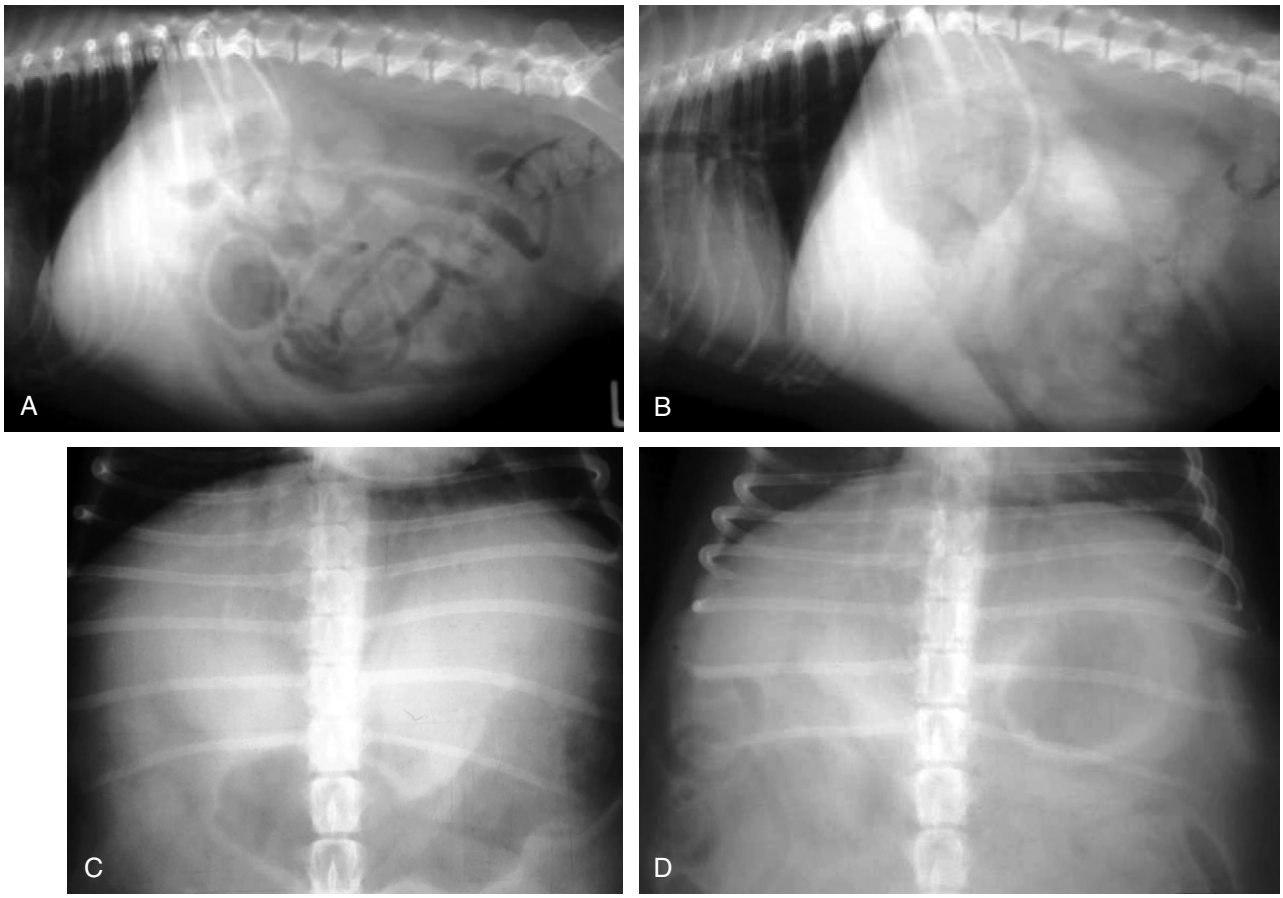

Figure 26-1 Abdominal radiograph, normal dog. (A) Left lateral recumbent, **(B)** right lateral recumbent, **(C)** dorsally recumbent, and **(D)** sternally recumbent. Note the shifting of gastric gas and fluid between the four different views.

Figure 26-2 **Horizontal-beam radiography.** This lateral abdominal radiograph was taken with a horizontal beam. The radiograph shows small intestinal loops dilated with fluid and gas. Note the flat air–fluid interface in each of the loops.

the study is to outline the esophageal mucosa, liquid barium (i.e., >30% weight per volume [w/v] or a >25% wet weight [w/w] suspension) should be used. If the intent of the study is to instead assess esophageal peristalsis, a mixture of barium and canned food should be used. The barium/food mixture is best offered voluntarily, but could be force-fed if necessary. Contrast studies may not be needed if the esophagus is grossly dilated on survey radiographs.

Radiographic Views

All alimentary contrast procedures must be preceded by survey radiographs of the area of interest. The contrast agent should be given with the patient in the position that is intended to be obtained (i.e., usually lateral recumbency). The radiograph should be taken within 10 to 15 seconds of administration of the food, but is best taken 5 to 10 seconds after the first swallowing attempt to assess esophageal mucosal integrity. If trying to assess esophageal motility, the views should be taken within 15 to 30 seconds of the first swallowing episode. Solid food will normally be evacuated from the cervical and intrathoracic esophagus in less than 1 minute and any food remaining in the esophagus for more than 2 minutes is considered grossly abnormal. Radiographs may need to be repeated depending upon the effectiveness of esophageal clearance. Repeating the sequence with different types of food may be necessary as some patients may have adequate motility for liquids, but may not have adequate motility for solid food.

Upper Gastrointestinal Series

Contrast Media, Dose, and Route of Administration

There are several variations of the traditional upper gastrointestinal contrast series, including the air gastrogram and the double-contrast gastrogram. However a standard single-contrast study is recommended in most cases. For a routine upper GI study, approximately 6 mL/kg body weight (BW) of a 30% to 60% w/v (approximately 25% to 40% w/w) preparation of micropulverized barium sulfate suspension is administered via stomach tube. The concentration of the material can be readily adjusted by adding water. The only indication for ionic iodinated compounds is if a perforation of the GI tract is suspected. In those cases, the barium sulfate should be substituted with half-strength ionic iodinated or a more costly nonionic iodinated agent, which are given at an equal volume as for the barium. Nonionic agents are better if large volumes are needed, but are also more expensive.

Radiographic Views

Survey radiographs of the area of interest should be taken first. If the stomach is the site of a suspected abnormality, an image should be taken immediately after the administration of the contrast agent. The bulk of the liquid barium should be used to distend all aspects of the gastric lumen, and right and left lateral images as well as VD and dorsoventral (DV) views should be taken. If the small bowel is the site of an abnormality, only a right lateral and either a DV or a VD views are taken immediately after contrast administration. After these initial images, followup images are taken at least every 30 minutes until the contrast agent has reached the colon and the stomach is evacuated. In patients with a rapid onset of gastric emptying, as indicated by an almost immediate duodenal opacification, images should be taken every 15 minutes during small intestinal transit.

Barium Enema

Contrast Media, Dose, and Route of Administration

Approximately 20 mL/kg of a 30% w/v (approximately 25% w/w) preparation of micropulverized barium sulfate suspension is administered via hanging bucket and delivery tube. The barium product used may be packaged either as a liquid or a powder as flocculation in the colon is nonspecific.

Radiographic Views

Survey radiographs are taken of the area of interest. VD and left and right lateral views are taken immediately after complete filling is achieved. However if a patient shows signs of discomfort, it may be necessary to take an occasional lateral view before the entire dose has been given. In addition, it may be necessary to administer more than the initial dose to achieve complete filling. Therefore, one lateral view should be taken after the initial dose has been administered to determine if all parts of the rectum, colon, and cecum have been distended. Distention should be continued until questionable areas are either distended or reveal a specific defect.

Interpretation

Alimentary disease should be classified as luminal, mural, extramural, or transmural (e.g., perforation [Fig. 26-3]). The intent of this classification is to define the general likelihood of various differential diagnoses. An understanding of basic principles of pathology makes this less complicated. For example, extramural lesions affect alimentary organ position and dimensions (e.g., compression of the colorectal junction by an enlarged prostate gland), but do not originate in the alimentary organ itself. Intraluminal lesions, on the other hand, are generally completely surrounded by the administered contrast medium. Finally, mural lesions, such as tumors or strictures, are generally only partially surrounded by the administered contrast medium. When considering mural lesions, wall thickness measurements play an important role. The normal wall

thickness is 2 to 4 mm for the esophagus, 4 to 5 mm for the stomach (interrugal), and 3 to 4 mm for the small bowel and the colon.[1,3-6] Any deviation from these measurements is usually a result of local or regional infiltrates causing wall thickening that can range from diffuse infiltrative bowel disease to focal/multifocal mural infiltrates such as tumors and strictures. Annular lesions are a unique subset of mural lesions and resemble either a napkin ring or an apple core because of their circumferential distribution and concentric luminal narrowing. Although possibly seen with strictures, this pattern is most commonly seen with intestinal neoplasia.

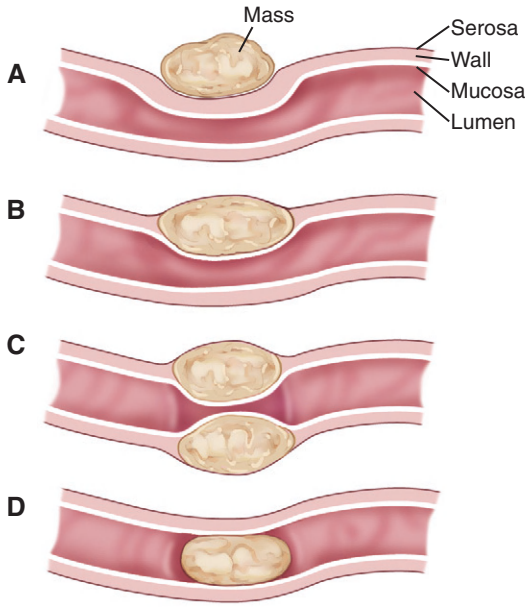

Figure 26-3 Types of intestinal lesions. This figure shows a diagrammatic representation of (**A**) extraluminal, (**B**) intramural, (**C**) annular intramural, and (**D**) intraluminal gut lesions.

Considerations for Alimentary Tract Imaging

The use of a few common sense rules can greatly simplify the imaging of the alimentary tract. Survey radiographs are crucial for the diagnostic process as they allow assessment of the GI tract without being affected by procedure-related stress and aerophagia, peristaltic effects of drugs or tube passage, and the soothing (barium) or irritating (ionic iodine) effects of contrast agents. It is also important to have a perspective on the relative roles of imaging procedures and endoscopic procedures. In general, endoscopic procedures are superior to imaging procedures for mucosal characterization, although this may change as imaging-based virtual endoscopic procedures are further investigated and refined. By comparison, radiographic procedures, particularly positive contrast procedures, are superior for characterization of intramural, transmural, and extramural diseases.

Of particular value is an assessment of the fluid and gas volumes along the gastrointestinal tract. First, any reproducible distention of the esophagus is abnormal. As a general rule, approximately 30% to 60% of the small bowel in dogs contains air, which is spread evenly throughout the bowel and relates in some reasonable proportion to the gas and fluid in the stomach. By comparison, most of the feline alimentary tract is devoid of gas, except in aged cats. This is a consequence of both anatomy and physiology (Fig. 26-4). The

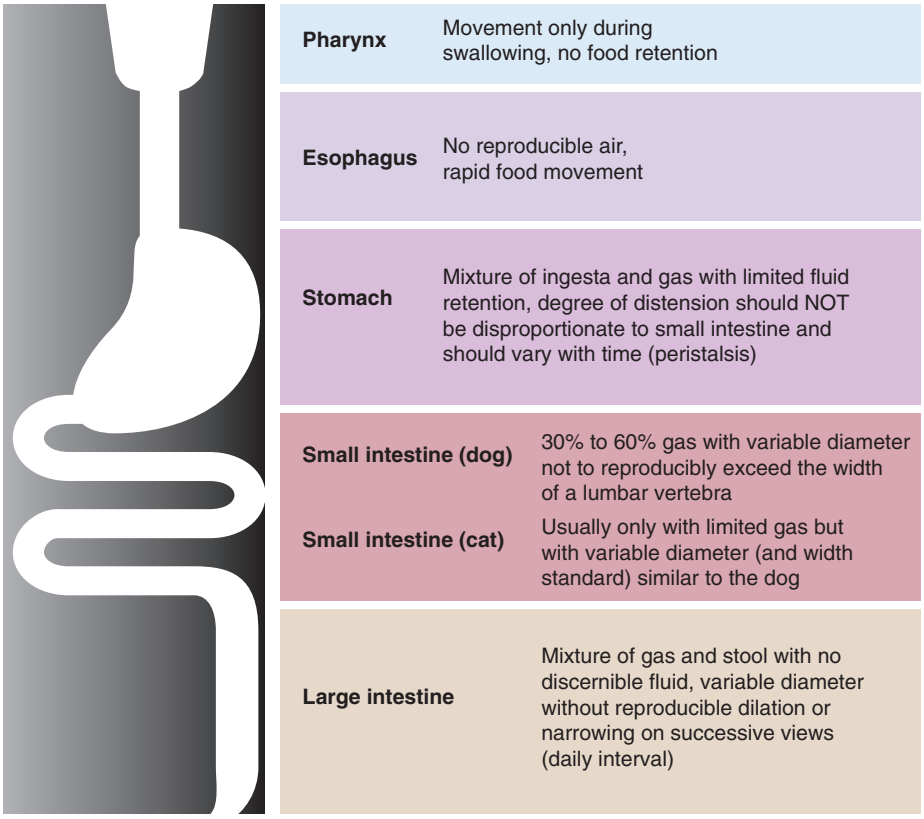

Figure 26-4 Radiographic parameters along the alimentary tract. This figure shows an illustration of the expected alimentary content, motility, and proportionality along the alimentary tract in small animals.

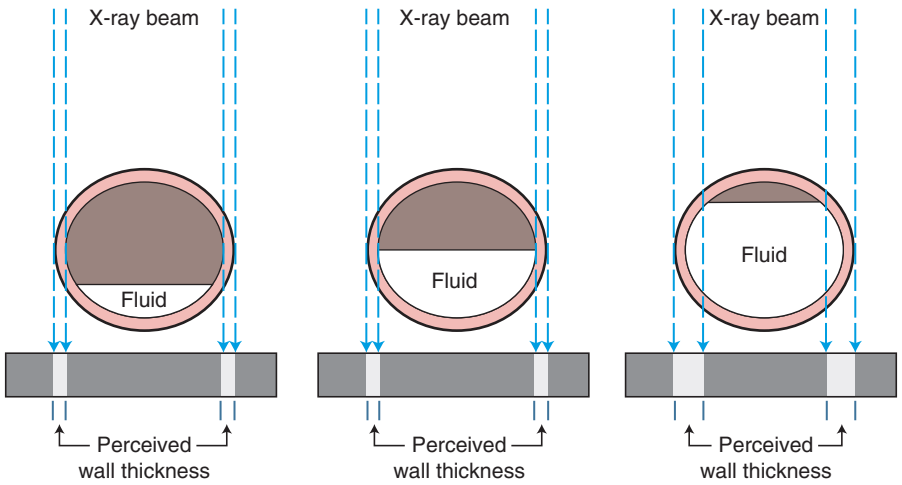

Figure 26-5 Perception of wall thickness. Illustration of perception of bowel wall thickness caused by fluid content of the stomach.

gastrointestinal tract is one continuous tubular lumen and there should be an orderly flow of ingesta from proximal to distal. There should be no disproportionate accumulation of fluid or solute or lack of any of these contents along the course of the GI tract. If such changes are identified on survey radiographs, this is an indication for further imaging investigation. The alimentary organs can be affected by regional and systemic influences as well as the local effects of the ingesta. The fluid/gas balance coupled with the organ size or diameter and distribution of a perceived abnormality can provide clinically useful insights into the pathophysiology of the disease. For example, a focal or multifocal distribution is associated with foreign bodies, tumors, strictures, and small incarcerations. In comparison, a diffuse distribution is associated with widespread intramural disease (e.g., infiltrative bowel disease), as well as widely differing luminal osmolarities related to bacterial proliferation, digestion, or absorption. A diffuse distribution can also result from disease involving other components of the digestive system, especially the liver (e.g., portal hypertension causing fluid buildup in the small bowel). Regional effects can be the result of intraluminal, intramural, or serosal irritation or inflammation (e.g., caused by peritonitis, pancreatitis, or a migrating foreign body).

The size of an alimentary organ as well as its contents can provide an insight concerning the underlying abnormality. Organ size is governed by several factors, including peristaltic capacity (i.e., neuromuscular disease, ischemia, inflammation, wall trauma, or altered electrolyte status), downstream or outflow resistance (i.e., sphincter dysfunction, strictures, or any obstruction), the digestibility and bulk of intraluminal contents (e.g., foreign material or engorgement), wall pliability (e.g., fibrosis or cellular infiltrates), wall thickness (e.g., tumor), upstream delivery of materials, and the volume and viscosity of ingested or administered material (e.g., aerophagia, psychogenic polydipsia, or polyphagia). Impedance to flow is characterized by buildup of fluid, ingesta, and air proximal to the impedance, and a lack of these contents distal to the impedance. Partial obstructions are characterized by buildup of fluid and ingesta with only small amounts of gas. Near complete obstruction is characterized by a mixture of gas and fluid, but with little accumulation of ingesta. Dysmotility may mimic any of the previously mentioned conditions.

Gas volume and its distribution can be key components in the interpretation of alimentary tract disorders. In omnivores, most alimentary gas derives from swallowed air. From low-grade impedance of gastrointestinal flow to complete obstruction, the likelihood of intraluminal buildup is air, fluid, digestible solids, and nondigestible solids (e.g., small bone fragments or small foreign objects). Unless an obstruction is nearly complete, only limited amounts of air will accumulate proximal to it because air can move past a partial obstruction more readily than fluid, food, or mobile fragments suspended in the partially digested chyme. The relationship of relative air versus fluid in a tubular organ segment and the influence of gravity are relevant variables to the assessment of gut wall thickness using survey radiography. As illustrated in Figure 26-5, the appearance of the wall of a hollow alimentary organ is based on the optical perception of the serosal and mucosal surfaces with the distance between them presumed to represent the wall thickness on routine vertical-beam radiographs. Overestimation occurs when the lumen is more than half full, which is common on alimentary survey radiography and must be factored into every attempt to assess wall thickness and may prompt a decision to perform additional imaging, including contrast or ultrasonographic procedures.

For interpretation of any survey radiograph, the well-accepted "Roentgen sign" approach (e.g., size, shape, location, surface characteristics, opacity, and function) provides useful basic information. Several questions should be considered to avoid over- or underinterpretation of these findings. Radiographs should be reviewed for any unexpected or disproportionate regions of organ distention, and whether any distention is caused by fluid, gas, solids, or some combination of all three phases. Radiographs should also be reviewed for signs suggestive of mechanical disruption or dysmotility. Gas-to-fluid ratios should be determined and whether luminal gas is randomly distributed. Another question that needs to be addressed is whether the distribution of fluid, gas, and ingesta is diffuse or segmental. Areas of segmental distribution, regional peristaltic abnormalities, and wall rigidity should be identified. The mixture of fluid and gas in the bowel should be assessed for evidence of obstruction and to differentiate it from ischemia, the latter of which is mostly associated with intraluminal air. Radiographic review should also include identification of unexplained localized intraluminal opacities or persistent material. Serosal contrast should especially be evaluated in areas of gut abnormalities. Masses should be identified and assessed for visceral displacements, invasion, or origination from the gut. Another very important question to pose is whether there is any free air or fluid in the peritoneal or retroperitoneal cavity. The etiology of the alimentary problem may not be obvious on survey

radiographs alone, and if that is the case, the radiographic interpretation may still help focus selection of more appropriate imaging techniques for further clarification or definitive diagnosis.

There are some useful clinical clues to the underlying etiology of an alimentary tract disease.[1,3-6] The buildup of a grainy opacity can indicate a chronic partial obstruction in either the stomach or the small intestine. A "thumbprinted" bowel, which describes a segment of the bowel that looks similar to a tubular piece of clay into which a thumb has been pressed, is suggestive of segmental or diffuse intramural infiltration because of neoplasia or pyogranulomatous infiltration. The thumb-printing effect comes from loss of wall pliability and variability in wall thickness. Another finding that can be observed is the so-called onion-skin or coil-spring appearance caused by contrast medium spreading between contiguous intestinal loops involved in an intussusception. The so-called washboard effect can be caused by regional mesenteric ischemia. The appearance of mural or wall layering may also be noted during radiography, which can be a result of infiltration of the wall with gas or minerals. Layering of luminal content may also be seen on horizontal-beam views, as different types of bowel content occupy different "layers" relative to gravity. Finally, the appearance of tubular plication, which appears as an eccentric accumulation of air, is caused by intestinal bunching occasioned by ingestion of linear foreign bodies (e.g., cloth, string).

The authors advocate two approaches to interpreting radiographs. The first is the gamut approach[9] in which the radiographic signs are listed and the pathophysiologic or pathoanatomic causes are considered. The findings are then ranked in descending order of likelihood based on risk modifiers including clinical history, age, gender, breed, and species. Another helpful approach is the use of the so-called DAMNIT system, which adopts a pathogenesis approach to diagnosing radiographic findings. The disease processes considered in the DAMNIT system are degenerative, drug-induced, and developmental (D); anatomic, allergic, autoimmune, and anomalous (A); metabolic and mechanical (M); nutritional and neoplastic (N); infectious (bacterial, fungal, viral, parasitic), inflammatory, and immune-mediated (I); and, toxic, traumatic, and teratogenic (T). Judicious use of the DAMNIT approach limits the likelihood of a diagnosis being missed because it was not included in the gamut approach.

Specific Considerations for Different Organs of the Gastrointestinal Tract

Oral Cavity and Pharynx

Anatomic considerations

Coordinated prehension, mastication, bolus formation, and swallowing are all necessary to facilitate coordinated aborad propulsion of food and water into the esophagus and beyond. Any morphologic or functional abnormality can be detrimental to the process of ingestion (see Chapter 54). The anatomic structures important for ingestion include the tongue, teeth, supporting bones of the maxilla and mandible, oropharynx, hyoid apparatus, and larynx. The tongue is important for complex movements that allow for prehension, mastication, and swallowing. The teeth and the supporting bones of the maxilla and the mandible are needed for mastication, and the oropharynx, pharynx, and larynx are needed for propulsion, swallowing, and protecting the airway during swallowing, respectively. The hyoid apparatus acts as a suspensory mechanism for tongue and larynx during swallowing. Positioning is crucial for radiographs of the aforementioned structures to avoid erroneous interpretation. A lateral view provides the most information, but orthogonal views should always be obtained.[10] The size and shape of the air-filled oropharynx varies with the position of the tongue, but the rectangular air-filled pharynx should maintain its size and shape independent of tongue position and phase of respiration (Fig. 26-6).

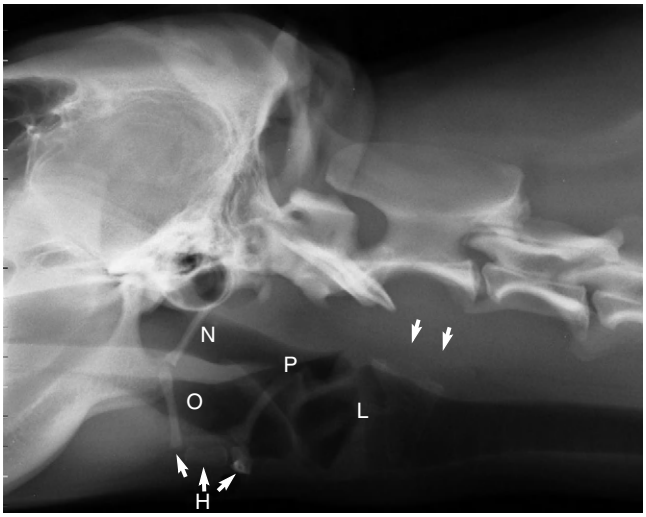

Figure 26-6 Normal canine pharynx. This radiograph shows a lateral view of the normal canine pharynx. Note the soft palate separating the air-filled nasopharynx (*N*) from the air-filled oropharynx (*O*), the air-filled pharynx (*P*), the hyoid apparatus (*H*), and the larynx (*L*; i.e., epiglottic, arytenoid, thyroid, and cricoid cartilages). Note the position of the structures relative to the cervical spine. Care must be taken not to mistake the normal cricopharyngeus muscle as a mass or foreign body (*white arrows*).

Functional Considerations

The primary functions of the oral cavity and pharynx are to prehend, masticate, and propel food into the esophagus. Prehension, mastication, and propulsion all require an intact innervation and coordinated relaxation response of the cricopharyngeus to permit passage of the bolus into the esophageal body. During these coordinated movements of swallowing, the soft palate closes the nasopharynx to prevent reflux of food into the nasal passage, and laryngeal closure protects the trachea from aspiration of food. A lesion associated with any of the involved structures can lead to an incomplete swallowing response.

Abnormal Radiographic Signs

Close inspection of lateral and DV or VD views will elucidate some of the diseases of the pharynx, but most will require further investigation by visual inspection, special procedures (e.g., contrast studies), and alternate imaging studies (e.g., fluoroscopy, ultrasound, computed tomography [CT], or magnetic resonance imaging [MRI]). It is important to closely evaluate the surrounding soft tissues for air, which can be caused by penetrating foreign bodies, lacerations, or abscessation. Poor pharyngeal tone, pharyngeal collapse, mural infiltrates, edema, and mural or extrinsic masses may lead to an abnormal size and shape of the pharynx (Fig. 26-7). Extrinsic masses often lead to displacement of the pharynx, larynx, and/or the trachea and are also often associated with accompanying compressions of these structures (Fig. 26-7C). The hyoid apparatus may become displaced or may contain fractures in association with dysfunction (Fig. 26-7A and B).

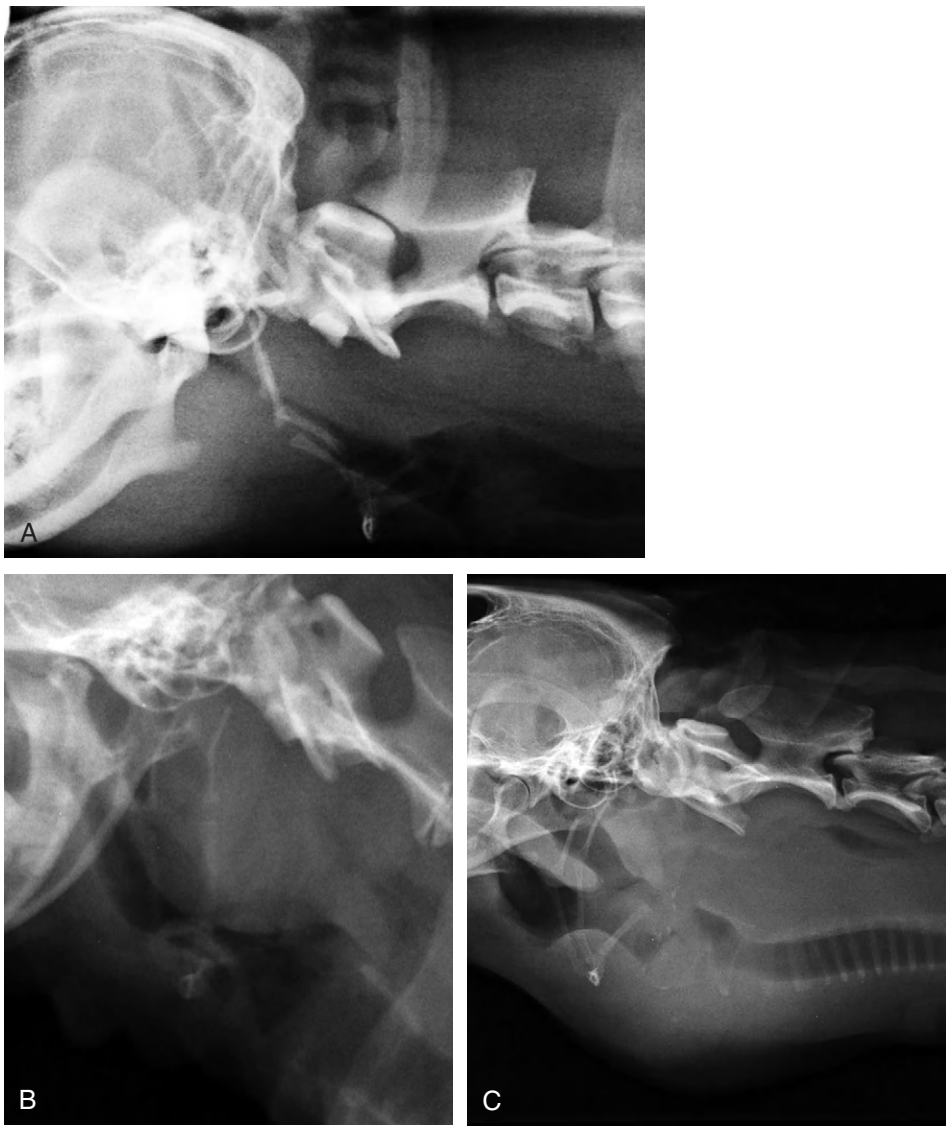

Figure 26-7 Pharyngeal disorders. This figure shows a variety of pharyngeal disorders. **A,** Lateral view of a dog with pharyngeal collapse. Note the lack of gas in the pharynx and the caudal migration of the hyoid apparatus as the dog inspires. No mass is present. **B,** Lateral view of a dog with a pharyngeal/retropharyngeal mass. Note the rounded mass causing compression leading to narrowing of the pharynx and to ventral displacement of the hyoid apparatus. **C,** Lateral view of a dog with a large circumferential neck mass causing compression and displacement of the pharynx, larynx, and trachea.

A contrast procedure utilizing a nonionic iodinated contrast agent can be helpful when evaluating the pharyngeal region for draining tracts. It is important to determine the extent of tissue involvement, especially as it is not uncommon for foreign bodies to penetrate the oropharynx or pharynx. Interpretation of the study involves determining the direction and extent of the tract, communication of the tract with the oropharynx, pharynx, esophagus, or other regional structures, and the cause of the draining tract (Fig. 26-8).

Dysfunction. Pharyngeal function is best observed fluoroscopically using liquid barium and barium-coated material (dynamic fluoroscopy).[11] Sometimes an impression regarding pharyngeal function can be gained using static survey radiographs obtained during inspiration and expiration. Survey radiographic findings suggesting pharyngeal dysfunction include caudal migration of the hyoid apparatus during inspiration, hyperinflation of the pharynx during expiration, collapse of the pharynx during inspiration (see Fig. 26-7A), and persistent gaseous distention of the proximal esophagus. These findings should be further evaluated with the use of pharyngeal fluoroscopy. Diseases associated with pharyngeal dysfunction include myasthenia gravis and other muscular disorders; cricopharyngeal achalasia, which is characterized by cricopharyngeal hypertension and inability of the sphincter to relax; and cricopharyngeal dyssynchrony, which is characterized by an incoordination of pharyngeal contraction and cranial esophageal sphincter relaxation.[11,12]

Pharyngeal Diseases

Disease processes resulting in abnormal size and shape of the pharynx will be governed by multiple factors. Downstream resistance leading to hyperinflation can be caused by laryngeal paralysis, laryngeal neoplasia, laryngeal pyogranulomatous inflammation, and tracheal obstruction as may occur due to a foreign body. Abnormal pharyngeal tone may be caused by neuromuscular disorders such as

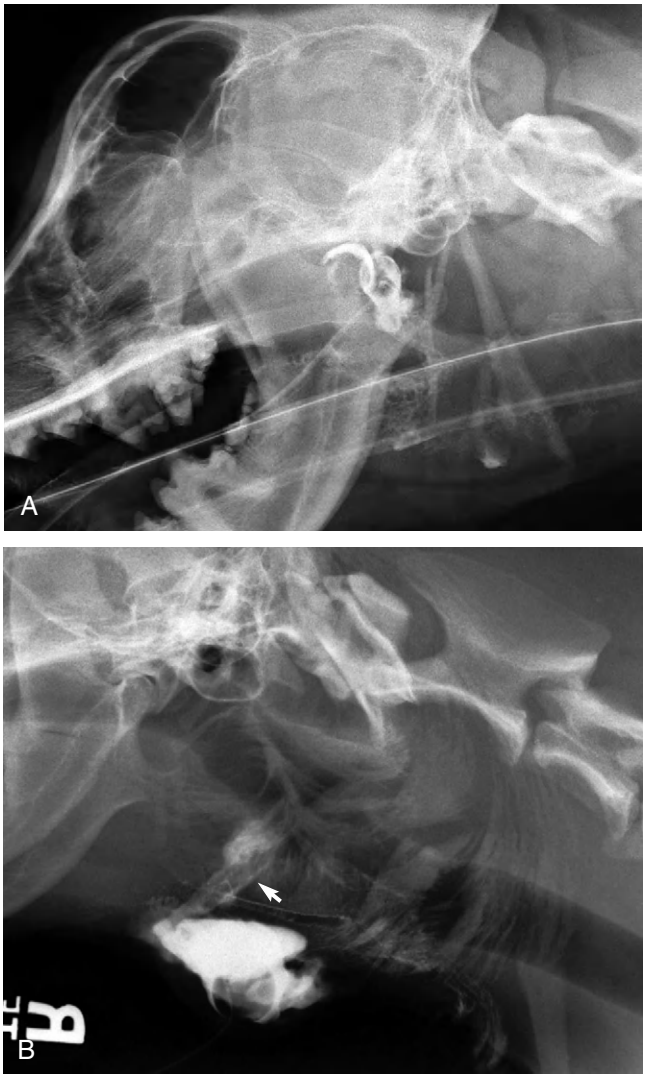

Figure 26-8 **Fistulograms. A,** Lateral view of a fistulogram. A balloon catheter was placed into a draining tract in the oral cavity of a dog and a nonionic iodinated contrast agent was injected. Note the contrast outlining the right temporomandibular joint. **B,** Lateral view of a fistulogram. Note the rectangular filling defect in the contrast area (*white arrow*), which was later identified as a piece of wood.

myasthenia gravis. Upstream resistance may be a result of stenotic nares, severe obstructive rhinitis, nasal neoplasia, or an inflammatory polyp. Pharyngeal collapse or mural lesions may be caused by redundant pharyngeal tissue, pharyngeal edema, inflammation, polyp, granuloma, or neoplasia. Extrapharyngeal lesions, such as retropharyngeal lymphadenopathy, neoplasia, abscess, granuloma, or foreign body, may also lead to pharyngeal compression.

The location and shape of the larynx may be governed by similar and additional factors. As with pharyngeal disease, downstream resistance may be a result of laryngeal paralysis, laryngeal neoplasia, laryngeal pyogranulomatous inflammation, or various causes of tracheal obstruction, including foreign bodies. Extralaryngeal lesions, such as retropharyngeal lymphadenopathy, neoplasia, abscess, granuloma, foreign body, or failure of the supporting structures such as hyoid luxation or hyoid fracture can all lead to radiographic changes of the larynx. An additional important consideration is that of regional opacity. Radiographic signs noted may include extrapharyngeal or laryngeal radiolucency caused by regional emphysema from pharyngeal or laryngeal perforation. Regional mineralization due to neoplasia, chronic hematoma, abscess, pyogranulomatous inflammation, or foreign body may also be observed. Penetrating pharyngeal foreign bodies can be potentially serious events in the dog and cat.[13] Metal foreign bodies are usually easily identified, but less-dense objects may be easily missed. The most frequent radiographic abnormality identified in patients with a pharyngeal foreign body is subcutaneous gas accumulation or gas in fascial planes or gas accumulating subcutaneously.[13] In some cases, a foreign body may be misinterpreted as a soft-tissue mass caused by regional inflammation or edema.[10]

Esophagus

Anatomic Considerations

The canine and feline esophagus is usually not visible on survey radiographs. There are occasional exceptions to this rule, including the increased likelihood of gastroesophageal reflux in left lateral recumbency and stress-induced or spontaneous reflux. These instances usually only involve the distal half of the esophagus and are transient. When visible, particularly when coated with barium, the normal esophagus exhibits bolus propulsion with interbolus linear stranding of the collapsed portion of the esophagus (Fig. 26-9A). There are some important species differences. The distal one-half to two-thirds of the feline esophagus normally has a "herringbone" appearance in the mucosal surface due to the presence of smooth muscle (Fig. 26-9B).

Functional Considerations

The primary function of the esophagus is the propulsion of food boluses. There is some fluid, mucus, and cation secretion, but the primary function is one of motility. If the propulsive functional capacity is sufficiently poor the esophagus will dilate. In most cases there is little need for contrast studies unless there is a suspicion of an obstruction causing the dilation. However the degree of esophageal dysfunction can be variable, ranging from diffuse dilation and complete flaccidity to a seemingly normal esophagus that fails to propel dry kibble but will move fluids and most soft foods without difficulty. The latter point illustrates the importance of esophageal imaging studies.

Abnormal Radiographic Signs

The normal esophagus is not visible on survey radiographs and needs to be rendered visible by contrast agents. The esophagus originates dorsal to the larynx and the proximal cervical trachea, courses gradually to the left of the trachea at the thoracic inlet to again become dorsal to the trachea in the cranial mediastinum, and track caudally dorsal to the heart to the esophageal hiatus of the diaphragm (Fig. 26-10). When rendered visible by positive contrast media, the location, morphology, and distribution of esophageal dysfunction can be identified (Figs. 26-11 and 26-12).[6,14] In addition, when surface-coating agents such as barium are being used, the mucosal surface can be assessed. In normal patients the esophageal mucosal surface should be smooth and regular. The most common cause of ventrally displaced trachea is esophageal dilation.

Esophageal Diseases

As with other parts of the digestive system, a systematic approach should be used to arrive at a list of differential diagnoses based on radiographic findings. The peristaltic capacity of the esophagus can be altered by idiopathic megaesophagus, dysautonomia, esophagitis, overt electrolyte imbalance, heavy metal toxicity, congenital or

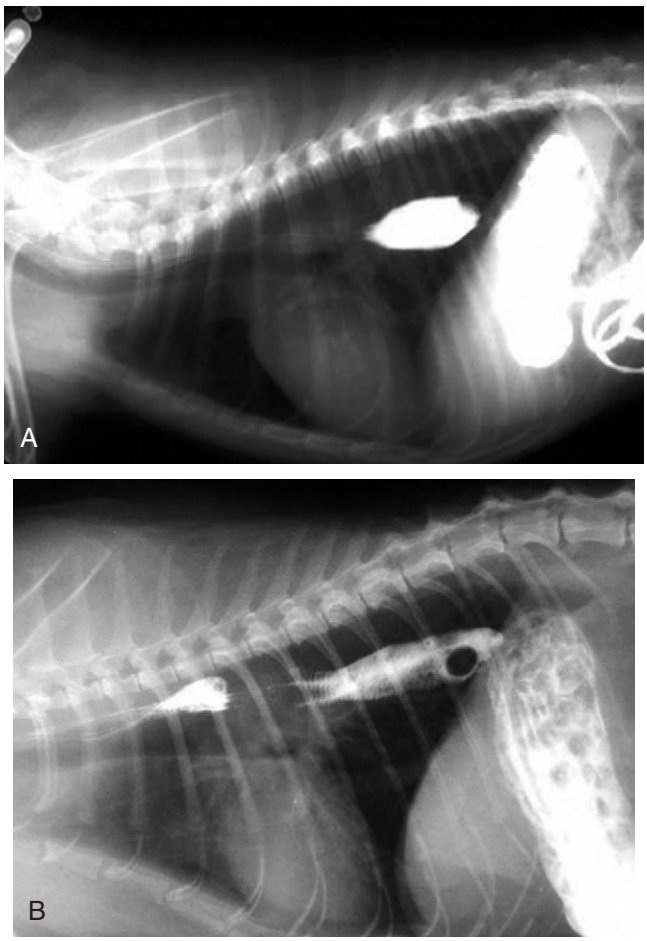

Figure 26-9 Normal esophagus. A, Lateral view of an esophageal bolus that is driven by peristalsis in a normal dog. Note the barium-coated linear folds in the collapsed esophagus cranial to the bolus. **B,** Lateral view of an esophageal bolus that is driven by peristalsis in a normal cat. Note the herringbone mucosal pattern in the esophagus between the heart and the diaphragm.

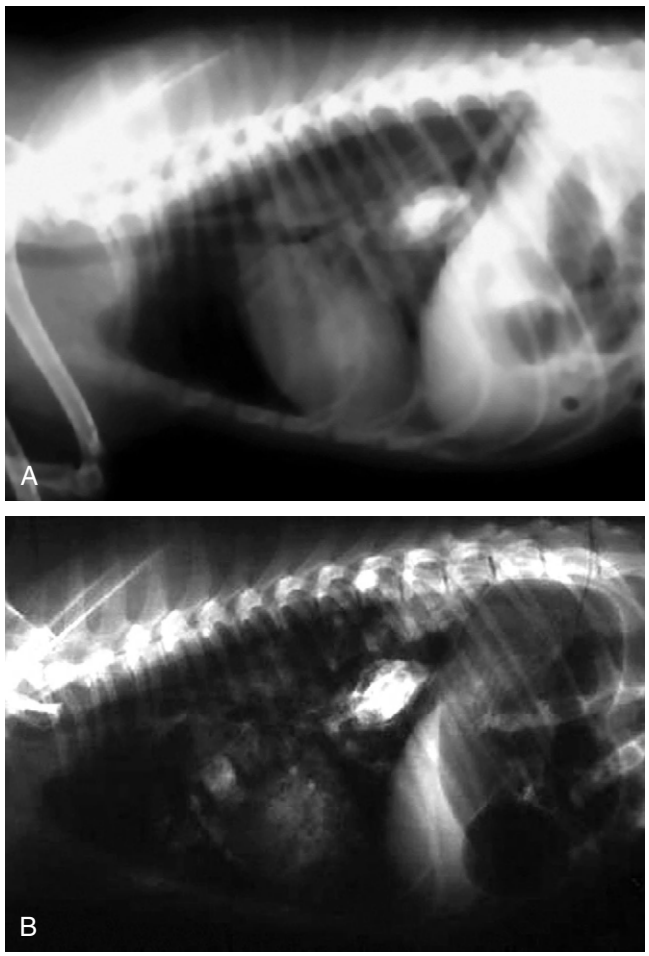

Figure 26-10 Survey radiograph and esophagram. (A) Left lateral recumbent survey radiograph and **(B)** left lateral recumbent contrast radiograph made after dilute iodine was administered to determine if there was leakage caused by the bony foreign body. Note the patchy opacity of the lung that occurred because of a caudal lobar bronchoesophageal fistula.

acquired diverticula, and thyroid status (see Chapter 55). Downstream resistance can be the result of a stricture, tumor, anomalous constrictions such as vascular ring anomalies, or any intraluminal obstruction, such as a foreign body. Wall thickness and pliability can also be altered because of fibrosis, inflammatory reactions, or neoplastic infiltrates. The upstream delivery of ingested materials is governed by a primary esophageal peristaltic wave that takes less than 10 seconds to move from the pharynx to the stomach. Luminal distention triggers a secondary peristaltic wave that originates at the site of the distention and proceeds toward the stomach in less than 5 to 10 seconds. Esophageal abnormalities should be further classified as intraluminal, intramural, transmural, or extramural. Examples of intraluminal abnormalities are foreign material or retained ingesta because of ineffective peristalsis or increased downstream resistance. Intramural abnormalities can be a consequence of strictures or tumors. Transmural abnormalities can be caused by penetrating objects or by bronchoesophageal fistulae. Extramural abnormalities can be caused by compression, distortion, or displacement by a regional organ or mass. Finally, the esophageal mucosa should be evaluated. Mucosal ulceration can be caused by erosion from gastric or gastrointestinal reflux, trauma from lodged or migrating foreign bodies, tumors that disrupt the mucosal surface, or the ingestion of corrosive chemicals such as sodium hydroxide. Esophageal leakage because of traumatic or ulcerative lesions can lead to septic mediastinitis and should be carefully considered. In the authors' experience, pneumomediastinum is a rare finding with esophageal penetrating lesions. The material that leaks into the mediastinum is usually of insufficient volume to noticeably distend the mediastinum. This makes the positive contrast esophagram all the more important in the assessment of a suspected esophageal perforation. This is usually initially performed with an iodine-based contrast agent, as these agents are isotonic and do not cause irritation if there is a tract involving the airway or lung. If the initial study is negative, it is followed by a barium study, which is more useful for detecting and localizing small leaks. Any barium contamination of the mediastinum should be surgically irrigated as soon as is practicable, but definitely in less than 12 hours.

Stomach

Anatomic Considerations

The canine and feline stomach usually contains modest amounts of fluid, but generally not enough to cause the appearance of distention on any radiographic view or recumbency. If the stomach begins to appear rounded rather than elongated in the transverse plane in a

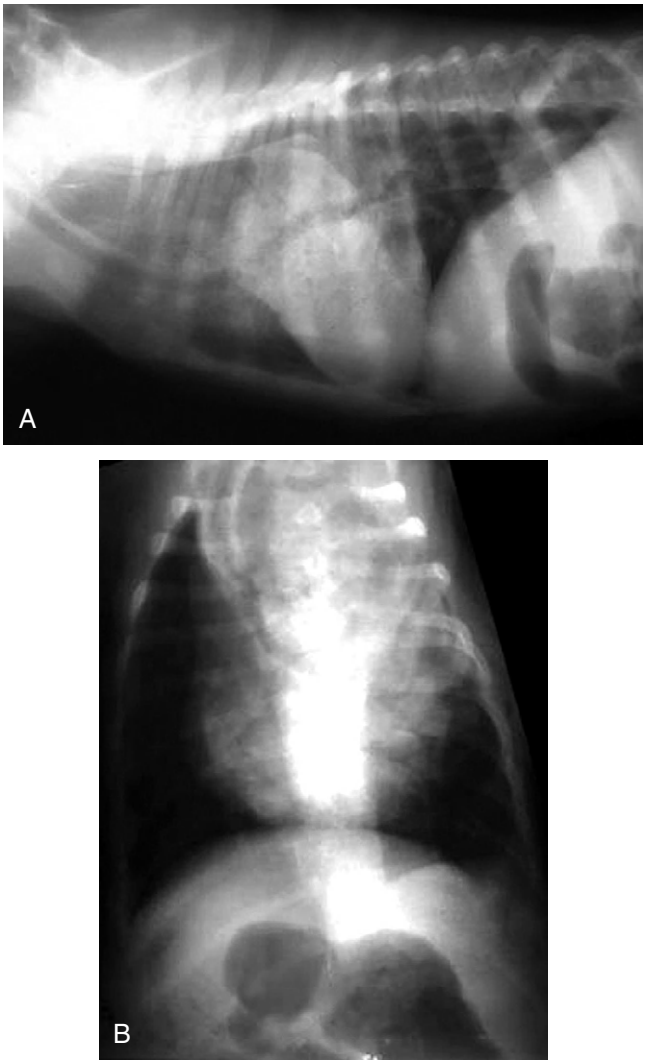

Figure 26-11 Vascular ring anomaly. (**A**) Left lateral recumbent and (**B**) dorsally recumbent survey radiographs of a dog. A gas-containing structure can be seen deviating the cranial mediastinal part of the trachea ventrally caused by a vascular ring anomaly. Note the alveolar disease in the left cranial lobe caused by aspiration pneumonia.

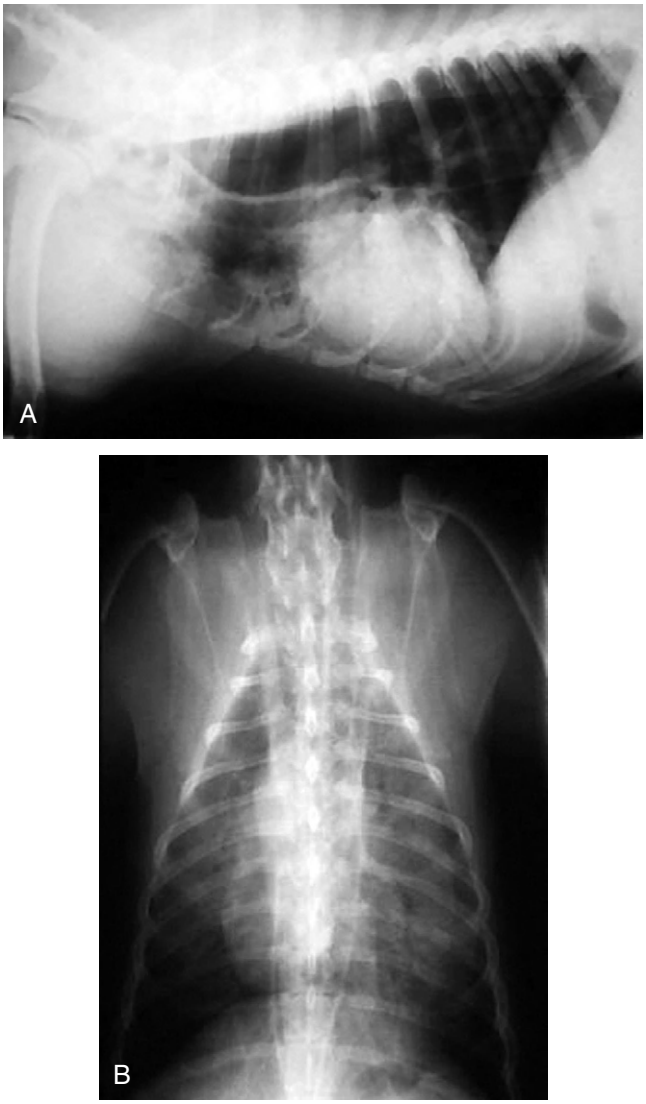

Figure 26-12 Megaesophagus. (**A**) Left lateral recumbent and (**B**) dorsally recumbent survey radiographs from a dog. A gas-containing structure is deviating the intrathoracic trachea ventrally. This structure can be identified as a diffusely dilated esophagus. Note the alveolar disease in the cranial and middle lobes, which are a result of aspiration pneumonia.

fasted animal, it should probably be considered to be abnormal. The cardiac region is more or less anchored behind the left diaphragmatic crus as a result of the distal esophagus passing through the esophageal hiatus. The stomach position is influenced by the liver, and to a lesser degree by the spleen, regional masses, the morphologic and functional integrity of the diaphragm, as well as the degree of luminal distention. In general, the long axis (i.e., fundus to pylorus) of the stomach is parallel to the last few ribs in lateral recumbency and perpendicular to the spine in sternal or dorsal recumbency. The cardiofundic region of the stomach is in the left craniodorsal abdomen behind the left diaphragmatic crus and the gastroesophageal junction is located on the right medial aspect of the cardia. The pylorus is in the right cranioventral abdomen behind the liver near the right lateral abdominal wall in the dog, and just to the right of the midline in the cat. Cats usually have little gastric gas, whereas dogs often have equal amounts of fluid and gas in the stomach. The position of the fluid and gas as a function of gravity and recumbency can influence the appearance of the stomach, giving the illusion of a thickened wall (see Fig. 26-5) or a ball-shaped foreign body, which can be a result of fluid accumulating in the pylorus in right lateral recumbency. Depending on whether the patient is fed or unfed, the stomach may contain varying amounts of food. Unfortunately, many ingested foreign materials cannot be distinguished from food except by recheck radiographs after 18 to 24 hours. Digestible solid food will exit the stomach by 14 to 18 hours after eating, unless there is an outflow problem (see Chapter 26). In contrast, nondigestible foreign material will persist for many hours. Gaseous distention of the stomach has many causes including aerophagia and atony, which can be pathologic, but can also be caused by sedative or anesthetic drug effects. By comparison, gastric distention caused by an outflow obstruction is usually associated with a mixture of fluid and gas and is often accompanied by the retention of grainy material. This tends to accumulate proximal to the outlet obstruction and may gravitate within the lumen depending on patient recumbency. These opacities may be an indication

for a foreign body or they may simply indicate the buildup of materials normally dispersed in food (e.g., bone fragments).

Functional Considerations

The stomach has many functions, including storage, digestion, propulsion of solids and liquids, and secretion of gastric acid, pepsins, and mucus (see Chapters 1 and 56). A disease process involving any one of these functions can result in gastrointestinal signs ranging from anorexia to vomiting and can affect the size of the stomach as well as the makeup of the luminal contents. Because of pyloric resistance, fluid may remain in the stomach for up to 2 to 3 hours after ingestion, whereas solid food requiring greater breakdown can remain in the stomach for up to 18 hours. From a practical standpoint, the least invasive and most cost-effective radiographic procedure to determine whether gastric outflow is decreased is to repeat survey radiographs the following day or to obtain an alternate radiographic view. However retention of material in the stomach can be secondary because of reflex inhibition of gastric emptying by various intestinal (see Chapter 1) and/or peritoneal conditions. However retention can also be pathologic as a result of pyloric stenosis, foreign body, or tumor. Considerations of the various causes of gastric retention may help to facilitate the decision to use endoscopy, upper GI, laparoscopy, or exploratory laparotomy to further investigate the problem. To further characterize stomach wall conditions, including those of the pyloric sphincter, contrast gastric radiographic studies should be considered. The most practical and useful is a barium-based upper GI study.

Abnormal Radiographic Signs

The normal and abnormal stomach are both visible on survey radiographs. Consequently, it is important to differentiate transient physiologic conditions, such as postprandial gastric distention from disorders that may cause alterations of gastric size, shape, and position. The localization of gas and fluid in the stomach depend on the position of the patient during radiography. Before arriving at a definitive diagnosis based on one radiographic view, additional views may provide helpful clues and limit the likelihood of premature or inaccurate diagnosis. Identification of discrete cardiofundic, gastroesophageal, and pyloric regions is clinically important and is usually accomplished by shifting the gas–fluid interface with changes in patient positioning (Fig. 26-13). Once an assessment of physiologic versus pathologic distention has been made, an assessment of gastric contents and presence or absence of segmental mural variations can be carried out. Other important parameters such as mucosal integrity, which may be altered because of ulceration, luminal status that may indicate the presence of a foreign body (Fig. 26-14), and wall thickness, which may be altered as a consequence of hypertrophy or tumor (Fig. 26-15), are best assessed by use of contrast studies.[15-19] Similarly, the position of the gastroesophageal junction, and integrity of the gastric wall can be best assessed by contrast studies. Finally, the initiation and continuity of the peristaltic wave (normally there are two to five peristaltic waves per minute) are best assessed by gastric contrast studies. The choice between barium and an iodinated contrast medium should be made based on the goals of the study, such as mucosal coating, assessment of peristaltic capacity and pyloric function, or the identification of a leak.

Gastric Diseases

The overall size and position of the stomach should be evaluated, particularly as it relates to regional changes, such as a diaphragmatic hernia or microhepatica. The position of each of the gastric compartments (i.e., cardia, fundus, corpus, antrum, and pylorus) should be assessed at the same time. The size of the stomach or any of its compartments is governed by multiple factors including peristaltic capacity, dysautonomia, inflammation, chemical corrosion, overt electrolyte imbalance, and smooth muscle disorders. Downstream resistance caused by pyloric spasm, stricture, or tumor, for example, can affect gastric size and position. Intraluminal obstruction and alterations in gastric wall pliability have predictable effects on gastric size, position, and function. In case of a gastric outflow problem, reflex inhibition of gastric emptying may be contributing to the overall pathology. As with other components of the gastrointestinal tract, a useful classification of gastric abnormalities is to consider them as intraluminal, intramural, transmural, or extramural. Gastric mucosal abnormalities, including ulceration, can be caused by acid or peptic erosion, trauma from stationary or migrating foreign bodies, surface disruption caused by tumors, and ingestion of corrosive substances. Although the assessment of gastric erosions is possible by radiographic and ultrasonographic techniques, it is best assessed by endoscopy. Gastric perforation should always be ruled out as leakage from traumatic, neoplastic, and ulcerative lesions may lead to septic peritonitis. In the authors' experience, horizontal-beam radiography is a clinically useful tool for the initial assessment of free peritoneal air and suspected gastric perforation. If free peritoneal air is found and cannot be attributed to a recent surgical intervention, the next step should be a positive-contrast gastrogram. That said, the identification of unexplained free intraperitoneal air is always sufficient justification for an exploratory laparotomy. If a contrast procedure is deemed necessary to further investigate potential gastric leakage, this is usually performed initially using iodine-based contrast agents and, if negative, followed by barium, which is more useful for detecting and localizing small leaks. Any barium contamination of the peritoneum or retroperitoneum should be surgically irrigated as soon as is practicable, but definitely in less than 12 hours.

Small Intestine

Anatomic Considerations

The amount of gas normally contained in the small intestine differs between dogs and cats. In dogs, typically 30% to 60% of the small bowel volume is gas unless the space is occupied by ingesta. In contrast, the normal adult cat usually has almost no gas in the small bowel unless ingesta are moving through it. In aged cats, there may be some stress-induced excess small intestinal gas, which must be taken into account during interpretation. Excessive, but evenly distributed, gas in the small bowel has been reported in association with mesenteric volvulus. The small intestine is usually evenly distributed along the ventral abdominal wall caudal to the stomach and liver and cranial to the urinary bladder. On VD views of obese cats, the left perirenal fat may give the illusion of right displacement of the small intestine. Both species have some degree of diffuse mucosal surface irregularity as can be identified using positive contrast materials. These irregularities in normal patients are a result of the normal mucosal villi.[20,21] In both species small intestinal loops should appear homogeneous throughout. That said, active peristalsis will influence the perceived external diameter of small bowel loops and some variation of bowel loop diameter may be observed. The best approach to assess effects of peristalsis is to repeat survey radiographic views. This assures that patterns are not reproducible and that changes of loop content do occur.

To facilitate assessment of small intestinal size, the authors suggest a subjective comparison of the diameter of the small intestinal lumen to the size of a midlumbar vertebral endplate. Canine and feline small bowel diameter is usually less than the DV diameter

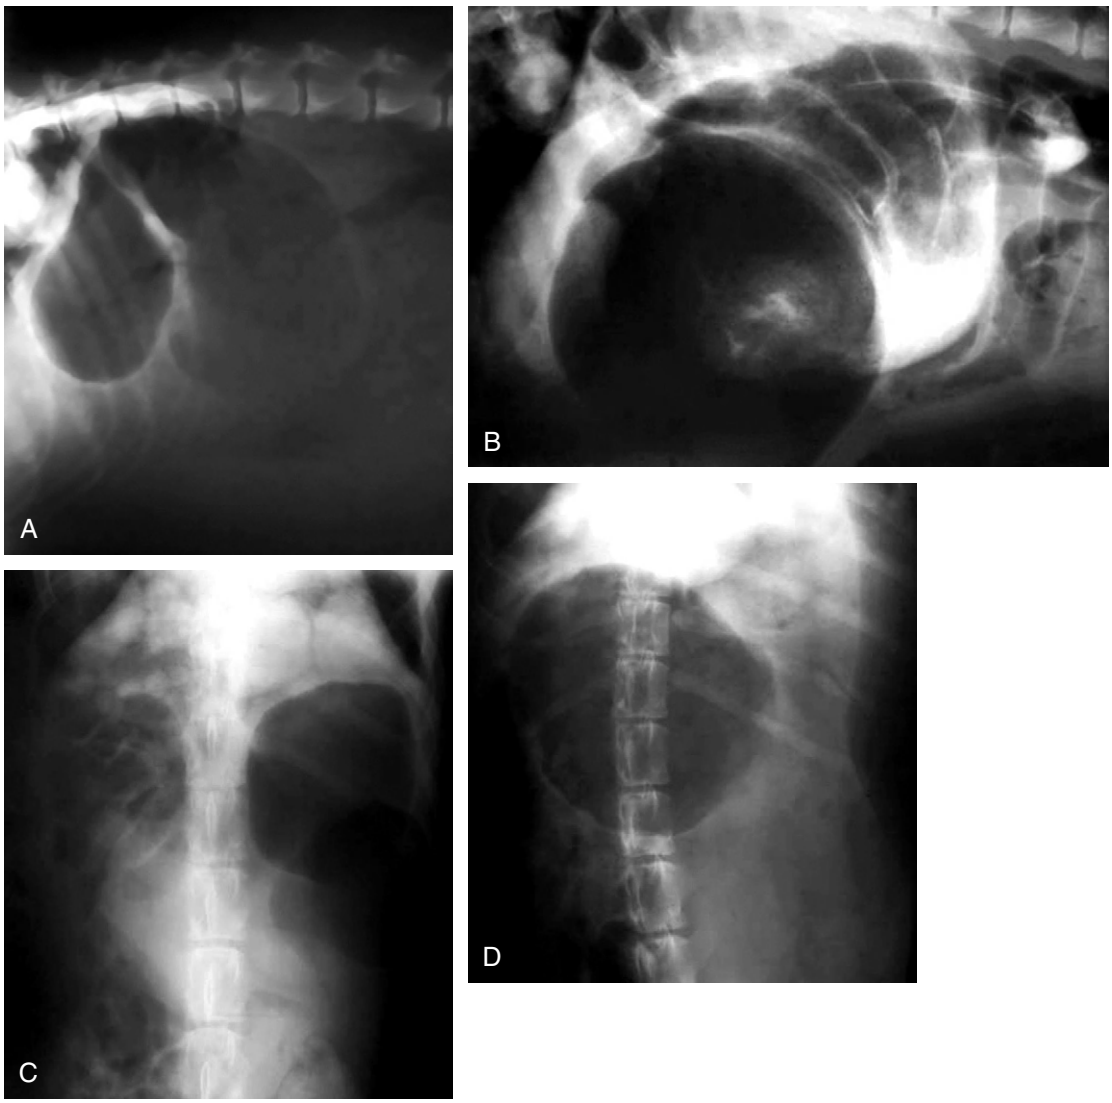

Figure 26-13 Gastric volvulus. Radiographs of a (**A**) Right lateral recumbent, (**B**) left lateral recumbent, (**C**) sternally recumbent, and (**D**) dorsally recumbent dog with gastric volvulus. Note the positional effects on the pyloric gas and fluid, which is why the right lateral and DV views are the preferred images for the diagnosis of this condition. The right lateral view should be an inverted "U" with the pylorus cranially while the DV view shows the so-called double-bubble with the pylorus cranially.

of a vertebral endplate. Further assessment and/or observation by repeat radiographic views should be considered if the small bowel diameter exceeds the transverse diameter of a vertebral endplate. If the small bowel diameter approaches or exceeds the length of a vertebral body, pathologic dilation is likely present. Small bowel dilation can be a result of obstruction, inflammation (e.g., luminal, mural, or serosal), trauma, irritation (e.g., by a migrating foreign body), or ischemia (incarceration or thromboembolism). Ingesta have a grainy appearance and, if present, should be evenly distributed throughout the length of the small bowel. Well-organized contents, particularly when seen in only one section of small bowel, should be noted. Such organized contents are a common indicator of a soft-tissue opacity foreign body. Reproducibly dilated small bowel segments can be associated with foreign bodies, annular lesions (i.e., tumor or stricture), intestinal incarceration, and infiltrative bowel disease–induced bowel wall rigidity. In addition, gas in the bowel lumen should be centrally distributed. Peripherally distributed gas may indicate a diverticulum or plication because of a linear foreign body. Finally, gas in the gut wall, which is termed *pneumatosis intestinalis*, can be associated with ulceration, ischemic necrosis, or bacterial translocation.

Functional Considerations

The small intestine has many functions, including propulsion and segmentation, secretion, digestion, and absorption. These functions are achieved through the interaction of peristalsis, small intestinal microbiota, and the nutritional or volume effects of the chyme. A problem with any one of these can result in signs of gastrointestinal disease, ranging from anorexia to vomiting and diarrhea, and can affect the size of the small bowel as well as its luminal contents. Fluids normally move through the bowel in 2 to 3 hours, whereas solid food is slower and quite dependent upon the rate of gastric emptying. As with gastric studies, the least-invasive and most cost-effective special radiographic procedure may be repeated or alternate radiographic views may be obtained within 24 hours. Retention of material in small bowel segments can be a result of inadequate

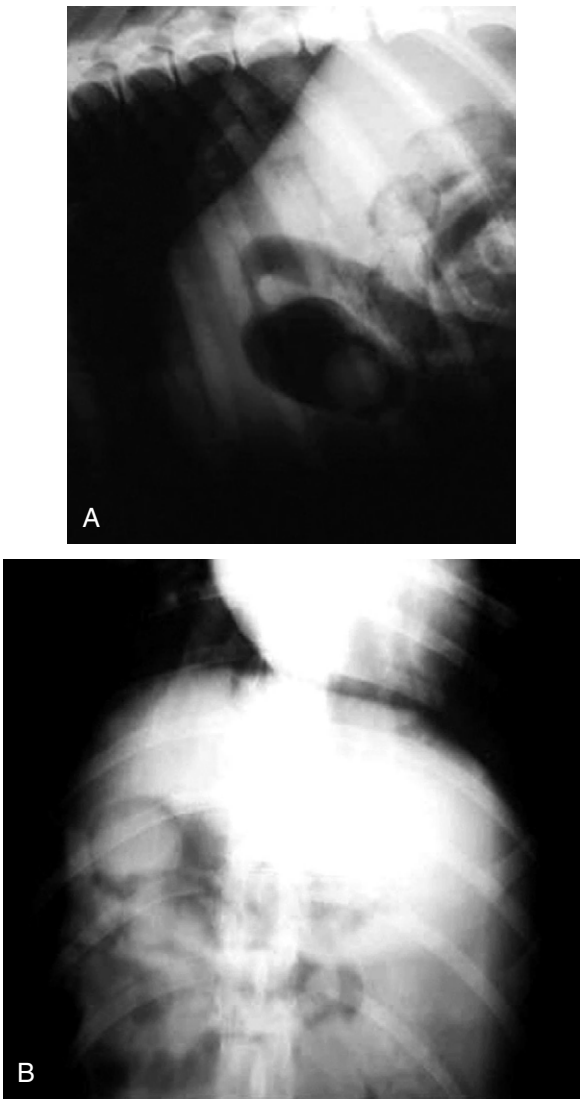

Figure 26-14 Gastric foreign body. Survey radiographs of a (**A**) Left lateral recumbent and (**B**) dorsally recumbent dog showing a soft tissue, dense, round object (foreign body) in the stomach that contains excess gas and fluid. Varying the position of the gas and fluid using gravity effects facilitated the identification of the foreign body in this case without the need for administration of a positive contrast material.

short-segment peristalsis; downstream intraluminal mechanical impedance to fluid, gas, or ingesta; or local disruptions in bowel homeostasis as a consequence of mucosal, mural, or perimural inflammation. Other intestinal pathologies, like ischemia, fibrosis, neoplasia, malabsorption, maldigestion, and bacterial overgrowth, can contribute to chyme retention. The decision to commit to small bowel endoscopy requires consideration of disease type and distribution as well as potential morbidity associated with anesthesia. Other imaging procedures, particularly upper GI contrast studies and abdominal ultrasound, may provide useful, cost-effective information with less patient stress.

Abnormal Radiographic Signs

In most patients, the normal or abnormal small bowel is readily visible on survey radiographs. The key to interpretation of survey radiographs is to be sure to differentiate transient physiologic

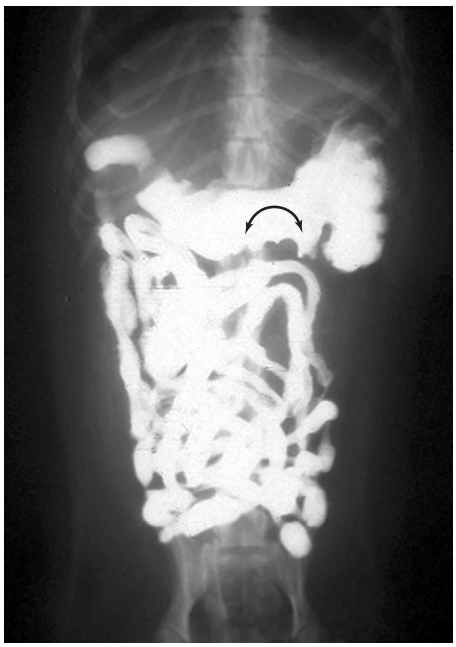

Figure 26-15 Gastric mass. Radiograph of a dorsally recumbent dog following barium administration. An irregularity of the greater curvature can be seen and is indicative of an infiltrative mass (*curved arrow*) impeding pyloric peristalsis.

changes such as postprandial luminal distention from pathologic changes in small bowel size, shape, and position. The localization of gas and fluid in the small bowel depends on the position of the patient during radiography. Several survey radiographic views may help to differentiate pathologic from physiologic findings. As discussed previously, the type and distribution of luminal contents may provide clues to the duration and severity of a disease process. In general, large-diameter intestinal loops are associated with greater duration, and high gas-to-fluid ratios are associated with greater severity. It should be kept in mind that bowel dilation has four specific causes: obstruction, inflammation, trauma or irritation, and ischemia. Large quantities of gas involving many or all small bowel segments may be a result of ischemia or severe serosal inflammation (Fig. 26-16), and not necessarily distal small bowel obstruction. There is also a continuum of bowel luminal compromise ranging from partial to complete obstruction. The recognition of these differences is paramount to the diagnostic process. Partial obstructions are usually segmental (i.e., two distinct populations of bowel can be recognized) and are characterized by greater fluid accumulation (than gas) whereas a complete or high-grade obstruction is characterized by equal amounts of gas and fluid or a clear predominance of gas. Partial obstructions can be due to mural lesions, such as tumors, strictures, or other intraluminal abnormalities like foreign bodies. The relative likelihood of these vary with age, behavior, and medical history (Figs. 26-17 and 26-18). As a general rule, conditions associated with large gas accumulations in the small intestine tend to be surgical diseases. Those conditions with proportionally more fluid than gas are more of a diagnostic and prognostic dilemma.[22-25] Assessment of small bowel mucosal changes (e.g., ulcerations), luminal abnormalities (e.g., foreign bodies), wall thickness, peristaltic capacity and continuity, as well as wall integrity is best achieved by positive contrast studies. However the choice of barium versus an iodinated contrast medium should be made based on the goal of the study, including mucosal coating, assessment of peristaltic

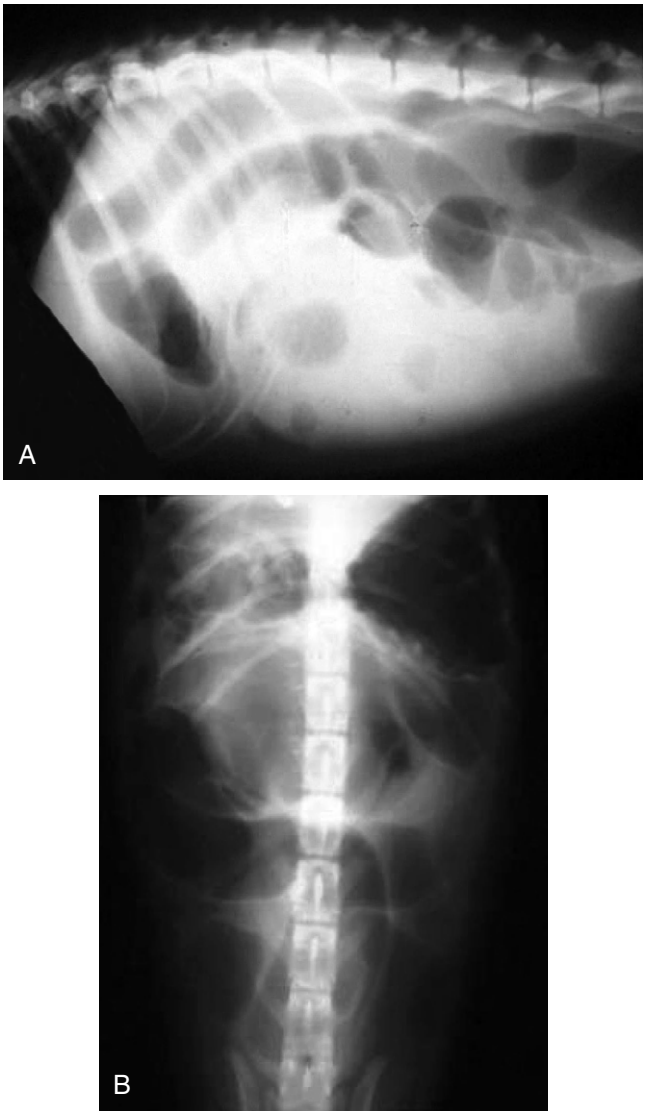

Figure 26-16 Septic peritonitis. Radiographs of a (**A**) left laterally recumbent and (**B**) dorsally recumbent dog. The radiographs show numerous tubular gas-containing structures. The peritoneal contrast is poor because of confirmed septic peritonitis. The small bowel loops are distended with fluid and gas to a degree consistent with intraluminal obstruction due to severe intestinal inflammation.

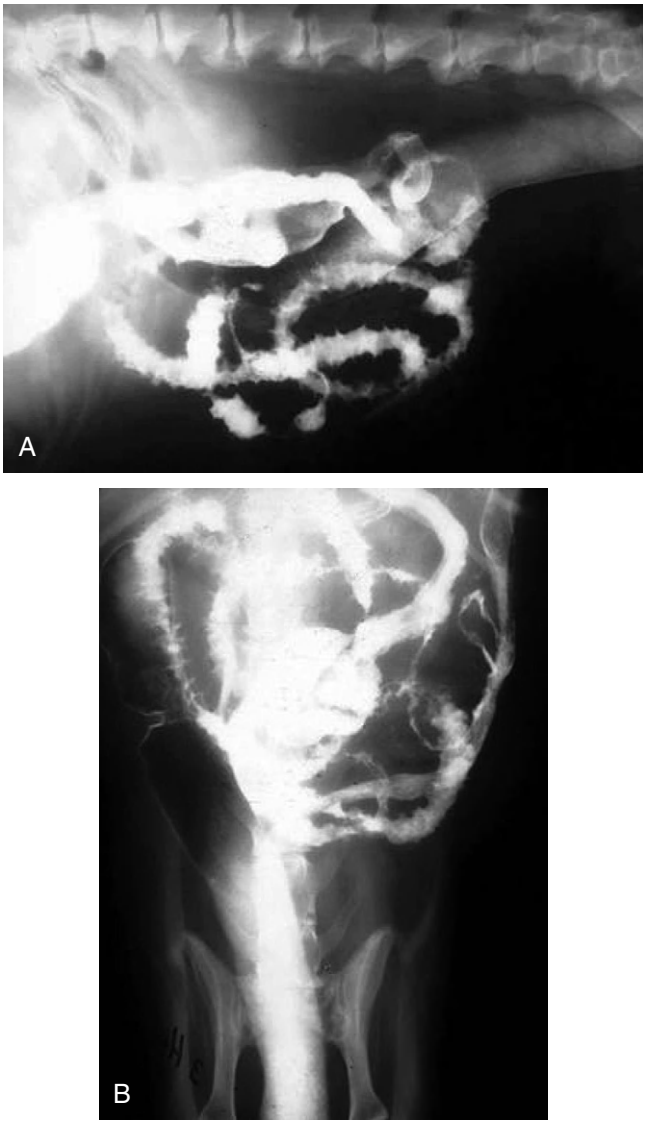

Figure 26-17 Lymphoma. Survey radiographs of a (**A**) Right laterally recumbent and (**B**) dorsally recumbent dog showing a corrugated ("thumbprinted") appearance of the small intestine caused by intramural infiltrative disease, which was later histologically confirmed as a Lymphoma.

capacity, or the identification of a leak. The role of abdominal ultrasonography in relation to contrast radiography has not been systematically studied and needs to be determined in large prospective studies. Concerns persist regarding the predictability of the sonographic diagnosis in the hands of inexperienced individuals and problems associated with user-dependent techniques such as ultrasound.[23-25]

Small Bowel Diseases

Differentiation of small intestinal abnormalities into intraluminal, intramural, transmural, or extramural lesions is useful not only for narrowing the list of differential diagnoses, but also for determining what diagnostic or therapeutic procedures may be useful in the further management of the patient.

Small intestinal mucosal ulceration is uncommon, except when associated with neoplasia. Smoothly marginated rectangular outpouchings of the duodenal lumen are occasionally seen in normal dogs, and have been termed *pseudoulcers* (Fig. 26-19). Although identification of small bowel surface erosion is possible by radiographic and ultrasonographic techniques, these lesions are best assessed by endoscopic techniques bearing in mind that only the descending duodenum and the ileum are accessible using this technique. Moreover, visual assessment of the mucosal brush-border to diagnose small intestinal disease or to differentiate between different disease processes has not been shown to be clinically useful.[21] As with gastric pathology, the unexplained presence of free peritoneal air is usually associated with alimentary tract perforation. If there is any question about the presence or absence of free air, horizontal-beam radiography is a very useful technique (Fig. 26-20). The assessment of free peritoneal air as discussed for gastric disease is equally applicable for diseases of the small bowel.

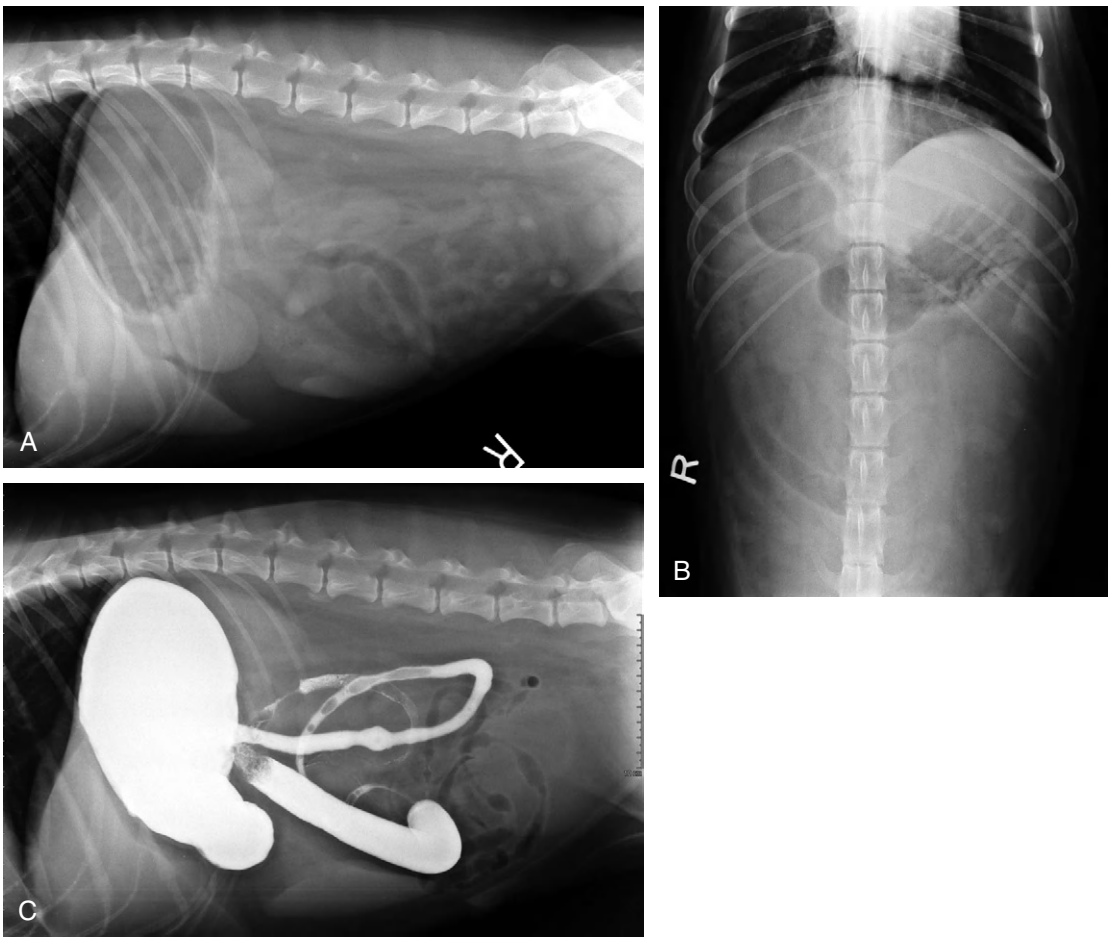

Figure 26-18 Intraluminal obstruction. Survey radiographs of a (**A**) Right laterally recumbent and (**B**) dorsally recumbent dog. Excess gastric gas and some fluid are visible. Also, there are two different diameters of the small bowel loops. (**C**) View in right lateral recumbency made 30 minutes after barium administration from the same patient. An intraluminal obstruction is visible in the ascending duodenum causing the disproportionate duodenal dilation.

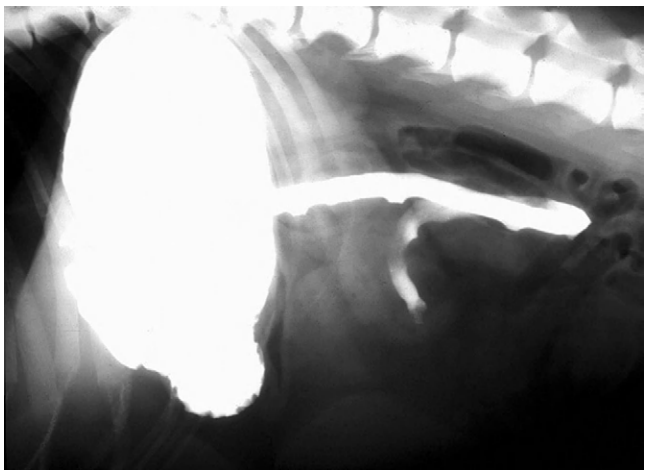

Figure 26-19 Pseudoulcers. Radiograph of a right laterally recumbent dog following barium administration. Three smooth, nearly rectangular, areas of widening of the descending duodenum are visible. These represent pseudoulcers and are a normal observation in the canine duodenum caused by foci of normal lymphoid tissue.

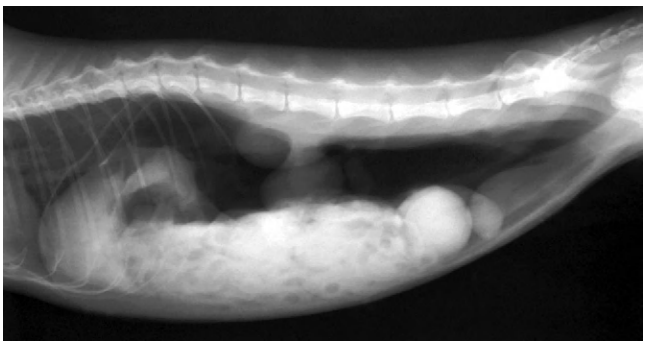

Figure 26-20 Intestinal rupture. A radiograph from a laterally recumbent dog with visible air outside the bowel loops in the peritoneal space, which is caused by an intestinal rupture. The kidneys are visible because they protrude into the peritoneal space.

Large Intestine

Anatomic Considerations

The large intestine is organized anatomically into the cecum, colon (ascending, transverse, and descending portions), rectum, and anal canal. The large intestine is most readily thought of as a distensible, thin-walled (2- to 4-mm) tube (see Chapters 1 and 58). The cecum is located to the right of the midline at approximately the level of L3 and is a gas-filled sigmoid or corkscrew-shaped structure in the dog, and a conically shaped end of the ascending colon in the cat. In most cases the ascending colon is to the right of midline. The transverse colon passes from right to left cranial to the root of the mesentery. The descending colon is located to the left of the midline and then courses toward the midline when entering the pelvic canal, where it may be displaced toward the right by a distended urinary bladder. The colon is held relatively loosely by the mesocolon and its position in the dorsal- or mid-abdomen can therefore be variable. In the normal canine and feline patient, the colon contains a variable amount of gas and formed fecal material and is generally visible and traceable on survey radiographs. The rectum is located midway between the ventral surface of the sacrum and the floor of the pelvis on the lateral view, and on the midline on the VD view. The colonic and rectal diameters can be quite variable, including regional areas of narrowing and dilation, depending upon the amount of feces. However the colon is approximately twice the diameter of the small intestine. The upper limit of normal colonic diameter should be considered to be less than 1.5 times the length of the body of L7. Reproducible focal narrowing or dilation should always be noted, particularly when fecal material accumulates proximal to the narrowing. This finding would be suspicious for a tumor or stricture and should be further evaluated, especially if persistent over time.

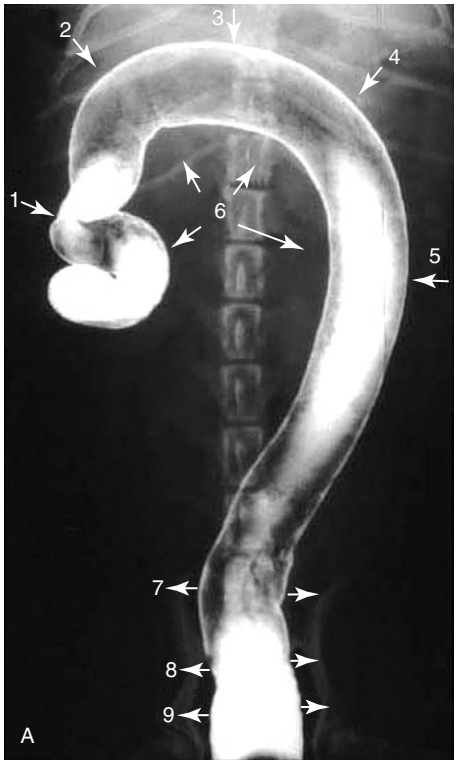
Functional Considerations

The colon has several functional properties. One of the most important functions is the absorption of water, electrolytes, ammonia, and short-chain fatty acids in the cecum and proximal ascending colon (see Chapters 1 and 58).[26] The colon also serves as a storage site for fecal material prior to propulsion.[26] In the normal patient, these peristaltic waves, which are infrequent, are generally not appreciated radiographically. Final evacuation from the large bowel is controlled by the defecation reflex (Chapters 1 and 59).

Abnormal Radiographic Signs

Because of the variable radiographic appearance of the normal colon, it can be difficult to detect early or mild abnormalities. Colonic position is often best determined by tracing the large bowel proximally from the rectum. Interpretation of malpositioning of the colon is based upon knowing the normal position of the colon as well as the regional effects of extracolonic structures (Fig. 26-21). Excessive gas and fluid could be consistent with colitis. Excessive gas alone might also be indicative of ischemia, which if seen with abnormal colonic positioning could suggest the presence of colonic torsion (Fig. 26-22). Diffuse distention with highly opaque fecal material is consistent with constipation (i.e., difficult, infrequent, or painful defecation) or obstipation (i.e., intractable constipation). Anorexic patients may have no feces in the colon as a consequence of a completely empty GI tract, but may also show evidence of fecal accumulation because the colon has not been stimulated to empty by a full stomach.

Dysfunction. Dysfunction of the colon is generally recognized as a dilated colon filled with feces. Constipation should always be treated as a primary diagnosis of abnormal motility unless a cause,



1. Duodenum, pancreas, liver
2. Liver (rt)
3. Pancreas, stomach, liver (caudate)

such as a pelvic fracture, mural infiltrate or tumor, or stricture can be identified (Figs. 26-23 and 26-24). There are no proven imaging procedures for studying colonic motility in animals. It should also be noted that anorexic or dehydrated patients may show evidence of fecal build up.

Large Bowel Diseases

The clinical presentation of the case aids in the inclusion and exclusion of differential diagnoses. Initial review should include assessment of the position of the large bowel, which is generally determined by the anchoring tissues of the mesorectum and mesocolon as well as regional organ enlargement or malpositioning. Displacements of the large bowel are generally caused by extramural lesions, which can also cause compression or distortion, or less often may lead to colonic torsion. The size of the colon can be governed by a

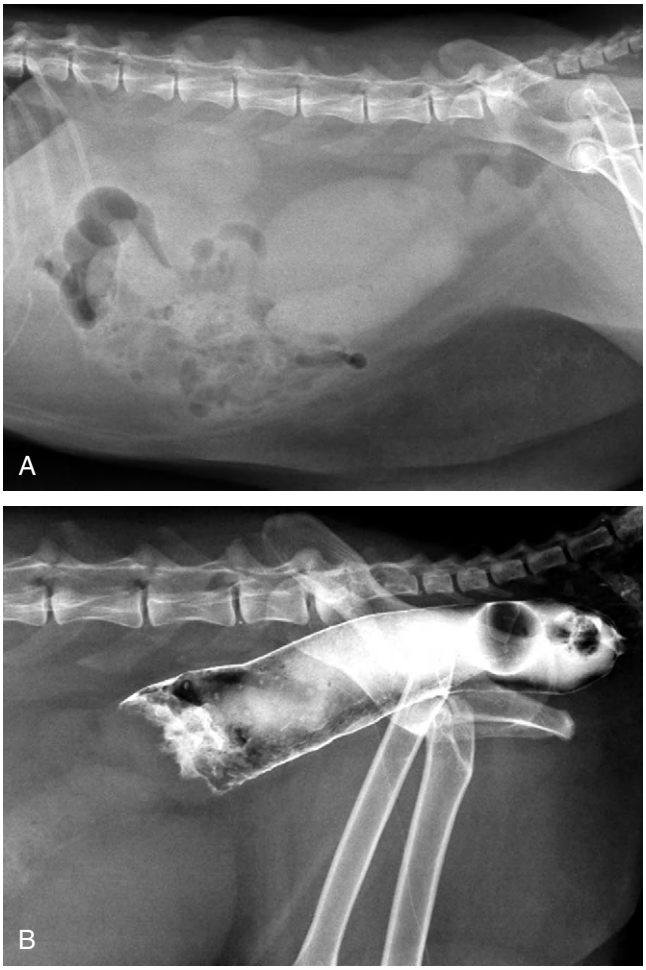

Figure 26-25 Colonic adenocarcinoma. A, Lateral view of the abdomen of a cat with a colonic adenocarcinoma. A mural mass is apparent as a soft-tissue mass in the distal descending colon caudal to the bladder neck. An abnormal gas pattern is visible within the lumen at this level and fluid is accumulating in the colon proximal to the mass. **B,** Lateral view of a double-contrast barium enema from the same patient. Note that a mural mass with an irregular mucosa is causing complete luminal obstruction.

multitude of factors including the evacuation frequency of the patient, anorexia, dehydration, peristaltic capability, inflammation, smooth muscle disorders, downstream resistance, wall pliability, and wall thickness. As for other gastrointestinal segments, differentiation into intraluminal, mural (Fig. 26-25), transmural, or extramural lesions is useful not only for narrowing the list of possible/likely diagnoses, but also for determining additional diagnostic and therapeutic approaches.

As with gastric and intestinal disease, the unexplained presence of free peritoneal air is usually associated with alimentary tract perforation. Colonic perforations generally occur secondary to foreign-body penetration, or are secondary to deep ulceration of a tumor or granuloma. It is important to determine that the air is free within the peritoneal cavity and not dissecting within the wall of the colon (i.e., pneumatosis coli). To determine if the air is free within the peritoneal cavity, the authors recommend horizontal-beam techniques (see Fig. 26-20). The consequences of and approaches to free peritoneal air are similar to those discussed for the upper gastrointestinal tract.

Liver and Biliary System

Survey radiography is an inexpensive and noninvasive diagnostic test for the workup of hepatobiliary disorders in small animals. Patients often have a nonspecific history and clinical signs in conjunction with specific laboratory parameters suggesting hepatic or biliary pathology (see Chapter 25). Survey radiographs are indicated in these patients to assess liver size, shape, and margination, as well as opacity of the liver and biliary tract. Survey radiographs are also useful to assess patients for changes associated with hepatobiliary disorders, such as ascites, which may consist of a transudate because of portal hypertension, hemorrhage caused by coagulopathy or bleeding masses, peritonitis caused by gallbladder rupture, or neoplasia from carcinomatosis. Another radiographic finding secondary to hepatobiliary disease may be nodules in the lungs on the edge of the radiograph, which may indicate metastasis of hepatic neoplasia. Unfortunately, survey radiography is limited in its ability to assess the internal architecture of the liver and the appearance of the biliary tract.

Anatomic Considerations

In general, the normal canine and feline liver are easily evaluated for size, shape, margination, position, and opacity on the survey right lateral and VD radiographs. The liver is bordered cranially by the diaphragm, on the left and right hand side by the body wall, and caudally by the stomach on the left and the duodenum and right kidney on the right. The liver of the dog and cat is divided into several lobes (i.e., left lateral and medial lobe, quadrate lobe, right medial and lateral lobe, and caudate lobe with its caudate and papillary process), the divisions of which are not typically seen on survey radiographs. If the patient is overweight, fat may dissect between some of the lobes. The left lobe of the liver is the largest and makes up the majority of the ventral shadow on the lateral view. In the dog, the right kidney silhouette joins with that of the caudate lobe as it is nestled in the renal fossa. Liver size is assessed by identification of the gastric axis (i.e., a line drawn from the mid portion of the fundus through the pylorus), which parallels the last few ribs on the lateral view and is perpendicular to the spine on the VD view in normal patients. The liver generally shouldn't extend beyond the costal arch and the margins should be sharp and well-defined. In the cat the liver often appears smaller on lateral radiographic views because of right-sided positioning and the large falciform fat pad that leads to dorsal elevation of the liver (Figs. 26-26 and 26-27). The normal liver is of uniform and soft-tissue opacity.

The components of the biliary tract include the gallbladder, the cystic duct, the intrahepatic ducts, the extrahepatic ducts, and the common bile duct. The normal biliary tract is not seen on survey radiographs. One exception is a distended gallbladder in anorexic cats, which may appear as a round, soft-tissue shadow at the ventral hepatic margin in the lateral view (Fig. 26-28). The gallbladder is situated between the quadrate and right liver lobe just to the right of midline.

Functional Considerations

Although liver function cannot be determined radiographically, certain radiographic signs may infer abnormal function. Peritoneal effusion in a patient with liver disease may be a result of ascites because of hypoalbuminemia, portal hypertension, portal thrombosis, or portosystemic shunting or a result of hemorrhage as a consequence of coagulopathy or disseminated intravascular coagulation (DIC).

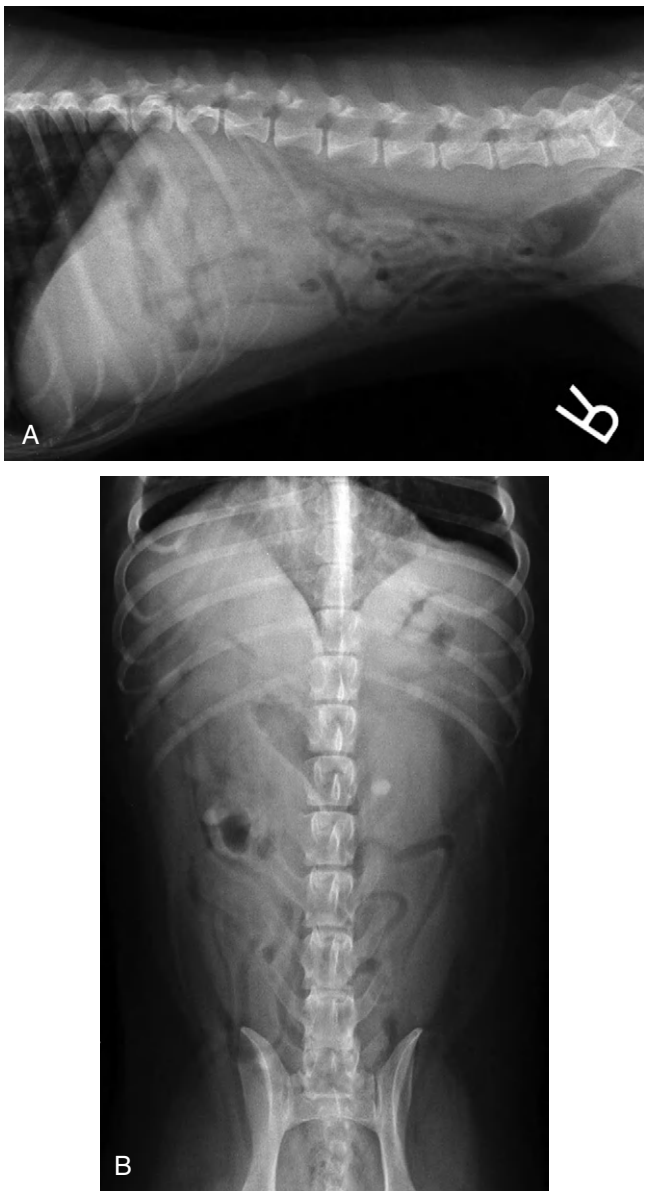

Figure 26-26 Normal liver in a dog. (**A**) Lateral and (**B**) VD views of a normal liver in a dog. Note that the gastric axis essentially parallels the last few ribs on the lateral view and is perpendicular to the spine on the ventrodorsal view. The ventral hepatic margin appears sharp.

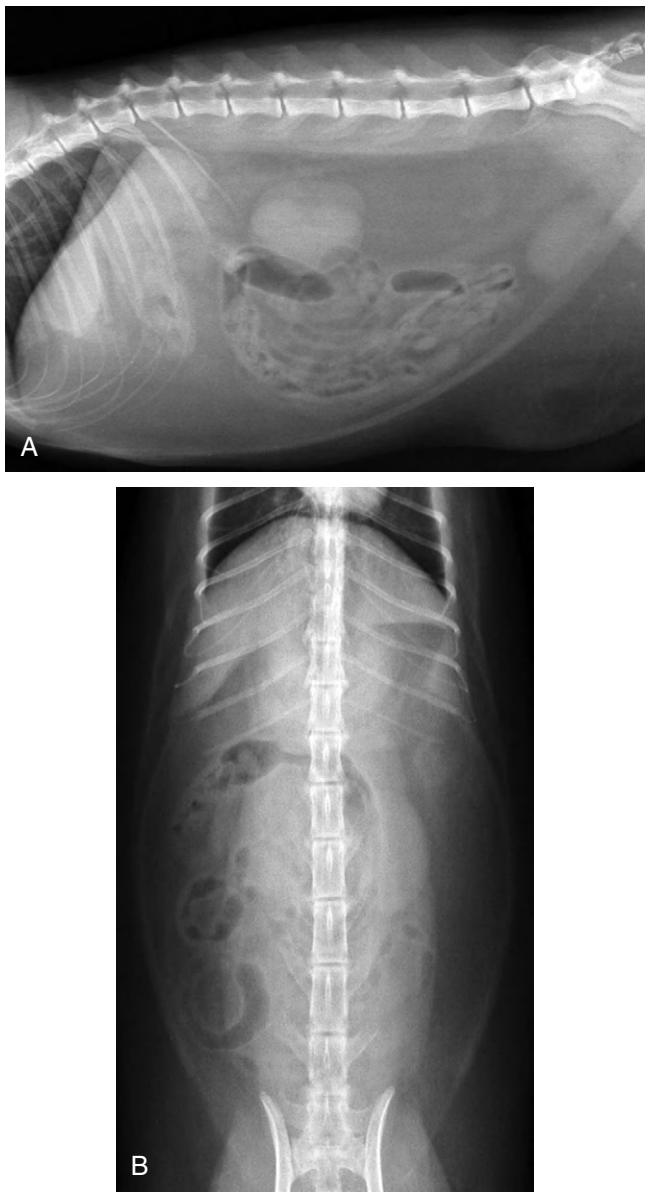

Figure 26-27 Normal liver in a cat. (**A**) Lateral and (**B**) VD views of a normal feline liver. Note that the large falciform fat pad causes the liver to artifactually appear small.

Abnormal Radiographic Signs

A change in liver size is one of the most common abnormal radiographic signs. Microhepatia, or a small liver, is recognized by the gastric axis being shifted cranially and/or a decrease in distance between the stomach and diaphragm (Fig. 26-29). It should be noted that this appearance could also be caused by a congenital or traumatic diaphragmatic hernia and thus the thorax should be assessed concurrently. Additionally, hepatic size should be assessed cautiously in obese cats (see Fig. 26-27) and deep-chested dogs. Hepatomegaly, or an enlarged liver, should be characterized as being either due to a generalized or focal enlargement. In patients with generalized hepatomegaly, the entire shadow of the liver is enlarged causing the stomach to be uniformly displaced caudally on both the lateral and the VD views (Fig. 26-30). Focal hepatomegaly is recognized when only a portion of the liver is enlarged. Regional organ displacement will often aid in the localization of a focal hepatic mass. A left-sided hepatic mass is seen ventrally on the lateral view displacing the pylorus caudally or dorsally, and is seen to the left of the stomach on the VD view, displacing the fundus towards the midline. A central hepatic mass in the midportion of the liver may displace and distort the stomach caudally on the lateral view, may displace the pylorus caudally on the lateral view, or may displace the pylorus towards the midline on the VD view (Fig. 26-31). A right-sided hepatic mass can be seen dorsally and possibly caudal to the fundus of the stomach on the lateral view, and can be seen to the right of the stomach on the VD view, displacing the pylorus toward the midline. A right-sided hepatic mass may also displace the right kidney caudally and toward the midline. Changes in hepatic shape

Figure 26-28 **Distended gallbladder.** Lateral view of a cat with a distended gall bladder. Note the round, soft-tissue shadow (*white arrow*) ventral to the ventral liver margin.

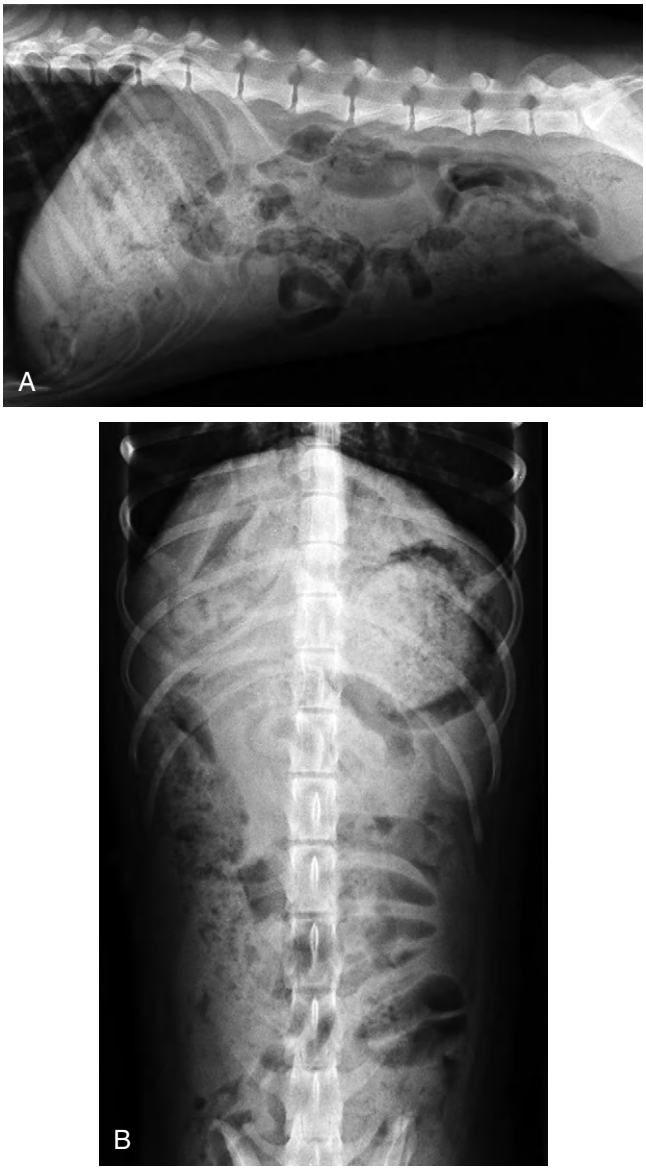

Figure 26-29 **Microhepatia.** (**A**) Lateral and (**B**) VD views of a dog with microhepatia. Note the displacement of the gastric axis cranially and the small liver shadow. The stomach is very close to the diaphragm on both views.

may alter the normal triangular shape of the liver on the lateral view and the dome shape of the liver on the VD view. Most masses will present as bulges or as alterations in the margin of the normal hepatic shadow. However a ventral round soft-tissue structure may indicate a distended gallbladder in an anorexic patient, especially in cats (see Fig. 26-28).

The edges of the normal liver are sharp and well defined. Careful evaluation of the hepatic margins aids in detection of hepatic disease on survey radiographs. In patients with generalized hepatomegaly, the margins are often rounded. Focal masses (i.e., those due to neoplasia, granuloma, large regenerative nodule, abscess, cyst, or hematoma) generally have round margins, but may also be nodular or irregular. Nodular margins may indicate nodular regeneration seen with cirrhosis, multifocal diseases, or neoplastic disorders (Fig. 26-32).

The normal liver and biliary tract are of a uniform soft-tissue opacity. Gas radiolucencies within the liver shadow may be focal, such as those due to hepatic abscessation or emphysematous cholecystitis. They may also be diffusely distributed throughout the branching biliary tract. Figure 26-33 illustrates a radiograph of a dog with a hepatic abscess. Mineralized opacities may be seen within the hepatic parenchyma (i.e., dystrophic mineralization associated with granuloma, hematoma, or hepatic tumor) or may be seen within the biliary tract (i.e., due to choleliths or choledocholiths; Fig. 26-34).

Any abnormal radiographic findings should be further investigated. Transabdominal ultrasound permits excellent evaluation of the internal architecture and parenchymal changes of the liver.

Dysfunction and Special Procedures. No special radiographic procedures for evaluation of the liver itself are currently performed. An upper GI study may allow for better delineation of hepatic size and shape by evaluating the position of the GI tract, especially if detail is diminished because of ascites. Portography, most commonly an operative mesenteric study, but in some cases splenoportography, can be useful for the diagnosis and characterization of congenital or acquired portosystemic shunts[27] and portal vein thrombosis. Caval venography can be used to diagnose Budd-Chiari syndrome. However it should be noted that vascular ultrasound can be both sensitive and specific for these conditions. Special radiographic procedures for assessment of the biliary tract include oral and intravenous cholangiocystography,[27,28] but these studies are not routinely performed in veterinary medicine. Percutaneous transhepatic ultrasound-guided cholangiocystography with followup radiographs has been described for assessment of patency of the biliary tract.[27,28] Another uncommonly performed special procedure for assessment of the hepatobiliary system is retrograde cholangiography utilizing endoscopy and fluoroscopy.[29,30] Patients must be under general

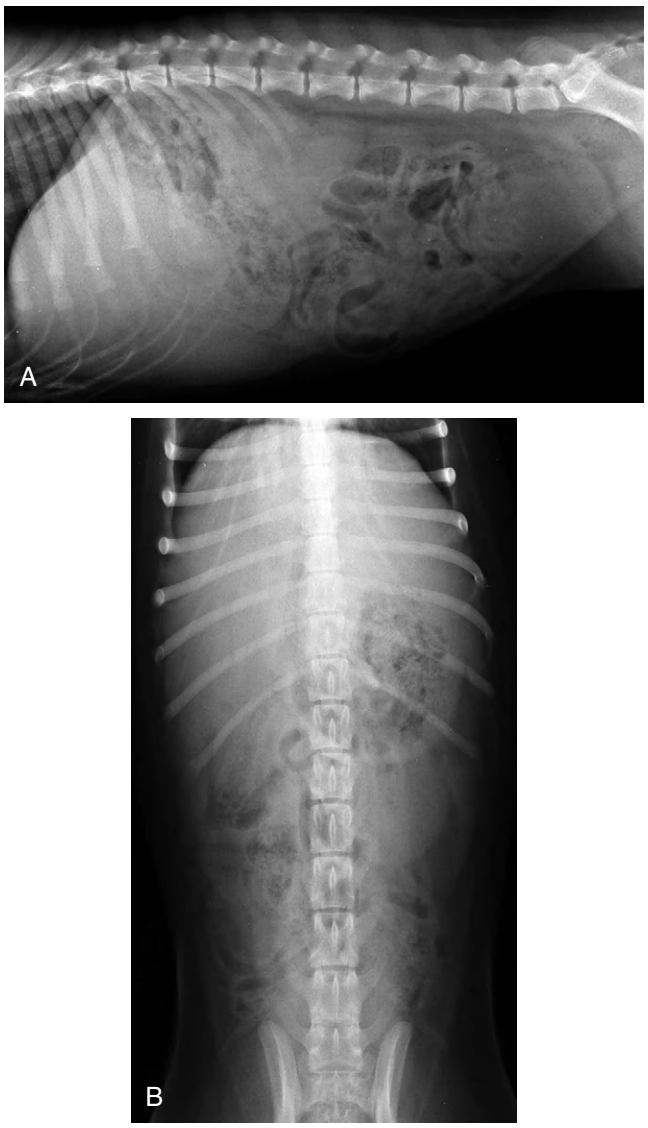

Figure 26-30 **Hepatomegaly.** (**A**) Lateral and (**B**) VD views of a dog with generalized hepatomegaly. Note the caudal displacement of the gastric axis on both views. The liver extends beyond the costal arch and the margin is rounded.

anesthesia for this procedure. Advanced imaging procedures (i.e., ultrasound [US], CT, magnetic resonance [MR], and nuclear scintigraphy) are generally necessary to further characterize hepatic disorders.

Hepatobiliary Disorders

Careful evaluation of survey radiographs in combination with signalment, history, and laboratory data should allow for the development of an appropriate list of differential diagnoses. In most cases, the patient will need to be further characterized with transabdominal ultrasound and fine-needle aspiration or biopsy for definitive diagnosis.

Initial evaluation of the liver should include determination of hepatic size and shape. Microhepatia can be caused by vascular abnormalities, such as a portosystemic shunt, portal atresia, or microvascular dysplasia or by cirrhosis, secondary to chronic inflammatory or fibrotic disorders. Generalized hepatomegaly may be associated with smooth margins and may be a result of hepatic congestion; steroid hepatopathy; fatty infiltration of the liver associated with diabetes mellitus; hepatic lipidosis; toxic, inflammatory, or infectious hepatitis; round cell neoplasia; or amyloidosis or other storage disorders. Hepatomegaly and nodular margins can be associated with nodular regeneration, metastatic disease, or multifocal primary neoplasia. Focal hepatomegaly is generally caused by a primary hepatic tumor, such as a hepatocellular carcinoma, bile duct carcinoma, hemangiosarcoma, hepatoma, or biliary cystadenoma, but may also be caused by metastatic neoplasia, a large regenerative nodule, hematoma, cyst, granuloma, or abscess. The radiographic sensitivity for hepatic metastasis is low. However one should carefully evaluate hepatic margins for nodularity. Nodular margins can also be seen with hepatic cirrhosis with nodular regeneration. In conjunction with evaluation of the liver shadow, other radiographic

signs, such as peritoneal effusion as a consequence of ascites, hemorrhage, or neoplasia, may also aid in refining the list of differential diagnoses.

Survey radiographs are not very sensitive for disorders of the biliary tract. Changes in opacity, such as those due to mineralization or gas may be seen. Regional loss of detail in the area of the porta hepatis or perigastric area may be the only finding in patients with cholecystitis, mucocele, gallbladder obstruction, or gallbladder rupture. Patients should be closely evaluated for an enlarged gallbladder, signs of peritonitis (i.e., effusion or sentinel intestinal loops), or causes of bile duct obstruction, such as stones, pancreatitis, or pancreatic masses.

Pancreas

Survey radiography is an inexpensive and noninvasive first-level diagnostic test for the workup of pancreatic disorders. Generally, patients with exocrine pancreatic disorders have a nonspecific history and clinical presentation related to the gastrointestinal tract. Survey radiographs are indicated in these patients and are useful in combination with biochemical testing to rule out nonpancreatic disorders such as disorders of the intestinal tract, the liver, the kidneys, the peritoneum, and other abdominal organs. Unless a patient is too compromised for positioning for survey radiography, there is no reason not to perform survey radiography consisting of a right lateral and VD view with a technique that provides good contrast of the abdominal organs. If a patient cannot tolerate being placed in a VD position, opposite lateral views are better than just one lateral view.

Anatomic Considerations

The normal pancreas is not generally visible on survey radiographs. However the knowledge of where the pancreas is located in normal

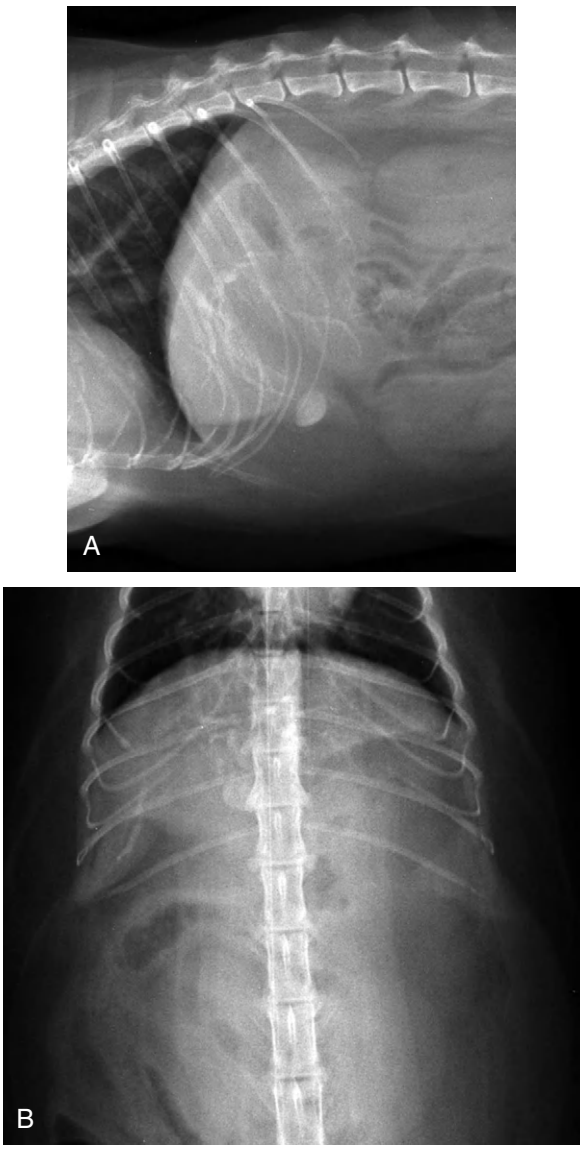

Figure 26-34 Cholelith. (**A**) Lateral and (**B**) VD views of a cat with mineralization of the biliary tract and a cholelith.

patients is crucial when evaluating for radiographic evidence of exocrine pancreatic diseases. The pancreas is divided into a body and right and left lobes. The right lobe lies in the mesoduodenum extending from the caudal thoracic to the mid-lumbar region along the right flank, and is usually medial to the descending duodenum. The body lies adjacent to the pyloric region of the stomach. The left lobe lies caudal to the greater curvature of the stomach ending in close relationship to the cranial pole of the left kidney and middle portion of the spleen. These boundaries describe the general location of the pancreas. The accessory pancreatic duct and the pancreatic duct serve as conduits for pancreatic secretions into the proximal duodenum. The pancreas is situated in close proximity to the following organs: the ventral aspect of the right kidney, the caudate lobe of liver, sublumbar fat (ureter), duodenum, cecum, ascending colon, gastric pylorus, dorsal wall of the body and fundus of stomach, cranial aspect of the left kidney, the middle portion of the spleen, and the transverse colon. Although the usefulness of survey radiography of the normal pancreas is limited, the left lobe of the pancreas can sometimes be seen radiographically in obese cats (Fig. 26-35).

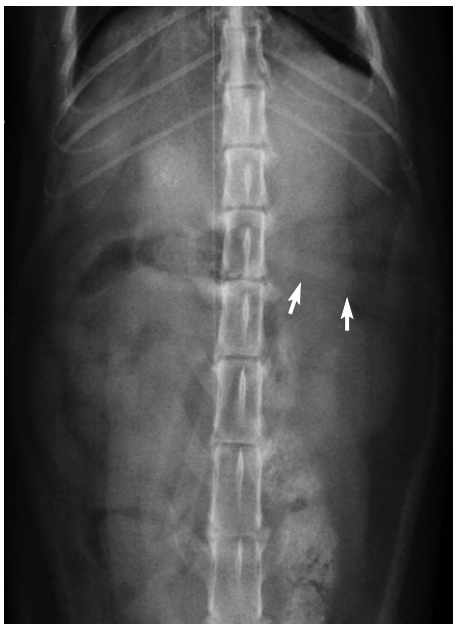

Figure 26-35 Pancreas. Ventrodorsal view of an overweight cat showing the left lobe of the pancreas (*white arrows*).

Functional Considerations

The major functions of the exocrine pancreas are secretory and include the secretion of digestive enzymes, bicarbonate, intrinsic factor, and antibacterial proteins (see Chapters 1 and 60). Diseases of the exocrine pancreas, such as pancreatitis, pancreatic abscess, pancreatic pseudocyst, and pancreatic carcinoma commonly cause survey radiographic changes. Exocrine pancreatic insufficiency (EPI) cannot be diagnosed radiographically, but in some patients may be associated with abnormalities of the GI tract on survey radiographs, such as excess bowel fluid and dilation, which may suggest malabsorption or bacterial dysbiosis. Endocrine disorders such as diabetes mellitus, insulinoma, and gastrinoma either do not cause primary macroscopic changes of the pancreas or cause changes that are too small to identify on survey radiography.

Abnormal Radiographic Signs

The normal soft-tissue shadow of the pancreas is not identifiable on survey radiographs, with the exception of the left pancreatic lobe in obese cats. In general, as the pancreas enlarges, there will be a poorly defined or well-defined soft-tissue mass or mass effect, dependent on the disease process (Fig. 26-36). Diseases with associated inflammation (i.e., pancreatitis, pancreatic abscess, or pancreatic pseudocyst), will be poorly defined because of regional effusion or peritonitis. The earliest detectable abnormal opacity with pancreatitis is often seen caudal to the stomach on the lateral view and in the right upper quadrant in the dog, and in the left upper quadrant in the cat on the VD view. The abnormal opacity is often granular in nature (ground-glass appearance). Rarely there will be dystrophic mineralization associated with pancreatic inflammation or gas associated with pancreatic abscessation. Enlargement of the pancreas on a survey radiograph is generally considered abnormal. A well-defined soft-tissue mass is more suggestive of a pancreatic pseudocyst or pancreatic carcinoma. Changes in the position or radiodensity of adjacent organs are also more suggestive of exocrine pancreatic disease. Pancreatic enlargement will cause organ displacements depending on the focal or diffuse nature of the enlargement. Focal

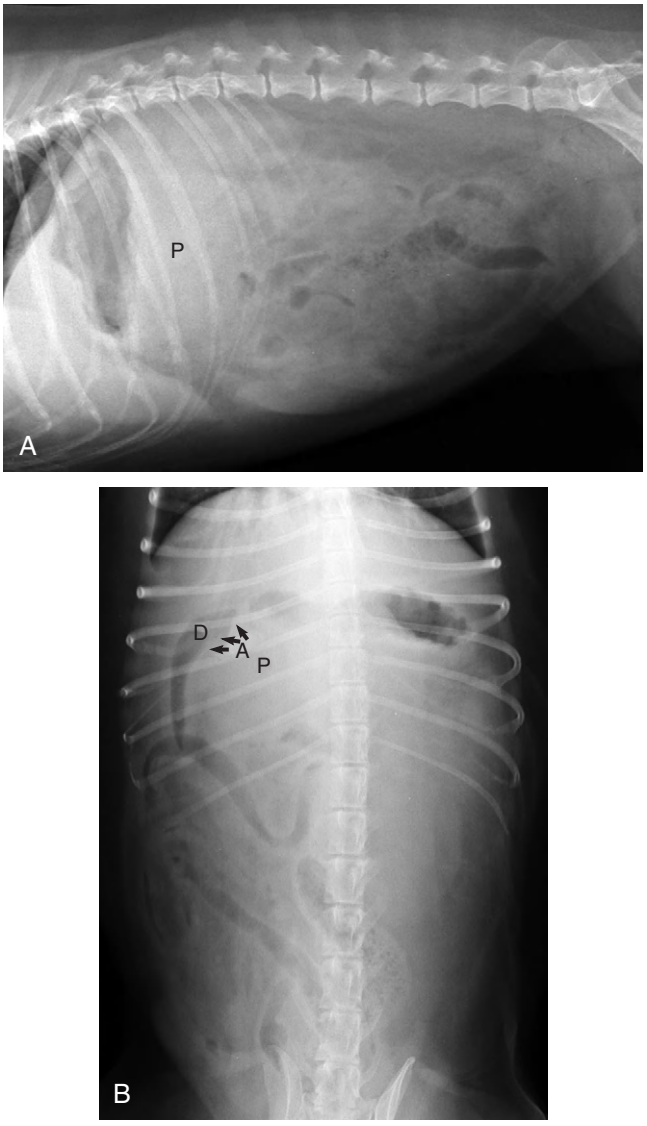

Figure 26-36 Pancreatitis. (**A**) Lateral and (**B**) VD views of a dog with severe pancreatitis. Note the poorly defined soft-tissue mass effect in the right upper quadrant displacing the pylorus toward the midline and increasing the cranial duodenal angle (*A*). The enlarged pancreas (*P*) is easily seen caudal to the stomach on the lateral view. Other findings include a dilated descending duodenum (*D*) and effusion. Other differentials for the pancreatic mass should include pancreatic abscess, pancreatic neoplasia, and pancreatic pseudocyst.

enlargements of the right lobe of the pancreas often displace the duodenum laterally and the cecum and ascending colon toward the midline. Focal enlargements of the body of the pancreas may enlarge the cranial duodenal angle by displacing the duodenum laterally and the pylorus or pyloric antrum toward the midline, and may displace the transverse colon caudally. Focal enlargements of the left limb of the pancreas may displace the transverse colon caudally, indent the body and fundus of the stomach, and displace the middle portion of the spleen laterally and caudally. Other indicators of pancreatic disease include changes caused by regional inflammation, such as persistent dilation of the descending duodenum and stomach with gas and/or fluid buildup. Survey radiographic may show findings that are suggestive of bowel wall thickening as a result of edema and/or inflammation due to pancreatitis. It is important to note that all of these radiographic findings are rather subjective and a definitive diagnosis of pancreatitis based on radiography alone is not possible.

Dysfunction and Special Procedures. In some patients, exocrine pancreatic disorders can be indirectly suspected through the use of an upper contrast GI study. As barium outlines the GI tract, the displacements described previously will be more easily recognized. Other findings may include delayed gastric emptying, diminished gastric peristalsis, persistent duodenal dilation secondary to regional inflammation, and thickened and rigid stomach and duodenal walls with or without thumbprinting. An uncommonly performed pancreatic special procedure in dogs and cats is endoscopic retrograde pancreatography (ERP),[29,30] utilizing endoscopy and fluoroscopy. Patients must be under general anesthesia for this procedure. Advanced imaging (e.g., US, CT, MR, nuclear scintigraphy) is generally necessary to further characterize exocrine pancreatic disorders.

Exocrine Pancreatic Diseases

Careful description of the radiographic signs in combination with signalment, history, and laboratory data should allow for the generation of an appropriate list of differential diagnoses. Additionally, the survey radiographic study is helpful for ruling out other gastrointestinal disorders, such as intestinal obstruction and intestinal perforation that may be associated with similar presenting clinical signs. In most cases, the disease will need further characterization with specific serum markers and ultrasound evaluation possibly with concurrent fine-needle aspiration for a definitive diagnosis.

Often the only radiographic finding associated with exocrine pancreatic disorders is a hazy or "ground-glass" loss of detail in the cranial abdomen in patients with acute or chronic pancreatitis. However this finding has been reported with other abdominal disorders, such as hepatic disease, biliary tract disease, peritonitis, intestinal perforation, and nonpancreatic effusions. A poorly or well-defined mass effect in the right or left cranial quadrant, which may be seen in patients with severe acute pancreatitis, pancreatic abscess, pancreatic pseudocyst, or pancreatic carcinoma, warrants further imaging with ultrasound. Any regional organ displacements indicating a potential pancreatic mass or mass effect should be noted. Supporting radiographic signs of possible exocrine pancreatic disorders include effusion, sentinel intestinal loops (a result of regional inflammation and wall edema), or regional lymphadenopathy. As mentioned previously, exocrine pancreatic diseases are rarely associated with gas or mineralization.

A specific presentation in cats warrants further mention. Common survey findings in cats with pancreatic carcinoma are marked accumulation of fluid, a nodular or irregular diffuse opacity, and/or ground-glass loss of detail in the area of the central omentum, which is consistent with carcinomatosis (Fig. 26-37A-B).[31] The origin of this opacity must generally be determined with ultrasound and cytology.[32]

ULTRASONOGRAPHIC IMAGING OF THE GASTROINTESTINAL TRACT

Lorrie Gaschen

The sonographic examination of the gastrointestinal tract should be interpreted in conjunction with the findings of abdominal radiographs in most instances. Abdominal radiography provides an

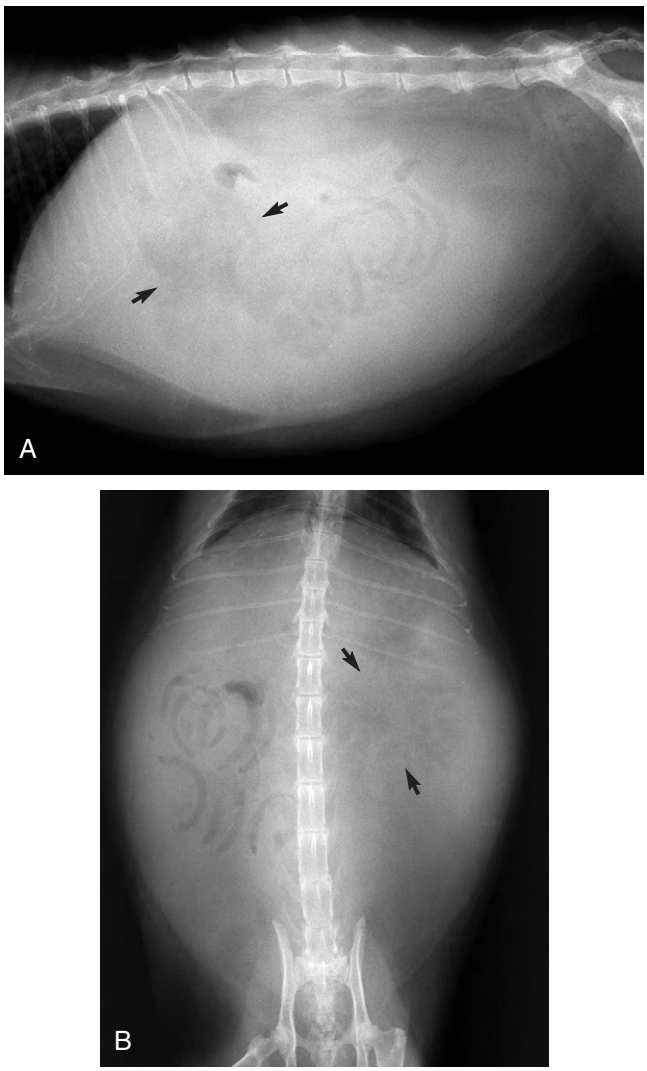

Figure 26-37 Carcinomatosis. (**A**) Lateral and (**B**) VD views of a cat with carcinomatosis. Note abdominal distention secondary to marked effusion. The effusion is asymmetrically distributed with a central area of ground-glass loss of detail (*white arrows*).

overview of the abdomen that the sonographic examination does not allow and can greatly aid in the understanding the sonographic features that are being observed. Patient preparation is another key to a successful ultrasonographic examination of the gastrointestinal tract. Dogs and cats should have food withheld for at least 12 hours prior to examination. This aids in the examination of the stomach, intestines, and adjacent structures and organs. Pressure exerted on the abdomen when the stomach is full results in patient discomfort and lack of compliance. In dogs and cats with a painful abdomen, analgesia or sedation may be necessary to perform a complete ultrasonographic examination. Some sedatives, however, can influence gastrointestinal motility, and this should be taken into account if assessing motility.

High-frequency curved- and linear-array transducers are best for examination of the gastrointestinal tract. Curved-array, 5 to 7.5 MHz transducers are best for the stomach, whereas either curved- or linear-array transducers of higher frequency (>10 MHz) are better suited for the small intestine and colon. High-frequency linear-array transducers are best suited for high-resolution imaging of the small intestinal and wall of the colon.

Patients may be positioned in dorsal, right, or left lateral recumbency for the examination based on the sonographer's preference and region being examined. By varying the position of the animal, gas is displaced to the nondependent region of the lumen and fluid can settle to the dependent regions for better visualization of the bowel wall.

Stomach

Five alternating hyper- and hypoechoic gastric wall layers are evident using high-frequency ultrasound: hyperechoic outer serosa, hypoechoic muscularis, hyperechoic submucosa, hypoechoic mucosa, and interface between mucosa and intestinal lumen (Fig. 26-38), which is hyperechoic. The stomach should be scanned in the axial and longitudinal planes, avoiding oblique planes, which can give the false impression of wall thickening. When empty, the stomach will be contracted and the close approximation of the rugal folds can also give the false impression of a thickened wall. Encouraging the animal to drink water will help to distend the stomach and allow reassessment of the area in question (Fig. 26-39). Gastric

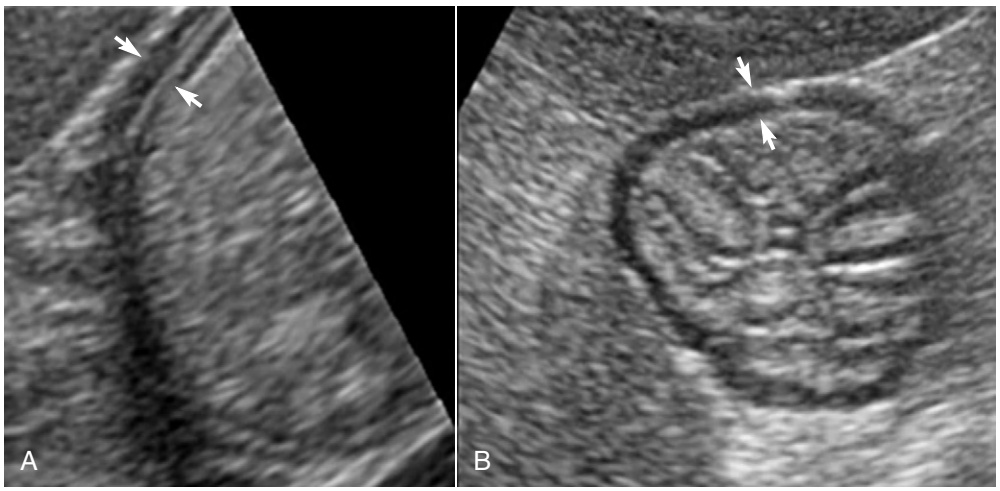

Figure 26-38 Normal canine gastric wall layering. (**A**) Food-filled stomach and (**B**) contracted stomach. The *arrows* mark the outer serosal and inner mucosal borders to show proper placement of calipers for measurement of wall thickness. Five alternating hyper- and hypoechoic layers of the gastric wall are identified.

Figure 26-39 Normal canine stomach following oral fluid administration. The stomach is mildly distended and the wall appears thin with normal layering. Reverberation artifacts caused by gas are often present when the animal drinks water and can affect visualization of the wall in some regions.

content is typically gas, food, and/or fluid. Food particles produce a hyperechoic surface and distal shadowing, much like foreign material in the gastrointestinal tract. A recent dietary history is important for this reason. Repeat ultrasound examinations and abdominal radiography after withholding food are often necessary to confirm the presence of ingested food versus foreign material (Fig. 26-40). Gastric gas is common even when food has been withheld. Artifacts produced by gas make assessment of the wall and content more difficult. Gas causes reverberation artifacts, which can obscure the presence of fluid, wall thickening, or foreign material. For this reason, patients should be examined in several positions, and intercostal as well as substernal probe placement should be used. In general, a left intercostal approach is helpful for examination of the gastric fundus, whereas a right intercostal approach is useful for visualizing the duodenum and the pylorus.

Gastric wall measurements of thickness should be made between rugal folds. Normal gastric wall thickness in the dog is 3 to 5 mm, whereas in the cat it is less than 2 mm.[1] The number and prominence of the rugal folds decreases as one scans from the fundus toward the antrum. At the pylorus, the muscularis layer may appear more prominent in cats than in dogs, but this should not be mistaken for hypertrophy or infiltrative disease. At the cranial duodenal flexure there is a short zone where the wall appears diffusely hyperechoic with less distinct wall layering and is a normal finding in both dogs and cats (Fig. 26-41).

Gastric slow waves propagate at the rate of three to five contractions per minute in a stomach with some fluid or food content (see Chapter 1). However this may not be as apparent in the contracted stomach. Gastric emptying disorders can be assessed using a number of methods (see Chapter 26), including ultrasound. There are two main types of gastric emptying disorders: those that are anatomic or mechanical, and those that are functional or physiologic (summarized in Chapter 56). In general, diagnostic imaging should always begin with survey abdominal radiographs. Gastric size, position, and content can be rapidly assessed with survey radiographs. Barium contrast study, barium-impregnated polyethylene spheres (BIPs), gastric emptying scintigraphy, or ultrasound examination should follow abdominal radiography to diagnose the cause of a chronically dilated stomach.[2-6] Ultrasound is used to identify nonradiopaque foreign bodies, pyloric hypertrophy, and gastric wall–associated masses that are obstructing gastric outflow. The pyloric region in dogs can be very difficult to visualize sonographically and often depends on the operator's experience as well as patient conformation.[7] In cats, it is fairly consistently identified. Pyloric outflow obstruction should be suspected with any of the following findings:

- Abnormal gastric content with fluid and gas layers in the nondependent portion and particulate matter in the dependent portion;
- Contractions that do not propel gastric content into the duodenum;
- Circumferential thickening of the antral or pyloric wall;
- Wall-associated mass in the antrum, pylorus, or proximal duodenum;
- Extraluminal mass compressing the antrum or pylorus; or
- Intraluminal foreign body obstructing the pylorus or proximal duodenum.

Gastric foreign bodies can almost always be detected ultrasonographically. In most instances they have a hyperechoic surface with a strong acoustic shadow (see Fig. 26-40C). Their shapes are variable and dependent upon the nature of the foreign body. Wooden sticks, hard plastic, and balls have different shapes, but all exhibit strong acoustic shadowing (Fig. 26-42). Gastric trichobezoars can frequently be seen in cats and have a bright, hyperechoic surface with a clean acoustic shadow as a result of their compact nature. Food particles, such as pieces of meat and kibble, have variable sonographic appearances. Dense objects with smooth surfaces have bright reflective surfaces with clean acoustic shadow. Because of the variable and sometimes confusing nature of gastric content, radiography should be used as a comparative diagnostic tool and the patient should be held off food and reexamined sonographically before a definitive diagnosis is being made.

One of the most important indications for gastric ultrasound is for the detection of wall thickening. Detection of gastric wall thickening depends on extent and severity as well as patient condition. Gastric wall thickening can be characterized as focal, diffuse, concentric, or asymmetric, and with or without loss of wall layering. Loss of wall layering is commonly associated with neoplastic or fungal infiltration of the gastric wall as well as with gastric ulceration. Gastric wall thickening can also occur with gastritis, edema, neoplasia, fungal disease, congenital hypertrophic pyloric stenosis, and chronic pyloric hypertrophic gastropathy. Although ultrasonography is sensitive to gastric wall thickening, it lacks specificity.[8-10] Consequently, gastric biopsy is required for a definitive diagnosis of gastric wall thickening.

Gastric neoplasia typically leads to wall thickening and loss of layering, much like fungal infiltration.[8,11,12] Gastric neoplasia can be pedunculated and protrude into the lumen, to the extent of causing pyloric obstruction. Leiomyoma, leiomyosarcoma, carcinoma, and lymphoma are the most common types of gastric neoplasia in dogs and cats.[12] Gastric lymphoma is often typified by focal or diffuse transmural thickening with a hypoechoic wall, loss of wall layering, and regional lymphadenopathy (Fig. 26-43). Regional lymph nodes may become so enlarged that they create the effect of a midabdominal mass. Gastric carcinoma has an unusual ultrasonographic pattern of thickened alternating hypo- and hyperechoic layers that has been referred to as pseudolayering (Fig. 26-44).

Inflammatory diseases of the stomach include chronic gastritis caused by diseases such as eosinophilic, lymphocytic, and uremic

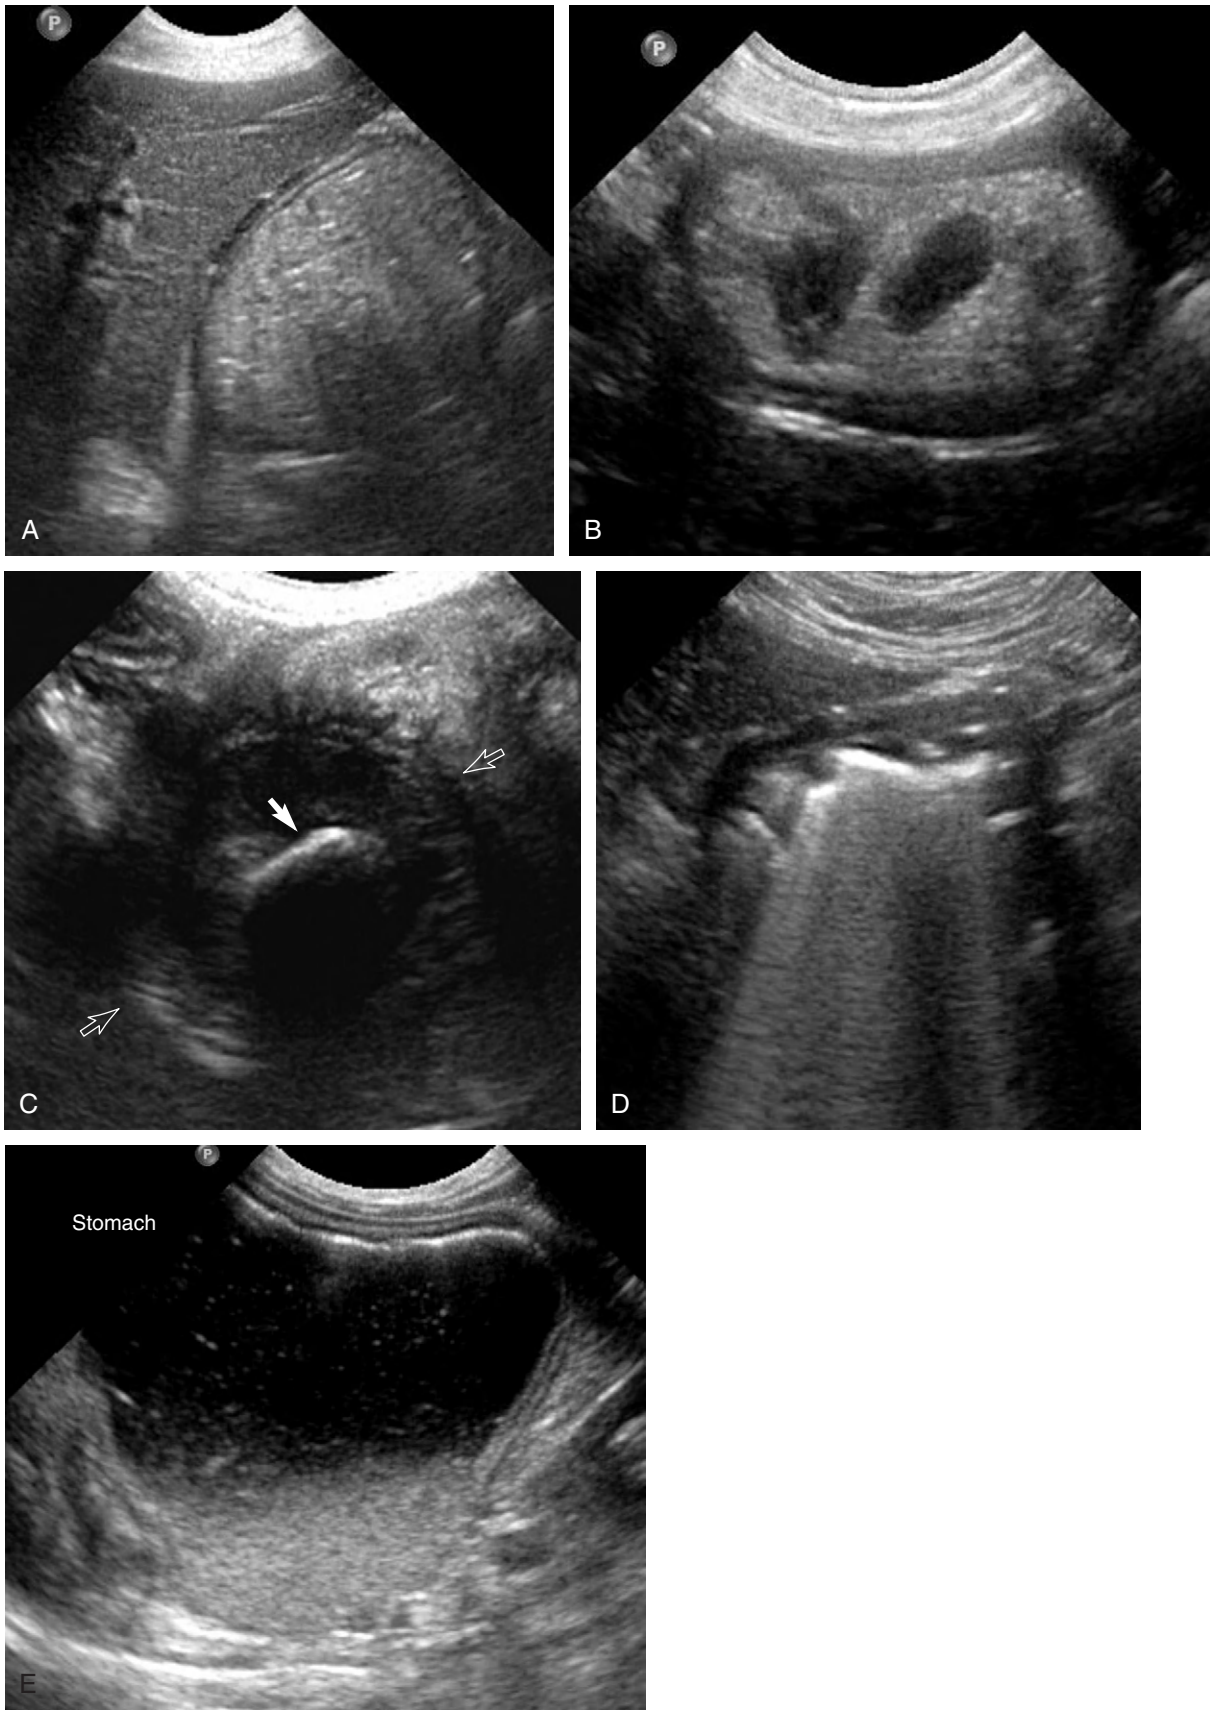

Figure 26-40 **A,** Appearance of a normal canine stomach with uniform food content. **B,** Appearance of a normal canine stomach showing large pieces of soft food (meat and potatoes). The hypoechoic mass-like appearance of the food should not be confused with wall infiltration or a gastric mass. Repeat ultrasound should be performed in the fasted state in such instances. **C,** Foreign body in the pylorus of a dog with chronic vomiting. Note the hyperechoic reflective surface and clean distal shadowing associated with the foreign material. Abdominal radiographs are indicated to further ascertain the type of foreign body (radiopaque versus radiolucent). **D,** Gas in the stomach. Gas creates dirty shadowing and reverberation artifacts that obscure most of the abdominal wall. In such instances, instilling water orally or changing the position of the dog helps to displace gas away from the region of interest in the stomach. **E,** Layered gastric content. The more dependent regions of the stomach have more echogenic layers whereas the nondependent region has less echogenic fluid content. This finding is indicative of a gastric outflow obstruction.

Figure 26-41 Cross-sectional ultrasound image of the normal canine cranial duodenal flexure. The wall appears diffusely hyperechoic over a very short length and should not be mistaken for a disease process.

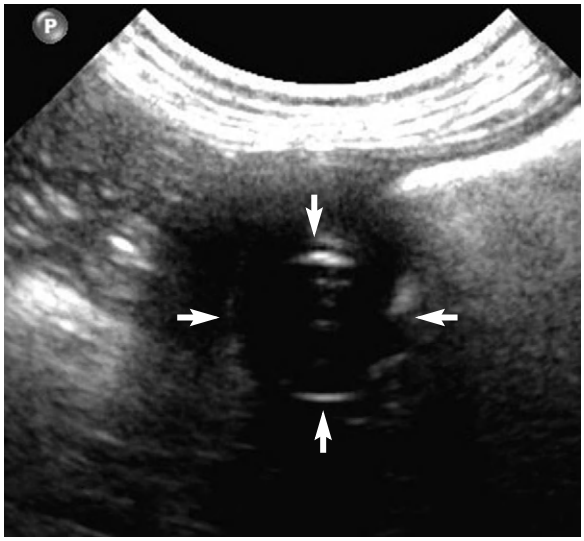

Figure 26-42 Gastric ball foreign body made up of a soft, gel-like substance in the pylorus of a Dachshund causing obstruction. The ball creates a hyperechoic rim as a result of its smooth surface (*arrows*) but is anechoic in the center because of the nonattenuating material.

gastritis.[13] An ultrasonographic change consistent with gastric inflammation is diffuse wall thickening without loss of wall layering. The stomach is usually distended with fluid accumulation and decreased peristaltic activity. Gastric rugal folds may appear enlarged and blunted. Dogs with hypoproteinemia as a consequence of protein-losing enteropathy (PLE) may develop gastric wall edema. In PLE disorders, the gastric wall is usually thickened with rounded rugal folds and altered wall layers (Fig. 26-45). Uremic gastropathy has many ultrasonographic features typical of inflammatory disease but may also include mineralization of the gastric wall.[13] Mineralization is often diffuse and appears as a hyperechoic layer along the gastric mucosa. Gastric mucosal biopsy is required to differentiate benign from malignant disease.

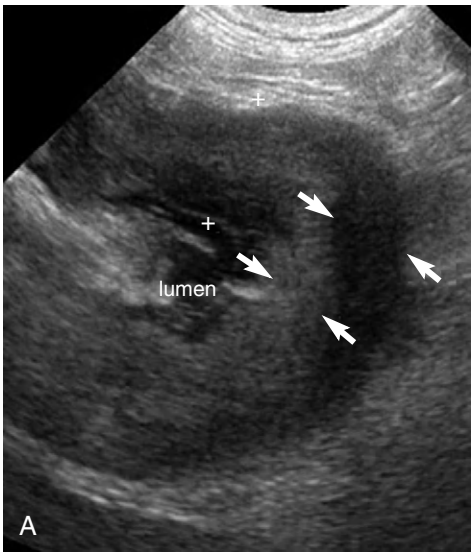
Figure 26-43 Transmural gastric thickening (1.5 cm) of the gastric fundus and body in a cat. The wall is diffusely hypoechoic with loss of wall layering. Histologic diagnosis: lymphoma.

Gastroduodenoscopy is clearly the diagnostic method of choice for detecting gastric ulcerative disease (see Chapter 27). However ultrasonography is a commonly used screening test for dogs with suspected gastric ulceration. Benign ulcers are often more difficult to detect ultrasonographically than malignant ones as they tend to be smaller in size and located in the pyloric canal. Malignant ulcers are generally larger and more readily detectable. They are associated with an adenocarcinoma, lymphoma, mast cell tumor, or gastrinoma. Gastric ulcers can lead to perforation, therefore abdominal radiographs should always be performed prior to the ultrasound examination in vomiting animals (Fig. 26-46). Depending on their size, location, and gastric content, some ulcers can be difficult to detect ultrasonographically. They appear as a focal wall thickening with loss of wall layering and a crater at the mucosal surface. The crater appears as a hyperechoic zone at the mucosal surface because of accumulation of necrotic debris and gas. The regional mesentery may appear hyperechoic and free fluid may be suggestive of peritonitis and a possible rupture. The nondependent region of the abdomen should be scanned for reverberation echoes adjacent to the peritoneal surface that could be consistent with pneumoperitoneum (Fig. 26-47).

Gastric intussusception is rare.[14] Gastrogastric, pylorogastric, gastroduodenal, and gastroesophageal intussusceptions have been reported and can be challenging to diagnose sonographically, as well.[14,15] The cause of most intussusceptions is unknown, but associations with vomiting disorders and gastric masses have been suggested. Gastric distention and a luminal gastric mass or concentric wall layers are potential sonographic findings. Gastric intussusceptions can be misdiagnosed as masses because of the presence of a thickened, edematous, and hypoechoic wall with indistinct layering.[16]

Small Intestine

The descending duodenum, ileum, and jejunum can be differentiated from one another ultrasonographically based on their location, wall layering, and communication with adjacent intestinal



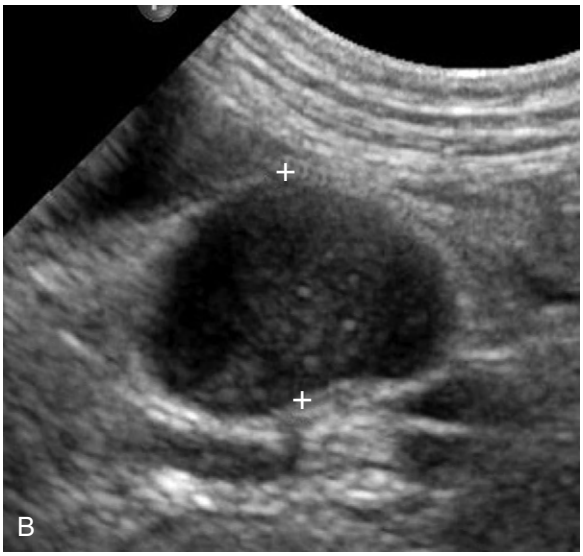


Figure 26-44 A, Transmural gastric thickening (1.2 cm marked on the image between the two "+" signs) of the gastric antrum in a dog with chronic vomiting and weight loss. Two thick layers (between *thin arrows*), one hypo- the other hyperechoic, replace the normal wall layering. **B**, The regional gastric lymph node is hypoechoic, enlarged (1.2 cm), and rounded. Histologic diagnosis: carcinoma with regional lymphatic metastasis.

Figure 26-45 Gastric wall edema in a Yorkshire Terrier with protein-losing enteropathy. The gastric wall is thickened (8 mm), hyperechoic, and with blunted rugal folds.

Figure 26-46 Benign perforating gastric ulcer in a dog caused by concurrent steroidal and nonsteroidal antiinflammatory drug therapy for orthopedic disease. The gastric antrum shows focal thickening and is hypoechoic with loss of layering. A "crater" can be identified (*arrow*) as a focal hyperechoic zone at the mucosal surface of the thickened region. The mesentery surrounding the stomach is diffusely hyperechoic and was a result of peritonitis.

segments. In dogs the duodenum is the most lateral intestinal segment in the right abdomen. The duodenum follows a straight course along the right body wall cranially to the cranial duodenal flexure where it abruptly turns toward the left to join the pylorus. The flexure is usually visible in all dogs, but may be difficult to locate in deep-chested breeds. The pyloroduodenal junction is not consistently identified in all dogs as a result of variability in thoracic conformation. A right intercostal approach may be necessary to examine it in some dogs. In cats, the duodenum has more of a midline location and the pyloroduodenal junction is just caudal to the hilus of the liver. A number of hyperechoic structures that appear like outpouchings of the lumen into the mucosa can often be detected at the antimesenteric border of the duodenal wall. These are normal structures associated with Peyer's patches and should not be misdiagnosed as ulcerations. Duodenal wall thickness varies with body size and weight.[17] In dogs weighing up to 20 kg, the jejunal wall thickness is less than or equal to 4.1 mm; dogs weighing between 20 and 39.9 kg have a thickness less than or equal to 4.4 mm; in dogs weighing more than 40 kg the thickness is less than or equal to 4.7 mm. Canine duodenal thickness is less than or equal to 5.1 mm for dogs weighing up to 20 kg, less than or equal to 5.3 kg for dogs weighing between 20 and 29.9 kg, and less than or equal to 6.0 mm for dogs weighing more than 30 kg. The normal feline duodenal thickness ranges from 1.9 to 3.8 mm.[18] The feline jejunum ranges from 1.6 to 3.6 mm. The luminal diameter is variable in

healthy dogs and cats, and depends on the duration of the period food has been withheld and gastric content at the time of examination. Small amounts of gas and fluid are normal findings. The walls of the duodenum and jejunum appear similar in dogs and cats (Fig. 26-48). The ileum can be recognized by its communication with the colon and its wall layering. The hyperechoic ileal submucosa is more prominent than that of the duodenum and jejunum (Fig. 26-49). In the transverse plane, the ileum has a rosette appearance because of its typically contracted state. The duodenum and jejunum should be observed for peristalsis, which occurs at the rate of approximately one per minute in normal animals (see Chapter 1).

The importance of the small intestinal ultrasound examination is to detect the extent and nature of anatomic and functional changes of the small intestine, and to determine if the changes are isolated to the gastrointestinal tract or involve other organ systems. When examining the small intestine with ultrasound, the wall thickness, wall layering, layer echogenicity, luminal content, and motility should be recorded. The length of an abnormality, the luminal diameter, regional lymph nodes, mesenteric echogenicity, and the presence of free fluid should be determined. Abnormalities should be characterized as focal or generalized.

Figure 26-47 Ultrasound image of the same dog as in Figure 26-46 showing reverberation artifacts caused by the presence of gas (*arrow*) between the liver lobes following gastric ulcer perforation.

Inflammatory diseases of the small intestine are common in dogs and cats. Because they do not always induce changes that can be detected with ultrasound, diagnosis of this group of diseases generally requires intestinal biopsy for confirmation. Although generally diffuse, the disease can also be present focally or segmentally. Inflammatory disease generally leads to mild to moderate transmural thickening of the intestinal wall with preserved wall layering. Decreased intestinal motility because of wall thickening can also be seen with diffuse or segmental inflammatory disease. In cats, the disease is often associated with a selectively thickened muscularis, which is caused by lymphoplasmacytic and/or eosinophilic infiltration (Fig. 26-50).[19] However a thickened muscularis layer in the cat also has been associated with other disorders such as mechanical obstruction or lymphoma.[20] One study showed a significant association between muscularis thickening and T-cell lymphoma in cats.[21] The presence of regional lymphadenopathy was not significantly different in cats with inflammatory bowel disease versus lymphoma. When disease was only present in the mucosa and lamina propria histopathologically, there were no abnormalities ultrasonographically in the cats in that study. Because of the overlap of diseases associated with muscularis thickening and lymphadenopathy in cats, full-thickness intestinal biopsies are likely indicated to reach a definitive diagnosis.

Marked thickening of the muscularis layer may also be observed in cats with eosinophilic enteritis, a condition that has been reported to occur in association with feline hypereosinophilic syndrome. Although the changes are diffuse in almost all instances, a focal intestinal mass was reported in one cat.[22] Feline gastrointestinal eosinophilic sclerosing fibroplasia also has been described in 25 cats.[23] All of these cats had an intestinal mass at the pylorus, jejunum, ileum, ileocecocolic junction, and/or colon, with the pyloric location being most common. They are usually transmural

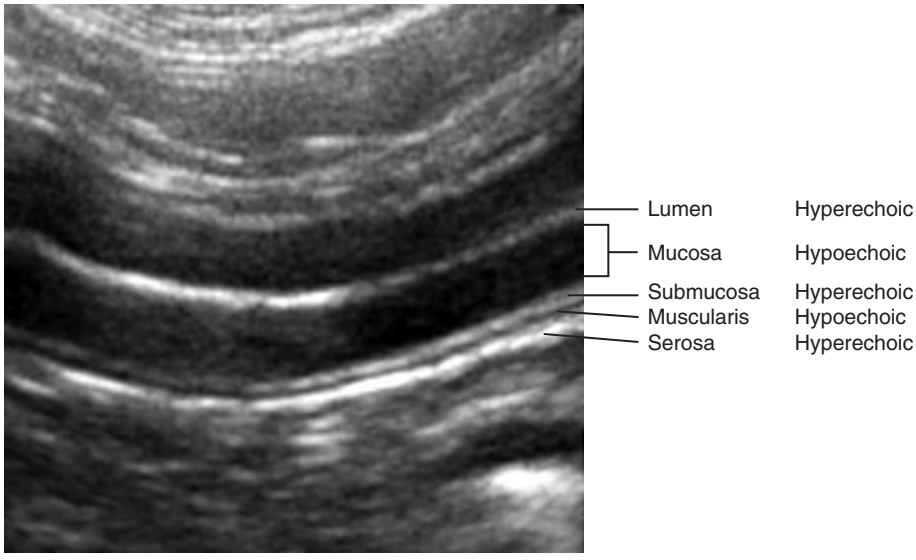

Figure 26-48 Normal small intestinal wall appearance showing the relationship of the layers and their echogenicity.

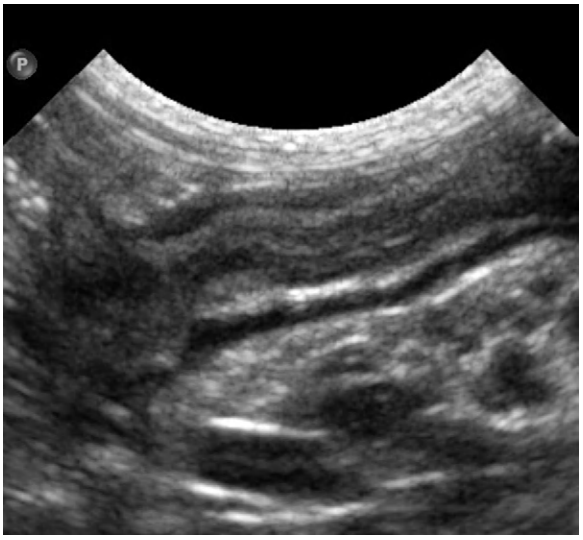

Figure 26-49 Normal feline ileum showing the ileocolic junction and prominent hyperechoic submucosal layer. The canine ileum shows a similar appearance.

Figure 26-50 **A,** Feline ileum with inflammatory bowel disease. The muscularis layer is thickened. An eosinophilic and lymphocytic infiltration was found on histopathology. **B,** Feline jejunum with inflammatory bowel disease. Multiple transverse jejunal segments are shown with a thickened muscularis layer but normal total wall thickness.

lesions but can also be mucosal and none extend beyond the serosa. Although wall layering is generally preserved in inflammatory infiltration, in severe instances it can be indistinct or completely lost. As ultrasound findings of inflammatory and neoplastic infiltration may be similar, intestinal biopsy is always required to confirm and differentiate the two diseases. The relative thickness of the layers also may change while maintaining a normal total wall thickness. Lymphoma is the most common neoplastic cause of diffuse infiltration and wall thickening that can appear similar to inflammatory disease (Fig. 26-51).Chronic inflammatory disease in cats may also produce a distinct, thin, hyperechoic line within the mucosa that is associated with fibrosis histopathologically.[24] The clinical relevance of this sonographic abnormality is uncertain as it can be found incidentally in cats without gastrointestinal disease.

Few data are available concerning the ultrasonographic monitoring of chronic enteropathies. A two-dimensional ultrasound score has been established for canine chronic enteropathies.[18] The ultrasound score correlates with the clinical inflammatory bowel disease activity index (CIBDAI) for dogs at initial presentation.[18] However it is important to note that improvement in the CIBDAI does not correlate with improvement of the ultrasound score following therapy.[18,25]

Canine intestinal lymphangiectasia can occur as a consequence of inflammatory bowel disease or as a primary disorder. Ultrasonographically, mild thickening may be the only abnormality observed. The ultrasonographic diagnosis usually rests on the ability to demonstrate hyperechoic striations that are aligned parallel to one another and perpendicular to the long axis of the intestine (Fig. 26-52).[26] Generalized mild dilation of the intestine and increased fluid content is commonly present and regional lymph nodes may or may not be enlarged. Free peritoneal fluid is usually present in this disease and can be mild, moderate, or severe.

Corrugation of the small intestine can be seen with inflammatory disease within or surrounding the intestinal wall (Fig. 26-53). In dogs with pancreatitis, the duodenum can appear corrugated because of the surrounding peritonitis. Hemo- and uroabdomen result in similar findings.[27-29] With ultrasound, the sonographer can also detect spastic activity of the intestine in real time. These appear as intermittent contractions resulting in a corrugated appearance of the wall which, when relaxed, appears more normal.

Focal intestinal wall thickening can be a result of neoplastic and nonneoplastic lesions. Neoplastic masses often are associated with concentric or eccentric wall thickening with loss of wall layering. The presence of air within an abdominal mass is an indication that it could be of intestinal origin. In this situation, one should strive to find a communication between the air in the mass and adjacent small intestinal segments. In the axial plane, hyperechoic foci due to air may invade the mucosa. The most common intestinal wall tumors in dogs include carcinoma, lymphoma, and leiomyosarcoma.[30-33] Intestinal carcinoma typically develops into a focal mass with loss of wall layering, regional lymphadenopathy, and mechanical obstruction. In cats, the most common malignancies are lymphoma, mast cell tumor, and adenocarcinoma. Lymphoma can diffusely involve the intestine in both species. Lymphoma often appears as a decreased wall echogenicity with focally or diffusely altered wall layering and regional lymphadenopathy. It may also cause partial obstruction of the intestinal lumen (Fig. 26-54). The ileum is a predilection site for lymphoma in cats. Regional lymph nodes are commonly enlarged, rounded, and hypoechoic in patients with either neoplastic or fungal infiltrations of the intestines. Widespread infiltration of the tumor throughout the mesentery and organs can also occur and is referred to as

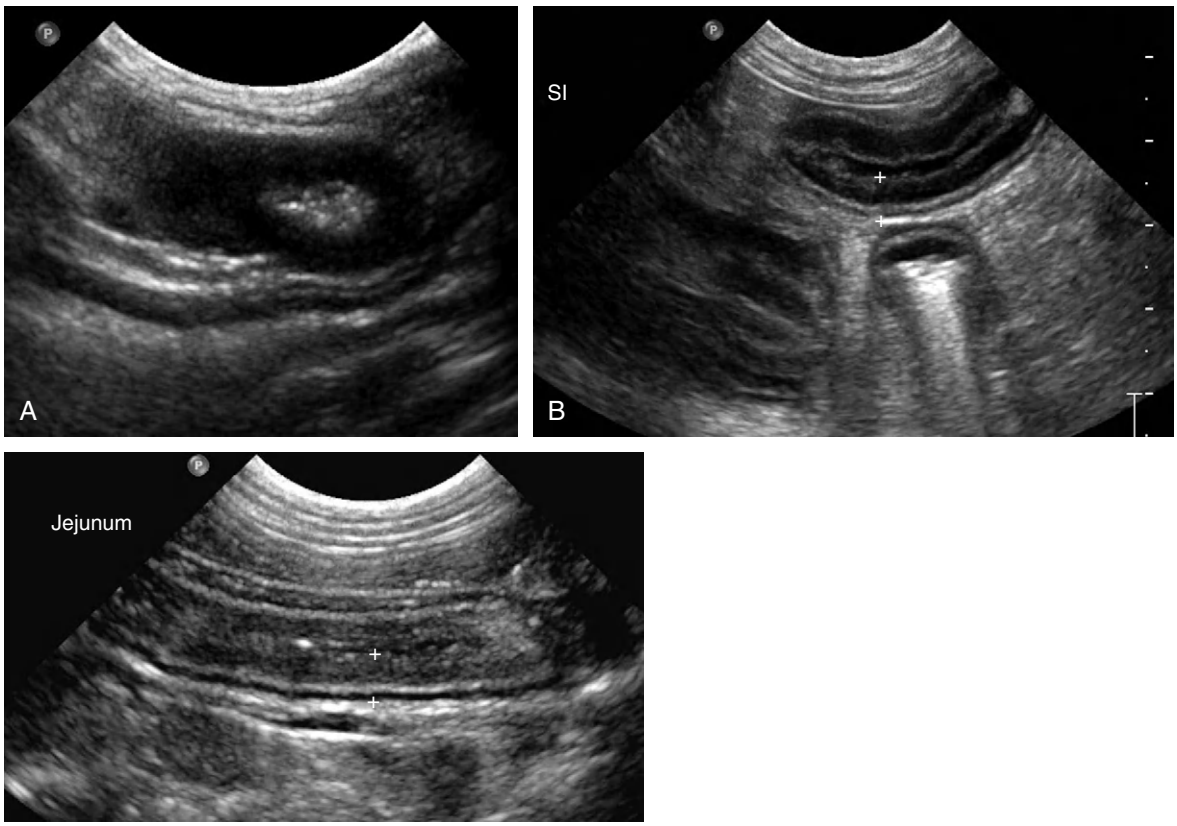

Figure 26-51 **A,** Feline small intestinal lymphoma. Focal transmural thickening with loss of wall layering. The wall appears diffusely hypoechoic and is a common appearance of gastrointestinal lymphoma. **B,** Canine inflammatory bowel disease caused by lymphoplasmacytic infiltration. The jejunum is mildly distended and has a stiff-walled appearance. The wall thickness was increased at 5.2 mm but there was normal wall layering. **C,** Canine inflammatory bowel disease caused by lymphoplasmacytic infiltration. The jejunum has a normal wall thickness but has a diffusely hyperechoic mucosa, in contrast to the dog in (**B**).

Figure 26-52 **Intestinal lymphangiectasia in a Yorkshire Terrier with protein-losing enteropathy.** Linear hyperechoic striations are aligned parallel to one another and perpendicular to the long axis of the small intestinal mucosa.

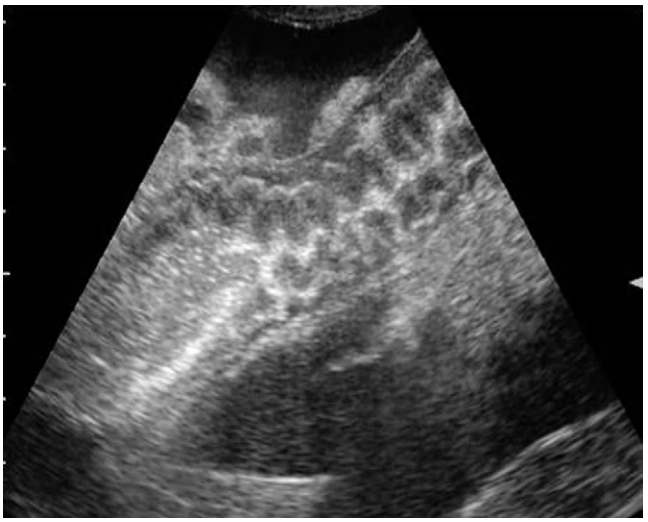

Figure 26-53 Corrugated duodenum in a dog with peritonitis.

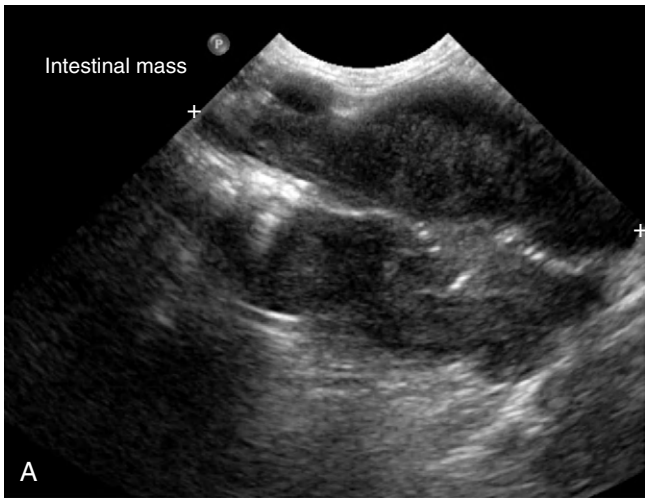
carcinomatosis. Ultrasonographically it appears as hypoechoic foci, usually nodular, throughout the mesentery along with free fluid. When free fluid is present, the visceral peritoneal lining should be carefully scanned for irregularities in contour. Leiomyosarcomas tend to grow out from the periphery of the intestinal wall and appear as eccentric or extraluminal masses.

Nonneoplastic masses include fungal infections with *Pythium* and *Histoplasma*, abscessation, cysts, hematomas, ulcers, intussusceptions and foreign-body granulomas (Fig. 26-55). A focal mass with loss of wall layering is a nonspecific sign and can be present in any one of these conditions. *Pythium* and histoplasmosis can lead to either intestinal wall thickening infection with pseudolayering or



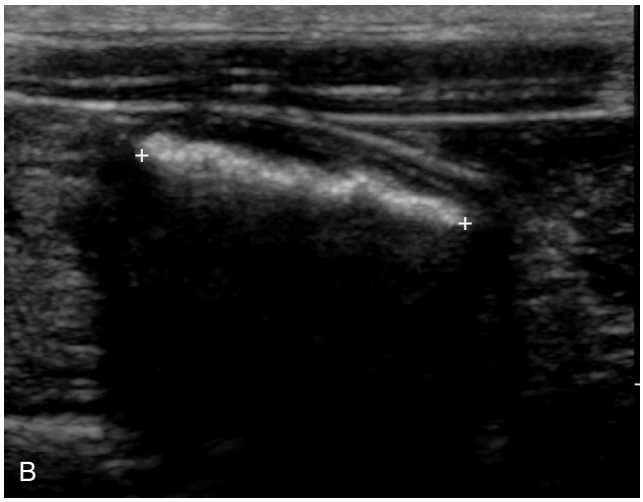


Figure 26-54 **A,** Feline intestinal lymphoma creating stenosis. The jejunal lumen is narrowed as a consequence of asymmetric thickening of the small intestinal wall that is hypoechoic and exhibits a loss of wall layering. **B,** Orad to the stenosis the jejunum contains hyperechoic foreign material with acoustic shadowing as a result of the accumulation of mineral food content over time.

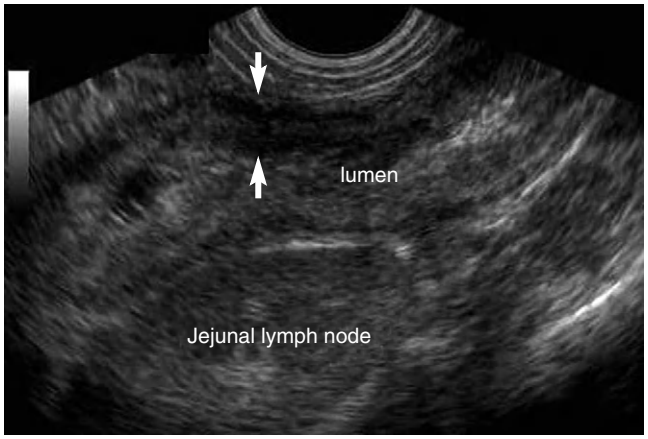

Figure 26-55 Diffuse intestinal thickening with transmural loss of wall layering and increased echogenicity of the wall and regional lymphadenopathy. Histologic diagnosis: pythiosis.

Figure 26-56 Mixed population of empty, contracted intestines adjacent to dilated, fluid-filled ones as a result of the presence of a small intestinal foreign body causing obstruction. The *arrow* shows a small amount of free fluid between the two intestinal segments.

transmural loss of layering as well as a focal mass (see Fig. 26-51).[9] Histoplasmosis has been reported in the cat and can spread throughout the entire abdomen and lungs.[34] Abdominal ultrasound of intestinal histoplasmosis can show lymph node enlargement, a mass of uncertain origin, thickening of the muscularis layer of the small bowel, focal thickening of the ileum with loss of layering, and free peritoneal fluid. These changes are similar to those of lymphoma and other neoplasms ultrasonographically. Histology is required for differentiation between neoplastic and nonneoplastic masses of the intestine.

Functional ileus is usually well-differentiated from mechanical ileus on ultrasound examination. Generalized, mild dilation of the intestinal lumen with fluid accumulation are the predominant features of functional ileus. Intestinal motility is decreased or absent and the intestinal walls may appear stiffened with to-and-fro movement of the fluid content. These changes may be observed with any cause of gastroenteritis, diffuse neoplasia, or peritoneal inflammation (see Chapter 57). An end-jejunal partial obstruction caused by a foreign body or stenosis caused by neoplasia can lead to similar findings.

Ultrasonography is often used in dogs and cats with suspected intestinal obstructions that are not evident radiographically. Similar principles are used as in radiography for diagnosing an obstructing foreign body (see Chapter 26). The gastrointestinal tract is scanned for small and large diameter intestinal segments. With mechanical ileus, the intestinal segments proximal to the obstruction usually show hyperperistalsis and are moderately to severely dilated whereas intestinal segments caudal to the obstruction are of small diameter (Fig. 26-56). Foreign-body material appears hyperechoic with shadowing. The uniformity of the shadowing is dependent on the material itself. With solid homogeneous material, the shadowing will appear more homogenous and anechoic. With heterogeneous material, the shadowing will also appear heterogeneous. If the material contains gas, reverberation artifacts may be present. Metallic foreign material is associated with "ring-down" artifacts (Fig. 26-57). Linear foreign bodies will cause plication of the intestine that should not be confused with corrugation (Fig. 26-58). Plication appears as bunching of the intestine and is static in nature. Occasionally a thin, linear echo representing the string may be seen.

Figure 26-57 Alternating hyperechoic stacked bands can be seen emanating from a small intestinal segment. The intestine itself cannot be seen because of the artifact that was caused by the presence of two sewing needles in the midjejunum. Abdominal radiography was necessary to ascertain the source of the artifact.

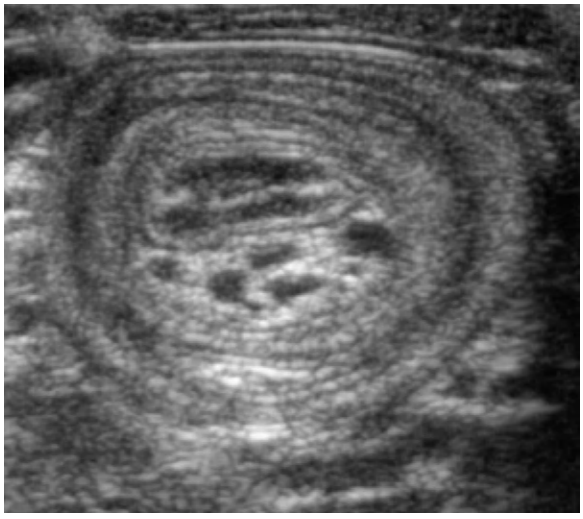

Figure 26-59 **Jejunojejunal intussusception.** Cross-section of the intussusceptions showing concentric rings of intestinal walls. The intussusceptum is in the center and is surrounded by hyperechoic mesentery and small round anechoic vessels. The outer wall or intussuscipiens has a less distinct wall.

Figure 26-58 The jejunum in the same cat as in Figure 26-57 was found to be plicated. The sewing needles had a string attached and a linear foreign body was diagnosed ultrasonographically.

Intestinal intussusceptions cause a mechanical obstruction because of telescoping of the intestine. Underlying pathology such as a mass, particularly in cats, or segmental motility disorders may cause these intussusceptions. They can also be seen in patients with intestinal parasites, linear foreign bodies, and any disease associated with diarrhea. Ultrasonographically, a focal intestinal thickening with a multilayered or concentric ring appearance is diagnostic for intussusceptions in dogs and cats (Fig. 26-59).[35-37] The most common form is the ileocolic intussusception.[38] Intussusception occurs more commonly in young dogs at the ileocecocolic junction.[39-41] The intussusceptum is directed aborally to reside inside the cecocolic lumen. As intussusceptions can be intermittent, their presence should be confirmed immediately prior to surgery.[37] Color Doppler technology can be used to assess for ischemia in the mesentery of the intussuscepted bowel and is a useful technique for determining reducibility.[36]

Perforations of the intestine by a foreign body, ulcer, or neoplasia can also be detected with ultrasound. The perforation site may be observed directly or indirect signs of perforation such as regional accumulation of fluid and corrugated bowel may increase the suspicion for a perforation. Free peritoneal air may also be observed. Intestinal abnormalities are often present and include focal thickening and possible loss of layering at the site of the perforation. Postoperative ultrasound may be required in those patients manifesting abdominal pain post-enterotomy. Primary features used in identifying the surgical site include irregular hypoechoic serosal margins, a focally thickened bowel wall with altered to absent wall layering with adjacent hyperechoic fat and the presence of hyperechoic suture material.[42] Enterectomy sites are more readily visualized than enterotomy sites likely because of circumferential distribution and comparatively larger size of the surgical site.[42] Pneumoperitoneum, echogenic abdominal effusion, and hyperechoic mesenteric fat can be detected but should progressively resolve over 10 days in most patients.

Cecum and Colon

Ultrasonographically, the ileum, ileocecal junction, cecum, and ascending, transverse, and descending colon can be identified in the dog and cat. The bony pelvis limits examination of the colon, but the rectum as well as perirectal and perineal regions can be examined via perineal probe placement. If the region of interest within the pelvic canal cannot be assessed because of overlying bone, radiographic contrast studies or computed tomography can be helpful in determining the origin of soft-tissue masses causing displacement or compression of the colon. When distended, the wall should have the appearance of three layers and a thickness of 1 to 2 mm independent of the size of the animal. The empty colon will appear contracted and many layers can be appreciated. This should not be

Figure 26-60 **Normal appearance of the colon.** The near wall (*white arrows*) is thin (1 to 2 mm) in dogs and cats and three distinct alternating layers (hyper-, hypo-, and hyperechoic) can be detected with high-resolution probes. Only the near wall is visible because of the hyperechoic reflective nature of the fecal and air content (*black arrows*).

Figure 26-61 **Diffuse colonic wall thickening in a cat with tenesmus.** The colon wall ranges from 3 to 4.5 mm in thickness (delineated by the two "+" markers) and is diffusely hyperechoic such that the three thin layers are no longer visible. Histologic diagnosis: lymphoma.

misinterpreted as colonic wall thickening however. The large bowel is often filled with feces or air creating an artifact that permits only the wall closest to the transducer to be examined (Fig. 26-60). To differentiate dilated small intestines from the colon, the colon should be traced from the pelvic inlet cranially along the left abdominal wall to the stomach where it turns toward the right and courses caudally to the midabdomen. On the right side of the abdomen, the cecum and ileum can be identified medial to the midpoint of the descending duodenum. Upon visualizing the ileocecocolic junction, the large bowel can be traced cranially. The ileum is a short segment in the dog and cat and has a thicker wall and more prominent submucosa in both species (Fig. 26-61). Animals in which the right intercostal approach may prove most useful for examining the colon include large- and giant-breed dogs, deep-chested dogs, and dogs with gaseous distention of the stomach, duodenum, or colon.[43]

In dogs with diarrhea caused by colitis, the colon may appear normal or thickened ultrasonographically and the lumen may be filled with gas or fluid. In general, mild to moderate forms of colitis as a result of diffuse inflammatory infiltration often show no ultrasonographic changes, and colonoscopy is the diagnostic method of choice in both dogs and cats. Colonic wall thickening can be either focal or diffuse and a result of either neoplastic, benign inflammatory or granulomatous infiltration. Focal thickening or intramural masses of the colonic wall are associated with both neoplasia and granulomata. Both MRI and CT are alternative methods for examining the pelvic region or determining the involvement of the colon and surrounding tissues, especially when space-occupying lesions are present in that region.

Gastrointestinal Hemodynamics

Doppler ultrasound provides a noninvasive method of assessing gastrointestinal hemodynamics in dogs.[44] Assessment of systolic and diastolic arterial blood flow in the large upstream arteries supplying the gastrointestinal tract is aimed at detecting abnormally increased or decreased resistance to flow to the intestinal capillaries during digestion. The resistive and pulsatility indices (RI and PI, respectively) have historically been used to infer the degree of resistance to flow in downstream capillary beds. A lowered index indicates lowered resistance to flow and vice versa. The spectral waveforms of the celiac (CA) and cranial mesenteric arteries (CMA) in normal dogs have been described as being of moderately high resistance in the fasted state (CMA RI = 0.803 ± 0.029, CA RI = 0.763 ± 0.025, CMA PI = 2.290 ± 0.311, CA PI = 1.962 ± 0.216).[44,45] The CA and CMA feed two different capillary beds. The CA supplies the upper gastrointestinal tract, including the stomach and pancreas, whereas the CMA supplies the small intestine. Reference values for RI and PI in normal dogs both pre- and postprandial have been published.[45] The method involves measuring the RI and PI in the CA and CMA percutaneously at fasting (time 0) and at 20, 40, 60, and 90 minutes postprandially. Vasodilation during digestion leads to decreasing Doppler indices and increasing diastolic blood flow velocity, which infers decreased resistance to flow in the downstream capillary bed of the gastrointestinal tract. The effect lasts 40 minutes in the CA and 60 minutes in the CMA, and increased resistance to flow can be demonstrated at 90 minutes postprandially in normal dogs during reversion to the fasting state.[44] Prolonged vasodilation at 90 minutes has been demonstrated in normal dogs eating a high-fat diet compared with high-protein and high-carbohydrate diets that have the same response as a normal maintenance diet.[44]

In dogs with proven food allergies and clinical symptomatology, dietary provocation with the allergen results in prolonged vasodilation at 90 minutes postprandially.[46] Abnormal hemodynamics also have been shown in dogs with chronic enteropathies from other causes.[47] This noninvasive ultrasound method shows promise for assessing hemodynamic pathophysiology in dogs with adverse reactions to food and chronic enteropathies as a consequence of other causes, but further studies are required to determine the value of this technique in larger clinical populations.

Endoscopic Ultrasound

Endoluminal ultrasound (EUS; Fig. 26-62A) was developed in humans to overcome problems associated with transabdominal imaging difficulties including large penetration depths, presence of intestinal gas, and obesity.[48] Ultrasound endoscopes integrate endoscopic and ultrasonographic principles, permitting the mucosal

Figure 26-62 **A,** Ultrasound endoscope. The tip of the scope has a curved array transducer, optic, working channel, and a port for suction and fluid instillation. The handle has two dials, one for left–right movements and one for up–down movements of the ultrasound tip. The tip can be bent to 90 degrees. **B,** Endoscopic ultrasound image of the normal canine stomach.

surface to be visualized optically while the intestinal wall layering and contiguous organs are examined sonographically (Fig. 26-62B). In humans endoscopic ultrasonography is an accurate tool for staging malignant tumors of the esophagus, stomach, duodenum, rectum, major duodenal papilla, extrahepatic bile duct, and pancreas.[49]

A standardized EUS examination technique of the canine abdomen is possible by using five anatomic landmarks.[48] The upper gastrointestinal tract and cranial abdominal organs can be examined. EUS in dogs allows excellent visualization of the stomach from the distal esophagus to the proximal duodenum, independent of patient size, thoracic conformation, and body condition or luminal gas content. Because of the direct placement of the transducer on the stomach wall or with the aid of an inflated balloon, gastric wall layering can be visualized with excellent resolution (Fig. 26-63). EUS has potential for improving diagnostic capabilities for the gastrointestinal tract and assessment of wall layering when conventional transabdominal methods fail; however the equipment is costly and has limited availability.

Ultrasound-Guided Interventional Procedures

Ultrasound-guided fine-needle aspiration can be performed on the gastrointestinal wall and regional lymph nodes, as well as intestinal masses, to provide a cytologic diagnosis. Limitations to performing the procedure are size and location of the structure to be sampled, vascularity, and skill of the sonographer. Generally, a free-hand technique is indicated for fine-needle aspirations. However an ultrasound guide can also be used. Gastrointestinal masses are generally easier to sample than sites of mild intestinal wall thickening. The motility and mobility of the small intestine makes it more difficult to perform tissue aspiration. Furthermore, tissue aspiration of the intestinal wall to differentiate inflammatory from neoplastic disease has low sensitivity and specificity, and mucosal or full-thickness biopsy are still the best methods for differentiation of these two conditions.

For tissue aspiration of the gastrointestinal wall and regional lymph nodes, the skin should be clipped of hair, prepared aseptically, and the ultrasound probe should have a sterile cover. Alcohol is

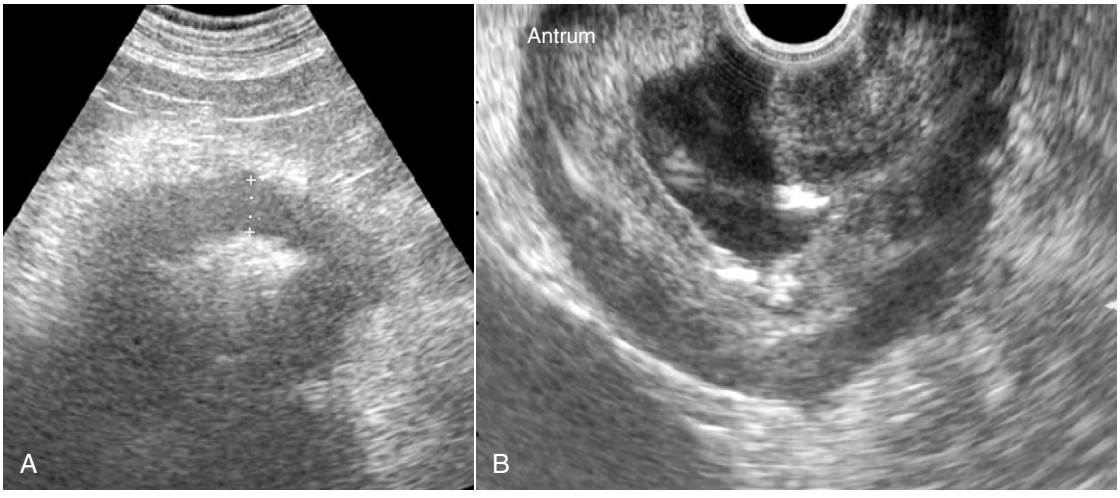

Figure 26-63 **A**, shows a transabdominal ultrasound image of the stomach in a dog with chronic vomiting and weight loss. There is poor visualization of the stomach wall as a consequence of the size of the dog and resulting poor resolution. **B**, The same dog examined with an echoendoscope. The wall can be well visualized and thickening with pseudolayering could be diagnosed. Histologic diagnosis: carcinoma.

generally adequate as a coupling agent. A 20- to 22-gauge (G), 2.5-inch needle is adequate in both small and large patients. For deeper-lying lymph nodes in larger animals, a spinal needle may be required. Tru-Cut biopsy for histology should generally be reserved for lesions greater than 2 cm in size. Biopsies can be performed with an 18 G spring-loaded or manual biopsy device.

ULTRASONOGRAPHIC IMAGING OF THE PANCREAS AND LIVER

Gabriela Seiler

Ultrasonographic Imaging of the Pancreas

Normal Ultrasonographic Anatomy

Technique

Ultrasonographic examination of the pancreas is challenging because of the small size and indistinct margins of the organ.[1] Additionally, deep-chested body conformation, overweight body condition, and a full gastrointestinal tract may hinder ultrasonographic visibility of the pancreas. However experience, excellent understanding of the anatomy, and use of different scan windows allow a thorough examination of the pancreas. Because it is small in size and superficially located, the highest possible transducer frequency should be used to assess the pancreas (usually 7.5 to 15 MHz).

Normal Pancreas

The normal pancreas has a fine texture and is iso- or slightly hypoechoic compared with the mesenteric fat.[2] Figure 26-64 shows schematic images of the canine and feline pancreas. In the dog, the right lobe of the pancreas is more easily seen than the body or the left lobe of the pancreas (Fig. 26-65A). It extends along the duodenum ventral and lateral to the portal vein. Because this right lobe of the pancreas is very superficial, using a high-resolution transducer (7.5 to 15 MHz) and application of minimal transducer pressure is important. In the transverse plane, the right lobe of the pancreas is triangular in shape and located between the duodenum and ascending colon. In contrast, the right lobe of the feline pancreas is very thin and not consistently or easily seen. In both species, the pancreatic body is found by following the right lobe of the pancreas cranially or by imaging it at the hilus of the liver just ventral to the portal vein and caudal to the pylorus. The left lobe of the pancreas is a small, triangular structure caudal to the greater curvature of the stomach in the dog, which is also located cranial to the transverse colon and cranioventral to the splenic vein. The left lobe of the feline pancreas is larger, often extending to the cranial pole of the left kidney (see Fig. 26-65B). Pancreatic thickness rarely exceeds 1 cm in dogs. Table 26-1 summarizes the normal dimensions of the feline pancreas. Pancreatic size and echogenicity have been reported to be unaffected by age in cats.[3] The pancreatic duct is not usually seen in dogs, but is visible in the center of the pancreatic parenchyma in cats (see Fig. 26-65B and Table 26-1). Ductal size increases with age, with a mean width of 0.13 cm (± 0.04 cm) in a group of older cats.[4] The pancreatic duct primarily enters the duodenum through the major (cats) or minor (dogs) duodenal papilla. In dogs the visible pancreaticoduodenal vessels may be used to confirm (i.e., blood flow can be confirmed by using color Doppler) identification of pancreatic tissue (see Fig. 26-65A).

Pancreatitis

Canine Pancreatitis

In the initial stage of severe acute pancreatic necrosis, the pancreas becomes thickened, hypoechoic and contains well-defined linear anechoic fissures and subcapsular stripes ("tiger-stripe" appearance), produced by pancreatic edema, which usually precedes necrosis

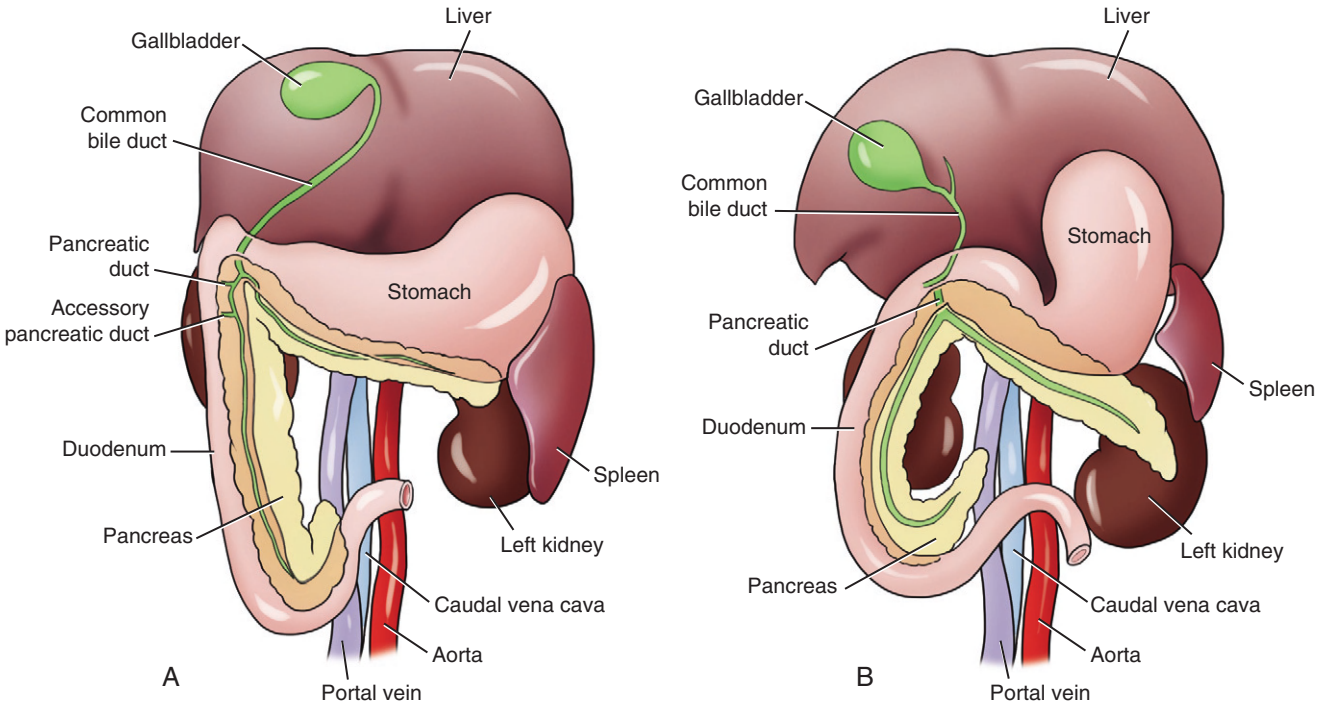

Figure 26-64 Schematic view of the ventral aspect of the (**A**) canine and (**B**) feline pancreas and adjacent organs.

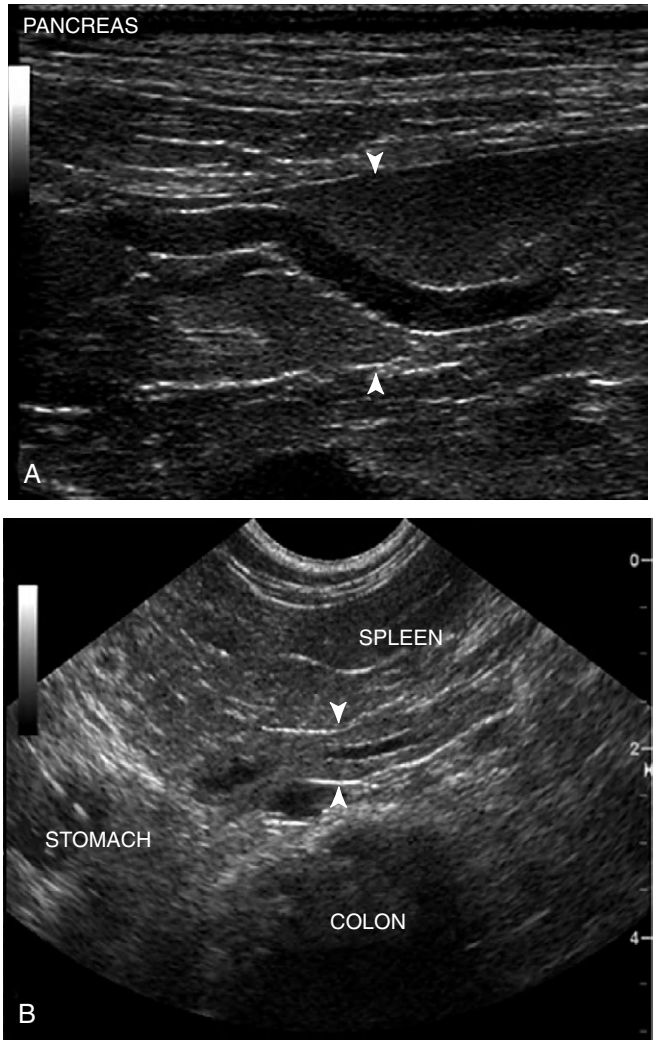

Figure 26-65 Long axis view of the (A) right lobe of a normal canine pancreas and the (B) left lobe of a normal feline pancreas. The pancreas is outlined by *arrowheads*. Note the smooth, uniform echogenicity and the regular surface of the normal pancreas. The echogenicity is slightly hypoechoic to the surrounding fat. The tubular hypoechoic structure in the center of the canine pancreas (**A**) represents the pancreaticoduodenal vein. The pancreatic duct in the center of the feline pancreas (**B**) has a similar appearance, but no flow is apparent when using color flow Doppler.

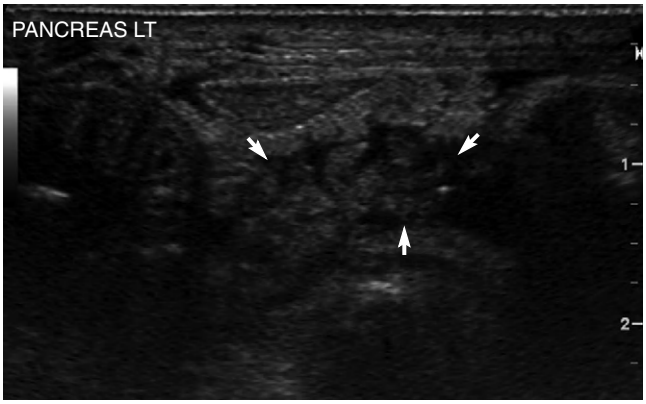

Figure 26-66 Long axis view of the left lobe of the pancreas of an 8-year-old female, spayed, Chihuahua dog with pancreatic edema. The pancreas is outlined by *arrows*. Note the hypoechoic fissures in the pancreatic parenchyma, resulting in a "tiger-stripe" appearance.

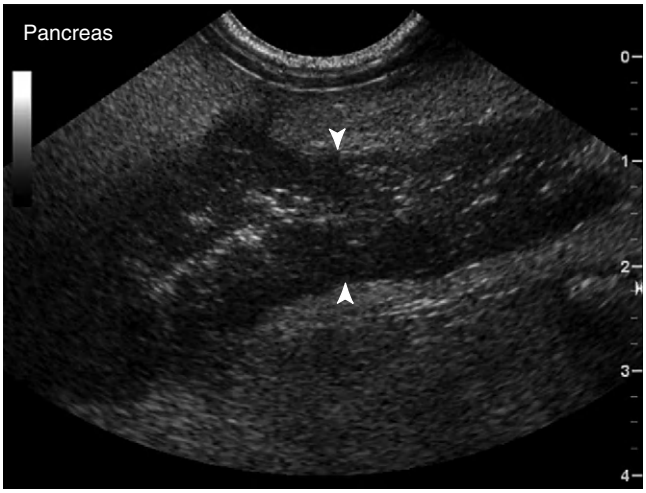

Figure 26-67 Long axis image of the right lobe of the pancreas of a 7-year-old male, castrated, Dachshund with acute pancreatitis. The pancreas is enlarged, hypoechoic, and irregularly outlined (*arrowheads*). Note the hyperechogenicity of the surrounding mesentery, indicating regional inflammation and peripancreatic fat necrosis. The hyperechoic area within the pancreas may represent fibrosis.

Table 26-1 Ultrasonographic Dimensions of the Normal Feline Pancreas

Anatomical Structure	Mean (mm)	Range (mm)
Left lobe	5.4	3.4 to 9
Body	6.6	4.7 to 9.5
Right lobe	4.5	2.8 to 5.9
Pancreatic duct	0.8	0.5 to 1.3

(Fig. 26-66). Irregular, hypoechoic tissue, representing necrotic, hemorrhagic pancreatic, and peripancreatic tissue is subsequently seen in the pancreatic region. The pancreas may not be seen distinctly or may appear mass-like.[5] Also, the pancreas is usually surrounded by hyperechoic peripancreatic mesentery, caused by inflammation, edema, and peripancreatic fat necrosis (Fig. 26-67). Other extrapancreatic changes include peritoneal effusion, a fluid- or gas-filled thick-walled atonic descending duodenum, pancreaticoduodenal lymphadenomegaly, and extrahepatic biliary obstruction. Mild acute pancreatic necrosis will have less-severe ultrasonographic changes; the pancreas is more distinct, contrasting with the slightly hyperechoic peripancreatic mesentery. Hyperechoic areas, which are consistent with fibrosis or saponification of fat may be present in the pancreas. Effusion, duodenal and biliary tract abnormalities are commonly absent. The sensitivity of ultrasound in the diagnosis of acute canine pancreatitis has been reported to be approximately 68%,[5] so an unremarkable ultrasonographic examination does not rule out pancreatitis. Pancreatic edema alone can also be encountered in canine patients with portal hypertension, hypoalbuminemia, or free peritoneal fluid in general.[6]

Feline Pancreatitis

Pancreatitis in cats is difficult to diagnose and the sensitivity of ultrasound for detection of feline pancreatitis is relatively low (most studies: 11% to 35%[7,8]; however, one small study reported a sensitivity of 80%).[9] The appearance of acute pancreatic necrosis and chronic nonsuppurative pancreatitis are not significantly different.[10] This is likely related to the fact that histologically, hemorrhage and edema, which are responsible for parenchymal hypoechogenicity, are less frequently seen in cats.[8] If present, an enlarged hypoechoic pancreas, hyperechoic peripancreatic tissue, free fluid, thickening of the gastric and duodenal wall, and extrahepatic bile duct obstruction all may lead to a diagnosis of pancreatitis. Concurrent diseases such as hepatic lipidosis, cholangitis, enteritis, diabetes mellitus, and interstitial nephritis are frequently present. Also, ultrasonographic evidence of hepatic lipidosis together with the presence of free fluid has been associated with acute pancreatitis.[11]

Chronic Pancreatitis

Chronic pancreatitis is characterized by interstitial fibrosis with acinar atrophy and often lymphoplasmacytic infiltrates. Ultrasonographic signs have not been well described and include a heterogeneous echogenicity, mineralizations, an irregular surface, and widening of the pancreatic duct. This form of pancreatitis is very difficult to differentiate from other pancreatic diseases, such as nodular hyperplasia.[2]

Cystic Pancreatic Lesions

Pancreatic abscesses or pancreatic pseudocysts are uncommon sequelae of pancreatitis. Both appear ultrasonographically as fluid-filled cavities with distal acoustic enhancement, but abscesses may also have a mass-like appearance (Fig. 26-68). Pancreatic pseudocysts are fluid accumulations within or adjacent to the pancreas with a capsule of granulation/fibrous tissue, which is thought to be the result of pancreatic duct rupture. Differentiation between a pancreatic abscess and a pseudocyst requires cytology or even histopathology.[12] Small cystic lesions without other pancreatic abnormalities are either congenital cysts or retention cysts caused by obstruction and focal dilation of the pancreatic duct. A rare anatomical variation with unknown clinical significance is called pancreatic "pseudobladder," an abnormal distention of the pancreatic duct.[13]

Pancreatoliths

Calculi, recognized as hyperechoic structures with distal acoustic shadowing, are occasionally seen in the pancreatic duct and are suggestive of chronic or intermittent pancreatitis.

Pancreatic Neoplasia

Pancreatic Carcinoma

Pancreatic adenocarcinomas arising from exocrine tissue or excretory ducts are rare in dogs and cats, but are highly malignant. The ultrasonographic findings are similar to pancreatitis: the pancreas is hypoechoic and enlarged, only occasionally a mass can clearly be delineated (Fig. 26-69). Metastasis disease to the liver, lymph nodes, and lungs is common and frequently already present at the time of diagnosis. Pancreatic adenocarcinoma is the most common primary pancreatic tumor, but the incidence of metastatic tumors appears to outweigh primary pancreatic tumors in both dogs and cats, and differentiation from nodular hyperplasia is difficult. Single masses larger than 2 cm have been reported to be more consistent with neoplasia.[14] Peripancreatic lymphadenopathy is commonly present but can be seen with various other abdominal diseases.

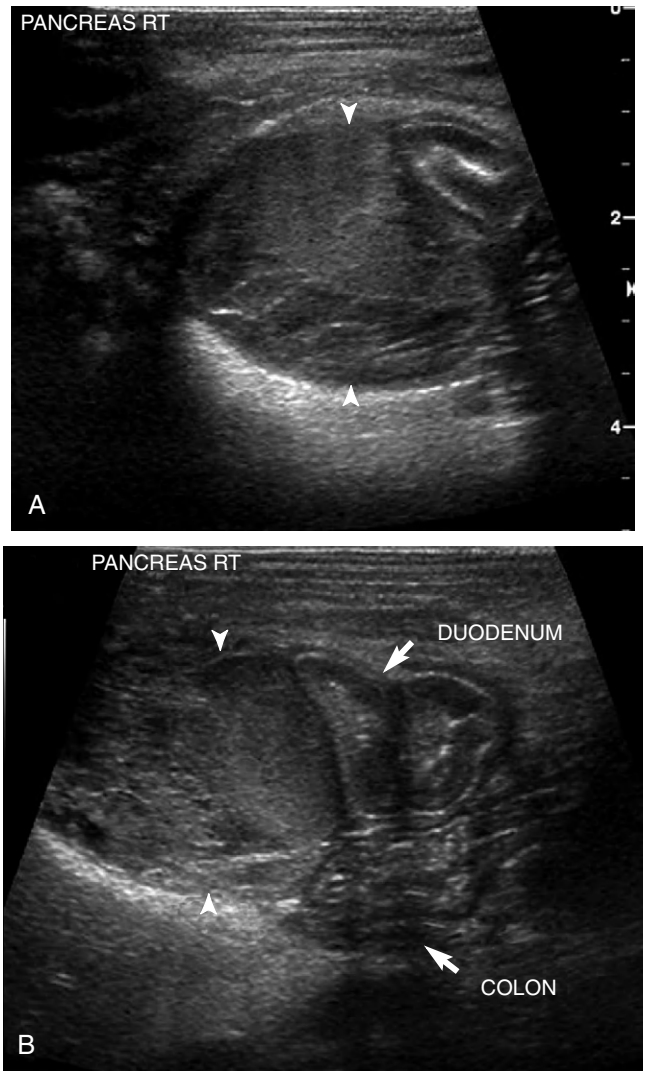

Figure 26-68 **A,** Transverse ultrasound image of the right cranial abdomen of an 8-year-old male, castrated, Miniature Schnauzer presented for vomiting of several days duration and a painful abdomen. In the right lobe of the pancreas there is a round cavitary lesion with echogenic material (*arrowheads*). The remainder of the right pancreatic lobe and the pancreatic body show signs of severe pancreatitis. **B,** The distortion of the shape of the adjacent duodenum and colon indicates presence of adhesions. Pancreatic abscessation and extensive adhesion formation were confirmed during surgical exploration.

Endocrine Tumors of the Pancreas

Gastrinomas, glucagonomas, and insulinomas are rare in dogs and cats. Insulinoma is the most common tumor type of this group and affects dogs more frequently than cats. If visible, pancreatic insulinomas appear ultrasonographically as well-defined hypoechoic round or lobulated nodules (Fig. 26-70). Nodules in the left lobe are harder to identify because of adjacent gastric and colonic gas. Metastatic disease is often present in the liver, seen as hypoechoic nodules or target lesions, and in the regional lymph nodes. Small pancreatic insulinomas, however, are poorly delineated from the pancreatic tissue and are not always visible ultrasonographically. The sensitivity of ultrasound for detection of primary lesions is quite low (35% in one study).[15]

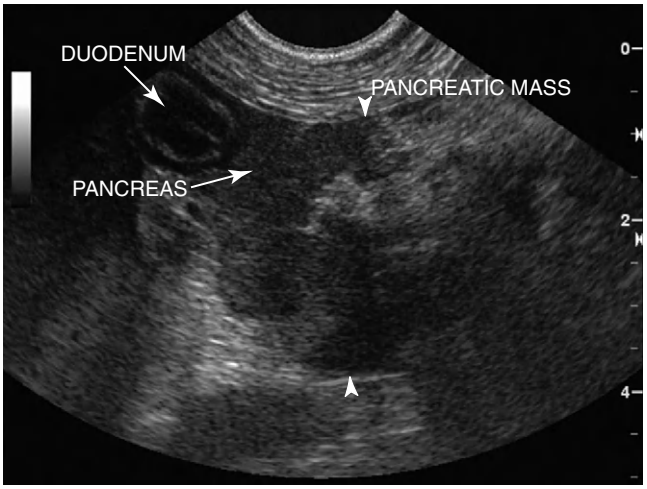

Figure 26-69 Transverse image of the right lobe of the pancreas of a 13-year-old male, castrated, Labrador Retriever. The duodenum is seen in cross-section in the *top left corner* of the image; the hypoechoic tissue next to it is the pancreas, which expands into a hypoechoic lobulated mass (*arrowheads*). The mass contains hyperechoic areas with some distal shadowing, likely representing some degree of dystrophic mineralization and necrosis. Pancreatic carcinoma was diagnosed histopathologically.

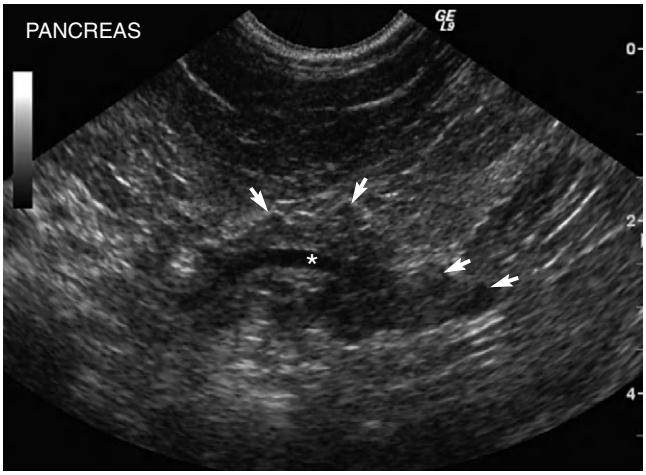

Figure 26-71 Nodular hyperplasia of the left pancreatic lobe in a 12-year-old Domestic Shorthair cat. The image shows a long axis view with the cranial aspect to the left. The pancreas is irregular in outline and multiple hypoechoic nodules are visible throughout the parenchyma (some are indicated with an *arrow*). None of the nodules were larger than 1 cm. The pancreatic duct is visible in the center of the pancreas (*asterisk*) and is normal in size for an older cat.

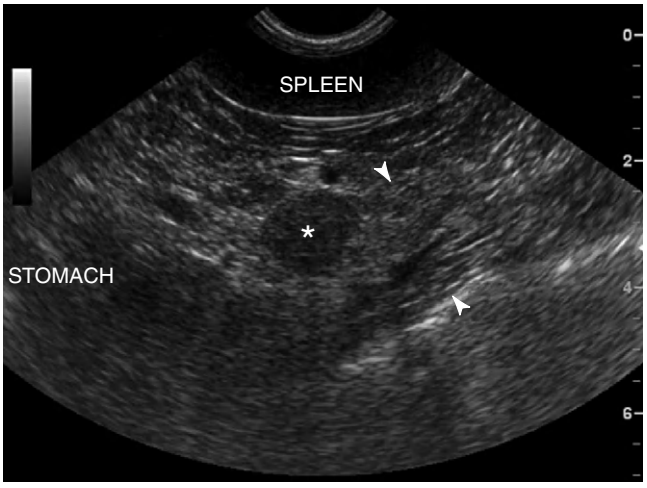

Figure 26-70 Long axis view of the left lobe of the pancreas of a 10-year-old female, spayed, mixed-breed dog presented with severe hypoglycemia. The pancreas is outlined by *arrowheads*. There is a 1-cm round, hypoechoic nodule present arising from the pancreatic tissue (*asterisk*). Histopathology confirmed the diagnosis of an insulinoma.

Nodular Hyperplasia

Nodular hyperplasia may be seen in up to 80% of older animals. Multifocal hypoechoic nodules may lead to an enlarged, hypoechoic, and irregularly outlined pancreas (Fig. 26-71). The nodules rarely exceed a diameter of 1 cm but can be poorly delineated. Fine-needle aspirates or pancreatic histopathology may be necessary to differentiate them from pancreatic neoplasia.[14]

Pancreatic Insufficiency

The ultrasonographic appearance of exocrine pancreatic insufficiency has not been described in dogs, but in cats it may lead to inhomogeneous pancreatic parenchyma or pancreatic nodules.[4] However in both species a diagnosis of EPI cannot be based on abdominal ultrasound alone and the functional reserve of the pancreas must be assessed with laboratory testing.

Fine-Needle Aspirate and Biopsy of the Pancreas

The main indication for fine-needle aspirates of the pancreas is the presence of a mass or cystic lesion. An ultrasound-guided tissue core biopsy is only recommended for larger masses. Pancreatitis as a complication has not been reported in cats or dogs, but has been described in humans; however, the complication rate for pancreatic fine-needle aspirates is very low.[16]

Contrast-Enhanced Ultrasound of the Pancreas

Ultrasound contrast media increase the sensitivity of ultrasound to image the blood supply to the pancreas. In human patients, contrast-enhanced ultrasound allows a distinction between malignant and focal inflammatory lesions and also the differentiation between hypoperfused adenocarcinomas and heavily vascularized neuroendocrine tumors.[17] The normal enhancement pattern of the feline pancreas has been described, and increased vascularity and perfusion have been reported for cats with pancreatitis.[18]

Endoscopic Ultrasound of the Pancreas

EUS is a potentially valuable method for investigation of the pancreas, as the ultrasound probe integrated into the endoscope is positioned within the stomach and therefore in close vicinity of the pancreas.[19] It has been suggested that EUS is superior in delineating focal nodular lesions, as well as imaging and measuring the right pancreatic lobe. However it should be noted that in one study findings on EUS were not different between healthy cats and cats with pancreatitis.[20]

Ultrasonographic Imaging of the Liver

Technique

Ultrasound provides information about the structure of the liver parenchyma, the biliary tract, the portal and hepatic vasculature, as

well as an opportunity to perform guided aspirates or biopsies. Consequently, ultrasound should be performed in patients with suspected hepatic disease even if no abnormalities are seen radiographically. Transducer choice largely depends on patient size; the highest possible frequency to still penetrate the depth of the parenchyma should be used (5 to 10 MHz). Most of the liver parenchyma can be imaged from an acoustic window just caudal to the xiphoid process. Subcostal and intercostal windows on both sides are then used to image the dorsal aspects of the liver. Curvilinear or sector probes are best for imaging these subcostal or intercostal windows. For a thorough interrogation of the hepatic vasculature a systematic approach and various image planes using grayscale imaging and color and spectral Doppler are used, protocols for which have been described in detail elsewhere.[21,22]

Normal Liver and Biliary Tract

Criteria for determining normal liver size ultrasonographically have not been well established. Hepatomegaly should be suspected if the liver lobes extend caudally well beyond the xiphoid process or if there is an increased distance between the diaphragm and the stomach. Similarly, microhepatia is suspected if the distance between the stomach and the diaphragm is decreased. Marginal changes in liver size require confirmation with abdominal palpation and conventional radiography.

The normal hepatic parenchyma has a homogenous texture, which is slightly coarser and less echogenic than the spleen. Echogenicity of the right renal cortex is less useful for comparison, as there is a large individual variability in the echogenicity of the renal cortex. The falciform fat is normally hyperechoic to the liver parenchyma in cats. The normal liver capsule is smooth and hyperechoic with sharp liver lobe margins.

The normal gallbladder has a very thin, smooth, and slightly hyperechoic wall, if it is visible at all. In cats, gallbladder wall thickness should be less than 1 mm.[23] The bile duct is rarely visible in dogs, whereas in cats it is usually seen and can be tortuous. Common bile duct diameter should not exceed 3 mm in dogs and 5 mm in cats.[24] In dogs, presence of biliary sludge is common and usually not associated with hepatobiliary disease.[25]

The portal vein is formed by the cranial and caudal mesenteric veins and the splenic vein, and is joined by the gastroduodenal vein from the right side just caudal to the porta hepatis. The diameter of the portal vein is largest at the porta hepatis. It is best visualized either from a ventral or a right intercostal approach. The normal ratio of the portal vein to the aorta ranges between 0.7 and 1.25.[26] Blood flow within the main portal vein is directed toward the liver with a normal mean velocity of 15 to 20 cm/sec in dogs and 10 to 18 cm/sec in cats.[26] The portal vein then divides into several branches that taper toward the periphery of the liver lobes. The intrahepatic portal veins can be distinguished from the hepatic veins by their hyperechoic wall structure.

Diffuse Liver Disease

A diffuse change in hepatic echogenicity usually represents diffuse infiltrative disease. However ultrasonographic findings are nonspecific and some diffuse hepatopathies may not be associated with any alterations in liver echogenicity. Attempts have been made to correlate ultrasonographic criteria with different groups of diffuse liver disease, but without much success.[27,28] The diagnostic accuracy for diffuse liver disease by abdominal ultrasound ranges between 36.5% and 39.1% in dogs and 54.6% and 57.7% in cats. The accuracy for differentiation between normal and diffusely abnormal hepatic parenchyma is also highly variable and ranges from 0% to 80%.[28] Consequently, histology is necessary for accurate diagnosis of diffuse liver disease.

Hypoechoic Liver

Decreased hepatic echogenicity (Fig. 26-72) has been reported with diffuse neoplastic infiltration, such as lymphoma or leukemia, but also with amyloidosis, acute hepatitis, or cholangitis in cats.[27] Right-heart failure with secondary hepatic congestion leads to hepatic hypoechogenicity, but also is characterized by distended hepatic veins and ascites. Focal hypoechogenicity or heterogeneity of a single liver lobe with a "lacy" pattern of the parenchyma and focal peritoneal effusion is consistent with a liver lobe infarction (Fig. 26-73) or liver lobe torsion. In this case, Doppler examination will reveal decreased blood supply and/or the presence of thrombi.[29]

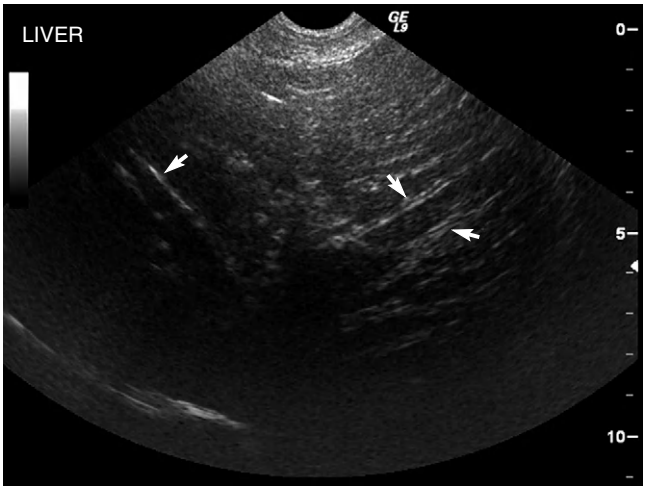

Figure 26-72 Long axis view of the liver of a 7-year-old Labrador Retriever dog with leptospirosis and acute hepatitis. The hepatic parenchyma is hypoechoic in this image, evidenced by the markedly hyperechoic portal vessel walls (*arrows*) compared with the surrounding liver parenchyma.

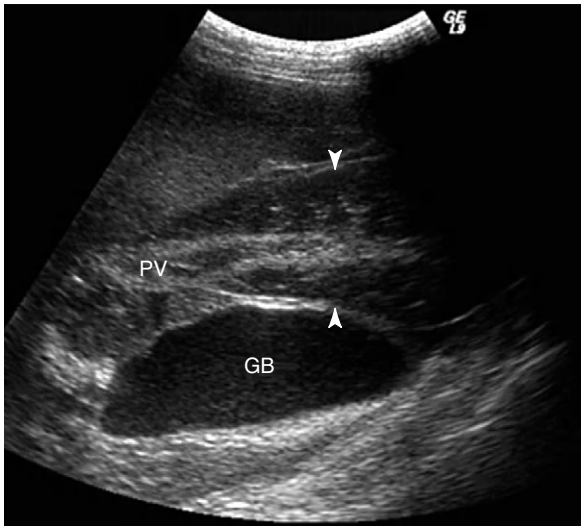

Figure 26-73 Acute infarction of the right medial liver lobe (between *arrowheads*). The infarcted liver lobe is hypoechoic compared with the adjacent normal right lateral liver lobe. The portal vein branch entering the affected lobe contains hyperechoic material; blood flow could not be detected with Doppler ultrasound. The infarcted lobe was surgically removed.

Hyperechoic Liver

A diffusely hyperechoic liver parenchyma is associated with a poor delineation of the walls of the portal vein and can give a false impression of a reduced number of hepatic vessels. Increased beam attenuation in the deeper portions of the hepatic parenchyma is consistent with fatty infiltration of the liver either caused by obesity, hepatic lipidosis (in cats), or diabetes mellitus (Fig. 26-74).[30] Other differentials for a diffusely hyperechoic and enlarged liver are steroid hepatopathy and diffuse hepatic lymphoma. A hyperechoic, but small and nodular liver is indicative of chronic liver disease (e.g., fibrosis, cirrhosis) (Fig. 26-75).

Mixed Hepatic Echogenicity

Neoplastic processes, such as metastatic disease or neoplastic round cell infiltrates, can lead to a generalized inhomogeneous echotexture. Other differentials include chronic liver disease of various etiologies with associated nodular hyperplasia. During early stages of chronic liver disease the liver may appear ultrasonographically normal, but as the disease progresses to cirrhosis, the hepatic surface tends to become irregular, and the parenchyma becomes heterogenic, with hyperechoic areas and hypoechoic regenerative nodules (see Fig. 26-75). Presence of microhepatia, ascites, and extrahepatic shunts is usually a sign of chronic "end-stage" liver disease.[31,32] Hepatocutaneous syndrome in dogs is characterized by a "honeycomb" appearance in which hypoechoic nodules are surrounded by a network of hyperechoic tissue.[33] The ultrasonographic appearance of hepatic amyloidosis in cats has been described as a diffuse process with heterogeneous echogenicity of the parenchyma with hypoechoic and hyperechoic foci. This process may also lead to spontaneous rupture of the liver.[34] Hepatic rupture should be suspected in patients with hemoabdomen and a focal area of overall hypoechoic but heterogeneous hepatic parenchyma.

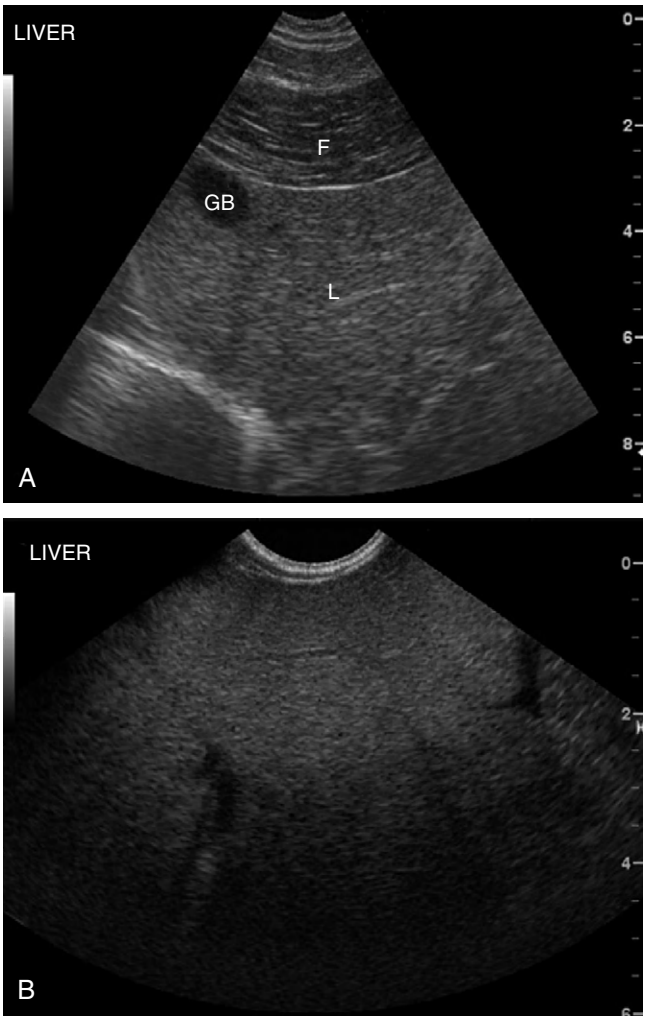

Figure 26-74 Ultrasonographic images of two different cats diagnosed with hepatic lipidosis. A, The liver (*L*) is hyperechoic compared with the falciform fat (*F*). The gallbladder (*GB*) is also labeled. **B,** The ultrasound beam is attenuated in the deeper portions of the liver, caused by the increased absorption and reflection of the sound beam as it penetrates the fatty tissue.

Focal and Multifocal Liver Disease

Masses and Nodules

Differential diagnoses for a solitary hepatic mass include primary hepatic neoplasia, focal hyperplasia, hematoma, or abscess, all of which can have a similar appearance and fine-needle aspiration or biopsy is required for a definitive diagnosis (Fig. 26-76). Hepatocellular adenomas and carcinomas have a similar appearance and typically present as solitary heterogenic or hyperechoic masses, often with a cystic component. Primary hepatic neoplasia can also present as multifocal hyperechoic or mixed-echoic nodules.[35] Histologically, nodular hyperplasia consists of hepatocytes (often vacuolated), blood-filled sinusoids, and areas of atrophic and necrotic tissue and most commonly results in multifocal uniformly hypoechoic nodules, which may be cavitated. Because of its similarity to the normal hepatic parenchyma, nodular hyperplasia is not always detected ultrasonographically. In contrast, extensive necrosis, fatty degeneration, or sinusoidal dilation may all result in heterogenic masses with or without cavitations, which may have a similar ultrasonographic appearance to hepatic neoplasia.[36] Appearance of metastatic liver disease ranges from hypoechoic to hyperechoic nodules surrounded by a rim of hypoechoic tissue (so-called target lesions). However there are also benign lesions that are reported to present as target lesions, including nodular hyperplasia, pyogranulomatous hepatitis, and chronic active hepatitis.[37]

Cystic Liver Lesions

Solitary or multifocal thin-walled cysts with a normal appearance of the surrounding hepatic parenchyma are occasionally seen within the hepatic parenchyma and often represent biliary cysts or may be

Figure 26-75 Long axis image of the liver of a 12-year-old male Beagle with liver failure. The liver is small and irregular. The parenchyma contains multiple hypoechoic nodules surrounded by hyperechoic tissue, consistent with cirrhosis.

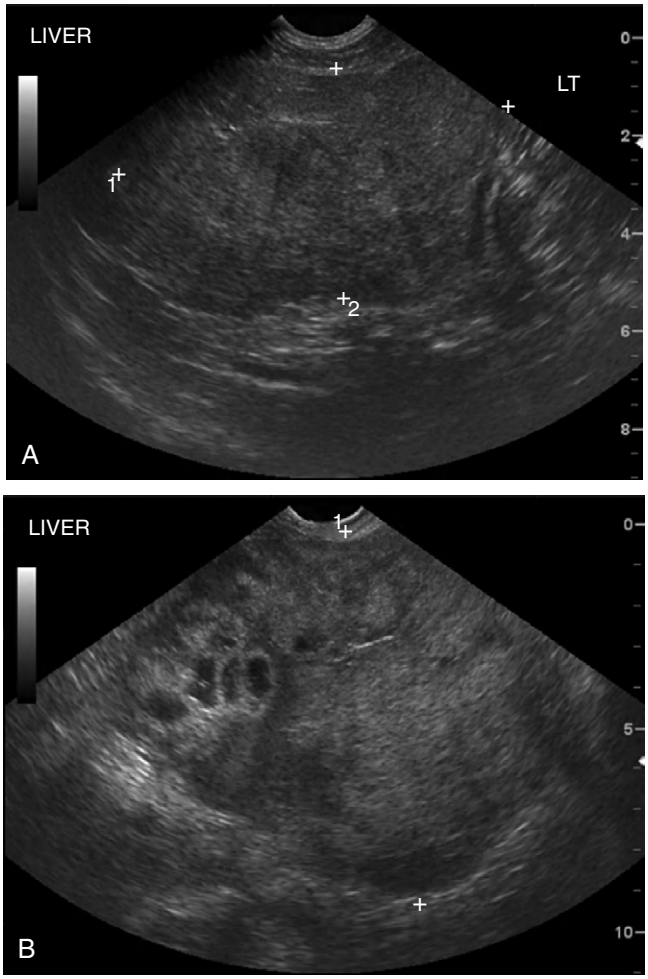

Figure 26-76 Long axis view of the liver of a (A) 12-year-old Bichon Frise with a hepatocellular adenoma and (B) a 13-year-old mixed breed dog with a hepatocellular carcinoma. The masses are outlined between the *cross-marks*. Note the similar appearance of the two masses: both are solitary, heterogenic, and with a lobulated appearance. The hepatocellular carcinoma also contain a few cystic areas as well.

Figure 26-77 Multiple cystic lesions in the liver of an 8-year-old Domestic Shorthair cat with biliary cystadenomas. The hepatic parenchyma is hyperechoic distal to the cysts, consistent with acoustic enhancement.

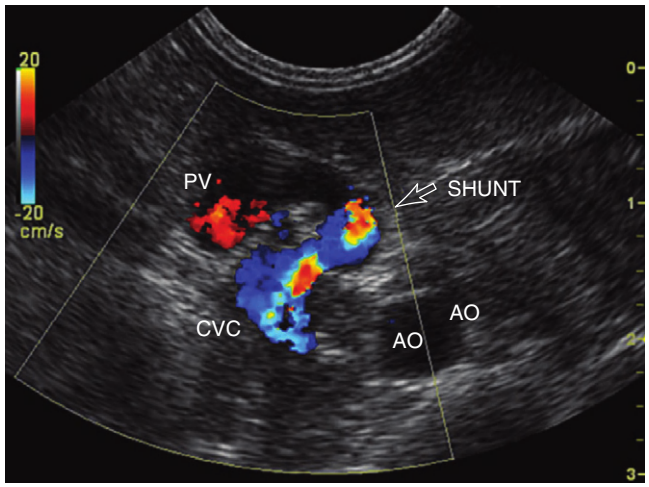

Figure 26-78 Transverse view of the right craniodorsal abdomen (dorsal to the right). The aorta (AO), caudal vena cava (CVC), and portal vein (*PV*) are labeled. A curvilinear shunt vessel connects the portal vein with the caudal vena cava (*arrow*).

a part of a polycystic disease process affecting the kidneys and the liver. Both types of cysts usually contain bile, and fine-needle aspiration can be used to differentiate them from other cystic liver lesions. Biliary cystadenomas are benign solitary or multifocal tumors mainly seen in older cats. The ultrasonographic appearance is variable, ranging from multiloculated masses composed of thin-walled cysts, hyperechoic or mixed echoic masses with cystic components (Fig. 26-77).[38] The hyperechoic portions of a mass are often composed of clusters of tiny cysts that are seen histologically but are not apparent ultrasonographically. The cysts contain clear or mucinous fluid when aspirated. Hepatic abscesses are more commonly solitary than multifocal in dogs and cats. The fluid-filled center of the abscess can appear echogenic if it contains a large amount of cellular debris, but can also appear anechoic. Similarly, not all abscesses have a thick wall. In some instances the wall is poorly discernible and the abscess has to be differentiated from other cystic lesions cytologically. Presence of gas within the lesion facilitates the diagnosis of an abscess.[39,40] Other differential diagnoses for cystic lesions include parasitic disease such as liver flukes or hydatid disease, which appears as thick-walled nodules with an echogenic center and occasional mineralizations. Echinococcosis is characterized by large cavitary masses predominantly in the portal hepatic region. The cysts have irregular walls with some echogenic material and possibly small mineralizations.[41] Hematomas, nodular hyperplasia, metastatic disease, or primary liver tumors all may be cavitated, and fine-needle aspiration or biopsy is required for definitive diagnosis.

Vascular Disorders of the Liver

Portosystemic Shunts

Portosystemic shunts can be congenital or acquired, and congenital shunts can be further differentiated into intra- and extrahepatic portosystemic shunts (Fig. 26-78). In patients with an intrahepatic shunt, the left or right portal branches run cranially and enter the caudal vena cava or the left hepatic vein at the level of the diaphragm. Blood flow in the main portal vein is often increased. Extrahepatic portosystemic shunts originate most commonly from

the splenic vein or left gastric vein and enter the caudal vena cava or the azygos vein. It has previously been reported that a PV:AO ratio of equal to or greater than 0.8 can be used to rule out an extrahepatic portosystemic shunt in both dogs and cats.[26] The portal blood flow at the hepatic hilus is often reduced as most of the portal blood is directed into the shunt vessel. Multiple acquired portosystemic shunts should be suspected if the left gonadal vein entering the left renal vein is dilated and if clusters of tortuous vessels are observed in the area of the left renal vein.[42]

Arteriovenous Fistula

Ultrasonographic findings in patients with arteriovenous fistulas include a dilated portal venous system with hepatofugal, pulsatile venous flow. Most animals have a reduced liver size and peritoneal effusion. Acquired extrahepatic portosystemic shunts as a consequence may also be observed.[43]

Portal Hypertension

Chronic liver diseases such as cirrhosis, surgical occlusion of a single shunt vessel, portal vein thrombosis, or arteriovenous fistulas can cause portal hypertension. Portal vein flow velocity is reduced below 10 cm/sec or may even be reversed. Persistent portal hypertension leads to opening of portosystemic collaterals or acquired portosystemic shunting.

Portal Vein Thrombosis

Portal vein thrombi are usually visualized as hyperechoic intraluminal structures in the main portal vein or one of the portal vein branches. Chronic thrombi may be mineralized. Doppler examination is used to determine if there is residual flow around the thrombus, and if there is any evidence of portal hypertension. Focal dilation of the vessel at the level of the thrombus is indicative of a tumor thrombus.[44]

Biliary Tract Disease

The main indication for the ultrasonographic evaluation of the biliary tree is to determine possible causes for icterus and to evaluate the gallbladder for signs of infection, cholelithiasis, or mucocele formation.

Cholecystitis

The main finding in patients with cholecystitis is a thickened gallbladder, and sometimes also a thickened cystic or common bile duct wall. Transhepatic fine-needle aspiration of the bile for culture and sensitivity testing has been shown to be safe and yield a significantly higher percentage of positive cultures than cultures of hepatic tissue.[45]

Cholelithiasis

Choleliths, a concretion of cholesterol, calcium, and bilirubin are uncommon in dogs and cats and are asymptomatic in many cases. However, they can also be a cause or consequence of bile duct obstruction. Calculi present as round or irregular hyperechoic structures with distal shadowing. Although rarely reported, bile duct obstruction secondary to choleliths can lead to bile duct rupture. In these cases, the choleliths may be found in the peritoneal cavity.

Mucocele

Mucinous gland hyperplasia and inspissation of bile can lead to formation of biliary mucoceles. The ultrasonographic appearance of the gallbladder is characteristic in these cases. The enlarged gallbladder is filled with immobile bile in a stellate, striated, or mixed pattern (Fig. 26-79). The gallbladder wall in patients with a biliary mucocele is prone to rupture and surgery for removal of the gallbladder is often indicated.[46,47] Evidence of gallbladder rupture includes focal peritonitis characterized by echogenic fluid and hyperechoic inflamed tissue in the gallbladder fossa of the liver, a discontinuous gallbladder wall, and in rare cases a clump of inspissated bile that may be observed free in the peritoneal cavity.[48]

Figure 26-79 Gallbladder mucocele in a 14-year-old Bichon Frise presented because of several days of vomiting and anorexia. The gallbladder is filled with hypoechoic material peripherally and hyperechoic striations centrally, resulting in a "stellate" appearance.

Biliary Tract Neoplasia

Neoplasia of the gallbladder is extremely rare, and only a few cases of adenocarcinoma and neuroendocrine carcinoma have been reported,[49] but biliary adenomas and adenocarcinomas are more common, particularly in the cat.[50]

Bile Duct Obstruction

The most common cause for biliary tract obstruction is inflammation, often secondary to pancreatitis, cholelithiasis, or neoplasia. Bile duct enlargement is the main indicator of extrahepatic biliary obstruction. In cats with extrahepatic bile duct obstruction, 97% were found to have a common bile duct diameter greater than 5 mm (Fig. 26-80).[51] Dilation of the gallbladder and/or intrahepatic bile ducts is seen in a percentage of animals and is likely related to location, duration, and severity of the obstruction. Nevertheless, the appearance of an enlargement of the biliary system always has to be interpreted in light of clinical and blood chemistry findings, as common bile duct dilation can persist after a previous obstruction. Sequential measurement of serum bilirubin concentration should be monitored to determine if an obstruction is currently present.

Fine-Needle Aspiration and Ultrasound-Guided Biopsy

Fine-needle aspirates or biopsy of the liver is required for a definitive diagnosis of most hepatic lesions. Fine-needle aspiration is easy to perform and associated with a low risk for complications. The accuracy of cytologic diagnosis is limited, although agreement between histopathology and cytology was found in only 30% of canine and in 51% of feline liver samples in one study.[52] Agreement between the morphologic diagnosis determined from needle biopsies and wedge biopsies was reported to be between 56% and 67% in another study.[53]

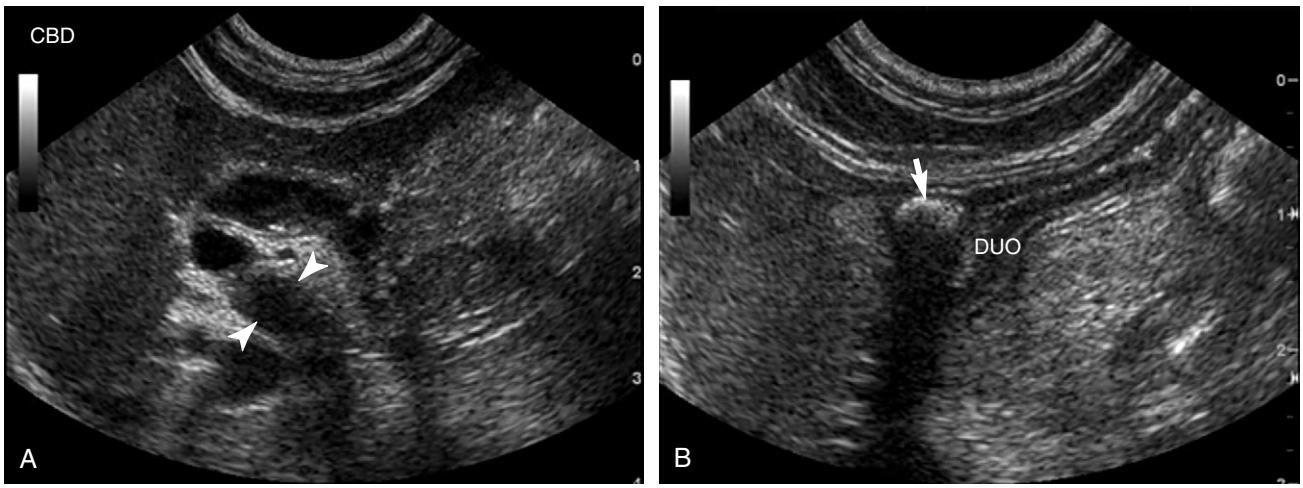

Figure 26-80 Common bile duct obstruction in a 12-year-old Domestic Shorthair cat with icterus. A, The bile duct is enlarged with a diameter of 8 mm (outlined by *arrowheads*). **B,** At the level of the papilla duodeni, a round hyperechoic structure with distal shadowing (*arrow*) could be seen lodged in the common bile duct and papilla. A cholelith was removed surgically.

Contrast-Enhanced Ultrasound

Unlike other contrast agents used for diagnostic imaging, microbubble ultrasound contrast medium does not leave the vascular system and is therefore useful to assess hepatic perfusion and vascularity. Lesion detection is improved after contrast application, and differentiation of benign and malignant hepatic nodules is possible with a high accuracy.[54,55] Benign liver nodules have a similar blood supply and vascularity and therefore show similar enhancement compared with the normal liver parenchyma, whereas malignant nodules lack the extensive venous sinusoids and remain relatively hypoperfused at peak liver enhancement (Fig. 26-81). When using contrast-enhanced ultrasound, the accuracy for detecting metastatic liver disease was very high (97% to 100%).[54,55]

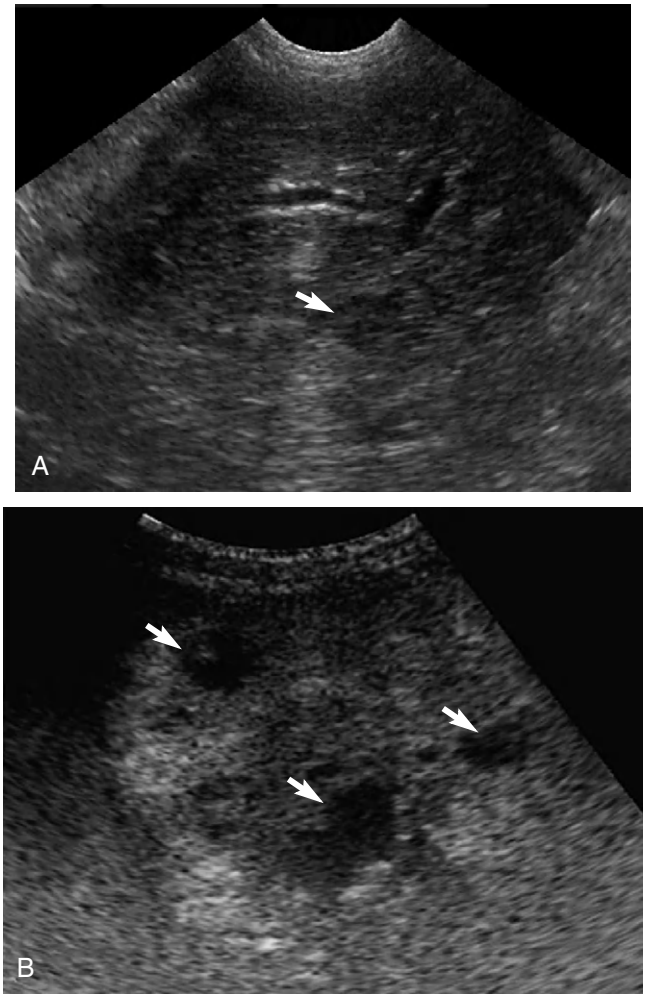

Figure 26-81 (**A**) Conventional and (**B**) contrast-harmonic ultrasound images of the liver of a 12-year-old mixed-breed dog with a metastatic hemangiosarcoma. The image was recorded during the portal phase of the contrast enhancement. In the precontrast image (**A**) the liver is mottled and a hypoechoic nodule is visible (*arrow*). After injection of microbubble contrast (**B**) there are multiple hypoperfused nodules seen throughout the parenchyma; the three largest ones are marked by *arrows*.

NUCLEAR SCINTIGRAPHY

Federica Morandi

Scintigraphy is a medical imaging modality utilizing radiopharmaceuticals (compounds containing a radioisotope bound to a pharmaceutical) that concentrate in a specific region of interest, ideally involving one specific physiological function, and relies on the detection of radioactive decay in the diagnosis of disease. Following administration, the radiopharmaceutical distributes within the body according to its specific mechanism of localization and emits gamma radiation, which is detected by a scintillation camera, thereby creating an image that depicts distribution of radioactivity within the body. The most commonly used isotope is technetium-99m (^{99m}Tc), which is very suitable for diagnostic imaging because of its short half-life ($T_{1/2}$, the time it takes for the initial activity to decrease by 50%: 6.02 hours for ^{99m}Tc) and ideal energy emission (140 KeV) for detection by a gamma camera. The use of scintigraphy is well established for the evaluation of portosystemic shunts[1-9] and the hepatobiliary system.[10,11] Scintigraphy has also been used to evaluate gastrointestinal blood loss,[12-14] esophageal motility, gastric emptying time,[12] and pancreatic inflammation in cats.[15,16]

Hepatobiliary Scintigraphy

Principles, Indications, and Radiopharmaceuticals

Hepatobiliary agents are lidocaine analogues, exploiting the fact that lidocaine's primary site of metabolism is the liver.[10] Lidocaine, however, cannot be directly bound to ^{99m}Tc, therefore iminodiacetic acid (IDA) analogues (mebrofenin or disofenin) are used as bifunctional chelates, bound to lidocaine on one side of the molecule and ^{99m}Tc on the other.[10] After intravenous (IV) injection, ^{99m}Tc-IDA agents are transported to the liver loosely bound to serum albumin. They dissociate in the space of Disse, where they come in contact with membrane receptors on the hepatocyte, and compete for dye anion class receptors. ^{99m}Tc-IDA agents are taken up by hepatocytes in a carrier-mediated, non–sodium-dependent transport mechanism similar to that of bilirubin, and are secreted into the bile and small intestine in their native form. Thus, ^{99m}Tc-IDA uptake is dependent upon serum albumin binding, systemic circulation, hepatic arterial blood flow, serum bilirubin concentration, hepatocyte function, and biliary secretion. Of these multiple sequential processes, ^{99m}Tc-IDA handling depends primarily on hepatocyte uptake and biliary secretion. Normal hepatocytes extract the radiopharmaceutical rapidly from the blood pool, whereas poorly functioning hepatocytes do not extract the radiopharmaceutical as efficiently. In the presence of severe hepatocellular disease, the urinary system becomes the primary route for excretion.[10] Although hepatobiliary scintigraphy permits the evaluation of hepatic morphology, its primary uses are in the determination of hepatic function and biliary tract patency.[10,11]

Technical Considerations

In dogs and cats, a dose of 2 to 6 mCi (74 to 222 MBq) is used. Static 60-second lateral and ventral images are acquired at 5, 10, 15, 30, 45, 60, 90, and 240 minutes following IV injection. If activity is not seen in the intestines by 240 minutes, images at 8 and 24 hours should be obtained in all cases to evaluate for extrahepatic obstruction.[10] For quantification of the hepatic extraction index, a dynamic acquisition is obtained, starting the acquisition just prior to injection.[10]

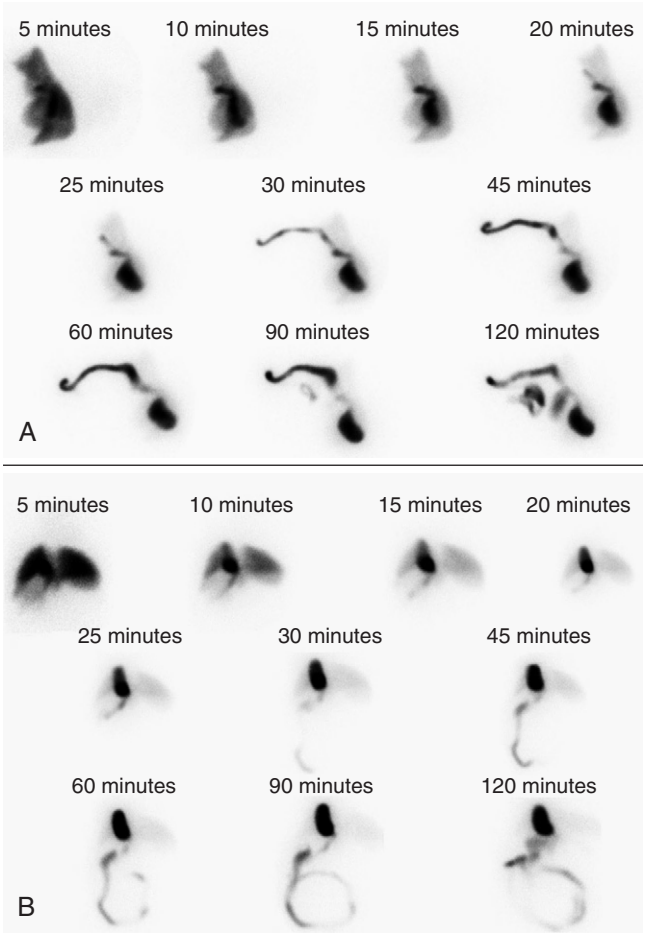

Figure 26-82 Right lateral (**A**) and ventral (**B**) views after IV injection of ^{99m}Tc-mebrofenin. Notice the absence of blood pool and cardiac activity at 5 minutes, and the progressive and rapid clearance of hepatic activity into the gallbladder, which is already visible at 10 minutes. On the 20-minute images, hepatic counts have dropped more than 50% compared with the 5-minute images, indicating normal hepatic half-life. Activity is then visible in a tubular structure consistent with the common bile duct at 20 minutes, and is clearly visible in the duodenum at 30 minutes.

Interpretation

As for any scintigraphic study, the raw images should be evaluated first, before any quantitative analysis is done (Fig. 26-82). In a normal dog, the 5-minute images provide the best assessment of hepatic morphology, Hepatic extraction is characterized by rapid radiopharmaceutical uptake by the liver, with clearance of the blood pool and washout of cardiac activity by 5 minutes, and peak liver uptake at 6 to 8 minutes. Hepatic excretion is characterized by a $T_{1/2}$ of 19 minutes.[10] In other words, the 20-minute image should show approximately 50% of the liver activity seen on the 10-minute image. Although gallbladder activity and intestinal activity should be visible within an hour, it is the author's experience that in dogs with large amounts of biliary sludge, the gallbladder may never be visible. However there should be progressive centralization of activity around the area of the gallbladder, followed by visible intestinal activity. Quantification of hepatic function requires the calculation of the hepatic extraction fraction (HEF), which is the percentage of radiopharmaceutical removed by the liver on each circulatory pass. In normal dogs, the HEF is on average 95%.[10]

The presence of hepatocellular disease is characterized by decreased hepatic radiopharmaceutical uptake (HEF <90%), prolonged blood pool and cardiac activity (visible beyond 5 minutes), intrahepatic cholestasis ($T_{1/2}$ >19 minutes), delayed excretion into the intestinal tract, and visualization of the kidneys and urinary bladder as alternate routes of excretion.[10] Complete extrahepatic obstruction is characterized by normal to decreased hepatic uptake and excretion (depending on the duration of obstruction) and no visible intestinal activity at any time, including the 24-hour images.[10,11] In cases of partial extrahepatic obstruction, the appearance of gastrointestinal activity can be markedly delayed (>18 hours), and the volume of activity present may be very small (Fig. 26-83).[10,11] It was initially reported that lack of GI activity at 3 hours was indicative of complete obstruction.[17] A more recent study[11] found that the 3-hour cutoff overestimates the frequency of complete obstruction, resulting in high sensitivity (100%) but very low specificity (33%), while the 24-hour cutoff yields improved specificity (83%) with good sensitivity (83%), thereby minimizing the number of unnecessary surgeries in animals with partial obstructions.

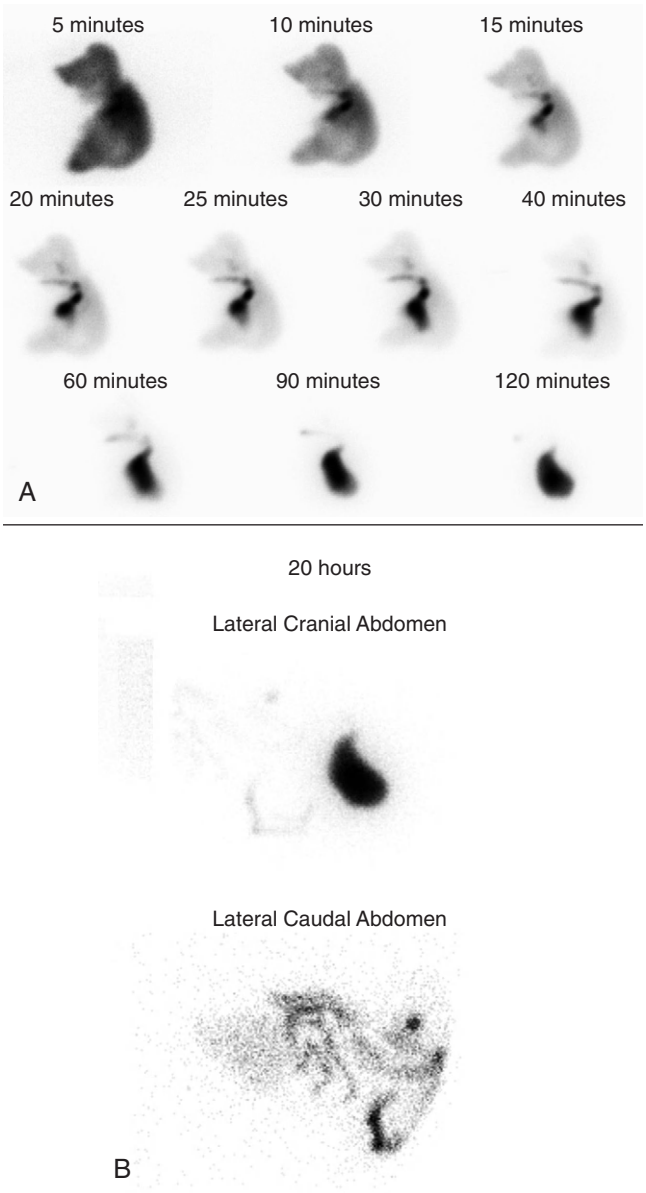

Figure 26-83 Right lateral views after IV injection of ^{99m}Tc-mebrofenin in a dog with partial biliary obstruction. A, Images obtained up to 3 hours and 40 minutes after injection, documenting mild hepatomegaly, rounded liver margins, normal hepatic uptake and secretion into the gallbladder and proximal aspect of the bile duct, with lack of progression of the radiopharmaceutical in the intestinal tract. **B,** Lateral views obtained the following morning (20 hours postadministration) that show a small amount of activity with linear distribution in the mid to caudal abdomen, consistent with passage of ^{99m}Tc-mebrofenin in the intestinal tract.

Portosystemic Shunt Imaging

Principles, Indications, and Radiopharmaceuticals

Scintigraphy has been used to evaluate dogs and cats with macroscopic portosystemic shunts (PSSs) since the early 1980s.[1] It was not until the early 1990s that the development of per-rectal portal scintigraphy (PRPS) provided a highly sensitive and specific technique in the diagnosis of PSSs. PRPS exploits the unique ability of ^{99m}Tc in the form of pertechnetate to be absorbed through the colonic mucosa into the portal venous system.[1-4] With normal portal venous circulation, activity appears first in the liver followed by the heart, after a delay of approximately 8 to 12 seconds. With portal venous shunting, activity arrives in the heart before or at the same time as it appears in the liver.[1-4] PRPS has some distinct disadvantages, chiefly the inability to identify the morphology and location of the shunt.[1,5] This study therefore provides a simple "yes" or "no" answer to the question, "Is there a macroscopic PSS?" Another limitation of PRPS is that study quality is extremely variable and depends on the degree of isotope absorption from the colon. Colonic absorption of pertechnetate is often poor (<15%). Consequently, high doses of isotope (10 to 20 mCi, or 370 to 740 MBq) are needed to achieve a diagnostic study. Such a high dose, however, results in higher patient and personnel exposure.[5]

In recent years, transsplenic portal scintigraphy (TSPS) was developed to overcome the limitations of PRPS.[5-7] This technique requires an ultrasonographically guided injection of a small volume of ^{99m}Tc (either pertechnetate or ^{99m}Tc-mebrofenin) into the splenic parenchyma. In normal dogs, the radiopharmaceutical is rapidly absorbed in the splenic vein, emptied into the portal vein, reaching the liver first, and appearing in the heart thereafter with a delay of approximately 7 seconds.[5] Because of the much higher tracer absorption from the spleen compared with the colon (53% vs. 9% in a recent study),[5] TSPS requires a much smaller ^{99m}Tc dose and therefore decreased patient and personnel exposure compared with PRPS. TSPS is as sensitive and specific as PRPS for the detection of PSS, but, because it provides a nuclear angiogram and studies of consistently higher quality, it has the further advantage of enabling identification of the number and termination of shunting vessels.[8] The ability to differentiate between single and multiple shunts is especially important, because the latter are managed medically, while the former require surgical occlusion.[8] At the author's institution, TSPS has replaced PRPS, and since 2004 we have performed more than 700 TSPS studies with no significant complications and a rate on nondiagnostic studies (mostly because of leakage of tracer from the spleen into the peritoneum or nonabsorption) of <5%.

Technical Considerations

Either pertechnetate[5] or ^{99m}Tc-mebrofenin[7] can be used, at a dose of 0.5 to 2 mCi (18.5 to 74 MBq) in 0.2 to 0.5 mL volume. The animal is placed on the gamma camera in right lateral recumbency, and a dynamic acquisition at 4 frames/sec is started at the time of needle placement (22 G) in the splenic parenchyma.[5,7] If ^{99m}Tc-mebrofenin is used, a static right lateral image is also obtained 5 minutes after transsplenic injection.[7]

Interpretation

As mentioned previously, in normal dogs undergoing TSPS with pertechnetate, the radioactive bolus will be rapidly absorbed from the splenic injection site, outlining the splenic and portal veins, reaching the liver first, and being visible in the heart after an average delay of 7 seconds.[5] If the study is done using ^{99m}Tc-mebrofenin, the radiopharmaceutical will remain trapped within this organ as a result of the high first-pass extraction of this IDA compound by normal hepatocytes after it reaches the liver. From there it will be gradually cleared into the biliary system (Fig. 26-84).[7]

In dogs with macroscopic PSS, three patterns of uptake are easily distinguished. With portocaval shunts the radioactive bolus is transported in a linear fashion toward the caudal vena cava, entering the heart from its caudal aspect (Fig. 26-85). With portoazygos shunts, the bolus is transported dorsally, running parallel to the thoracic spine, and enters the heart from the craniodorsal aspect with a 90°

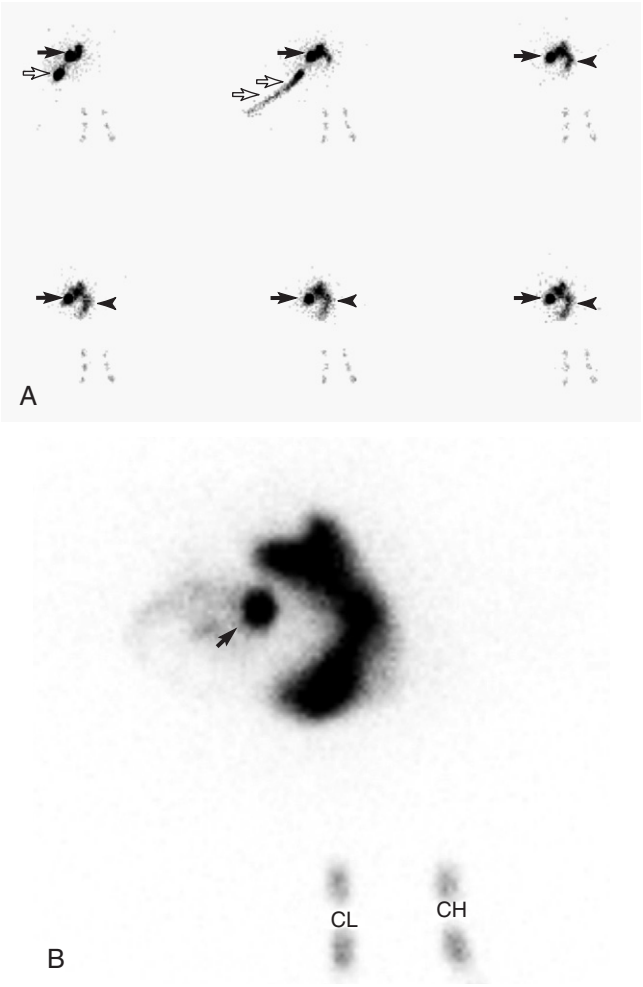

Figure 26-84 Right lateral reframed dynamic images, each representing 0.5 seconds of data (**A**) and a static 5-minute image (**B**) in a normal dog after transsplenic injection of ^{99m}Tc-mebrofenin. The *white arrows* indicate the tip of the syringe, which is removed on the second image. After injection into the spleen (*black arrow*) the radiopharmaceutical travels slightly dorsally, then curves ventrally and becomes trapped in the liver (*black arrowhead*). On the 5-minute image, there is no residual blood pool or cardiac activity, and only the liver and spleen are visible. The dotted area of activity ventral to the dog represent ^{57}Co markers, one placed ventral to the liver region (*CL*) and one ventral to the apex of the heart (*CH*).

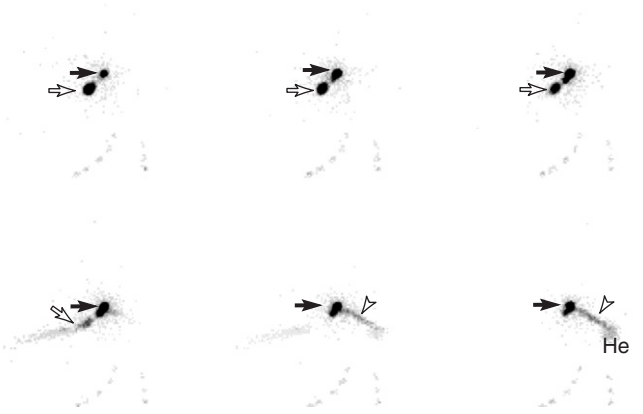

Figure 26-85 Right lateral reframed dynamic images, each representing 0.5 seconds of data, after transsplenic injection of ^{99m}Tc-mebrofenin in a dog with a splenocaval shunt. The *white arrows* indicate the tip of the syringe, which is removed on the fourth image. After injection into the spleen (*black arrows*), the radiopharmaceutical travels immediately cranioventrally (*white arrowhead*) entering the heart (*He*) from the caudal aspect.

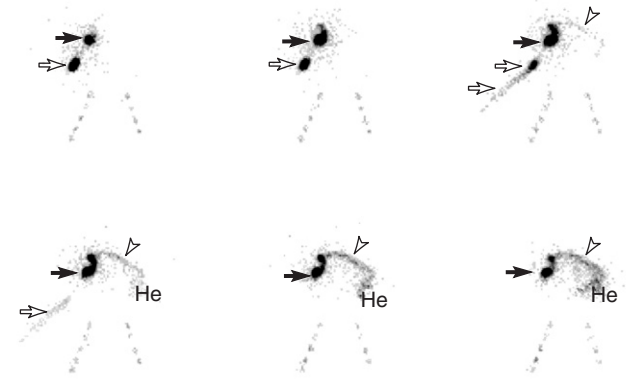

Figure 26-86 Right lateral reframed dynamic images, each representing 0.5 seconds of data, after transsplenic injection of ^{99m}Tc-mebrofenin in a dog with a portoazygos shunt. The *white arrows* indicate the tip of the syringe, which is removed on the fourth image. After injection into the spleen (*black arrows*) the radiopharmaceutical travels immediately dorsally, then cranially in a vessel along the dorsal aspect of the thorax (*white arrowhead*), and enters the heart (*He*) from the dorsal aspect with a 90° angle.

angle (Fig. 26-86). With internal thoracic shunts, the bolus is transported ventrally along the thorax and abdomen entering the cranial aspect of the heart.[6] Most multiple acquired shunts are easily identified because the bolus outlines a well-defined plexus of vessels in the mid to caudal abdomen (Fig. 26-87).[6,9] Not all multiple shunts, however, show this typical pattern, most likely because some acquired shunts are smaller than the limit of resolution of the gamma camera, and may therefore appear as a single vessel. A recent study found that a plexus of anomalous vessels was visible in 64% of cases of multiple acquired shunts, while hepatofugal flow caudal to the cranial margin of the kidneys was present in 93% of cases, indicating that the latter is the most reliable imaging feature in cases of multiple acquired shunts.[9]

^{99m}Tc-mebrofenin has two distinct advantages over pertechnetate. First, mebrofenin is actively extracted by the hepatocytes, and liver size and shape are more easily identified, compared with a study done with pertechnetate.[7] This is a useful characteristic in that it permits the accurate tracing of regions of interest (ROIs) over the liver and heart for determinations of shunt fraction (SF). Net hepatic and cardiac counts are calculated in the ROIs in a 7-second time frame (normal hepatic to cardiac transit time for TSPS), and SF is determined by calculating the ratio of cardiac counts to cardiac plus hepatic counts; normal mean SF with TSPS is 2.6%.[5] It is important to note that, other than confirming the presence of a PSS, SF values do not have any prognostic or predictive value.[1] A second advantage of ^{99m}Tc-mebrofenin is in the use and interpretation of the 5-minute static image. In a normal dog, this image will show activity limited to the normal-size liver, some residual activity at the site of splenic injection, but no blood pool or cardiac activity.[7] Animals with PSS, on the other hand, show variable amounts of blood pool and cardiac activity, as well as decreased hepatic volume.[7]

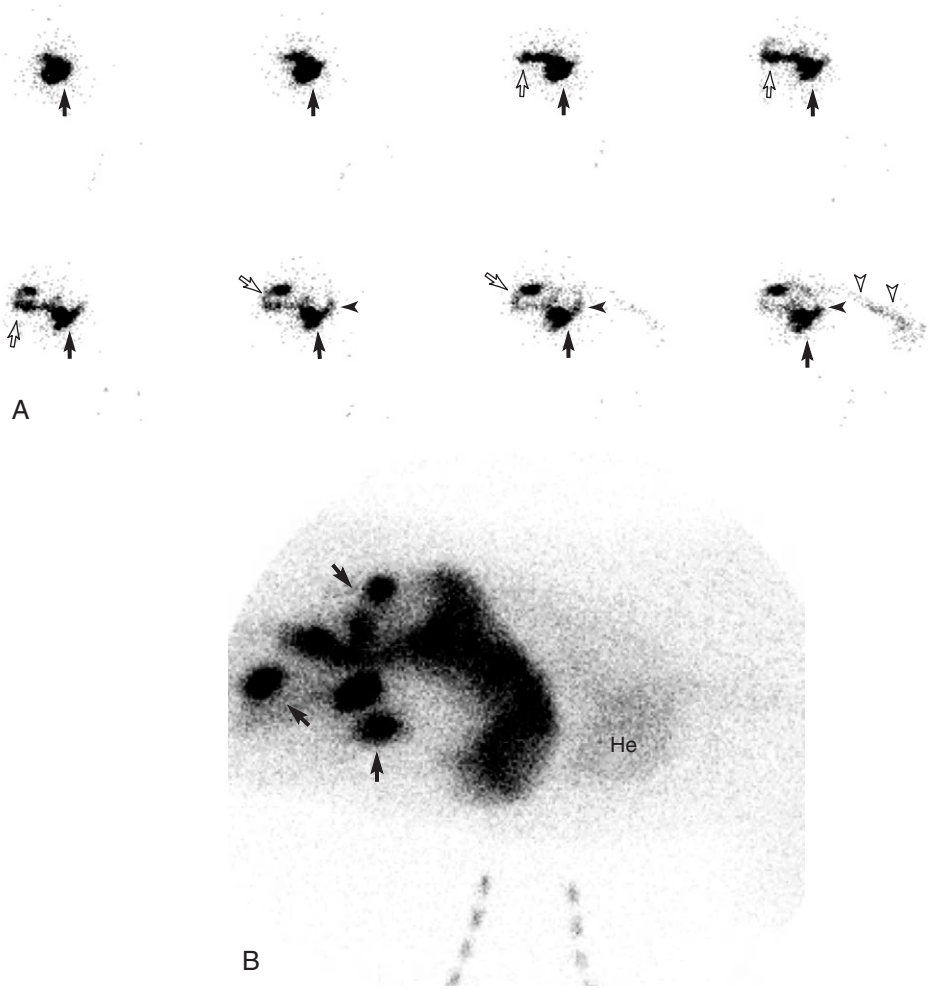

Figure 26-87 Right lateral reframed dynamic images, each representing 0.5 seconds of data (**A**) and a static 5-minute image (**B**) after transsplenic injection of ^{99m}Tc-mebrofenin in a dog with multiple acquired shunts. After injection into the spleen (*black arrows*) the radiopharmaceutical travels caudally with marked hepatofugal flow before curving in a cranial direction (*white arrows*); a second vessel travels from the injection site cranially and dorsally (*black arrowhead*). Activity from these two anomalous vessels enters the caudal vena cava (*white arrowheads*) bypassing the liver and reaching the heart from its caudal aspect. On the 5-minute image, there is moderate residual blood pool and cardiac (*He*) activity.

Animals with underlying hepatocellular disease but without macroscopic PSS will show persistent blood pool and cardiac activity, but the dynamic acquisition will have excluded a macroscopic PSS. They often show increased hepatic size and rounded liver margins.

Because TSPS requires injection into the spleen, some shunts originating distal to the splenic vein might not be identified using this technique, although this has not been the author's experience. The flow of the small volume of injected radiopharmaceutical likely occurs preferentially through the shunt. Furthermore, extrahepatic portosystemic shunts arise from the main portal, left gastric, or splenic veins, and empty into the caudal vena cava cranial to the phrenicoabdominal vein, and would not be missed with TSPS.[5]

Gastrointestinal Bleeding

Principles, Indications, and Radiopharmaceuticals

Scintigraphy can be used to document gastrointestinal bleeding, by detecting the accumulation of either ^{99m}Tc-sulfur colloid or ^{99m}Tc-labeled red blood cells (^{99m}Tc-RBCs) into the gastrointestinal tract lumen.[12-14,17] The technique does however have two limitations. It does not accurately localize the precise anatomic site of bleeding, and active bleeding must be present at the time of the imaging procedure.[12] ^{99m}Tc-sulfur colloid is more sensitive to small volumes of blood loss (down to rates of 0.1 mL/min) because of the absence of background activity. ^{99m}Tc-RBCs require greater rates (3 mL/min) because of the presence of higher background activity, but allows delayed imaging at 24 hours postinjection when labeled red blood cells (RBCs) can be more readily identified in the colon.[12,13]

Technical Considerations

For both radiopharmaceuticals, a dose of 5 to 20 mCi (185 to 740 MBq) is injected intravenously and static lateral and ventral images are acquired at 0, 5, 15, and 30 minutes. For ^{99m}Tc-RBCs, additional images are obtained every 30 minutes for 4 hours, followed by a final set of images at 24 hours.[12] Two methods, in vivo and in vitro, for labeling RBCs are available.[12,14] The in vivo method is easy, quick, and requires only an IV injection of stannous chloride followed by pertechnetate.[14] Despite these advantages, the in vivo method yields a comparatively low labeling efficiency of approximately 90%. The

in vitro method requires collection and incubation of the patient's RBCs, which are reinjected into the patient after the labeling process is completed. Although more time-consuming, the in vitro method yields labeling efficiency of greater than 98%, thereby minimizing background activity.[12]

Interpretation

Gastric, intestinal, or colonic radioactivity is indicative of gastrointestinal hemorrhage (Fig. 26-88).[12,14]

Pancreas

Leukocytes labeled using ^{111}In-oxine, ^{111}In-tropolone, or ^{99m}Tc-hexamethylpropyleneamine oxime (^{99m}Tc-HMPAO) can be used to image inflammation. ^{99m}Tc-HMPAO-labeled granulocytes have been used in one confirmed case of feline pancreatitis.[16] Although in normal cats there is no visible accumulation of ^{99m}Tc-HMPAO in the region of the pancreas,[15] progressive radiopharmaceutical uptake, first visible at 2 hours, most intense at 4 hours, and persisting at 17 hours postinjection,[16] was documented in one case of pancreatitis. The time-consuming procedure to label feline granulocytes and the variable labeling efficiency of ^{99m}Tc-HMPAO (15% to 42%) have been limiting factors for the clinical use of this technique, and this diagnostic test would be most useful for research purposes rather than for routine clinical cases of suspected feline pancreatitis.

Esophageal Motility and Gastric Emptying Studies

Esophageal transit and gastric emptying times (solid and liquid phases) can be quantified using scintigraphy with radiolabeled meals or liquids.[12] Because of the broad range of normal values and the variable protocols reported in the literature, the usefulness of these studies is generally limited to research settings. The best clinical application of scintigraphic motility studies is perhaps when serial studies are performed on the same animal, as a tool to monitor response to therapy.[12]

Figure 26-88 Left lateral and ventral views of a dog 20 hours after IV injection of ^{99m}Tc-RBCs. There is abnormal activity in a linear structure in the caudodorsal abdomen (*black arrow*) consistent with colon, indicating that the study is positive for GI blood loss. Activity is also present in the urinary bladder (*white arrowhead*), because of dissociation of ^{99m}Tc from the erythrocytes.

COMPUTED TOMOGRAPHY/MAGNETIC RESONANCE IMAGING

Travis C. Saveraid

The clinical use of CT and MRI in companion animal diagnosis has increased dramatically in the last decade. CT and MR scanners are now available at nearly all academic hospitals and many specialty centers. However there are still relatively few studies describing the clinical use of CT or MRI in the medical investigation of hepatobiliary, pancreatic, and gastrointestinal tract diseases. The majority of publications are restricted to single case reports or descriptions of normal anatomy.[1-6] CT and MR imaging studies of the abdomen in general, and the hepatobiliary, pancreatic, and gastrointestinal systems in particular are poised to become increasingly relevant imaging tools in the next 5 to 10 years.

Advantages

CT and MRI allow complete visualization of organs of interest and adjacent regional structures without the visual obstructions prevalent with radiographs and US images. Both modalities allow for multiplanar display of the anatomy of interest. Because of superior anatomic resolution, normal and abnormal anatomic structures are more intuitively obvious even to the inexperienced observer. In addition, both modalities can be used for dynamic functional assessment of organs and vessels through various contrast (CT and MRI) and advanced imaging techniques (MRI).

Disadvantages

Two significant disadvantages to CT and MRI are the requirement for general anesthesia and the cost of higher technology compared with other imaging modalities. In many situations, however, general anesthesia may be a benefit as it allows for greater control of the patient's respiration and decreases gastrointestinal movement. Patient immobility improves cranial abdominal imaging studies. With the advent of more advanced multidetector CT scanners, the speed of image acquisition may obviate the need for general anesthesia and heavy sedation protocols may prove sufficient in the future.

CT and MRI have higher capital expense costs and exam charges will likely always be higher than for other imaging studies, but when appropriately used, a CT or MRI study may save the cost of multiple less-definitive diagnostic tests. Continuous improvements in computer hardware and the introduction of newer technologies have created an active secondary market of refurbished systems more economically competitive for the veterinary market.

A more insidious disadvantage is the lack of understanding and interpretation of CT and MR images. Clinicians often need confidence building in a new imaging method before recommending a more expensive diagnostic test. In that regard, there is a general perception of higher comfort level with CT imaging as it is a technology that is loosely based on x-ray technology. MR image interpretation is not necessarily more difficult than that of CT images,

but MRI physics is based on detection of protons in a magnetic field, and is unique from other imaging modalities. Despite a number of advantages of MRI in certain situations, many clinicians continue to choose traditional imaging methods because of their discomfort with newer technologies.

Methods and Techniques

Because of the great technical variation in CT and MR systems available to veterinary medicine, detailed specific protocols for imaging the hepatobiliary, pancreatic, and gastrointestinal systems are beyond the scope of this book. Generally speaking, for abdominal imaging, faster scanning techniques combined with respiratory pause methods are ideal. Respiratory pause methods include hyperventilation prior to scanning, controlled ventilation (e.g., breath holding), or controlled ventilation combined with pharmacologic paralysis. Faster scanning techniques can be accomplished in a variety of ways depending on the modality system but may include adjustments to the slice thickness (CT and MR), pitch (CT), sequence selection (MR), phase-encoding steps (MR), parallel imaging (MR), or scanning smaller selected regions of interest (CT and MR).

Computed Tomography

Specific protocols vary depending on the scanner type and regions of interest. Single-detector/single-slice systems with and without helical option or multidetector/multislice systems are now widely used in academic and specialty hospitals. With single-slice scanners, 3- to 5-mm transverse slices with overlap in image reconstruction are usually adequate for the liver, pancreas, gastrointestinal tract, and abdominal vasculature. With multidetector systems, slice thickness and acquisition times can be greatly reduced with significant improvements in spatial and temporal resolution. Many of the multidetector systems can scan and reconstruct images using isotropic voxels allowing for pixel-perfect multiplanar reconstructions (MPRs). Pixelated MPRs with poor image resolution have historically been a detriment for CT studies as compared with the native multiplanar acquisition methods of MRI. With improved multidetector CT technologies, MPRs have greatly improved. Viewing CT images in the original transverse and multiplanar reconstructions are essential for complete evaluation of the study.

Early studies of the utility of abdominal CT focused primarily on CT angiography (CTA). Single-phase and dual-phase (arterial and venous) angiographic techniques have been successfully applied in the examination of the portal, hepatic, and pancreatic vasculatures.[6-10] The timing of the contrast injection is a critical part of this exam. Newer CT systems with dynamic bolus tracking technology have simplified this process. A new contrast injection and angiography technique has shown great promise in providing sustained contrast within the arterial and venous vasculature for the duration of the angiography study regardless of patient size.[11]

Magnetic Resonance Imaging

With MRI studies of the abdomen, particularly of the liver, pancreas, and gastrointestinal tract, multiple planes should always be employed. These planes should include at least one sequence in all three of the standard planes: sagittal, dorsal, and transverse. Dorsal plane and transverse plane images are the most commonly used. Dorsal plane images have the distinct advantage of providing a larger field of view per unit acquisition time thereby facilitating more rapid imaging and initial anatomy interrogation compared with transverse images. Sagittal plane images have similar advantages and can be used if preferable. Once appropriate anatomy or lesions of interest are identified with dorsal plane images, transverse images of the region of interest are then prescribed. While the field of view can be focused over the area of interest, for example, liver or pancreas, the images will typically encompass the cranial half of the abdomen when evaluating for pancreatic and hepatobiliary disease. General sequences for abdominal imaging include T2-weighted and T1-weighted pre- and postcontrast with fat saturation techniques applied on at least one of the postcontrast planes. If fat saturation is ineffective or unreliable, additional short tau inversion recovery (STIR) sequences will be necessary. Many scanners can take advantage of more rapid imaging methods such as three-dimensional (3D) volumetric acquisition, variations of gradient recalled echo (GRE) and echo planar sequences, and parallel imaging techniques, to create sequences, which rapidly cover the region of interest and avoid respiratory motion artifacts. Higher field scanners (1 Tesla and greater) have superior fat-saturation techniques compared with low-field scanners. When using a high-field scanner the author prefers using a T2-weighted sequence with fat saturation in at least the dorsal plane, followed by a T2-weighted transverse sequence and T1-weighted pre- and postcontrast sequences in the area of interest.

Similar to advances with CT angiography of the portal and hepatic vasculature, high-field MR systems can create excellent vascular roadmaps of the abdomen. An early MR angiographic technique called two-dimensional (2D) time-of-flight was used successfully to characterize canine portal vasculature and portosystemic shunting.[12,13] More recently, a faster, more robust, and technically easier method of multiphase time-resolved contrast-enhanced MR angiography (CE-MRA), has been used to characterize normal and abnormal portal and hepatic vasculature.[14,15]

Indications

Under ideal circumstances, a lesion or abnormality would be identified with more common imaging methods such as radiography or ultrasound, and then CT and/or MRI could be used for greater clarification, narrowing the list of differential diagnoses, or establishing a specific imaging diagnosis. Where appropriate, multiple imaging tests are preferable, but often not feasible because of escalating cost to the client. The clinician is then faced with the difficult question of selecting one or two imaging modalities that will best reveal the clinical diagnosis (Boxes 26-1 and 26-2).

In the author's opinion, if abdominal imaging beyond radiography is required for evaluation of a mass, metastasis, intraabdominal vasculature, or preoperative planning in canine patients weighing more than 50 lbs (23 kg), the clinician should strongly consider the use of CT or MRI rather than abdominal ultrasound. A recent abstract supports this opinion when comparing helical CT versus US.[16] In ultrasonography exams, the ultrasonographer must make simultaneous interpretation while dealing with the challenges of gastrointestinal gas, limited patient cooperation, near and far field artifacts, and demanding, repetitive physical actions. Detailed evaluation of dorsal liver regions, complete biliary system, entire pancreas, and entire gastrointestinal tract is vastly improved and less distracting in CT and MRI exams compared with US. In situations where fine-needle aspiration or needle core biopsy is required after CT or MRI, US can be employed for rapid, guided sampling.

Box 26-1 Conditions for Which CT or MRI Should Be Considered Instead of Ultrasound for the Evaluation of Hepatobiliary, Pancreatic, or Gastrointestinal Disease

- Patient weighs more than 50 lbs (23 kg)
- Evaluation for portosystemic shunt (PSS)
- Investigation of non-PSS vascular lesions such as arteriovenous shunts, other anomalous vessels, and mesenteric vessels
- Determination of the dynamic contrast enhancement of a mass
- Evaluation of entire GI tract
- Patient with excessive GI gas on radiographs
- Surgical assessment of known large masses including involvement of regional vasculature
- Assessment for anatomic extent of a mass including metastases

Box 26-2 Preferences for CT Versus MRI in the Imaging of Hepatobiliary, Pancreatic, and Gastrointestinal Disease

CT preferred
- Primary GI tract evaluation, especially if extensive gas is present or a perforation is suspected
- When rapid results are required, such as in a sedated patient or critical care patient unstable for anesthesia

MRI preferred
- Evaluation of primary neoplasia or other known mass, especially in the liver
- Assessment for metastatic neoplasia, especially in the liver
- Investigation of regional inflammatory disease, such as pancreatitis with adjacent peritonitis

Either CT or MRI
- Angiography for portosystemic shunt evaluation
- Angiography for hepatic, pancreatic, or mesenteric vessels

*Assuming a high field (1 Tesla or greater) MR system.

Hepatobiliary Computed Tomography and Magnetic Resonance Imaging

MRI allows for highly accurate differentiation of benign and malignant neoplasia of the liver.[17] Evaluation of hepatic masses with multiple sequence types and pre- and postcontrast sequences permits more specific clarification and easier surgical planning, particularly with regard to the location and involvement of the main hepatic vasculature (Fig. 26-89). In human medicine, MRI is considered superior to CT for detection of focal liver lesions. In veterinary medicine, MRI and CT have been used for the evaluation of primary and metastatic hepatic lesions.[12,17,18] CT is an excellent method for the assessment of liver volume before and after correction of portosystemic shunting.[19,20] Preliminary MR studies showed that it underestimates liver volume compared with CT, but these studies were likely limited by magnet field strength. Clinical imaging of the gallbladder and biliary tract has not yet been described. Anecdotally, both modalities provide excellent visualization of the gallbladder wall, cholecystoliths, and the common bile duct, although MRI has superior tissue contrast.

Pancreatic Computed Tomography and Magnetic Resonance Imaging

CT has been used for the evaluation of pancreatitis in both dogs and cats.[21-24] However in two separate feline studies, in which patients had a definitive diagnosis of pancreatitis, only 20% had lesions consistent with pancreatitis on CT examination.[21,22] In a case report of two dogs with acute pancreatitis, contrast-enhanced CT identified changes of pancreatitis, central regions of necrosis, and sites of regional vascular thrombosis.[24] Evaluation of the pancreas for endocrine neoplasia, specifically insulinomas,[23-25] has been described several times but there are no case series describing CT or MRI findings of pancreatic exocrine neoplasia.[25-27] Evaluation of the normal pancreatic vasculature has been reported using dual-phase CTA.[1] In practical use, the entire pancreas is more consistently visible on CT and MRI than with US.

Intestinal Computed Tomography and Magnetic Resonance Imaging

The use of MRI to evaluate intestinal disease has not yet been reported in companion animal medicine, but CT has been used as a primary or ancillary imaging technique to evaluate suspected intestinal or peri-intestinal lesions.[28-30] In a recent case series of intrapelvic masses identified with CT, four of 14 masses were identified with imaging characteristics strongly supportive of benign intramural neoplasia of the colonic wall and were subsequently histopathologically proven as leiomyomas.[29] Anecdotally, CT has also been used in the evaluation of gastric masses and intestinal masses and intestinal foreign bodies. Imaging of the intestinal tract with CT, and especially MRI, is likely underused and underreported. Intestinal wall imaging using CT and MRI for mural infiltrates or mural masses is increasingly reported in the medical literature.[31-35] Identification of intestinal foreign bodies and mesenteric vascular disease using CT is also described.[35-39]

In veterinary medicine, there are many unexplored uses for CT and MR in intestinal tract evaluation, particularly in the mid and distal small intestine, for infiltrative disease, focal masses, intestinal foreign bodies, and mesenteric vascular disease. The use of general anesthesia in veterinary patients will be beneficial to imaging of the gastrointestinal tract because of decreased motion and the opportunity for instillation of gastrointestinal contrast via orogastric or orointestinal deposition for optimal distention (enteroclysis). CT or MR enteroclysis or enterography has not been published in veterinary medicine but has potential for future application in intestinal imaging.

Angiography of the Hepatic and Portal Vascular System

The most commonly reported use of CT and MR in the abdomen has been in the CT and MR angiographic evaluation of the hepatic and the portal vascular systems. CTA and MRA have a high success rate at finding extrahepatic versus intrahepatic shunting, single versus multiple shunts, and areas of arterial venous fistulas (Fig. 26-90).[7,9,10,13,14,40-42] CTA and MRA provide a vascular roadmap allowing for more rapid and precise surgical intervention. One of the great strengths of CTA and MRA is the ability to identify not only single versus multiple shunts, but also the end location of the shunting vessel. This is particularly important for left gastric shunts as they frequently pass dorsal to the stomach and liver and then course ventrally ending in the caudal vena cava immediately prior to passage through the diaphragm. The terminus of these shunts is difficult to identify with ultrasound or during surgery. Depending on the availability of the type of CT or MR system, both systems have

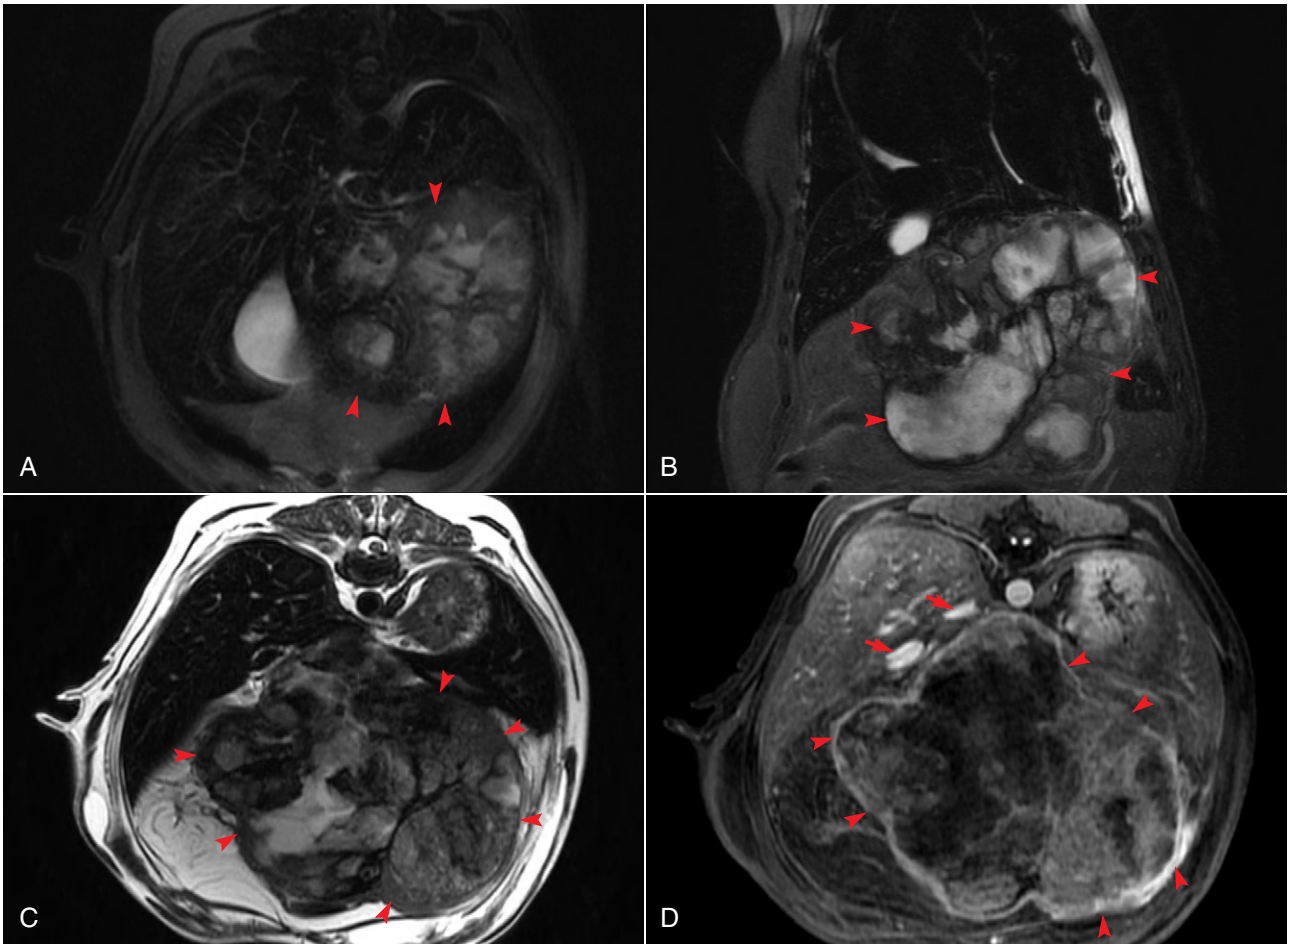

Figure 26-89 Transverse and dorsal plane MR images at the level of the mid liver. The images were acquired on a high-field scanner. A 12-year-old male neutered, mixed breed dog was positioned in dorsal recumbency. **A,** Transverse T2-weighted with fat saturation; **B,** dorsal T2-weighted with fat saturation; **C,** transverse T2-weighted; **D,** transverse spoiled gradient recalled echo (SPGR) early after IV gadolinium contrast. The *arrowheads* outline a large hepatocellular carcinoma with chaotic internal architecture. The gallbladder and the majority of the normal liver are displaced cranially. Postcontrast images show early peripheral contrast enhancement and large, central, nonvascularized regions. The *arrows* on the postcontrast image show the displacement and compression of the portal vein and caudal vena cava.

Figure 26-90 Oblique sagittal plane, maximal intensity projection CT angiography image of the cranial abdomen of a 1.5-year-old, spayed female Shih Tzu positioned in ventral recumbency. The *arrows* depict a single, large, portoazygos vascular shunt. The *arrowheads* outline the small liver. Multiple other major abdominal vessels, such as the aorta, celiac artery, and cranial mesenteric artery are also easily visualized.

been used to create high-resolution, relatively rapid images (less than 15 minutes total study time) of the abdominal vasculature. Multidetector helical CT is preferable to single-source helical for these studies. MRA is best performed with a high-field system. Low-field systems, generally 0.3 Tesla or smaller, are incapable of creating an adequate abdominal angiographic study. In the author's opinion, if there is access to a capable CT scanner or high-field MRI system, these imaging systems are the best choice for verification and identification of suspected portosystemic shunts.

ASSESSMENT OF GASTROINTESTINAL MOTILITY

Robert Washabau

Disorders of Gastrointestinal Motility

Disorders of gastrointestinal motility represent a diagnostic and therapeutic challenge. Gastrointestinal motility disorders may result in delayed transit, accelerated transit, impaired relaxation, or inappropriate relaxation.[1] The delayed transit disorders are the most

important motility disorders of companion animals and may involve the esophagus (e.g., idiopathic megaesophagus), stomach (e.g., delayed gastric emptying), small intestine (e.g., ileus or pseudoobstruction), or colon (e.g., constipation) independently, or as a more generalized and diffuse gastrointestinal motility disorder (e.g., dysautonomia).[2]

Idiopathic Megaesophagus

Idiopathic megaesophagus is the most common form of regurgitation in the dog. The disorder is characterized by esophageal hypomotility and dilation, progressive regurgitation, and loss of body condition. Several forms of the syndrome have been characterized, including congenital, acquired secondary, and acquired idiopathic megaesophagus.[2-4]

Gastric-Emptying Disorders

Gastric-emptying disorders are fairly common in dogs and cats and are an important cause of nausea and vomiting. Primary conditions that have been associated with delayed gastric emptying include infectious and inflammatory disease (e.g., inflammatory bowel disease [IBD]), ulcer, and postsurgical gastroparesis, while secondary conditions include electrolyte disturbances, metabolic disorders, concurrent drug usage (cholinergic antagonists, adrenergic agonists, opioid agonists), acute stress, and acute abdominal inflammation.[5] Recovery from gastric dilation volvulus (GDV) is almost always associated with significant myoelectrical and motor abnormalities in the dog.[6]

Small Intestinal Transit Disorders

Several small intestinal transit disorders have been described in the dog and cat, including IBD, postsurgical pseudoobstruction, nematode infection, intestinal sclerosis, and radiation enteritis.[2] Vomiting and diarrhea are the most important clinical signs associated with these disorders. Dysbiosis of small intestinal bacteria, a common sequela to disordered motility, may contribute to these clinical signs.

Colonic Motility Disorders

Constipation, obstipation, and megacolon are primarily disorders of the domestic cat.[2,7,8] An extensive list of differential diagnoses (e.g., neuromuscular, mechanical, inflammatory, metabolic, endocrine, pharmacologic, environmental, and behavioral causes) has been proposed, but most (>96%) cases are accounted for by idiopathic megacolon (62%), pelvic canal stenosis (23%), nerve injury (6%), or Manx sacral spinal cord deformity (5%).[7]

Dysautonomia

Dysautonomia is a generalized autonomic neuropathy that was originally reported in cats in the United Kingdom, but that has now been documented in dogs and cats throughout Western Europe and the United States. The clinical signs reflect a generalized autonomic dysfunction, including megaesophagus and esophageal hypomotility, gastric dilation and delayed gastric emptying, ileus and intestinal pseudoobstruction, and megacolon and obstipation.[4,9]

Methods for Measuring Gastrointestinal Motility

Methods available for the evaluation of gastrointestinal motility include (a) radiography—survey, barium contrast, and radiopaque-indigestible solids (e.g., barium-impregnated polyethylene spheres [BIPSs]); (b) quantitative videofluoroscopy; (c) ultrasonography; (d) nuclear scintigraphic imaging; (e) tracer studies; (f) manometry; and (g) functional MRI (Table 26-2).

Survey Radiography

Survey abdominal radiography provides very little information about GI motility, but it is the imaging technique of choice in the initial assessment of any gastrointestinal disorder. Survey radiographs are useful in providing information about gastrointestinal tract position and content that may help to delineate mechanical obstruction from functional motility disorders. Survey radiographs are also helpful in determining the size and shape of other abdominal organs (e.g., spleen, liver, biliary tract, and urogenital tract) and their relationship to the gastrointestinal tract.

Contrast Radiography

Liquid Barium

Barium-contrast radiography is often used in clinical practice to detect gross abnormalities of esophageal peristalsis, gastric emptying (Table 26-3), intestinal transit (Table 26-4), and colonic motility, but the technique does have some distinct limitations.[10,11] In gastric-emptying studies, for example, gastric emptying of a radionuclide was markedly delayed in a group of dogs with pyloric hypertrophy although liquid emptying of barium was thought to be normal.[12] Similarly, the barium-swallow technique used to assess esophageal

	–	–	3.5 h	Liquid barium	Radiography	dog	44

50% GET, 50% gastric-emptying time, or the time it takes to empty 50% of the ingested/fed meal; 95% GET, 95% gastric- emptying time; 100% GET, 100% gastric emptying time; BIPSs, barium-impregnated polyethylene spheres.

Table 26-4 Orocecal Transit Times in Dogs and Cats

OCTT	Substrate	Method	Species	Reference
3.4 ± 0.75 h	Mashed potatoes	Sulfapyridine transit	Dog	24
3.7 ± 0.9 h	Dog food	Sulfapyridine transit	Dog	45
3.0 ± 0.9 h	Dog food	Sulfasalazine transit	Dog	25
2.3 ± 0.8 h	Dog food	Breath H_2 excretion	Dog	25
1.6 ± 0.4 h	Lactulose	Breath H_2 excretion	Cat	46
2.8 ± 0.34 h	Cat food	1.5 mm BIPSs	Cat	19
3.0 ± 0.23 h	Cat food	1.5 mm BIPSs	Cat	47

BIPSs, Barium impregnated polyethylene spheres; OCTT, orocecal transit time is the time taken from the oral administration of the test meal to the time when the first portion of the meal reaches the colon.

peristalsis provides only a qualitative assessment unless it can be coupled with quantitative videofluoroscopy.[13,14] The latter technique requires sophisticated equipment and computer software that are generally not available in most clinical practices. Barium enema is now rarely performed in clinical practice, and has been superseded by other imaging techniques. In general, liquid barium studies will be useful only in documenting gross abnormalities of gastrointestinal motility.

Barium Meal

Esophageal peristalsis, gastric emptying (see Table 26-3), and intestinal transit (see Table 26-4) are affected by the physical properties of the meal (solid vs. liquid), size of the ingested particles (large vs. small), and chemical composition (lipids vs. proteins vs. carbohydrates)[5,15]; consequently, barium mixed with food is thought to be a better contrast agent for the determination of gastrointestinal transit. Despite this, barium can dissociate from the food and redistribute into the liquid phase of the ingested meal, which likely accounts for the wide variability in reported transit times. For example, the gastric-emptying time of ground kibble (8 g/kg) mixed with barium sulfate suspension (5 to 7 mL/kg) was reported in the range of 5 to 10 hours in mature Beagles,[16] while total gastric-emptying time ranged from 7 to 15 hours in another study.[17] As with liquid barium studies, GI motility disorders can be diagnosed only if the transit/emptying times are markedly prolonged.

Barium-Impregnated Polyethylene Spheres

Small, indigestible radiopaque markers such as BIPSs have been used to quantitate gastric emptying (see Table 26-3) and intestinal transit times (see Table 26-4) in dogs and cats.[18,19] BIPSs are administered in food as recommended in the manufacturer's package insert, and

two to four abdominal radiographs are taken at convenient intervals over the next 13 to 24 hours.[18,19] The percentage of BIPSs that have transited the stomach and intestine is calculated and compared with standard emptying and transit curves (provided in the manufacturer's package insert). Unfortunately, interpretation of BIPSs emptying and transit data has some of the same limitations as liquid barium and barium meal studies. However because of the widespread availability of radiographic equipment and practitioner expertise, radiographic methods employing liquid barium, barium meal, or BIPSs will continue to be the methods of choice for most practitioners.

Ultrasonography

Ultrasonographic equipment is now more widely available in veterinary practice, and recent studies suggest that US may be a useful noninvasive method for quantitative assessment of gastric emptying (see Table 26-3) in dogs and cats.[15,20] In healthy dogs fed a solid meal labeled with ^{13}C-octanoic acid, there was a strong correlation between the rate of solid-phase gastric emptying assessed by use of gastric emptying ultrasonography and the ^{13}C-OBT (carbon 13-labeled octanoic acid breath test) in dogs.[21] Further research is necessary to validate this method against nuclear scintigraphic imaging and to describe reference ranges for healthy and diseased animals.

Nuclear Scintigraphy

Nuclear scintigraphic imaging is a very effective means of evaluating gastrointestinal motility and is now considered to be the standard method of assessment.[12,15,21-23] ^{99m}Technetium (bound to sulfur or albumin colloid, disofenin, or mebrofenin) and ^{111}indium (bound to diethylene triamine pentaacetic acid [DPTA]) are the radioisotopes most widely used because they are safe, simple to use, and nonabsorbable. Two radionuclide markers can be tracked simultaneously, which allows solid and liquid emptying to be assessed during the same test period. Animals are fasted for 12 to 24 hours after which a test meal is fed incorporating one or two radioisotopes. Left lateral, right lateral, and ventral images are acquired with a gamma camera and integrated nuclear medicine computer system. Gastric, intestinal, and/or colonic regions of interest are identified, and the radioactive counts in these regions are recorded, usually at regular intervals for 6 to 9 hours (gastric emptying), 12 to 24 hours (intestinal transit), or 24 to 36 hours (colonic transit). The expense, limited availability, and radiation hazards associated with this method have limited its widespread clinical application in dogs and cats.

Tracer Studies

Several kinds of tracer studies, including gastric, plasma, and breath tracers, have been developed for the assessment of gastric emptying and/or intestinal transit (see Tables 26-3 and 26-4).

Gastric

Gastric tracer studies involve the serial aspiration of gastric contents after administration in food or by gastric intubation of a known concentration of a nonabsorbable marker substance.[15] Chromium oxide, polyethylene glycol, and phenol red have all been used to assess solid- (chromium oxide) or liquid-phase (polyethylene glycol or phenol red) gastric emptying. The invasive nature of this method precludes its use in anything other than the research setting.

Plasma

Plasma tracer studies take advantage of the site-specific absorption of orally administered drugs following gastric emptying (acetaminophen) or orocecal transit (sulfasalazine). Acetaminophen is poorly absorbed in the stomach and rapidly absorbed in the duodenum, and the appearance of acetaminophen in plasma therefore reflects the gastric-emptying time of acetaminophen.[15] Sulfasalazine is a compound molecule of sulfapyridine and 5-aminosalicylate linked in an azo chemical bond. After oral dosing, most of the sulfasalazine is transported unmetabolized to the distal GI tract where cecal and colonic bacteria metabolize the drug to its component parts. Sulfapyridine is largely absorbed by the colonic mucosa but much of the 5-aminosalicylate remains in the colonic lumen where it inhibits mucosal cyclooxygenase and the inflammatory cascade. The appearance of sulfapyridine in plasma therefore reflects the orocecal transit time of sulfasalazine. Acetaminophen and sulfasalazine plasma tracer studies have been validated in the dog,[15,24,25] but there are no published studies comparing animals in health versus disease. Breath tracer studies take advantage of the site-specific absorption of orally administered compounds following gastric emptying (^{13}C-octanoic acid), or of the site-specific fermentation (molecular hydrogen [H_2] generation) of orally ingested food or carbohydrate following orocecal transit. Both can be detected in expired breath, one reflecting gastric emptying time (^{13}C), the other representing orocecal transit time (H_2). The ^{13}C-OBT has been validated as a measure of solid phase gastric emptying in the dog, but there are no published studies comparing animals in health versus disease.[21] The H_2 breath test has been validated as a measure of orocecal transit time in both dogs and cats.[25]

Manometry

Manometry will have limited application in the diagnosis of cricoesophageal and gastroesophageal achalasia, gastroesophageal reflux, and aganglionic megacolon (Hirschsprung disease),[26] but this technique is currently only performed at major referral centers and university teaching hospitals.

Functional Magnetic Resonance Imaging

Functional MRI has been used to quantitate gastric emptying in humans,[27] but this technique has not yet been validated in the dog or cat. Future MRI usage will likely be limited by expense and necessity for access to specialized equipment.

CHAPTER 27

Endoscopy

ENDOSCOPIC INSTRUMENTATION

Christopher J. Chamness

Overview of Endoscopy Systems

Endoscopy is a medical procedure that permits the clinician to examine internal structure and to perform diagnostic and therapeutic procedures in a minimally invasive manner. The term *endoscope* originally referred to first-generation flexible gastroscopes, which were also used for upper and lower gastrointestinal (GI) endoscopy, as well as bronchoscopy, in larger patients. The term *endoscope* now refers to all sizes and styles of optical instruments used for internal exams, including both rigid and flexible gastroscopes, bronchoscopes, cystoscopes, arthroscopes, laparoscopes, and otoscopes.

A basic endoscope system typically consists of the endoscope, light source, air pump, video camera (or camera processor), and video monitor. Although it is possible to perform endoscopy without a camera and monitor, the current availability, advantages, and superiority of video systems have rendered fiberscopes and their eyepieces much less popular. The endoscope, light source, camera, and monitor comprise the "imaging chain," which is ultimately responsible for creating the image viewed on the monitor. All of the components contribute to the displayed image, whose quality can only be as good as the weakest link in the chain.

Figure 27-1 illustrates a simple gastrointestinal endoscope "tower." A mobile cart improves portability and accessibility, and should be capable of accommodating all of the components of the endoscope system. Much of the equipment (e.g., light source, camera, monitor) can be used for other endoscopic applications including arthroscopy, laparoscopy, cystoscopy, bronchoscopy, and video otoscopy.

In addition to the components of the imaging chain, the following equipment will be required for a state-of-the-art gastrointestinal endoscopy program:

- Suction pump;
- Biopsy devices, foreign-body retrieval devices, cytology brushes, and balloon dilators; and
- An image-capture system or printer for documentation of findings (optional).

Flexible Gastrointestinal Endoscopes

Not all flexible endoscopes are suitable for gastrointestinal endoscopy. The following features of a gastrointestinal endoscope are essential for the successful imaging of the GI tract:

- Four-way tip deflection (up, down, left, and right);
- At least 180° deflection in the up direction;
- Insufflation, to distend the gastrointestinal tract;
- Irrigation, to clean the distal lens or gastrointestinal mucosa; and
- Suction, to remove air and fluid.

A typical gastrointestinal endoscope consists of three main components: the hand piece, the insertion tube, and the umbilical cord (Fig. 27-2).

Endoscope Hand Piece

The hand piece is held in the left hand as shown in Figure 27-3. The index and middle fingers of the left hand control the suction and air/water valves. Fully depressing the suction or air/water valves will activate suction or irrigation (lens cleaning), respectively. Insufflation is activated by simply covering the hole in the top of the air/water valve using either the index or middle finger. The left thumb is used to control one or both deflection control knobs, which cause the bending motion of the insertion tube. The right hand is used to advance the insertion tube and to turn the deflection control knobs when the left thumb cannot easily reach them.

Each of the deflection control knobs has a lock mechanism, which will secure the tip deflection in a fixed position. These locks may be useful when a lesion or structure is located and the examiner wishes to fix the deflected tip position for a period of time while performing the examination or recording images. In the author's experience, most veterinarians rarely use these locks, and it is important to remember not to attempt to deflect the tip while the locks are engaged.

The hand piece also contains the inlet to the instrument channel, which is contiguous with the suction channel. When not in use, the channel inlet is kept closed with an airtight cap, so that air cannot escape or enter under the pressure of insufflation or when applying suction.

Some video endoscope hand pieces also contain buttons to control some of the electronic features such as image capture, white balance, light intensity, freeze frame, picture-in-picture, and electronic zoom.

Figure 27-1 A gastrointestinal endoscope tower including (*top to bottom*) monitor, camera processor, light source, and digital capture system.

Endoscope Insertion Tube

The insertion tube is the portion of the endoscope that goes into the patient. The tube is marked with 10-cm gradations that indicate the depth of penetration of the tube inside the patient. The insertion tube should be handled with care, as it is prone to damage for the following reasons:

- It contains glass fiber bundles and should not be crushed or excessively bent.
- It can be bitten by the patient if an oral speculum is not securely in place.
- Instruments passed through the channel may cause damage with excessive force.

Figure 27-3 Recommended position of video endoscope handle in left hand.

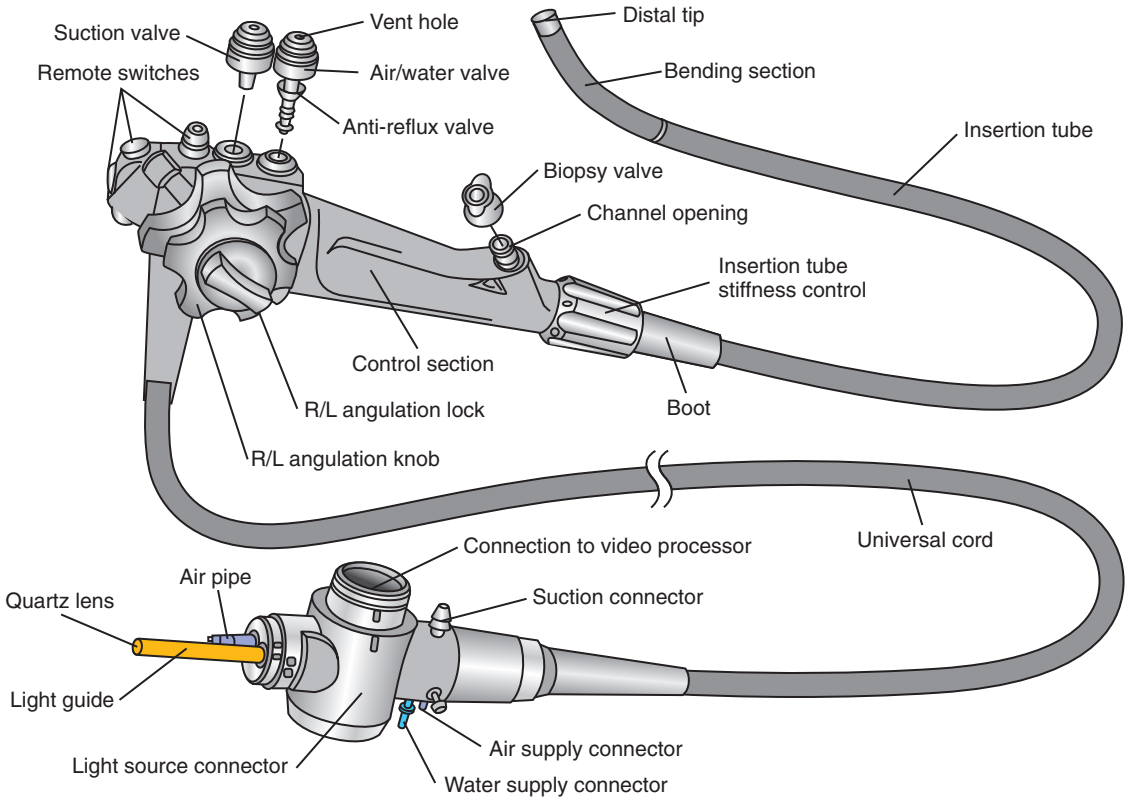

Figure 27-2 External anatomy of an Olympus flexible video endoscope. (Reprinted with permission of Olympus America Inc.)

- It is easy to bang the tip on a hard surface or to close it in a carrying case.
- In the case of video endoscopes (see next section), it contains the sensor chip.

A close examination of the distal tip of the insertion tube reveals the complexity of its array. Three lenses and three channels are located within the tip. The objective lens is the first part of the optical system through which the endoscopic image passes. Light transmitted from the light source passes through two bundles of optical fibers that terminate at two light-guide lenses. The three channels consist of a single large channel for suction and passage of instruments, and two smaller ones for irrigation and insufflation. The irrigation and insufflation channels are covered with small nozzles that direct the flow of air and water across the objective lens.

The nozzles and lenses must be kept meticulously clean for proper functioning and viewing during an endoscopic procedure. Tips and channels are kept free of proteinaceous material and mineral deposits by using (a) an approved enzymatic cleaning solution and (b) demineralized or distilled water during the cleaning process.

The insertion tube also contains the four deflection cables, and many layers of protective materials responsible for keeping the endoscope flexible and watertight.

Endoscope Umbilical Cord

The umbilical cord is the portion of the endoscope that connects to the light source and video processor. The light post and air inlet are inserted into an appropriate light source, which usually contains an integrated air pump for insufflation. Also found in this region are the connectors for a suction pump and the irrigation bottle. A standard suction pump is connected with plastic tubing of appropriate diameter. The irrigation water bottle is an accessory usually supplied by the manufacturer, and it is recommended that only demineralized water be used to prevent the buildup of minerals in the irrigation channel of the endoscope.

The pressure compensation valve found in this part of the endoscope serves two important functions. Before and after every procedure, a simple leakage test should be performed by attaching the manometer provided by the manufacturer (Fig. 27-4) and following factory instructions. Detecting leaks early can minimize costly repairs. The other purpose of the valve is to equalize the pressures between the interior and exterior environment during ethylene oxide gas sterilization or air shipment. The pressure compensation cap should never be left in place when the endoscope is being submerged in fluid, as this will cause fluid to leak into the endoscope.

The video cable connection with tight cap pictured in Figure 27-2 is a feature of true video endoscopes, but not fiberscopes (see next section). It is here that a video cable would be attached to connect the endoscope to a video processor.

Endoscope Dimensions

The key dimensions of an endoscope are its working length, outer diameter, and channel size. The preferred working length depends upon patient size. For example, a working length of 140 cm or more may be required to reach the duodenum of some giant breed dogs, whereas that length would be inconvenient and unnecessary in feline only practice. A small outer diameter (less than 8 mm) is most convenient for traversing the pylorus of cats and small dogs, but a large working channel (2.8 mm) is preferred to maximize the size of biopsy and foreign-body retrieval devices. Because of the diversity in body size and species differences, the desired combination of options may not be available in one model. The most versatile gastrointestinal endoscope for general small animal use will be at least 125 cm in length, no more than 9 mm in outer diameter, with a biopsy channel of at least 2.2 mm. Figure 27-5 shows a gastrointestinal endoscope designed for small animal use with these parameters in mind.

Fiberscopes Versus Video Endoscopes

Before the advent of endoscopic video technology, all flexible endoscopes were dependent upon fiber optics to transmit an image from the tip of the scope to the eyepiece. Thousands of long thin fibers of optical glass are bundled into "coherent image bundles" capable of transmitting images over long distances while curving and bending through tortuous anatomy. Fiberscopes, as they are known, are still very much in use today, especially small-diameter models that are commonly used for respiratory and urinary endoscopy. However, they are most commonly used with a video camera attached to the eyepiece (Fig. 27-6), which enables the endoscopist and other members of the endoscopy team to view an enlarged image on a video monitor.

True video endoscopes were introduced into medical and veterinary practice in the mid-1980s. A video endoscope image is initially

Figure 27-4 Manometer for testing leakage of the endoscope.

Figure 27-5 A small animal gastrointestinal endoscope with 140-cm working length, 7.8-mm diameter, and 2.8-mm channel.

Figure 27-6 Fiberscope with endoscopic camera attached to the eyepiece.

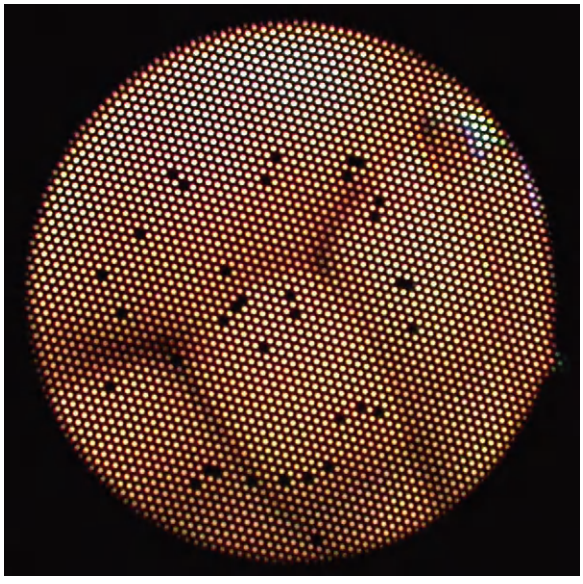

Figure 27-7 Fiberoptic image showing "pixelation" and broken fibers.

sensed by a computer chip (image sensor) in the tip of the endoscope and transmitted electronically to a video processor, and finally onto the viewing monitor. While these endoscopes come at a higher cost, the images are not dependent on fiber technology, consequently they produce images of superior quality. The resolution of fiberoptic images is limited, and they often appear pixelated because of the cladding that surrounds individual glass fibers. Furthermore, it is inevitable that individual fibers in the image bundle will break over time, causing small black spots in the image (Fig. 27-7).

What is often referred to as the "chip in the tip" of a video endoscope is either a charge-coupled device (CCD) or complementary metal oxide semiconductor (CMOS) image sensor. Although both technologies were invented in the late 1960s, the CCD became dominant because it offered superior images with the technology available at the time. These days, both types of image sensors offer excellent performance with proper design. There is renewed interest in CMOS image sensors for endoscopes because of improvements in quality, potential cost savings, and the availability of smaller sensors that could be used to manufacture smaller diameter endoscopes.

It is worth noting that both fiberscopes and video endoscopes contain glass fibers extending the entire length of the umbilical cord and insertion tube. The fiber bundles found in both kinds of scopes are called incoherent because the orientation of the fibers is unimportant. Rather than transmitting images, these fiber bundles transmit light from the light source to the distal tip of the endoscope to illuminate the subject.

Accessories and Instruments for Flexible Endoscopes

A variety of instruments and accessories are available for flexible endoscopes, which may be designed for single or multiple usage (Fig. 27-8). Although single-use instruments have the advantage of being new and sharp, the multiuse instruments tend to be more cost-effective over time. A typical veterinary practice should have at least two biopsy forceps, three or more foreign-body graspers, and two or three balloon dilators available for immediate usage (see Chapter 55). Among the most popular styles of foreign-body retrieval instruments used by veterinarians are two-prong graspers, basket retrievers (dislodgers), and snares. Additionally, a cytology brush with protective tube is useful for both gastrointestinal and respiratory sampling. It is critical that only instruments of the appropriate size, style, and specification are used with any given endoscope. Channel damage by inappropriate instrumentation is a common cause of fluid invasion, which can result in costly repairs. Above all, instruments should never be forced through the channel against obvious resistance. If resistance is met while trying to pass an instrument through a deflected tip, it is recommended to straighten the tip, then pass the instrument before repositioning the tip.

Light Sources and Pumps

Most endoscopic light sources are either halogen or xenon. Halogen is the economical choice, whereas xenon offers a brighter, whiter light at a higher cost. It is important to realize that wattage alone is not necessarily a good indicator of brightness. The wattage simply refers to how much power is being used, but different light source technologies can provide vastly different amounts of light output using the same number of watts of electricity. For example, a 175-watt xenon light source is typically much brighter than a 175-watt halogen light source. Illumination will also depend on the condition and model of endoscope, as well as the light sensitivity of the camera being used. The best way to determine the adequacy of a given light source is to test the complete system in a patient.

Newer light-emitting diode (LED) light sources are becoming more readily available and offer several distinct advantages, including lower cost, longer lamp life (thousands of hours), and improved energy efficiency.

Light sources designed for gastrointestinal endoscopes typically have an integrated air pump and connector that accommodate both the light post and air inlet of an endoscope (Fig. 27-9). The air pump also provides the pressure for irrigation from the water bottle. In some instances the light source and air pump may be separate units, requiring connection by using a special light source adapter and tubing to connect the light source to the air pump.

A suction pump is also required for gastrointestinal endoscopy. A standard unit available in most veterinary practices is sufficient in most cases. It is attached to the connector found on the distal end of the umbilical cord of the endoscope.

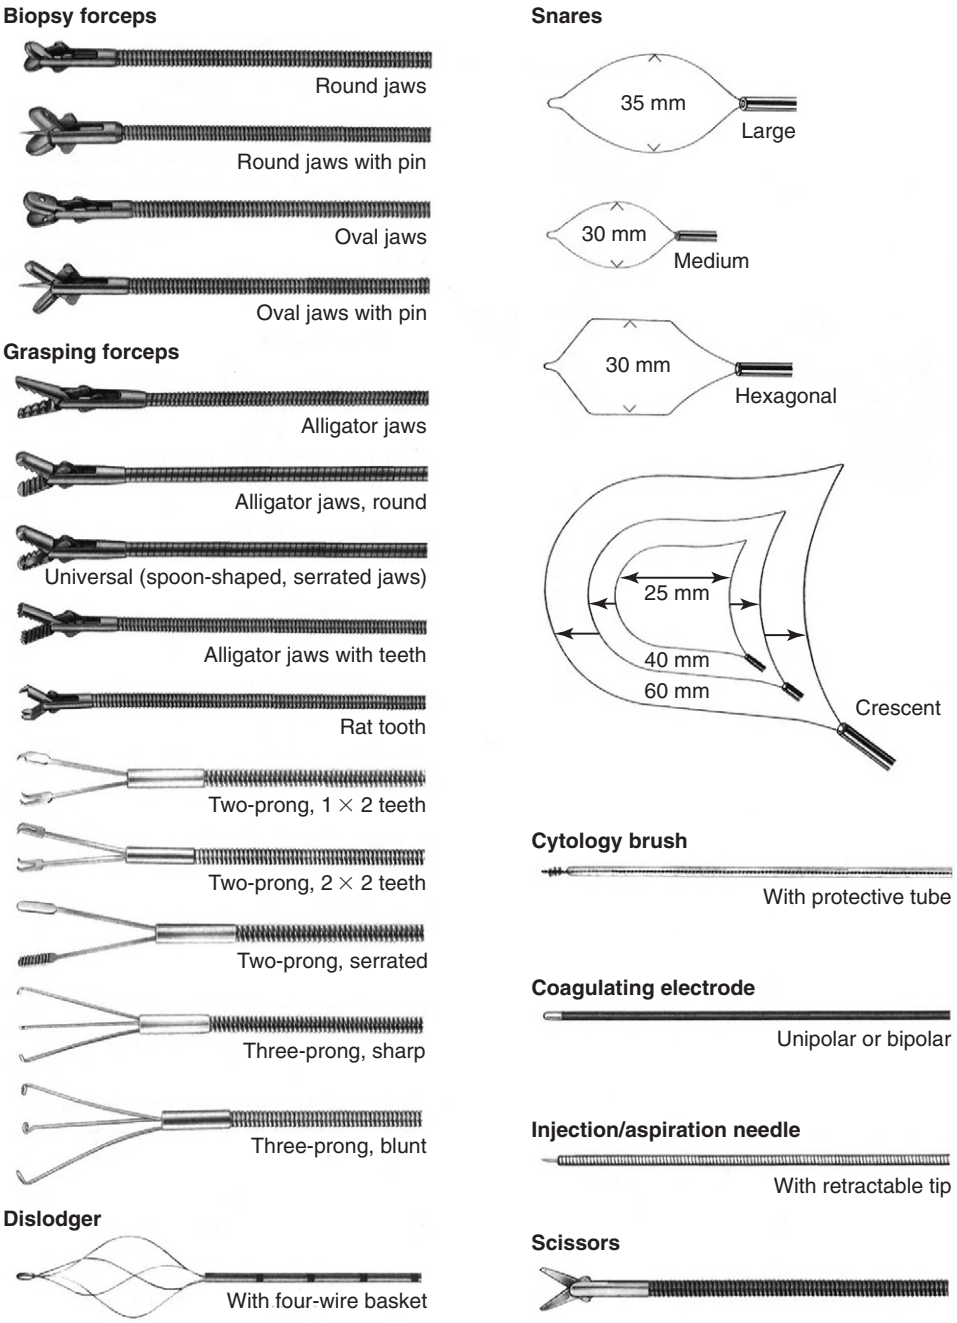

Figure 27-8 Flexible instruments for use through the channel of flexible endoscopes.

Figure 27-9 Endoscope light source with integrated air pump.

Endoscopic Cameras and Monitors

Video cameras and monitors offer the following distinct advantages:

- Enlarged image provides better view of anatomy, pathology, and foreign bodies.
- Ergonomic operation during procedures makes procedures easier to perform.
- Viewing of live video by multiple persons during a procedure facilitates assistance and training.
- Ability to record images or video for medical records, clients, and colleagues.

Figure 27-10 Video endoscope attached to camera processor (*top*) and light source (*bottom*)

The basic components of an endoscopic camera system are the processor or "box" and the camera head, which contains an integral cable and connects to the eyepiece of an endoscope (see Fig. 27-6). As camera systems are usually designed to work with specific endoscopes, it is important to consider the compatibility of one with the other before making a purchase. Some camera systems are more versatile than others. The camera head contains a sensor (either CCD or CMOS) similar to the one found in the tip of a video endoscope. A camera head is only necessary, therefore, when using a fiberscope or rigid endoscope with an eyepiece. A video endoscope on the other hand will attach directly to the camera processor (also known as a camera control unit [CCU]) with a cable adapter that is inserted into the same receptacle for a camera head (Fig. 27-10).

Endoscopic cameras are commonly classified as single chip or three chip, and the quality varies widely. Three-chip cameras theoretically provide higher resolution and more accurate color reproduction than single-chip cameras. However, high-quality single-chip video systems currently available may provide excellent image quality suitable for even the most demanding gastroenterologists. High definition (HD) video cameras are a newer technology for the endoscopy industry, fueled by the successes of the consumer electronics industry. It is beyond the scope of this chapter to discuss the intricacies of endoscopic video technology, but the reality is that numerous factors contribute to image quality. The best method of selecting a quality system is to work with a reputable manufacturer who is able to provide a demonstration of various options as well as a warranty. It is also important to take into account the supplier's ability to service the unit over the period of time for which one expects to use it.

Monitor size and style is a matter of preference, but 13- to 20-inch monitors are most commonly used. Because of their size and weight, flat screen monitors are rapidly replacing the standard cathode ray tube (CRT) monitors of the past. The monitor should have the correct input to accept the highest quality video signal (cable) coming from the camera processor, and be of adequate resolution to take full advantage of the camera's capabilities.

Capturing Images and Video

One of the most significant advantages to endoscopic video technology is the capability to capture images during a procedure for review at a later time. This can be achieved in a number of ways, from simply printing images on paper during the procedure to capturing digital images and videos with a dedicated archiving system that can store and manage the data for later retrieval (a searchable database). Some systems also have networking capability, including Digital Imaging and Communications in Medicine (DICOM) compatibility, so that the patient information and image data can be transmitted directly to a hospital's central patient database. Newer digital image capture systems are contained within the same housing as the camera itself, which provides the advantages of space savings and portability (Fig. 27-11).

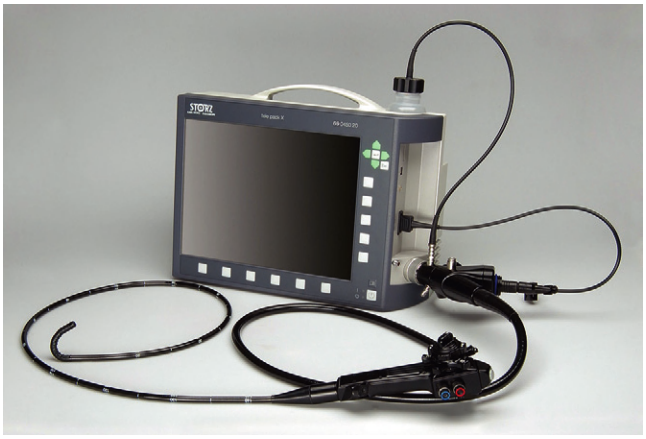

Figure 27-11 Compact unit for veterinary endoscopy includes camera processor, light source, monitor, and digital capture system all in one housing.

ESOPHAGEAL ENDOSCOPY

Michael S. Leib

Indications

Regurgitation is the most important clinical sign associated with esophageal disease in the dog and cat. The initial diagnostic plan usually involves survey thoracic radiographs, barium esophagram, or fluoroscopic evaluation. Endoscopy is often utilized after radiographic studies to obtain supplemental diagnostic information or to provide direct therapy. Esophageal endoscopy with biopsy may assist in the diagnosis of esophagitis, granulomas associated with *Spirocerca lupi* infection, neoplasia, and strictures, as well as to facilitate removal of impacted foreign bodies and stricture dilation.[1-5] A thorough endoscopic examination of the esophagus should also be undertaken whenever gastroduodenoscopy is performed. Chapters 21 and 55 provide more details about the clinical signs related to esophageal disease.

Instrumentation

A flexible endoscope with a working length of at least 100 cm, an outside diameter less than 10 mm, and a 2.8-mm diameter biopsy channel is appropriate for endoscopic examination of the esophagus in most dogs and cats.[6-8] A flexible endoscope should also have four-way distal tip deflection, automatic water–air insufflation, and separate suction pump to evacuate fluid and gas from the gastrointestinal tract. In addition to channel biopsy with a flexible endoscope, rigid biopsy forceps can be passed alongside the endoscope, directly through a rigid endoscope (see the following), or a suction biopsy capsule can be used to obtain samples of the intact esophageal mucosa.

Although not optimal, rigid proctosigmoidoscopes have been used to examine the proximal portions of the esophagus. These instruments are inexpensive and available in a variety of diameters and lengths.[9,10] Rigid biopsy forceps permit sampling of larger pieces of tissue than those obtained with flexible biopsy forceps. Care must be taken during this procedure to grasp only mucosa and submucosa, so as not to perforate the esophageal wall. Rigid endoscopes do have some obvious limitations compared with flexible endoscopies. With rigid endoscopes, the ability to visualize the entire circumference of the esophagus is limited by the rigidity of the scope. Moreover, rigid endoscopes do not have the clarity of mucosal visualization and forceps dexterity associated with flexible endoscopes. Despite these limitations, rigid endoscopes are useful in the removal of foreign bodies lodged in the esophagus.[9,10]

Patient Preparation and Restraint

Endoscopic examination of the esophagus requires the withholding of food, but not water, for at least 12 hours prior to the procedure.[6,11] If esophageal dilation or obstruction is present, endoscopy should be delayed until the esophagus is cleared of ingesta, which may require at least a 24-hour fast. Small amounts of fluid or food within the esophagus can be suctioned or lavaged into the stomach. Larger amounts of food impair visualization and increase the risk of aspiration during extubation and anesthetic recovery. Endoscopic examination of the esophagus requires general anesthesia to restrain the patient and protect the endoscope.[6,12,13]

Diagnostic Procedures

The patient should be positioned in left lateral recumbency.[14] A mouth speculum should be placed between the left upper and lower canine teeth to protect the endoscope from rubbing along the surface of the teeth, and to protect the endoscope if the patient were to awaken during anesthesia. To facilitate passage of the endoscope, the tongue should be grasped and the head and neck slightly extended by an assistant. The insertion tube of the flexible endoscope is passed over the base of the tongue, through the pharynx dorsal to the endotracheal tube, and into the proximal esophagus. The tip of the endoscope should be deflected slightly downward (ventrally) to follow the normal anatomic bend between the mouth and pharynx. The endoscopic tip usually passes easily through the upper esophageal sphincter during the initial insertion, generally making lubrication of the endoscope unnecessary. The proximal esophagus is best examined at the end of the procedure as the endoscope is withdrawn while air is being insufflated (Fig. 27-12).

The esophageal lumen is usually in a state of collapse and when slightly distended has visible longitudinal folds (Fig. 27-13).[6,11,13,15] Constant air insufflation may be necessary to distend the proximal esophagus to allow visualization of the lumen and safe advancement of the endoscope. The endoscopic tip should be centralized within the esophageal lumen by adjusting the inner and outer control deflection knobs. Only minor tip adjustments are necessary, as the esophagus is a relatively straight tube from proximal to distal. By advancing the endoscope only when the lumen is clearly visible, the endoscopist will reduce the risk of esophageal perforation. The endoscope should be advanced until the tip veers away from the center of the lumen. The control knobs should be adjusted slightly to reposition the tip within the center of the lumen, and the endoscope advanced further along the esophagus. In this manner, the endoscope is slowly advanced through the esophagus and into the stomach. Although the entire esophageal mucosa can be visualized as the endoscope is slowly advanced, biopsy and cytologic samples should not be collected until the endoscope is slowly withdrawn at the end of the procedure. Otherwise, hemorrhage could obscure visualization of the esophagus distal to the biopsy site.

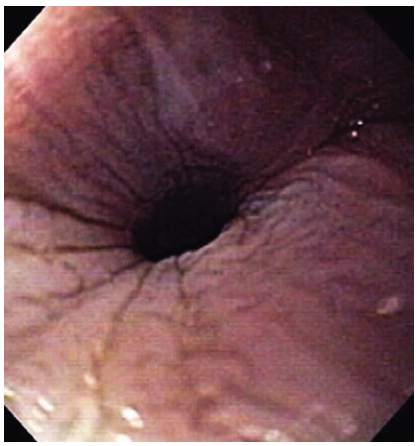

Figure 27-12 Pharyngoesophageal junction. Endoscopic image of the pharyngoesophageal junction of a dog. This view is best obtained as the endoscope is being withdrawn and air is insufflated.

Figure 27-13 Proximal esophagus, dog. Endoscopic image of the proximal esophagus of a dog. The lumen is collapsed and longitudinal folds are visible. Air insufflation will expand the visible lumen and allow the endoscope to be safely advanced while the mucosa is examined.

The normal esophageal mucosa is pale pink, smooth, and glistening. In health, the esophageal lumen is usually devoid of food and fluid. The trachea will indent the distended esophagus, and the tracheal rings should be clearly visible (Fig. 27-14). At the tracheal bifurcation, it is common to see pulsation of the heart and/or aorta. The distal esophageal lumen often remains distended and air insufflation is less necessary. As the esophagus passes through the diaphragm and into the abdomen it may deviate as much as 30° toward the animal's left side.[15] The gastroesophageal junction is normally closed and often assumes a stellate mucosal pattern (Figs. 27-15, 27-16, and 27-17). A small amount of red gastric mucosa can be seen within the distal esophageal lumen.[6]

The normal esophageal mucosa is lined by a stiff stratified squamous epithelium and, because of these properties, it is often difficult to obtain mucosal samples using flexible biopsy forceps. On the other hand, tissue sampling of an intraluminal mass or ulcerated mucosa is relatively easy. To obtain a biopsy sample, the endoscope

Figure 27-14 Tracheal indentation. Endoscopic image of the tracheal indentation of a dog (seen between the 3 to 4 o'clock position). Air is insufflated to distend the esophageal lumen, which is the dark area at the center of the photograph.

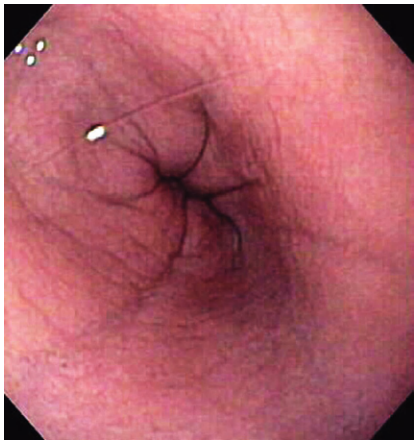

Figure 27-16 Gastroesophageal sphincter. Closeup endoscopic image of the gastroesophageal sphincter of a dog. The sphincter is closed and a stellate mucosal pattern is visible.

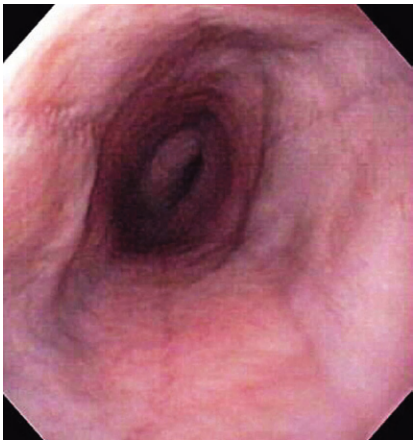

Figure 27-15 Distal esophagus, dog. Endoscopic image of the distal esophagus of a dog. The gastroesophageal sphincter is closed and is visible at the center of the image.

Figure 27-17 Gastroesophageal sphincter. Closeup endoscopic image of the gastroesophageal sphincter of a dog. The directional change of the esophagus, as it passes through the diaphragm into the stomach, is visible as the center of the sphincter is displaced laterally toward the 3 o'clock position of the distal esophageal lumen.

tip should be placed 1 to 2 cm from the area to be sampled and angled toward the esophageal wall. The biopsy forceps are advanced through the biopsy channel until they are visible through the endoscope. The biopsy forceps are opened by an assistant, and the endoscopist advances the forceps until mucosal contact is made. The forceps should be gently advanced until a slight bowing of the forceps can be seen. The assistant closes the forceps and the endoscopist snaps off the tissue sample by withdrawing the closed forceps into the biopsy channel. A small amount of hemorrhage may appear at the biopsy site. For more difficult biopsies, a rigid forceps can be passed alongside a flexible endoscope, or through an accessory rigid endoscope (see next), or a suction biopsy capsule can be used to obtain mucosal samples. As the endoscope is withdrawn, fluid, mucus, and blood should be aspirated through the biopsy channel. After the examination is completed, the area surrounding the endotracheal tube should be examined and any residual fluid should be aspirated to prevent aspiration during recovery.

When passing a rigid endoscope, the head and neck should be fully extended and the endoscope well lubricated. The endoscopic obturator should be placed inside of the rigid scope to facilitate passage into the proximal esophagus. To view the esophagus, the obturator should then be removed, the viewing lens closed, and air manually insufflated with the bulb to distend the esophagus. The endoscope should be slowly advanced as long as the lumen is clearly visible. To obtain a biopsy sample the endoscope should be placed within 1 cm of the lesion, the viewing lens opened, and rigid forceps passed into the endoscope. The esophageal mucosa should be gently grasped and the forceps moved back and forth within the endoscope. If the grasped tissue moves easily, it is safe to completely close the forceps and excise the sample. If the grasped tissue remains fixed to the esophageal wall, the forceps should be opened and the tissue released as a full-thickness tissue sample may have been grasped.

Besides the obvious length and diameter differences between dogs and cats, there are several other differences encountered when performing esophagoscopy in cats.[15,16] First, transverse folds are normally evident in the distal one-third of the feline esophagus as the muscular layer consists entirely of smooth muscle (Fig. 27-18). Second, it is common to visualize superficial blood vessels throughout the length of the feline esophagus (Fig. 27-19).

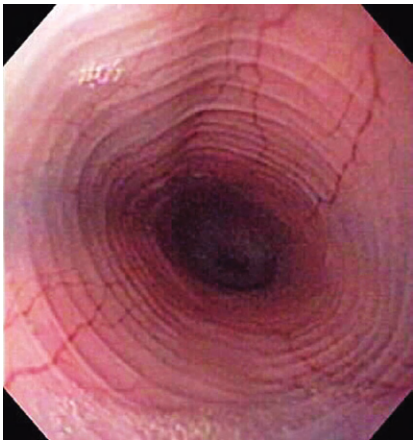

Figure 27-18 Distal esophagus, cat. Endoscopic image of the distal esophagus of a cat. The transverse folds associated with smooth muscle in the distal third of the esophagus are visible. Superficial blood vessels can be seen at 1, 5, and 8 o'clock.

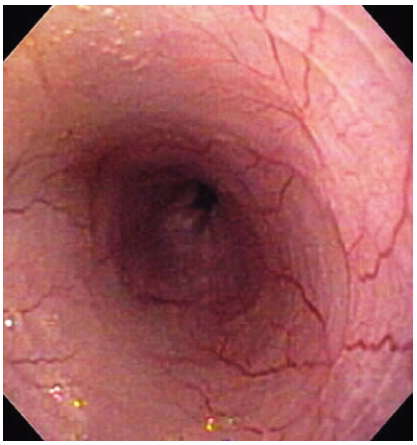

Figure 27-19 Distal esophagus, cat. Closeup endoscopic image of the distal esophagus of a cat. Superficial blood vessels are visible throughout the image. The transverse folds are indistinct because of overdistention of the esophagus with air.

Therapeutic Procedures

Esophageal Stricture Balloon Dilation

Esophageal strictures are best managed with mechanical dilation (Fig. 27-20). Dilation may be achieved with balloon dilation catheters or bougienage tubes.[4,17-19] Esophageal tears have been reported with balloon dilation catheters, but the technology is still thought to be relatively safe in applying radial forces to the stricture site. A greater risk of perforation because of shearing forces applied by the instrument has been attributed to the use of bougienage tubes, although one recent report showed outcomes similar to those reported for balloon dilation.[20] Table 27-1 outlines the parameters needed for a successful balloon dilation. Multiple redilations at 1- to 2-week intervals may be necessary until the stricture is resolved.[3,4,17,21] Esophageal dilation is best performed with direct observation at the time of endoscopy, but it could be performed with videofluoroscopy.

Esophageal Foreign-Body Retrieval

Esophageal foreign bodies should be removed promptly. Prolonged retention increases the likelihood of esophageal mucosal damage, ulceration, and perforation. Rigid or flexible fiberoptic endoscopic retrieval should be the initial approach to treating an esophageal foreign body although fluoroscopic-guided retrieval is also possible.[22]

Figure 27-20 Saline-filled balloon dilation catheter for esophageal dilation. (Courtesy of Cook-Medical.)

Table 27-1 Strategies for Balloon Dilation Treatment of Esophageal Strictures

Intervention	Rationale	Implementation
Barium swallow	Determine location, length, and number of strictures	Barium suspension–30% weight/volume
General anesthesia	High-pressure esophageal dilation stimulates visceral pain	Inhalant anesthesia–e.g., sevoflurane, isoflurane
Patient positioning	Inspection of esophagus and stomach poststricture dilation	Left lateral recumbency for maximal maneuverability
Endoscopes	Direct observation, balloon placement, postdilation trauma	7.5- to 8.5-mm insertion tube, 2.8-mm biopsy channel
Balloon dilation catheters	Multiple catheter lengths and balloon diameters	8 mm × 8 cm to 18 mm × 8 cm balloon catheters*
Procedure	Repeated balloon dilations to achieve increase in luminal diameter	1 to 3 cycles of balloon inflation and deflation/procedure
Manometry	Monitoring of inflation and deflation pressures	Vacuum to 160 psi pressure gauges
Gastrostomy tube placement	Nutritional maintenance during recovery phase with severe strictures	Low-profile gastrostomy tube systems
Recovery phase	Protect esophageal mucosa, inhibit acid secretion, promote healing	Sucralfate, histamine H_2-receptor antagonists
Recurrence/prevention	Most esophageal strictures require 2 to 4 successive balloon dilations	Repeat endoscopy at 13-day intervals as needed

*Sure-Flex Esophageal Balloon Dilation Catheters, Rigiflex Esophageal Balloon Dilation Catheters

A rigid endoscope is most useful in retrieving large foreign bodies, particularly bones or bone fragments.[23] Large grasping forceps are passed through the rigid endoscope to retrieve the foreign body, and in many cases, the foreign body can be pulled into the endoscope for safe removal. Large foreign bodies that cannot be safely removed through the mouth can occasionally be pushed into the stomach and removed by gastrotomy. Smaller foreign bodies are best managed with a flexible fiberoptic endoscope and basket, tripod, or snare retrieval forceps.[24] Flexible endoscopes are particularly useful in retrieving fishhooks.[2]

Esophagostomy Tube Placement

Chapter 33 has a detailed discussion of esophagostomy, gastrostomy, and enterostomy tube placement.

GASTRIC ENDOSCOPY

Albert E. Jergens

Gastric endoscopy (gastroscopy) is a valuable diagnostic tool for evaluating gastric mucosal disease in dogs and cats.[1] The gastric mucosa can be visualized directly and tissue samples can be obtained quickly under endoscopic guidance for histopathologic and/or cytologic evaluation. Gastroscopy is usually performed in conjunction with esophagoscopy and duodenoscopy, and is considered more sensitive than barium-contrast studies for the diagnosis of gastric mucosal disorders.[1] Knowledge of normal versus abnormal appearances, biopsy techniques, and specimen handling are essential to making the correct diagnosis. Therapeutic interventions may also be performed and include foreign-body removal and placement of feeding tubes.

Clinical Indications

Indications for gastroscopy include clinical signs of vomiting, hematemesis, anorexia, nausea, and/or melena. Endoscopically detectable gastric diseases have multiple underlying pathogeneses (Table 27-2). Although gastroscopy is usually performed in animals with chronic signs of gastric disease, it should also be considered in animals with acute vomiting caused by gastric foreign body or gastric ulceration causing hematemesis. Followup gastroscopy may be used to monitor effects of therapy in patients with chronic gastritis or ulcers.[2] Initial diagnostic testing (e.g., complete blood count, serum chemistry, urinalysis, abdominal imaging) serves to eliminate common metabolic disorders (e.g., renal failure, hepatobiliary disease, hypoadrenocorticism, or feline hyperthyroidism) that might mimic primary gastric disease. Endoscopic examination should only be performed after thorough history, physical examination, and diagnostic testing have failed to identify the cause of clinical abnormalities.

Table 27-2 Gastric Diseases or Interventions That Typically Require Gastroscopy

Clinical Problem	Biopsy Recommended
Gastritis (varied causes)	Yes
Gastric neoplasia	Yes
Ulcer erosions	Yes
Chronic hypertrophic gastropathy	Yes
Foreign bodies	No
Physaloptera rara	No
Percutaneous endoscopic gastrostomy (PEG) tube placement	No

Endoscopic Instruments

A flexible endoscope having a working length of at least 100 cm, an outer insertion tube diameter of 9 mm or less, and four-way tip deflection is ideal for most gastroscopic examinations. Endoscopes with an accessory channel diameter of greater than 2.2 mm will accommodate larger biopsy forceps and foreign-body retrieval devices. For inexperienced endoscopists and feline practitioners, an outer insertion tube diameter of 7.9 mm or less will permit easier duodenal intubation when performing esophagogastroduodenoscopy. Video endoscopes are the current gold standard for clinical practice as they provide superior optics with higher resolution when compared to conventional fiberoptic endoscopes. Video endoscopes also permit simultaneous viewing of procedures by multiple personnel (advantageous for training or assistance with interventions such as gastric foreign-body retrieval) and image capture options, such as video recording. The obvious disadvantage of the video endoscopic systems is their cost. Fiberoptic endoscopes are less expensive, and are equally useful for performing a detailed gastroscopy with collection of targeted mucosal biopsies by an experienced endoscopist.[3]

A variety of endoscopic accessories should be on hand for both diagnostic and therapeutic purposes. Multiple biopsy forceps and cytology brushes will be needed for adequate tissue sampling and histologic diagnosis. Both multiple use and "single-use" biopsy forceps are available in a variety of styles for gastroscopic examinations. Similarly, gastric foreign bodies come in all shapes, sizes, and angularities, and will often require specific and sometimes several different types of retrieval instruments to successfully remove the object(s) from the gastric lumen.

Patient Preparation

Dogs and cats requiring gastroscopy should have food withheld for 12 to 18 hours prior to endoscopic examination. This minimizes the amount of residual ingesta in the gastric lumen in most instances. Animals with delayed gastric-emptying disorders may have retained luminal debris, ingesta, or fluids in spite of proper patient preparation. Large-breed dogs (>30 kg bodyweight) undergoing gastroscopy may also have gastric retention of fluids, possibly associated with the stress of hospitalization and handling by strangers. In these instances, careful aspiration of free gastric fluid may still permit adequate visualization of mucosal surfaces for lesion detection and tissue sampling.

Gastroscopy should not be performed for 12 to 24 hours following a barium-contrast study, particularly if gastric retention is suspected. The delay should be sufficient time for gastric emptying of barium to occur and to permit optimal endoscopic viewing of all gastric mucosal regions. Survey abdominal radiography will confirm the presence of retained (gastric) barium if there is a question as to its presence. Suction of liquid barium through the accessory channel should never be performed as residue might adhere to the walls of the biopsy channel.

General anesthesia will be required for gastric endoscopy whether it be for diagnostic or therapeutic purposes. Patients should always be placed in left lateral recumbency as this facilitates passage of the endoscope through the antrum and pylorus. This allows any retained fluid to drain away from these regions into the gastric body and

facilitates examination of these structures prior to duodenal intubation. Lastly, a mouth gag or oral speculum should be placed to prevent damage to the endoscope in case the animal should awaken from anesthesia during the procedure.

Performing Gastroscopy

A proper gastroscopic procedure should include direct visual inspection of all areas of the stomach.[1] A working knowledge of the normal gastric mucosal anatomy and anatomic landmarks will help the endoscopist to correctly maneuver the endoscope for viewing the gastric fundus, body (corpus), cardia (retroflexed view), incisura angularis (key anatomic structure), antrum, and the pylorus prior to duodenoscopy. Recognition of the location and appearance of normal gastric landmarks will also help to distinguish morphologic abnormalities of these structures, such as focal ulcers that may occur along the incisura or chronic pyloric mucosal hypertrophy, which might obscure the pyloric orifice.

As the endoscope is advanced along the distal esophagus toward the gastroesophageal sphincter (GES), the endoscopist should note the tone (i.e., open vs. closed) and position of the sphincter orifice. Using gentle forward pressure while insufflating air, the endoscope is directed through the GES and passed with minimum resistance into the gastric lumen. Once the GES is traversed, the endoscope is advanced only a short distance while variable degrees of air are insufflated to gently separate the rugal folds. This allows the endoscopist to achieve spatial orientation within this viscus by visualizing the gastric body (corpus), antrum, and incisura angularis. This "birds-eye" view of the stomach permits a panoramic view of the *gastric body* and greater curvature of the stomach as the insertion tip is moved laterally in a sweeping fashion using both left and right tip deflections (Fig. 27-21). Care is taken to control insufflation such that moderate separation of the rugal folds occurs without overly distending the stomach. A combination of insufflation and aspiration of air optimizes visualization of individual rugal folds and the mucosa along the greater curvature of the gastric body. Once these structures are adequately visualized, the endoscope is advanced through the proximal stomach toward the antrum until the incisura angularis can be identified (Fig. 27-22). This key anatomic landmark appears as a distinct ridge of tissue that serves to separate the body of the stomach from the antrum. The identification of the angularis also allows the endoscopist to orient themselves to the location of the lesser curvature (to the right) and the greater curvature (to the left) when the animal is in left lateral recumbency.

The next endoscopic maneuver performed is the retroversion or J-maneuver, which allows a "head-on" visualization of the angularis and the cardiac and fundic regions of the stomach.[1] This procedure begins as the endoscope tip is positioned at about the level of the angularis or is deflected off the greater curvature proximal to the antrum while the endoscope tip is deflected maximally in an upward direction. With slight forward advancement of the endoscope, the endoscope tip is then rotated laterally until the angularis is visualized "head-on." This view allows the endoscopist to see both the antrum located below this structure and the air-distended gastric body located above it (Fig. 27-23). This "head-on" view of the angularis may not be possible in cats because of anatomic constraints when manipulating the endoscope. To view the cardia and fundus, the endoscope tip is now rotated 180° and retracted toward the esophagus. The endoscope tip is rotated laterally left and right to closely inspect these areas and to view the endoscope as it passes into the stomach through the cardia (Fig. 27-24). Although these regions of the stomach are less

commonly affected by mucosal disease, this procedure is generally performed quickly and can identify foreign bodies or gastric ulcers, especially in dogs. Retroversion is slowly reversed by advancing the endoscope forward until the proximal antral mucosa and angularis return into view.

The antrum is readily identified by the location of the angularis, the absence of rugal folds, and the observation of peristaltic waves of contraction (usually seen in dogs) that propagate down toward the pylorus. In cats, passage of the endoscope past the angularis and into the proximal antrum may result in a temporary "red out" as the endoscope tip abuts against the antral mucosa. Advancing the endoscope forward with the tip deflected in an upward direction results in observation of the antral canal and pylorus. In most dogs the endoscope can easily be passed around the angularis and through the antral canal. The pylorus is easily visualized in most animals. Exceptions include patients with retained ingesta or accumulated fluids within the pyloric canal. In dogs, the pyloric orifice is often located off center and is partially obscured by fold(s) of mucosa (Fig. 27-25). Cats have a pyloric orifice that is more centrally

located in the pyloric canal. Passage of the endoscope through the pylorus may be easy or difficult. The key to successful passage is keeping the pylorus in the center of the endoscopic field.[1] The position of the pylorus can change as a consequence of antral contractions or breathing patterns by the animal, necessitating slight directional changes of the endoscope tip as it is advanced toward the pylorus. In many dogs, the endoscope is often passed through the pylorus with relative ease. However, in other patients the endoscopist may find it challenging to intubate the duodenum through a closed or "spastic" pylorus. This situation is further complicated by mucosal "red out" as the endoscope tip contacts the pyloric mucosa. Slow gradual directional changes of the endoscope tip will usually be successful in identifying the pyloric orifice in these instances. Steady forward pressure is then applied to advance the endoscope. Excessive force should never be used. Gentle insufflation and careful repositioning of the endoscope tip while advancing will result in eventual success in traversing the pylorus. Pharmacologic manipulation to decrease pyloric tone and facilitate passage of the endoscope through the pylorus has not proven successful in either dogs or cats.[4,5]

Technical Concerns

Gastroscopy can be easily and safely performed in most dogs and cats. Cardiopulmonary complications related to anesthesia or excessive prolonged air insufflation causing gastric distention are uncommon.[6] If respiratory compromise is noted, the stomach should be rapidly deflated to stabilize the patient. The respiratory rate may increase in patients while advancing the endoscope through the pylorus. Passing the endoscope into the antral canal and pylorus of large dogs (>30 kg body weight) may result in inadvertent retroversion (e.g., looping) of the endoscope in the stomach.[1] This situation may occur when excessive air insufflation causes gastric distention and the endoscopist loses orientation within the cavernous lumen. If loop formation occurs, the endoscopist should retract and reposition the endoscope while suctioning off air until the angulus can be viewed. This procedure allows the endoscopist to regain spatial orientation and once again advance the endoscope forward to the pylorus. Small diameter endoscopes (7.9 mm or less) should be used in cats as they are more maneuverable and permit easier duodenal intubation. Gastric perforation is a potential complication of gastroscopy but is rare.

Normal Endoscopic Appearance

The gastric mucosa is normally smooth, pink, and glistening. The rugae appear as linear folds that are uniform in size, shape, and distensibility. Even small amounts of retained gastric or duodenal secretions may obscure portions of the mucosa. Hair can also occasionally be observed within the gastric lumen of cats. The antrum is delineated by the presence of the incisura angularis and is characterized by a paler pink mucosal appearance and an absence of rugal folds. Antral contractions may be observed during gastroscopy in both dogs and cats. The pylorus is easily identified in most animals and may be open or closed.

Abnormal Endoscopic Appearance

Gross mucosal abnormalities are commonly seen in dogs and cats with gastric disease (Fig. 27-26). Lesions may be focal or diffusely distributed throughout the entire gastric mucosa; consequently, careful inspection of all gastric regions will enhance the likelihood that mucosal abnormalities will be detected. Endoscopic lesions of mucosal friability, granularity, and ulcers or erosions are commonly associated with histopathologic abnormalities.[7-10] Friability describes the ease with which the mucosa bleeds upon contact with the endoscope or biopsy instrument (see Fig. 27-26A). An increase in mucosal texture is termed increased granularity (see Fig. 27-26B). Mucosal ulceration-erosion refers to an endoscopically visible breach in the mucosal surface that is often associated with active hemorrhage. Ulcers are focal defects that extend deeply into the adjacent mucosa and often contain hemorrhage and a fibrinonecrotic center (see Fig. 27-26C). Erosions are discrete, superficial mucosal defects that do not have raised margins or necrotic centers (see Fig. 27-26D). Erythema denotes mucosal redness that can be a pathologic or a physiologic response to altered mucosal blood flow, which, in turn, is associated with anesthesia. Mass lesions may be benign (e.g., antral polyp) or malignant (e.g., tumor) and are not readily differentiated based on appearance alone. The presence of food or large volumes of gastric fluids in a properly prepared patient is suggestive of gastric retention. Gastric nematodes (*P. rara*) may also be observed along the gastric body of a dog with a history of chronic vomiting. Finally, alterations in the distensibility of the gastric wall suggest submucosal infiltrative disease or extragastric compression.

Gastric Biopsy

Gastroscopy is usually performed to obtain gastric-tissue biopsies. Tissue samples should be obtained during gastroscopy whether or not endoscopic abnormalities can be identified.[1,3] Histopathologic lesions of the stomach may be present in patients with an endoscopically normal gastric mucosa. Several different styles of biopsy forceps should be available, including those with smooth or serrated cups, with or without a central spike (Fig. 27-27).[11] Personal preference and operator experience are often the main reasons for selection of specific types of forceps. Serrated cup forceps without a central spike are often preferred because they cause fewer biopsy artifacts. The diameter of the endoscope's accessory channel will dictate what size forceps may be used. A channel size of 2.8 to 3 mm facilitates the use of large forceps for mucosal biopsy. The advantage of large forceps is the ability to sample larger and more diagnostic tissue samples. However, the use of forceps that can be passed through smaller diameter endoscopes might still yield excellent quality biopsies for diagnostic purposes.[12]

If gastric lesions are not obvious, the best biopsy samples are obtained from rugal folds along the gastric body. The rugae are prominent and it is easy to grasp large-size tissue samples for diagnostic evaluation. The biopsy forceps are advanced at a 45° to 90° angle into the rugal folds and six to eight mucosal biopsies are collected. Cytologic specimens obtained with a sheathed cytology brush or cytologies made as imprints directly from tissue samples will complement mucosal histopathology.[13] Gross abnormalities of mucosal friability or increased granularity may be biopsied directly. Superficial mucosal erosions should be biopsied at the edge of the lesion. Gastric ulcers require that tissue sampling be performed along the rim of the ulcer at the interface of abnormal and normal tissue. Taking biopsies from the ulcer pit is not advised as the diagnostic yield is minimal and there is some risk of perforation during the procedure. Masses should be biopsied deeply to avoid necrotic surface debris and superficial cells, which may confound the diagnosis. If diffuse neoplasia is suspected, multiple biopsy specimens

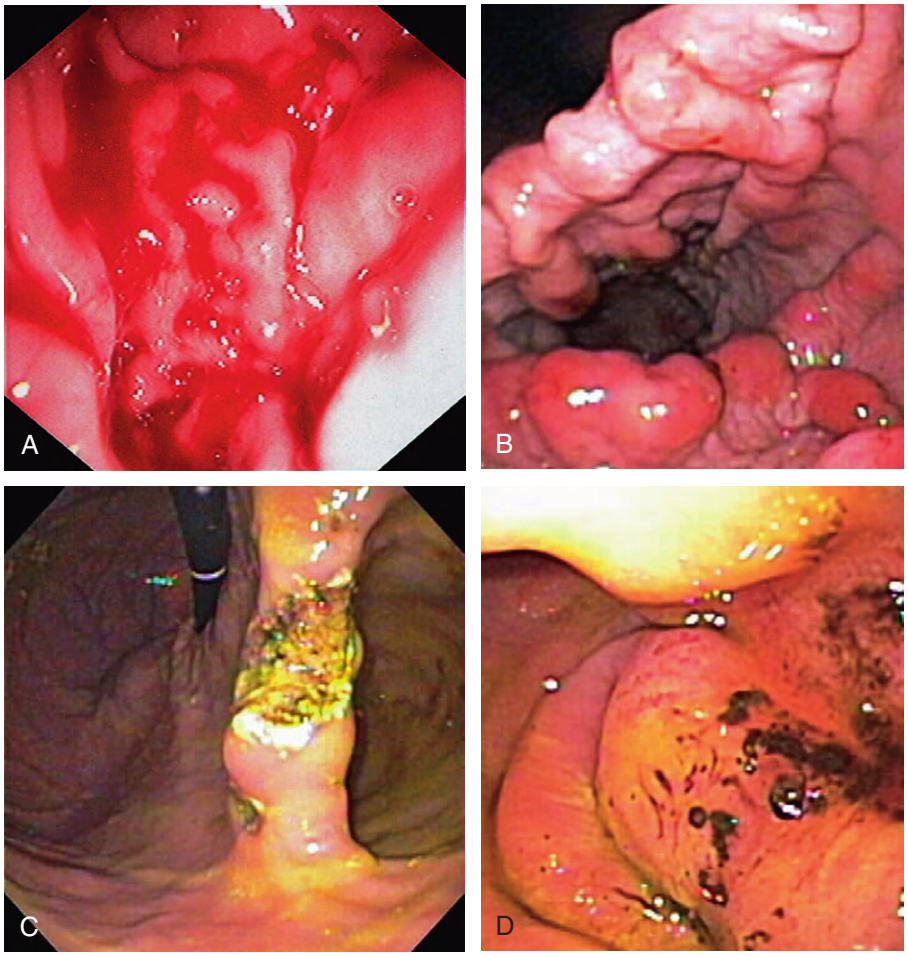

Figure 27-26 Gross mucosal abnormalities seen with gastric diseases. **A**, This image shows mucosal friability of the gastric body. **B**, A severely increased granularity of the gastric rugae. **C**, A focal ulcer along the angularis. **D**, Numerous superficial erosions of the mucosa on the rugal folds. Note that all of these abnormal appearances are commonly associated with infiltrative and inflammatory disorders affecting the gastric mucosa.

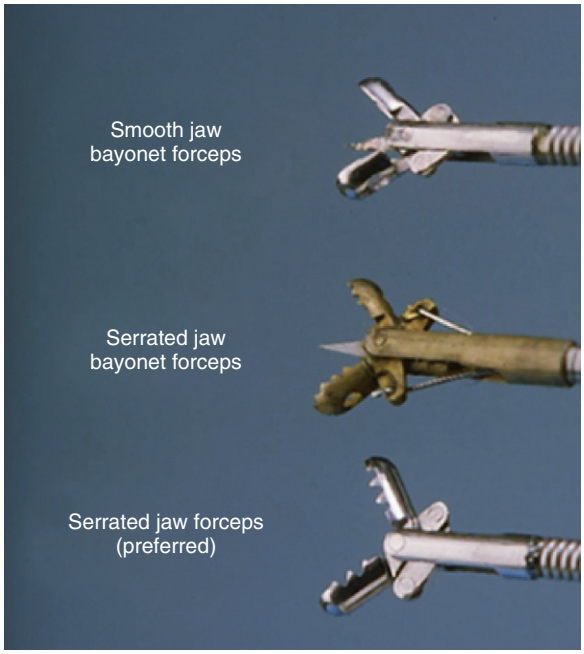

Figure 27-27 A variety of pinch forceps used for acquiring gastric biopsies. The serrated jaw forceps consistently provides the largest tissue samples for histopathologic evaluation and is thus preferred.

collected from deep within the lamina propria should be obtained from both the normal and abnormal appearing mucosa.

Handling of Biopsy Specimens

Endoscopic biopsy specimens are small, fragile pieces of tissue subjected to artifact from handling during the biopsy procedure, mounting, and processing, including microtome sectioning of the paraffin wax–embedded tissue. Biopsy artifacts can be minimized if care is exercised in procuring and handling the specimen. Tissue specimens should be gently teased from the forceps with a needle and placed on lens paper, a cucumber slice, or a specially designed biopsy sponge. Commercial cassettes with precut "sponges" can be used for the submission of endoscopic biopsy specimens (Fig. 27-28). Multiple biopsy specimens can be placed on a sponge, and the sponge is then placed directly into the cassette. The closed cassette is immersed in 10% neutral buffered formalin and submitted to the laboratory.

Cucumber slices can be substituted for plastic sponges and are an excellent medium for the submission of endoscopic biopsy specimens.[11] Mucosal tissue samples are placed on thin slices of cucumber (preserved in alcohol), which are then deposited into formalin containers and submitted for processing. At the laboratory the cucumber slices are removed from the formalin. Then smaller cucumber

Figure 27-28 Endoscopic samples placed in a biopsy cassette for laboratory processing. Samples are aligned in rows on cucumber slices to maintain optimal orientation during tissue sectioning.

sections containing multiple biopsy specimens are arranged in parallel rows and are trimmed away and placed on their side in the processing cassette (e.g., perpendicular to the cassette surface to optimize tissue orientation after sectioning). The tissues are then embedded in paraffin wax. The specimens do not have to be removed from the cucumber slices prior to embedding because the microtome can readily cut through the vegetable material. This technique minimizes specimen handling at the laboratory and consistently yields well-oriented tissues of high diagnostic quality.

Attempts to reorient specimens on biopsy sponges or cucumber slices prior to formalin fixation should be avoided. Specimens should be placed in formalin as soon as possible as tissue dehydration can contribute to artifactual change. Overly dried samples might adhere tightly to the sponge or cucumber and be damaged when removed by the histopathology service. Samples from different sites (e.g., gastric body versus antral mass) should be placed in separate containers and appropriately labeled. The endoscopist should record the number of specimens obtained from each site, relevant endoscopic observations, and salient historical and clinical data on the histopathology form.

Histopathologic Considerations

Taking too few samples during endoscopic examination is generally more problematic than taking too many. Superficial, focal disease generally warrants procurement of fewer samples (e.g., three to four) versus deep focal disease (i.e., a mass that is covered with normal-appearing mucosa) where probably six or more samples should be obtained. If no focal lesions are seen, then the presence of diffuse disease is assumed and multiple specimens should be obtained. A recent study aimed at identifying the minimum number of biopsy specimens to be collected from the stomach suggested a minimum of six marginal or adequate biopsy samples from the feline stomach and six adequate or 10 to 15 marginal samples from the canine stomach.[14] This practice helps ensure that several adequate tissue samples will be available for review by the pathologist, and that focal, patchy lesions will not be missed. The morphologic information obtained from such evaluation depends on the depth of the tissue, total volume of tissue obtained, and orientation of the tissue sample.

Proper orientation of biopsy specimens is an important consideration. Paraffin wax embedding of each biopsy specimen individually within a composite block increases the likelihood that several tissues will be optimally oriented. Serial sections placed in several rows on a single slide are then evaluated. Careful orientation, expert serial sectioning, and the avoidance or recognition of mechanical artifacts typically yields histopathology slides of consistently high quality that allow the pathologist to provide the most accurate evaluation possible.

Interventional Gastroscopy

Percutaneous endoscopic gastrostomy (PEG) tube placement has found wide application in providing enteral nutritional support to small animal patients (see Chapter 33).[15,16] Placement of a PEG tube is useful for feeding dogs and cats when it is necessary to bypass the mouth, pharynx, or esophagus. Common indications for gastrostomy tubes include esophagitis or esophageal trauma, pancreatitis, megaesophagus with aspiration pneumonia, or feline hepatobiliary disease. Gastroscopy is required to assure correct placement of PEG tubes; specifically that the bulb of the feeding catheter is not positioned near the antrum or the cardia. Complications associated with PEG placement are rare. Occasionally, a portion of the feeding catheter breaks away during catheter removal, requiring repeat gastroscopy to remove the retained catheter fragment.

Removal of gastric foreign bodies can often be performed with flexible equipment.[3,17] Endoscopy provides minimally invasive visual assessment of the retained object and permits adept retrieval in comparison to surgical removal. Bones, fishhooks, sewing needles, and linear foreign bodies can all lodge in the stomach. A variety of instruments available for foreign-body retrieval with flexible endoscopes are reviewed elsewhere.[3,17] The diameter of the accessory channel of the endoscope will significantly influence the type and size of grasping instruments that can be used. A working channel diameter of 2.8 mm is ideal for accommodating the most useful retrieval devices.

Sturdy forceps, such as a two-pronged rat-tooth instrument, are essential for removal of large heavy objects (e.g., bones) that create considerable resistance when dragged across the mucosa. A four-wire basket works well for balls and some rocks. One limitation of this instrument is that the wires may be spaced too closely together to fit around some objects. Three-prong wire snares can readily grasp soft pliable foreign bodies (e.g., clothing, tinsel, cellophane) but are insufficiently strong for heavy objects. An "overtube" may be useful in protecting the mucosa during removal of sharp foreign bodies such as bones, glass, and fishooks.[3,17] The endoscope is passed through the larger-diameter overtube. After grasping the foreign body, the endoscope with the attached foreign body is pulled into the overtube thereby protecting the mucosa from further trauma. Some foreign bodies may not be able to be pulled through the lower esophageal sphincter (LES) regardless of the retrieval instrument used. Overall, complications associated with the presence or extraction of gastric foreign bodies are uncommon and long-term prognosis is excellent with successful endoscopic removal.[18]

INTESTINAL ENDOSCOPY

Thomas Spillmann

Intestinal endoscopy has been used primarily in the diagnosis of intestinal inflammation, malignancy, ulcer, and anomalies such as lymphangiectasia. More recently, advanced interventional procedures have been introduced such as endoscopic retrograde cholangiopancreatography and endoscopy-assisted nasojejunal tube placement. More advanced endoscopic methods such as endoscopic ultrasound, double-balloon endoscopy, and wireless capsule endoscopy are now being introduced into clinical veterinary medicine.

Standard Push Enteroscopy of the Small Intestine

Indications

Small intestinal endoscopy (standard push enteroscopy) is indicated in dogs and cats with chronic or recurrent small bowel diarrhea, ill-defined vomiting disorders, recurrent abdominal pain, weight loss of unknown origin, and signs of gastrointestinal bleeding, such as hematemesis, melena, and microcytic, hypochromic anemia.[1-3] The decision to perform endoscopy should be based on the risk of anesthesia, and the likelihood of establishing a definitive diagnosis, prognosis, definitive treatment plan, and positive outcome.

Standard push enteroscopy of the small intestine is limited to the duodenum, proximal jejunum, and terminal ileum, the latter of which can be reached via colonoscopy.[1] Most of the jejunum is inaccessible with standard 100-cm gastrointestinal endoscopes. To diagnose pathologic processes that affect the jejunum in dogs and cats, laparoscopy and laparotomy with full-thickness biopsy are reasonable alternatives to standard push enteroscopy. Endoscopic alternatives such as double-balloon and wireless capsule endoscopy for distal enteroscopy have proven efficacy in humans,[4] and have already been used in dogs. Wireless capsule endoscopy may be more useful in larger-breed dogs in which the intestinal diameter permits passage of the capsule.[5-7] One experimental study in Beagle dogs concluded that wireless capsule endoscopy detected more artificial lesions (sutured plastic beads) in the small intestine than push enteroscopy.[7] More studies will be needed to determine the overall efficacy of wireless capsule endoscopy in the diagnosis of canine and feline gastrointestinal disease. Because double-balloon and capsule endoscopy still have limited distribution in veterinary medicine, most clinical decisions will be based on standard push enteroscopy, laparoscopy, or diagnostic laparotomy.

Chronic or recurrent small bowel diarrhea and weight loss can be caused by either systemic or intestinal diseases. After systemic diseases have been excluded, the decision for or against endoscopy is based on:

- Clinical assessment of disease severity,
- Response to previous empirical treatments,
- Results of laboratory tests, and
- Findings from other noninvasive imaging techniques (e.g., abdominal radiology and ultrasound).

Disease severity in dogs with suspected inflammatory bowel disease (IBD) may be quantified with the canine IBD activity index (CIBDAI), an index representing the sum of six clinical variables, including attitude/activity, appetite, vomiting, stool consistency and frequency, and weight loss.[8] A similar feline IBD (FIBD) index has been developed for use in cats.[9] A definitive relationship between CIBDAI and FIBD index scores and histopathologic findings has not yet been established. In contrast to an initial report that the CIBDAI correlates well with histology,[8] more recent studies have been unable to show any correlation.[10,11] At this time, high CIBDAI (and FIBD) scores should probably be seen as an indication for intensifying the diagnostic workup, especially when the patient does not respond to empirical treatment, laboratory results suggest systemic consequences of an intestinal disease process, or imaging results point to a specific disease process. The role of endoscopy in the monitoring of therapy and CIBDAI scores is also unsettled, because histologic changes might not improve, despite significant clinical improvements.[11,12]

Nonresponse to empirical treatment is another indication for direct endoscopy. In patients that have failed to respond to dietary modification, parasiticides, and antibiotics (with or without modulatory effect),[13,14] it seems reasonable to expect a higher likelihood of endoscopic findings that will influence treatment decisions. It has been shown in one study, for example, that dogs with glucocorticoid-responsive enteropathy have more severe histologic changes in the small intestinal mucosa than dogs with food-responsive enteropathy (60%).[15]

Push enteroscopy is clearly indicated in patients with clinical signs of upper gastrointestinal hemorrhage, that is, melena and hematemesis. It should be remembered however that push enteroscopy has distinct limitation in identifying jejunal sites of hemorrhage. Laparoscopy or laparotomy may be needed to diagnose causes of jejunal bleeding.

Laboratory tests are used in the assessment of systemic involvement and the need for intensified diagnostic workup. Useful laboratory parameters include serum total protein, albumin, cobalamin, folate, and C-reactive protein (CRP). Fecal α_1-antiprotease determinations will confirm protein-losing enteropathy (PLE) but will not differentiate among the various causes of PLE.

Hypoproteinemia is generally associated with a poorer prognosis and the necessity for more intensive medical therapy.[10,15,16] Push enteroscopy is a favorable alternative to laparotomy in PLE patients, especially when it is used to prove lymphangiectasia as the cause of PLE.[17]

Low serum cobalamin (vitamin B_{12}) and folate concentrations may be another indication for endoscopy. Concurrent cobalamin and folate depletion implies longstanding malabsorption when exocrine pancreatic insufficiency and small animal bacterial overgrowth have been excluded as the cause for vitamin B_{12} deficiency.[18,19]

Serum and fecal markers of inflammation may provide useful indicators of the need for small intestinal endoscopy. Canine serum CRP[8] and fecal calprotectin[20-22] have been suggested as noninvasive biomarkers of active inflammation, although the sensitivity and specificity of these assays have not been determined. Increased fecal α_1-antiprotease concentrations are associated with intestinal histopathology more often than not,[23] and may signal the need to perform gastrointestinal biopsies.[24]

Abdominal ultrasound is helpful in determining whether endoscopy, laparoscopy, or laparotomy should be chosen as the next diagnostic step. Laparotomy with full-thickness biopsy of the intestinal wall is indicated when ultrasound reveals marked thickening, irregularity, and loss of structure of the intestinal wall. These sonographic findings are strongly associated with neoplastic processes.[25-27] Endoscopy is indicated when abdominal ultrasound reveals intestinal hyperechoic mucosal striations in a hypoproteinemic patient. The finding is associated with lacteal dilation in patients with intestinal lymphangiectasia.[28] However, mucosal striations are neither specific enough to differentiate lymphangiectasia from other intestinal disorders nor predictive of the histopathologic severity.[29] Consequently,

ultrasound cannot replace endoscopic and histologic examination of the small intestinal mucosa. This is particularly true for IBD.[30]

In cats, because standard push enteroscopy may not have the same diagnostic value as in dogs, laparoscopy or laparotomy may be the preferred diagnostic method. In cats with IBD, ultrasonographic findings appear to have a better association with the histologic grade than endoscopy.[31] It has also been reported that full-thickness biopsy specimens are more useful in differentiating lymphoma from IBD in the small intestine.[32,33] In another important species difference, chronic FIBD may be complicated by concurrent pancreatitis and cholangitis (so-called triaditis). If these conditions are to be considered, laparotomy or laparoscopy with biopsies from all three sites may be more appropriate.[34]

Contraindications, Complications, and Limitations

Hypoproteinemia, hypovolemia, hypotension, coagulopathy, and excessive anesthetic risk are the most important contraindications for intestinal endoscopy. Intestinal distention and perforation are the most important (and life-threatening) complications of intestinal endoscopy. The most important limitations of intestinal endoscopy are the inability to differentiate lymphoma from severe IBD in some cases,[32,33,35] and the inability to safely retrieve many intestinal foreign bodies

Technical Requirements

Standard push enteroscopy of the small intestine requires the same flexible endoscopy equipment as described for gastroscopy. The diameter of the outer insertion tube should not exceed 9 mm. A 9-mm–diameter endoscope can be used in all cats and dogs weighing 4 or more kg. For cats and dogs weighing less than 4 kg, an endoscope with smaller diameter (e.g., 7.8 mm) would be more appropriate. In large-breed dogs, to achieve duodenal intubation and examination, the length of the endoscope should be at least 130 cm. In humans, four tissue biopsies are usually sufficient to characterize the disease and its severity.[36-38] In companion animals, it has been recommended that at least eight individual tissue pieces should be taken.[39] The best tissue sampling is performed with a biopsy forceps of 2.8-mm diameter. For biopsies of the small intestinal mucosa, side-opening cup forceps provide the best mucosal biopsies. With this approach the intestinal villi are sampled in the longitudinal rather than the transverse orientation. This allows better processing of the samples for histopathologic evaluation Spike forceps may be used but it should be recognized that they induce puncture artifacts.

Patient Preparation

Standard patient preparation for push enteroscopy includes a 12- to 18-hour fast, preoperative medications (e.g., dexmedetomidine and butorphanol), propofol induction, and isoflurane/oxygen or sevoflurane inhalant anesthesia. Atropine or glycopyrrolate should be given 30 minutes before dexmedetomidine to diminish the undesirable side effects of dexmedetomidine.[40] Duodenal intubation is technically more difficult in animals premedicated with atropine, butylscopolamine, atropine/opioid combinations, L-methadone, metoclopramide, or glucagon.[41,42]

Procedure

The patient is initially placed in left lateral recumbency to facilitate passage of the endoscope into the pylorus and duodenum. Following intubation of the esophagus and stomach, the endoscope is advanced into the distal antrum, and the endoscopic tip is pressed gently against the pylorus while maintaining it in the center of the pyloric lumen. The distal end of the endoscope is advanced slowly downward while maintaining pressure against the pylorus, which eventually opens to permit passage into the duodenum.

The small intestinal mucosa and villi are assessed while pushing the endoscope under visual control as far as possible into the duodenum. In cats and small dogs, it is often possible to reach the proximal jejunum. The World Small Animal Veterinary Association (WSAVA) Gastrointestinal Standardization Group has developed a standard protocol for the assessment of endoscopic findings (see Figs. 27-46 and 27-47). The report should contain general macroscopic findings such as mucosal appearance, masses, polyps, foreign bodies, parasites, and other luminal abnormalities. A grading system (normal, mild, moderate, severe) should be used to describe lesions such as failure to inflate the lumen, hyperemia/vascularity, edema, discoloration, friability, texture, hemorrhage, erosion/ulcer, and lacteal dilation.[43]

Findings

The normal duodenal and jejunal mucosa has a velvet appearance caused by the villi of the small intestine. The color of the canine intestinal mucosa is reddish pink (Fig. 27-29), while the feline intestinal mucosa has a lighter color, varying from cream to slightly reddish (Fig. 27-30). Peyer's patches represent the lymphatic tissue

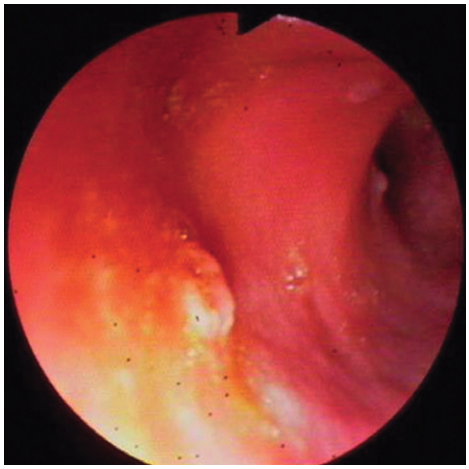

Figure 27-29 Endoscopic picture of normal small intestinal mucosa in the duodenum of a healthy Beagle, showing also the major, minor, and accessory papillae.[54]

associated with the intestine. They appear as shallow, 2- × 1.5-cm craters and can nearly always be visualized in dogs on the lateral wall of the small intestine, starting from the descending duodenum distally. The major duodenal papilla, representing the opening of the common bile duct and the pancreatic duct, can be found in both cats and dogs. Dogs usually also have a minor duodenal papilla, which is the opening of the accessory pancreatic duct of the exocrine pancreas. Dogs can have up to two accessory papillae corresponding with pancreatic ducts (Fig. 27-31). In cats, a minor papilla is rare but possible (Fig. 27-30).

When ileal endoscopy is performed (see "Colonic Endoscopy" section), the patient must be prepared as for colonoscopy to successfully intubate the ileocolic sphincter. Biopsies of the ileal mucosa can be sampled directly or taken blindly by gently passing the biopsy forceps through the ileocolic sphincter if passage through the sphincter is impossible.[1]

Macroscopic findings in the duodenum include intraluminal contents such as bile, food, foreign material (e.g., trichobezoars in cats), blood, and occasionally helminths. Abnormalities affecting the intestinal wall include edema, discoloration, friability, hemorrhage, erosion/ulcer, lymphangiectasia (see Fig. 27-31), and masses (Fig. 27-32 and 27-33). The absence of macroscopic abnormalities does not exclude severe histologic changes in the mucosa and submucosa. Furthermore, macroscopic changes are never pathognomonic for one disease process; for example, endoscopic findings of alimentary lymphoma can resemble lymphoplasmacytic enteritis.[44] Therefore, endoscopy of the small intestine should always be accompanied by mucosal biopsies for histologic interpretation.

Biopsies should be taken with a standard biopsy forceps or forceps with side-opening cups to preserve the longitudinal orientation of the intestinal villi. The best biopsy results are achieved when the cups of the biopsy forceps can be attached at a 90° angle to the intestinal wall. If this is not possible, sampling can be improved by air suction applied during the biopsy. Tissue samples are taken out of the forceps without squeezing, by using a blunt probe instead of a sharp needle to avoid damaging the forceps cups. The biopsies should be placed on a small wooden plate, plastic platform, or cassette in the same direction as they were in the cups of the biopsy forceps. This will facilitate the positioning of the intestinal villi (by the pathologist) in the longitudinal orientation. Tissue dehydration, for example, under a strong light source, should be avoided. The tissue platform is placed in a transport tube containing 10% formalin solution. The number and quality of the tissue samples plays an important role in the sensitivity of histologic findings.[43] A minimum of eight biopsies should be taken per site or gastrointestinal lesion.[39]

Endoscopic aspiration of the intestinal contents has been recommended for protozoal diagnosis, but is probably of limited diagnostic value. In one study, only six of 394 endoscopic aspiration samples from dogs and cats were diagnostic for *Giardia*, of which three cases were also positive in fecal flotation.[45] Duodenal fluid culture has been recommended for the diagnosis of small intestinal bacterial overgrowth (SIBO), but it, too, has limitations in sensitivity and specificity.[46,47]

Endoscopic Retrograde Cholangiopancreatography

Endoscopic retrograde cholangiopancreatography (ERCP) is a combination of endoscopy and fluoroscopy that is used to perform radiographic imaging of the biliary and pancreatic ductal systems.[48-55]

Indications

Endoscopic retrograde cholangiography (ERC) has had most of its applications in human medicine and is indicated in the diagnosis of extrahepatic cholestatic disorders caused by biliary tract stones, papillary stenosis, biliary tract inflammation, and acute (obstructive) pancreatitis, and in the control of postsurgical bile duct pathology.

Endoscopic retrograde pancreatography (ERP) is mainly used to differentiate pancreatic carcinoma from chronic pancreatitis.[48,56] Therapeutic applications for ERCP include extraction of bile stones, placement of drainage tubes or biliary stents, and performance of endoscope-guided sphincterotomy or papillectomy for the treatment of papillary stenosis.[48]

Contraindications, Complications, and Limitations

ERCP is contraindicated in patients with complete extrahepatic biliary obstruction when diagnostic endoscopy cannot be followed immediately by therapeutic intervention. Another contraindication is a pancreatic pseudocyst when the cyst cannot be drained immediately. Bacterial contamination of a pancreatic pseudocyst or of dilated bile ducts above a stenosis can cause life-threatening complications. Therefore, pseudocysts should be ruled out with abdominal ultrasound before performing ERCP.[49]

Complication rates of 0.7% to 1.38% for diagnostic ERCP have been reported in human studies.[57,58] Complications include acute pancreatitis (0.2%), purulent cholangitis (0.16%), sepsis (0.12%), injury of the common bile duct (0.08%), misinterpretation of artifacts (0.08%), and sedative-induced adverse effects (0.08%).[57] ERCP studies performed in healthy beagle dogs and dogs with chronic gastrointestinal disturbances have not revealed any important clinical complications,[54,55] although ERCP may be followed by a transient increase in serum amylase, lipase, and trypsin that returns to reference range within 1 to 2 days.[53]

In veterinary medicine, most uses of ERCP are limited by the size of the duodenoscope. Using a standard duodenoscope with a distal end outer diameter of 11 mm (JF 1T10; Olympus Medical Systems Corp., Tokyo, Japan), ERC was successful in 20 of 30 dogs (67%) and ERP in 21 of 30 dogs (70%). Successful intubation was impacted by intraduodenal food, mucus, or blood, problems in papillary cannulation, stomach overdistention, changes in duodenal mucosa, and body size. Because of size differences, ERCP is impossible to perform with a standard duodenoscope in dogs weighing less than 10 kg.[55] However, own investigations have shown that ERCP is also possible in cats with a body weight of 4 kg when using a pediatric side view duodenoscope (e.g., PJF 160, Olympus Medical Systems Corp., Tokyo, Japan).[56]

Technical Requirements

In contrast to standard push enteroscopy, ERCP requires a duodenoscope with a 90° side viewing optic (Fig. 27-34). For dogs larger than 10 kg body weight, a standard duodenoscope with a distal end outer diameter of 11 to 12 mm can be used.[53-55] For smaller dogs and cats, a pediatric duodenoscope (e.g., PJF 160; Olympus) with a distal end outer diameter of 7.5 mm is a viable option (Fig. 27-35).[56,59]

ERCP guidewires and catheters are necessary for intubation of the duodenal papilla and for injection of an iodine contrast medium into the biliary and pancreatic duct system (see Fig. 27-34). Additionally, fluoroscopy equipment is needed to monitor the filling of the biliary and pancreatic ducts and to obtain still or dynamic images. The contrast medium used for radiographic imaging of the pancreatic and extrahepatic biliary ducts by ERCP are iomeprol (Imeron 300; Bracco Byk Gulden, Konstanz, Germany)[53-55] and iohexol (Omnipaque 350; Schering, Berlin, Germany).

Patient Preparation

Patient preparation and anesthesia are similar to those for standard push enteroscopy of the upper gastrointestinal tract. The anesthetic regimes reported consisted of premedication with dexmedetomidine and butorphanol, followed by induction with propofol, and maintenance with isoflurane/oxygen inhalation.[53-55] Dogs should be treated with either enrofloxacin (5 mg/kg body weight)[53-55,60] or gentamicin and ampicillin 1 hour before ERCP.[48] Management of postoperative pain should always be considered.[54]

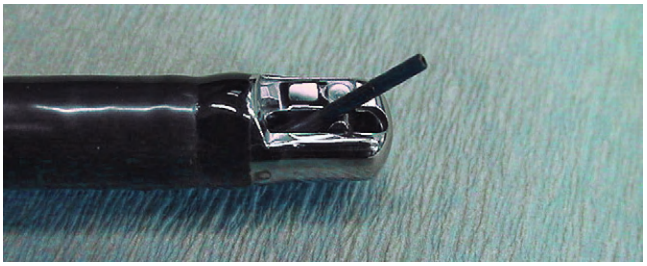

Figure 27-34 Distal end of a pediatric duodenoscope with 90° side view optic (PJF 160, Olympus). The inserted standard ERCP catheter is lifted up by the forceps elevator integrated into the tip of the endoscope.

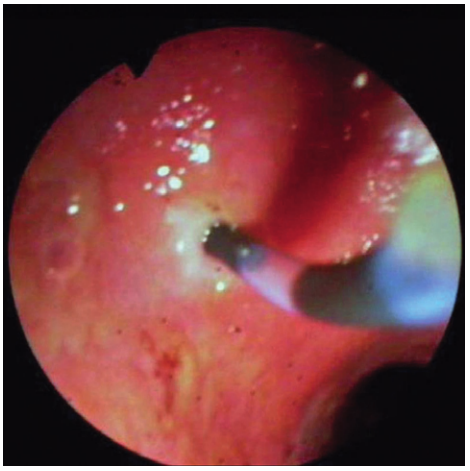

Figure 27-35 Endoscopic picture of the cranial duodenum of a dog. A contrast-filled ERCP catheter is placed into the minor papilla.

Procedure

As with push enteroscopy, the patient is placed in left lateral recumbency. Once the intestine has been intubated, the endoscope is pushed into the distal duodenum for safe placement prior to positioning the patient in dorsal recumbency. The duodenoscope is then gently pulled back into the proximal duodenum. In dogs, the distance between the pylorus and major papilla is approximately 5 cm (range, 3 to 7 cm). The proximal major papilla is observed at the 7 o'clock position and the distal minor papilla at the 11 o'clock position (see Fig. 27-29). When pancreatography is indicated, the minor (more distal) papilla should be cannulated first for contrast filling of the pancreatic ducts prior to cannulating the major papilla for cholangiography.

For radiographic imaging of the pancreatic and extrahepatic bile ducts, an ERCP catheter (e.g., standard CAN2 reusable ERCP catheter; Medwork Medical Products, Neuss, Germany) is filled with the contrast medium and pushed through the working channel of the duodenoscope. To insert the catheter into one of the papillae, it is necessary that the papilla is visible in the center of the image. For contrast filling of the common bile duct, gallbladder, and hepatic

bile ducts, 20 to 40 mL of iodine contrast medium is administered through the major papilla. A smaller volume of 1 to 2 mL iodine contrast medium is administered via the minor papilla (see Fig. 27-35) into the accessory pancreatic duct system.[54,55] Contrast filling is stopped when the main pancreatic ducts are clearly visible by fluoroscopy.[61] Overfilling of the pancreatic parenchyma should be avoided because of the high risk of inducing acute pancreatitis.[48,49,57,58]

Findings

The common bile duct in healthy Beagle dogs has a straight craniomedial course when assessed with ventrodorsal radiographs (Fig. 27-36). The duct diameter is 3.04 ± 1.89 mm at the proximal end, and tapers gradually to 2.11 ± 0.84 mm at the distal end. The right and left branches of the accessory pancreatic duct unite in the pancreatic body. The mean diameter of the two branches is 0.88 ± 0.14 mm at their junction, and 0.61 ± 0.11 mm at their distal ends. The mean length of the right and left branches was 81.6 ± 14.3 mm and 107.0 ± 24.9 mm, respectively (Fig. 27-37).[54]

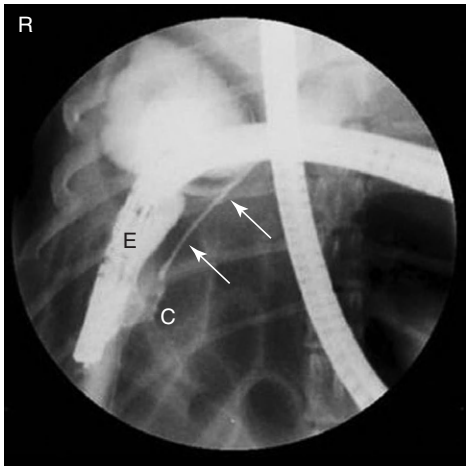

Figure 27-36 Endoscopic retrograde cholangiography of a healthy Beagle (dorsal recumbency). Marked structures from left to right are side view endoscope (*E*), catheter (C), and common bile duct (*arrows*).[54]

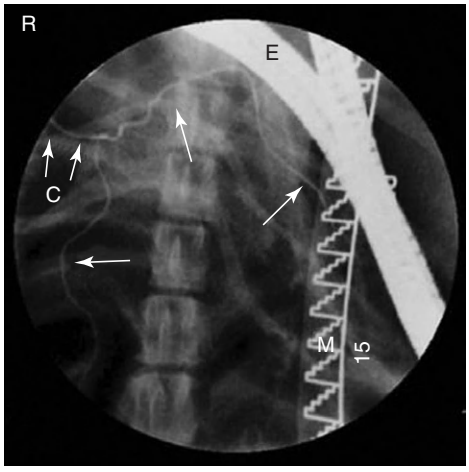

Figure 27-37 Endoscopic retrograde pancreatography of a healthy Beagle (dorsal recumbency). Marked structures from left to right are catheter (C, *open arrows*), right and left branches of the accessory pancreatic duct (*closed arrows*), side view endoscope (*E*), and radiopaque measure (M).[54]

Abnormal findings on endoscopic retrograde cholangiography (ERC) in dogs with chronic gastrointestinal problems have included enlarged common bile duct, intraductal filling defects (Fig. 27-38), deviated course of the common bile duct, and major papilla stenosis (Fig. 27-39). In one dog with stenosis of the major papilla and intraductal filling defects, endoscopic-guided sphincterotomy was successfully performed and led to improvement in the clinical signs of recurrent diarrhea, abdominal pain, and weight loss.[55]

Abnormal ERP findings in clinical patients have included accessory ductal deviation and end-stage pancreatic acinar atrophy (Fig. 27-40).[55] Experimental studies in dogs have revealed severe changes in pancreatograms after induction of chronic pancreatitis or pancreatic carcinoma.[62,63] ERP can probably be used in canine patients to differentiate pancreatic carcinoma from chronic pancreatitis, and to

grade chronic pancreatitis by the shape and degree of pancreatic duct dilation or stricture formation.[48,49]

Endoscopically Assisted Nasojejunal Tube Placement

Indications

Nasojejunal tube placement is indicated for postduodenal feeding of patients with uncontrollable gastric-origin vomiting, gastroparesis, biliary tract disease, and increased risk of aspiration secondary to impaired mentation, prolonged recumbency, or unprotected airways.[64,65] Another indication may be acute pancreatitis, because intrajejunal nutrition does not stimulate enterohormones, pancreatic secretion, or enzyme–protein synthesis and release. Although somewhat controversial in light of more recent ideas about the underlying pathogenesis of acute pancreatic necrosis, intrajejunal feeding may permit the inflamed pancreas to remain in a state of physiologic rest.[66,67] An experimental study in healthy dogs proved the feasibility of using nasojejunal tubes for short-term postduodenal feeding (3 to 5 days) without complications.

Procedure

A nasojejunal tube is placed under general anesthesia according to standard protocols for enteroscopy of the upper gastrointestinal tract. According to a placement protocol developed by Papa and colleagues,[63] the distal end of a standard gastroscope with a working channel diameter of 2.8 mm (e.g., GIF-100; Olympus) is inserted into the proximal duodenum and a Seldinger guidewire (350-cm long) is advanced through the working channel of the endoscope deep into the jejunum. The distal end of a polyvinyl chloride (PVC) tube (diameter 2.6 mm, length 250 mm) is marked with waterproof ink, using the following marking scheme: 20 cm = one ring, 40 cm = two rings, and 60 cm = three rings. The tube is placed over the Seldinger guidewire via the working channel into the duodenum until the three-ring mark is visible. Thereafter, the endoscope is removed while keeping the wire-stabilized tube in place. The endoscope is then reinserted into the stomach to ensure that the three-ring mark is within the duodenum. To avoid looping of the tube in the gastric lumen, it is necessary to pull the tube orally to place it close to the angulus fold after removal of the Seldinger guide wire. For nasal placement of the tube, a lidocaine-lubricated red rubber urinary catheter of similar diameter as the tube is inserted through one nostril into the nasopharynx and oral cavity. The proximal end of the feeding tube located in the oral cavity is firmly attached to the rubber catheter and pulled retrograde through the nasopharynx until it comes out of the nostril and straightens in the naso- and oropharynx. The tube is sutured to the skin lateral to the external nares, to the dorsal nasal midline, and to the forehead. To prevent self-removal of the feeding tube, an Elizabethan collar should be used. The appropriate placement of the tube in the jejunum is ensured by radiography. The tube can remain in place for up to 5 days.[64] One complication is the hardening of the PVC tube if it is maintained for several days in the stomach and small intestine. For guidelines and more details on how to perform nasojejunal intubation and feeding, see Chapter 33 and additional reference material.[68]

COLONIC ENDOSCOPY

Patrick LeCoindre

Colonoscopy refers to the endoscopic examination of the large bowel—the ileocolic sphincter, cecum, ascending colon, transverse colon, descending colon, and anorectal canal. Endoscopy of the distal ileum (ileoscopy) is often performed during the same procedure. Patient preparation is more cumbersome for colonoscopy, but the technique has become the method of choice for investigating clinical signs of colonic disease in dogs and cats. The inexperienced endoscopist will undoubtedly find this procedure technically challenging, but, the canine and feline large intestines are anatomically simple compared with other species and therefore are more readily accessible for direct examination. Furthermore, this technique will usually provide a definitive diagnosis of common colonic conditions, especially in the dog. Colonoscopy should not be regarded as a procedure that replaces complete history-taking, physical examination (including rectal examination), or laboratory-based investigations. Endoscopy should instead be seen as complementary to other parts of the medical investigation.

Instrumentation

Standard colonoscopes differ from most gastroduodenoscopes in their outer tube diameter (10 to 13 mm), working tube length (150 mm), and biopsy channel diameter (2.8 mm). For clinical practices unable to make the investment in two endoscopes, gastroduodenoscopes have also been used to perform colonic examination. Their major limitation will be in small-breed dogs and cats in which it may be more difficult to traverse the splenic flexure to reach the transverse and ascending colon.[1]

Ileocolic sphincter intubation is impossible to perform safely in small dogs and cats (weighing <10 kg).[2] Standard gastroscopes (9.0 to 9.8 mm) in dogs weighing more than 20 kg and pediatric gastroscopes (7.9-mm diameter) in dogs weighing 12 to 20 kg can be used to safely intubate the ileocolic sphincter and ileum.

Many practitioners have used rigid proctoscopes and sigmoidoscopes designed for human studies, but these devices are solely limited to visualization of the rectum and descending colon. They should instead be used to obtain deeper and larger biopsy samples, especially in the rectum which is most commonly involved in locally invasive neoplastic processes in dogs.[2]

Useful endoscopy accessories include multiple biopsy forceps, polyethylene catheters, and diathermy probes. There are several types of biopsy forceps, but the author favors the use of flexible biopsy forceps with fenestrated, ellipsoid jaws without needle. Some endoscopists will prefer using a central needle point to facilitate biopsy sampling of tubular organs, but it should be remembered that these devices produce puncture artifacts.[2,3]

Indications

Colonoscopy

Colonoscopy is indicated for patients exhibiting signs of large bowel diarrhea—tenesmus, dyschezia, fecal mucus, and hematochezia—that do not respond to dietary, antibiotic, and other empirical therapeutic trials.[3,4] Weight loss, hypoalbuminemia, and anemia are secondary but important indications for colonoscopy and biopsy.[3]

Hematochezia with normal or diarrheic stools is an important indication for colonoscopy. This sign is frequently observed in cats with chronic colitis and is the first and often the only clinical sign associated with rectal tumors in dogs.[4]

Although vomiting is reported more often with proximal digestive tract disorders, it may be observed in 30% of cases of large bowel disease. In fact, it may be the only clinical sign reported in cats with colonic disease. Because of the greater difficulty in using clinical signs to localize gastrointestinal disease in this species, it is generally advisable to perform a complete endoscopic screening including upper and lower digestive tract endoscopy.

Dyschezia, tenesmus, and constipation are another indication for coloscopy, particularly when anal and perineal examination have not yielded a definitive diagnosis. Colonoscopy is not necessary for the diagnosis of prostatomegaly, rectal diverticula with perineal herniation, or common diseases such as anal sac disease or perianal fistulae (anal furunculosis). It is most useful to diagnose infiltrative disorders, such as inflammatory bowel disease, neoplastic disease, fungal infections, and other anatomic abnormalities such as strictures. Ileocolic intussusceptions are readily diagnosed by colonoscopy, but ultrasound has a high sensitivity and specificity without the need for anesthesia.[5]

Finally, colonoscopy is indicated in cases of diarrhea of unknown origin to confirm functional disorders, for example, irritable bowel syndrome.[5,6]

Ileoscopy

Ileoscopy has several important clinical indications. It should be performed in conjunction with duodenoscopy when a severe, diffuse infiltrative disease of the small intestine, for example, lymphoma, IBD, protein-losing enteropathy, and lymphangitis, are suspected.[4,7,8] Ileoscopy may yield a diagnosis in some focal intestinal disorders such as regional granulomatous enteritis and focal lymphoma. Ileoscopy should also be considered when colonic disease is associated with systemic signs such as unexplained weight loss and chronic anemia.[2]

Ileoscopy can be performed on a more routine basis as part of the investigation of colonic inflammatory disorders as the disease process may extend into the distal ileum. Ileoscopy also permits the assessment of ileal sphincter incontinence and colorectal reflux, which are not uncommon complications of chronic colonic disease. Nevertheless, these observations should be confirmed on a large-scale study. As with more proximal GI disorders, histopathology may not correlate very well with endoscopic appearance, and therefore the endoscopist must be prepared to take serial biopsy samples from the area under investigation.[9]

Patient Preparation

Preparation of the Colon

The aim of patient preparation is to completely evacuate the colon of feces from the cecum to the rectum, for adequate visualization of the mucosa and enhanced biopsy quality.

Three days of fasting prior to colonoscopy would be ideal, but is rarely practical. As a compromise, 24 to 48 hours of (food) fasting is usually adequate. A low-residue diet (e.g., chicken, cheese, and water) may be fed prior to fasting to decrease the fecal load.

Oral laxatives should be administered on the day before the procedure. Laxative solutions containing polyethylene glycol with electrolytes (sodium chloride, potassium chloride, sodium bicarbonate, and sodium sulphate) (GoLYTELY; Seward) generally result in most reliable colonic cleansing. The electrolytes prevent dehydration and there is limited net fluid exchange in the small intestine.[10] Contraindications for administration of laxatives include patients who are already severely dehydrated, patients with intestinal obstruction, and those with severe colonic pathology that might be placed at increased risk for perforation.[11]

Polyethylene glycol solutions are recommended at a dose of 20 to 30 mL/kg body weight, for a total volume of 400 to 600 mL for a 20-kg dog. Administering such volumes often necessitates the use of nasogastric or orogastric intubation and is best performed in the hospital environment.[2,4]

Warm-water enemas can be used to augment oral laxatives, but are no substitute for them.[12] Large volumes are required (500 mL for a 10 kg dog, and up to 1.5 L for a 30-kg dog). Enemas can be given repeatedly on the day prior to colonoscopy and again a few hours before the procedure.

Enemas are less effective in cats because of the adherence of the feces to the feline colonic mucosa. They are necessary, however, because the administration of oral laxatives is not well tolerated in many cats. Moderate volumes are used (50 to 75 mL per cat) and are introduced slowly as brisk and excessive dilation of the colon can lead to vomiting and even cardiovascular shock.

Careful examination of the anal and perineal area by palpation is warranted prior to colonoscopy in order to rule out obstructive rectal conditions and rectal diverticula that could perforate during colonoscopy.

Restraint, Neuroleptanalgesia, and Anesthesia

In most cases of colonoscopy, moderate neuroleptanalgesia may be sufficient. Anesthesia is recommended, however, whenever ileoscopy or deep biopsies in the anal or rectal area are to be performed.[2,11] General anesthesia will be also needed, particularly in cats, when colonoscopy is performed as part of a full endoscopic evaluation of the lower and upper digestive tract.

Specific Procedures

Endoscopic Technique

Endoscopy of the colon is performed with the animal placed in left lateral recumbency to avoid the accumulation of fluid in the transverse colon and to facilitate passage of the colonoscope at the splenic flexure. In the dog and cat, there is no sigmoid flexure and the colon is fairly easily intubated. After a digital rectal examination has been performed, the endoscope is lubricated with a local anesthetic gel and the endoscope is advanced into the rectum using moderate insufflation to lift the rectal mucosa off of the endoscope.

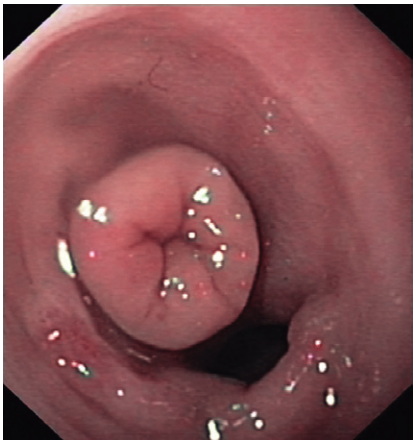

Figure 27-41 Endoscopic view of the cecocolic opening and the ileocolic sphincter in a normal dog. In dogs, the latter structure appears as a round cuff of mucosa membrane which is often very congested.

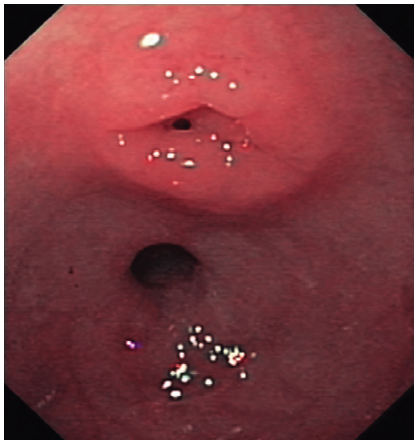

Figure 27-42 Endoscopic view of the ileocecocolic sphincter area of the cat. The ileocolic sphincter appears as a small mucosal fold.

Occlusion of the anal orifice improves insufflation by preventing air leakage.

Once the colon has been adequately distended, the endoscope is advanced into the descending colon up to the splenic flexure (i.e., the junction between the descending and transverse colon). The transverse colon is entered by directing the end of the endoscope dorsally at the splenic flexure. The transverse colon is short in the dog (on the order of 5 to 8 cm) and is delimited proximally by the hepatic flexure.[1,4]

Passing the endoscope beyond the hepatic flexure permits visualization of the ascending colon.

For inexperienced endoscopists, it may be difficult to pass the endoscope through these two flexures, especially in small-breed dogs and cats.[1] In the cat, the transverse and ascending colon are very short segments and form a single curvature that links the descending colon to the ileocecocolic sphincter. Care must be taken not to exert too much physical pressure on the endoscope when passing through these flexures. In some patients, it may be necessary to alternately move the endoscope forward and backward while maintaining insufflation.[1]

Despite the best of planning and patient preparation, residual fecal fluids and adherent fecal material may make it necessary to irrigate the colon to achieve adequate visualization.

In dogs, the ileocolic sphincter appears as a round cuff of mucosa membrane, which is often very congested (Fig. 27-41). The ileocolic sphincter is different in the cat in which it appears as a small mucosal fold (Fig. 27-42). It is not always possible to intubate the ileocolic valve, particularly in small dogs and cats, but biopsy samples can be obtained by passing the biopsy forceps from the ascending colon into the distal ileum to obtain blind ileal tissue biopsy samples (Fig. 27-43).

The entrance to the cecum is located to the side of the ileocolic sphincter. It is often folded upon itself and contains chyme, such that irrigation and insufflation may be necessary before the mucosa can be examined. Examination of the cecum can reveal whipworms or inflammatory lesions that can easily be biopsied.[2]

Endoscopic examination of the descending colon is carried out as the instrument is withdrawn at the end of the procedure. During endoscopic retraction, the tip of the endoscope should always be positioned in the center of the lumen.[4] The normal mucous membrane is pale pink, smooth and shiny. Submucosal blood vessels and

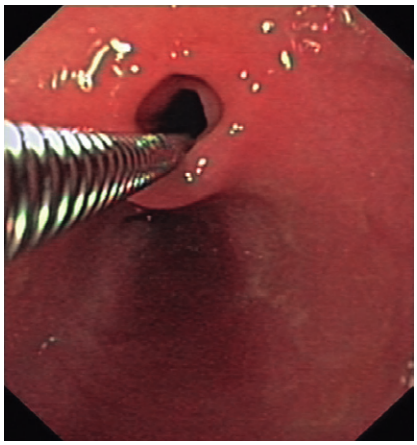

Figure 27-43 It is not always possible to advance the endoscope through the ileocolic sphincter, particularly in small dogs and cats, but biopsy samples can be obtained by passing the biopsy forceps into the distal ileum to obtain blind ileal tissue biopsy samples.

lymphoid patches (2 to 3 mm in diameter) are readily observed. Hyperemia of the mucosa is frequently seen but this change can be physiological, as a consequence of water enemas or of endoscopic passage. Varying amounts of mucus may be observed.

The anorectal canal is easily distended to permit retroflexion of the endoscope and examination of the anal margin from the rectal side. This procedure is possible only in dogs more than 20 kg of bodyweight, because retroflexion and rotation of the endoscope require a minimal luminal diameter. This latter procedure should be performed whenever possible as lesions are common in this part of the alimentary tract (Fig. 27-44).[2]

Colonic Biopsies

Most colonic diseases are associated with mucosal pathology and occasionally with submucosal pathology at some time during their development. Endoscopy enables the clinician to detect small lesions at an early stage, and, as with the small intestine, histologic examination of biopsies is the only means of determining the exact nature of the lesion. Biopsies should be acquired in a systematic way at every level of the colon, even if the mucosa membrane appears normal, because endoscopic changes and histopathologic findings are not always well correlated.

Figure 27-44 Retroflexed view of the rectum of a dog with granulomatous and ulcerative lesions of the rectal mucosa.

Endoscopic biopsy forceps take small pieces (rarely larger than 2 mm) of the mucosa and occasionally the submucosa. As with the esophagus and intestine, endoscopic biopsy in a tubular organ like the colon is more difficult than biopsy procedures in a hollow viscus like the stomach. Using the control mechanism at the handle, the end of the endoscope should be deflected until it is at an angle of 70° to the gut wall, at which time the jaws of the forceps can grasp the colonic mucosa. Applying concurrent suction will decrease tension in the colonic wall so that larger and deeper samples may be obtained. The associated risk of perforating the wall is negligible.[11]

Collection of brush samples for cytological examination may be useful in the diagnosis of certain conditions, such as histoplasmosis, protothecosis, and neoplasia.

BIOPSY GUIDELINES

Michael Willard and Joanne Mansell

Endoscopy has been called "minimally invasive surgery." If endoscopy can be done well enough that it replaces the need for invasive surgery, then it is usually worth doing. If endoscopy cannot be done well enough to avoid the need for invasive surgery, then it is often a waste of time and money. In particular, obtaining good quality diagnostic endoscopic biopsies can be difficult,[1] and consistent success requires practice, constructive criticism, and attention to detail.

Laboratory Testing

Complete blood count and serum biochemistry are routinely indicated prior to flexible endoscopic biopsy, and the same tests plus at least a mucosal bleeding time are important when performing rigid laparoscopy to collect biopsy samples from the liver. These tests are important not only to prepare for anesthesia, but also to alert the endoscopist to risks (e.g., hemorrhagic tendencies) or lesions that may require special consideration (e.g., lymphangiectasia).

Diagnostic Imaging

Abdominal ultrasound is routinely indicated before endoscopic biopsy of almost any abdominal organ. Finding a mass or infiltrate may allow percutaneous aspiration that diagnoses lymphoma, carcinoma, histoplasmosis, and so on. Ultrasound may also reveal localized lesions that are outside the range of the endoscope (e.g., a mass in the mid-jejunum) or that cannot be detected endoscopically (e.g., mass in the middle of a lung lobe), thus alerting the clinician that a surgical rather than an endoscopic biopsy is necessary.

Flexible Endoscopic Biopsies

An important advantage of endoscopy is its ability to reveal focal mucosal lesions that cannot be identified from examination of the serosal surface of the intestine, thus allowing the endoscopist to direct the biopsy forceps to the lesions.[2] Mucosal lesions can be very localized (Fig. 27-45A to C), and there may be more normal-appearing mucosa than abnormal mucosa, even in severely ill patients. Sampling the gross lesions may be crucial to obtaining a diagnosis as nonaffected tissue millimeters away may be nearly normal (Fig. 27-45D to F). Detailed endoscopy reporting forms were developed by the WSAVA Gastrointestinal Standardization Group in an attempt to promote complete endoscopic examinations (Figs. 27-46 and 27-47) that will hopefully result in fewer missed lesions.

It is crucial to provide the pathologist with the best possible tissue samples. Tissue samples should be as large as possible, free from artifact, and include the full thickness of the mucosa (with or without submucosa; Fig. 27-48). It is often easier to obtain high-quality tissue samples from smaller animals and from the ileum, probably because the mucosa is thinner. Taking multiple, high-quality samples from one site may be necessary to find certain lesions. Recent work shows that the quality of the endoscopic biopsy is inversely proportional to the number of samples that are required to find specific lesions. For example, to have 95% confidence in finding intestinal crypt lesions or lymphangiectasia with inadequate samples requires 28 or 62 pieces, respectively. If the tissue samples are adequate, those numbers fall to four and nine, respectively. In general, a minimum of eight to 10 good-quality duodenal tissue samples are recommended.[3]

There are numerous techniques and types of forceps.[2,4-6] The authors prefer reusable forceps with elongated, fenestrated jaws having serrations on the sides. To obtain the best possible tissue samples, the biopsy forceps are typically pushed into the intestinal mucosa at as close to a 90° angle as possible. The authors' technique (sometimes described as the "turn-and-suction" technique) is as follows[2]: (a) advance the biopsy forceps several millimeters in front of the tip of the endoscope; (b) open and then retract the jaws until they rest against the tip of the endoscope; (c) maximally deflect the tip of the endoscope so as to come as close as possible to looking at the adjacent intestinal mucosa at a 90° angle, typically causing a "red out"; (d) apply suction and advance the opened biopsy instrument 3 to 5 mm into the mucosa. There should be substantial resistance while advancing the biopsy forceps, in this way you are pushing the forceps deep enough into the mucosa to obtain full-thickness of mucosa (and maybe submucosa); (e) the jaws of the biopsy forceps are closed, the tip of the scope straightened out, and the biopsy instrument is withdrawn. Pushing too hard may cause the tip of the biopsy forceps to turn and start sliding along the mucosal surface. If substantial resistance is not encountered, the tip of the biopsy forceps is sliding along the mucosal surface. Good tissue samples obtained should have a consistency that is relatively "solid" as opposed to the "jelly-like" consistency seen when more superficial samples are obtained.

Text continued on page 296

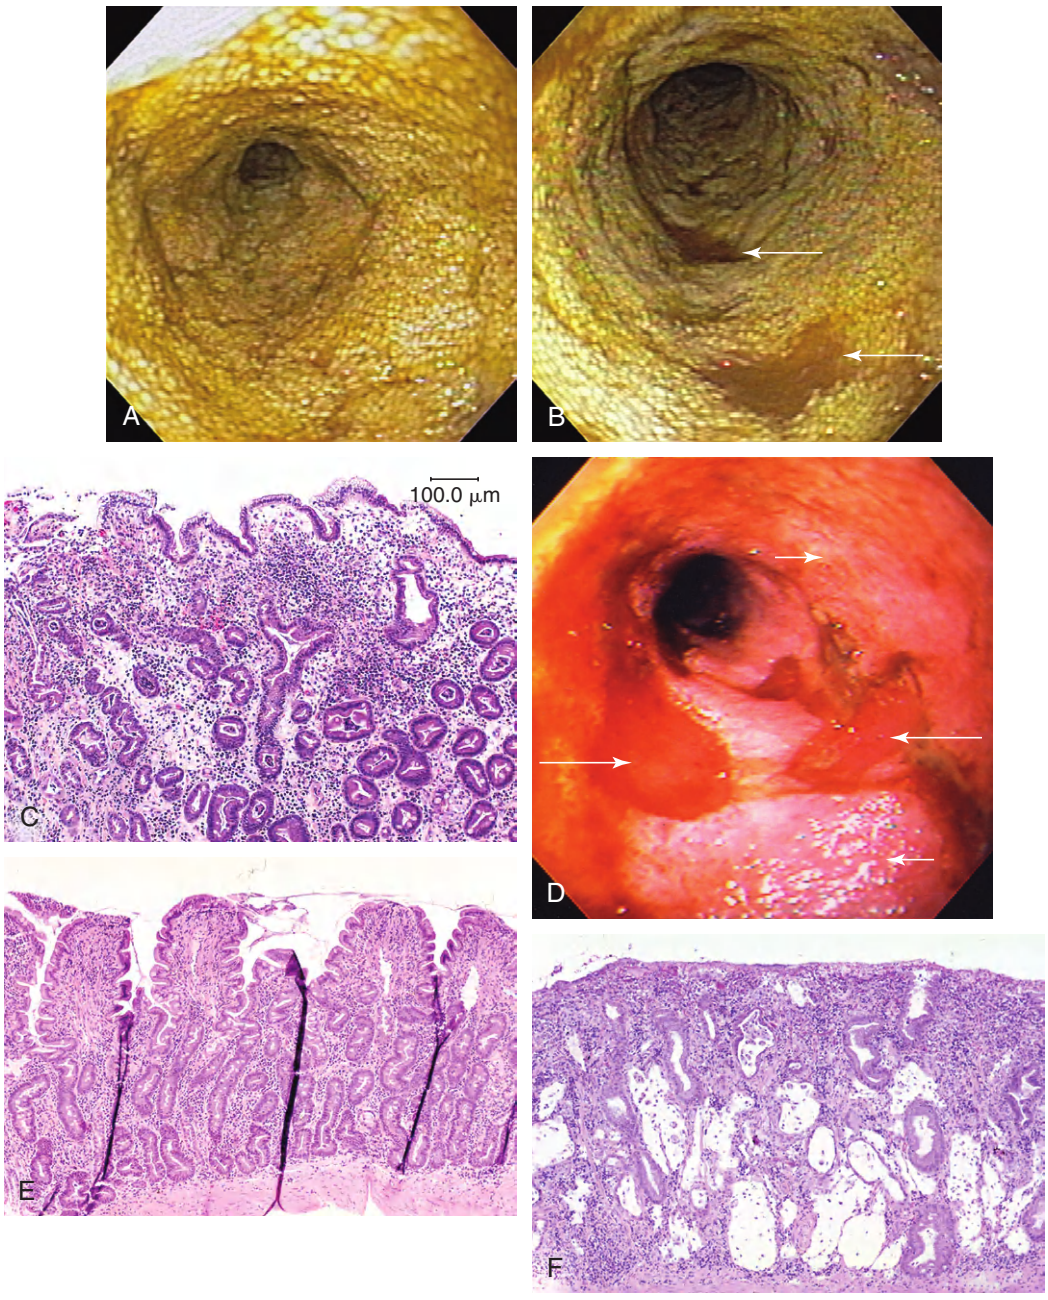

Figure 27-45 **A**, Endoscopic view of the duodenal mucosa of a Pug with a severe protein-losing enteropathy (serum albumin 1.4 g/dL). The mucosa appears uniformly normal throughout this image. **B**, Endoscopic view of the same duodenum. This image was taken several centimeters further aborad. Now focal areas that appear to have loss of villi (i.e., the surface is depressed relative to the rest of the mucosa and is smooth, *arrows*) can be seen. However, there is still more normal-appearing mucosa than abnormal-appearing mucosa. **C**, Photomicrograph of a tissue sample from the depressed, smooth areas seen in **(B)**. Note that there is an intact epithelial surface but a complete loss of villi plus a marked inflammatory cell infiltrate. **D**, Endoscopic view of the duodenum of a Bedlington Terrier with severe diarrhea and protein-losing enteropathy. Note that there are areas of the mucosa that are relatively light colored (*small arrows*) and other areas that are darker red in color (*larger arrows*). Also note that the darker red areas comprise a much smaller portion of the surface area of the duodenal mucosa. **E**, Photomicrograph of the light-colored duodenal mucosa seen in **(D)**. Note that this is relatively normal except for some villus blunting. **F**, Photomicrograph of the darker-colored duodenal mucosa seen in **(D)**. Note that there is fusion of villi (despite an intact but damaged and attenuated epithelial surface) and severe distortion of mucosal crypts. This is severe mucosal disease.

This standard form was developed by the WSAVA Gastrointestinal Standardization Group (Drs. Washabau, Willard, Hall, Jergens, Day, Mansell, Wilcox, Minami, Guilford, and Biltzer) with sponsorship from Hill's Pet Nutrition.

Figure 27-47, cont'd

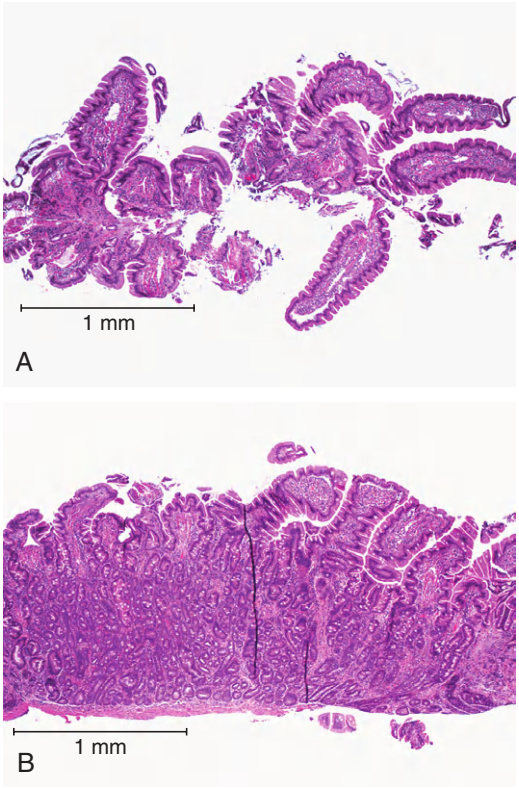

Figure 27-48 **A**, Photomicrograph of duodenal tissue taken endoscopically from a dog. Note that there are several villi but the subvillus mucosa is severely distorted and largely absent. **B**, Photomicrograph of duodenal tissue taken endoscopically from same dog shown in **A**. One can see the full thickness of the duodenal tissue, including a little submucosa. The orientation is not optimal as evidenced by the fact that the crypts are not perpendicular and are cross-sectioned, and accurately judging villus length would be impossible in this section.

Ileal biopsies can sometimes provide a diagnosis not available from duodenal biopsies, especially in cats.[2,7-9] If the endoscope can be inserted into the ileum, then the technique for obtaining ileal biopsies is essentially as described previously. If the endoscope cannot be inserted into the ileum, then the biopsy forceps are blindly passed through the ileocolic valve, the forceps jaws opened, and the forceps advanced until resistance is felt. Then the jaws are closed and the sample retrieved.

Gastric biopsies are relatively easy to obtain because it is usually easy to have a near–right-angle approach to the gastric mucosa. Antral and pyloric mucosa is typically much "tougher" than other parts of the gastrointestinal tract; therefore, one must typically close the endoscopic forceps very tightly, straighten the tip of the endoscope and vigorously "jerk" the forceps back through the endoscope.[2]

Colonic mucosa is sampled much as described for duodenal mucosa.[2,7,8] The flat surface and thin nature of the mucosa make it relatively easy to obtain excellent tissue samples. Rigid colonoscopic biopsies are now performed infrequently, but they typically retrieve tissue samples far superior to anything a flexible endoscope can produce. Using rigid as opposed to flexible endoscopic biopsy forceps is often necessary to diagnose submucosal rectal and colonic lesions (e.g., scirrhous carcinomas). For submucosal rectal lesions, it is often easier to sample "blindly," digitally guiding the biopsy forceps instead of visualizing the lesion with an endoscope.

Laparoscopy

As for flexible endoscopy of the gastrointestinal tract, rigid endoscopic procedures must be done accurately to ensure that focal lesions are identified.[10] Laparoscopic biopsies should generally be obtained with rigid forceps as opposed to core biopsy needles; otherwise one might just as well take the biopsies with ultrasound guidance instead of laparoscopy. "Double-spoon"–type forceps are preferred for hepatic biopsies, whereas pancreatic biopsies generally require a "punch"-type forceps. It is reasonable to obtain at least one and preferably two samples from each hepatic lobe that is accessible, unless there is one lesion that is obviously the problem (e.g., tumor) or there are marked bleeding tendencies. Hepatic samples are generally obtained from the margins of the liver lobes, but one can thrust one side of the double spoon forceps into the surface of the hepatic lobe to obtain samples from the middle of the lobe. Laparoscopy can also be used to sample the pancreas, kidney, and intestines.[11]

Submission for Histopathology

Flexible endoscopic samples of the duodenum and ileum are fragile and must be handled carefully to minimize artifact and allow the laboratory to orient the tissues properly. It is important to traumatize the villi as little as possible so that the pathologist may accurately determine if villus atrophy is present.

Submission of the tissue samples is equally important.[2,4] In the authors' practice the tissue is first examined while still in the biopsy forceps to see if it is folded. Once it is unfolded, it is carefully lifted out of the jaws with the tip of a needle and laid on a histopathology sponge (commercially available sponges precut to fit a histology cassette) with the submucosal side down and the villi up. After all the samples are obtained, the sponge is gently placed in formalin with the specimen side down. The histopathology laboratory knows to embed these samples at a right angle relative to how they are placed on the sponge. In this way, most of the samples will hopefully be sectioned longitudinally (i.e., parallel to crypts and villi). If the laboratory does not know (or care) how the tissues are oriented when sectioned, then you may need to consider whether this laboratory is providing the information you need for your patients.

Gastric and colonic mucosal samples are relatively easy to handle; they have no villi making it irrelevant whether the mucosal surface or submucosa is placed down on the sponge. The most important aspect of handling these samples is to ensure that they are not folded; but it is critical not to "stretch" the samples when unfolding them and placing them on the sponge.

Laparoscopic hepatic and pancreatic biopsies are relatively easy to handle compared with endoscopic biopsies of the intestines and they can be placed directly into formalin. The major artifact to avoid is drying of the tissue before it is placed in formalin. Orientation is not important.

Histopathology Reports

It is important for the clinician to understand what information an endoscopic biopsy can provide and not have unrealistic expectations of how much information can be obtained from biopsies (endoscopic or full-thickness). It is essential that the clinician provide a full clinical history. In addition, it is important for clinicians to state what they need to know from the biopsy because this information can affect how the pathologist asks the laboratory to process or stain the specimens. Without a clinical history, it is often impossible for the pathologist to know what information is desired. Clinicians

should understand that distinguishing between some diseases with histopathology may not be possible because the intestine responds to many stimuli in a general way (e.g., lymphocytic and plasmacytic infiltrates). Currently it is difficult (perhaps impossible) to distinguish between canine IBD, antibiotic-responsive enteropathy, and diet-responsive enteropathy, or between severe feline lymphocytic enteritis and well-differentiated mucosal lymphoma.

Use a laboratory and pathologist with whom you feel comfortable communicating. The interaction of clinician and pathologist is essential to producing informative results.[12] Endoscopic biopsies of the gastrointestinal tract are relatively difficult to evaluate histologically, and this process is not made easier if inadequate specimens are submitted or inadequate clinical history is supplied. Conscientious pathologists typically feel pressure to find a pathologic change in tissues, and there can be a tendency to overread endoscopic biopsies, assuming that a disease process must be present because the area was sampled. Feel comfortable in calling the pathologist if you have queries about the diagnosis and feel comfortable if the pathologist calls you with queries about the specimens or history. Communication is essential in jointly forming the correct diagnosis.

It is important that the pathology report include the number of pieces of tissue submitted, the presence/absence and severity of collection or processing artifacts, general quality of the samples in terms of the depth of the mucosa that can be examined (e.g., full mucosal thickness, partial mucosal thickness, mostly villus fragments), orientation on the glass slide, a description of the severity of the lesions found, and a diagnosis when appropriate. A conscientious endoscopist will want to know if the samples submitted were adequate or inadequate, and will typically ask the pathologist to comment on this in the report. Without this information, it becomes very difficult for the clinician to know how much faith to place in the histologic diagnosis.

Interpretation of Biopsy Results

There are two questions that must always be asked when evaluating a diagnosis (histologic or otherwise). First, does the diagnosis fit the patient (i.e., does the diagnosis seem reasonable)? Although it is possible that any particular patient may have some strange, unexpected disease, these are not common. Second, does the response to treatment fit the diagnosis (i.e., do the drugs, diets, etc. that the books say should work actually help this patient)? If the answer to either of these questions is "no," then it is appropriate to reconsider whether the histologic diagnosis was correct.

INTERVENTIONAL ENDOSCOPY

Massimo Gualtieri

Flexible endoscopy has a fundamental role in the treatment of specific diseases of the GI tract. The most common therapeutic indication of endoscopy in small animals is the removal of GI foreign bodies. Gastric and esophageal foreign bodies are frequently encountered in dogs and cats and endoscopic retrieval is currently considered the therapeutic procedure of choice for this condition. Endoscopic treatment is critical also for other less-common lesions of the digestive tract, such as esophageal strictures and GI polyps, for which surgery represents an invasive option, often associated with a high rate of failure (e.g., thoracic esophageal strictures, rectal polyps). A further possible therapeutic indication of endoscopy is the excision of preneoplastic mucosal lesions such as gastric intestinal metaplasia and mucosal dysplasia.

Treatment of Esophageal Strictures

Esophageal strictures may be classified as congenital or acquired, benign or malignant, and, based on their origin, as intramural or extramural. Endoscopic treatment of esophageal strictures finds its best indication in acquired benign intramural forms. Congenital forms are extremely rare and may appear as fibrous rings or membranes rings at different levels in the esophagus.[1-4]

An esophageal stricture may develop secondary to severe mucosal lesions or esophagitis of different origin extending to the submucosal or muscle layer of the esophagus.[5-12] The reparative process by intramural fibrosis leads to the stricture formation. Malignant strictures (squamous cell carcinoma and primitive or secondary esophageal sarcoma) are very rare in small animals and, unlike in people where palliative dilation is performed, are usually not treated because of their advanced clinical stage when clinical signs appear.[13-16]

Treatment options for benign esophageal strictures include conservative and surgical procedures. Conservative treatment is based on mechanical dilation of the narrowing (bougienage, balloon catheter dilation),[6,7,9-11,17-21] endoscopic electrocautery incision of the fibrous tissue,[6,11,22] and stent placement[9] (Fig. 27-49). Surgery includes resection and anastomosis, esophagoplasty or reconstructive procedures (patch grafting), and is indicated when conservative treatment fails or in case of neoplastic or large strictures.[23-28] Conservative endoscopic dilation of esophageal strictures by bougienage or balloon catheter is preferred over surgical treatment. In veterinary literature, a success rate of 50% to 75% for bougienage and as high as 85% for balloon catheter dilation is reported, whereas surgery is successful in less than 50% of cases.[6,18,20] Similar success rates for conservative and surgical treatment have also been obtained by the author,[29] who did not experience major success differences between bougienage and balloon catheter technique, as reported in humans.[30-32] The main consideration in choosing between the two procedures appears to be financial, as balloon catheter instrumentation is far more expensive than bougienage; furthermore, the pneumatic material of a balloon catheter is far less durable than the rigid material of bougies.

Esophageal surgery is usually technically demanding and associated with a high frequency of complication such as stricture formation and/or leakage at the anastomosis site.[17,23,26,29]

Bougienage

Bougienage involves the passage of progressively larger instruments through the stricture. Several bougienage techniques are available but the most widely used are semiflexible polyvinyl bougies with conic tips (Savary-Gillard, Stark, Celestin, etc.) and metallic olives (Eder-Puestow), both with progressively larger diameter and driven

Figure 27-49 Nitinol stent for stabilization of esophageal stricture. (Courtesy of Christopher J. Chamness.)

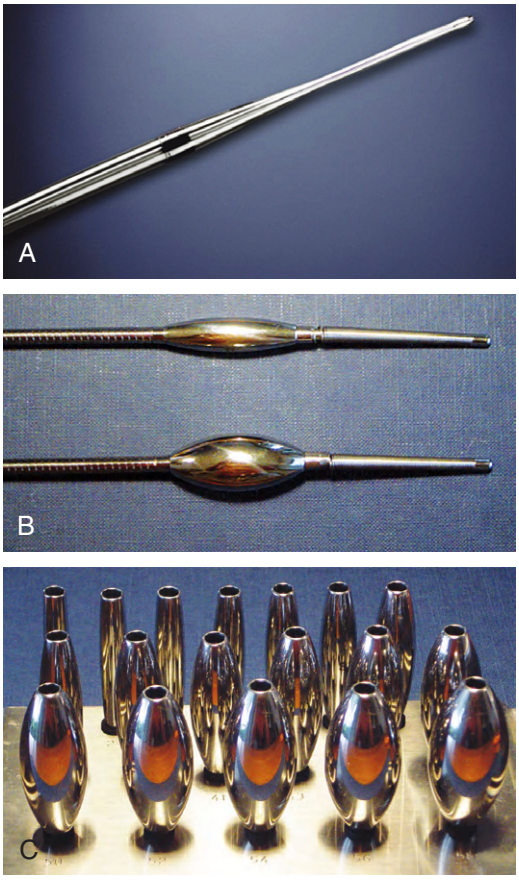

Figure 27-50 Bougienage. **A**, Savary-Gillard dilator. These dilators consist of a range of polyvinyl tubes (5- to 20-mm diameter), each with a 20-cm tapered tip. A radiopaque band at the widest point of the dilator aids radiologic localization. **B**, Eder-Puestow dilator. Metal olives are mounted on a flexible shaft and moved on a guidewire. **C**, Series of graduated metal olives (6.6- to 19.3-mm diameter). (**A** is courtesy of Cook-Medical.)

on a guidewire (Fig. 27-50). With bougienage, the longitudinal forces applied are transformed into radial forces that dilate the stenotic tract.

The dilation is performed with the patient under general anesthesia and after a complete assessment of the stricture site has been done. Probes are driven on a metallic guidewire to prevent the risk of perforation as a result of the blind introduction of the dilator through the stricture. The tip of the endoscope is advanced to the stricture; then the guidewire with flexible tip is introduced in the instrument's operative channel. It is advanced through the stricture, at least 20 to 30 cm below the lowest point of the stricture, usually in the gastric antrum. In the gastric cavity, the harmonic steel guidewire winds in coils assuring its stability in the stomach. When retrieving the endoscope, the guidewire is left in situ and fixed externally to minimize the risk of internal displacement.

When flexible bougies are used, a well-lubricated bougie is introduced on the guidewire and is advanced to the stricture, which is passed by applying a gentle pulsion until a lower resistance of the fibrous tissue is felt (Fig. 27-51). It is crucial in this phase to avoid excessive forces so as to prevent the severe complication of esophageal laceration. The bougie is passed forward and backward through the dilated tract; then it is retrieved and the procedure is repeated with a larger bougie. Between dilations, repeated endoscopies should be done to assess the evolution of the blind procedure (Fig. 27-52). The introduction of progressively larger probes causes the distention

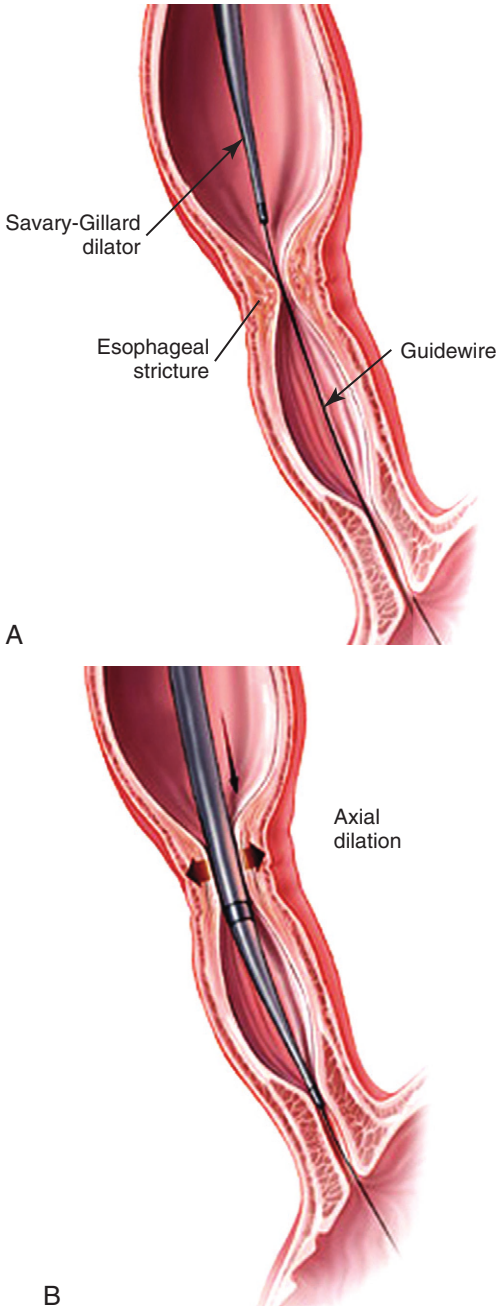

Figure 27-51 **A**, Esophageal dilation with Savary-Gillard device. The dilator is introduced on the guidewire and advanced until the stricture. **B**, The dilator is gently advanced through the stricture. Wire-guided dilation gives greater assurance that the dilator is following the line of the esophageal lumen, thus reducing the risk of perforation.

and subsequent dilation of the stricture; the procedure should be repeated until an improved lumen diameter is obtained. A 1-cm diameter is usually appropriate for cats and small-size dogs (≤10 kg). In larger dogs, a 1.5- to 2-cm diameter may be required.

The Eder-Puestow device includes metallic olives with graduated diameter that are assembled on a flexible supporting pole. The metallic supporting pole with progressively larger olives is assembled on the guidewire and passed through the stricture repeatedly until an improved lumen diameter is obtained, as seen for semiflexible bougies.

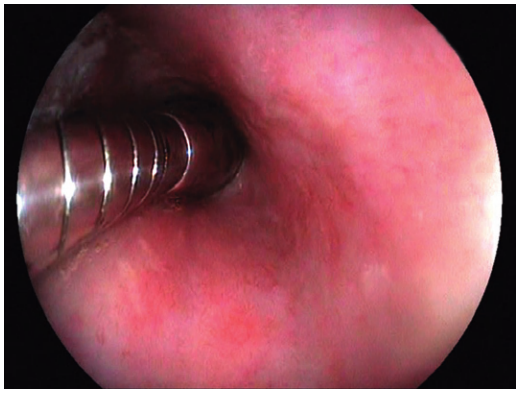

Figure 27-52 Esophageal dilation with Eder-Puestow device. A metal olive, a few millimeters larger than the stricture, is mounted on a flexible shaft and advanced through the lesion.

Figure 27-53 Inflation device used to inflate, deflate, and monitor pressure of the line of balloon dilators during esophageal stricture balloon dilation. (Courtesy of Cook-Medical.)

Key to a successful outcome of the procedure is the accurate endoscopic assessment of the esophageal mucosa of the prestenotic and stenotic tract before dilation. Prestenotic mucosa may show inflammation, erosion, and even ulceration, while the fibrous tissue may be limited to the stenotic ring. A similar condition means that the lesion is still evolving as the inflammatory process underlying the condition and/or the healing–scarring process has not completed ("active stricture"). Any dilation procedure attempted in this phase induces an adjunctive trauma on an already altered and inflamed substrate (the esophageal wall). The consequence is a strong inflammatory response of this tissue increasing the scarring process. When instead the scarring process has ultimate ("stable stricture"), the prestenotic mucosa appears whitish with an irregular surface, sometimes cribrous and markedly thickened. The endoscopic assessment of these aspects is of great importance for therapeutic and prognostic purposes. Treatment of "stable" strictures results, in the author's experience,[9,29] in a lower rate of early relapse compared with active lesions. For this reason, treatment of these forms should be delayed, if appropriate, for 2 to 3 weeks, during which the patient can be fed by a gastrostomy tube and treated for the underlying disease (e.g., gastroesophageal reflux disease). Regardless of the dilation device used, the procedure may be repeated at 7- to 15-day intervals until a lumen diameter large enough to allow adequate feeding is achieved. The total number of dilation procedures may vary from one to seven and may be dictated by the severity of the stricture and the clinical answer to treatment (clinical signs of obstruction).

Balloon Catheter Dilation

In this procedure, stationary radial forces dilate the stricture in a centrifugal manner. Polyethylene balloon catheters (Wilson-Cook, Rigiflex Dilator; Microvasive Inc., Milford, MA) are available with different inflated diameters up to a maximum of 20 mm (see Figs. 27-20 and 27-53). Balloon catheters can be passed through a 2.8-mm accessory channel of the endoscope, or alongside the scope under direct endoscopic or fluoroscopic vision. The catheter of appropriate diameter (i.e., based on the lumen diameter desired) is advanced until the lumen of the stricture is reached (Fig. 27-54A). Once positioned, the balloon is distended with air or filled with water (or contrast medium for fluoroscopy) to the pressure recommended by the manufacturer (usually 45 to 50 psi) (Fig. 27-54B). Balloon catheter dilation may be achieved by suitable devices. A dilation time of approximately 60 seconds seems to be adequate and the procedure is immediately repeated with progressively larger catheters. The choice of using water or air for distending the balloon catheter

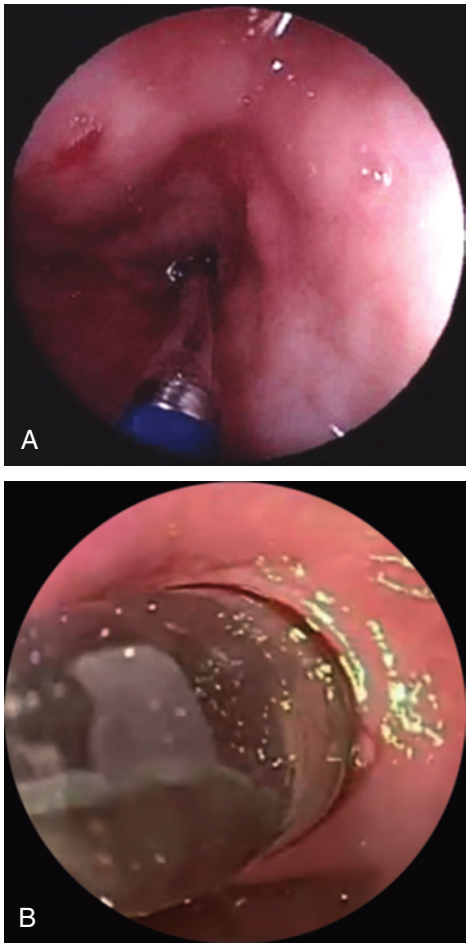

Figure 27-54 Balloon (hydropneumatic) esophageal dilation in a cat. **A,** The deflated catheter is positioned in the stenotic lumen. **B,** The inflated balloon catheter dilates the stricture. Recommended inflation times range from 20 to 60 seconds but the optimum is unknown.

depends on the stricture resistance and the fragility of the esophageal wall. Owing to the physical principle of liquid incompressibility, water distention of the catheter induces an even pressure at any site of the balloon surface, being particularly suitable for the dilation of strong strictures. Catheters distended with air are characterized by higher deformability and are better indicated for cats or young

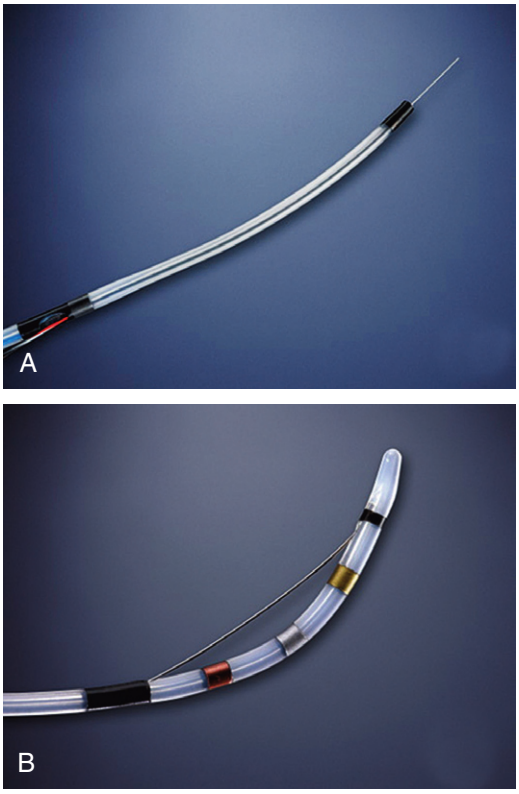

Figure 27-55 Electrocautery incision instruments. **A,** Needle knife. **B,** Sphincterotome. Both instruments are connected to an electrosurgical unit. (Courtesy of Cook-Medical.)

animals whose esophageal wall is thin and fragile. Balloon dilation technique and frequency of application is similar to that of bougienage, but it is easier and faster and can be done under direct vision and without a guidewire.

Endoscopic Electrocautery Incision

Dilation of certain types of resistant annular stricture or tortuous strictures may be done by electrocautery incision of the fibrous tissue followed by dilation,[33,34] a technique first developed in veterinary medicine by the author.[22] It requires a flexible endoscope, an electrosurgical unit, a needle knife, and a dilation device (radial or axial) (Fig. 27-55). Before electrocautery, a 360° gentle palpation of the stenotic ring (annular strictures) is performed with an open biopsy forceps, assessing sites of greater resistance characterized by a deeper infiltration of fibrous tissue into the esophageal wall ("traction sites"). During stenotic ring development, traction induced by the developing fibrous tissue on the esophageal wall is not homogeneous. In fact, the healing response is influenced by the severity and deepness of the insult. As a result, traction will be higher in some areas (traction sites) and lower in others, even without changes in the circumferential morphology of the stricture. "Traction sites" are areas offering a greater resistance to the dilation procedure. After retrieving the biopsy forceps, a needle knife connected to the electrosurgical unit is introduced into the biopsy channel of the endoscope and three equidistant electrocautery incisions are made around the circumference of the stricture (Fig. 27-56). Alternatively to the needle knife, a polypectomy snare partially extracted from the Teflon sheath or a standard papillotome can be used. The electrocautery incisions should be initially superficial and then deepened until an almost complete cut of the fibrous tissue is achieved. This procedure should be made cautiously to avoid esophageal perforation. After electrocautery, dilation by bougienage or balloon catheter is conventionally done.[35] Electrocautery incisions alone without dilation are particularly useful for treating semilunar and mucous branches strictures (Fig. 27-57). When this technique is performed by an expert endoscopist, encouraging results may be obtained both as long-term control of clinical signs and as definitive cure.[6,9,11,22,29,33-35] Dogs treated by the author with electrocautery did not require further procedures.

Strictures in the cervical tract of the esophagus may also be incised using standard or diathermic laparoscopy scissors. Best results are obtained with a 360° rotating shaft control scissors (Fig. 27-58). This instrument is introduced alongside the endoscope and allows

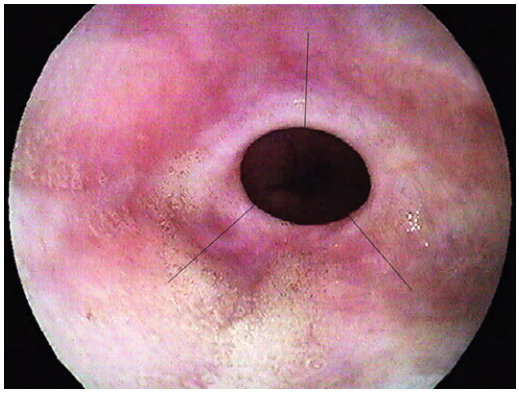

Figure 27-56 Esophageal annular stricture. The *black lines* indicate the sites of incision of the fibrous tissue of the stricture.

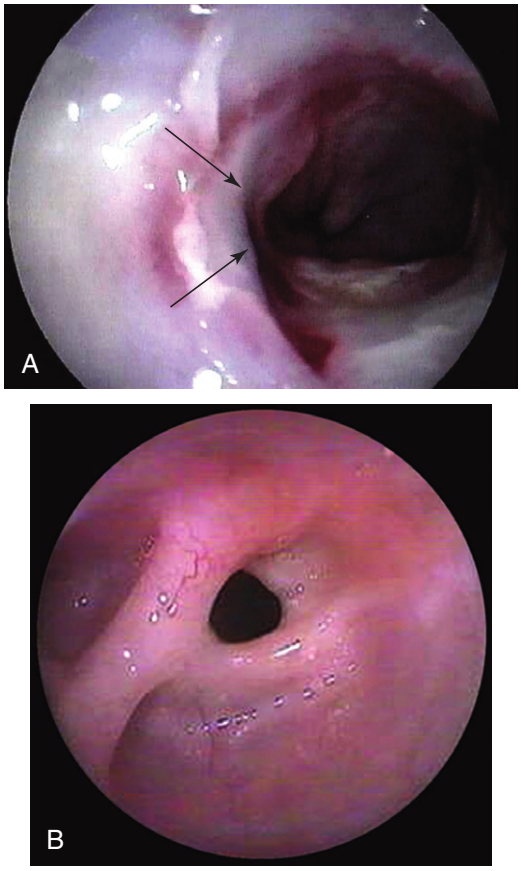

Figure 27-57 **A,** Semilunar esophageal stricture (dog). A white flap of fibrous tissue (*arrows*) occludes partially the lumen. **B,** Mucous branches stricture. The esophageal lumen is narrowed by a mesh of fibrous tissue occluding the organ.

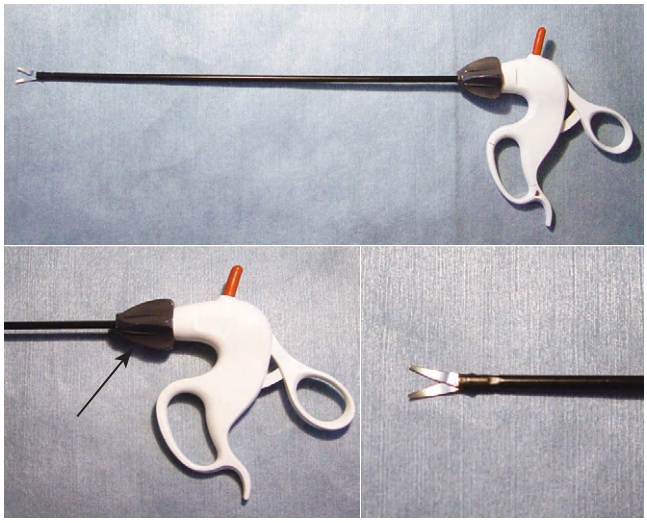

Figure 27-58 Laparoscopy scissors. The distal end can be rotated 360° on scissors' long axis by the nut ring on the handle (*arrow*), making the procedure easier and safer.

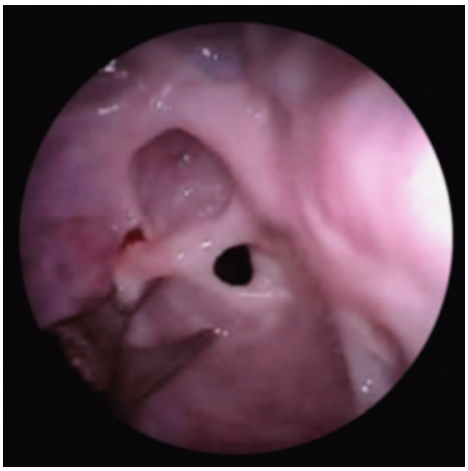

Figure 27-59 Incision of a mucous branches stricture (dog, cervical tract). Laparoscopy scissors are introduced alongside the endoscope to cut the fibrous tissue, allowing the spontaneous relaxation and dilation of the stenotic tract.

accurate incision of the fibrous tissue under direct vision (Fig. 27-59). Strictures located more than 35 cm distant from the scissors are not suitable for this technique as laparoscopy forceps are usually less than 40 cm long.

Postoperative Care

Whatever the dilation technique used, medical treatment should be instituted as adjunctive therapy to dilation. A broad-spectrum antibiotic (e.g., ampicillin, 20 to 40 mg/kg TID) and prednisolone (0.5 to 1 mg/kg BID, IM, SC, or PO) should be administered for 10 to 14 days. Prednisolone is used to diminish fibroblastic activity and fibrous connective tissue formation. Regardless of the dilation technique used, oral feeding may be initiated after 6 hours, starting with single bites of raw meat of a size similar to the lumen diameter achieved by dilation, every 2 to 3 hours. The food bolus will help to maintain the dilation, together with standard nutrition that should be initiated within 24 hours. Key for the positive outcome of the dilation procedure is the diagnosis and treatment of the underlying disease (gastroesophageal reflux, hiatal hernia, etc.).

Esophageal Stents

For strictures that fail to respond to repeated dilation procedures, because they are too extended or not surgically treatable, palliative endoscopic stent placement to permit oral feeding and diminish the risk of aspiration may be considered. Esophageal stents are rarely used in veterinary medicine because of the high rate of complication and elevated cost.

Esophageal stents can be plastic or self-expanding.[9,36,37] Plastic stents (Wilson-Cook, Atkinson, Tygart, etc.) are radiodense tubes of different length and diameter, with a tapered proximal end (Fig. 27-60). Before placement, the stricture must be dilated to the same diameter as the stent. Stent placement can be accomplished by an appropriate device (pusher) or by endoscopy (Fig. 27-61A). Owing to the space occupied by the endoscope and the pusher, placement is better done under fluoroscopic than endoscopic guidance. With the pusher, a mild force is applied to the stricture and the stent is released. The healing response of the esophagus will help maintaining the stent in situ. After placement, a semiliquid diet should be exclusively fed to avoid stent obstruction.

Self-expanding stents (Z-stent, EsophaCoil, Wallstent, InStent, Ultraflex, etc.) are metallic tubes characterized by strong radial forces (see Fig. 27-49). Once placed, the stent expands until a predetermined diameter (up to 22 mm). They differ in their design (coils, mesh), material (stainless steel, nitinol) and physical properties. Metallic stents are mainly used in human medicine for the palliative treatment of malignant strictures (Fig. 27-61B). This type of stent has never been used by the author because of the elevated cost and the difficult removal in case of wrong positioning or complications.

Complications

Iatrogenic gastric overdistention can be a common complication of endoscopy in animals with strictures, since air inflated with the endoscope cannot be aspirated if the stricture precludes passage of the instrument in the stomach. During stricture assessment and dilation, air inflation should be careful and moderate. If not promptly recognized, gastric distention can cause severe circulatory (caudal vena cava compression, hypotension, and bradycardia as a result of vagal stimulation), respiratory (respiratory failure), and gastric (wall ischemia) problems. Stomach decompression should be done with an 18-gauge needle.

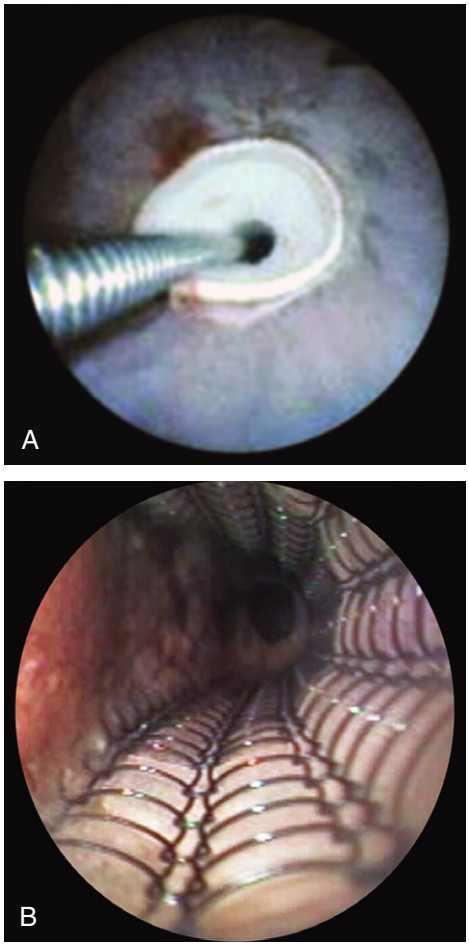

Figure 27-61 **A,** Positioning of a plastic stent (Atkinson) with a pusher in an esophageal stricture of a dog. **B,** A self-expanding metallic stent used to palliate an esophageal cancer in man.

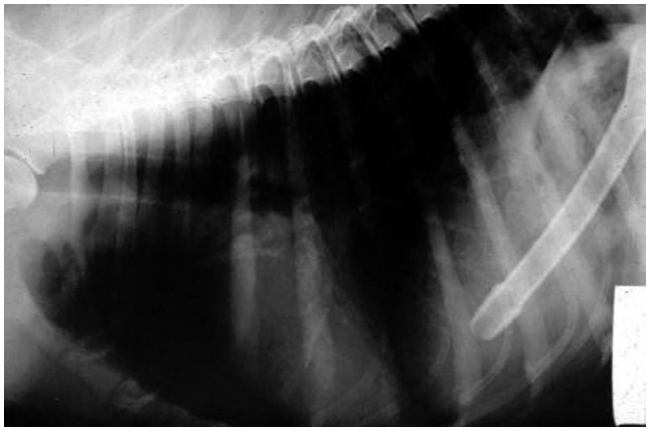

Figure 27-62 Complication after placement of an esophageal plastic stent (Atkinson) in a dog with cervicothoracic stricture. The stent has dislocated into the stomach.

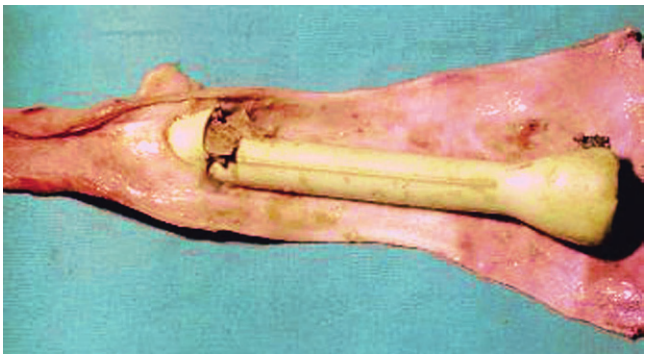

Figure 27-63 Gross aspect of the cervicothoracic tract of the esophagus of a dog with a stricture. The distal part of the esophageal plastic stent (Atkinson) caused compression and trauma to the point of passage between the cervical and the thoracic portion of the esophagus, causing proliferation of the esophageal wall and impingement of the stent.

The most severe complication of stricture dilation and stent placement is esophageal laceration/perforation. Regardless of the technique used, during the dilation procedure the esophageal wall may suddenly rupture, especially if the stricture is in active phase or in cats, where the organ wall is thin and fragile. An inadequate assessment of the lumen diameter to achieve dilation or excessively powerful procedures are often responsible for this complication.

Electrosurgical instruments (polypectomy snare, sphincterotome, needle knife) can also induce complications such as perforation or cardiac interference (arrhythmias, cardiocirculatory arrest).

A esophageal stent may be occluded by coarse food, dislocate in the stomach (Fig. 27-62), or cause mechanical compression (Fig. 27-63) and/or fistulization of the esophageal wall.

Treatment of Gastrointestinal Polyps

Although uncommon, polyps of the gastrointestinal tract have been diagnosed more frequently in dogs and cats, probably because of the increased use of endoscopy in approaching gastrointestinal disease. Unlike small incidental lesions, large polyps or polyps located close to sphincters can cause severe clinical signs such as vomiting, diarrhea, and hemorrhage, depending on level of the GI tract involved. Treatment is mandatory in these cases and current options are endoscopy or surgical polypectomy. Because of the possible malignant nature of polyps, small and clinically silent polyps should also be removed. The preneoplastic nature of some benign polyps in men stimulate a deeper knowledge of these lesions also in animals. The fact that some benign polyps may be preneoplastic lesions, justifies more attention being paid to these changes in dogs and cats.

The term *polyp* describes any circumscribed lesion protruding from the GI mucosa without specifying the nature of the lesion. Used alone, polyp is a purely descriptive term, while the specific nature of the lesion is defined by histopathology.[38,39] Most commonly, polyp refers to a process involving the mucosa (epithelial polyps), but it also indicates submucosal lesions.[40,41] Polyps of the GI tract are rarely observed in small animals, although their incidence is probably higher, as they can be clinically silent and often incidentally diagnosed (particularly in the esophagus, stomach, and duodenum) during endoscopy or necropsy.[42,43,45] Polyps can be pedunculated, sessile, or have a large base (intermediate form). The most common histologic types encountered in dogs and cats are adenoma–adenocarcinoma and hyperplastic polyp.[43,44] Inflammatory and hamartomatous polyps have been also reported in dogs.[15,38,45] Canine GI polyps are mainly located in the rectum,[41-51] rarely in the stomach,[40,45,52-55] and exceedingly rarely the duodenum, esophagus, colon, and ileum.[45,56-58] The occasional reports of GI polyps in cats include mainly duodenal adenomatous polyps.[45,58,59]

Endoscopic Polypectomy

Endoscopic polypectomy can be considered the procedure of choice for GI polyps; features that influence the choice of the therapeutic procedure are the size and location of the lesion and the presence or absence of a stalk. A coagulation panel should be done before polypectomy to determine the risk of bleeding. The technique differs based on the presence or absence of a stalk. Endoscopic polypectomy of pedunculated polyps requires a flexible endoscope, a polypectomy snare, and an electrocoagulation unit. With the patient under general anesthesia, the polyp is visualized, the polypectomy snare (standard or asymmetrical) (Fig. 27-64) is advanced through the operative channel of the endoscope and connected at the handle to the electrocoagulation unit. The snare is opened and the polyp surrounded at the base. Before closing the snare, its correct position should be assessed to make sure that the GI wall has not been included in the snare and avoid the risk of perforation. The snare is then gently closed around the base of the polyp until a mild color change in the polyp head is observed, indicating a degree of ischemia. The snare is now tightly closed. Before activating the current, the polyps is pulled toward the center of the organ lumen to avoid contact with the wall and secondary energy dispersion or burns (Fig. 27-65). The current is now activated and the polyp excised. The site of excision is assessed to exclude hemorrhage; then the polyp is retrieved with grasping forceps and submitted in toto for histopathology to characterize the histologic nature and the completeness of excision. In experienced hands, this technique is usually followed by recovery and a low incidence of complication[45]; it is best used with 3-cm or smaller polyps. For larger polyps (3 to 6 cm in diameter), the lesion can be excised in smaller multiple pieces (piecemeal resection), lowering the risk of burn and hemorrhage (Fig. 27-66). This technique is useful when the large size of a pedunculated or sessile polyps hinders assessment of the correct positioning of the snare around the base of the lesion. Partial portions of the head of the polyp are repeatedly removed until the base of the lesion can be completely excised with the snare.

The head of the polyp is pulled toward the center of the organ lumen to avoid energy dispersion and burns.

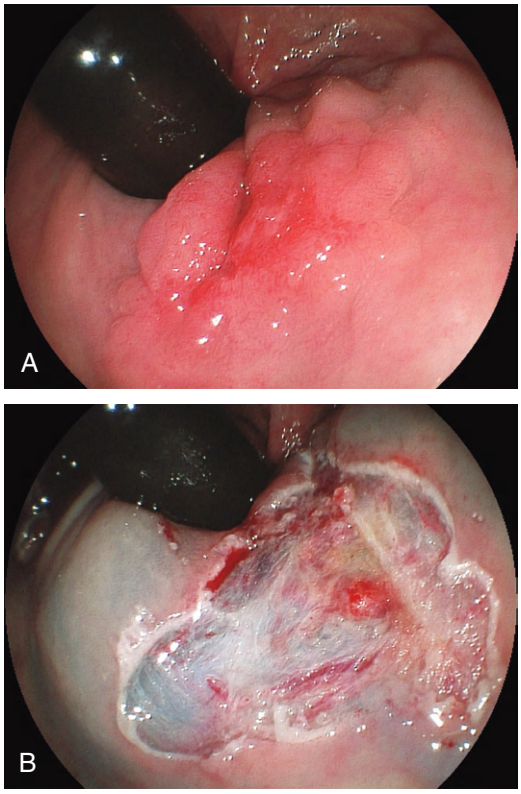

Figure 27-67 Endoscopic view of a raised, bleeding lesion near the anal sphincter in an 8-year-old, male dog before (**A**) and after (**B**) mucosectomy. Histopathology revealed an adenomatous polyp.

Surgical excision is instead indicated when the polyp is close to "difficult" sphincters (pylorus), when too large (>6 cm in diameter), or when the malignant invasion of the stalk or a previous incomplete excision is histologically demonstrated.

Complications

Complications of endoscopic polypectomy are usually a result of improper technique, inexperience, and nonobservance of contraindications. Possible complications are mainly bleeding and perforation.

Bleeding after endoscopic polypectomy may originate from incomplete coagulation of blood vessels of the stalk or of the base of the polyp. If bleeding is not severe, a systemic hemostatic treatment and, when necessary, blood transfusion may be curative. If bleeding does not stop, surgery is recommended.

Perforation during polypectomy is not common and can be due to the operator's hazardous maneuver or inexperience. Not including the organ wall in the polypectomy snare is key to minimize the risk of perforation. Consequences of perforation depend on the organ involved.

Endoscopic Mucosectomy

Endoscopic mucosectomy is a well-described procedure in humans[60-63] that, in the author's experience, also can be useful to treat some pathologic conditions in dogs and cats. Mucosectomy involves the removal of a portion of the gastrointestinal wall including the mucosa, muscularis mucosae, and submucosa. It is a therapeutic procedure that may be useful for the excision of benign sessile or pedunculated polyps difficult to excise with a polypectomy snare (Fig. 27-67) or of metaplastic/dysplastic areas of the mucosa that could become neoplastic. The multiple technical variants used in human medicine require specific and expensive instruments (dual-channel endoscope, elastic ligature unit, plastic hood, etc.) that are currently not justified in veterinary medicine because of the different clinical significances of the lesions. A simple and inexpensive technique that can be used in animals is the saline lift technique,[64] which is useful for the excision of sessile polyps that are difficult to remove with a snare because of their localization (sphincters, gastric angulus, tubular organs), morphology (villous polyps), or size (small polyps); another indication to use this technique is for excision of an epithelial lesion.[65] Besides a standard endoscopic polypectomy set, instruments needed are a sclerosing needle (Fig. 27-68), saline solution, and methylene blue solution. The needle is introduced into the operative channel of the endoscope and the lesion-bearing mucosa is submucosally injected with saline in multiple sites, so that the lesion is lifted on the organ wall. The amount of saline used depends on the degree of lifting desired and on the size of the lesion (5 to 30 mL). Epinephrine (1:10,000) to minimize bleeding and methylene blue to better delineate the lifted area from the healthy tissue may be diluted in the saline. With a polypectomy snare, it is possible to grasp all the lifted tissue and excise the lesion with standard polypectomy technique or other techniques (Fig. 27-69).

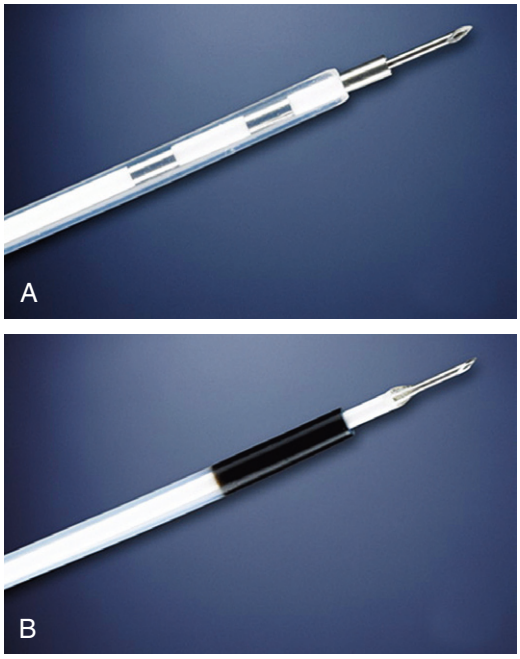

Figure 27-68 **A** and **B**, Devices used for endoscopic injection into gastrointestinal mucosa. (Courtesy of Cook-Medical.)

Endoscopic mucosectomy can be used also to obtain large biopsies for diagnosis. This technique is, however, indicated only for biopsy of intraepithelial lesions as the submucosal injection of saline modifies the normal anatomy of the submucosal layer, hindering histopathologic examination.

Complications

The complications of endoscopic mucosectomy are similar to those for endoscopic polypectomy.

Endoscopic Removal of Gastrointestinal Foreign Bodies

GI foreign bodies are common in small animals and are more frequent in the stomach than in the esophagus or in other

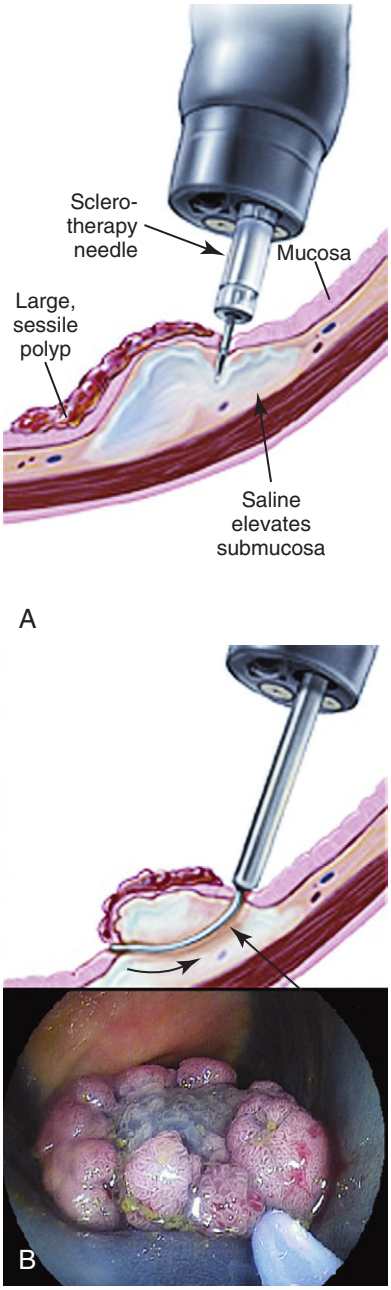

Figure 27-69 Saline lift technique. **A**, The needle is introduced in the operative channel of the endoscope and the lesion-bearing mucosa is submucosally injected with saline in multiple sites so that the lesion is lifted on the organ wall. **B**, With a polypectomy snare it is now possible to grasp all the lifted tissue and excise the lesion.

intestines.[9,66,67] They are more common in the dog than in the cat, as a result of the different feeding behavior of the two species. The variety of foreign bodies that can be encountered in the digestive tract is infinite, but they may be distinguished as sharp, pointed, smooth, linear, or toxic. Retrieval technique could be surgical or endoscopic and depends on the anatomic site and type of the foreign body.[66-68] Endoscopic retrieval should be considered the elective procedure for treatment of most esophageal and gastric foreign bodies, either symptomatic or clinically silent. A number of ancillary instruments exists for removal of different objects (Fig. 27-70).[67] In most cases endoscopy allows a nontraumatic retrieval of foreign bodies, except when the extended contact time with the gastric fluid modifies the physical state (from soft to rigid) of the foreign body, or for linear objects (ropes, wires, clothes, etc.) that extend into the duodenum.

Esophageal Foreign Bodies

An esophageal foreign body should always be promptly removed because the likelihood of complication depends on the duration of the foreign body's contact with the mucosa. Foreign bodies in the cervical esophagus can also cause dyspnea secondary to tracheal compression. Because it is usually successful, endoscopic removal should be considered as the first approach to esophageal foreign bodies.[7,9,67-70] Surgery should be considered when endoscopic removal fails or when there is evidence of esophageal perforation.[68]

The technique used for removing a foreign body varies with the type and size of the object ingested. Rigid or flexible grasping forceps can be used based on the foreign body's location (proximal or distal, respectively) and the size of the patient. A laparoscopy rigid instrument is passed alongside the endoscope to firmly grasp large proximal and well-anchored objects (Fig. 27-71). The length of rigid instruments (40 cm maximum) limits their use, as foreign bodies in the thoracic esophagus of medium- or large-size dogs cannot be reached in this way. Flexible forceps are instead inserted into the working channel of the endoscope. Once the object has been grasped, if no resistance is felt, both the endoscope and the forceps are withdrawn simultaneously, paying particular attention to the passage through the upper esophageal sphincter. To facilitate this passage, the endotracheal tube cuff is deflated. The removal of pointed or sharp bones should be done with particular care and gentleness.

Pointed objects that have been embedded in the esophageal wall for long periods can be gently pushed–pulled and rotated to grasp the object on its distal side (Fig. 27-72). If the object does not move by these attempts, a flexible overtube with a smooth end and a diameter slightly larger than the foreign body may be introduced into the esophagus. The endoscope is passed inside the tube. The tube will mildly dilate the esophageal lumen, facilitating the dislodgment of the foreign body under direct endoscopic visualization. Preanesthetic administration of high-dose atropine (0.04 mg/kg IM) to prevent or reduce the vagal stimulation induced by the manipulation during retrieval is important. Cardiac-circulatory arrest is possible during this procedure, especially for foreign bodies located at the cardial region**.** When an esophageal foreign body cannot be retrieved, it can be pushed into the stomach and removed by gastrotomy. Bone foreign bodies can be left in the stomach as they dissolve rapidly in the gastric cavity, but abdominal radiographs should be taken to confirm the dissolution. Pointed objects such as fishhooks should be first dislodged from the esophageal wall and then turned with the pointed end toward the cardia so as to avoid further anchoring to the wall during retrieval (Fig. 27-73). An overtube should be used to remove sharp objects such as razor blades or bone fragments to protect the esophageal mucosa and the larynx (Fig. 27-74). The residual foreign body's site and the proximal esophageal mucosa (e.g., iatrogenic lesions) should always be assessed after removal. Esophageal perforation should be radiographically ruled out in case of pointed and sharp objects or long-standing foreign bodies; sometimes the foreign body plugs the perforation and clinical signs manifest only after its retrieval. Postoperative treatment is based on the administration of a broad-spectrum antibiotic (e.g., ampicillin, amoxicillin-clavulanic acid, cefazolin) and treatment of possible complications.

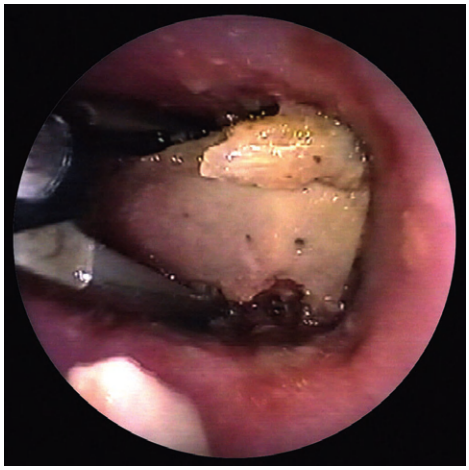

Figure 27-71 Endoscopic removal of an esophageal foreign body (bone fragment occluding the lumen) in a dog. The object is removed using a laparoscopic grasping forceps introduced alongside the endoscope.

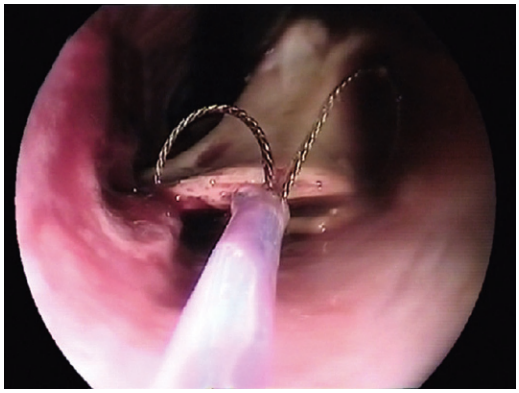

Figure 27-72 Endoscopic removal of an esophageal foreign body (bone fragment) in a dog. The object is firmly grasped with a snare. The snare is gently pushed–pulled and rotated on its long axis to free the bone from its site and retrieve it through the mouth.

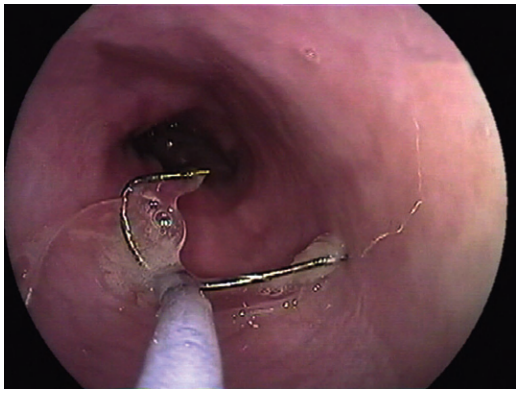

Figure 27-73 Removal of a fishhook from the esophagus of a dog. A flexible grasping forceps is used to unhook the object from the esophageal wall and to orient the pointed end distally. Keeping the pointed end close to the endoscope tip, the object is retrieved with no risk of sticking.

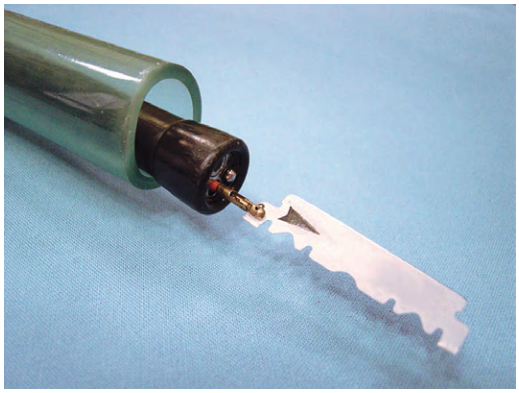

Figure 27-74 Technique for removing a sharp foreign body (razor blade). A plastic overtube is introduced in the esophagus and the endoscope is inserted in the tube until the object is reached. The grasped foreign body can now be pulled inside the plastic tube and retrieved together with the tube, avoiding lesions to the esophagus and larynx.

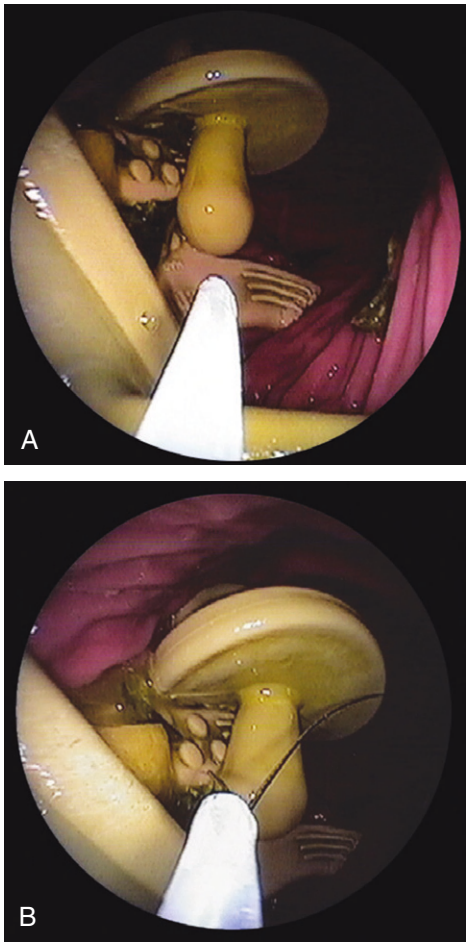

Figure 27-75 **A**, Multiple foreign bodies (three rubber dummies) in the stomach of a dog. **B**, The objects are singularly grasped with a flexible snare and retrieved. When present for a long time, rubber objects can become fragile and break down during removal, requiring time and patience for complete retrieval.

Gastric Foreign Bodies

The best strategy for removing a foreign body from the stomach is to grasp the object as firmly as possible so that it can be moved retrograde through the LES, the esophagus, and the upper esophageal sphincter (UES). Passage of the object through the LES is the most difficult phase of this procedure (Fig. 27-75).[67,68,70,71] Long foreign bodies (long bones, skewers, etc.) should be grasped by the distal end to minimize resistance to the passage of the LES. Removal of blunt objects (stones, small balls, toys, etc.) may benefit from a reduction of gastric distention (air deflation) so that the Hiss angle (angle formed by the entrance of the esophagus in the stomach) becomes less acute. Simultaneously the tip of the endoscope should be slightly deflected to the left to align it with the gastric cardia.

Foreign bodies in other portions of the GI tract are not often removeable by endoscopic procedures. Linear foreign bodies (ropes, socks, clothes) can be found in the duodenum, but they are better removed surgically to avoid the risk of intestinal invagination. A gentle attempt to remove endoscopically a duodenal foreign body is justifiable.

Rare, foreign bodies that successfully traverse the upper GI tract can be encountered in the distal intestinal tract and the rectum (e.g., pointed bone fragments, glass fragments, needle). Because of anal spasm induced by pain and trauma, these objects may not be passed out with normal defecation and removal with a rigid or flexible endoscope can be attempted.

Complications

Complications of foreign body removal are infrequent and endoscopy can be safely used in most cases. Possible complications are laceration/perforation, gastric overdistention, and sphincter neurologic dysfunction.

COMPLICATIONS

Olivier Dossin

Although well documented in human medicine, complications of GI endoscopy are rarely reported in dogs and cats. Complications, as defined in human gastroenterology, have the following characteristics: (a) they are a result of the procedure; (b) they are deviations from the expected course and tend to delay or impair recovery; (c) they cause changes in the management of the patient; and (d) they lead to morbidity or even mortality.[1]

A major advantage of GI endoscopy is the minimal morbidity and mortality associated with this procedure,[2] implying that complications are rare. In human gastroenterology, the overall rate of GI endoscopy-associated complications is reported to vary between 0.1% and 1.9%.[3,4] Most of these complications are minor, but some, such as perforation, can be life-threatening.

Complications of Diagnostic Endoscopy

Preprocedural Complications

Contraindications

Contraindications to endoscopy are always important to consider. The risks of general anesthesia must be considered as GI endoscopy is almost always performed under general anesthesia in dogs and cats. The only absolute contraindication for endoscopy is the presence of, or risk for, digestive tract perforation. Air insufflation, which is a prerequisite for GI endoscopy, may cause further perforation along a plane of tissue devitalization, the consequence of which will be bacterial and GI fluid effusion into the thoracic or abdominal cavity.[5] In patients with uncontrolled coagulation disorders, GI biopsies and other procedures, such as tube placements, should be postponed until the coagulation disorder can be controlled.[5]

Patient Preparation

Large volumes of oral lavage solutions can be associated with vomiting, aspiration pneumonia, hypovolemia, and electrolyte disturbances,[3,6,7] and even with gastric dilation and volvulus in the dog.[8] Enema-associated complications are related to the volume or to the method of administration, but can also be metabolic in cases of hypocalcemia secondary to phosphate enemas,[9] especially in small dogs and cats. Such patients may develop acute dehydration associated with hypernatremia and hyperphosphatemia with secondary decreases in serum calcium concentrations and life-threatening hypocalcemia.[10] In the author's experience, bowel perforation during preparation for colonoscopy is a rare complication and only occurs when the colon is severely damaged (e.g., necrosis or neoplasia) or when inappropriately stiff catheters are used for enema procedures. Inadequate bowel preparation may predispose to missed lesions as well as bowel perforations.[3] In human medicine, 6% to 17% of colonic adenomas may be missed during colonoscopy, some of which are attributable to poor bowel preparation.[7] Poor bowel preparation is a frequent problem in veterinary medicine, but can be avoided by following an appropriate procedure (see "Colonic Endoscopy" section). Cats are very sensitive to rapid and voluminous colonic distention, which can induce vomiting or even shock. Consequently, enema volume should not exceed 50 to 75 mL in this species.[8]

Barium contrast agents and mucosal-adherent medications such as sucralfate should be discontinued for at least 8 to 12 hours prior to endoscopy,[11,12] as they may mask mucosal lesions.[7] Animals that are severely anemic should receive component transfusion therapy before anesthesia and endoscopy.[2]

Anesthesia

General anesthesia complications are the same as for other procedures and include hypotension, reduced cardiac output, hypoventilation, and airway aspiration. Lidocaine jelly or benzocaine sprays used for local anesthesia in human patients are infrequently used in veterinary medicine as the patient is usually under general anesthesia. Some complications, such as methemoglobinemia with benzocaine[13] and reduced pharyngeal motor function with increased risk for aspiration, may occur.[3] This is especially true for veterinary patients because vomiting is sometimes associated with the recovery phase of anesthesia following GI endoscopy.[6]

Procedural and Postprocedural Complications

Endoscopy and Biopsy

Gastric overdistention is probably the most frequent and important complication of endoscopy. In extreme cases it can be associated with respiratory depression because of decreased respiratory tidal volume, caudal vena cava compression, and a secondary drop in cardiac venous return and blood pressure.[14] Gastric overdistention may occur not only during gastroscopy, but also during esophagoscopy and duodenoscopy. During esophagoscopy for very small strictures, insufflated air can be trapped as the stricture may prevent gastric air from being spontaneously expelled or aspirated by the endoscope from the esophagus.[5,11] Extreme cases may require gastric trocarization.[14] Overinflation of the stomach may also induce difficulties in pyloric intubation because of decreased endoscopic maneuverability and reflex antral and pyloric contractions.[14] This is especially true of large-breed dogs in which the endoscope may be too short to even reach the pylorus. Gastric overdistention has also been reported as a rare complication of colonoscopy in dogs.[6] Laceration of major organs or vessels adjacent to the GI tract can also occur because of overdistention, stretching, or perforation.[15,16]

Cats and small dogs are especially sensitive to stretching and displacement of the gastric body and pylorus.[5,17] This may induce bradycardia and significant respiratory depression, which should prompt the operator to deflate the stomach and withdraw the endoscope until the patient stabilizes.[5,16]

Gastroesophageal reflux or retching may occur, especially when attempting to advance the endoscope through the pylorus. It usually subsides after a short period of time and the endoscope can be advanced after fluid and air aspiration.[17] Fluids refluxed into the esophagus should be aspirated at the end of the procedure as they may induce esophagitis and secondary esophageal stricture. Esophageal entrapment of an endoscopic tip deflection has been described in human medicine as a consequence of belching during gastroscopy,[18] but this is an unlikely scenario with veterinary patients as they are maintained under general anesthesia. Entrapment could theoretically occur in hernia pouches.[7]

Gastric perforation may occur when excessive force is applied and occurs mostly in the hands of an inexperienced operator.[17] Keeping the lumen within the field of vision at all times is one way to avoid perforation associated with excessive pressure or stretching.[5] Perforation rates associated with colonoscopy have been estimated to be less than 0.2% in human medicine.[7] A similar rate was reported in a retrospective study of colonoscopy-associated complications in dogs[6] in which only one case of perforation was reported in more than 355 total colonoscopies (0.28%). The dog that suffered the perforation had a colonic stricture associated with pyogranulomatous colitis and recovered after surgical treatment of the perforation.[6] Perforation can be a result of any of four different causes: (a) direct force applied by the tip of the endoscope against the bowel wall, (b) biopsy, (c) lateral pressure of the endoscope tube during tip deflection, or (d) pneumatic distention.[3] Perforations associated with the last two causes are the most difficult to diagnose as they may not occur under direct endoscopic visualization. No attempts should be made to push the endoscope forward while in the cecum, as its thin wall can easily be perforated.[12] Perforation of blind pouches is also possible, especially when a perineal hernia is present and the endoscope is advanced against excessive resistance.[8] The best way to avoid such complications is to systematically perform a digital rectal examination before inserting the endoscope.[12] Perforation of the intestinal wall with flexible biopsy forceps is unlikely to occur unless the biopsy is made in the middle of a necrotic lesion. Special precaution is advised when using rigid biopsy forceps to obtain biopsies in the rectum or the

descending colon.[8] Blind biopsies of the duodenum may be dangerous, too, because of the sharp angulation of the cranial duodenal flexure. A biopsy forceps that is blindly advanced through the pylorus may sample deep into the mucosa at the same location without bending downstream, increasing the risk for duodenal perforation. The author had this experience in one dog in which the technique resulted in biopsies of the serosa. The dog recovered uneventfully and no postendoscopic complication occurred, but perforation and peritonitis are possible complications in such a situation. Another risk of blind biopsy in the duodenum is the slight possibility of damaging the duodenal papilla,[19] which may induce scarring and secondary cholestasis or pancreatitis. If there is no alternative to blind biopsy through the pylorus, it is recommended to perform no more than three to four superficial mucosal biopsies. Perforation may occur when the endoscopist attempts deeper biopsies in the attempt to sample the submucosa.[14] The risk of perforation increases when the tissue is very friable or necrotic. Hemorrhage associated with biopsies is usually mild, but can be severe when dealing with necrotic neoplastic tissue.[6] Bleeding may persist in this instance,[6] in which case severe hemorrhage may require blood transfusion and emergency endoscopic cauterization or celiotomy.

When moving the patient from left lateral to dorsal recumbency to facilitate endoscopic intubation of the pylorus,[16] gastric torsion may be induced, particularly if the stomach is dilated. Gastric dilation and volvulus may also occur after the endoscopic procedure.[5] The best way to avoid this complication is to carefully assess gastric distention during the procedure and to aspirate all gastric gas and fluids before the endoscope is removed, and by closely monitoring the patient during the recovery phase of the procedure.

Glutaraldehyde-induced colitis has been reported in human medicine and reproduced in a rodent model.[3,20] It is characterized by an acute ischemic, ulceronecrotic colitis.[20] This complication can be avoided by proper endoscope cleaning after glutaraldehyde disinfection.[3,21]

The endoscope can be a source of transmission of various infectious agents, including bacteria, fungi, viruses, and parasites.[22] If current guidelines for endoscopic management are followed (see "Care and Cleaning of Instruments" section) the risk of disease transmission is greatly reduced.[3,7] The water bottle or irrigation tubes may also be colonized by pathogens, such as *Pseudomonas* spp.,[22,23] and can act as a source of endoscope-borne infections. It is important to use sterile water[22] and to disinfect or sterilize the water bottle on a regular basis.[8] For the same reason, cleaning and disinfection of reusable biopsy instruments, foreign-body retrieval devices, and esophageal balloon dilators is mandatory.

Bacterial translocation and secondary bacteremia following GI endoscopy have been reported in the human literature with rates ranging from 0% to 8% for gastroscopy,[3] 0% to 25% for colonoscopy,[7] and 12% to 45% for esophageal dilation,[23] but the actual risk of dissemination appears to be very low. Antibiotic prophylaxis has been recommended only for patients with mechanical heart valves or a history of endocarditis.[7,23] Bacteremia is also likely to occur in dogs and cats, but has never been documented in these species.

The risk of aspiration pneumonia during upper GI endoscopy[3] can be minimized by endotracheal intubation and close monitoring during the recovery phase of anesthesia. To further reduce this risk, aspiration of esophageal and gastric fluids should always be performed before endoscopic extubation.

Cholangiopancreatography is rarely performed in veterinary medicine, but has not been associated with major or minor clinical complications either in healthy dogs[24] or in dogs with chronic gastrointestinal disease.[25] Transient increases in serum activities of amylase and lipase and serum concentrations of canine trypsin-like immunoreactivity (cTLI) have been reported, but these did not translate into clinical signs.[26] Pancreatitis is the most important complication in human patients undergoing ERCP.[3]

Complications of Therapeutic Endoscopy

Therapeutic endoscopy procedures are more frequently associated with complications[7] and are better documented in small animal medicine than are complications of diagnostic endoscopy.

Perforation is the most serious complication of esophageal foreign body retrieval. It is more likely to occur when the foreign body is lodged in the mucosa.[11] Perforations are usually small, but sometimes very large tears occur with lung lobe visualization and severe pneumothorax (Fig. 27-76). Fatal hemothorax caused by laceration of pulmonary vessels has been described as a delayed complication of foreign-body retrieval in a dog.[15] In a case series of esophageal fishhook foreign bodies,[27] full-thickness lacerations in two of 41 animals was reported, one of which healed without surgical treatment. In one dog, the fishhook was embedded in the esophageal wall near the heart base and retrieval resulted in fatal laceration of a pulmonary vein.[27] The author has experienced an incarceration of a basket foreign body forceps around a foreign body, which was then impossible to retrieve. Surgery was necessary to remove the forceps and the foreign body.

Complications are best documented for dilation of esophageal strictures in dogs and cats. Bleeding is the most frequent complication,[28-30] but rarely requires aggressive treatment.[28-32] Perforation occurred in one of 13 cats in one study[28] and in one of 28 cats in another study.[29] Both cats were euthanized as a result of those perforations.[28,29] In another study, two of 23 animals developed esophageal perforation and secondary pneumothorax, which resolved spontaneously.[30] Adamama-Moraitou and coworkers[33] reported a case series of 13 dogs and seven cats with esophageal strictures. One developed an esophageal perforation and was euthanized. Gualtieri[11] reported perforation in one dog and one cat in a series of 40 cases. One perforation was associated with the application of electrocautery prior to balloon dilation. Other, less-severe complications, such as superficial mucosal tears, diverticulum formation, and aspiration pneumonia have also been reported.[30] In human studies, the rate of perforation associated with esophageal dilation is 0.1% to 0.4%,[31] and complex or malignant strictures are at the highest risk.[31] Most often the perforation is not noted at the end of the procedure,[31]

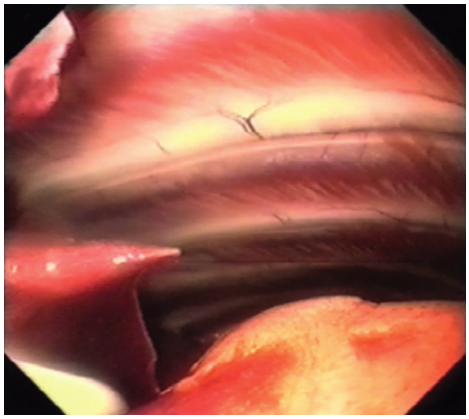

Figure 27-76 Esophageal tear. Endoscopic view of an esophageal tear during esophageal foreign body extraction. Note the fragment of the torn esophagus, the lung lobe margin, ribs, and intercostal muscles.

especially because of extensive hemorrhage, which may obscure the tear.[32] Therefore, the patient should be closely monitored after stricture dilation. If there is any suspicion of a perforation, it is advisable to investigate for a perforation by survey and/or contrast (e.g., using a nonionic, water-based, soluble agent) thoracic radiographs and to closely monitor the patient for respiratory or other clinical signs. Some perforations can heal spontaneously.[30,31] Bacteremia following esophageal stricture dilation is a frequent occurrence in human medicine (12% to 22%), although infectious sequelae appear to be rare.[31] Although bacteremia has not been documented in animals after stricture dilation, it is likely that such bacteremia does take place.

Endoscopically placed gastrostomy feeding tubes are extensively used in dogs and cats. Reports of complications associated with tube placement are more often complications of tube handling rather than tube placement.[34] Complications associated with tube placement include splenic laceration, gastric hemorrhage, peritonitis, and early tube removal,[35] and are the same as have been reported in human medicine.[36] Complications associated with tube placement are usually minor,[37] except for splenic laceration,[38] which can be prevented by careful abdominal palpation before inserting the stylet or needle. Pneumoperitoneum and gastric bleeding[38,39] have been described and gastric bleeding may be associated with secondary melena for a few days after the procedure.[38]

Endoscopic surgery is infrequently reported in veterinary gastroenterology. Transanal endoscopic treatment has been evaluated for benign canine rectal neoplasia in 13 dogs.[40] Reported complications included rectal perforation in two of 13 cases. Both patients had to be euthanized as a consequence. Fatal peritonitis was reported in one of 13 patients, and acute paraplegia and delayed acute rectal bleeding were reported in one of 13 dogs each.[40] Because of these complications, hospitalization for 5 days of monitoring has been recommended following these procedures.[40]

Complications for the Operators

As endoscopy is an invasive procedure, there is the possibility for exposure of the endoscopist and staff to the animal's endogenous bacterial flora, including to some potentially zoonotic agents. A case report of herpes virus transmission from a jet of fluid originating from the biopsy channel[3] underscores the importance of protecting the endoscopy team to avoid such complications.

CARE AND CLEANING OF INSTRUMENTS

Diane Levitan

The importance of proper handling, care, and cleaning of the endoscope and accessories cannot be overstated. The return on investment in endoscopic equipment for veterinary practice is optimized by strict adherence to an established care-and-cleaning procedure, as this will extend the life of the equipment and minimize the need for expensive repairs. Arguably more important, following such guidelines will ensure the greatest level of safety for the patient, staff, endoscope, and accessory equipment. To date, there is little emphasis in the veterinary literature on proper cleaning and disinfection of endoscopes and accessories for gastroenterology; however, there are significant risks imposed on our patients and staff.[1-5] A number of reports document the risk of infection through a contaminated endoscope, specifically with *Salmonella*, *Pseudomonas*, *Mycobacterium*, *Escherichia*, *Serratia*, and *Helicobacter* spp., but also with hepatitis B virus and many more.[1-3] Transmission of infection in humans occurs most commonly because of failure to adhere to proper cleaning and disinfection procedures, contamination of endoscopes in automatic reprocessing machines, and the inability to decontaminate endoscope valves or channels because of endoscopic configuration.[1-3]

Reprocessing refers to the sequence of cleaning, lubricating (if necessary), and high-level disinfecting or sterilizing steps that assure endoscopes and accessories are appropriate for the patient of interest.[6] Every veterinary endoscopy facility should implement strict care-and-reprocessing guidelines for endoscopes and accessories (Boxes 27-1 through 27-4). Detailed training protocols for any personnel involved in the care, use, and reprocessing of endoscopy equipment should be mandatory. Training should include a thorough understanding of the proper use and handling of the equipment, personnel safety measures, knowledge of chemicals used for manual

Box 27-1 Spot Cleaning Protocol

Perform spot cleaning at procedure site immediately after procedure.

- Place all accessories in ultrasonic cleaner with enzyme solution and then clean along with endoscope. Any instruments that break the mucosal barrier should be steam or gas sterilized according to manufacturer's recommendations.
- Wipe the insertion tube with an enzymatic detergent.
- Suction enzymatic detergent through the instrument channel for 30 seconds.
- Suction air through the instrument channel for 10 seconds.
- Attach the air/water channel cleaning adapter; depress to feed water through the air and water channels for 30 seconds.
- Release the air/water channel cleaning adapter to feed air through the air and water channels for 10 seconds.
- Use the special cleaning adapters as recommended in your endoscope's instruction manuals for precleaning.
- Clean all valves with brushes and place valves and removable parts in detergent solution.
- Inspect and attach the water resistant caps.
- Cover the endoscope and transport to the reprocessing area.

Box 27-2 Leakage Testing Protocol

- Connect the leakage tester connector according to manufacturer's guidelines.
- Check that the leakage tester is emitting air and confirm that the connector cap is dry.
- Attach the leakage tester's connector to the water resistant cap and verify that the endoscope is pressurized.
- Immerse the *entire* endoscope in a basin of water and observe for 30 seconds; visually inspect for potential leaks.
- Manipulate the angulation knobs and video switches to check for potential leaks.
- Remove the endoscope from the water and then turn off the air supply.
- Disconnect the leakage tester from the air supply and allow the endoscope to depressurize.
- Disconnect the leakage tester from the water-resistant cap. (Do not remove the water-resistant cap.)

Box 27-3 Manual Cleaning Protocol

- Immerse the entire endoscope in freshly prepared enzymatic detergent solution with angulation in free position.
- Clean the exterior of the endoscope with a soft brush or lint free cloth.
- Brush biopsy/suction channel in the insertion tube with the channel cleaning brush until all debris is removed.
- Brush biopsy/suction channel in the universal cord with channel cleaning brush until all debris is removed.
- Brush suction valve housing and instrument channel port with channel opening brush until all debris is removed.
- Use manufacturer provided cleaning adapters to suction detergent through the suction/biopsy channel for 30 seconds.
- Use manufacturer provided cleaning adapters to inject detergent through the air/water channel.
- Disconnect cleaning adapters when you are certain all channels are filled with detergent.
- Soak the endoscope in the detergent solution for the amount of time recommended according to detergent manufacturer's guidelines.
- Brush and flush the valves and removable parts until all debris is removed.
- Perform the final rinses and air purges using manufacturer's recommended cleaning adapters.
- Thoroughly dry the exterior of the endoscope and all removable parts using a clean lint-free cloth.
- Inspect the endoscope for residual debris and repeat the manual cleaning process if debris remains.
- Prepare compatible valves and removable parts for steam sterilization or high-level disinfection.

Box 27-4 Manual Disinfection Protocol

- Test the high-level disinfection (HLD) potency and record.
- Fully immerse the entire endoscope, valves, and removable parts in a basin of HLD solution.
- Use manufacturer-provided cleaning adapters to suction disinfectant through the suction/biopsy channel slowly until no air bubbles are produced and the channel is completely filled with disinfectant.
- Use manufacturer-provided cleaning adapters to suction disinfectant through the air/water channel slowly until no air bubbles are produced and the channels are completely filled with disinfectant.
- Disconnect all cleaning adapters and let them soak in disinfectant.
- Allow all to soak in HLD solution for the recommended time and temperature.
- Flush air through the endoscope channels using recommended cleaning adapters.
- Use filtered, tap, or sterile water to rinse the endoscope and accessories and flush all channels thoroughly.
- Perform a channel air flush followed by an alcohol purge and an air purge.
- After rinsing, dry or steam sterilize accessories.

and automatic equipment reprocessing (if applicable), and how to meticulously clean endoscopes and accessories. Because specific manufacturer recommendations and guidelines vary, the protocol established in each facility should be specific to equipment in use. Most endoscopy manufacturers can provide excellent resources such as videos, wall charts, and training guides for proper care, use, and cleaning of instruments. All resources are readily available through the manufacturer's Web site or by contacting company representatives. The following recommendations are adopted from standards and guidelines for care and cleaning of these instruments in human medicine[7,8] and should be considered the standard of care for veterinary medicine.

Endoscope Cleaning and Care (Reprocessing)

Intact Endoscope

Endoscopes are complex devices that have many small interconnecting parts, several long narrow channels with bifurcations, and complex connections to external sources. Familiarity with the external and internal anatomy of the endoscope and the ancillary devices is important for proper handling, use, care, and cleaning (see Figs. 27-2 and 27-77). Channels, accessories, small parts, and connections vary by manufacturer, brand, type, and use. Consequently, it is essential to refer to the manufacturer's guidelines for each endoscope. The following general overview applies to most endoscopes used in veterinary medicine.

Equipment and Procedure Checklist

Set up and careful inspection of the endoscope should begin well before the patient is anesthetized. The entire endoscope, forceps, cleaning tools, and accessories should be thoroughly examined and tested for viability. Postprocedure cleaning tools should be set up and readily available to minimize the lag time before cleaning. Suction devices, light source, camera attachments, and air/water supplies must all be clean and in good working order. The surface of the insertion tube should be inspected for dents, bulges, small holes, and other irregularities. The deflection control knobs should be tested for maximal deflection without resistance and that the deflection locks are functioning. If water enters the protected portions of the endoscope, permanent and serious damage will result, therefore leak testing should always be performed prior to the beginning of a diagnostic procedure.

The endoscope should be connected to the light source and camera fittings, and the optical system's focus, field of view, fiber conditions, and video image should be evaluated. A biopsy instrument should be passed through the biopsy channel to ensure smooth passage. All ports should be inspected. The air, water, and suction lines and other connections must be secure and air, water, and suction functions should be tested. The air delivery mechanism should be tested by immersing at least 10 cm of the distal tip of the endoscope in water and covering the air/water valve. A constant stream of air bubbles should emerge from the distal tip. When the valve is uncovered, the flow of air should stop. The lens-cleaning mechanism should also be tested by making sure water comes out of the distal tip when depressing the hole of the air/water valve. Suction should be verified by dipping the distal tip in water and depressing the suction button. Normally, water will move through the suction tube until the button is released, and will stop as the button returns to normal position. If there are additional elements, such as carbon dioxide gas or water feeding channels, similar testing should be performed to ensure their proper function. If the endoscope passes preliminary inspection, the procedure can begin. While the patient is prepared, the endoscope should be kept in a location safe from potential damage, such as in a device specifically made for suspending the endoscope.[4]

During the endoscopic procedure, safe and proper handling of the endoscope is essential. There should be an oral speculum or

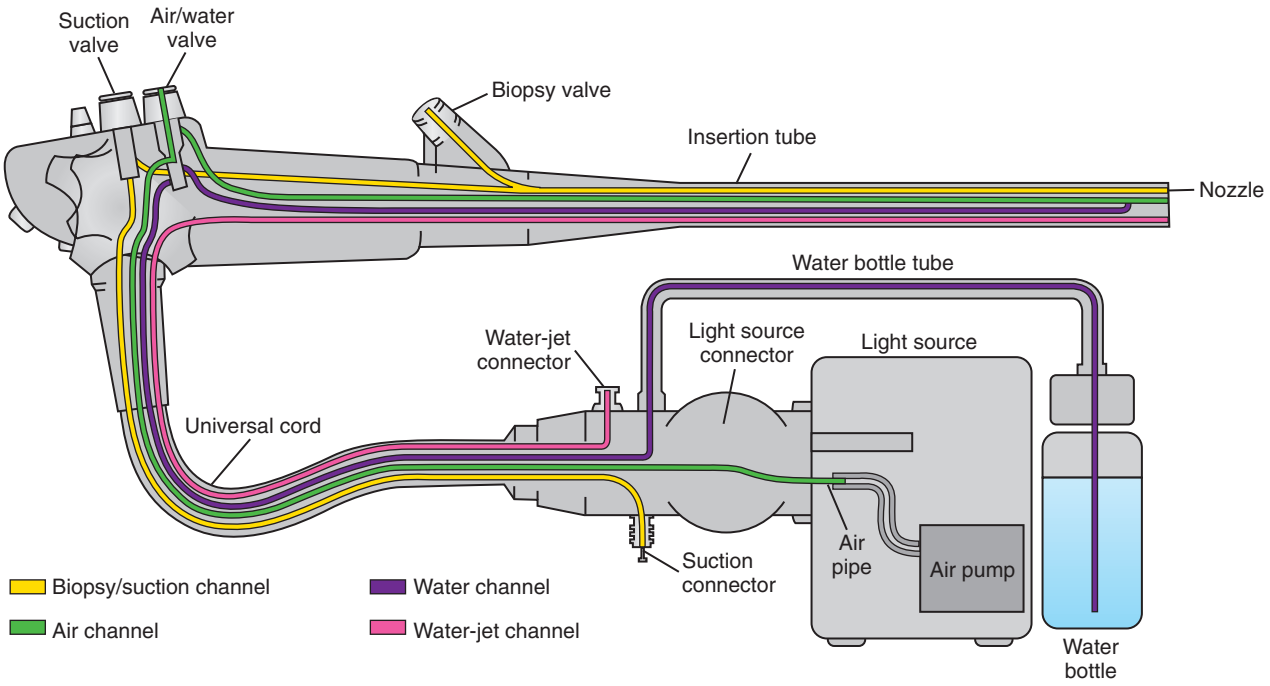

Figure 27-77 Internal anatomy of an Olympus flexible video endoscope. (Reprinted with permission of Olympus America Inc.)

mouth gag in the patient's mouth to prevent severe damage to the endoscope as a result of biting. The insertion tube should never be bent into acute angles during endoscope placement. The endoscopist should be standing in front of the patient at a distance that does not require excessive bending or awkward manipulation of the endoscope. To prevent damage to the shaft and delicate tip, the endoscope must never swing, drag, or slap onto surfaces. Devices used in the instrument channel must be of a diameter and length appropriate for the endoscope characteristics. Forcefully passage of an instrument within the biopsy channel will likely result in severe damage to the channel and the instrument. Resistance during forceps advancement is often the result of attempts to pass the instrument through the distal tip when it is deflected at a sharp angle. In this case, the insertion tube should be straightened inside the patient, the forceps should be advanced until only the tip is visible, and the endoscope should be redirected to the area of interest and the instrument advanced as necessary. Resistance upon advancement of an instrument may also be the result of an excessively firm grip on the biopsy forceps in the closed position. When forceps are gripped tightly in the closed position, the forceps shaft stiffens and will not bend, and the instrument will not move past a bend in the channel. Simply relaxing the grip while maintaining the closed position should allow for normal passage. When attempting to remove sharp foreign objects such as bones, fishhooks, or needles from a patient, the operator should avoid scraping against those sharp surfaces so as to prevent tears or damage to the endoscope liner. Large amounts of debris, such as hair or grass, should not be pulled through the instrument channel. Instead, the entire endoscope should be brought out with the debris in the grasper at the tip of the distal channel. Use of an endoscope in the presence of large amounts of barium, food, or feces will likely result in clogging of distal channels, poor cleaning, resistance to proper disinfection, potential future patient contamination, and potentially costly repairs. The improper use of needles, lasers, diathermy probes, and electrocautery devices can severely damage an endoscope. Therefore, such devices should be used only by individuals trained in proper use and techniques.

To prevent cross-contamination in an endoscopic procedure room, the room should have designated contaminated areas and designated clean areas. Contaminated endoscopes, accessories, and specimens should be handled in areas that are separate from clean counter areas. All contaminated areas should be cleaned and decontaminated between patients. The initial spot cleaning of the endoscope should be done immediately after the procedure and in the same location. The remaining reprocessing steps should take place in a room with conditions conducive to proper cleaning and disinfection of the endoscope and accessories. Federal and state requirements for reprocessing areas in human medicine may not be practical for many veterinary medical suites; however, close compliance is recommended.[9]

The following steps are recommended for reprocessing in a veterinary setting. Most endoscopes in use today are fully immersible in water; however, older endoscopes (manufactured before 1983) may not have this feature. Endoscopes that are not waterproof cannot be adequately cleaned or disinfected and are therefore not recommended for use. Endoscopes that cannot undergo the processes described in these guidelines because of water permeability, age, design, or damage should not be used.[7-9] It is important to note that steps may differ based on the manufacturer's recommendations and that these guidelines may not apply to every endoscope.

All products and methods for cleaning and disinfection/sterilization should be selected based on specific manufacturer recommendations. In preparation for any endoscopic procedure, the following should be prepared and readily available:

- Personal protective gear (gloves, eye protection, nonabsorbent apron or gown, and face shield or surgical mask that will not trap vapors)
- Large container or sink with warm water and freshly prepared low-foaming enzymatic detergent solution at appropriate dilution

- Sponge or soft cleaning cloth (lint-free)
- Specific channel-cleaning brushes
- Specific channel-cleaning and auxiliary adapters
- 30- to 50-mL Luer-lock syringe
- Protective video caps for video endoscope
- Watertight caps
- Leak-testing equipment
- Active disinfectant in covered basin
- Clean, filtered, or sterile water

Initial Spot Cleaning

Spot cleaning should take place immediately following the endoscopic procedure. This step removes gross debris (organic and inorganic) and large numbers of bacteria before they dry on or within the endoscope.

Wearing protective gear (nonabsorbent gown, mask, eye protection, and gloves), the insertion tube is wiped clean with gauze or towel moistened with enzymatic detergent.[2,7,8] Removable waterproof video attachments and accessories should be placed into the enzymatic cleaning solution. To clean the suction/instrument channel, detergent solution should be suctioned for 15 to 30 seconds, which should be followed by suctioning of air for 10 seconds. Suctioning enzymatic cleaner and air through the suction/instrument channel results in agitation of debris and more effective cleaning than suctioning fluid alone.[3] This cleaning step should be repeated using clean water and air. For each endoscope there may be different cleaning attachments and manufacturer's recommendations that should be closely followed. The suction tube, water bottle, video connections, and all valves and removable caps (over instrument channel) should be removed and placed into detergent solution. The endoscope should be disconnected from the light source and a protective video cap attached if using a video endoscope. After this initial cleaning procedure, the scope is ready for reprocessing.[7,8]

Leak Testing

Leak testing detects internal or external damage that may render the scope permeable to fluid and water damage. The manufacturers provide leak testers specific for each endoscope. Before submersion of the endoscope in any solution, the leak tester must be attached and pressurized according to manufacturer instructions. While the device is pressurized, the distal segment of the endoscope is immersed in water, the distal portion of the scope is flexed in all directions, and the immersed tip of the endoscope is closely observed for the presence of a persistent stream of bubbles for at least 30 seconds. A continuous series of bubbles indicate a leak. If no leaks are detected in the distal segment, the entire endoscope is submerged and closely observed for persistence of small bubbles coming from the head of the scope, insertion tube, distal bending section, and the universal cord. Bubbles indicate a leak and the scope must be removed from use and repaired prior to reuse. If the endoscope passes the leak test, it is ready for manual cleaning and further reprocessing.

Manual Cleaning

Manual cleaning of the entire endoscope, including valves, channels, connectors, detachable parts, and accessories is the most important step in reprocessing as it is the final stage for debris removal, sterilization, and infection control. Thorough manual cleaning can remove 99.99% of the bioburden from the endoscope.[2] Because improper cleaning can overwhelm high-level disinfection (HLD) regardless of subsequent steps, meticulous cleaning is essential.[2,10] Failure of adequate manual cleaning is reported to be the most common reason for infection transmission in human endoscopy.[2]

Endoscope cleaning requires the use of a detergent that breaks down organic and inorganic materials, prevents waterborne deposits, and is compatible with the materials being cleaned. The best detergent characteristics are minimal foaming, easy rinsing, and a neutral pH.[7,8] Enzymatic solutions are the most frequently used detergents. Cleaning failure at the enzymatic cleaning stage is commonly a result of improper detergent dilution or inadequate contact time. If the concentration of detergent is too low, adequate cleaning is less likely. When detergent concentration is higher than recommended, the endoscope can be left with residual detergent, which can reduce the efficacy of high-level disinfectants.[7,8,11]

Endoscope Reprocessing

After passing the leak test, the endoscope is carefully coiled and immersed in a basin filled with a freshly made low-foaming enzymatic detergent. While fully submerged, debris is brushed and wiped from the surface of the endoscope. All valves, channel covers, and any other removal parts are detached. A soft brush is used to carefully clean all removed parts and allow them to soak in the detergent. Using recommended cleaning brushes and adapters for each port, all accessible channels in the body, insertion tube, suction port, air/water port, biopsy channel, and any special ports/channels are cleaned. Brushes should be disposable, sterilized, or "high-level" disinfected between cases. Frayed, worn, or bent brushes should not be used as they will have decreased efficacy and may cause damage to the channels. After each passage through a channel, all debris should be removed from the brush before repassing it through the channel. Channels should be brushed until all visible debris is removed. Appropriate cleaning adaptors should come with any endoscope. However, refurbished equipment is often sold without all cleaning adapters and adapters may need to be purchased from the manufacturer of the endoscope. Substitute cleaning equipment is not recommended unless approved by the manufacturer.[7,8]

Cleaning the suction channel requires two steps. To brush from the valve housing to the distal tip, the brush is inserted into the suction valve opening at a 45° angle. To clean from the valve housing to the suction connector, the brush is inserted straight into the center from where is will pass through the universal cord and out at the suction connector. The channel openings are also brushed after passing the brushes through the lumens. Flushing while keeping the scope immersed reduces the possibility of trapping air in the channels. Removal of air is crucial as the detergent cannot contact surfaces where there are pockets of air.

The endoscope is soaked and accessories are cleaned for the period specified by the detergent manufacturer. Enzyme solutions require a specific temperature and contact time to effectively dissolve all organic material. The endoscope should not be left soaking for longer than recommended by the manufacturer.[7-9] After soaking, the equipment is removed from the detergent solution and placed in a clean water bath. The surfaces are wiped with a clean cloth or sponge. Using cleaning adapters, all channels must be flushed with clean water to remove any detergent residues as residual detergent in the endoscope may interfere with the effectiveness of high-level disinfection (HLD) or sterilization.

After rinsing, the endoscope is removed from the water bath and purged by flushing air through all channels. This may require use of the cleaning adapters, syringes of air, or a forced air supply. For forced air supply, the pressure should not exceed 21 psi for most endoscopes; however, some endoscopes may tolerate higher pressures.[7,8] The outside of the endoscope is dried using a soft,

lint-free cloth. Finally, the endoscope and accessories are carefully inspected for any residual debris and if found, the manual cleaning procedure must be repeated. Once clean, the scope should undergo HLD.

High-Level Disinfection

HLD is the accepted standard for reprocessing gastrointestinal endoscopes.[6-9,11,12] HLD specifically refers to the destruction of all microorganisms (i.e., bacteria, viruses, fungi, mycobacteria), with the exception of high numbers of bacterial spores.[12] HLD is required in human medicine because of the contact of the endoscope and accessories with mucous membranes. Sterilization is required only when the endoscope is used for a sterile procedure (e.g., intraoperative procedure, airway, etc.).[11] HLD can be performed manually, or by using an automatic reprocessor. Automatic reprocessors standardize the disinfection procedure and decrease exposure of personnel to high-level disinfectants. However, no automatic reprocessor is currently available that provides adequate cleaning of endoscopes; consequently, all of the steps for manual cleaning of endoscopes must take place prior to using an automatic reprocessor.[7] Because of their expense, size, and limited return on investment, using an automatic reprocessor is impractical in most veterinary settings and thus is not covered further in this text.

Few high-level disinfectants are approved for use by all endoscope manufacturers. Therefore the manufacturer's specifications should be reviewed before choosing a high-level disinfectant. The high-level disinfectant must be prepared for use according to the high-level disinfectant manufacturer's directions. Two disinfectants compatible with most endoscopes are glutaraldehyde and orthophthalaldehyde (OPA). Glutaraldehyde has been used since the 1960s as a sterilant and a high-level disinfectant (commonly known as Cidex, Johnson & Johnson Medical Products; or, Metricide, Metrex Research, Inc.). A 20-minute exposure time is required for HLD when using a 2.4% solution at room temperature. Concentrations range from 2.4% to 3.4% and the maximum use life can vary from 14 to 28 days.[12] Efficacy must be tested before each use with product-specific test strips. Glutaraldehyde is an irritant and users can develop sensitivity, which may manifest as itchy skin, skin redness and swelling, irritation to eyes and mucous membranes, headaches, and/or respiratory symptoms. Glutaraldehyde can be absorbed by inhalation, ingestion, and through the skin. When using glutaraldehyde, a local exhaust system or a ductless fume ventilation system with filters to absorb vapors is required for user safety. Whenever the glutaraldehyde solution is not in use, it should be covered with a tight seal.[12]

OPA 0.55% is a high-level disinfectant introduced in 1999 as Cidex OPA solution (Advanced Sterilization Products). OPA solution achieves HLD in 12 minutes at room temperature, and 5 minutes when used in an automatic endoscope reprocessor at a temperature of 25°C (77°F). OPA is a reusable product and has a maximum shelf life of 14 days.[12] As with glutaraldehyde, the solution must be tested to determine strength prior to each use.

OPA is a clear blue solution with little odor, that is ready to use and requires no mixing. It has a very low vapor pressure and does not require special ventilation or air monitors when handling. It can stain fabric, skin, and many surfaces that it contacts. It is a potential respiratory and skin sensitizer and may result in exacerbation of bronchitis or asthma or dermatitis if there is prolonged, repeated contact. It can also be an irritant to the eyes, skin, nose, and other tissues. OPA solution is contraindicated for cystoscopy procedures on patients with a diagnosis of bladder cancer.[12,13]

HLD is best achieved after the endoscope is thoroughly cleaned, rinsed, and fluid is evacuated from all channels. The disinfectant product must be prepared according to the manufacturer's label instructions. Using a product specific test strip, the minimum effective concentration (MEC) of the biocide must be tested on each day of its use and more frequently if many endoscopes are reprocessed in one day. A log of the results should be kept.[7-9]

The endoscope, all removable parts, and the cleaning adapters are completely immersed in a basin of the HLD. As during manual cleaning, the disinfectant must be injected into all channels of the endoscope until it can be seen exiting the opposite end of each channel and the operator is confident that there are no air bubbles within the channels. All tub contents should be kept completely submerged, including all removed attachments. The soaking basin should be covered with a tight-fitting lid to decrease chemical vapor exposure.[7-9,11,12]

The manufacturer's recommendations should be followed for the time and temperature required to achieve HLD. A timer should be used to ensure proper soaking times. Once soaking times have been met, cleaning accessories are reattached and all channels are completely purged with air before removing the endoscope from the high-level disinfectant.[7-9,11,12]

Residual disinfectant is toxic; therefore, adequate rinsing is essential to protect the next patient (and operator) against injury from exposure to residual chemicals. After the appropriate amount of time, the endoscope and accessories are moved to a clean basin or sink filled with clean water. Sterile water is ideal, but filtered water or tap water are acceptable alternatives.[7-9,11,12] Then all external surfaces and removable parts are wiped and rinsed and all channels are flushed copiously with clean water.

Drying

Bacteria such as *Pseudomonas* or *Mycobacterium* spp. can be found in tap or filtered water and may multiply in moist environments. Therefore it is important to achieve and maintain a dry endoscope.[2] After rinsing, the endoscope and all accessories are moved to a dry surface or bin. The water is purged from the inside of the scope by injecting air into all channels. If forced air is used, endoscope damage can be avoided by maintaining forced air pressures less than 21 psi.[7-9,11,12] Suction is connected and air is aspirated for at least 15 seconds. To assist drying, all channels should be flushed with 70% isopropyl alcohol and then purged again with air. All channel adapters are removed and the exterior of the endoscope and channel adapters are dried with a lint-free soft towel. All removable parts are dried, but are not reattached during storage. Storing the endoscope without the valves and other removal parts aids in drying and decreases the risk of trapping moisture in the channels.[7-9,11,12]

Storage

The endoscope should be suspended vertically with the distal tip hanging freely in a well-ventilated, dust-free area. The endoscope should be stored in a way that protects it from physical damage. Padding on the bottom of the storage area will help prevent damage to the distal tip. Providing good ventilation in the storage area will help keep the endoscope channels dry, thereby reducing the chance of bacterial contamination.[7-9,11,12]

Sterilization

GI endoscopy rarely requires the use of a sterilized endoscope. Should sterilization be required; manufacturer's instructions should be followed for ethylene oxide gas or chemical sterilization.

Endoscopic Accessory Cleaning and Care

Endoscope accessories should undergo the same steps of manual cleaning and disinfection as the endoscope itself and in many instances, sterilization will be required. Careful and thorough manual cleaning with an enzymatic agent is required for all accessories utilized during an endoscopic procedure and should be done as soon as possible after any procedure. All equipment should be disassembled as much as possible and immersed in enzymatic solution following use. Endoscopic accessories that penetrate the mucosal barrier such as biopsy forceps, guidewires, cytology brushes, snares, dilators, cytology brushes, papillotomies, or any cutting instruments should be manually and ultrasonically cleaned and then sterilized using a chemical sterilant, ethylene oxide gas, or autoclave.[7-9,14,15] Ultrasonic cleaning is necessary to effectively remove debris from all spiral coiled, hinged, or complex structured accessories that hand cleaning cannot clean effectively. Any cannula or tubing accessories require thorough flushing with enzymatic detergent. Other accessory items, depending on design, require a combination of flushing and brushing to clean surfaces.[7-9,14,15]

Biopsy forceps have very tight metal coils with a spring-like structure that are surprisingly difficult to clean. One study indicated that manual and ultrasound-only cleaning methods for biopsy forceps were ineffective in removing material from within the biopsy forceps, suggesting that current recommended cleaning methods of reprocessing biopsy forceps are not adequate.[16] Chemical sterilization does not completely penetrate the coils and therefore is ineffective. Steam under pressure (autoclaving) is the only method that will effectively sterilize the coiled instruments, as it can penetrate the metal coils of the spring-like structure and any residual organic material within the coils.[16] When possible, all accessories should undergo heat sterilization via steam under pressure (autoclaving). Whenever an alternative exists, all nonsterilizable, reusable accessories should be phased out.[7,8,14-16] Lubrication of any device should be done after cleaning and before sterilization.[14,16]

For heat-sensitive equipment, the first alternative should be another form of sterilization such as gas plasma sterilization. Chemical disinfection should be the last option to be considered. Single-use biopsy forceps (i.e., forceps that are disposed of after first use) are the safest to use if sterile equipment is required.[14-16] Even though reusable instruments are a more cost-effective, practical solution in veterinary medicine, the user should be aware of the challenges of sterilization. Although commonplace in many practices today, items labeled for single-use should not be reprocessed and/or reused.[7,8,14-16]

Conclusion

In human health care, more health care–associated infections have been associated with contaminated endoscopes than with any other medical device.[3] Comparable data are unavailable for veterinary medicine. Efforts to make endoscopy safer and to eliminate the risk of cross-contamination have resulted in endoscope design changes and a move to create practical disposable or single-use devices. Quality assurance methods to verify adequate cleaning and HLD have also been developed.

The use of nonimmersible endoscopes is no longer acceptable because endoscopes that cannot be completely immersed in liquid cannot be adequately cleaned and undergo HLD.[8] Endoscope design and technology is changing rapidly. For example, autoclavable video bronchoscopes are now available and are designed for effective sterilization.[17] There is industry movement toward the development of flexible gastrointestinal endoscopes that can be easily disassembled for reprocessing. New products such as the Slide-On EndoSheath, a sterile barrier sheath system, slides over the endoscope to eliminate the need for HLD of nasendoscopes.[18] Another example is the Stryker ProtectiScope CS, a colonoscope that has all of the features of leading colonoscopes, but also has a unique disposable sleeve that covers the ProtectiScope CS as it advances into the colon. In addition to the disposable sleeve, all internal and external channels are disposable ensuring that contaminants do not enter the colonoscope.[19]

Policies and procedures for cleaning and reprocessing endoscopes, accessories, and associated equipment are needed in veterinary medicine. These guidelines should be readily available to all users and should be reviewed and revised as necessary to continue to provide the safest procedures for the patients and clinicians. Further advancements in methodology are likely to develop in the next decade. It is important to regularly review, update, and implement cleaning and disinfection protocols. By placing greater importance on disinfection and proper care of the endoscope and its accessories, quality of patient care will undoubtedly improve.

CHAPTER 28

Laparoscopy

INSTRUMENTATION

Keith Richter

The use of laparoscopy for diagnostic and therapeutic purposes has increased dramatically during the last 20 years. Increased use and acceptance of laparoscopy stems from technical advances in equipment and instrumentation, improved access and training, client expectation, and excellent results with these minimally invasive procedures. Advanced therapeutic procedures will be performed more commonly as veterinarians adopt these techniques. Compared with open abdominal surgery, laparoscopy has several distinct advantages, including less postoperative pain, lower infection rates, improved visualization in many cases, lower cost, and shorter hospitalization times. Laparoscopy also has some advantages over other minimally invasive procedures, such as ultrasound and ultrasound-guided biopsy, including sample quality and direct visualization.

Equipment

Light is transmitted from a remote light source via a fiberoptic light cable to the rigid fiberoptic laparoscope (telescope). Light transmitted through the light cable passes through incoherent bundles (randomly aligned), whereas light passing through the telescope passes through coherent bundles (spatially oriented). This creates a proper image when the lens system focuses the light at the eyepiece. The fibers in the telescope are delicate, and care must be taken to avoid bending or crimping the shaft. Modern telescopes are constructed so they can be sterilized with a conventional steam autoclave. For purposes of illumination, a light source of 150 to 300 watts is required to adequately illuminate the abdomen, particularly in large- and giant-breed dogs.

Size and viewing angles of laparoscopes vary, some of which are depicted in Figure 28-1. Small-diameter scopes (2.7 to 5.0 mm) have a smaller image with a narrower field of view. Light sources with greater intensity and video cameras with greater light sensitivity are needed with smaller scopes. Scopes up to 10-mm diameter can be used, and although these generate a bigger and brighter image than 5-mm–diameter scopes, this advantage applies only to very large dogs. Scopes are also available in various degrees of angulation of view, from 0° (direct forward viewing) to 70° angle viewing. The 0° angle view has the field of view centered on the long axis of the scope, and thus is easier to use and generally preferred for most procedures. A 30° angle scope can be used to view structures to the side of the tip, and through rotation can be used to expand the field of view. Angled scopes are more difficult for inexperienced operators with regard to spatial orientation, and they pose greater difficulty when using instruments through a second or accessory puncture site. The technique of triangulation to find the tip of the instrument is particularly more difficult with an angled field of view. Taking all these factors into account, a forward-viewing (0°), 5-mm outer diameter, 35-cm long scope is preferred for most dogs and cats. As most laparoscopic instruments are 5 mm in diameter, this provides more versatility by allowing the scope and instruments to be interchangeable with the same cannula. The operator must ensure the scope fits properly through the selected cannula, that the light cable has the appropriate connection to the telescope, and that the video camera fits properly onto the eyepiece.

Most scopes have no biopsy channel. Operating scopes have a 5- to 6-mm channel, with an eyepiece extending from the proximal end (see Fig. 28-1C). These scopes allow introduction of instruments through the same puncture site as the scope. This has the advantages of reducing the number of puncture sites and facilitating identification of the instrument tip for inexperienced operators. The major disadvantage of operating scopes is the limited ability to manipulate instruments passing through the channel. An accessory or secondary puncture technique is usually preferred by more experienced laparoscopists (see "Accessory Puncture Sites" section).

Video capabilities can be achieved with a charge-coupled device (CCD) video camera mounted onto the eyepiece of the telescope. These video cameras have a high resolution, an image magnification by 5 to 15×, and a high image quality. Cameras are constructed with a lens, prism assembly, and one or three chips that convert light to an electronic signal. Cameras with three chips (each representing the primary colors of red, green, or blue) generally produce better images than cameras with just one chip. More recently, high-definition (HD) cameras have become available and produce a superior image quality. Video technology is now essential for interventional or operative laparoscopy.

To visualize abdominal structures, a pneumoperitoneum must be created to lift the abdominal wall away from the viscera. This is accomplished by insufflating gas through tubing attached to a Veress needle (Fig. 28-2). The Veress needle has a spring-loaded blunt inner portion and an outer cannula with a sharp point. The sharp point is used to penetrate the abdominal wall. The inner blunt portion is then protruded past the sharp point and is maintained in that position to avoid traumatizing abdominal organs. Gas can be continually insufflated as needed throughout the procedure. Carbon dioxide gas (CO_2) is recommended because it has the advantage of being rapidly absorbed, thereby minimizing the risk of air embolism. Air embolism is a complication that is more likely to take place if using room air. The disadvantage of CO_2 is that it is slightly more irritating to the peritoneal surface and therefore requires a slightly

greater depth of anesthesia. The pneumoperitoneum is maintained throughout the procedure with an automatic insufflator, which continuously administers gas to maintain pressure. Insufflators regulate both flow rate and intraabdominal pressure. Initial gas insufflation should be at a low flow rate (e.g., 1 L/min) to permit accommodation to the increasing intraabdominal pressure. If the pressure suddenly rises during insufflation, it is often a result of omental or mesenteric obstruction, or the incorrect placement of the needle. The position of the needle should be adjusted by gently moving it in and out of the abdomen; occasionally it must be replaced completely. Once optimal insufflation has been achieved, a higher flow rate can be used to maintain desired pressures. Ideally, intraabdominal pressure should not exceed 10 mm Hg (cats and small dogs) to 15 mm Hg (large dogs). Excessive pressure decreases central venous return and reduces diaphragm movement, causing decreased ability to ventilate. These effects are unlikely to occur at recommended abdominal pressures, but should be considered in patients with preexisting cardiopulmonary disease.

After the creation of the pneumoperitoneum, the laparoscope is introduced into the abdomen with the use of a trocar/cannula assembly (Fig. 28-3). The cannula is a metal or hard plastic sleeve with a one-way valve that permits passage of instruments (such as the trocar, laparoscope, and accessory instruments) and prevents the escape of gas. The trocar is a sharp-pointed stylet that is used to penetrate the abdominal wall. Once the trocar/cannula assembly penetrates the body wall, the trocar is then removed, leaving the cannula in place for introduction of the laparoscope.

Trocar/cannula assemblies come in a variety of sizes and styles. Trocars with a pyramidal tip have a cutting edge that penetrates the abdominal wall more readily than trocars with noncutting conical tips, although they are also potentially more traumatic. Some trocars have a retractable blade within the tip. A well-established pneumoperitoneum must be present for this style to be used to avoid the risk of intraabdominal organ trauma. Cannulae are used to allow passage of instruments in and out of the abdominal cavity while maintaining the pneumoperitoneum. They are constructed with a one-way valve to permit introduction of instruments without the escape of abdominal gas. Additionally, there is a rubber seal at the proximal tip to prevent escape of gas when an instrument is in place. Some cannulae have a side port to allow attachment of insufflation lines to introduce gas during the procedure. The shaft of the cannula can be smooth or threaded. A threaded cannula is more stable and unlikely to move within the abdominal wall during the procedure. Sometimes it is desirable for the cannula to move in and out of the abdominal cavity, such as when the cannula is inserted deep into the abdominal cavity for tissue biopsy. In these instances, a smooth nonthreaded shaft is preferred. For imaging purposes, an appropriately sized cannula must be used to ensure adaptation to the telescope and other instrumentation.

Accessory Puncture Sites

Accessory puncture sites are made for introduction of additional trocar/cannula assemblies. Accessory puncture sites permit the introduction of a variety of palpation, biopsy, and surgical instruments. These instruments are elongated, narrower versions of standard surgical instruments. A "basic" laparoscopic accessory pack should consist of a blunt metal probe, "spoon" or "clamshell" style (oval cup) biopsy forceps, grasping forceps, scissors, suction device, cautery instrument, and Babcock forceps (Fig. 28-4). An "advanced" laparoscopic accessory pack should also include retractors, reticulating instruments (which allow the tips to bend or be deflected), clip applicators, suturing devices, advanced hemostasis devices such as the Harmonic scalpel (Ethicon) and the LigaSure device (Covidien), and stapling equipment. The use of stapling equipment permits additional procedures such as vessel ligation and bowel resection.

Figure 28-4 Laparoscopic instruments. From *top* to *bottom*: blunt metal probe, "spoon" or "clamshell" style (oval cup) biopsy forceps, grasping forceps, scissors, suction device, cautery instrument, and Babcock forceps.

Indications and Contraindications for Laparoscopy

Common indications for laparoscopy are for the evaluation of hepatobiliary disease. Laparoscopy allows procurement of large specimens (similar in size to surgical biopsies) using a 5-mm "spoon" or "clamshell" forceps (see Fig. 28-4). Samples obtained with these instruments have a superior diagnostic yield compared with needle biopsies, which have a reported 50% concordance with histologic findings from surgical biopsies.[1] Furthermore, the ability to visualize the liver gives the clinician a better feel for the pathologic process present and its distribution. Laparoscopy can also be used to examine and biopsy the right limb of the pancreas, an organ that can be difficult to image with abdominal radiographs and ultrasound. Other organs that can be biopsied via laparoscopy include the kidney, spleen, prostate, intestine, mesentery, omentum, and parietal peritoneum. Laparoscopy can be used to diagnose and stage abdominal tumors through direct visual assessment and biopsy. Laparoscopy can detect lesions less than 1 mm in diameter on the surface of organs. It can guide the aspiration of gallbladder, loculated ascites, and abdominal cysts or abscesses. Laparoscopy can guide transabdominal intrauterine artificial insemination. Laparoscopy can also be used for the evaluation of abdominal trauma. Injuries such as hepatic or splenic laceration, diaphragmatic hernia, bladder rupture, renal rupture, and abdominal hernia can be readily identified. There are also a variety of surgical or interventional procedures that can be accomplished laparoscopically.

Contraindications for laparoscopy include general anesthesia in an unstable patient, coagulopathy, diaphragmatic hernia, abdominal adhesions, and insufficient clinical experience. It must be emphasized that these are all relative contraindications, and the risks of a laparoscopic procedure must be weighed against the benefits of the procedure to the patient.

General Laparoscopic Technique

Several skills are required to perform a successful laparoscopic procedure.[2] The operator must have a good grasp of abdominal anatomy, surgical principles, anesthetic induction and maintenance, and operative use of laparoscopic equipment. Compared with surgery, laparoscopy poses three additional challenges—two-dimensional imaging, lack of tactile sensation, and problems with depth perception—all of which pose significant challenges for the inexperienced laparoscopist. The operator must be familiar with the general feel of the instruments, and how slight movements of the camera head can result in wide excursions of the image. Tactile sensation can be developed with practice through the use of a blunt probe. Fluctuant structures can usually be distinguished from solid structures using the blunt probe. There is also a fulcrum sensation that occurs with instrument movement. Because the instruments and scope are entering the abdominal cavity through a cannula, movement of the tip is in a direction opposite to that of the handle. Thus, when the hand and handle are moved upward, the tip of the instrument moves downward. When the hand and handle are moved to the left, the tip of the instrument moves to the right. Another necessary skill necessary is triangulation, because the angle of the scope and the angle of the instrument form a triangle. Triangulation permits the operator to find an instrument placed through a secondary or accessory cannula in the field of the scope. The angle of entry of each component of the triangle must be recognized to

avoid frustration when attempting to find the instrument tip. One technique that is helpful is to move the scope further away from the anticipated point of the instrument tip. This will increase the field of view. Once the tip of the instrument is located, the scope can be moved closer to the instrument to improve visualization. At this point the instrument and scope are moved in parallel so that the instrument tip never leaves the field of view. This technique will reduce unnecessary anesthesia time. The skill of triangulation becomes more challenging when using an angled scope (such as a 30° telescope). If the viewing angle is directed upward and an instrument is inserted from the side, it appears to come from below and to the side of the field of view.

Laparoscopy is best performed under general anesthesia. The position of the dog or cat and the location of the various puncture sites depend on the procedure, patient's size, and organ of interest. Because the port placement is so critical to a successful procedure, placement of the ports must be carefully planned and the site marked on the patient ahead of time to ensure a sterile field. In general, ports should not be placed too close together to avoid crowding of instruments with each other or with the scope. Furthermore, triangulation to locate instruments and subsequent manipulation of instruments is more difficult when they are placed too close to the scope. If it is determined that port placement is not acceptable, it is often better to place an additional port to allow completion of the procedure than to struggle through the procedure with suboptimal port location. Prior to starting the procedure, the urinary bladder should be emptied.

A right lateral or right lateral oblique approach is generally preferred for the liver, gallbladder, biliary tract, pancreas, right kidney, and right adrenal gland. The main advantage of this approach is that it avoids the falciform ligament, which is commonly encountered with a midline approach. The main disadvantage of a right-sided approach is the inability to see most left-sided abdominal structures. A midline approach is occasionally used for more complete evaluation of the liver (more of the liver can be seen by this approach than by a right-sided approach) and many interventional surgical procedures. Although the falciform ligament may impede the procedure, it can be avoided by placing the central port just lateral to midline and caudal to the umbilicus. In a lateral approach, the scope is placed several centimeters lateral to midline, depending on the size of the patient. A left-sided approach is seldom used, but is necessary to visualize the left kidney and left adrenal gland.

Complications of Laparoscopy

Potential complications of laparoscopy include those related to general anesthesia, inadvertent organ damage during instrument introduction, excessive bleeding during biopsy or other intervention, other surgical complications, overdistention of the abdomen, air embolism, subcutaneous instillation of gas, tension pneumothorax if the diaphragm is inadvertently punctured, and postoperative infection. Operator experience, good patient planning, and meticulous attention to procedural detail minimizes the probability of these complications. Postoperative pain should be anticipated and should be addressed with appropriate analgesics.

Laparoscopic Surgery

Many laparoscopic surgical procedures are currently being performed on dogs and cats. These include ovariectomy and hysterectomy, adrenalectomy, bile duct exploration, gastropexy, cystotomy with calculus removal, cryptorchid testicle removal, jejunostomy tube placement, splenoportography, cholecystectomy, and others. Limitations of laparoscopic surgery include the two-dimensional image, restricted freedom of movement of the instruments, restricted sense of touch, limited opportunity to move the position of instruments once cannulae have been placed, the need for extensive training, and limitations on instrumentation available for laparoscopy. As clinicians and equipment manufacturers address technical limitations, many surgical procedures should become more amenable to laparoscopic surgery.

Newer Laparoscopic Techniques

One recently developed innovative laparoscopic technique described in human beings is natural orifice transluminal endoscopic surgery (NOTES). This technique involves insertion of an endoscope into a natural orifice (such as the stomach, vagina, or colon), access to which is then used to perforate the wall to gain entrance to the peritoneal cavity. Many interventional procedures can be performed using this technique. The approach is thought to limit postoperative pain, decrease wound problems, and offer improved cosmesis. Transvaginal cholecystectomy is the main procedure being performed to develop the NOTES technique, although other surgical procedures can also be performed with this approach. There are many challenges to overcome to accomplish these procedures successfully. Luminal access can be achieved with new steerable trocar/cannulae. Flexible scopes have been developed with multiple steerable channels to allow introduction and manipulation of a variety of instruments to be used for the surgical procedure. Tissue or organ retraction is also very challenging. This has been overcome by use of special intraluminal retraction devices (Endograb, Ethicon), articulated graspers, and deployable devices (T-tag suture devices). Closure devices also have been developed, including endoscopically deployed clips. These include the Resolution Clip (Boston Scientific) and the QuickClip2 (Olympus).

Another method of overcoming these technical challenges is to combine a single puncture transabdominal laparoscopic port with transluminal access (called hybrid NOTES). This improves retraction and allows more versatile instrumentation.

The single-incision laparoscopic surgery (SILS) is another newly introduced technique. This technique permits the introduction of multiple instruments through one large port into the abdominal cavity. Several manufacturers have developed these devices. Furthermore, gently curved rigid instruments have been developed for this technique. The gentle curve permits better triangulation of instruments despite their insertion into a common port. In addition, reticulated instruments with steerable tips make this technique more versatile.

Intraoperative ultrasound (IOUS) during laparoscopic cholecystectomy is becoming increasingly commonplace in human laparoscopic surgery. High-resolution ultrasound probes are integrated into the tip of laparoscopically deployed instruments. The use of IOUS can help define biliary anatomy, including the entire common bile duct. Abnormalities, such as common bile duct calculi, sludge, or aberrant biliary anatomy, can be identified. The procedure only adds 5 to 7 minutes to a cholecystectomy, and can potentially change the management of the patient.

Only time will tell whether NOTES, SILS, or IOUS will be routinely applied in dogs and cats. Controlled clinical trials will be necessary to define the role of all laparoscopic procedures in veterinary medicine.

LIVER AND BILIARY TRACT

Eric Monnet and David C. Twedt

Laparoscopy is a simple procedure associated with few complications. Despite the advent of newer laboratory tests, imaging techniques, and ultrasound-directed fine-needle biopsy, laparoscopy remains a valuable tool when appropriately applied in the diagnostic plan in patients with suspected hepatobiliary disease. Laparoscopy can be used to safely evaluate the liver and the biliary system. Laparoscopy can replace laparotomy for the visual inspection of the liver and biliary system, and to obtain biopsies. Laparoscopy may reveal small (0.5 cm or less) metastatic lesions, peritoneal metastases, or other organ involvement that is not easily identified by other imaging techniques.

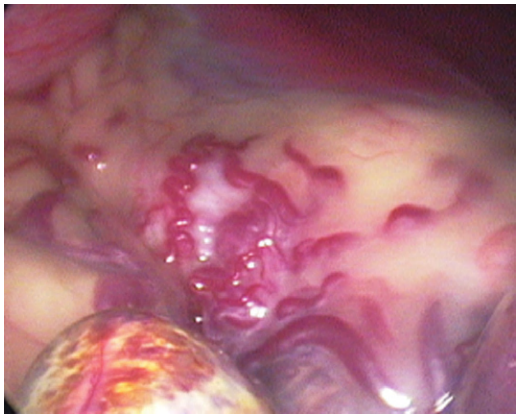

Figure 28-5 Acquired portosystemic shunts in a dog with end-stage liver disease.

Preparation, Restraint, and Surgical Considerations

With few exceptions, laparoscopy is performed under general anesthesia. However, because liver biopsy is a procedure of relatively short duration, it can be accomplished in some patients under light sedation and local anesthesia at the cannulation sites. If the pneumoperitoneum with CO_2 insufflation interferes too much with the excursion of the diaphragm and ventilation of the patient, general anesthesia with intubation and positive ventilation will be required.

The right lateral approach is recommended for diagnostic evaluation of the liver and extrahepatic biliary system. With this approach the right limb of the pancreas can also be identified, evaluated, and biopsied. During the right lateral approach, the patient is in left lateral recumbency and the portals are placed in the caudal part of the abdominal cavity from the right side. Two portals are sufficient to perform a liver biopsy. A ventral approach can also be used to visualize the liver, gallbladder, and biliary tract. In the ventral approach, the primary portal is placed on the midline caudal to the umbilicus. The secondary portal is introduced in either the right or left side of the abdominal cavity. With the ventral approach the left lobes of the liver can be more readily visualized although the falciform ligament may hinder visualization of the anterior abdomen, especially in obese animals during a ventral approach.

Ascites, prolonged bleeding time, and poor patient condition are the only relative contraindications to laparoscopy. If ascitic fluid accumulation is mild, it can be removed prior to or during the laparoscopic procedure. Closed suction drainage can be placed in the abdominal cavity at the end of the procedure to prevent continued leakage through the portal sites. Coagulation parameters (prothrombin time, partial thromboplastin time, buccal mucosal bleeding time) should be evaluated prior to laparoscopy and liver biopsy. Although coagulopathy is a relative contraindication to liver biopsy, coagulation status does not necessarily predict whether the patient will bleed from laparoscopy or liver biopsy. Laparoscopy does permit the operator to visually select biopsy areas that are less vascular and to monitor the extent of bleeding following a biopsy.[1]

Evaluation of the Liver and Liver Biopsy

Eighty-five percent of the liver surface can be visualized during routine laparoscopy As with exploratory laparotomy, the liver is evaluated for size, color, shape, and sharpness of edges. For the diaphragmatic surface of the liver, an angle endoscope can be used to image the more cranial aspects of the liver. A palpation probe is used to manipulate the different lobes and to visualize the visceral surface of the liver and extrahepatic bile ducts. Grasping forceps should not be used to manipulate liver lobes because the liver parenchyma is often too friable and at risk for traumatic injury and bleeding. With the right lateral approach, the portal vein can be evaluated for size and turbulent flow. Acquired shunts can be observed across the omentum and around the left kidney if portal hypertension is present (Fig. 28-5).

Portal pressure can be measured directly after exteriorization of a loop of jejunum and catheterization of a jejunal vein. Manometry is used to measure portal pressure, and a portovenogram can be performed to further evaluate the portal vasculature. After completion of the portovenogram and measurement of portal pressures, the catheter is removed and the loop of bowel is returned into the abdominal cavity.

Laparoscopic liver biopsy is considered by many to be the preferred method of obtaining liver tissue for routine histopathology.[1] A 5-mm cup biopsy forceps provides sufficient liver tissue for routine analysis and is superior in quality to 18-gauge (G) needle biopsy.[2] During laparoscopy, the biopsy forceps can be directed toward lesions of interest and to monitor for excessive bleeding. The liver biopsy can also be obtained with an ultrasonically activated scalpel.[3] Ultrasound scalpels provide good tissue sampling for histologic analysis with minimal bleeding from the biopsy site. The amount of collateral tissue damage induced with an ultrasonically activated scalpel is similar to the damage induced by the cup biopsy forceps. The cup biopsy forceps causes crush injury to collateral tissue, whereas the ultrasound-activated scalpel causes thermal injury at collateral sites. The authors recommend the use of a 5-mm oval cup biopsy forceps for most liver biopsies, and the ultrasonically activated scalpel for biopsy of vascular masses involving the liver.

Postbiopsy, the biopsy site must be closely monitored for excessive bleeding. The amount of bleeding associated with routine liver biopsy is usually minimal. If bleeding is considered to be excessive, several steps should be taken. First, the palpation probe can be placed into the biopsy site and pressure applied over the area with the tip of the probe. Alternatively, a small piece of saline soaked Gelfoam can be placed into the biopsy site using laparoscopic grasping or biopsy forceps. These options are sufficient to control excessive bleeding in most instances.

In general, the liver should be biopsied on the surface and at an edge (Fig. 28-6), although some have suggested that edge biopsies may not reflect pathology of deeper samples because the subcapsular tissues are more reactive and fibrotic. It is always important to biopsy

Figure 28-6 Biopsy of the liver with a 5-mm cup biopsy forceps.

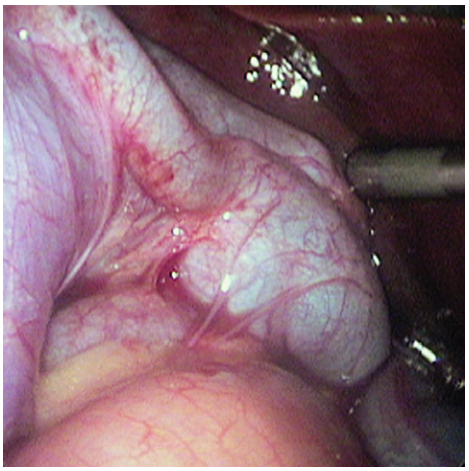

Figure 28-7 Severe dilation of the common bile duct in a patient with bile duct obstruction.

three to four areas of the liver, including areas that appear grossly normal as well as abnormal. The biopsy forceps cups should be tightly closed over the tissue biopsy for approximately 15 to 30 seconds before pulling the sample away from the liver.

Evaluation of the Biliary Tract

The extrahepatic biliary tract can be examined during laparoscopy when the quadrate liver lobe is retracted toward the diaphragm. The hepatic, cystic, and common bile ducts can be evaluated for their size, color, shape, and patency. Dilation of the bile ducts is readily appreciated at the time of laparoscopy (Fig. 28-7).

The size and health of the gallbladder can also be evaluated at the time of laparoscopy. A palpation probe is used to palpate the gallbladder to assess its stiffness or flaccidity. An 18-G spinal needle can be advanced percutaneously into the gallbladder to sample bile for culture and cytology, and to decompress the gallbladder and biliary system (Fig. 28-8). The needle has to be introduced in a location caudal to the insertion of the diaphragm. The line of insertion of the diaphragm on the last rib is outlined by a line of fat, which can be used as a reference point. If the needle is introduced through the diaphragm, there is a significant risk of inducing a pneumothorax with diffusion of CO_2 under pressure from the abdomen. The gallbladder should be emptied as much as possible to prevent leakage of bile from the puncture site into the abdominal cavity.

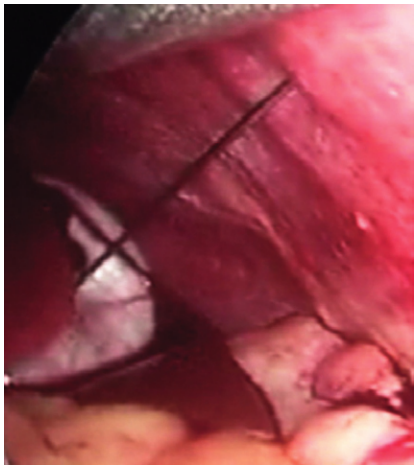

Figure 28-8 Aspiration of the gallbladder with an 18-gauge spinal needle.

At the conclusion of the procedure, the instruments and telescope are removed and the pneumoperitoneum is vented. The cannulas are then removed and the puncture sites are sutured in a routine manner to conclude the laparoscopic procedure. For postoperative pain management, the authors recommend bupivacaine locally at the trocar cannula sites and also systemic analgesia (see Chapter 38).

PANCREAS

Thomas Spillmann

The era of laparoscopy in human and veterinary medicine began in 1901 when Georg Kelling of Dresden, Germany, performed the first celioscopy in a dog.[1,2] There were many anatomic descriptions reported thereafter, but it was not until 1957 that the use of laparoscopy in the diagnosis of intraabdominal disease was first reported. In that year, Hans Eikmeier of Giessen, Germany, published his habilitation thesis on the laparoscopic diagnosis of canine liver disease.[3] The laparoscopic diagnosis of canine pancreatic diseases was first reported in the early 1970s, and the authors concluded that the technique might include the possibility of tissue sampling for histologic examination.[4-6] With the advent of noninvasive abdominal ultrasonography, laparoscopy was nearly forgotten as a diagnostic tool. With renewed emphasis on minimally invasive procedures in both human and veterinary medicine, laparoscopy has experienced a resurgence of interest and application.[7-10]

The advantages of diagnostic laparoscopy in comparison to other advanced imaging techniques, such as contrast-enhanced computed tomography or endoscopic ultrasonography, are less-expensive equipment, technical ease of the procedure, and feasibility of direct sampling of biopsies from regions of interest.[11-16]

Indications

Laparoscopic examination of the pancreas is indicated when the clinical signs, laboratory test results, and other imaging findings provide evidence for the existence of a pancreatic disorder that demands further macroscopic and histologic examination without an obvious need for diagnostic or therapeutic laparotomy.[10,16-18]

Tissue sampling at the time of laparoscopy enables the further differentiation of the many primary diseases of the pancreas and liver. In dogs, laparoscopy is used mainly to diagnose chronic pancreatic disease, such as chronic pancreatitis and subclinical pancreatic acinaratrophy.[10,16-18] In cats, the addition of liver biopsy and laparoscopy-assisted small intestinal full-thickness biopsy to the procedure enables diagnosis of concurrent cholangiohepatitis, pancreatitis, and inflammatory bowel disease (termed "triaditis" by some authors).[16,19,20]

Contraindications and Limitations

As with other laparoscopic procedures, the general contraindications for laparoscopic examination of the pancreas include poor patient condition with increased anesthetic risks, hemorrhagic diathesis, diaphragmatic hernia, abdominal effusion (especially septic peritonitis), abdominal adhesions, and renal, cardiac, or pulmonary insufficiency.[10,16-18]

The specific contraindications for laparoscopic examination of the pancreas include mass-forming pancreatic diseases (with or without extrahepatic biliary tract obstruction) such as pancreatic necrosis, pseudocyst, abscessation, and neoplasia. Mass-forming disease processes of the pancreas are better differentiated via laparotomy, which offers the possibility of immediate surgical intervention, such as debridement, omentalization, and resection of necrotic areas.[21] Surgery also permits the restoration of patency to an obstructed common bile duct through surgical placement of temporary or permanent stenting.[22]

For pancreatic pseudocysts, surgical intervention is indicated when pseudocysts are symptomatic, in a phase of growth, complicated (infected, hemorrhagic, or associated with biliary or bowel obstruction), concurrent with chronic pancreatitis, and when malignancy cannot be excluded. Depending on the mode of presentation, cystic morphology, and available technical expertise, the recommended treatment options include percutaneous catheter drainage, duodenoscopy, or surgery.[23,24] In dogs and cats, ultrasound-guided cystic puncture with cystic fluid evacuation has shown distinct clinical usefulness.[25,26] Among surgical treatment options, cystoduodenostomy, cystic omentalization, and biliary diversion have a more favorable outcome than cystogastrostomy.[27-29] The reader is referred to Chapter 60 for further information and detail.

Multiple abdominal adhesions represent a general contraindication for many laparoscopic procedures.[10,18] Unfortunately, there are no routine imaging techniques for the identification of pancreatic or peri-pancreatic adhesions prior to laparoscopy. If adhesions are encountered at the time of laparoscopy, a decision should be made to advance to laparotomy if the goals of laparoscopy cannot be achieved.

Technical Requirements

Standard laparoscopic equipment is needed, including light source, automatic CO_2-insufflation unit, endoscopy camera, monitor, and computer or video recorder for procedural documentation. Sterilized instrumentation needs to include a Veress insufflation needle and obturator, one optical trocar, one or two working trocars, a rigid laparoscope (0° or 30° viewing angle), and grasping and biopsy forceps.[10,17,30,31]

Use of a 10-mm–diameter optic containing an integrated working channel (Fig. 28-9) is well worth the investment. This particular instrumentation permits the pancreas to be maintained in place with a grasping forceps while taking a pancreatic biopsy through the working channel. If a more conventional optic is available, two working trocars will be needed to simultaneously negotiate the grasping (duodenal) and biopsy (pancreatic) forceps in the sampling of pancreatic tissue. Laparoscopy scissors are useful if small, nonvascular adhesions must be broken down.

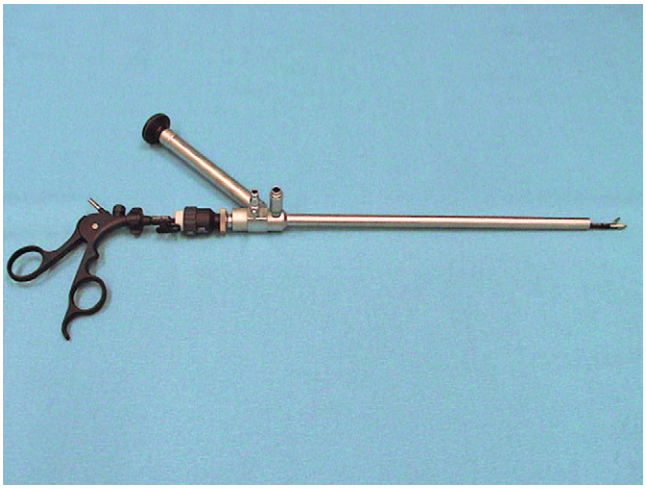

Figure 28-9 Hopkins straight-forward telescope with angled eyepiece and integrated instrument channel with inserted click line dissecting and biopsy forceps. (Courtesy of Karl Storz, Tuttlingen, Germany.)

Patient Preparation

As with other laparoscopic procedures, patient screening should include complete blood count, serum chemistry, and coagulation times (prothrombin, partial thromboplastin, buccal mucosal bleeding) to assess for the risk of anesthesia and abnormal bleeding tendencies.[10,17,30,31] Animals should be starved for a period of 12 to 18 hours prior to laparoscopy to ensure an evacuated upper gastrointestinal tract. Gaseous gastric distention can be managed with orogastric intubation in the anesthetized patient. To the extent possible, the distal colon/rectum and urinary bladder should be evacuated of feces and urine, respectively, before trocarization. Insufflation of CO_2 into the abdominal cavity increases intraabdominal pressure (IAP), which may lead to spontaneous emptying of the urinary bladder when the patient is anesthetized. Therefore, it is recommended that a urinary catheter and collection system be placed in dogs prior to the procedure. This decreases the risk of accidental urine contamination of the operation field. Prior to laparoscopy, the operation field is prepared as for an aseptic laparotomy to allow immediate surgical intervention in case of pathologic findings or complications that demand a surgical approach.[10,17,30,31]

Anesthesia

General anesthesia is necessary to perform laparoscopy. Canine patients can be premedicated with butorphanol and medetomidine, followed by anesthetic induction with propofol. Other induction protocols for dogs include a diazepam and L-methadone combination, or premedication with atropine, acepromazine, and morphine. Anesthesia is maintained with inhaled isoflurane (1% to 2%) in oxygen.[17,32] In cats, induction can be performed with ketamine and xylocaine before intubation for isoflurane inhalant anesthesia.

A study on the hemodynamic and respiratory effects of increased IAP and positive end-expiratory pressure in 10 healthy anesthetized

dogs undergoing laparoscopic pelvic lymphadenectomy revealed that an increase of IAP up to 15 mm Hg had no negative effect on the cardiovascular system. However, when increased IAP was combined with increased positive end-expiratory pressure (8 cm H_2O), arterial CO_2 and fractional end-tidal CO_2 measurements revealed significant CO_2 retention. Study results led to the recommendation for expanded cardiopulmonary monitoring during general anesthesia in high-risk patients.[33] Another study assessed the cardiopulmonary effects of laparoscopic surgery in five dogs anesthetized with thiopental and maintained with halothane at 1.5 times minimal alveolar concentration in oxygen. Abdominal insufflation of CO_2 to a pressure of 15 mm Hg for 180 minutes resulted in significant increases in heart rate, minute ventilation, and saphenous venous pressure, and decreases in pH and partial pressure of oxygen in arterial blood (PaO_2). However, the observed changes were well within physiologically acceptable limits.[34] Studies by the author in 23 dogs undergoing laparoscopy with an intraabdominal CO_2 pressure of 11 mm Hg revealed no side effects of an anesthetic regimen using diazepam and L-methadone for induction and spontaneous, partly assisted isoflurane inhalation for maintenance of anesthesia. The same IAP can be used in cats. When possible, anesthetic monitoring should include clinical examination of reflexes, spontaneous breathing, and pulse, as well as pulse oximetry, capnography, and blood pressure measurement.[17]

Patient Positioning and Procedure

For placement of the optic trocar, the dog or cat is placed in dorsal recumbency. When an optic trocar for a 10-mm optic is placed, a 1-cm–long incision is made into the skin over the linea alba with a scalpel about 1 cm caudal to the umbilicus. For smaller-diameter optics, the length of the skin incision is adjusted accordingly. In the center of the surgical wound, a Veress needle is pushed through the abdominal wall into the abdominal cavity to create a capnoperitoneum with an end IAP of 11 mm Hg. The Veress needle is removed and the optic trocar is put in place. After connecting the trocar with the automatic CO_2 insufflator, the optic is introduced for the first general examination of the abdominal cavity. Using an endoscopic camera and monitor allows for a more convenient laparoscopic examination and better documentation of the findings than direct viewing through the optic.

After the initial examination, a working trocar (5- or 10-mm diameter, depending upon patient size) is placed into the right cranial quadrant of the abdominal wall, several centimeters caudal to the last rib. The patient is then moved into slight left lateral recumbency (30° to 45°). In this position, the optic can still be moved easily but the small intestine can glide to the left side, giving view to the cranial duodenum and the pancreas on the right side. In some cases, it will be necessary to push the intestine to the left by introducing a grasping forceps through the working trocar or the working channel of the optic.

When the pancreas is visible, a grasping forceps is introduced through the working trocar to grab the cranial duodenum close to the pylorus. Lifting the cranial duodenum toward the abdominal wall allows visualization of nearly the entire ventral part of the pancreas, except the distal tip of the left pancreatic lobe, which can be covered by the stomach and intestine, especially in large-breed dogs. Using the grasping forceps, the duodenum can be moved caudally to examine the dorsal part of the pancreas. Instrument-induced trauma to the pancreas can be minimized by grasping the intestine only.

Pancreatic Biopsies

A pancreatic biopsy is not as dangerous as once thought, although biopsy of the pancreas should always have ample justification. Studies in healthy dogs and in dogs with pancreatic diseases, such as subclinical pancreatic acinar atrophy and chronic pancreatitis, show that multiple pancreatic biopsies taken via laparoscopy or laparotomy cause no serious complications. The danger of inducing acute pancreatitis is almost negligible.[10,17,32,35-39] However, careful selection of the biopsy site is strongly recommended. Biopsies can be taken without apparent intra- or postoperative complications by using an endoscopic cup forceps,[17] endoscopic Metzenbaum scissors distal to a tissue Endoclip, and sampling with a harmonic scalpel.[32]

Pancreatic biopsies should be taken from the margins of the organ or from macroscopically changed areas, avoiding deep tissue biopsies that might injure major vessels or pancreatic ducts (Fig. 28-10).[10,17] Multiple biopsies should be taken even from macroscopically inconspicuous areas, as pancreatic inflammation tends to occur in discrete areas within the pancreas rather than diffusely throughout the entire organ. Single biopsies are seen as insufficient to exclude pancreatitis.[40]

Histologic assessment can be carried out according to a recently suggested grading system for nonneoplastic lesions of the exocrine pancreas. The histologic grading scheme includes scoring the biopsy for neutrophilic inflammation, lymphocytic inflammation, pancreatic necrosis, peripancreatic fat necrosis, edema, fibrosis, atrophy, and hyperplastic nodules.[41]

Laparoscopic Findings

The normal pancreas has a pale cream color and is coarsely lobulated (Fig. 28-11). In some cases the pancreas can appear diffusely granulated, with no histologic evidence of an abnormality. Because a morphologically normal appearance does not exclude histologic abnormalities, multiple biopsies should be taken to confirm normality.

Pancreatic pathology can vary in appearance. Loss of tissue can be a sign of pancreatic acinar atrophy of varying degree (Figs. 28-12 and 28-13). Histology helps to differentiate the finding from that of advanced chronic pancreatitis (Fig. 28-14). Swelling of the organ

Figure 28-16 Laparoscopy of a Cocker Spaniel one year after surviving severe necrotizing pancreatitis. The image shows marked adhesions of the pancreas to liver, duodenum, and omentum that hinder visualization of the pancreas. (Used with permission from Spillmann T, Moritz A, Burkhardt E. Diagnostic value of laparoscopy for pancreatic diseases in dogs. *Tierarztl Prax* 28[K]: 349–55, 2000.)

can be a sign of acute or chronic pancreatitis. Adhesions with the surrounding organs or the abdominal wall have been reported in cats and dogs with chronic pancreatitis or as part of the healing process following acute necrotizing pancreatitis (Figs. 28-15 and 28-16).

CHAPTER 29

Histopathology

STOMACH

Brian Wilcock

Like other portions of the gastrointestinal (GI) tract with which it shares embryologic origin, the stomach consists of a tunica muscularis, submucosa, muscularis mucosa, and an innermost mucosa. Almost all of the histologic lesions of clinical significance arise within the mucosa, so endoscopic biopsies are preferred to full thickness biopsies for investigation of almost all gastric diseases. The only exceptions are those that seem restricted to the submucosa or tunica muscularis based on ultrasonographic evaluation (i.e., suspected smooth muscle tumors, pythiosis, and pyloric muscular hypertrophy). The advantages of endoscopic biopsies over full thickness samples have been described elsewhere, but from the perspective of the pathologist the advantages are the greater number of samples that can be taken and the ability to specifically sample abnormal mucosa. The small size and limited depth of the samples are not usually problematic.

Gastric mucosa is similar to that of other portions of the GI tract in that it has a luminal surface of columnar epithelium rich in goblet cells, branched or coiled glands embedded in a fibrovascular lamina propria, and a population of resident leukocytes within the lamina propria. Because the stomach is adapted primarily for secretion rather than absorption, and because its acid environment does not permit much of a resident bacterial population, the leukocyte population is less than is found in the more distal portions of the GI tract. That should make detection of changes in leukocyte numbers easier than elsewhere in the GI tract. That same inhospitable environment also means that there are few infectious causes of gastritis compared with the numerous viral, bacterial, and protozoal diseases of the small and large intestine.

The stomach is divided into several anatomic regions that differ in histologic character and function. Most proximal is the cardia, which surrounds the entry of the esophagus into the stomach, and most distal is the pyloric antrum leading to the sphincter that separates the stomach from the duodenum. In between, and occupying about two-thirds of the stomach, is the gastric body. The gastric fundus is an outpouching of the gastric body at its proximal end where it joins the cardia. This nomenclature is not absolutely standardized, and many authors refer to the combined fundus and body as the "fundic region" and habitually refer to biopsies from this region as being from "fundic mucosa."[1,2] Each of these regions has distinctive histologic appearance, but the transition from one portion to the other is not abrupt and in some biopsies the mucosa has an appearance intermediate between one region and the other.

Almost all gastric biopsies, whether endoscopic or full thickness, are taken from the fundic mucosa and from the pyloric antrum. In all regions, the mucosa is divided into three horizontal zones. In the fundic/body region, the deepest 60% to 80% of the mucosa is occupied by densely packed branched glands consisting of mucus-producing cells and a variety of secretory cells. The glands are connected to the luminal surface by a narrow neck known as the foveola. In contrast to the more distal portions of intestine, the germinal population for all of the gastric epithelium lies at the junction between the glands and the foveolae, a region known as the isthmus, rather than at the base of the glands (Fig. 29-1). These germinal cells migrate upward to replenish the mucus neck cells and surface epithelium, and downward to repopulate the glands as part of normal mucosal turnover and in the event of unexpected epithelial loss. The overall mucosal turnover time is 4 to 5 days—a time that dictates the speed of wound healing, and the rate at which shallow ulcers disappear. The risk of a false-negative biopsy result when investigating episodic gastric disease has not been sufficiently emphasized.

The glands are populated by a mixture of pyramidal, brightly eosinophilic cells that produce hydrochloric acid and cuboidal chief cells with a more basophilic, foamy cytoplasm containing secretory granules of various types including precursors of pepsin and zymogen. Chief cells predominate in the deeper two-thirds of the fundic glands. Mucus-filled columnar cells similar to mucus neck cells persist throughout the full length of the glands. The fourth and final cellular constituent of the epithelium consists of neuroendocrine cells that are inconspicuous in routine histologic preparations.

The glands are separated from the underlying muscularis mucosa by a layer of dense fibrous tissue that varies substantially in thickness. They are separated from one another by a very small amount of fibrovascular lamina propria containing a mixture of lymphocytes, plasma cells, mast cells, and eosinophils. In the normal fundic stomach, the fibrous tissue and the leukocytes are most visible in the superficial 20% of the mucosa. The deeper glands are packed against each other with essentially no intervening lamina propria (Fig. 29-2). Defining the normal reference range for the fibrous tissue and for each cell population is essential to the proper identification and classification of gastric inflammatory disease—a goal that remains elusive.

Within the pyloric antrum, the glandular volume is substantially less, occupying less than 50% of the mucosal thickness. The glands are less branched than those of the fundic mucosa and are populated primarily by mucus-producing cells. They are separated from one another by more fibrous lamina propria than in the fundic mucosa, and leukocytes are about twice as numerous as in fundic stomach. Failure to recognize the differences in normal histologic structure

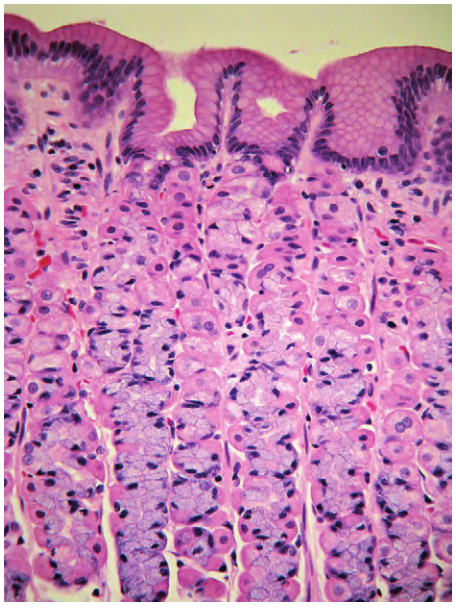

Figure 29-1 Normal canine fundic mucosa. The glands occupy 80% of the mucosal thickness and are densely packed with almost no intervening connective tissue and very few leukocytes. The inconspicuous germinal population lies at the junction between the glands and the foveolae, a region known as the isthmus.

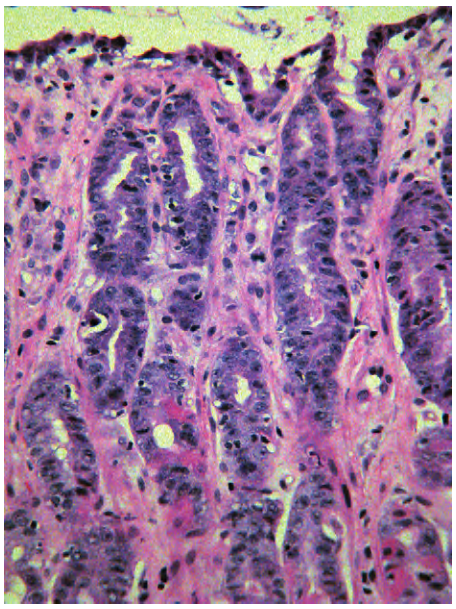

Figure 29-2 Persistent shallow gastric ulceration, with flattening and basophilia of the surface epithelium combined with loss of the foveolar mucus neck cells in favor of an expanding population of hyperchromatic germinal cells. As is typical for chemical or mechanical gastric ulceration, there is very little recruitment of leukocytes.

between fundic and pyloric mucosa can result in incorrect diagnoses of inflammation, fibrosis, and/or glandular atrophy in samples of pyloric stomach.

Histologic Classification of Gastric Disease

The most useful classification of gastric disease is based on histologic character, as there is rarely sufficient insight into etiology or pathogenesis to propose any other basis. Gastric lesions are classified as:

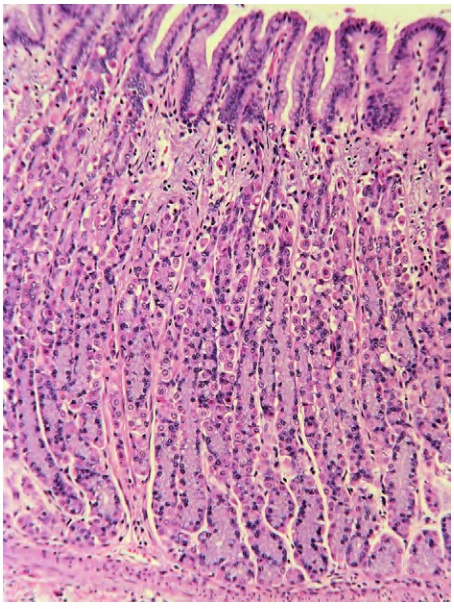

Figure 29-3 Uremic gastropathy, dog. Note the typical horizontal band of acute epithelial necrosis affecting mostly the parietal cells in the middle third of the mucosa. In severe cases there is mineralization of degenerate smooth muscle in the muscularis mucosa and submucosal blood vessels.

- Gastric ulceration
- Mucosal atrophy and fibrosis
- Mucosal inflammation and its consequences
- Proliferative disease including neoplasia

These lesions are not mutually exclusive, but most examples of gastric ulceration have surprisingly little inflammation, and most examples of gastritis do not have ulceration. It is worth emphasizing that gastric lesions are common in dogs and cats even when there are no clinical signs. This is particularly true of mucosal fibrosis and atrophy.

Gastric Ulceration

The stomach is surprisingly susceptible to transient shallow ulceration caused by ingested materials ranging from abrasive foods to household chemicals, numerous common garden and woodland plants, an endless variety of clothing items or household decorations, and hairballs. Although one would assume that the abundant mucus lining the stomach would protect it from abrasion, such is not the case. The mucus is probably more important for protection against endogenous acid.

Ulceration caused by mechanical abrasion is usually shallow and transient. Like other portions of the alimentary system, shallow ulcers heal within hours by flattening and sliding of adjacent epithelium followed by replacement of mucus cells generated by a transient increase in mitotic activity within the isthmus zone at the base of the foveolae. The regenerating epithelium is flatter and more basophilic, with little mucus and slight irregularity in orientation of the nucleus (Fig. 29-3). Shallow ulcers heal completely within just a few hours. The adjacent superficial lamina propria will usually have at least some edema and perhaps even hemorrhage, but the leukocytic reaction is usually minimal. A few neutrophils may be found in the very superficial lamina propria or intermingled with some fibrin and mucus filling in the ulcer. The paucity of leukocytes is in part because the injured tissue is sloughed into the intestinal lumen so that there is little chemical stimulus for leukocyte

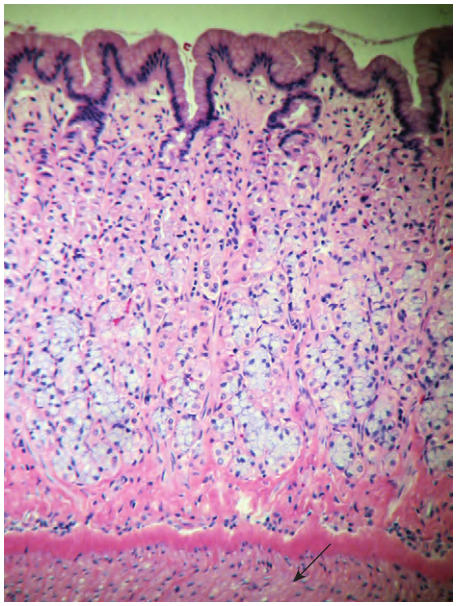

Figure 29-4 Normal feline stomach with a substantial amount of fibrous tissue between the base of the glands and the muscularis mucosa, including the very distinctive lamina densa (*arrow*).

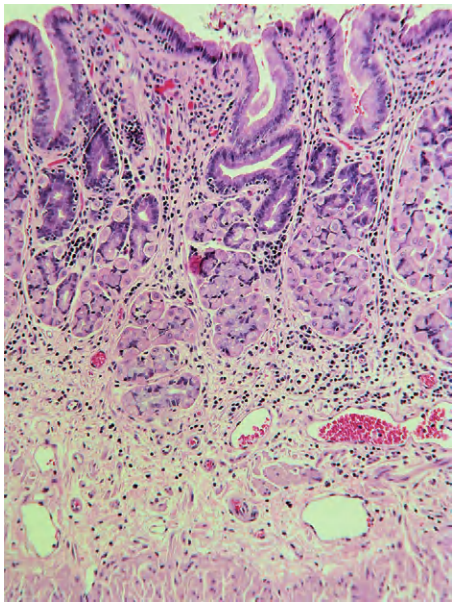

Figure 29-5 Canine fundic stomach with glandular atrophy, glandular nesting, and lamina propria in the absence of any significant infiltration of leukocytes. This is a common lesion, but with no proof that it is medically significant.

recruitment, and partly because the stomach has almost no resident bacteria to contaminate the wounds. With deeper or more persistent ulceration, there will be more obvious hyperplasia and basophilia within the isthmus region reflecting a greater need for mitotic replacement of injured epithelium. Deeper ulcers that have destroyed the isthmus and portions of the lamina propria will take longer to heal and will require stromal proliferation to build a scaffold for effective epithelial healing, but remodeling is extremely effective and it is rare to see any permanent residual scarring. Regardless of the severity of the original lesion, the usual outcome is histologic normalization (Fig. 29-4).

Causes of ulceration other than mechanical abrasion are numerous and include histamine-induced ulceration in dogs with mast cell tumor,[3,4] accidental chemical ingestion, ulcers caused by steroidal and nonsteroidal antiinflammatory (and occasionally other) drugs,[5-7] and exercise-induced ulcers that are best documented in racing sled dogs.[8] In general, the histologic character of the ulceration provides no clue as to the pathogenesis. Careful estimation of the age of the lesions (distance of epithelial sliding, restoration of the normal columnar epithelial shape and normal cytoplasmic eosinophilia, and the maturity of subepithelial fibrosis) will often allow the clinician to identify the causative drug or event. Progression to perforation is rare and usually requires continued application of the injurious stimulus (e.g., continued administration of ulcerogenic drugs or persistent histamine production by a mast cell tumor).

Gastric Necrosis Other Than Ulceration

Epithelial necrosis not typically associated with superficial ulceration is seen with uremia and sometimes with mucosal ischemia secondary to thromboembolic disease, submucosal vasculitis, or gastric dilation/volvulus.

Uremic gastropathy occurs almost exclusively in dogs and its exact pathogenesis remains unknown. The distinctive lesions include mineralization and necrosis of the parietal cells occupying the middle third of the gastric mucosa, mineralization of basement membranes of the glands and of the submucosal blood vessels, and mineralization of degenerate smooth muscle within the muscularis mucosa or even tunica muscularis (Fig. 29-5). Mineralization of submucosal blood vessels may become extensive, involving the full thickness of the vessel wall and accompanied by medial necrosis and endothelial destruction.[9]

With ischemic injury related to vasculitis or vascular occlusion, the character of the lesion depends on the duration and completeness of obstruction. In gastric volvulus, venous obstruction is complete and the intensely congested gastric wall dies following infarction. The mucosa dies first, undergoing coagulation necrosis that quickly becomes lost amid diffuse hemorrhage. In cats with vasculitis caused by feline infectious peritonitis (FIP) or in dogs with disseminated intravascular coagulation (DIC), the necrosis is often patchy.

Gastric Mucosal Fibrosis and Atrophy

Varying degrees of mucosal fibrosis and glandular atrophy are common in biopsy samples of the gastric mucosa. Such lesions have received almost no attention in the veterinary literature, but are common sources of confusion for pathologists attempting to interpret endoscopic biopsies. Some have referred to this as "atrophic gastritis," with no proof that the pathogenesis of the fibrosis is linked to previous inflammatory disease. In the only study to specifically address this question, noninflammatory atrophy and/or fibrosis was seen in 128 of 482 vomiting dogs. Similar lesions were also seen in five of 19 clinically healthy dogs.[10] It is not clear whether the fibrous tissue represents a true increase in the volume of collagen or simply a condensation of resident collagen subsequent to glandular atrophy. The two lesions (mucosal fibrosis and glandular atrophy) are almost always concurrent.

There remain numerous questions related to gastric atrophy and fibrosis, including these:

1. What is the normal amount of fibrous tissue within the lamina propria in different portions of the stomach?
2. Does it increase with age?

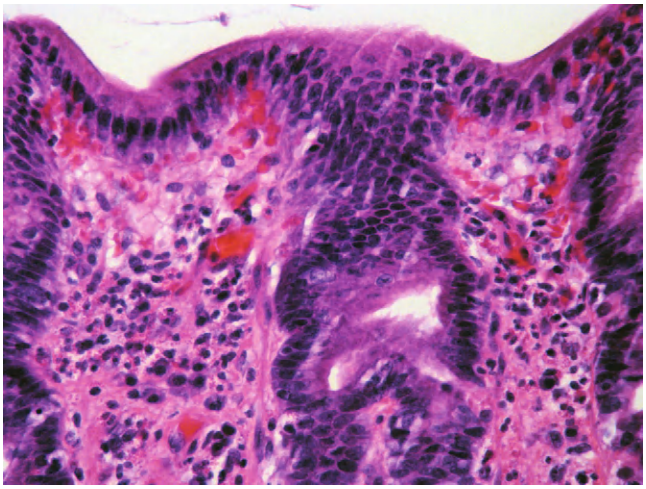

Figure 29-6 Superficial mucosal eosinophilic gastritis, dog. This microscopic field corresponds to Southorn's "mucosal unit." In this instance, it has approximately twice the allowable number of leukocytes, and five times the normal number of eosinophils. Despite the severity of the infiltration, note that the overlying epithelium (as usual) remains virtually normal.

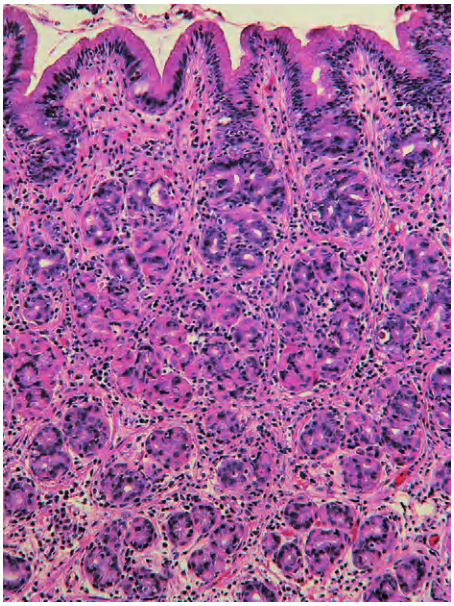

Figure 29-7 Transmucosal gastritis, dog. There is a threefold increase in mononuclear leukocytes throughout the lamina propria, with some mild glandular nesting accentuated by the inflammatory edema and fibrosis. The lack of architectural effacement distinguishes this, even at low magnification, from lymphoma.

3. How commonly is such fibrosis a marker of previous inflammatory disease?
4. Is it permanent?
5. Is it functionally significant, significant only as a diagnostic marker, or not significant at all?

Normally, the glands within the fundic mucosa lie against each other with almost no intervening fibrous tissue. There is a small amount of loose connective tissue among the foveolae, and there can be substantial fibrous tissue separating the base of the glands from the muscularis mucosa. The amount of fibrous tissue in this deep location is greater in cats than in dogs. In cats there is also a distinct, very dense band of hyalinized fibrous tissue just superficial to the muscularis mucosa, known as the *lamina densa* (Fig. 29-6). Within the pyloric antrum there is substantially more fibrous tissue throughout the lamina propria, so any diagnosis of mucosal fibrosis in the pyloric stomach should be viewed with skepticism.

Dogs and cats with chronic gastritis often have persistent mucosal edema that matures into fibrosis. Concurrent inflammatory injury to the gastric glands is followed by regeneration that creates "nests" of hyperplastic glands embedded within the fibrous tissue (see "Atrophic Gastritis" section). It is also common to see the combination of fibrosis and glandular nesting with no evidence of active inflammation and no clinical history of gastric disease (Fig. 29-7). The glands within these nests usually have at least some degree of atrophy of the parietal cell mass with a relative increase in the prominence of the columnar mucus-producing epithelial cells. The combination of glandular atrophy, dysplastic repair, and mucus (intestinal) metaplasia represents a strong risk factor for progression to gastric carcinoma in people,[11] an association that has not been proven in dogs.

Gastritis

The gold standard for the histologic diagnosis of gastritis is an increase in mucosal leukocytes accompanied by other evidence of inflammation such as hyperemia, edema, and bystander injury to the adjacent structural components of the mucosa (e.g., epithelial injury or reparative fibrosis). That gold standard is met in a proportion of the cases, but not in all. The lack of uniformity in the criteria used to diagnose gastritis impacts on the credibility of virtually all of the published literature on the prevalence, classification, etiology, and treatment of gastric inflammatory disease. To many, gastritis is defined simply as an increase in the number of leukocytes within the lamina propria beyond the normal range. The most obvious problem with this definition is that we do not know the normal range. Less obvious but even more fundamental is the question of whether an increase in leukocytes within a tissue designed to respond to antigenic challenge by increasing the number and activity of resident leukocytes should be interpreted as "inflammation." An increase in lymphocytes or plasma cells in a lymph node is usually assumed to reflect an appropriate and purposeful response to antigenic stimulation. In the intestinal lamina propria, the largest lymphoid organ in the body, a similar increase in lymphocytes and plasma cells is generally viewed as pathologic and therefore deserving of therapeutic intervention. The distinction between adaptive and pathologic lymphoid proliferation lies not just in the number of leukocytes, but also in the phenotype and cytokine production profile of the cells. These complexities are beyond routine histopathology and immunohistochemistry, but should not be ignored.

Normal Gastric Mucosal Cellularity

Only three studies address the critical question of the reference range for leukocyte types in the normal canine gastric mucosa. The first reports findings from examination of endoscopic biopsies from 20 clinically normal young adult dogs (Table 29-1).[12] These dogs had no history of vomiting or diarrhea for at least 2 months prior to entering the study, and were all fed a standardized diet and had the same husbandry conditions. Leukocytes were identified with light microscopy and immunohistochemistry, and were counted separately in both superficial and deep lamina propria in "mucosal units" of 250 μm^2 (corresponding to approximately one-half of a ×40 microscopic field). Within the superficial lamina propria of the fundic mucosa, this corresponds to a rectangle of tissue

Table 29-1 Leukocyte Numbers in the Superficial Gastric Mucosa of Healthy Dogs

Cell Type	Superficial Fundic*	Superficial Pyloric†
Lymphocytes (CD3 and CD79)	8.4 (1.5-27.0)‡	22.9 (11.5-32.0)§
Plasma cells	1.6 (0-5.8)‡	6.8 (0.5-15.5)§
Eosinophils	0.5 (0-2.0)‡	2.7 (0-6.0)§
Total leukocytes**	10.4 (3.6-26.2)‡	32.6 (20.0-46.5)§

*Number of cells within a rectangle of lamina propria encompassed horizontally by three foveolae, and vertically to the level of the first parietal cell.
†Number of cells in a square of lamina propria encompassed by two adjacent foveolae with the deep border at the foveolar–glandular junction.
‡Mean (range) of three cell counts in each of 20 dogs.
§Mean (range) of two cell counts in each of 8 dogs.
**Sum of $CD3^+$ and $CD79^+$ lymphocytes, plasma cells, and eosinophils, but excluding mast cells and unidentified cells.

incorporating three adjacent foveolae and the associated lamina propria, and extending vertically to the level of the first parietal cell. Within the pyloric antrum, the "mucosal unit" corresponds to an area of lamina propria bordered by two adjacent foveolae, with its deep border capturing the most superficial portion of the gastric glands.

The other two studies were not specifically designed to provide data about normal gastric mucosal cellularity or other features relevant to the diagnosis of gastritis. Nonetheless, both provide a series of pictorial templates of normal and diseased stomachs in an attempt to reduce interobserver variation in interpretation of gastric histopathology. Neither study provided any information about how the photographic templates identified as "normal" were selected.

The first of these studies was based on 18 client-owned dogs with GI disease and eight dogs euthanized for nonenteric disease. None of the dogs had been treated with antibiotics, corticosteroids, or antacids in the months prior to sampling. Lesions within the fundic mucosa alone were graded by two pathologists using pictorial templates adapted from the human Sydney system that depicts various severities of atrophy, fibrosis, and cellular infiltration. The results from the eight "normal" dogs were not separately identified when tabulating the results (presented as the mean grading results from all 26 dogs).[13]

The second and much larger study provided not only a series of pictorial templates, but also a brief text to guide the grading of GI biopsies, including those from stomach. It included pictorial templates for leukocyte accumulations, fibrosis, ulceration, and other parameters within the fundic and antral mucosa.[14]

In both of these latter studies in which the pictorial templates were specifically designed to reduce interobserver variation, the results showed poor correlation among grading scores assigned by different pathologists. Painful though it is, we must collectively confront the reality that it is essentially impossible to compare results from different studies claiming to evaluate causation or therapy of "gastritis." In most published studies of gastritis in either dogs or cats, the descriptions of leukocyte numbers or the published photographs of lesions claimed to represent mild and even moderate gastritis would be considered "normal" using criteria in the three studies listed previously. This is particularly true of the many studies attempting to establish the pathogenicity of *Helicobacter* spp. for dogs and cats in which any histologic changes were described as mild increases in superficial mucosal cellularity.[15-23]

Histologic Classification of Gastritis

The previously mentioned problems notwithstanding, there is no doubt that genuine gastritis does exist and is quite common. Most cases are part of more generalized GI inflammatory disease,[24] but some are purely or predominantly gastric. There is no evidence that histologic classification based on the distribution or type of leukocytes has relevance to pathogenesis, treatment, or prognosis, nor is there evidence to the contrary. Thus it is appropriate to use (at least for the moment) a classification system that reflects histologic changes, with the expectation that at least some of these differences will eventually prove to have etiologic, therapeutic, or prognostic significance.

Superficial Mucosal Gastritis

Most examples of gastritis in dogs and cats involve leukocyte infiltration of the superficial 20% of the mucosa. In almost all cases, the surface epithelium remains normal. In most cases, lymphocytes and plasma cells predominate, but there are almost always at least some eosinophils. Neutrophils are rarely present, but their presence almost always means nearby or recent ulceration. There may be a concurrent increase in intraepithelial lymphocytes, and in cats there can be an increase in intraepithelial large granular lymphocytes (formally known as globular leukocytes) that are of unknown significance. Edema accompanies the leukocytes and there is often activation of resident fibroblasts and blood vessels (Figs. 29-8 and 29-9).

It has been traditional to describe the predominant cell type (lymphocytic, plasmacytic, eosinophilic) as part of the classification system, but there is no evidence that this is useful.[7,14,24] First, there is no uniformity between laboratories in how well eosinophils, mast cells, or even plasma cells are stained. Second, pathologists differ in defining what proportion of cells is required before that cell type is considered "predominant." Some will diagnose a lesion as "eosinophilic" if they believe that the eosinophils are the most numerous cells entering the tissue on an hourly basis, even if they are outnumbered by lymphocytes or plasma cells that have accumulated over weeks and months. Others use a more traditional approach and name the lesion based on the cell type that is most numerous within the tissue at the time of assessment. That means that almost any chronic gastritis will be classified as "lymphoplasmacytic." Until everyone uses the same convention for naming such lesions, subclassification based on the predominant cell type will remain unreliable. It makes more sense to simply list each identifiable cell type as a percentage of the total infiltrate, so that such information can later be analyzed to see if it influences therapeutic response or other clinical parameters.

Transmucosal Gastritis

Approximately 30% of samples identified as having gastritis by conservative histologic criteria have an increase in leukocytes with variable degrees of edema and/or fibrosis throughout the full thickness of the lamina propria, causing separation of the gastric glands from each other and from the underlying muscularis mucosa (Figs. 29-10 and 29-11). There usually is no obvious necrosis within the glands or along the surface. Lymphocytes and plasma cells predominate, but eosinophils are often conspicuous and sometimes even predominant.

Even though it is unusual to see actual necrosis, there often is some glandular atrophy so that the glands appear in isolated nests

Figure 29-8 Focal gastric pyloric mucosal hypertrophy, dog. The hypertrophy is limited to the foveolae and surface epithelium. The elongation of the foveolae may be so marked that a routine endoscopic biopsy will capture only the surface and foveolar epithelium and none of the underlying pyloric glands. This justifies a presumptive diagnosis of mucosal hypertrophy in an endoscopic biopsy.

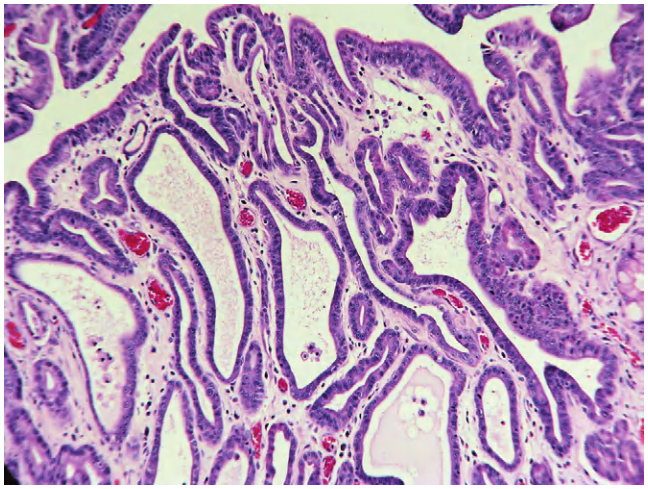

Figure 29-9 Gastric polyp within the fundic mucosa, cat. In contrast to pyloric mucosal hypertrophy, the proliferation here is by hyperchromatic germinal epithelium with a little mucus production and parietal cell differentiation. Cystic glandular dilation is common. The lack of invasion into the lamina propria distinguishes this from papillary gastric carcinoma (which would be exceedingly rare in a cat).

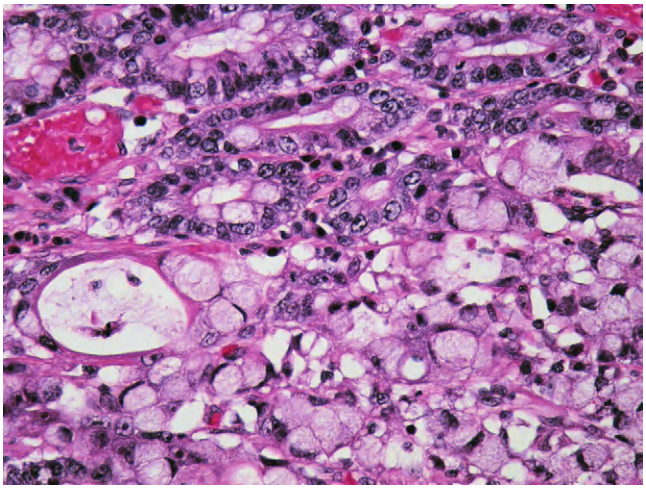

Figure 29-10 Early gastric carcinoma in the fundic mucosa, dog. In early cases, the diagnosis can be difficult and is based on detecting invasion and replacement of lamina propria by monotypic mucus-producing epithelial cells. Formation of tubules is not common within the intramucosal portion of such tumors.

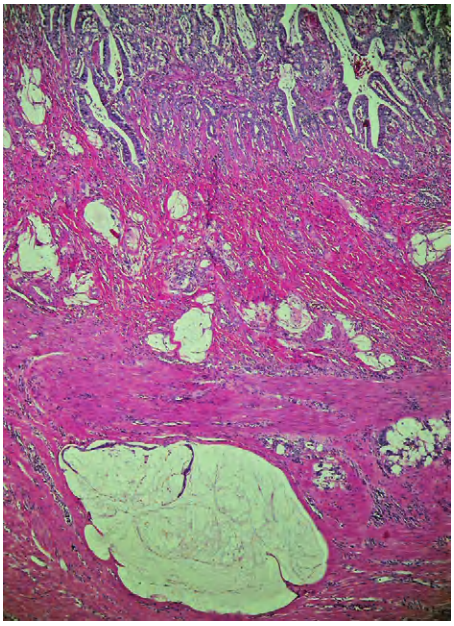

Figure 29-11 Gastric carcinoma, dog. There is abundant reactive fibrosis induced by transmural invasion of a mucus-producing tubular carcinoma. The large lakes of mucin within the tunica muscularis are often more obvious than the tumor cells themselves.

separated by a mixture of leukocytes, edema, and fibrosis. This is probably the precursor for the lesion usually referred to as atrophic gastritis, an extremely frequent but controversial microscopic entity that usually has no clinical counterpart.

Atrophic Gastritis

Atrophic gastritis is a purely descriptive name for chronic gastritis that combines the elements of chronic inflammation, glandular atrophy, regenerative glandular nesting, and mucosal fibrosis. Lymphofollicular hyperplasia may accompany these changes. There is reduction in overall mucosal thickness and in most cases an obvious reduction in the number of parietal cells with a corresponding absolute or relative increase in the proportion of mucus-producing epithelial cells within the glands. If there are functional consequences to the reduction in glandular mass, they are rarely recognized clinically. Pathologists are not uniform in the criteria used to make this diagnosis, so it is difficult to assess the scattered literature related to pathogenesis and clinical significance. Atrophic gastritis may be just the residual lesion of transmucosal gastritis described previously. Atrophic gastritis has also been used as the

name for the parietal cell atrophy and neuroendocrine cell hyperplasia that precedes the development of anaplastic and neuroendocrine gastric carcinomas in Norwegian Lundehund dogs with a distinctive, familial protein-losing enteropathy.[25]

Etiologic Classification of Gastritis

The majority of cases classified as gastritis by histologic criteria have no identified cause. The list of potential causes includes infectious agents, chemical irritants, toxic plants, and immune-mediated diseases.[7] Most of the chemical and plant irritants cause transient gastric ulceration rather than true gastritis, and the inclusion of various allergic or other immune-mediated pathogeneses is based on assumptions rather than proof. Because the stomach is not a site of any significant protein absorption, assumptions of immune-mediated disease may be more appropriate for small intestine than stomach.

Instances of gastritis with a known cause are almost always related to specific infections. These represent a very small proportion of all examples of gastritis, and for most of these agents infection is not usually linked to clinical signs of gastritis or to significant histologic lesions. Parasitic agents include the nematodes *Physaloptera*, *Gnathostoma*, and *Cylicospirura* in dogs and cats, and *Ollulanus* in cats alone. Infrequent but devastating examples of infection with the fungus *Pythium insidiosum* cause mucosal and submucosal suppurating granulomas in the stomach and elsewhere in the GI tract of dogs. The stomach is an occasional victim in the course of systemic fungal diseases (e.g., blastomycosis, cryptococcosis). Finally, the crusade to establish *Helicobacter* as a cause for clinically significant gastritis or gastric ulceration in dogs or cats has triggered more descriptions of alleged gastric lesions than has any other proposed agent of gastric disease.

Parasitic Gastritis

Among the nematode parasites that may infect the stomach and cause histologic lesions, the only ones usually considered of potential significance are *Physaloptera* and *Ollulanus*. *Gnathostoma* and *Cylicospirura* may cause small submucosal suppurating granulomas, but they do not cause clinical signs. Infection with *Physaloptera* has been reported to cause persistent vomiting in dogs, and elimination of the worms following treatment resulted in reversal of clinical signs.[26] Descriptions of histologic lesions are few and vague.

Ollulanus is sometimes listed as a cause of vomiting in cats. It has been described as a cause for fibrosis, lymphofollicular hyperplasia, and increased intraepithelial large granular lymphocytes in cats, but in the original report there was no clinical disease associated with the infection.[27] In some cats the worms can be seen embedded within the foveolae, with no histologic changes. The association between *Ollulanus* infection and apparent increases in intraepithelial large granular lymphocytes remains unproven. The latter is a frequent observation in the stomach and small intestine of cats with GI disease and is of unknown significance.

Cryptosporidiosis has been reported in the stomach of cats and dogs, but with no proof of pathogenicity.[28]

Pythiosis

P. insidiosum is an aquatic oomycete fungus found primarily in tropical and warm temperate climates. Most reported cases in dogs have been from the southeast United States, but the disease is seen worldwide. Lesions in the stomach have the same histologic character as those seen elsewhere: destructive coalescing necrotizing granulomas found randomly within submucosa, tunica muscularis, or within the serosa.[29,30] The diagnosis depends on identifying characteristic fungal hyphae. These are often difficult to see without special stains (e.g., periodic acid-Schiff [PAS] or silver stain), but the necrotizing lesions throughout the stomach wall are not easily mistaken for anything else.

Helicobacteriosis

Helicobacter spp. are normal inhabitants of the surface and foveolae of dogs and cats. In dogs, most infections are with *Helicobacter bizzozeronii* or *Helicobacter heilmannii*, while in cats *H. heilmannii* and *Helicobacter felis* predominate. These large spiral bacteria are easily seen in routine endoscopic biopsies, and their detection is enhanced by the use of silver stains. More elaborate and sensitive detection methods (e.g., polymerase chain reaction [PCR] or tissue urease activity) are research tools rarely if ever used in a diagnostic setting. In the past 15 years, there have been at least nine studies specifically examining the relationship between *Helicobacter* infection, development of histologic lesions, and clinical disease. None of these studies has proven any causal relationship between infection and disease.[13,15-20] All but one, however, have claimed that infection is associated with an increase in gastric mucosal leukocytes, fibrosis, and lymphoid follicles. The problem is that the increased leukocytes claimed to represent "gastritis" invariably fall within the normal range for gastric mucosal cellularity as established by Southorn and as subsequently adopted by the World Small Animal Veterinary Association (WSAVA) Gastrointestinal Standardization Group.[12,14] Most of those studies had no uninfected control against which to measure the claims for increased cellularity. Even if one were to accept the hypothesis that colonization by *Helicobacter* causes a small increase in mucosal leukocytes (including lymphofollicular hyperplasia), the most plausible explanation is that the *Helicobacter* simply represent an increased antigenic challenge to the resident mucosal leukocytes that respond in an entirely appropriate fashion, analogous to what occurs when gnotobiotic animals are first introduced to a "normal" bacterial flora.[31]

Gastric Proliferative Disease

Proliferative changes within the stomach include focal adenomatous hyperplasia in the form of gastric polyps, more diffuse but rare canine hypertrophic gastropathy, and genuine neoplasms.

Focal Adenomatous Hyperplasia

Focal adenomatous hyperplasia occurs in two forms. The more prevalent is focal pyloric mucosal hypertrophy in which the foveolae of the pyloric antrum become greatly exaggerated and form villus-like protrusions covered by mature and otherwise normal epithelium.[32] The lamina propria sometimes contains an increase in eosinophils, but it is unknown whether those examples with eosinophils have a different pathogenesis than those without. It is unknown whether the eosinophils are involved in the development of the lesion, are the result of the lesion, or are unrelated.

The prevalence of these lesions is directly related to the frequency of endoscopy and many are clinically silent. They become significant only if they grow large enough and if they are located where they may cause pyloric obstruction. The diagnosis is difficult to confirm in endoscopic samples. If orientation and depth are both perfect, then the diagnosis is based on seeing the biopsy filled with superficial and foveolar epithelium with no glands because the increased thickness of the foveolar region occupies the entire capacity of the biopsy forceps (Fig. 29-12).

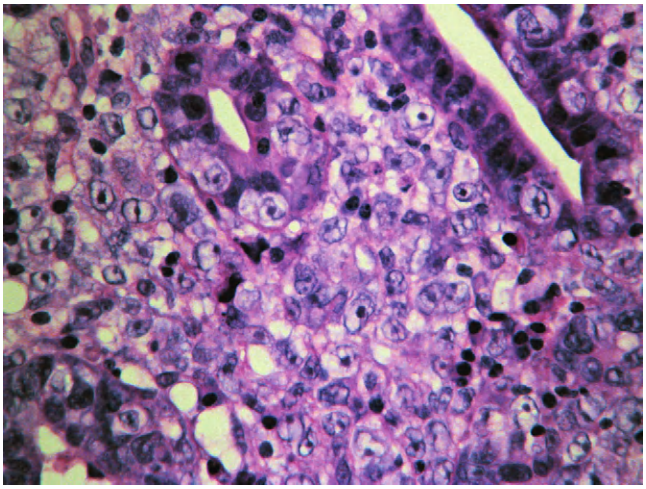

Figure 29-12 Large cell "lymphoblastic" lymphoma, cat. Typically, these form a solitary discrete mass originating within the lamina propria. This is traditional lymphoma with architectural obliteration by a diffuse sheet of large monotypic lymphocytes (in a cat, virtually always B cells), here leaving only a few lingering remnants of preexistent glands.

Less prevalent than pyloric mucosal hypertrophy is focal adenomatous hyperplasia creating polyps in the gastric body or fundus. These are about three times more prevalent in cats than in dogs. In contrast to the proliferation of mucus-laden superficial epithelium typical of pyloric mucosal hypertrophy, these gastric polyps are formed primarily by papillary proliferation of hyperchromatic glandular epithelium forming branching and sometimes cystic tubules. Most of the epithelium is hyperchromatic and primitive columnar epithelium with no mucus production, but with occasional maturation into parietal and chief cells. They differ from papillary adenocarcinomas by not showing any invasion across the basement membrane and into the lamina propria or submucosa. The lack of invasion is the only reliable criterion distinguishing gastric polyp from a well differentiated papillary adenocarcinoma. There is no proof that these lesions progress to neoplasia.

Gastric Neoplasia

Although a wide variety of neoplasms are reported within the stomach,[35,36] the majority fall into one of three groups: gastric carcinoma, lymphoma, and smooth muscle tumors.

Gastric Carcinoma

Mucus-producing, scirrhous tubular adenocarcinoma is the most common tumor of the canine stomach, but gastric carcinomas are almost nonexistent in cats. In dogs, they usually occur as a regional plaque-like thickening with ulceration in the distal body or within the pyloric antrum. Ulcerated tumors may be confused both macroscopically and microscopically with chronic ulcers that have stimulated abundant reactive fibrosis and dysplastic epithelial repair.

The earliest recognizable histologic lesion is focal obliteration of mucosal glandular architecture by proliferating polygonal epithelial cells that violate the basement membrane of the glands/crypts to proliferate as individualized cells within the lamina propria. These cells, which may not be easily recognized as epithelial cells, may be found only deep within the lamina propria. They may be difficult to capture in endoscopic biopsies especially if the tumor is arising in pyloric mucosa (the thickness of the pyloric mucosa makes it difficult to capture the deep third of the mucosa). There will be times in which full-thickness samples are required to confirm the diagnosis, but that is the exception rather than the rule. The tumor cells invade the submucosa and then the tunica muscularis. In most cases, the initial invasion is in the form of slender cords or tubules of mucin-producing epithelium within or surrounding lymphatics. They penetrate the serosa and exfoliate into the peritoneal cavity to seed the omentum and mesentery. In most cases the tumor cells are well differentiated and form easily recognizable tubules, but some examples comprise only lakes of mucin within the tunica muscularis, or nodules of reactive fibrous tissue on the mesentery or omentum. In such cases, the use of a PAS stain will accentuate the mucus within the cytoplasm of the anaplastic epithelial cells that will be around the mucus or buried within the fibrous tissue.

It is traditional to subclassify gastric carcinomas based on histologic pattern (e.g. papillary, tubular, scirrhous),[35] but most examples exhibit substantial regional variation that includes more than one subtype. In addition, there is no proven prognostic or therapeutic significance to these patterns so it is difficult to justify subclassification.

Lymphoma

The identification, classification, and treatment of alimentary lymphoma in dogs and cats is a "work in progress," with dramatic changes in our understanding arising from more widespread use of immunohistochemistry and clonality testing. Most of what was written prior to 2005 is more or less irrelevant and even misleading, especially with respect to cats. Alimentary lymphoma in cats is very different from that in dogs, although the differences are perhaps less obvious in gastric lymphoma than in examples affecting small intestine.

Feline Gastric Lymphoma. Lymphoma in the stomach of cats occurs in two different forms. The first and more prevalent is solitary large B-cell lymphoma that occurs as a space-occupying mass. The second is diffuse infiltrative small T-cell lymphoma that occurs in the stomach only as part of more generalized alimentary lymphoma that affects primarily the small intestine. There are a few cases that conform to neither of those descriptions, including a few large granular cell lymphomas and "mixed" or "histiocytic" lymphomas with intermingled eosinophils, T cells, and B cells.

Small cell lymphocytic (usually T-cell) lymphoma in the stomach is initially detected as an excessive accumulation of monotypic, hyperchromatic small lymphocytes within the superficial lamina propria and the epithelium. The accumulation is usually diffuse and may result in obliteration of the distinction between the lamina propria and the epithelium. As the disease progresses, tumor cells invade deeply into the lamina propria, obliterating glandular architecture, and spread throughout submucosa and tunica muscularis to completely replace the gastric wall. At that stage, the diagnosis is simple, but it is more challenging when dealing with early disease in endoscopic biopsies. The question is always the same: is this severe lymphocytic gastritis or early lymphoma? With inflammatory bowel disease, the increased cells are usually a mixture of lymphocytes and plasma cells, and there is no obliteration of the distinction between epithelium and lamina propria.

Large-cell (lymphoblastic) lymphoma is a more traditional lymphoma in the sense that it creates an unmistakable "mass" with early obliteration of mucosal architecture and invasion across the gastric wall. Perhaps because this disease is typically focal and limited to

the stomach rather than being part of a more diffuse GI disease, the lesion is usually advanced at the time of initial diagnosis; consequently, histologic confirmation via endoscopic or ultrasound-guided core biopsies is not usually problematic. Most examples seem to arise from the diffuse lymphoid population in the superficial third of the gastric mucosa. The tumor spreads rapidly to destroy mucosal, submucosal, and muscular architecture, creating a diffuse sheet of monotypic large lymphocytes with nuclei at least twice the diameter of a red blood cell. Epitheliotropic behavior is rarely observed. In a series of 26 sequential examples studied in preparation for this chapter, all were confirmed as B-cell lymphomas. In a recent published study, nine lymphomas limited to the stomach were all immunoblastic B-cell lymphomas.[37]

Large granular lymphoma is a rapidly progressive transmural lymphoma with a unique histologic and cytologic appearance. The cells are pleomorphic large lymphocytes with distinctive large red cytoplasmic granules. The nuclei are often cleaved or even convoluted. The malignant cells are often accompanied by other cell types, including small benign lymphocytes, eosinophils, and fibroblasts. Most published examples have arisen in distal small intestine, but there are a few that arise in the stomach. At least in the small intestine, almost all are $CD3^+CD8^+$ T-cell tumors that probably arise from intraepithelial lymphocytes. Historically, these tumors were mistaken for mixed transmural granulomatous inflammation or mast cell tumors.

Canine Gastric Lymphoma. Approximately 5% of all canine lymphomas arise within the alimentary tract, and only a small percentage of those arise within the stomach. Gastric lymphoma is substantially less prevalent than gastric carcinoma. It is perhaps for this reason that these tumors have received less attention than feline GI lymphomas. There have been no studies specifically of canine gastric lymphomas, and it is necessary to extrapolate from information derived from GI lymphomas in general. In four different published studies, 54 of 65 canine intestinal lymphomas subjected to immunohistochemical characterization were of the T-cell phenotype and the majority of the others were not classifiable.[38-41] There are case reports of epitheliotropic lymphomas and of eosinophil-rich T-cell tumors, but it is not clear whether these are anything other than just variants of "ordinary" T-cell lymphomas.

Leiomyoma and Leiomyosarcoma

Any published estimates of the prevalence of smooth muscle tumors must be viewed with skepticism. In part this is because smooth muscle tumors are usually small and affect tunica muscularis only, so the majority do not cause clinical signs and cannot be detected endoscopically. Estimates of prevalence therefore differ in studies based on clinical signs as contrasted with postmortem studies.[42,43] Further confusion arises from the fact that many of those tumors initially classified as leiomyosarcomas based on traditional histopathology have been reclassified as gastrointestinal stromal tumors (GISTs) on the basis of immunohistochemistry (positive for CD117, negative for smooth muscle actin).[44,45] Those papers addressed small intestinal, cecal, and colonic tumors rather than specifically looking at those in stomach, and in addition specifically addressed smooth muscle tumors initially diagnosed as poorly differentiated leiomyosarcomas rather than more common, mature leiomyomas. It is therefore a mistake to assume that all tumors previously diagnosed as well-differentiated smooth muscle tumors are at risk of having that diagnosis "overturned" by immunohistochemistry.

Smooth muscle tumors usually occur as focal, solitary, discrete masses arising within the tunica muscularis. They represent a continuum from benign to malignant, with no precise histologic division between leiomyoma and leiomyosarcoma. Those with discrete, purely expansile growth and formed of histologically and cytologically mature smooth muscle cells are called leiomyomas. At the other end of the spectrum are primitive stromal tumors with invasive growth, increased mitosis, and only vague resemblance to smooth muscle cells that have traditionally been classified as leiomyosarcomas. Many examples lie in the middle of that continuum, and pathologists are not uniform in how they classify these. Leiomyomas are formed by cells virtually indistinguishable from normal smooth muscle, except that they grow in interlacing bundles to create a disorganized nodule clearly different from the surrounding, laminar arrangement of the tunica muscularis. These tumors may protrude outward through the serosa or inwardly to cause bulging of the mucosa with subsequent ulceration.

The poorly differentiated tumors are comprised of pleomorphic spindle cells with the usual criteria of malignancy, including regional invasion. Any decision to refer to these as smooth muscle tumors rather than GISTs is subjective and should be confirmed with immunohistochemistry.

There is poor correlation between histologic appearance and biologic behavior. As a group, the smooth muscle tumors have a relatively good postoperative prognosis with prolonged postoperative tumor-free intervals and survival times regardless of histologic appearance.[45] For those tumors that behave aggressively, the initial histologic appearance (i.e., leiomyoma vs. leiomyosarcoma) is not predictive.

INTESTINE

Michael Day

Small Intestinal Biopsies

Assessment of tissue pathology has now become a routine component of the clinical evaluation of small intestinal disease. The traditional means of sampling the small intestine is by laparotomy and the collection of full-thickness surgical biopsies of the duodenum, jejunum, and ileum. This method of sample collection provides a greater chance of meaningful diagnostic outcome and it has been suggested that assessment of full-thickness biopsies increases the likelihood of successful diagnosis of alimentary lymphoma.[13,35] Most clinicians are familiar with the benefits of fixing such samples while the tissue is stretched over a cardboard base to avoid artifactual "curling" of the specimen during fixation. The histology laboratory should then be able to prepare a longitudinal section of tissue with well-orientated mucosa through to serosa (Fig. 29-13). Laparoscopy may also permit collection of intestinal biopsies, but the diagnostic value of such samples has not been formally evaluated.

Increasingly, however, both first opinion and referral practitioners have access to flexible endoscopy and this technique has become the preferred means of acquiring small intestinal mucosal biopsies. Although many clinicians will only sample the duodenal mucosa, wherever possible the ileum should also be sampled as there is evidence that many small intestinal diseases may have focal anatomical distribution. The challenges of successful endoscopic biopsy are numerous and are dealt with elsewhere in this text. From the pathologist's perspective, the number, size, and handling of such samples is directly related to outcome (i.e., a meaningful histopathology report). A minimum of six to eight biopsies of duodenal and ileal mucosa should be collected, and these should be sufficiently

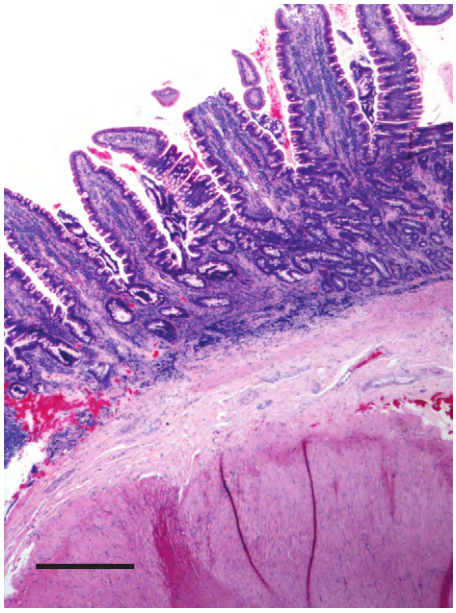

Figure 29-13 A full-thickness biopsy of the canine jejunum. The sample is well-orientated and includes mucosa, submucosa and muscularis. This biopsy has normal histologic microarchitecture. Hematoxylin and eosin stain; bar = 1 mm.

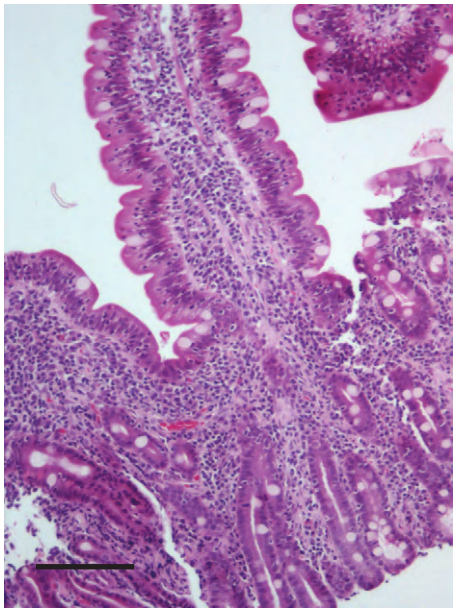

Figure 29-14 An adequate endoscopic biopsy of the feline duodenum. The sample is well-orientated and includes both villus and cryptal mucosa to the level of the muscularis mucosa. This biopsy displays changes consistent with mild lymphoplasmacytic enteritis. Hematoxylin and eosin stain; bar = 500 μm.

deep to include the entire mucosa to the level of muscularis mucosa (Fig. 29-14). The diagnostic value of biopsies that comprise only individual villi that are "scythed" from the surface is severely limited (Fig. 29-15).

Consideration should also be given to the handling of such samples postcollection.[72] For transport, it is often optimal to place these delicate tissues between prewetted purpose-designed plastic "sponges" that can be sandwiched directly into a histologic cassette.

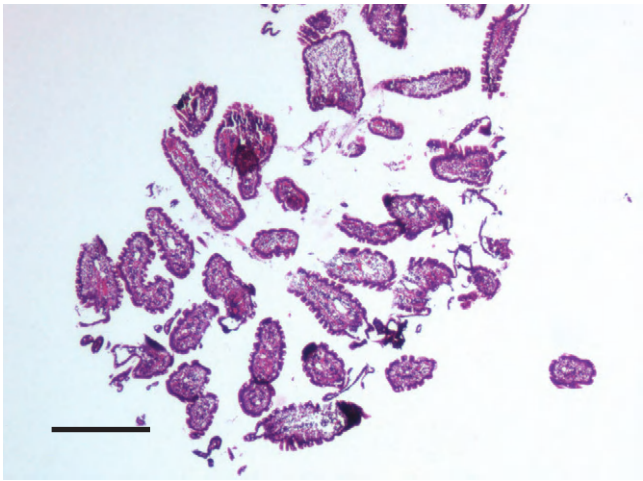

Figure 29-15 An inadequate endoscopic biopsy of the small intestine. The sample comprises individual villi cut in either cross- or longitudinal-section. The villi are fragmented and no cryptal tissue is present for evaluation. Hematoxylin and eosin; bar = 1 mm.

This prevents disruption of the tissue following any vigorous agitation that might occur while the samples are in transit. Most histology laboratories are willing to supply these sponges and cassettes. Although it may appear a basic comment, where samples are submitted from different levels of the small intestine they should be sent in separate, clearly labeled, sample pots containing an adequate volume of formalin for rapid fixation. Samples should be submitted as soon as possible after collection as for some specialized (e.g., immunohistochemical) procedures it is optimal to process tissues into paraffin wax within 24 hours of collection.

The skill of the histology technician should not be underestimated in this regard. The process of embedding these minute tissue samples in molten paraffin wax while maintaining correct orientation and alignment within the block is highly demanding, and better results are obtained if the laboratory is well-practiced in these methods.

The clinician should pay particular attention to the history submitted with the samples. The more information that the pathologist has concerning the clinical presentation and suspected differentials, the more likely an informative and helpful report will ensue. A final consideration is that the microscopic interpretation of intestinal biopsies (particularly endoscopic samples) is not a simple procedure. There is considerable interobserver variation in assessment of intestinal biopsies between different pathologists.[71] The WSAVA Gastrointestinal Standardization Group has proposed that intestinal biopsies should be evaluated in a systematic way using a "tick-box" list that encourages the pathologist to examine and record all of the salient aspects of the samples.[11] In this way, the clinician can be ensured that all relevant components of the tissue were examined, even if they were histologically normal. Most initial microscopic evaluation will be done with sections stained by hematoxylin and eosin (H&E), but the pathologist should be able to follow this up where required with other histochemical stains (e.g., for identification of some infectious agents, for delineation of collagen in fibrosis).[10] It is also now generally possible for the pathologist to request immunohistochemical labeling, particularly in the case of phenotypic identification of round cell or stromal tumors. Clinicians should always develop a close working relationship with their

pathology laboratory, and feel comfortable about contacting the pathologist to discuss further any particular case.

This section provides an overview of the major histopathologic diagnoses made from small intestinal biopsies collected from dogs and cats. As such, the information is not an exhaustive list of minor disorders, but focuses on those of greatest clinical relevance.

Small Intestinal Histology

The basic tissue microarchitecture of the canine and feline small intestine is similar. The orderly arrangement of villus-crypt units (Fig. 29-16) is broken only by the intermittent presence of organized secondary lymphoid aggregates (Peyer's patches or individual lymphoid follicles) with characteristic modified overlying dome-shaped mucosa (Fig. 29-17). Morphometric measurements of canine villus length and crypt depth are reported for different ages of dog,[47] but such investigations do not appear to have been carried out with feline small intestine. Similarly, parameters such as the mean number of goblet cells per unit of a defined number of enterocytes and the mean lamina propria total cellularity per unit area have been reported for the dog.[21]

Figure 29-16 Small intestinal histology. Full-thickness biopsy of canine jejunum showing regular villus and cryptal microarchitecture. There is mild edema of the superficial cryptal lamina and one or two lacteals are mildly dilated. Hematoxylin and eosin stain; bar = 1 mm.

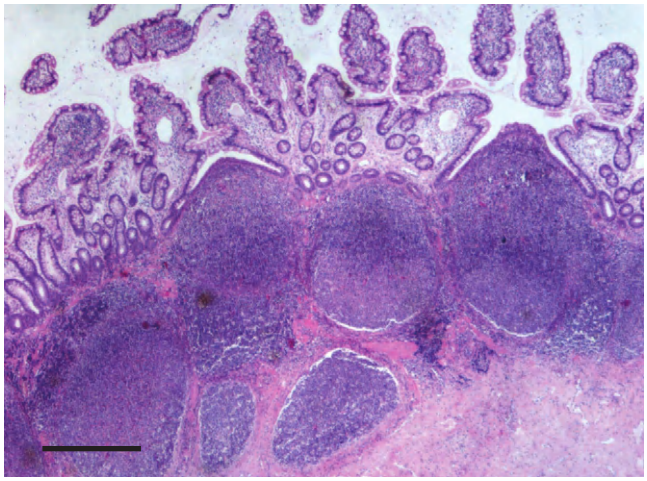

Figure 29-17 Small intestinal histology. Full-thickness biopsy of canine ileum showing a Peyer's patch lying within the mucosal–submucosal tissue. Note the modified "dome" shape of the villi overlying the lymphoid tissue and the extension of the perifollicular lymphoid population to the base of the enterocyte layer. Hematoxylin and eosin stain; bar = 1 mm.

The mean numbers of major leukocyte subpopulations within the canine duodenum, jejunum, ileum, and Peyer's patches have been defined by immunohistochemistry or flow cytometric assessment of disaggregated mucosal tissue.[21,24,27,57] The most interesting of these data report a trend toward an increasing number of lamina propria eosinophils and a decrease in immunoglobulin (Ig) A plasma cells from duodenum to ileum. Data are also available for vertical assessment of the villus and cryptal lamina propria. Plasma cells (of the IgG, IgM, and IgA classes) are enriched toward the base of the villus and cryptal regions, whereas the majority of T lymphocytes are located within the villus tips.

Similar data are reported for the feline small intestine[66] but these highlight some interesting differences between the two species. While cats also have more T cells in the villus (compared with cryptal) lamina propria, there is only enrichment of IgM and IgA plasma cells within cryptal lamina propria—with equal numbers of IgG plasma cells in villus and cryptal lamina. Also in contrast to the dog, cats have increasing numbers of T cells from duodenum to ileum, and an increase (as opposed to a decrease) in IgA plasma cells from anterior to distal small intestine. The two most striking differences between these species lies with epithelial expression of class II molecules of the major histocompatibility complex (MHC) and with the numbers of intraepithelial lymphocytes (IELs) (Fig. 29-18). Whereas dogs display constitutive epithelial expression of MHC class II, the normal feline enterocyte layer is devoid of this molecule.[20,66] Additionally, cats have significantly more IELs than dogs, with an increasing number of these cells from duodenum to ileum (there is no anatomical difference in the dog). The majority of feline IELs are $CD8^+$ (with an $\alpha\alpha$ homodimer)[52] and express the αE integrin that likely mediates their interaction with the epithelium.[73] It has been suggested that some of these changes may reflect the relatively greater number of microbial flora that are proposed to lie within the small intestinal lumen of the cat.[32,45]

Inflammatory Disease of the Small Intestine

Noninfectious Inflammatory Disease

Chapter 4 discusses inflammatory disease of the small intestine of the dog and cat. The three major noninfectious inflammatory diseases of the canine small intestine are idiopathic inflammatory bowel disease (IBD), food responsive diarrhea (FRD; also referred to as dietary hypersensitivity or food allergy), and antibiotic-responsive diarrhea (ARD; small intestinal bacterial overgrowth [SIBO]). The first two of these are also well-recognized in the cat. These disorders likely share elements of pathogenesis relating to the interaction between the intestinal immune system and bacterial or food antigens, and there is probably a pathologic continuum with overlap between the three entities.[23] A range of canine breed–associated enteropathies (e.g., those affecting Irish Setters,[50] soft-coated Wheaten Terriers,[61] Norwegian Lundehunds,[14] and Basenjis[4]) also likely fits within this pathologic spectrum. The clinical and pathologic definition of these specific diseases remains problematic, but all may involve a small intestinal mucosal inflammatory response, generally characterized by lymphoplasmacytic and/or eosinophilic infiltration.[29,30,32,67,74] Alternatively, examples of all three disorders are commonly found where there is no clear evidence for intestinal inflammation.

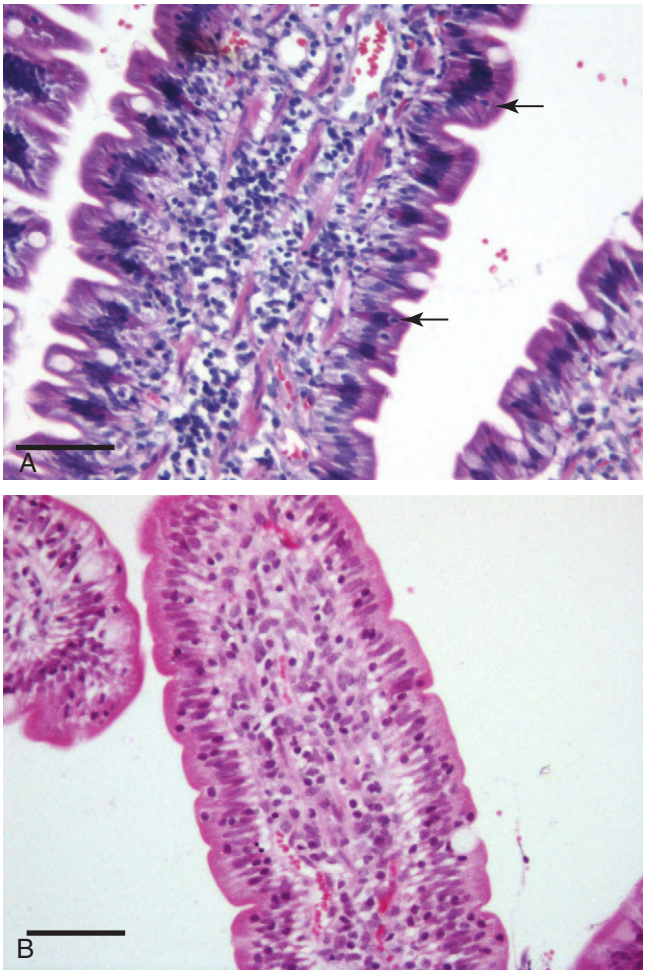

Figure 29-18 Intraepithelial lymphocytes. Villus epithelium from dog (**A**) and cat (**B**) showing the greater number of intraepithelial lymphocytes present in the cat. Hematoxylin and eosin stain; bar = 100 μm.

Given these difficulties, the WSAVA Gastrointestinal Standardization Group produced a monograph on the characterization of the small intestinal (specifically duodenal) inflammatory response per se, without relating these changes to any specific disease entity.[11] The monograph describes the major morphologic and leukocyte infiltrative changes that might occur in the small intestinal inflammatory response, and proposes descriptions of mild, moderate, and severe inflammatory change. The morphologic criteria that define small intestinal inflammation include villus stunting and fusion (Fig. 29-19), epithelial injury, crypt dilation, distention or abscessation (Fig. 29-20), lacteal dilation, and fibrosis. The types of inflammatory infiltrate that may occur are lymphoplasmacytic, eosinophilic, or neutrophilic (Fig. 29-21). Mixtures of these three types of response may also occur. Additionally, assessment of the IEL count is an important component of such evaluation, as elevation of IELs may occur in these inflammatory disorders.

The utility of examination of intestinal biopsies for the diagnosis and monitoring of these inflammatory enteropathies is widely debated. In some canine studies, histopathologic score correlates with the clinical score[31,41] (the "canine IBD activity index" [CIBDAI]) although this has not been replicated elsewhere.[1] Even where histopathologic grade may correlate with clinical severity, repeat biopsy following successful therapy may not necessarily reveal a reduction in the intensity of histopathologic change.[19]

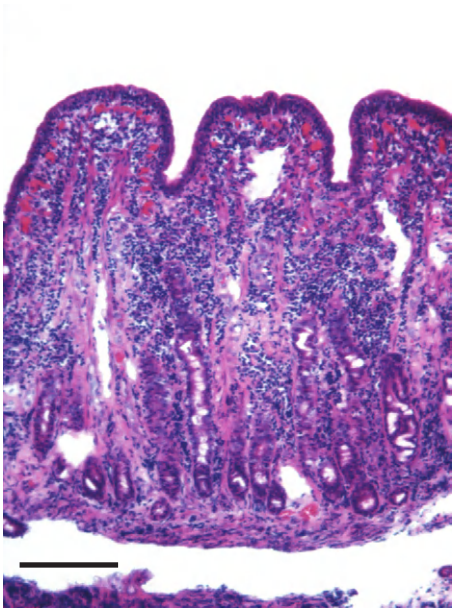

Figure 29-19 Villus stunting. Endoscopic biopsy from a dog with lymphoplasmacytic enteritis. In this well-orientated biopsy, the marked reduction in height of the villi may be clearly appreciated. Hematoxylin and eosin stain; bar = 500 μm.

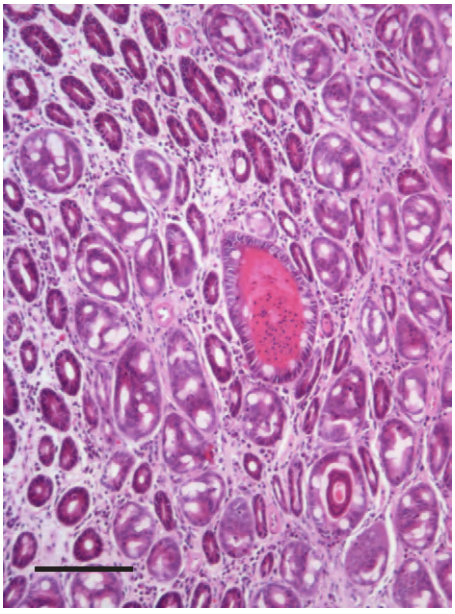

Figure 29-20 Crypt abscess. This biopsy of small intestinal mucosa has been cross-sectioned through the level of the crypts. Although not the optimum orientation for assessment, the central crypt is clearly dilated and filled by an accumulation of bright eosinophilic secretion and degenerate granulocyte nuclei. Individual "crypt abscesses" are considered an incidental feature within otherwise normal mucosa. Hematoxylin and eosin stain; bar = 500 μm.

Histopathology forms one part of a similar proposed composite feline IBD clinical severity scoring system.

Lymphangiectasia

The WSAVA criteria include villus lacteal dilation, which may arise secondary to a mucosal inflammatory response in which there is occlusion of lymphatic outflow. Extensive lacteal dilation is also a

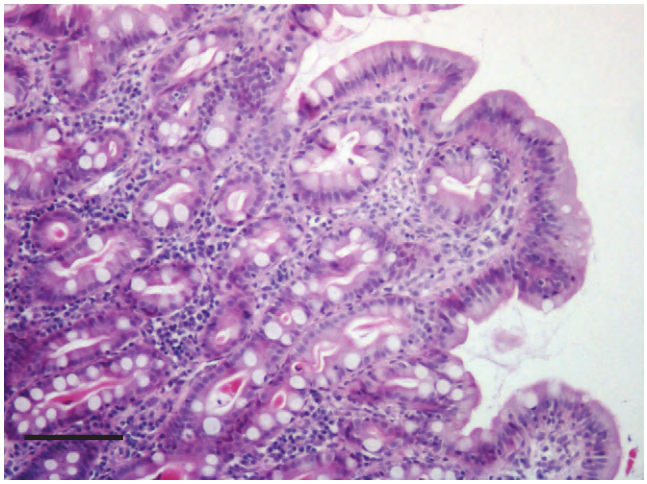

Figure 29-21 Lymphoplasmacytic enteritis. Small intestinal biopsy from a cat with lymphoplasmacytic enteritis. There is marked villus stunting and an infiltrate of predominantly lymphocytes and plasma cells into the lamina propria. Crypts have minimal change in this sample. Hematoxylin and eosin stain; bar = 500 μm.

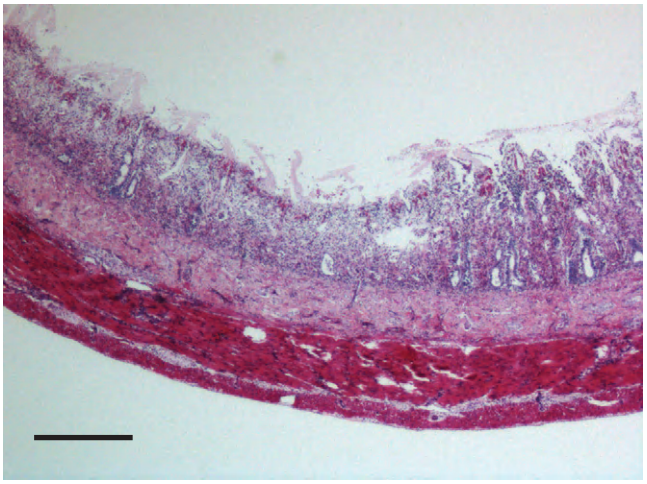

Figure 29-23 Parvovirus infection. Intestine taken at necropsy examination from a pup with polymerase chain reaction (PCR)-confirmed canine parvovirus infection. There is loss of villus structure and almost complete cryptal destruction. Hematoxylin and eosin stain; bar = 1 mm.

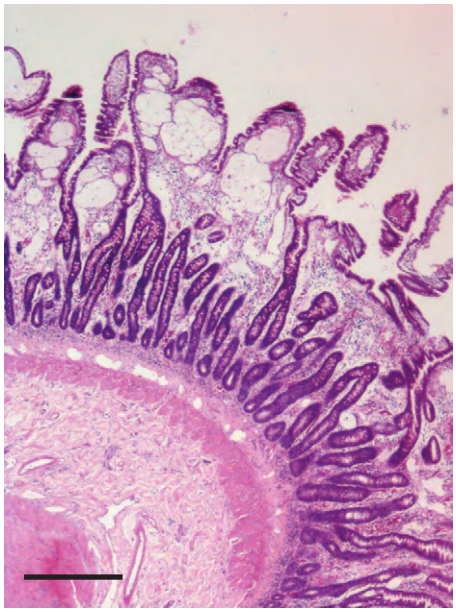

Figure 29-22 Lymphangiectasia. In this full-thickness biopsy there is marked ballooning dilation of the villus lacteals with reduction in the height of the affected villi. There is also lymphatic dilation within the pericryptal mucosa and the submucosa. Hematoxylin and eosin stain; bar = 1 mm.

hallmark of the entity termed *lymphangiectasia*, in which there is "ballooning" dilation of the lacteals accompanied by lamina propria edema and loss of lymphatic fluid (and associated cells and protein) into the intestinal lumen (protein-losing enteropathy) (Fig. 29-22). Affected villi are generally blunt. Lymphatic vessels in the submucosa, muscularis, serosa, and mesentery may also be dilated. Lymphangiectasia is recognized in the dog and may be a congenital developmental disorder or be acquired secondary to occlusion of lymphatic outflow by inflammatory or neoplastic processes.[37,58] Increased lamina propria cellularity is described in some cases, and specific elevation in the numbers of IgG plasma cells has been described. Lymphangiectasia may be accompanied by the formation of discrete microgranulomata (lipogranulomas) within the submucosa or deeper regions that generally center upon lymphatic vessels.[63] These inflammatory foci contain numerous highly vacuolated macrophages (lipophages) that take up the lipid-rich chyle that leaks from affected vessels. It is more likely that these lesions are a sequel to, rather than an initiating cause of, occluded lymphatic outflow. These key lesions may only be visualized on full-thickness (as opposed to perendoscopic) biopsy. As a distinct histopathologic syndrome, some dogs with protein-losing enteropathy have prominent crypt dilation/abscessation with mild lymphatic dilation, but an absence of villus pathology or mucosal inflammatory infiltration.[70]

Infectious Disease

Inflammatory change within the small intestine may also arise secondary to numerous defined causes, including parasitic, protozoal, bacterial, fungal, or viral infection. One example of such change is that which accompanies parvovirus infection of the cryptal epithelia. The hallmark features of parvoviral enteritis in dogs and cats are extreme villus atrophy, crypt dilation, and distention, with characteristic epithelial necrosis and bizarre squamoid morphology of surviving cells, and minimal lamina propria inflammation (Fig. 29-23).[5,64] Later in the course of disease there may be crypt hypertrophy as a consequence of compensatory crypt epithelial hyperplasia/regeneration. Feline leukemia virus has been proposed as a cause of cryptal necrosis similar to that caused by parvovirus. By contrast, feline (and canine) coronavirus enteritis causes loss of enterocytes from the tips of villi rather than affecting the crypts. Antigen from all three feline viruses may be identified within intestinal tissue by immunohistochemistry.[34] Crypt epithelial proliferation and mucosal erosion may occur in young pups with *Campylobacter* enteropathy and these bacteria may be identified within the crypt epithelial cell cytoplasm.[12] By contrast, in canine peracute hemorrhagic gastroenteritis (most often affecting young animals of toy and miniature breeds and suggested to have clostridial etiology; *Clostridium perfringens* type A) there is hemorrhagic necrosis of the mucosa with sparing of the crypts. In both dogs and cats, clinical disease and intestinal pathology associated with "attaching and effacing"

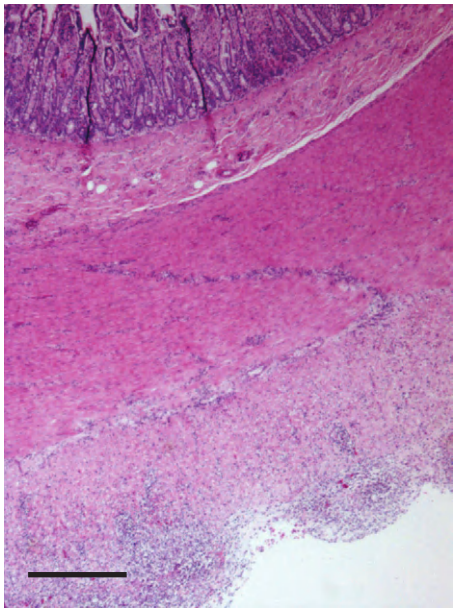

Figure 29-24 Feline infectious peritonitis. Intestine taken at necropsy examination from a cat with feline infectious peritonitis virus infection. There are discrete pyogranulomatous foci over the serosal surface extending into the muscularis. The mucosal and submucosal structure is unaffected. Hematoxylin and eosin stain; bar = 1 mm.

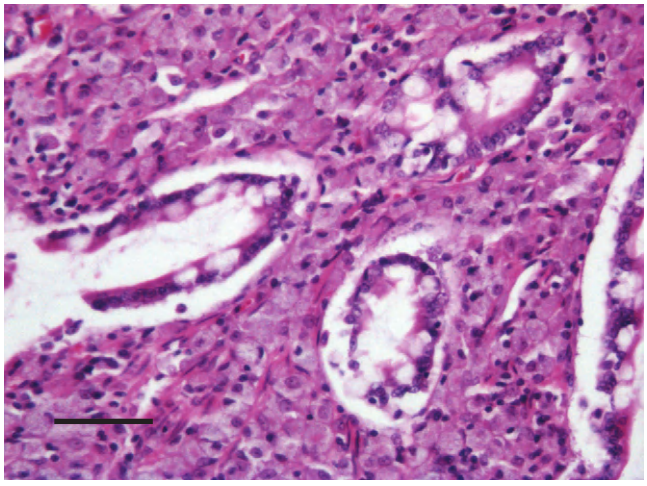

Figure 29-25 Intestinal mycobacteriosis. Section of intestine from a dog showing diffuse infiltration and aggregation of macrophages with expansive pale cytoplasm. Ziehl Neelsen staining of a serial section revealed that these cells contained large numbers of acid-fast organisms. In this dog, the primary lesion was intestinal (with secondary systemic dissemination) and thought to have occurred secondary to ingestion of an infected wild rodent. Hematoxylin and eosin stain; bar = 100 μm.

Escherichia coli (AEEC) is recognized but in many cases other concurrent intestinal pathogens are identified.[65]

A further specific example of a relatively common small intestinal inflammatory lesion is that which accompanies FIP virus infection. In this instance, the pathology is generally serosal (rather than mucosal) and characterized by the presence of vasculocentric pyogranulomatous reactions thought to be initiated by the deposition of antigen–antibody immune complexes (Fig. 29-24). Granulomatous enteritis secondary to mycobacterial infection may also occur in cats and dogs following ingestion of unpasteurized bovine milk or infected small rodent prey (Fig. 29-25). In certain geographical areas

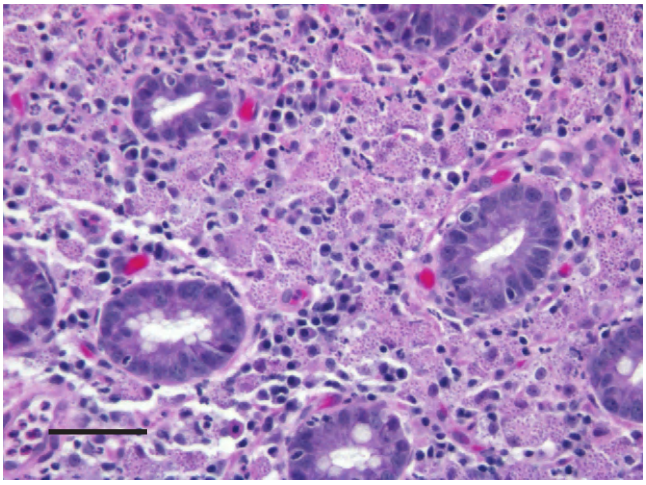

Figure 29-26 Histoplasmosis. Section of colon from a dog showing diffuse infiltration and aggregation of macrophages containing numerous cytoplasmic organisms with morphology consistent with *Histoplasma*. Although primarily a large intestinal disease, this infection may also involve the ileum. Hematoxylin and eosin stain; bar = 100 μm.

(e.g., the southern United States), granulomatous enteritis caused by the fungus *Histoplasma capsulatum* is prevalent in dogs.[7] Canine histoplasmosis most commonly affects the ileum and colon and organisms are prominent within the cytoplasm of infiltrating macrophages (Fig. 29-26). Hemorrhagic granulomatous enteritis may also occur in canine "salmon poisoning" in which dogs ingest salmon infected by the fluke *Nanophyetus salminicola*, which transmits the causative rickettsial organism *Neorickettsia helminthoeca*. Granulomas with prominent eosinophil infiltration may surround fragments of migrating *Toxocara canis* in the intestine of young dogs with poor husbandry. This change is generally considered an incidental finding, but has been termed *canine multifocal eosinophilic gastroenteritis*. The attachment of hookworms to the small intestinal mucosa may also induce local tissue damage related to the ingestion of blood by the parasite. Tapeworms also attach to the intestinal mucosa, but they generally have minimal clinical significance for the host. Although primarily a colonic infection, *Tritrichomonas foetus* may also infect and induce inflammation in the ileum of cats. Small intestinal giardiasis is not uncommon in young dogs and cats, but the *Giardia* organisms produce little intestinal pathology other than damage to the enterocyte microvillus border.

Neoplastic Disease of the Small Intestine

Alimentary Lymphoma

Neoplastic disease of the small intestine remains the major differential for inflammatory disease of this organ and is not an uncommon diagnosis in dogs and cats. These tumors may be of epithelial, mesenchymal, or hemopoietic origin. A frequent small intestinal neoplasm is alimentary lymphoma, which may concurrently involve other regions of the GI tract or mesenteric lymph nodes. Alimentary lymphoma is the most common tumor of the small intestine in cats. With the advent of successful vaccination and testing programs for feline leukemia virus (FeLV) infection there has been a change in the epidemiology of feline lymphoma. This disease now occurs principally in an older cohort of cats, is more likely to be unassociated with FeLV infection, and most frequently has alimentary

distribution.[62] In one study from Australia (where FeLV infection is uncommon), 15 of 118 cats with lymphoma had only intestinal involvement, a further 20 cats had alimentary lymphoma with involvement of other abdominal viscera, and another 25 cats had alimentary lymphoma with concurrent involvement of nonabdominal viscera.[18] In a retrospective study from California, 186 of 257 cases of feline lymphoma were recorded as having primary intestinal disease. Moreover, the incidence of intestinal lymphoma had increased in the latter 10 years of this 1983 to 2003 survey.[38] Feline alimentary lymphoma may give rise to a discrete nodular mass(es) within the intestine and/or may involve diffuse infiltration of the intestinal wall without producing mass lesions. The tumor may arise at any level of the gastrointestinal tract.

Feline alimentary lymphoma is generally considered to arise within the mucosa and to infiltrate into submucosa and muscularis (Fig. 29-27). Three distinct morphologic/phenotypic variants are described: small-cell lymphocytic villus lymphoma, large-cell or lymphoblastic lymphoma, and large granular lymphoma. Small-cell lymphocytic villus lymphoma affects older cats and begins as an accumulation of small T lymphocytes at the base of the villus. These cells gradually extend throughout the lamina propria and into the epithelium, and eventually the infiltrate becomes transmural.[6] Large-cell (lymphoblastic) lymphoma affects cats of any age and is a more aggressive, rapidly progressing, transmural tumor that forms nodular masses and metastasizes to mesenteric lymph nodes. At least a proportion of these tumors are of the B-cell phenotype. Large granular lymphoma is an aggressive metastatic form of disease involving large epitheliotropic lymphocytes with distinctive eosinophilic cytoplasmic granules that contain the molecule perforin immunohistochemically.[9,33] This finding suggested that these cells may be either cytotoxic T lymphocytes or natural killer (NK) cells, but further phenotypic investigation revealed that they are $CD3^+$ and also express a CD8αα homodimer, and are therefore likely to be intraepithelial T lymphocytes.[51] These large granular lymphocytes are also considered to be the same population as "feline globular leukocytes." Recent immunophenotypic studies have characterized the majority of feline alimentary lymphomas as being T-cell in phenotype (some of which may be epitheliotropic), but B-cell lymphoma or mixed phenotype tumors also occur.[40,68] By contrast, other studies report a dominance of B-cell lymphoma affecting the feline alimentary tract.[17] There is no clear evidence that immunophenotype is associated with survival time for feline alimentary lymphoma.[46]

The greatest challenge in the diagnosis of feline alimentary lymphoma is distinguishing early incipient neoplasia from chronic lymphoplasmacytic inflammatory disease. It is well-recognized that lymphoplasmacytic enteritis may progress to alimentary lymphoma in the cat, as is also documented for human patients with celiac disease.[2,38,40] The microscopical distinction between lymphoid inflammation and neoplasia is very difficult, but adjunct tests such as immunohistochemistry or molecular "clonality testing" increasingly have been shown to have a role in determining whether an infiltrating population of lymphocytes is clonal (and therefore neoplastic).[40,69]

Although canine alimentary lymphoma shares gross and microscopic features with the feline disease, there is no evidence for a specific etiologic agent. Canine alimentary lymphoma most commonly arises within the small intestine. The lesions may be diffuse or nodular and involve a number of segments of the gut. There are fewer data on the immunophenotype or molecular rearrangements of canine alimentary lymphomas (epitheliotropic T-cell lymphomas are more common than B-cell, mixed, or null cell tumors), and although a transition from lymphoplasmacytic enteritis to lymphoma is suggested to occur in the dog, this has not been well characterized.[15] In one retrospective study of 44 cases of GI lymphoma (of which 29 involved the small intestine) there were more $CD3^+$ T-cell tumors (n = 33) than either $CD20^+$ B-cell tumors (n = 3) or tumors expressing neither marker (n = 8). The T-cell tumors were invariably epitheliotropic.[8] Canine alimentary T-cell lymphoma may be accompanied by a significant infiltration of eosinophils, a state that must be distinguished from intestinal mast cell tumor.[42]

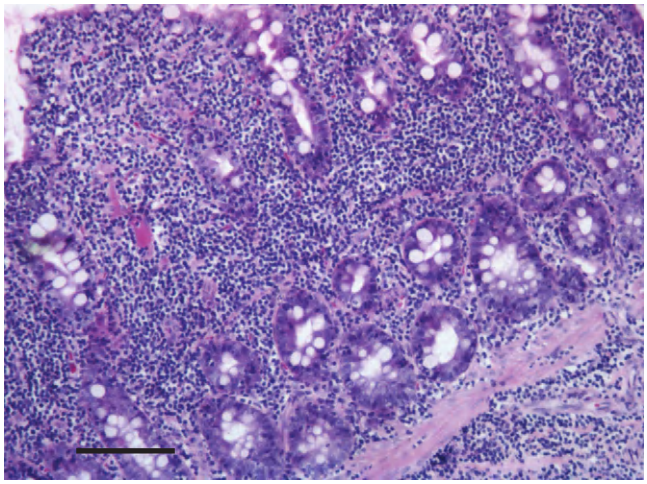

Figure 29-27 Alimentary lymphoma. Full-thickness biopsy from the ileum of a cat with alimentary lymphoma. In this section there is marked villus stunting with widespread infiltration of the lamina propria by a monomorphic population of small lymphocytes. These cells display epitheliotropism and also extend into the submucosa. The appearance is consistent with small-cell lymphocytic lymphoma and these are likely of the T-cell immunophenotype. Hematoxylin and eosin stain; bar = 500 μm.

Other Round-Cell Tumors

Solitary extramedullary plasmacytomas of the small intestine are rarely identified in dogs and cats and are considered to be low-grade malignancies. The malignant plasma cells are pleomorphic and arranged in packets. Immunoglobulin light chain amyloid (AL) may be associated with the tumors. The diagnosis may be confirmed by immunohistochemical evaluation of expression of immunoglobulin heavy and light chains.[49] These tumors are not associated with multiple myeloma of bone and affected animals are rarely paraproteinemic.

Uncommon examples of other intestinal round-cell tumors are recorded. Intestinal mast cell tumor is more common in cats than dogs and most frequently arises in the ileum and jejunum, respectively. These tumors may be difficult to identify when there is a prominent accompanying eosinophil infiltration or lack of metachromatic staining of mast cell cytoplasmic granules. Intestinal mast cell tumor carries a poor prognosis, with frequent metastasis and evidence of gastrointestinal ulceration.[59] The rare hypereosinophilic syndrome may involve the alimentary tract and is more commonly reported in cats[28] than in dogs.[48]

Intestinal Adenocarcinoma

A second important small intestinal neoplasm is adenocarcinoma which may also arise at other levels of the gastrointestinal tract. Most alimentary adenocarcinomas are of gastric origin in dogs,

whereas the majority appear to be intestinal in cats.[36,44] Within the small intestine, these tumors generally appear as solitary annular and stenosing masses and may be extensively infiltrative and metastatic to the serosa, mesentery, and via lymphatics to mesenteric lymph nodes. Transcoelomic or hematogenous metastasis is rare. Microscopically, there is often a marked scirrhous reaction with small nests of pleomorphic tumor cells embedded within this matrix (Fig. 29-28). The cells may form acinar structures or small aggregates, or be individual in distribution. The classic appearance of a "signet ring cell" is consistent with the secretory nature of the neoplastic epithelia. Some adenocarcinomas display "lakes" of pale mucinous material that may be identified by the Alcian blue/PAS reaction. Occasional carcinomas have a more solid lobular appearance and lack acinar differentiation or evidence of mucin production. Some tumors have evidence of metaplastic formation of bone or cartilage. Tumor cells of adenocarcinomas would be expected to express cytokeratin but not vimentin on immunohistochemical evaluation. Benign epithelial polyps or adenomas are rare in the canine and feline small intestine.[39]

Carcinoid

An intestinal carcinoid is a tumor of neuroendocrine cells of the mucosa that is rarely documented in dogs (mostly colonic) and cats (mostly ileal). These lesions are an important differential for carcinoma and distinguishing between these tumors may require immunohistochemical or electron microscopic evaluation. Grossly, carcinoids may be annular stenosing or nodular in appearance. They display similar infiltrative and metastatic behavior to adenocarcinomas. The histologic pattern is of nests or cords of cells packeted by fine bands of connective tissue stroma. The neoplastic cells have a granular, eosinophilic cytoplasm and label positively for synaptophysin and chromogranin by immunohistochemistry.[54]

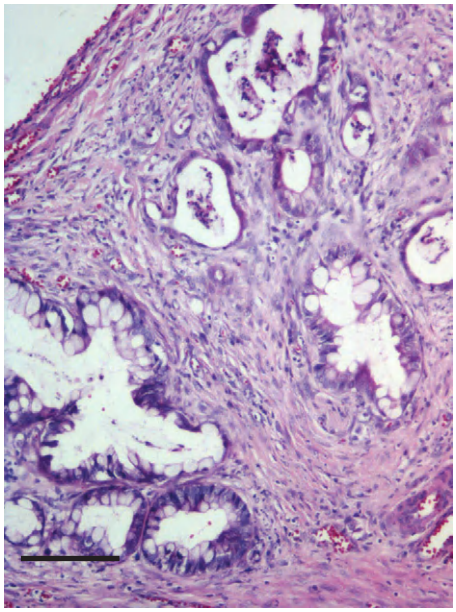

Figure 29-28 Adenocarcinoma. This section of canine colonic adenocarcinoma shows obliteration of normal microarchitecture by irregular infiltrative acinar elements within a scirrhous matrix. These tumors may arise at any level of the gastrointestinal tract. Hematoxylin and eosin stain; bar = 500 μm.

Intestinal Mesenchymal Tumors

Stromal neoplasms also arise in the small intestine, in particular the leiomyoma or leiomyosarcoma of smooth muscle origin. These are generally solitary nodular masses that most often arise in the muscularis of the small intestine of dogs and are considered uncommon in cats. The tumors are comprised of interlacing bundles of strap-like spindle cells with abundant eosinophilic cytoplasm compatible with the tissue of origin. Leiomyosarcomas generally have greater cellular pleomorphism and mitotic activity than leiomyoma. Leiomyosarcomas may be infiltrative but late-stage metastasis to mesenteric lymph nodes and/or liver is uncommon. Other intestinal stroma may rarely give rise to neoplastic lesions such as fibrosarcoma, myxosarcoma, or hemangiosarcoma.[55] Hemangiosarcoma may also metastasize to the small intestine from other primary sites. Nerve sheath tumors or tumors of ganglionated plexuses (ganglioneuroma) are also rare within the small intestine. The histogenesis of stroma cell neoplasms may be confirmed by immunohistochemical evaluation. Leiomyosarcomas will express vimentin, desmin, and muscle-specific actin (these molecules are also found in skeletal muscle) and the specific smooth muscle molecule α-smooth muscle actin. Expression of factor VIII–related antigen characterizes hemangiosarcoma.

Occasional tumors with morphology consistent with leiomyosarcoma fail to label with smooth muscle markers immunohistochemically and are classified as GISTs.[3,16] These tumors are thought to arise from the interstitial cells of Cajal or from a precursor cell that gives rise to these cells in addition to smooth muscle cells. GISTs may express immunohistochemically vimentin, S-100, neuron-specific enolase and c-kit. It would appear that many of the tumors previously diagnosed as intestinal leiomyosarcoma in fact may have been GISTs as defined by retrospective immunohistochemical evaluation.[53]

Miscellaneous Disorders of the Small Intestine

A variety of other disorders, many of which are relatively uncommon, may give rise to pathology within the small intestine of dogs and cats. Small intestinal inflammation might arise secondary to traumatic events or the presence of a penetrating or blocking foreign body. Intussusception of lengths of small intestine may occur and if sufficiently chronic lead to the development of adhesions and severe inflammatory responses. The cause of intussusception is often not identified, but in dogs this lesion may be secondary to inflammatory disease, parasitic infection, linear foreign bodies (e.g., string) or prior handling of the intestine during surgery. Ischemia may arise following mesenteric torsion or volvulus of lengths of the small intestine. Loops of intestine may be involved in external herniation from the abdominal cavity (e.g., diaphragmatic, umbilical, ventral, inguinal, or perineal hernia).

Proximal duodenal ulceration (peptic ulcer) is recognized most commonly in the dog and has complex pathogenesis that may result in concurrent ulceration of the pyloric antrum. There is a progression from mucosal erosion to deep ulceration with vascular thrombosis, and in some cases to perforation through the intestinal wall. Perforation may result in "silent healing" by omental adhesion and serosal granulation or may lead to hemorrhage and loss of luminal content into the peritoneum. Causative factors may include mast cell tumor leading to histamine-induced hypersecretion of gastric acid, pancreatic islet cell tumors or gastrinomas secreting excess gastrin (Zollinger-Ellison syndrome), administration of glucocorticoid or nonsteroidal antiinflammatory drugs, trauma, or major surgical intervention.

Rare examples of degeneration and inflammation of the muscularis (visceral myopathy) are reported, but the pathogenesis of this disorder is poorly understood.[26] Dysautonomia is recognized in both the cat (Key-Gaskell syndrome) and dog.[25,56] The etiology of this condition is uncharacterized but the clinical presentation may include constipation and ileal impaction. Characteristic lesions are present within the neurons of autonomic ganglia, including those of the myenteric plexus. These cells may be hypereosinophilic and shrunken with nuclear pyknosis or karyorrhexis. Cytoplasmic vacuolation and lack of Nissl granules is reported, and the surrounding stroma may contain mononuclear inflammatory cells. Finally, amyloid deposition may occur within the intestine of older dogs but is considered to be an incidental finding.[60]

COLON

Brian Wilcock

If one were to look at the records from any surgical pathology diagnostic laboratory, the picture that emerges with respect to the pathology of the canine and feline colon is very different from the impression one might get by reading standard clinical textbooks. Except for cases in which neoplasia is suspected, 90% of colonic histopathologic assessments are done on endoscopic biopsies. Among those cases in which histologic lesions are identified, at least 95% are interpreted as either lymphoplasmacytic or eosinophilic colitis, without offering any insight into the exact etiology or pathogenesis. Colitis may occur alone or as part of generalized GI inflammatory disease, usually interpreted by default as IBD. Because it is easier and more reliable to assess changes in mucosal morphology and leukocyte numbers in colonic biopsies than in those from the small intestine, assessment of the colonic mucosa is often helpful, even in those cases in which clinical signs suggest primarily small intestinal disease. Indeed, there is not a strong correlation between the assumed site of disease based on clinical signs and where the histologic lesions are most obvious.

Although the literature describes a plethora of bacterial, fungal, and parasitic agents capable of inducing colitis in dogs and cats, proving a causal link between such infections and clinical disease remains elusive. Most of the agents described can be isolated from clinically healthy dogs and cats, and many are part of the normal flora. For most, fulfilling Koch's postulates has proven impossible, especially when it comes to the experimental reproduction of disease.[1,2] Even for those in which a causal role has been proven, the diagnosis is rarely based on histologic assessment of colonic biopsies.

Our dismal record in correlating histologic lesions with a specific infectious agent or immune phenomenon may just be temporary as new molecular techniques to better identify potentially pathogenic colonic bacteria on the basis of genotype, identify and measure toxins, and identify potential agents of disease within the actual tissue biopsies move from the research laboratory into more general diagnostic use. While we all eagerly await this diagnostic revolution, this section reflects the current reality that specific infectious diseases are rarely identified as a cause of colonic lesions in dogs and cats.

Normal Colonic Mucosa

Interpretation of suspected colonic ulcerative or inflammatory disease requires a firm grasp of the normal range of colonic histology, mucosal kinetics, and principles of GI wound healing (Box 29-1).

Box 29-1 The Fundamental Rules of Colonic Biopsy Interpretation

- Colonic inflammatory disease is virtually always diffuse and uniform, so numerous biopsies are unnecessary.
- Because even very small decreases in absorptive efficiency can result in profound diarrhea, even very subtle colonic lesions can be clinically significant.
- Because colonic ulceration heals very rapidly and usually without any residual changes, biopsies must be taken during active clinical disease so as to avoid the risk of a misleading false-negative result.
- Leukocytes should not exceed four cell layers between adjacent crypts, and eosinophils should not appear in the superficial half of the mucosa.
- Credible etiologic candidates are rarely seen.

Figure 29-29 Normal canine colonic mucosa, with numerous goblet cells and a sparse population of leukocytes within the lamina propria separating adjacent crypts. Hematoxylin and eosin stain.

The normal canine colonic mucosa is made up primarily of straight cylindrical crypts oriented perpendicular to the underlying muscularis mucosa. The crypts lie against each other, surrounded by a cell-poor lamina propria populated by stromal cells, vessels, and a sparse population of lymphocytes, plasma cells, eosinophils, and mast cells. The base of each crypt is separated from the muscularis mucosa by no more than four cellular layers, in which eosinophils are often prominent. In dogs, crypt length varies from 400 to 600 μm, and in two-dimensional histologic sections consists of two parallel columns each with about 100 simple columnar epithelial cells. The lining of the superficial three quarters of the crypts appears dominated by goblet cells, but in fact the crypts are populated by a mixture of goblet cells, neuroendocrine cells, columnar absorption of epithelium, and germinal basal cells. Goblet cells are claimed to account for only approximately 10% of the total, but the distended mucus goblets often seem to crowd out the other cells and in routine histologic sections create the visual impression of an almost pure goblet cell population (Fig. 29-29). The number of recognizable

goblet cells in endoscopic biopsy specimens is only half that in specimens obtained at necropsy examination,[3] probably because mild irritation from enemas and instruments used in preparation for colonic biopsies results in disgorgement of some of the goblet cells.

Mitoses are found only in the basal third of the crypts and are generally inconspicuous in routine sections. The mean mitotic index throughout the colon is 1.13 mitoses per 100 cryptal epithelial cells, or about two mitoses per crypt.[3] Cells migrate from the base of the crypt to exfoliate from the luminal surface over an interval of about 4 days, representing the overall mucosal turnover time.

The crypts are separated from one another and from the muscularis mucosa by a small amount of cell-poor fibrovascular lamina propria containing no more than four layers of cells.[4] Eosinophils are often particularly conspicuous between the base of the crypts and the muscularis mucosa, and staining with toluidine blue will identify moderate numbers of mast cells that are essentially unrecognizable in ordinary H&E stains. Lymphocytes and plasma cells predominate throughout the more superficial lamina propria, although they may be accompanied by substantial numbers of eosinophils within the deep half of that mucosa. Eosinophils are not found in the superficial half of the lamina propria (Fig. 29-30). Intraepithelial lymphocytes are present throughout, but are much less obvious than in small intestine (with a mean of 1.5 intraepithelial lymphocytes per 100 enterocytes).[3]

Lymphoid aggregates are uniformly distributed within the deep lamina propria and superficial submucosa. Crypts may occasionally penetrate through the muscularis mucosa and into one of these submucosal lymphoid follicles, creating what are sometimes referred to as "submucosal glands." The follicles are particularly large in dogs and cats younger than about 2 years of age, and they can be seen from the external surface when examining the colon during exploratory surgery. They are commonly mistaken for significant lesions (like ulcers, tumor nodules, or parasitic cysts). The key to the distinction is that these lymphoid follicles are all the same size and shape, and never coalesce.

Figure 29-30 Normal canine colonic mucosa. No more than four layers of leukocytes (lymphocytes, plasma cells, eosinophils) separate adjacent crypts from one another and from the underlying muscularis mucosa. Hematoxylin and eosin stain.

General Pathology of the Colon

The reactions of the colon to injury are the same as in the rest of the GI tract. The common lesions include ulceration, depletion of recognizable goblet cells, shortening or elongation of crypts, and changes within the lamina propria that include edema, fibrosis, and increased leukocytes. Hypertrophy of the muscularis mucosa is a fairly common lesion of unproven significance. Changes within the submucosa are much less prevalent and ordinarily are seen only as part of invasive transmural disease occurring as a sequel to primary mucosal disease (the most notable exception being submucosal vasculitis in colonic FIP infection in which the mucosa often remains normal).

Ulceration

Surface ulceration triggers a rapid (minutes-to-hours) flattening and sliding of adjacent epithelium to quickly seal the defect. Any significant surface ulceration also stimulates increased mitotic activity in the basal half of the crypts with migration of flattened, hyperchromatic, immature epithelial cells upwardly to replenish those lost (Fig. 29-31). Temporary increases or decreases in cryptal length reflect the transient imbalance between epithelial loss and cryptal mitotic replacement.

Goblet Cell Atrophy

Even the mildest surface irritation results in almost instantaneous evacuation of goblet cells, particularly from the basal half of the crypts, resulting in cryptal distention with mucus and a disappearance of visible goblet cells. In truth, the cells are still present and it is only the goblets of stored mucin that have disappeared. The goblet cells continue to rapidly produce and export mucin, but the storage goblets will only reappear once the surface irritation has resolved and mucin production once again exceeds demand. The combination of reparative epithelial flattening and mucus accumulation may cause these crypts to appear cystic (Fig. 29-32).

Propria Edema and Fibrosis

Acute edema within the lamina propria is a common lesion that is probably just an endoscopic biopsy artifact because in most cases it is not accompanied by any other evidence of colonic disease.

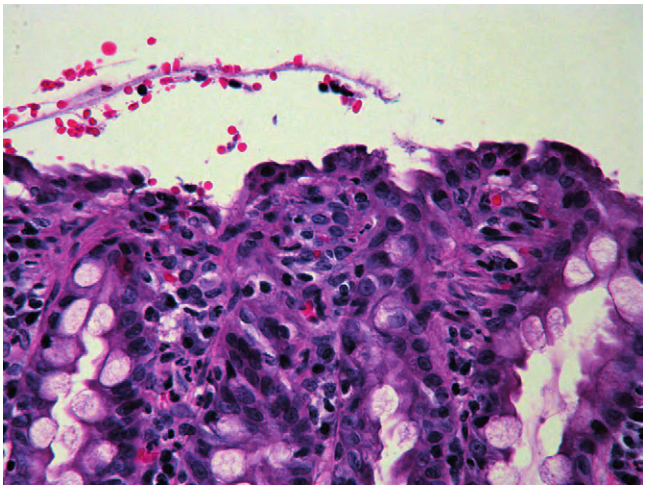

Figure 29-31 Canine colonic mucosa with recent superficial ulceration healing by epithelial sliding. Following a single injury, such healing occurs within hours and leaves no residual footprints. Hematoxylin and eosin stain.

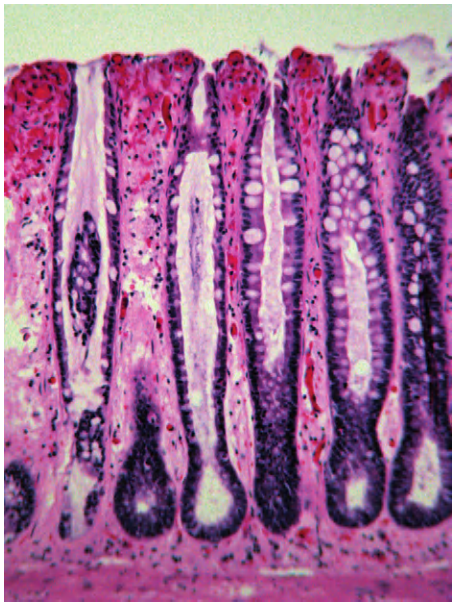

Figure 29-32 Even mild surface injury results in evacuation of goblet cells and cryptal epithelial flattening as a prelude to regeneration. The combination creates the impression of "dilated" crypts filled with mucus. Hematoxylin and eosin stain.

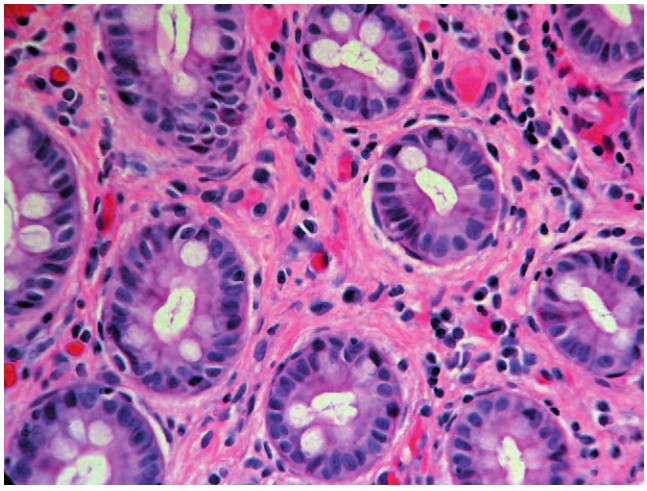

Figure 29-33 Diffuse fibrosis within the colonic lamina propria, a common lesion assumed to be a footprint of previous mucosal inflammation. It has no proven functional significance. Hematoxylin and eosin stain.

Significant edema, of course, can occur as an early manifestation of inflammatory disease or, rarely, as a manifestation of impaired venous or lymphatic drainage.

Propria fibrosis causing abnormal separation of the crypts or separation of the crypts from the muscularis mucosa is probably the most common lesion seen in colonic biopsies (Fig. 29-33). It is reasonable to assume that it is a footprint of previous inflammatory disease, but that is just an assumption. We do not know if it has any functional significance.

Increased Propria Leukocytes

As in other portions of the GI tract, perceived increases in leukocytes within the lamina propria is the traditional basis for the diagnosis of colitis. It is worthwhile noting that colonic ulceration may occur without any significant increase in leukocytes, and there are

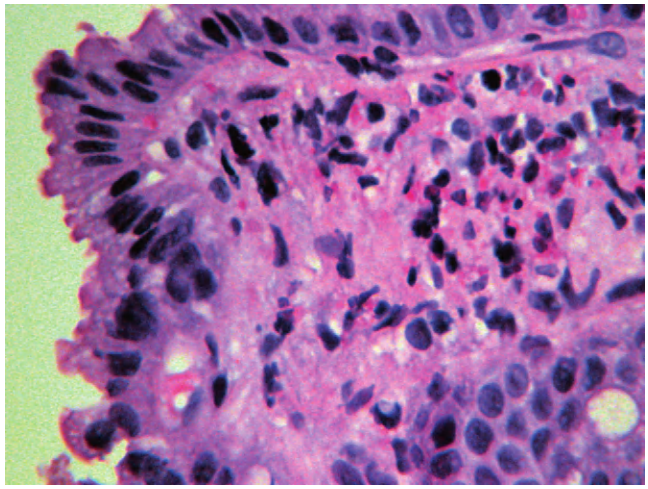

Figure 29-34 Canine eosinophilic colitis. Although eosinophils are normal in the deep half of the mucosa, they are normally absent from the superficial mucosa. The proportion of eosinophils required to classify colitis as "eosinophilic" has not been defined. Hematoxylin and eosin stain.

many examples of increased leukocytes in which there is no evidence of epithelial injury (Fig. 29-34). Developing valid and uniform criteria for assessing the mucosal cellularity and for promoting acceptable interobserver agreement among pathologists remains problematic within the colon as in other parts of the GI tract. Part of the problem lies with incredible variation in histologic staining from laboratory to laboratory, so that recognizing eosinophils, mast cells or sometimes even plasma cells is problematic.[5] Additionally, the range in leukocyte numbers among clinically healthy dogs is quite wide (although much less so than in small intestine). In the only study of its type, normal dogs had up to four layers of lymphocytes, plasma cells, and eosinophils separating adjacent crypts from one another.[4] There is no published range for eosinophil numbers, but eosinophils should be virtually absent from the superficial half of the mucosa.[3]

Additional information about normal colonic mucosal cellularity comes from two studies directed specifically at lymphocyte subpopulations. In healthy dogs, the mean number of immunoglobulin-containing cells and $CD3^+$ T cells per linear millimeter in routine histologic sections is approximately 300. Slightly less than half are T cells.[6,7] In 11 dogs with clinically diagnosed IBD, the mean increased to 438. The proportional increase among IgG^+, IgA^+, and $CD3^+$ cells was similar. In this study, only the IgM^+ cells failed to increase significantly.[6] There remains the fundamental question about whether an increase in leukocytes within any portion of the intestinal lamina propria should be considered "pathologic," or simply an appropriate physiologic response to antigenic challenge.

Because economic realities preclude immunohistochemical staining and arduous cell counting for the vast majority of diagnostic samples, the identification and characterization of colitis in dogs and cats is based upon simple rules of thumb (like a maximum of four cell layers separating the crypts from one another or the muscularis mucosa)[4] or on clear photographic templates illustrating acceptable and excessive cellular ranges.[8]

There are certainly some biopsies in which leukocytes exceed the limit of four layers separating adjacent crypts, and in which the increase in leukocytes is accompanied by other evidence of mucosal damage like edema, cryptal or surface epithelial injury, or distorted cryptal repair. The appearance of neutrophils anywhere within the

lamina propria is abnormal and usually indicates current or recent ulceration. Only rarely is it an indication of invasive bacterial disease. The observation of eosinophils in the superficial third of the mucosa should also be considered an indication of genuine colitis until we have data to the contrary.

Colitis

In reflecting upon the range of lesions seen in endoscopic or full-thickness colonic biopsies from dogs and cats with a history compatible with colitis, it seems reasonable to divide those biopsies into three broad histologic categories: those with no significant histologic lesions, those with convincing lesions of active colitis characterized by increased leukocytes and/or mucosal damage, and then a large group with more controversial "residual" lesions compatible with waxing and waning colitis captured during one of its quiescent intervals. Those residual lesions include one or more of mucosal fibrosis, cryptal atrophy or tortuosity, and increased leukocytes with no evidence of active epithelial injury or vascular changes appropriate to active inflammation. Considering the waxing and waning clinical signs in many examples of canine or feline colitis and the rapidity of colonic repair, we need to pay much more attention to when the biopsies were taken relative to the last "episode" of clinical disease when assessing colonic biopsies. Lesions of mature mucosal fibrosis and mucosal atrophy are not likely to be relevant if the biopsies were taken in the midst of an acute episode of classical colitis; on the other hand, they may be extremely significant as a footprint of previous inflammatory disease if the biopsies were taken, for example, 2 weeks after the last episode (which is often the case just because of scheduling appointments with a specialist).

Classification of Colitis

There is no official convention for the classification of colitis in dogs and cats. As the vast majority of cases have no demonstrated etiologic agent, colitis is usually classified based on the predominant type and location of the cellular infiltrate.[4,8-10] The shortcomings of such classifications are several. First, most of our biopsies capture only the mucosa and do not allow assessment of submucosa or muscularis propria. Second, because the normal colonic lamina propria is populated almost exclusively by lymphocytes and plasma cells, other infiltrating cell types have little chance of becoming "predominant" even when their increase may actually be greater and more directly related to the cause of the disease. For example, there is no agreement among pathologists about how many eosinophils it takes for colitis to be classified as "eosinophilic." This is further complicated by the fact that most biopsies are taken fairly late in the course of the disease, at which time the long-lived lymphocytes and plasma cells are almost certain to predominate even if their daily proliferation or recruitment is far less than the recruitment of eosinophils or other leukocyte types. Finally, and perhaps most importantly, there is a huge interobserver variation in how pathologists assess leukocyte numbers and other grading criteria even when using a pictorial guide.[5] Unfortunately, there is no obvious solution to any of these significant shortcomings. At the moment, all we can do is acknowledge that it is indeed a dilemma, not only when making the original diagnosis, but also when trying to compare the results of different studies.

Colitis can also be classified by etiology, but that is problematic because most of the agents appearing on such lists have not actually been proven to cause colitis. Almost all of them are part of the normal flora or at least are "common" isolates from clinically healthy dogs or cats. The common assumption that the isolation of such agents, the demonstration of their DNA via PCR testing, or the presence of their toxins somehow "proves" that they are causing disease has no credibility.[1,2]

Box 29-2 is a simple histologic classification that reflects the reality of what is seen by veterinary diagnostic laboratories receiving samples from primary care and specialty private veterinary clinics. Those interested in more refined grading schemes should see previously published studies.[4,8] These patterns are not mutually exclusive, in that the predominant leukocyte type may shift as the disease progresses, and a disease that is initially just mucosal may progress to submucosal or transmural colitis. Nonetheless, the classification proposed here is still useful for the vast majority of cases.

Idiopathic Lymphoplasmacytic (and Eosinophilic) Mucosal Colitis

This is garden-variety chronic episodic colitis in dogs and cats, probably accounting for at least 90% of all diagnoses made on routine colonic biopsies. The histologic diagnosis is based on seeing cryptal separation by a combination of edema, fibrosis, and a mixture of leukocytes that creates more than four layers of leucocytes separating adjacent crypts from one another and from the muscularis mucosa (Fig. 29-35). Ulceration is not a common feature, but when seen may take the form of shallow active ulceration, or, more commonly, superficial epithelial flattening and basophilia indicating recent ulceration in the midst of healing. Lesions are typically diffuse and uniform so that all colonic biopsies look essentially identical. A diagnosis of eosinophilic colitis can be made if eosinophils appear in the superficial half of the mucosa.

Box 29-2 Colitis Classified by Histologic Pattern

Mucosal colitis
- Lymphoplasmacytic
- Eosinophilic
- Granulomatous

Ulcerative colitis

Submucosal and transmural colitis

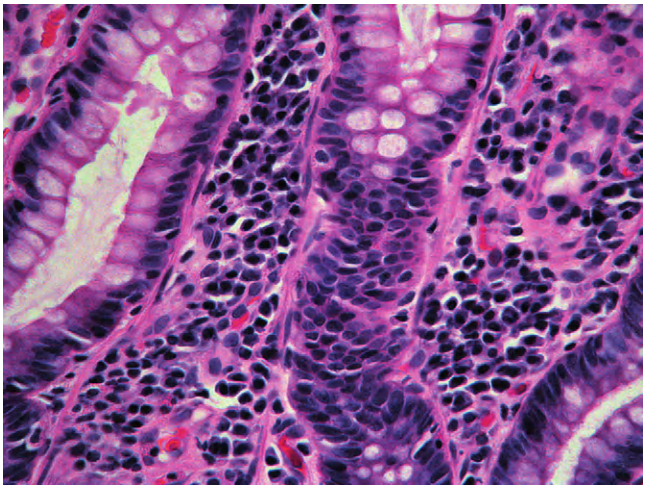

Figure 29-35 Traditional lymphoplasmacytic mucosal colitis with an increase in mononuclear leukocytes separating adjacent crypts, mucosal edema, and subtle fibrosis. This is by far the most common pattern of colitis in dogs and cats, with no proven etiologic implications. Hematoxylin and eosin stain.

Granulomatous Mucosal Colitis

Mucosal colitis in which the predominant leukocytes are macrophages is more or less limited to histiocytic ulcerative colitis (HUC) of Boxer dogs and to histoplasmosis. HUC is a distinct disease syndrome with characteristic histologic lesions seen in young Boxers and French Bulldogs. It is a chronic, progressive, and eventually transmural disease characterized initially by shallow microscopic erosion and ulceration of the colonic surface and by an accumulation of large epithelioid macrophages containing PAS-positive cytoplasmic vacuoles between the muscularis mucosa and the base of the colonic crypts (Figs. 29-36 and 29-37). Over time, the number of macrophages increases dramatically, with extension into submucosa and spread via lymphatics to occupy large portions of the draining colonic lymph nodes.[11,12] The granulomatous proliferative disease is usually more obvious than the ulceration. In the early disease, the patchy deep mucosal granulomatous infiltrates can be missed if one is looking only at shallow endoscopic biopsies. For many years, this disease was considered idiopathic and invariably fatal. More recently, the observation that most cases responded to antibiotic treatment with enrofloxacin stimulated a resurgence of interest in this disease.[13] Subsequently, fluorescence in-situ hybridization (FISH) in colonic biopsies from affected dogs and subsequent genomic analysis identified specific strains of *Escherichia coli* capable of adhering to, invading, and replicating within colonic epithelium. These strains were not found in colonic biopsies from healthy dogs and clinical response to treatment was accompanied by disappearance of the organisms.[14] Why the disease is limited almost exclusively to Boxers and related French Bulldogs remains an intriguing mystery worth solving.

Histoplasmosis frequently causes diffuse granulomatous colitis either alone or as part of systemic disease. The colonic lesions are usually diffuse and large numbers of organisms can be found in macrophages throughout the mucosa. The infected cells are usually most numerous in the deep third of the mucosa, and may extend through submucosa and even muscularis propria. The diagnosis is seldom problematic because the organisms are numerous and their morphology is distinctive.

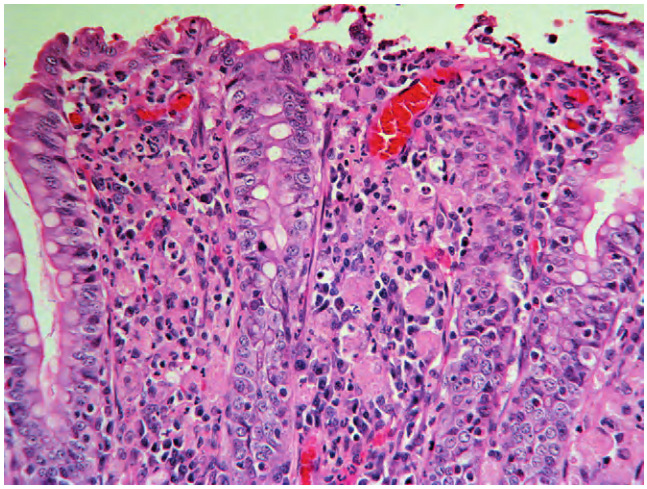

Figure 29-36 Early histiocytic ulcerative colitis in a young Boxer dog. The early lesion is usually found deep in the mucosa, associated with epithelial basophilia and flattening as evidence for ongoing superficial ulceration. Hematoxylin and eosin stain.

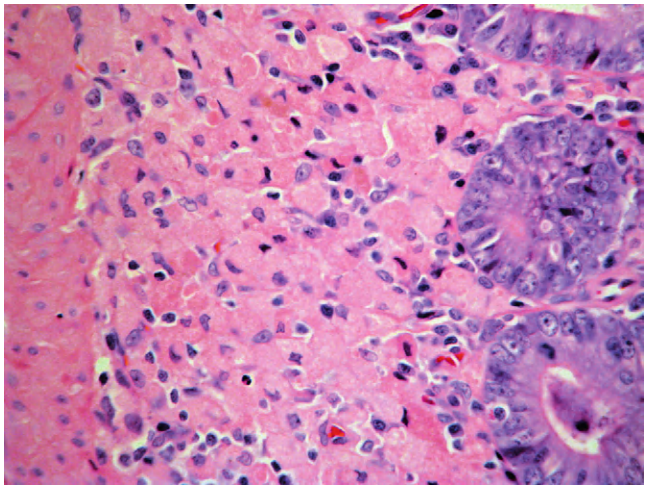

Figure 29-37 More advanced histiocytic ulcerative colitis in a Boxer. There is extensive replacement of mucosal architecture by proliferating histiocytes, including spread through the muscularis mucosa and into the submucosa. Hematoxylin and eosin stain.

Ulcerative Colitis

Ulcerative colitis may be seen as part of several specific etiologic diseases like HUC of Boxers, protothecosis, trichuriasis, and salmonellosis. The vast majority, however, have no proven etiology.

Colonic ulceration not associated with any proven infectious agent occurs under two different histologic settings. The more prevalent is where ulceration occurs without any concurrent increase in mucosal leukocytes. This is particularly prevalent in cats. In other cases, ulceration is accompanied by mucosal changes identical to those seen in idiopathic mucosal colitis described above. It is not clear whether those cases with ulceration alone have a different pathogenesis, prognosis, or response to treatment when contrasted to those examples with concurrent inflammation. It seems worthwhile to at least document the existence of these two different histologic patterns as a stimulus for further research.

Trichuriasis can cause patchy or diffuse ulcerative colitis in dogs with particularly heavy burdens in which the infection spreads beyond the usual cecal location. The worms embed themselves in shallow tunnels in the superficial epithelium and in most cases do not penetrate into the lamina propria. Only with particularly heavy infestations is there ulceration with resulting hemorrhage and mixed fibrinous and neutrophilic inflammation. In response to the ongoing shallow ulceration there is sometimes dramatic cryptal hyperplasia and depletion of recognizable cryptal goblet cells. Perhaps as a result of deep ulceration, worms can occasionally be found embedded within the submucosa and within colonic lymphoid follicles.

T. foetus is a cause of significant, diffuse shallow chronic ulcerative colitis in young cats, especially those in crowded communal husbandry settings. The shallow ulceration is accompanied by increased superficial mucosal neutrophils, and a diffuse increase in lymphocytes and plasma cells throughout the lamina propria. There is compensatory cryptal hyperplasia. The characteristic crescent-shaped protozoa (5×7 μm) are seen along the surface of the surviving colonic mucosa of all affected cats, but only in about half of the histologic sections from any one cat.[10] Their detection is greatly enhanced by FISH.[15]

Submucosal and Transmural Colitis

Biopsies in which the principal inflammatory lesions are found in the submucosa are infrequent, but important because they carry strong etiologic and prognostic significance. The most common of

these is the colonic form of FIP infection, but this is also the usual pattern seen with pythiosis and occasional cases of idiopathic vasculitis and intestinal ganglioneuritis.

The colonic form of FIP is usually seen as acute severe segmental-to-diffuse hemorrhagic colitis with no other clinical evidence of FIP. The classical lesion is a necrotizing submucosal vasculitis resulting in profound submucosal edema and hemorrhage (Figs. 29-38 and 29-39). As is typical for FIP in other tissues, leukocyte recruitment is variable and ranges from primarily neutrophilic to primarily granulomatous, with many cases having a mixture of virtually every leukocyte type. The key to the diagnosis is the vascular necrosis and the presence of a relatively normal overlying mucosa. Coronavirus can be demonstrated within macrophages and other leukocytes within the submucosa and in the adjacent colonic lymph node via immunohistochemistry, confirming the etiologic diagnosis. There are not enough reported cases accompanied by subsequent postmortem assessment to know the prevalence of microscopic lesions in other tissues. In the largest retrospective study, most cats initially diagnosed with FIP on the basis of intestinal lesions eventually died with clinical signs of systemic FIP.[16]

The fungus *P. insidiosum* causes characteristic necrotizing and granulomatous lesions anywhere in the GI tract of dogs. Lesions tend to be large, multifocal caseous nodules that are easily seen macroscopically. Lesions may be mucosal, submucosal, or transmural, but the submucosal lesions are probably the most prevalent. The fungi are numerous within such lesions, but they are difficult to see with H&E stain.[17] They are readily seen with any of the special fungal stains. As this disease has strong geographic predilections and is relatively common within those specific subtropical habitats, the lesions are usually quite familiar to pathologists working in those areas.

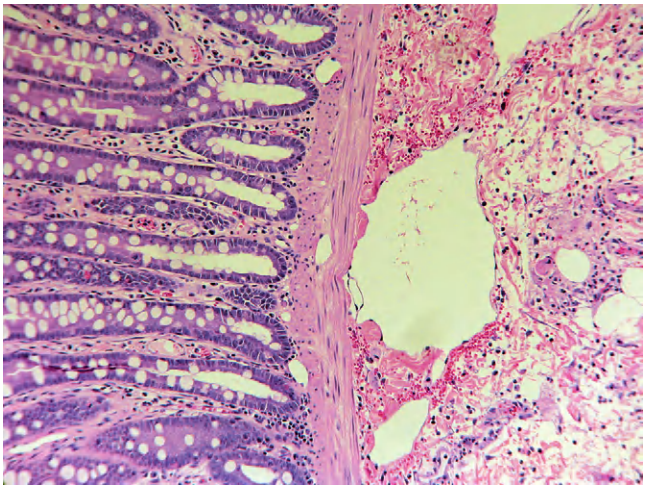

Figure 29-38 The colonic form of FIP in a young cat with acute onset of hemorrhagic diarrhea. In the early stages, there is a destructive submucosal vasculitis causing massive submucosal edema with fibrin and hemorrhage. The overlying mucosa often is almost completely normal. The magnitude of the cellular infiltration and the exact composition of that cellular mixture vary from case to case (and perhaps over time). Hematoxylin and eosin stain.

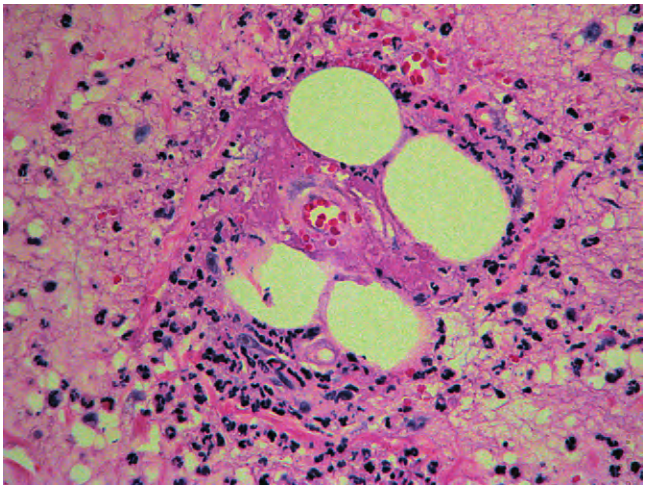

Figure 29-39 Colonic submucosa in a cat with acute hemorrhagic diarrhea. Severe edema, hemorrhage, and mixed pyogranulomatous submucosal inflammation are all suggestive of FIP, but the most specific lesion is neutrophilic leukocytoclastic submucosal vasculitis. Hematoxylin and eosin stain.

Colonic Neoplasia

Tumors affecting the colon and cecum of dogs and cats include virtually all of those documented for the stomach and small intestine. Because the histologic appearance and almost all aspects of the behavior of these tumors are the same regardless of their location within the GI tract, there is no point in repeating all of those details here. There are a few neoplasms, however, that are either substantially more prevalent within the large intestine or that have significant differences in appearance or behavior. Those tumors that occur exclusively or predominantly in the large intestine include rectal papillary adenoma (rectal polyp), rectal plasmacytoma, papillary colonic carcinoma, and cecal GIST in dogs.

Rectal papillary adenoma (rectal polyp, rectal carcinoma in situ) is the most common of the large intestinal tumors of dogs (Table 29-2), but is not seen in cats. It is detected as a focal, solitary sessile or pedunculated proliferation of rectal mucosa that protrudes into the rectal lumen to cause episodic hematochezia and dyschezia, but not diarrhea. All are found in the distal 10 cm of the large intestine. A similar lesion seen more proximally is more likely to be a papillary colonic carcinoma, with a vastly different prognosis. Unlike most neoplasms, there is no apparent increase in prevalence with age and any dog older than approximately 2 years of age can be affected. There is no proven link to diet or any other husbandry factors.[18,19]

Table 29-2 Relative Prevalence of Large Intestinal Tumors in Dogs and Cats*

Colonic Neoplasm	Dog	Cat
Carcinoma	80	134
Lymphoma†	46	80
Mast cell tumor	1	0
Rectal plasmacytoma	97	0
Leiomyoma‡	7	1
Leiomyosarcoma§	15	8
Rectal papillary adenoma	582	0

†Tumors limited to the large intestine, based on surgical assessment or imaging.
‡Predominance of endoscopic samples probably underestimates true prevalence.
§Not reviewed to distinguish from gastrointestinal stromal tumor.
Source: Histovet Surgical Pathology, Guelph, Ontario, Canada.

Most samples submitted for histologic evaluation are the result of attempts at complete excision per rectum. Particularly large samples, or those arising too far from the anus, may be submitted as full-thickness samples following exploratory surgery. There is remarkably little variation in the qualitative histopathology among such samples. There is abrupt proliferation of hyperchromatic, jumbled but otherwise quite mature columnar rectal epithelium causing a two- to fourfold increase in the thickness of the epithelium. The hyperchromatic and jumbled cells cover villus-like extensions of lamina propria that extend as papillary projections into the rectal lumen (Fig. 29-40). A characteristic feature is that the transition from normal rectal mucosa rich in goblet cells to this hyperchromatic and jumbled epithelium devoid of goblet cells often occurs in the superficial half of the rectal mucosa. The deep half of the mucosa often remains histologically normal. There is no invasion into the lamina propria or into the submucosa. There is often some degree of mechanical or even ischemic necrosis along the surface of the lesion secondary to abrasion from feces or previous prolapse.

Surgical excision is curative in the vast majority of cases. It is essentially impossible to determine whether the few postoperative recurrences are because of incomplete excision or additional, independent polyps.

The only significant differential diagnosis is well-differentiated and early papillary colonic carcinoma. Between 1% and 2% of the diagnoses of rectal papillary adenoma/rectal polyp must subsequently be amended to papillary carcinoma on the basis of postoperative recurrence and subsequent submucosal invasion. We do not know whether this represents progression of rectal polyp to true carcinoma, or whether it was simply a mistaken initial diagnosis. The diagnosis of true carcinoma is most reliably made by seeing invasion through the muscularis mucosa and into the submucosa, but many samples are not deep enough to allow that distinction. Even shallow samples of carcinoma may, however, allow observation of invasion across the basement membrane and into the lamina propria, a behavior not seen in otherwise identical papillary adenomas. It is also helpful to remember that most colonic carcinomas arise in the more proximal colon. Rectal papillary adenomas, by definition, are limited to the distal 10 cm of the intestine.

Dysplastic repair following rectal mucosal ulceration could be confused with a portion of a rectal papillary adenoma if the sample was limited to a tiny endoscopic biopsy. Dysplastic repair should be primarily a cryptal phenomenon, giving rise to tortuous cryptal proliferation accompanied by fibrosis and increased leukocytes. It should not create a macroscopic, intraluminal mass.

Plasmacytoma is the second most common tumor of the canine large intestine. Although these tumors may occasionally occur anywhere in the mucosa or submucosa throughout the GI tract, the majority occur as a focal, solitary, and discrete nodule of atypical plasma cells within the submucosa of the rectum that can be easily detected by digital palpation.

Microscopically, they are exactly the same as the plasmacytomas more commonly found in nonintestinal locations like the ear canal, gingiva, lip, and digital skin. The tumor is often found only in the submucosa, with seemingly hesitant extension into the deep half of the overlying lamina propria. It is formed by solid packets of pleomorphic round cells with various degrees of plasmacytoid maturation. The plasmacytoid maturation is often most obvious at the periphery of the tumor. As in all plasmacytomas, the presence of scattered very large cells with hyperchromatic convoluted nuclei, or even multinucleation, is a strong diagnostic clue. The cells are typically arranged in solid endocrine-like packets of 10 to 20 cells surrounded by a delicate fibrovascular stroma (Fig. 29-41). In 10% to 15% of cases, there are islands of hyalinized homogenous pink material, identified as Aλ-amyloid, among the tumor cells.

Most tumors have discrete local growth amenable to surgical cure. A small proportion exhibits invasion into more proximal submucosa or outwardly into muscularis propria. Metastasis to regional lymph node is seen only rarely. The prognostic significance of such spread is unknown.

Differential diagnoses are malignant lymphoma and mast cell tumor. Immunohistochemical labeling for immunoglobulin is definitive for plasmacytoma, but is rarely required.

Most papillary colonic carcinomas closely resemble gastric and small intestinal carcinomas in their histologic appearance and behavior. They originate from epithelial cells in the crypts, invade across the muscularis mucosa and into the submucosa, and spread by direct extension and intralymphatic permeation through the

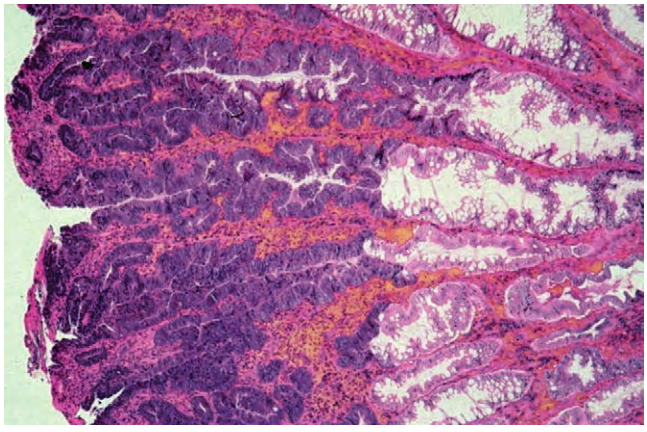

Figure 29-40 Canine rectal polyp. Transition from normal mucosa into the intraluminal papillary proliferation of hyperchromatic and slightly jumbled mature colonic epithelium is typical, and predictive of surgical cure. The absence of propria or submucosal invasion by the hyperchromatic epithelial cells is critical to distinguishing this from an early papillary colonic carcinoma. Hematoxylin and eosin stain.

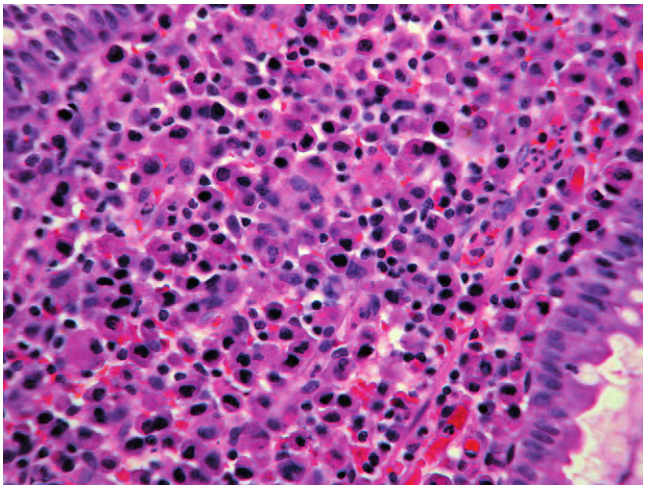

Figure 29-41 Canine rectal plasmacytoma, forming a discretely expansile mass of pleomorphic, atypical plasma cells with frequent nuclear gigantism and convolution. Hematoxylin and eosin stain.

muscularis propria. They then implant throughout the peritoneal cavity, and can also spread by lymphatic and venous dissemination to liver, lung, and any other location. They are often quite well-differentiated mucus-producing tubular carcinomas, and traditionally induce substantial scirrhous reaction. In the colon, however, approximately 25% of carcinomas are, at the time of initial diagnosis, extremely well-differentiated intraluminal papillary tumors that are seen rarely if ever in stomach or small intestine. If sampled just by shallow endoscopic biopsies, these can be mistaken for hyperplastic polyps (especially in dogs and especially if they occur in rectal mucosa where they overlap grossly and histologically with harmless rectal polyps). The key to the diagnosis of carcinoma is that these well-differentiated hyperchromatic columnar epithelial cells invade across the basement membrane and into the lamina propria (Fig. 29-42). In biopsies that are deep enough, one can usually detect at least some invasion into the submucosa. There is no information about whether these solitary discrete papillary carcinomas have a different prognosis from transmural invasive carcinomas.

GIST is a specific histologic entity with a predilection for the muscularis propria and submucosa of the canine cecum. GISTs can occur throughout the GI tract, including adjacent mesentery. To date, GIST has not been described in cats. There are only three studies describing the histologic appearance of GIST in dogs, especially the histologic criteria for distinguishing these tumors from smooth muscle tumors.[20-22] These retrospective studies, with a total of 165 canine intestinal tumors previously classified either as leiomyoma or leiomyosarcoma, reclassified 93 of the 165 as GIST based on immunohistochemical labeling. Making the distinction with ordinary histologic stains is clearly not reliable. The distinction is based on a panel of three immunohistochemical reactions: smooth muscle actin (SMA), desmin, and c-kit (CD117). GISTs are uniformly negative for expression of S-100 and desmin, and about half express c-kit. More importantly, virtually all of the smooth muscle tumors express SMA and two-thirds express desmin. None express c-kit.

In two studies, 41 of 101 tumors affected the cecum. All 41 of the spindle-cell tumors affecting the cecum were reclassified as GIST, making anatomic location alone a powerful predictor of the diagnosis.[21,22]

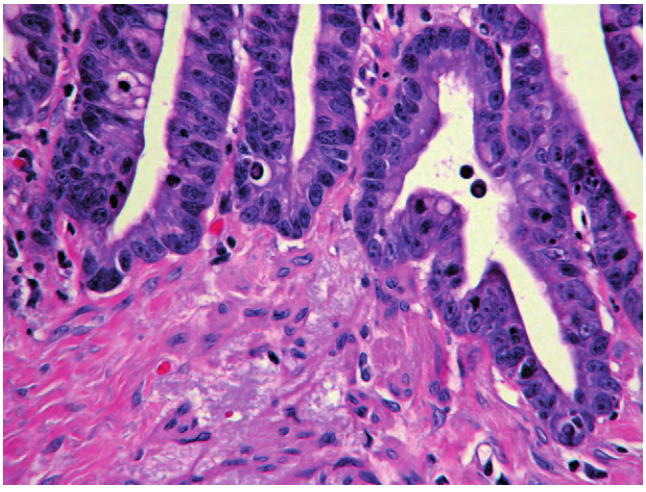

Figure 29-42 Papillary colonic carcinoma in a dog, with characteristic invasion of hyperchromatic and slightly jumbled epithelial cells across the basement membrane and into the lamina propria. Especially when these tumors occur in rectum, the invasion is essential to distinguishing these carcinomas from the much more prevalent entity of rectal polyp. Hematoxylin and eosin stain.

These tumors usually begin within the muscularis propria or in the submucosa, appropriate to their suspected origin from interstitial cells of the autonomic ganglia. They exhibit a wide range of histologic appearance with a wide range in mitotic activity and the degree of invasiveness. They are easily identified as pleomorphic spindle-cell tumors, but distinguishing whether they represent leiomyoma, leiomyosarcoma, or GIST requires immunohistochemistry. Traditional cytologic criteria of malignancy (e.g., mitotic index or nuclear pleomorphism) have little impact on biologic behavior. In one study, surgical excision of small intestinal or cecal tumors in 73 dogs resulted in 80% of these dogs being tumor-free at 1 year, and 62% tumor-free at 2 years.[21] A second and smaller study reported that 13 dogs with surgically excised GISTs that survived the immediate perioperative period had a mean survival of 37.4 months. Five dogs with excised leiomyosarcomas had a mean survival of 7.8 months. The difference was not statistically significant.[22] There are no adequate studies reporting the efficacy of chemotherapy alone or as adjunct treatment.

It will take some time to sort out what parts of the older literature pertaining to alleged smooth muscle tumors can be transferred to the GIST classification (observations like the great majority are behaviorally benign, and the great majority are clinically silent).

PANCREAS

Thomas Van Winkle

While the pancreas may be sampled routinely during necropsy examination, surgical biopsies are infrequently taken from this organ. Many of the major diseases of the pancreas, such as exocrine pancreatic insufficiency (EPI), diabetes mellitus (DM), and acute necrotizing pancreatitis (ANP), do not generally require histologic examination to either make or confirm the diagnosis. Pancreatic biopsy is useful in the diagnosis of neoplasms of the pancreas and to determine whether pancreatic enlargement is caused by inflammation or neoplasia. Many of the microscopic lesions seen in the pancreas are incidental findings and are not associated with serious clinical problems.

Pancreatic Atrophy

Atrophy of the pancreatic acinar cells can occur as a primary condition[1] or be secondary to chronic inflammation and fibrosis, starvation, or duct obstruction.[2,3]

Primary Pancreatic Acinar Atrophy Associated with Exocrine Pancreatic Insufficiency

Severe atrophy with loss of the majority of the pancreatic acini is an inherited condition in some canine breeds (German Shepherd dog, Rough-Coated Collie, and perhaps English Setter) that is caused by immune-mediated destruction of acinar cells and is associated with EPI.[1] It may occasionally be seen in other breeds. Before the pathogenesis was understood, this lesion was usually only observed in the later stages. Early lesions associated with subclinical disease are characterized by infiltration of lymphocytes, and fewer plasma cells and macrophages, at the border of normal and disorganized atrophic parenchyma and extending into the normal parenchyma. Lymphocytes may also be present within acinar and ductal epithelium and lymphoid follicles may be present. The lymphocytes

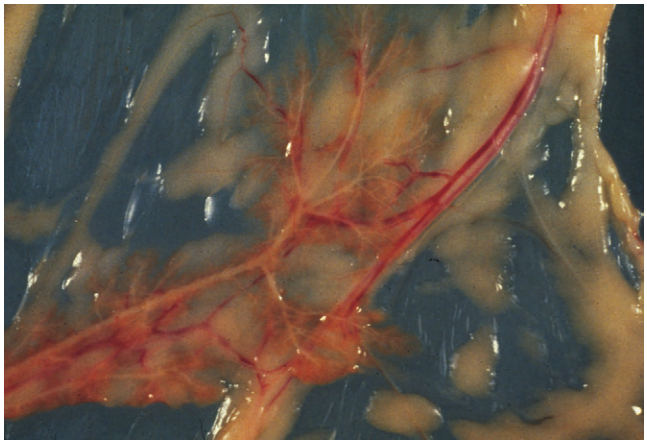

Figure 29-43 Severe pancreatic atrophy (canine); only pancreatic ducts, blood vessels, and adipose tissue remain.

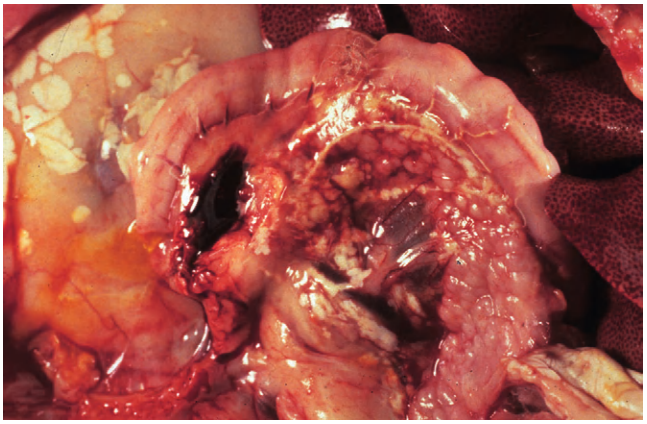

Figure 29-44 Acute pancreatitis (canine) with coagulation necrosis and hemorrhage of the pancreatic parenchyma. Cross-section of pancreas and duodenum (*below*).

are mostly $CD3^+$ T cells with $CD8^+$ cells more common than $CD4^+$ cells. There is multifocal destruction and loss of adjacent pancreatic acinar cells with individual cell necrosis associated with the lymphocytic infiltration. This stage has been called atrophic lymphocytic pancreatitis.

In later stages, dogs develop clinical EPI and have severe atrophy of the exocrine pancreatic tissue. Grossly, often only pancreatic ducts and adipose tissue are seen (Fig. 29-43). Histologically, only ducts, a few disorganized or normal acini, scattered lymphocytes, and islets remain, with extensive replacement of the pancreatic parenchyma by adipose tissue, but there is only limited fibrosis. Islets are usually normal histologically.

Secondary Pancreatic Atrophy

Mild pancreatic acinar atrophy is common in dogs and cats that are anorexic, starved, have specific nutritional deficiencies, or have maldigestion syndromes.[2,3] In these animals there is a generalized decrease in the size of the acinar cells, increased cytoplasmic basophilia, and zymogen granules are decreased. Cytoplasmic vacuoles may be present in acinar cells in some cases and apoptosis may occur in some conditions. Blockage of pancreatic ducts also leads to focal, regional, or diffuse decrease in acinar cell size and zymogen content. Ducts may be blocked by inflammation, fibrosis, or neoplasia. Experimental duct ligation leads to necrosis, duct dilation, acinar atrophy, secondary inflammation, and periductal fibrosis. Subsequently ductular hyperplasia may occur. Chronic pancreatitis may also lead to acinar cell atrophy associated with fibrosis. Rarely, the atrophy is sufficiently severe to lead to EPI.[4]

Pancreatitis

Pancreatitis is a broad term that includes all of the responses to acute and chronic damage to pancreatic acini and ducts associated with inflammation including edema, hemorrhage, necrosis, inflammatory cell infiltration, vascular dilation, and eventual fibrosis and atrophy. These lesions may be focal, multifocal, regional, or diffuse and vary from mild to severe. In the condition that is usually referred to clinically as *acute pancreatitis* or *acute necrotizing pancreatitis*, necrosis is primary and predominates and the lesion is perhaps better termed "acute pancreatic necrosis".[2] Mild to moderate acute and chronic pancreatic inflammation are common and of uncertain clinical significance in the cat[5,6] and dog.[7,8]

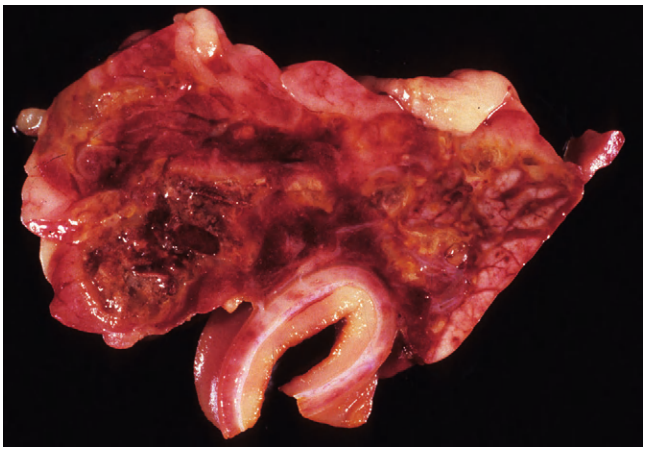

Figure 29-45 Acute pancreatitis (feline) with white plaques of peripancreatic fat necrosis and mineralization (saponification).

Acute Pancreatitis

In acute pancreatitis (acute necrotizing pancreatitis or acute pancreatic necrosis), necrosis usually predominates and is accompanied by varying degrees of inflammation in dogs[2,3,9,10] and cats.[2,3,11,12] Separation of the pancreatic lobes and lobules by edema occurs, and this is associated with early acute injury to the pancreas. Histologically, edema may appear as clear spaces or pale eosinophilic fluid separating cells, lobules, or lobes. Hemorrhage is also associated with acute injury and may be focal, multifocal, or diffuse.

In moderate to severe acute pancreatitis, focal, multifocal, confluent, or diffuse swollen, friable, and yellow-tan to red areas are seen grossly (Fig. 29-44). Multiple white plaques of fat necrosis and mineralization (saponification) in the peripancreatic fat (Fig. 29-45) are commonly associated with acute necrosis and inflammation of the pancreas. Areas of saponification also may be present throughout the abdominal fat and are occasionally seen in the subcutaneous or thoracic adipose tissue. The abdominal cavity may contain a serous to serosanguineous effusion with fat droplets and there may be fibrinous adhesions between the pancreas and the small intestine, colon, mesentery, or omentum. In very severe cases of acute pancreatitis, the adjacent wall of the duodenum may be necrotic and inflamed.

Histologically, in early acute pancreatitis, coagulation necrosis of the pancreatic parenchyma (Fig. 29-46) is often seen peripherally

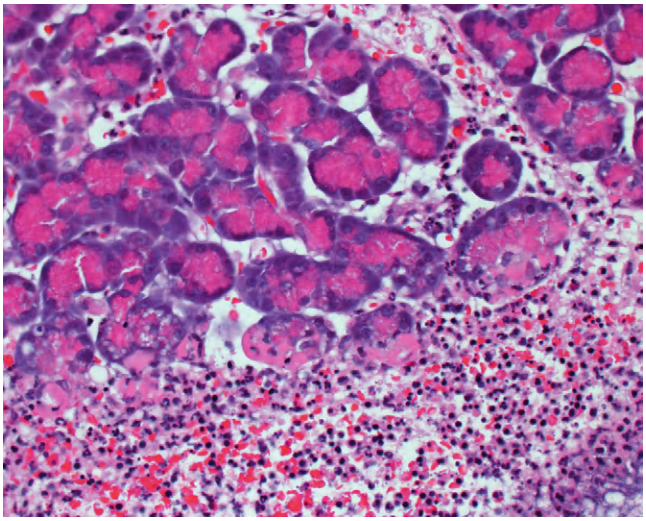

Figure 29-46 Acute pancreatic coagulation necrosis in a dog (*bottom*) showing infiltration of neutrophils and hemorrhage.

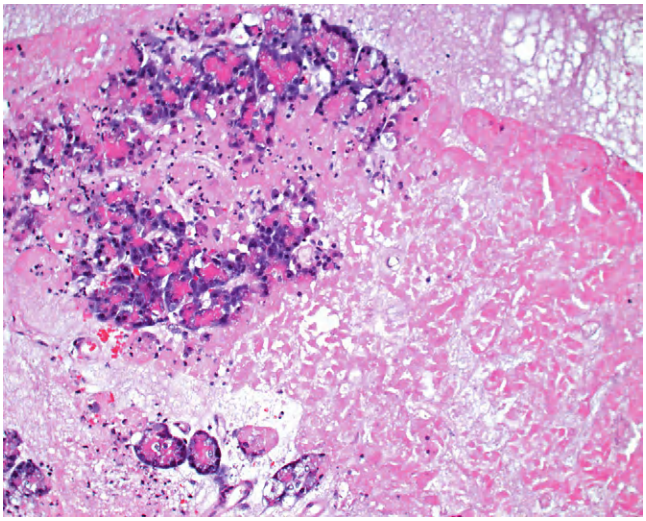

Figure 29-47 Acute coagulation necrosis of all but a few pancreatic acini (canine).

in the lobules in mild disease, but may involve the entire pancreas when severe (Fig. 29-47). Liquefactive necrosis may accompany or follow coagulation necrosis. Necrosis is often accompanied by peripancreatic fat saponification (Figs. 29-48 and 29-49). Infiltrates of neutrophils frequently accompany both pancreatic necrosis and peripancreatic fat necrosis (Figs. 29-48 and 29-49) and exacerbate injury to the pancreas by the release of enzymes. Septa between lobules are usually expanded by hemorrhage, fibrin, neutrophils, and macrophages. There may be local destruction of small blood vessels associated with hemorrhage, and thrombi are common in small veins and arteries in severe disease (Fig. 29-50) leading to further ischemic damage to the pancreas. Thrombi may extend into the portal vein from the pancreas.[13]

Occasionally, in both dogs and cats, neutrophils may predominate in acute pancreatitis without extensive necrosis. They may be seen in the parenchyma, in the interlobular septa, or in the

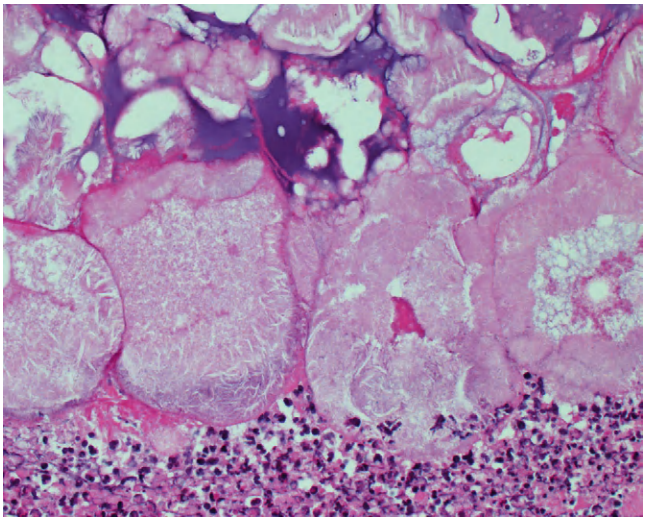

Figure 29-48 Peripancreatic fat necrosis and mineralization (*upper left*) surrounded by inflammatory cells (feline).

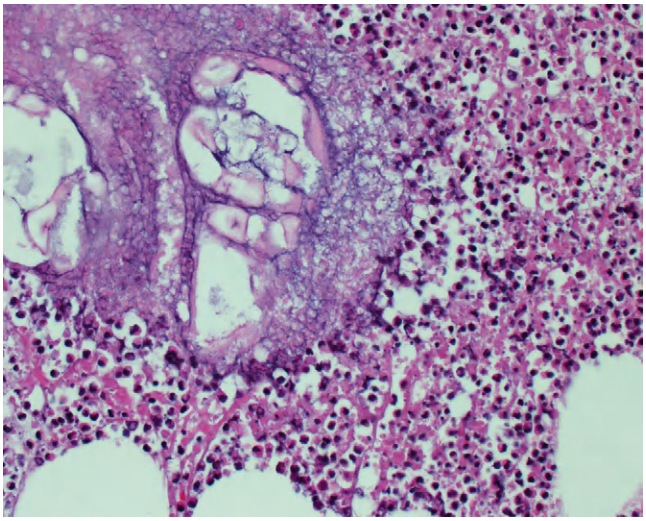

Figure 29-49 Necrotic and mineralized fat (*above*) and viable and necrotic neutrophils (*below*).

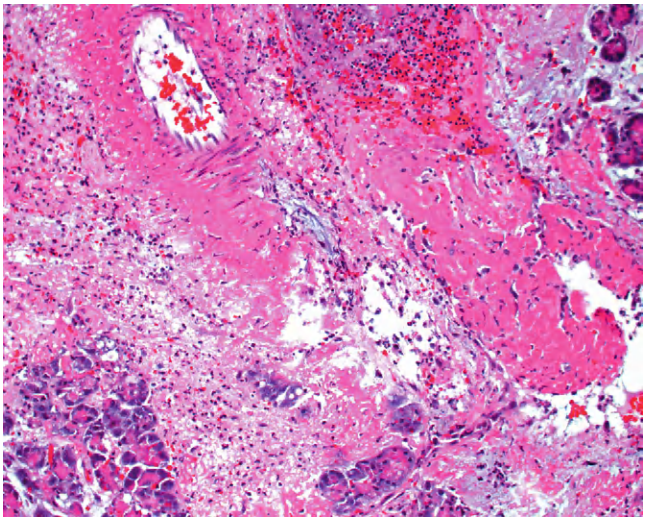

Figure 29-50 Acute pancreatitis with necrosis of arterioles (*upper left*) and venous thrombus (*upper right*).

pancreatic ducts. Suppurative ductal inflammation occurs in young cats,[11] but less commonly in dogs.

Abscesses and/or pseudocysts may occur in acute necrotizing or suppurative pancreatitis and may be found in the pancreas or adjacent to it.[14] These two conditions may be difficult to distinguish clinically and pathologically. Abscesses are localized collections of pus, which consist of neutrophils and necrotic tissue debris, and they are usually sterile. Pseudocysts are focal nonepithelial lined collections of fluid containing pancreatic enzymes, necrotic debris, and, in some cases, red blood cells and inflammatory cells. With time, both may develop peripheral granulation tissue and eventually an outer rim of mature fibrous connective tissue. Measurement of intralesional pancreatic enzymes may be necessary to distinguish abscesses from pseudocysts.[14]

Fibrosis and infiltrates of lymphocytes and plasma cells are seen in some dogs and cats with acute necrotizing pancreatitis, presumably because of previous bouts of necrosis and inflammation.

Acute multifocal pancreatic necrosis with minimal inflammation has been reported in association with canine parvovirus, canine distemper virus, and feline herpesvirus infections.[3] Pancreatic necrosis and inflammation can also be seen with toxoplasmosis and feline infectious peritonitis, although it is rarely clinically relevant. Pancreatic necrosis and inflammation has been produced experimentally in cats and naturally in dogs with zinc toxicity.[3]

Chronic Pancreatitis

Chronic pancreatic inflammation may be the result of acute pancreatitis or be a chronic process not preceded by clinical evidence of an acute injury. Some degree of inflammatory cell infiltration of the pancreas with age is common and of undetermined significance.[5,7,8] The pancreas may be grossly normal or small, firm, irregular, and nodular (Fig. 29-51). Peripancreatic fat saponification, pseudocysts, abscesses, and fibrous adhesions to adjacent abdominal structures may be present. Histologically, there are varying degrees of acinar atrophy and fibrosis (Fig. 29-52) with scattered or clustered lymphocytes and plasma cells (Figs. 29-53 and 29-54) and occasionally macrophages and neutrophils. Hyperplasia of ducts is relatively common in chronic disease and some ducts may be dysplastic. Lesions may be focal, multifocal, or regional, and mild to moderate lesions are common in dogs and cats without obvious clinical pancreatic disease.

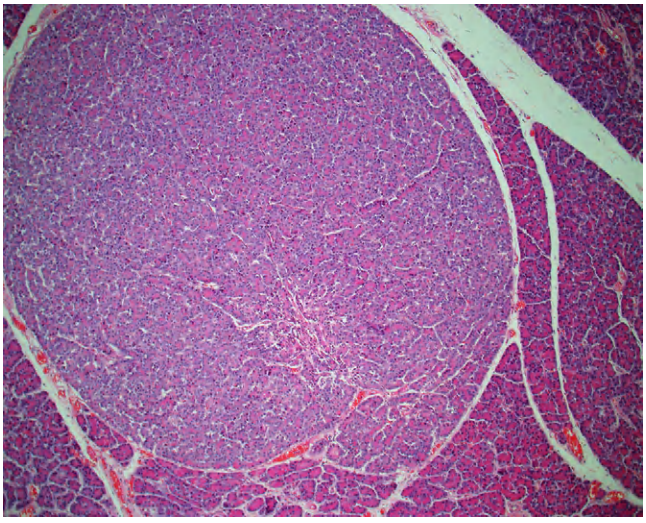

Figure 29-56 Pancreatic nodular hyperplasia (feline). An unencapsulated focal collection of well-differentiated acinar cells.

Incidental Findings and Lesions of Unknown Significance

Ectopic or Accessory Pancreatic Tissue (Pancreatic Choristoma)

Small masses of normal pancreatic acinar tissue are seen rarely in ectopic sites in the abdomen. Common sites are the serosa or muscular wall of the duodenum, mesentery, stomach, spleen, liver, and gallbladder. Islets are not always identified in ectopic pancreatic tissue.

Cysts and Ductal Dilation

Cystic ducts and acini and dilated pancreatic ducts are incidental findings in older dogs and cats. Many of these animals also may have mild to moderate chronic pancreatitis and nodular hyperplasia.

Vacuoles in Acinar Cells

Clear cytoplasmic vacuoles are seen sporadically in acinar cells, particularly in the cat (see Figs. 29-54 and 29-55). Epithelial vacuoles may also be seen in hyperplastic and dysplastic nodules.

Fat Infiltration

In older animals the pancreatic lobules may be surrounded and infiltrated by normal adipose tissue. This is particularly common in overweight animals. Fat infiltration is also common in severe pancreatic atrophy in dogs.

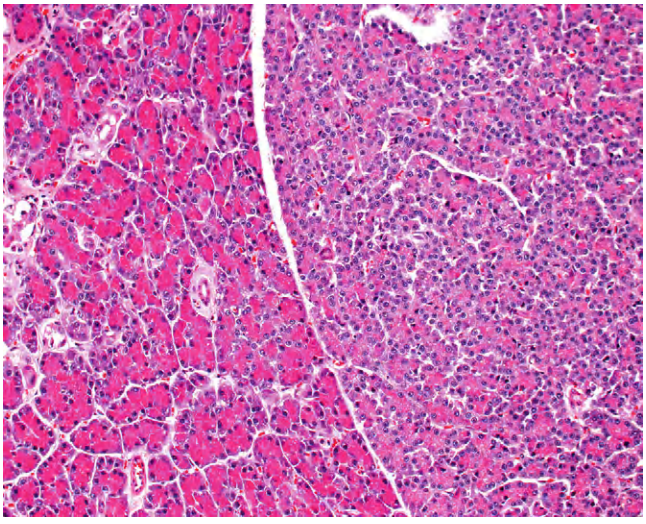

Figure 29-57 Pancreatic nodular hyperplasia (feline). The cells in the nodule (*right*) are more basophilic and contain fewer cytoplasmic zymogen granules.

Hyperplasia and Neoplasia

Nodular Hyperplasia

Small (1- to 10-mm diameter) tan or tan-pink, slightly firm nodules are common in the pancreas of dogs and cats and increase in number and frequency with age (Fig. 29-55). Histologically, even smaller nodules are common. The nodules are usually not encapsulated by fibrous tissue and do not compress the adjacent pancreatic parenchyma (Fig. 29-56). They are usually composed of clusters of well-differentiated cells that form acini and contain variable amounts cytoplasmic zymogen granules (Fig. 29-57). Nodules of less-well-differentiated cells with larger nuclear to cytoplasmic ratios and scant amphophilic cytoplasm containing clear cytoplasmic vacuoles without zymogen granules have been described in cats.[5] Nodules composed of ductular epithelial cells are less common in dogs and cats (Fig. 29-58).

Adenomas

Pancreatic adenomas are rare and are composed of well-differentiated acinar or ductular epithelial cells that are encapsulated and compress the adjacent parenchyma (Fig. 29-59). They are grossly similar to nodules of hyperplasia, and the two lesions may be difficult to distinguish histologically.

Carcinomas

Carcinomas of pancreatic acinar or ductular epithelial origin occur in cats and dogs.[2,3] They are usually firm and tan to pink in color, and may contain yellow-tan areas of necrosis, gritty white areas of mineralization, or red areas of hemorrhage. They are sometimes accompanied by inflammation and necrosis of the adjacent pancreas and by necrosis and mineralization of peripancreatic fat, which can

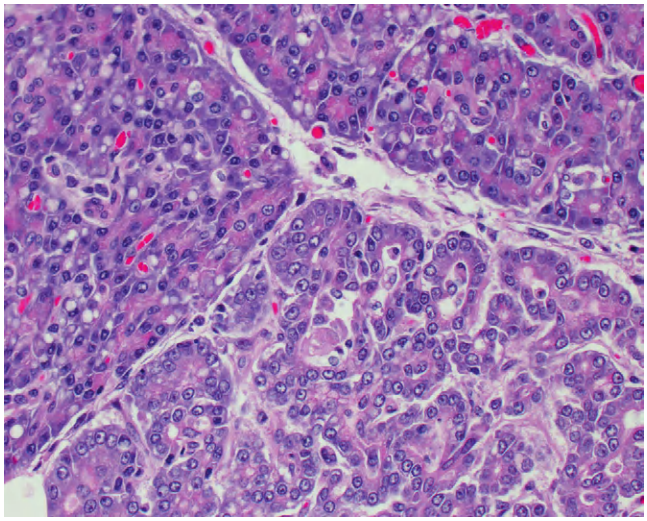

Figure 29-58 Pancreatic nodular hyperplasia (feline). Nodule of ductular origin (*lower right*). Some normal acinar cells contain cytoplasmic vacuoles.

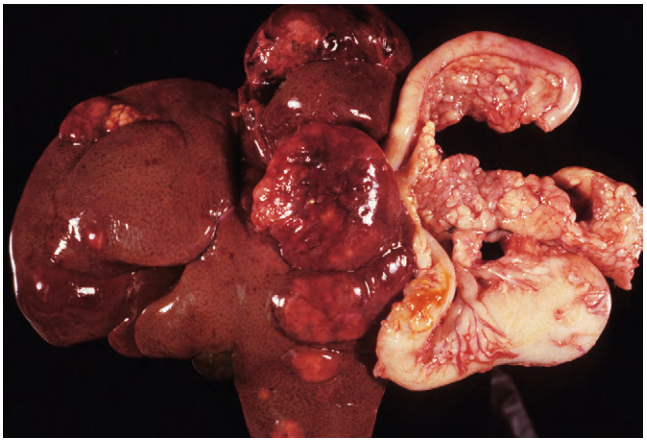

Figure 29-60 Pancreatic carcinoma (*lower right*) with multiple liver metastases.

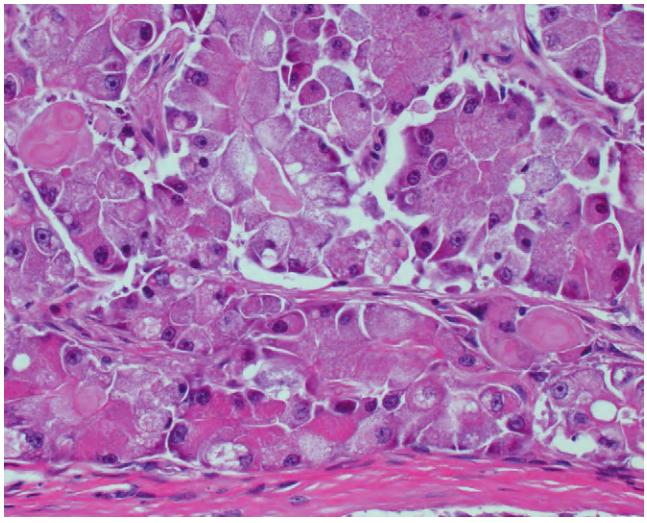

Figure 29-59 Pancreatic acinar adenoma composed of well-differentiated acini bordered by a fibrous capsule (*bottom*).

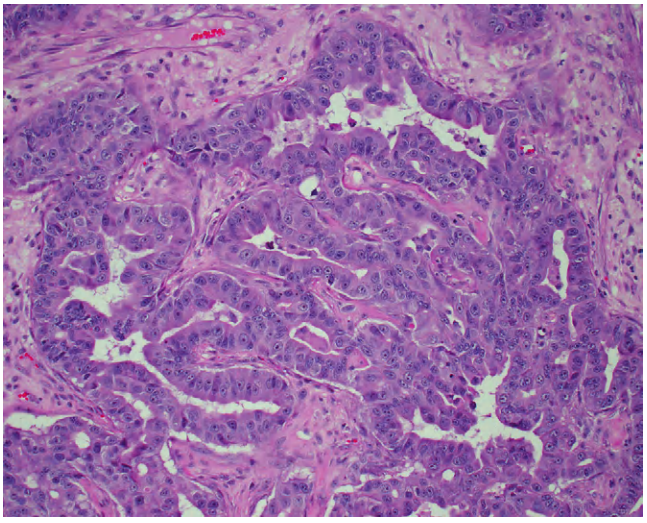

Figure 29-61 Pancreatic ductal carcinoma (feline).

mask the neoplasm, grossly. Carcinomas may present as a single nodule or coalescing nodules that may extend into the adjacent mesentery or invade the duodenum or liver (Fig. 29-60). The cells form ducts, tubules, or acini or have a solid pattern. The neoplastic cells exhibit a broad range of morphologies, from relatively well-differentiated acinar or ductular cells (Fig. 29-61) to poorly differentiated anaplastic polygonal cells with large nuclear-to-cytoplasmic ratios, scant amphophilic to basophilic cytoplasm, and numerous mitotic figures. In anaplastic tumors it may not be possible to determine if the tumor is of exocrine or endocrine (islet) origin by routine light microscopy. Islet cell tumors may be positive for insulin, glucagon, or somatostatin and are usually positive for chromogranin by immunohistochemistry. Carcinomas may spread into the adjacent duodenum, stomach, and liver, and also spread throughout the abdomen (carcinomatosis). Pancreatic carcinomas frequently elicit a desmoplastic response with cells surrounded by fibroblasts and collagen (Fig. 29-62). In poorly differentiated tumors that have spread into adjacent organs, it may be difficult to determine whether

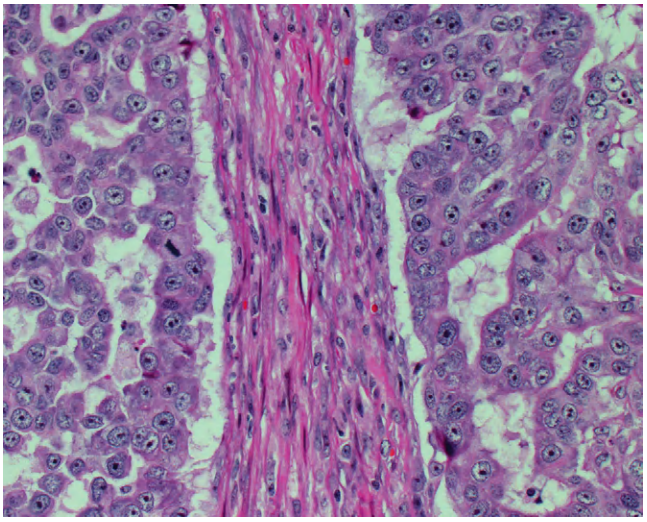

Figure 29-62 Pancreatic ductal carcinoma with desmoplasia (feline).

the carcinoma is of pancreatic, biliary, gastric, or intestinal origin by light microscopy.

Other Primary Neoplasms

Nonepithelial primary tumors of the pancreas are rare and include fibromas, fibrosarcomas, liposarcomas, and nerve sheath tumors.[3]

Metastatic Neoplasms

Metastatic neoplasms that may involve the pancreas include hemangiosarcoma, lymphoma, malignant melanoma, a variety of carcinomas, and osteosarcomas.[3,18]

HEPATOBILIARY

John M. Cullen

Normal Liver Histology

Abnormal histology of the liver can be best appreciated when the normal histologic appearance is well understood. There are a number of models that describe the structural unit of the liver.[1,2] In this section, the standard lobule is used as the structural unit of the liver. The liver is a three-dimensional structure and can be envisioned as a tightly packed cluster of grapes with each grape representing a lobule. From the two-dimensional microscopic perspective the "typical" lobule is outlined by a hexagon of portal tracts about 1 mm in diameter with a central vein (terminal hepatic venule) at its center, although some lobules form imperfect hexagons (Fig. 29-63). Portal tracts usually contain a branch of the portal vein and one or two branches of the hepatic artery, as well as a bile duct. In addition, the portal tract contains abundant connective tissue as well as lymphatics and nerves. However, there is normal variation in the number of bile ducts and hepatic artery branches. Usually, the portal vein profile is larger than the surface area of the bile ducts and the hepatic arteries. There is a distinct border between the portal tract connective tissue and the initial surrounding row of hepatocytes, termed the *limiting plate*. Between the portal tract and the central vein the hepatocytes are arranged in radial plates that are one or occasionally two cells thick. Normal hepatocytes have abundant cytoplasm that is more than three to four times the surface area of nucleus and the cytoplasm may be vacuolated to various extents. Frequently, there is a mild to moderate coarse, irregular, clear vacuolation caused by the presence of stored glycogen. Hepatocytes may vary in size in response to systemic or localized factors. Blood oxygen is highest in the periportal regions of the lobule where blood from the portal veins enters the sinusoids and lowest in the centrilobular areas. Centrilobular hepatocytes may become smaller than normal when blood oxygen levels become too low (e.g., during anemia or chronic congestion) or hepatocyte oxygen demands increase (e.g., during heat stroke). Centrilobular hepatocytes may become enlarged where there is induction of drug metabolizing enzymes as these enzymes are in the highest concentration in these hepatocytes. In older cats, the centrilobular hepatocytes often contain brown granular lipofuscin pigment. Mitotic activity of hepatocytes is rarely seen in the normal liver.

Hepatic plates are separated by vascular sinusoids formed by specialized endothelial cells, evident only by their flattened nuclei along the sinusoid, and characterized by fenestrations that are evident only at the ultrastructural level. The relationship between hepatocytes and sinusoids is viewed two-dimensionally under the microscope, but is ideally envisioned in three dimensions. The portal tracts can be viewed as tree trunks and the finest branches of the distributing portal veins and the hepatic arterioles as branches that extend into the hepatic parenchyma where they open into the sinusoids. These small caliber vessels can occasionally been detected histologically. There are no divisions between normal lobules and there is ready flow of blood between them.

The sinusoids also contain Kupffer cells, actively phagocytic cells that sit on the endothelial cells within the flow of sinusoidal blood. The number and size of these cells can vary with systemic and local inflammation or other stimuli, but they are usually evident histologically due to their abundant cytoplasm. Hepatic stellate cells reside between the hepatocytes and the endothelial cells, in the space of Disse. In normal circumstances these cells can be identified histologically, because they contain lipid vacuoles with stored retinoids. They are usually more prominent in cats than in dogs. It is important to "census" the normal structures as the initial step in the slide review process because the absence of a normal structure can be clinically significant. Pathologists are trained to search for abnormalities, but may overlook the absence of a normal structure, and consequently a diagnosis, if a consistent search pattern is not used during the examination.

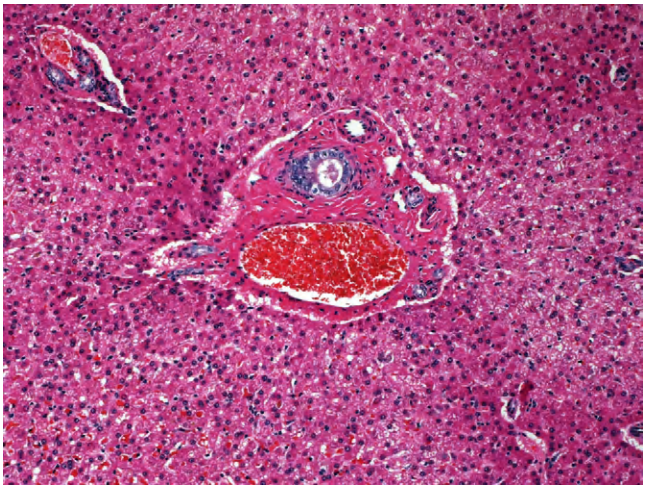

Figure 29-63 The normal portal tract contains a portal vein, hepatic artery, and bile duct gathered within a connective tissue sleeve that is bordered by a uniform row of hepatocytes, termed the *limiting plate*.

Gross Assessment of Liver Pathology

Gross examination of the liver may take place during laparotomy or postmortem examination. Table 29-3 summarizes the main gross pathologic changes and possible diagnoses. These disorders are described in detail in the following sections.

Optimal Liver Biopsy Collection

Consultation with the pathologist is often a useful first step in the biopsy procedure; particularly when there is a clinical indication for special handling of the specimen. The optimal size of the biopsy is determined by balancing the need for sufficient tissue to enable diagnosis and the clinician's concern for the patient. Disorders with diffuse and uniform appearance require the least amount of tissue to make a diagnosis. Other disorders, particularly chronic inflammation, can vary from lobe to lobe and even within a lobe and require multiple sections for accurate assessment of the

Table 29-3 A Gross Morphologic Approach to Liver Pathology

Gross Appearance	Possible Diagnoses
Uniformly small liver	Vascular anomaly Starvation Massive necrosis
Uniformly small, firm liver	Lobular dissecting hepatitis
Uniformly small liver with nodules	End-stage fibrosis with nodular regeneration (cirrhosis)
Uniformly enlarged liver	Infiltrative disease Round cell neoplasia Lymphoma Myeloid neoplasia Enlarged hepatocytes Glycogen Steatosis (lipid) Storage diseases Expanded sinusoids Acute congestion Amyloid Acute congestion Amyloid Expanded hepatocytes Lipid Glycogen storage products Expanded sinusoids Acute congestion Round cell tumor Expanded hepatocytes Lipid Glycogen storage Expanded sinusoids Acute congestion Amyloid
Normal-size liver: altered color	Anemia Bile retention Iron/hemosiderin Chronic passive congestion Hemochromatosis Copper Hemosiderin-CPC Copper bile
Normal-size liver: foci	Small white foci ~1 mm Gout/septicemia/viral Larger white/red foci Focal necrosis/acute toxicity Focal inflammation Granulomas Abscesses Metastasis Biliary hyperplasia Congenital biliary anomalies Focal inflammation Granulomas, abscesses Metastasis/biliary hyperplasia Biliary anomalies
Single lobe affected	Torsion other vascular accidents Portal streaming of toxic insult? Portal streaming/toxicity?
Nodular liver	Single nodule Nodular hyperplasia Biliary cysts Hepatic or biliary adenomas Primary carcinomas Multiple nodules Regenerative nodules/end-stage liver Nodular hyperplasia (dogs) Metastasis

health of the liver. Wedge biopsies provide a more accurate view of most liver disorders than needle biopsies,[3] but it is disappointing, at the least, for the pathologist to receive a single wedge of liver after the patient has undergone a laparotomy. Despite the apparent normality of liver at surgery, histologic evaluation is frequently useful. Multiple small wedges from several lobes are preferred over a larger section from a single lobe. Needle biopsies can be sufficient for many approaches, but multiple biopsies from more than one liver lobe are desired. In any event, properly collected and handled tissue is essential for optimal microscopic evaluation. Once collected, the liver tissue should be handled as little as possible to avoid physical distortion or loss of tissue. This is particularly true of needle biopsies. Small or fragmented biopsies can be placed into embedding bags or plastic cassettes with a screen mesh. In most circumstances, the tissue should be placed immediately into 10% neutral buffered formalin. Tissue should not be more than 0.5 to 1 cm at its greatest thickness and the ratio of formalin to tissue should be 10:1. If immunohistochemistry (IHC) is to be performed, the tissue should be processed within 48 hours to avoid overfixation.

If electron microscopy is required, sections should be cut with a scalpel into 1-mm pieces and then placed into an appropriate fixative such as Trump's. Electron microscopy can be useful in certain storage disorders, mitochondrial abnormalities or infectious diseases. Frozen sections are required for certain antibodies applied in IHC, particularly those used to identify various tumor cell types, as formalin fixation can destroy relevant antigens. Frozen sections can also be used for microbiology, genetic studies, and some special stains (e.g., lipid stains) more effectively than formalin-fixed samples. Frozen sections are also useful for evaluations of hepatic metals such as iron and copper. Formalin-fixed liver is also suitable for this purpose if the sample is sufficiently large (i.e., bigger than a needle biopsy)[4] and, in cases of storage disorders, analysis of stored material may be possible.

Liver biopsies are stained routinely with hematoxylin and eosin (H&E), but evaluation is often enhanced by a battery of special stains. Some pathologists advise that a particular set of stains is done on all samples as part of the routine evaluation, but this step varies with pathologists and financial constraints. Table 29-4 lists histochemical stains and their targets.

Table 29-4 Selected Special Stains Used in Diagnostic Histopathology of the Liver

Material Stained	Stain Name(s)	Stain Appearance
Amyloid	Congo red	Green under polarized light
Glycogen	Periodic acid-Schiff (PAS)	Purple (removed with diastase treatment)
Lipid	Osmium	Black
	Oil red O	Red
Connective tissue/ collagen	Sirius red	Deep red
	Masson's trichrome	Blue
Reticulin	Reticulin stain (Gordon and Sweet)	Black
Iron	Perl's Prussian blue	Deep blue
Copper	Rhodanine	Orange brown
Lipofuscin	Schmorl	Blue-green
	PAS (diastase resistant)	Magenta
	Acid-fast	Red

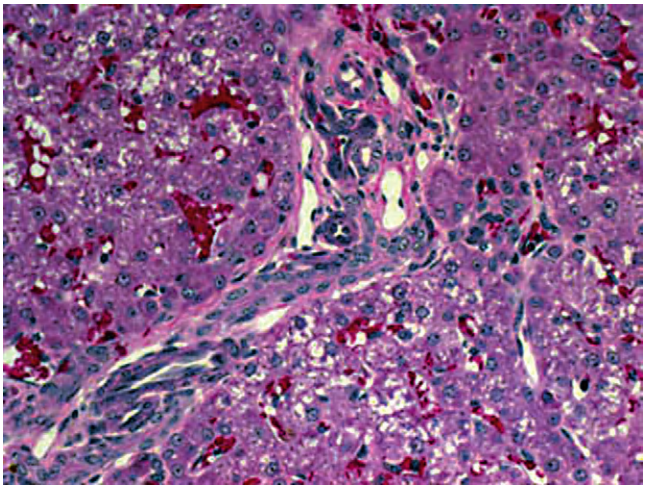

Figure 29-64 Portal tracts lack a normal portal vein profile and contain an increased number of small-caliber arterioles in cases of portosystemic shunts, as well as other conditions that lead to hypoperfusion of the liver via the portal vein. Lymphatics may also be dilated.

Circulatory Disorders

Congenital Vascular Anomalies

Normal liver function is dependent on a close interrelationship between hepatocytes and blood from the portal vein. Congenital abnormalities that lead to inadequate portal vein flow into the liver are manifested grossly as microhepatica, because of reduction in the size of hepatocytes and smaller lobules. Loss of sufficient nutrition, growth factors, and oxygen all contribute to the abnormalities of the hepatocytes. In addition to congenital vascular anomalies, starvation and anemia are should be considered when the liver is smaller than normal.

Congenital Portosystemic Shunts

A congenital portosystemic shunt is an abnormal vascular channel that allows a portion of the blood within the portal venous system to bypass the liver and to drain into the systemic circulation. Shunts occur most commonly in the dog, but are also described in cats.[5] A congenital shunt can be either intra- or extrahepatic in location, but is almost always limited to a single vessel.[5] Extrahepatic congenital shunts can occur between a variety of sites within the portal drainage and the systemic venous system. Extrahepatic shunts occur more often in small breeds of dog. Typically, intrahepatic portosystemic shunts involve failure of closure of the fetal ductus venosus at birth. These shunts, like the ductus venosus, are most often located in the left side of the liver. This anomaly occurs most often in large breed dogs. Regardless of the site of the shunt, affected animals are typically stunted and frequently develop signs of hepatic encephalopathy. The liver is small and microscopically displays hepatocellular and lobular atrophy.[5] There is an increase in the profiles of hepatic arterioles within the portal areas, presumed to relate to a compensatory increase in systemic arterial blood flow, in response to the inadequate portal flow. There is also sometimes a proliferation of small caliber bile ducts. Portal vein profiles are smaller than normal or absent (Fig. 29-64). Changes in the central and sublobular veins are often overlooked or misinterpreted. Dogs have a spiral smooth muscle surrounding the hepatic veins that can contract to restrict blood flow from the liver. This muscle constricts in response to various pharmacologic agents and presumably in shock. In some instances, dogs with hypoperfusion of the portal vein, regardless of the cause, have constricted smooth muscle, leading to a small-caliber hepatic vein with prominent smooth muscle (Fig. 29-65). This change has been misinterpreted as "arterialization" of hepatic veins. Surrounding lymphatics are also often distended. Variable numbers of lipogranulomas, collections of vacuolated and pigmented macrophages, can be found in the parenchyma or within the portal areas. Portal vein pressure is normal in congenital shunts and ascites does not occur. At postmortem examination abnormal vascular anastomoses are often difficult to identify without the benefit of antemortem imaging studies to localize the shunting vessel. The histologic appearance of congenital portosystemic shunts and other vascular anomalies of the liver have considerable overlap as the liver has a stereotypical response to inadequate portal perfusion. Clinical data, such as the presence or absence of shunt vessels and the determination of portal vein pressure, may be needed to achieve a final diagnosis.

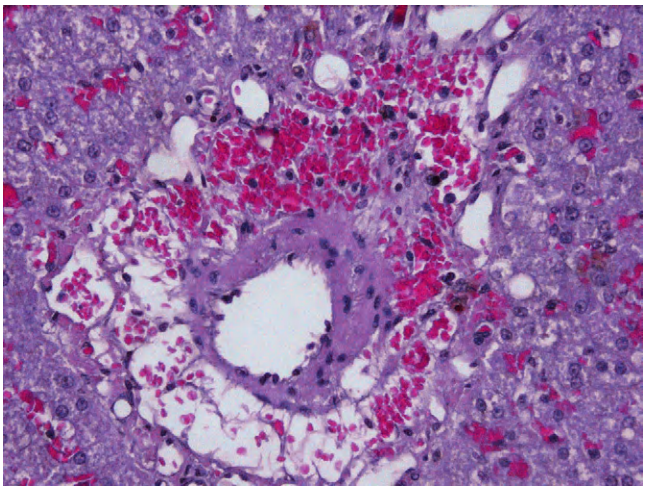

Figure 29-65 The spiral smooth muscle that surrounds sublobular veins can contract in cases of hepatic hypoperfusion, among other causes, increasing the prominence of the muscle, which can resemble an artery.

Disorders Associated with Portal Hypertension

Portal Vein Hypoplasia (Microvascular Dysplasia, Noncirrhotic Portal Hypertension)

Portal vein hypoplasia is a congenital vascular anomaly that occurs in dogs and occasionally in cats that is characterized by abnormally small extrahepatic or intrahepatic portal veins, diminished hepatic perfusion by portal vein blood flow and the potential for portal hypertension.[5] There is considerable discussion surrounding the preferred terminology for this condition and there are several synonyms associated with this condition.[6] Recently, the term *portal vein hypoplasia* has been recommended to identify this condition.[7] Typically, affected animals have small livers, and the microscopic changes include portal vein hypoperfusion, small or absent portal veins, proliferation of hepatic arterioles, and hepatocyte atrophy. Lipogranulomas, constricted hepatic veins, and distended perivascular lymphatics may also be present. This disorder resembles portosystemic shunting histologically, but affected animals often have portal hypertension and resultant ascites. Portal fibrosis and biliary hyperplasia occur in about half of the cases. Because of the histologic similarities between portal vein hypoplasia and congenital portosystemic shunts, clinical procedures (e.g., imaging to determine the presence of a shunt vessel) are often required to make a final diagnosis.

Intrahepatic Arteriovenous Fistulas

Intrahepatic arteriovenous fistulas arise from a direct communication between the hepatic artery and the portal vein and occur in dogs and cats. The size of the vessels involved affects the degree of injury. Arteriovenous fistulas may be single or multiple and occur anywhere within the liver. Affected portions of the liver contain dilated, tortuous, pulsating vessels.[8] Several histologic abnormalities are present in the hepatic artery branches, including partial elastosis, intimal hyperplasia, and smooth muscle hyperplasia with areas of degeneration and scattered disorganized elastin fibers and areas of degeneration (Fig. 29-66). Portal vein branch abnormalities include prominent dilation, with abnormal, thickened walls. The liver adjacent to the fistula has the typical appearance of portal hypoperfusion. Arterial shunting of blood may lead to portal hypertension or reversal of the direction of portal blood flow, and subsequent development of acquired portocaval shunts and ascites.

Portal Vein Obstruction

Obstruction of the portal vein may occur by thrombosis or by compression from local inflammation (e.g., acute pancreatitis or abscess formation) or neoplastic processes that surround the vein. In the affected livers, the portal vein profiles may be reduced in diameter as a consequence of restricted flow, or may contain thrombi or emboli. Depending on the cause of the obstruction, tumor emboli or inflammatory aggregates may also be found in portal vein branches.

Impaired Hepatic Perfusion

Ischemia

Reduced blood flow to the liver leads to hepatocyte atrophy or necrosis. The rate and magnitude of blood flow or oxygen content determines the balance between necrosis and atrophy. Hepatocytes are resilient and only sudden drops in perfusion lead to acute necrosis. Acute necrosis is evident first in the centrilobular areas, as the oxygen-rich blood enters at the periportal region and progressively loses its oxygen as it travels along the sinusoid toward the central vein. Sudden loss of perfusion from shock, ruptured chordae tendineae, or hemolysis can produce generalized centrilobular necrosis (Fig. 29-67). This lesion is histologically very similar to acute hepatotoxicity and clinical data are often needed to clarify the pathogenesis. Random foci of ischemic necrosis are more likely attributed to localized disruption of blood flow, which can follow fibrin deposition within sinusoids during DIC.

Infarction of the liver is uncommon because of its dual blood supply from the hepatic artery and the portal vein. Infarcts most often occur at the distal edges of the lobes where the perfusion fields dwindle. Affected areas are sharply delineated and dark red or pale. Histologically, coagulative necrosis of hepatocytes is evident.

Disturbances of Outflow

The most common cause of impaired outflow of blood from the liver is posthepatic and occurs in chronic passive congestion of the liver caused by cardiac disease. Histologically there is distention of

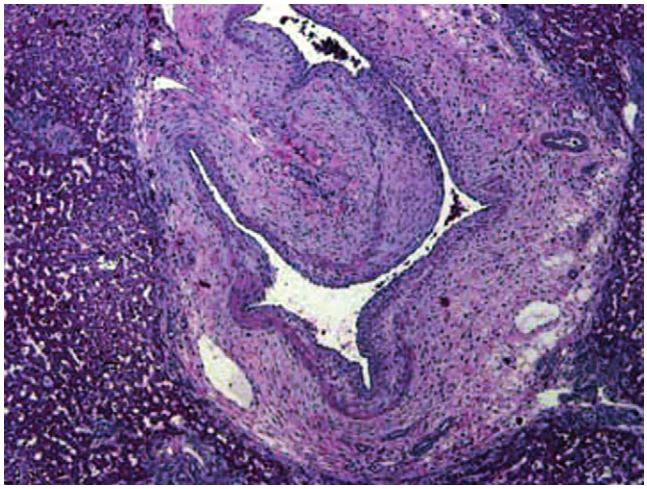

Figure 29-66 A hallmark of intrahepatic arteriovenous fistulas is the presence of a large distended vein with an altered wall formed in response to the increased and abnormal blood flow.

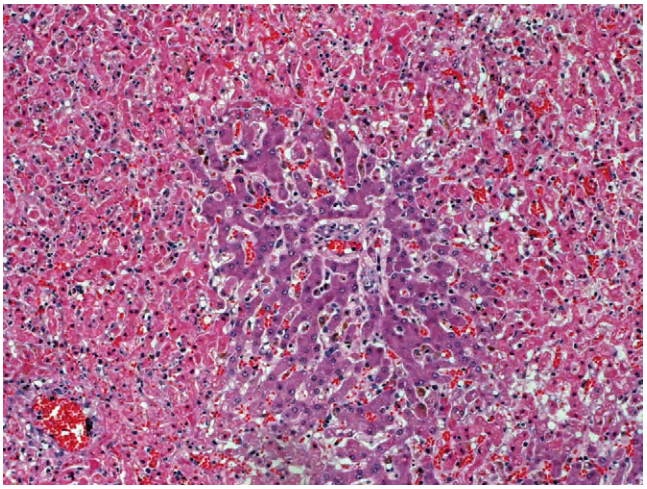

Figure 29-67 Acute centrilobular necrosis can occur in cases of sudden significant loss of oxygen delivery to the liver from acute anemia, blood loss, or cardiac decompensation.

hepatic veins, atrophy of centrilobular hepatocytes, and an abundance of hemosiderin within Kupffer cells. With chronicity, fibrosis emanating from the central veins can become prominent. Intrahepatic causes of outflow disorders are uncommon in cats and dogs.

Incidental Vascular Disorders

Peliosis Hepatis

Peliosis hepatis is defined as a random distribution of blood-filled cystic spaces in the hepatic parenchyma (Fig. 29-68). Grossly, these areas appear as variably sized dark blue-black foci within the liver that vary from pinpoint to several centimeters in size. Peliosis hepatis occurs in older cats and occasionally in dogs. Peliosis hepatis can be mistaken for a vascular tumor (e.g., hemangioma, hemangiosarcoma).

Biliary Disorders

Congenital Biliary Cystic Disease

Solitary Biliary Cysts

Solitary biliary cysts are uncommon in dogs and cats. They are thin walled and contain pale fluid. Histologically, the cysts are lined with a flattened single layer of biliary epithelium. It is not known if they are an acquired or a congenital disorder.

Congenital Cysts

Congenital biliary cystic diseases are a complex and potentially confusing collection of conditions of dogs and cats. In general they can all be attributed to abnormal development of the primordial biliary ductular system. The biliary tree arises from the ductal plate, an embryonic structure consisting of a two-cell-thick sheath of hepatoblasts that surround the primitive portal tract. Some cells in the ductal plate mature into the bile duct system, whereas others undergo apoptosis. Disturbances in development of this cell population give rise to a variety of biliary developmental abnormalities. Congenital biliary cystic disease is characterized by dilation of portions of the biliary tree and associated fibrosis. Similar lesions are frequently found in the renal tubules as well. Although the pattern of lesions and inheritance in domestic animals is not as clearly separated as it is in man, the WSAVA Liver Study Group[7] has proposed the following classification for congenital lesions of the biliary tree:

1. Congenital dilation of the large and segmental bile ducts (similar to Caroli disease)
2. Juvenile polycystic disease/congenital hepatic fibrosis
3. Adult polycystic disease (including von Meyenburg complexes)

Caroli Disease

Caroli disease is thought to be caused by an early defect in the formation of the bile duct system, affecting the larger-caliber bile ducts. In man, the disorder is characterized by saccular dilations of the larger intralobular, lobar, or common bile ducts, and cystic renal lesions may occur concurrently. Affected dogs have similar lesions, although the common bile duct was not abnormal.[9] Involved bile ducts often contain inspissated mucus, bile, and mineralized concretions. Histologically, the cystic bile ducts are lined by columnar epithelium and the portal tracts are fibrotic with bridging between portal tracts and proliferation of bile ducts within the areas of fibrosis. Acquired shunts may develop in affected dogs because of the extensive hepatic fibrosis.

Juvenile Polycystic Disease/Congenital Hepatic Fibrosis

Juvenile polycystic disease/congenital hepatic fibrosis can occur in dogs and cats.[10] This disorder is characterized primarily by microscopic abnormalities of the bile ducts. Typically there is formation of prominent portal-to-portal bridging fibrotic tracts within which there are abnormal, often irregular, mildly dilated biliary ducts (Fig. 29-69). The abnormal ducts are typically tortuous and may have small papillary projections into their lumina. Portal vein profiles may be reduced in area or absent, and arteriolar proliferation may be present. Portal vein hypertension can occur. Typically, this condition is recognized early in life, particularly when portal hypertension arises, but in other cases congenital hepatic fibrosis is only an incidental finding at postmortem.

Adult Polycystic Disease

In adult polycystic disease, the liver contains multiple unilocular or multilocular biliary cysts containing clear fluid that range from a few millimeters to several centimeters in diameter (Fig. 29-70).

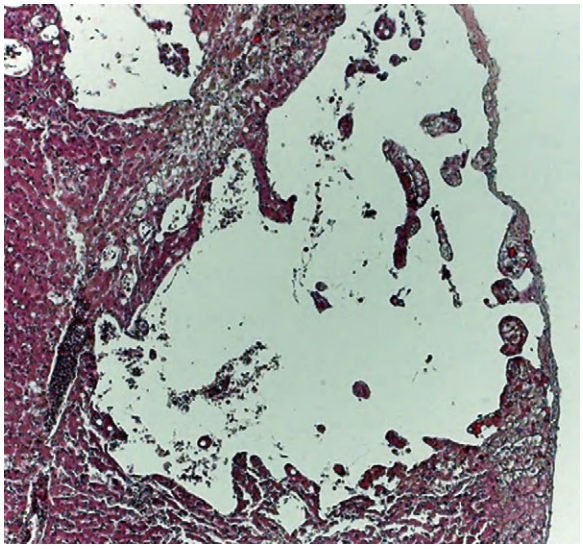

Figure 29-68 Peliosis hepatis is identified as a distended vascular space, usually a few millimeters in diameter, which may be lined by endothelium.

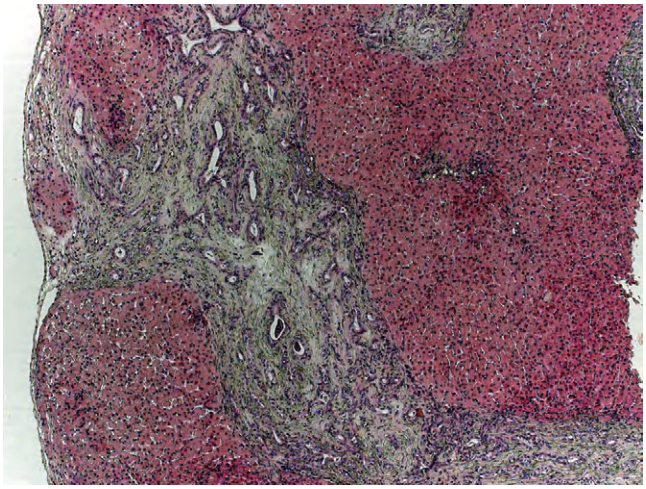

Figure 29-69 Congenital hepatic fibrosis in dogs or cats is characterized by portal-to-portal bridging fibrous bands of connective tissue that contain abundant, often abnormal, biliary ducts.

Hepatocytes are usually compressed at the margins of the cysts, or may, on occasion, be entrapped by expanding cysts. The stroma of the cyst wall consists of fibrovascular tissue with moderate amounts of collagen. Cysts are lined by normal biliary epithelium that may be simple cuboidal to flattened (Fig. 29-71). Another feature of affected livers is the presence of von Meyenburg complexes: discrete, usually subcapsular, fibrotic areas with small caliber bile ducts that typically have an irregular outline. They are usually smaller than a lobule. It is believed that some forms of this disorder have epithelial cells with a secretory phenotype and the production of fluid over time leads to the large cysts, while other forms do not secrete fluid and remain as the smaller von Meyenburg cysts. This would explain why cysts are not found in neonates despite the congenital nature of the disorders.

The well-known biliary and renal cystic disorder of Persian cats does not have a phenotype that allows consistent classification. Affected cats with renal cysts may develop biliary lesions typical of either juvenile polycystic disease or adult polycystic disease or a combination of the two. Other breeds of cats can develop congenital hepatic fibrosis and cysts; this may also occur in dogs.

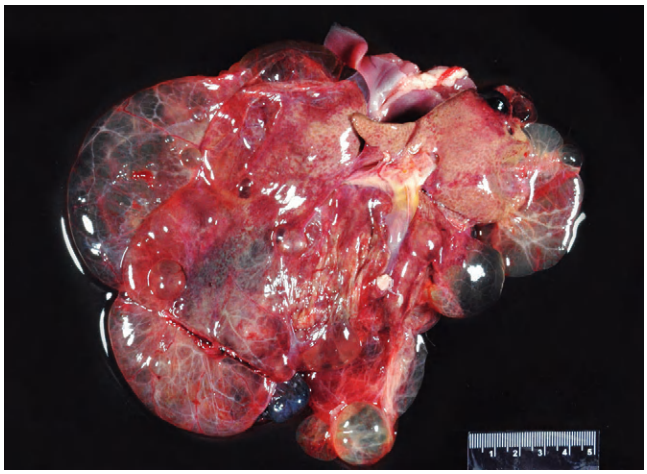

Figure 29-70 Polycystic biliary disease produces multiple cysts throughout the parenchyma of the liver. They are usually filled with clear to straw-colored fluid.

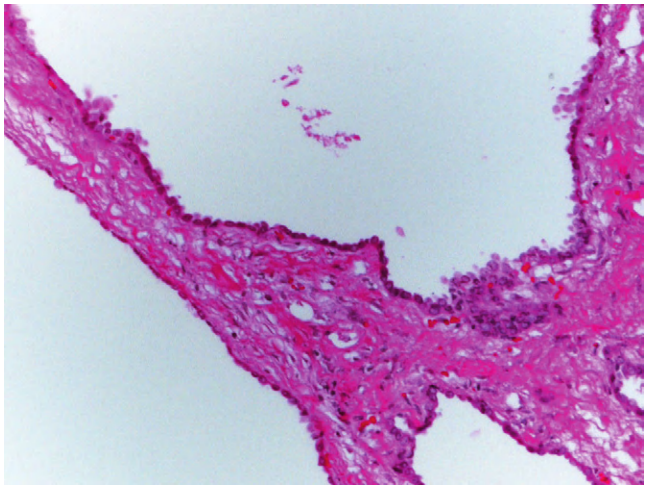

Figure 29-71 Congenital biliary cysts are lined by a single layer of cuboidal to flattened biliary epithelium.

Debate continues regarding the nature of multicystic biliary lesions in the canine liver. It is likely that the majority of these lesions are congenital ductal plate disorders, rather than neoplasms. Multicystic lesions in the kidney are recognized as congenital disorders and the multicystic biliary lesions found in dogs with simultaneous renal cystic disorders are similar to lesions previously diagnosed as biliary adenomas.

Cholestasis

Impaired bile flow accompanied by the accumulation in the blood of components normally secreted in the bile (e.g., bile acids, conjugated bilirubin, cholesterol) is termed *cholestasis*.[11] Cholestasis is characterized microscopically by the presence of bile in the hepatic parenchyma recognized as bile plugs in the canaliculi, phagocytosed bile in Kupffer cells or other macrophages, and, on occasion, as bile granules in the cytoplasm of hepatocytes. Cholestasis is easily recognized in cytologic preparations and frozen sections, but detectable bile is often reduced in the paraffin wax embedding procedure. Bile detection can be enhanced by using special stains (e.g., Hall's stain). In dogs, bile is rarely apparent histologically in hepatocellular cytoplasm.

Intrahepatic Cholestasis

Intrahepatic cholestasis is associated with a wide spectrum of liver diseases. In general, microscopic lesions apart from the cholestasis are related to the primary hepatic disease, but cholestasis may be the only histologic abnormality.[12] In acute cases, bile plugs in canaliculi and Kupffer cells may be evident, but this change is not specific for intrahepatic cholestasis (Fig. 29-72). Over time, bile plugs are less evident in canaliculi, but bile may be present somewhat longer in Kupffer cells.

Extrahepatic Cholestasis

Extrahepatic cholestasis can be associated with extraluminal compression of cystic or common bile ducts by tumors or local inflammatory processes. Intraluminal obstruction can arise from a variety of agents including choleliths, intraluminal neoplasia, parasites, or mucus plugs from gallbladder mucoceles. Regardless of the mechanism, the result is stasis of bile and dilation of the bile ducts proximal to the obstruction.

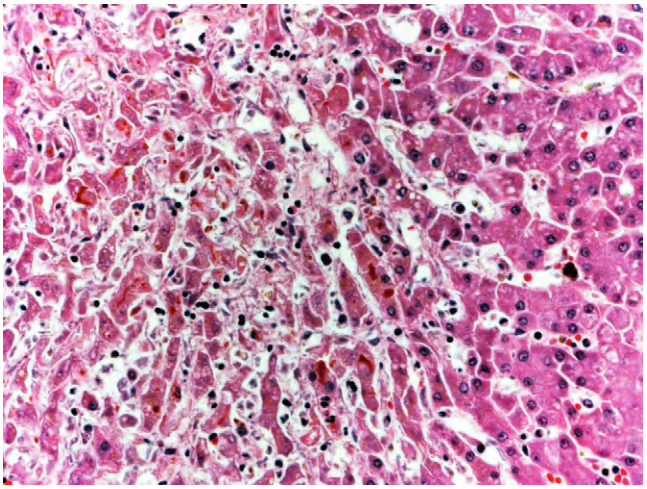

Figure 29-72 Acute intrahepatic cholestasis is characterized by the presence of bile plugs in the canaliculi that lie between adjacent hepatocytes.

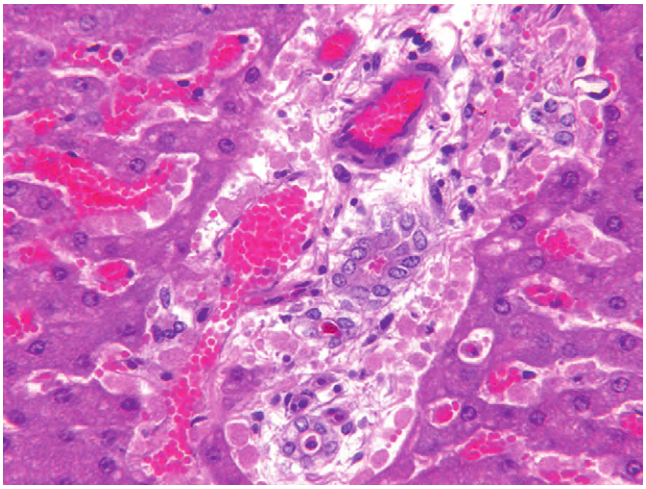

Figure 29-73 Acute extrahepatic cholestasis is characterized by portal tract edema, a light infiltrate of inflammatory cells, usually including neutrophils and degeneration or necrosis of biliary epithelium.

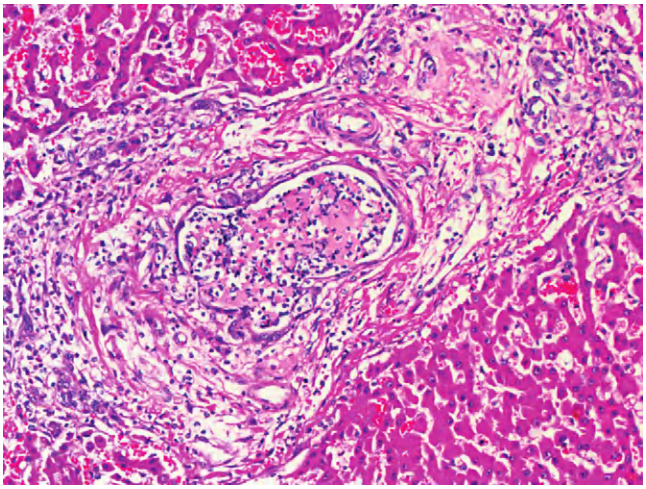

Figure 29-74 Neutrophilic cholangitis is characterized by the presence of degenerate or necrotic neutrophils within the lumen or within the wall of affected bile ducts.

The characteristic microscopic lesions of acute extrahepatic cholestasis in the dog are portal tract edema and infiltration of neutrophils around the interlobular bile ducts (Fig. 29-73). Biliary epithelium may be degenerate or necrotic, but more often the epithelium has a reactive morphology with variable cell swelling and mild basophilia creating a somewhat disorganized appearance. In acute cases, centrilobular bile plugs are present and in severe cases, canalicular plugs can extend to the periportal region of the lobule. As cholestasis becomes more chronic, portal tracts expand as a result of fibrosis, bile duct proliferation, periductal concentric fibrosis, and an increase in pigment-laden (lipofuscin and bile) macrophages, lymphocytes, plasma cells, and neutrophils. With increasing chronicity, the bile plugs become less evident and portal-to-portal bridging fibrosis with biliary hyperplasia and eventual biliary fibrosis may develop in cases of persistent obstruction.[12]

Inflammation

Cholangitis

Cholangitis may be classified as neutrophilic, lymphocytic, destructive, or chronic (associated with liver fluke infestation).

Acute Neutrophilic Cholangitis

Neutrophilic cholangitis (suppurative/cholangiohepatitis) is the most common type of cholangitis in dogs and cats, and more common in cats overall. The most likely pathogenesis of this lesion involves bacterial translocation from the intestine. Histologically, there is neutrophilic infiltration of the lumen or epithelium of the bile ducts (Fig. 29-74). In acute cases there is more edema around the bile duct and it extends into the portal tract. Neutrophils may also be found within the portal connective tissue, and neutrophilic inflammation may extend through the limiting plate leading to hepatocyte necrosis and, on occasion, to hepatic abscesses, at which point the diagnosis of cholangiohepatitis is appropriate.

Chronic Neutrophilic Cholangitis

Chronic neutrophilic cholangitis can be difficult to discern microscopically. The chronic stage is associated with a variable number of mixed inflammatory cells, neutrophils, lymphocytes, and plasma cells in the portal tracts (Fig. 29-75). Fibrosis and bile duct proliferation may be evident. Neutrophils persist, even in low numbers, in the lumina of the bile ducts.

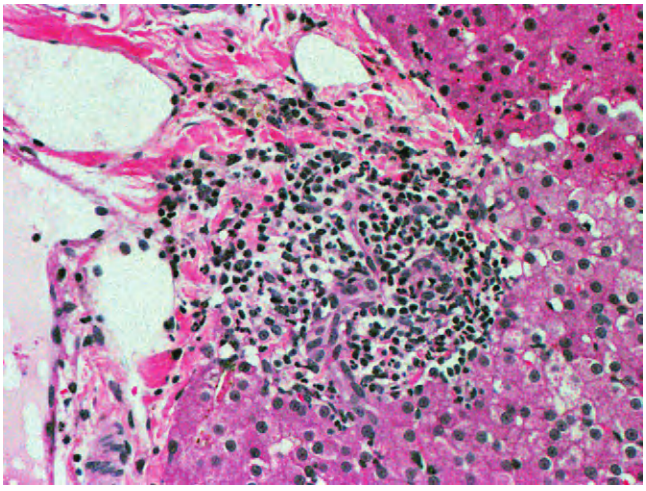

Figure 29-75 Chronic neutrophilic cholangitis retains the presence of neutrophils within the lumen of the bile ducts, but there may also be a significant number of mononuclear inflammatory cells and concentric peribiliary fibrosis may be evident.

Acute and chronic neutrophilic cholangitis occur in varying intensity and distribution. Some cases are uniform and diffuse and readily diagnosed, but in others there is an irregular distribution with only limited numbers of portal tracts affected and multiple biopsies may be required to confirm the diagnosis.

Lymphocytic Cholangitis

Lymphocytic cholangitis is characterized by infiltration the portal tracts by small lymphocytes, often associated with variable portal fibrosis, reactive biliary epithelium, and bile duct proliferation.[13] Lymphocytic cholangitis is a relatively common hepatic disease in cats; the pathogenesis is unknown. Lymphocytic infiltrates centered on bile ducts or present in the biliary epithelium are evident, but in severe cases these infiltrates can bridge portal tracts (Fig. 29-76). Lymphoid follicle formation may occur. Centrilobular areas of the

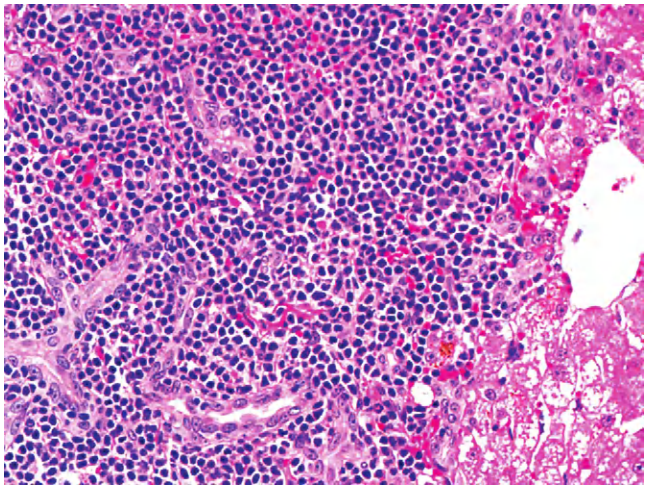

Figure 29-76 Feline lymphocytic cholangitis is recognized by the intense lymphocytic infiltration of the portal tracts and associated biliary hyperplasia.

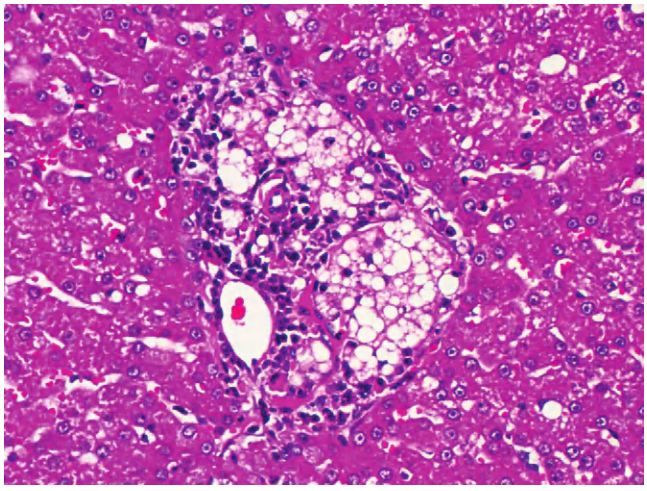

Figure 29-77 In destructive cholangitis the bile ducts are not evident within the portal tract and there is mononuclear cell infiltration with pigmented macrophages.

lobule are not affected. Apart from lymphocytes, occasional plasma cells and eosinophils may be present. The principal differential diagnosis for this disorder is lymphoma, and it can be difficult to discern the correct diagnosis on the basis of histologic evidence alone.

Destructive Cholangitis

Destructive cholangitis is characterized by necrosis or absence of biliary epithelium in smaller portal areas with infiltration of neutrophils and/or eosinophils and pigment laden macrophages (Fig. 29-77).[14] In chronic forms portal fibrosis may develop. The cause is unknown, but destructive cholangitis may result from an idiosyncratic reaction to drugs, particularly sulfonamides. Other toxic insults and viral infection (e.g., canine distemper) also may be associated with destruction of biliary epithelium. It is not known if destruction and loss of the bile ducts is always permanent or recovery can occur.

Chronic Cholangitis Associated with Liver Fluke Infestation

Several species of fluke can inhabit the bile ducts of cats and, less frequently, dogs. Chronic fluke-associated cholangitis results in dilated, fibrotic larger bile ducts. Histologically there are papillary projections and marked periductal and portal fibrosis with a slight to moderate inflammation within the ducts and portal areas (Fig. 29-78). Inflammatory cells within the lumina of the bile ducts are typically neutrophils and macrophages, while the portal inflammatory cells are usually neutrophils, lymphocytes and plasma cells. Eosinophils may be present, but usually only in small numbers. Typically there is no evidence of the adult flukes or eggs, but they may be present in a small proportion of cases.[7] Cholangiocarcinomas have been reported in dogs and cats with chronic cholangitis caused by chronic fluke infestation.

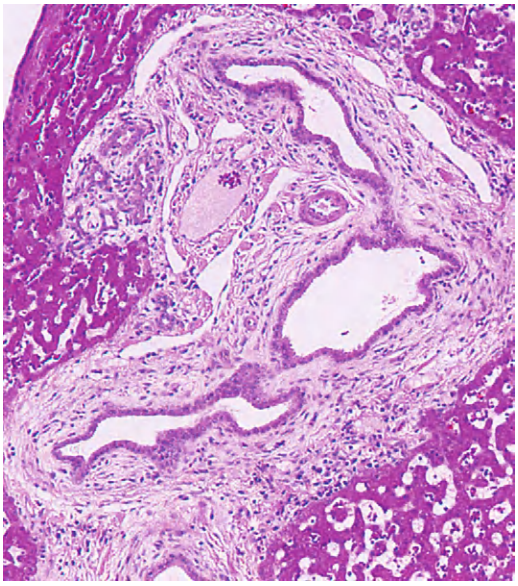

Figure 29-78 Fluke-associated cholangitis has a prominent dilation of bile ducts, an extensively thickened layer of connective tissue surrounding the duct, and, often, proliferation of the lining biliary epithelial cells. A moderate mononuclear cell infiltration is common.

Diseases of the Gallbladder

There are several disorders of the gallbladder that may be related, representing different stages of a single entity or separate disorders. These include cystic mucinous hyperplasia, gallbladder mucocele, and gall bladder infarction.

Cystic Mucinous Hyperplasia

Cystic mucinous hyperplasia of the gallbladder is characterized by prominent hyperplasia of the gallbladder epithelium. Well-differentiated hyperplastic epithelium forms numerous papillary projections that contain mucin and impart a honeycombed appearance to the mucosa. This change is common in older dogs, but uncommon in cats, and is of no clinical significance.

Gallbladder Mucocele

The accumulation of dark, gelatinous to semisolid bile-stained material, presumably abnormal bile or gallbladder epithelial secretions is characteristic of gallbladder mucocele. This disorder occurs in dogs and there is evidence of breed predisposition (e.g., Shetland Sheepdogs).[15] The gallbladder and, occasionally, the cystic and common bile duct, may become distended with this material and cause extrahepatic cholestasis. Histologically there are fine strands of hyperplastic biliary epithelium that extend into the intraluminal material.

Inflammatory changes are variable and may depend on the degree of injury or vascular compromise to the gallbladder wall caused by the expanding material within the gallbladder (Fig. 29-79). Inflammation can be negligible when affected gallbladders are removed early, but fibrin, neutrophilic infiltrates and acute necrosis can be evident where the gallbladder has ruptured. Adjacent liver parenchyma may display biliary hyperplasia and mild to moderate inflammatory infiltrates within the portal tracts, sometimes with reduced portal vein profiles.

Gallbladder Infarction

Gallbladder infarction occurs in dogs and appears to be distinct from cholecystitis (see "Cholecystitis" section below) in that inflammation is not reported to be significant.[16] Rather, there is acute full-thickness necrosis of the gallbladder wall, and on occasion, evidence of thrombi or degenerative changes in the cystic artery or its branches. Gallbladder rupture can be associated with infarction.

Cholecystitis

Neutrophilic Cholecystitis

Neutrophilic cholecystitis is typically associated with ascending bacterial infection from the intestine. It is common in cats and rare in dogs. Neutrophilic cholecystitis may occur in concert with neutrophilic cholangitis or as a single entity. Histologically there are neutrophils in the gallbladder lumen, as well as in the epithelium and muscularis of the gallbladder. In the acute stages only erosion and ulceration of the epithelium may be evident. Over time there is mixed inflammatory infiltration of neutrophils, lymphocytes, and plasma cells, and, in some cases, fibrosis.

Lymphoplasmacytic and Follicular Cholecystitis

This diagnosis is warranted when the lymphoplasmacytic infiltrate within the mucosa of the gallbladder exceeds the normal background content of these cells. The cause is unknown. Occasionally lymphoid follicles may be present in apparently normal gallbladder mucosa so it can be difficult to distinguish a true inflammatory condition if there is only a small amount of tissue to evaluate.

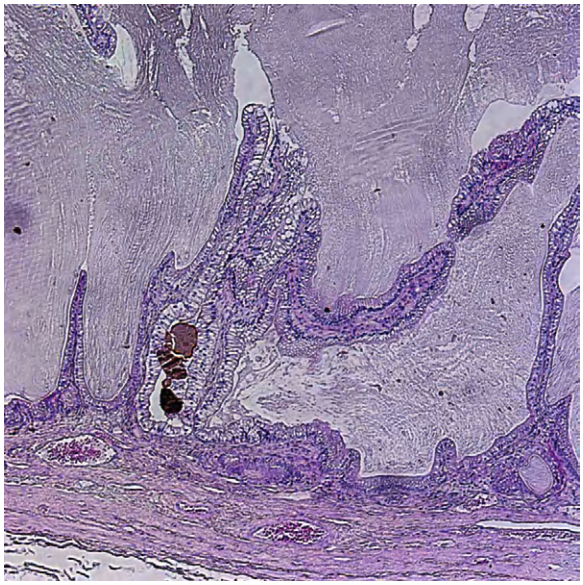

Figure 29-79 Gallbladder mucoceles are characterized by abundant, thick mucinous material within the lumen of the gallbladder. The mucosa is proliferative and may form papillary projections.

Parenchymal Disorders

Vacuolar Disorders

Cytoplasmic vacuolation of hepatocytes occurs for a variety of reasons, some physiologic and others as part of a disease process. Consequently, the diagnosis of vacuolar hepatopathy is vague and often uninformative.[17] In young animals, particularly those with abnormal growth, storage disorders may cause vacuolation of hepatocytes and possibly Kupffer cells. In older animals the vacuoles almost always contain lipid or glycogen. Identification of the contents can help determine pathogenesis, particularly in storage disorders. There are distinct syndromes involving either glycogen or lipid; however, there are circumstances in which both substances are present and their relationship to the disease state of the patient is unknown. The physiologic mechanisms that lead to glycogen or to lipid accumulation are, for the most part, different. Some disorders associated with vacuole formation are discussed later.

Hepatocellular Steatosis (Lipidosis or Fatty Liver)

Abnormally increased lipid within hepatocytes is termed *hepatocellular lipidosis* or *fatty liver*. Hepatic steatosis may be part of a normal physiologic response or, in more advanced cases, a form of reversible injury. Hepatocellular steatosis can occur in a variety of disturbances of normal lipid metabolism or disease syndromes in small animals.

Regardless of pathogenesis, the gross appearance of hepatocellular lipidosis is highly characteristic. Lipid accumulation imparts a pale yellow appearance to the liver. With increasing amounts of lipid the liver becomes progressively yellow and enlarges leading to hepatomegaly. The cut surface of the liver can develop a greasy texture and the liver becomes friable. Microscopically, lipid appears as clear, round, distinct cytoplasmic vacuoles. There are two microscopic forms of hepatic lipidosis, macro- and microvesicular.

Macrovesicular steatosis is the most common form of lipid encountered and is characterized by vacuoles that are larger than the hepatocyte nucleus and tend to displace the nucleus to the periphery of the cell (Fig. 29-80). Typically there are only one or two vacuoles per hepatocyte. Microvesicular steatosis is characterized by multiple fine vacuoles that are smaller than the nucleus and that fill the cytoplasm without displacing the nucleus (Fig. 29-81).

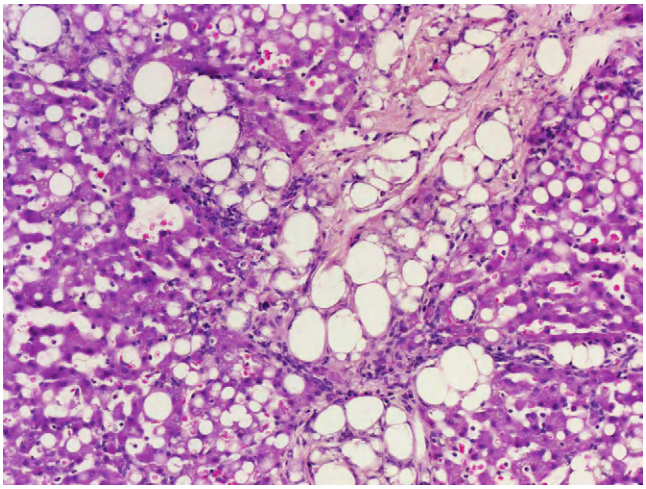

Figure 29-80 The macrovesicular form of steatosis or fatty liver has large, round, well-delineated and clear vacuoles that are larger than the hepatocyte nucleus and tend to displace the nucleus.

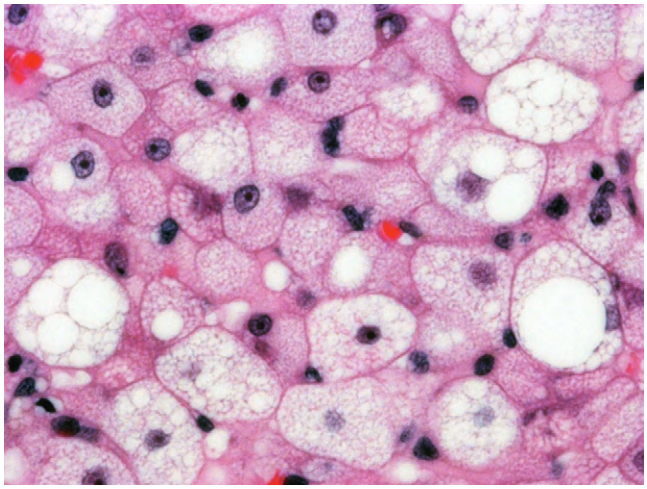

Figure 29-81 Microvesicular steatosis is recognized by the presence of multiple fine vacuoles that fill the hepatocyte cytoplasm but do not displace the nucleus.

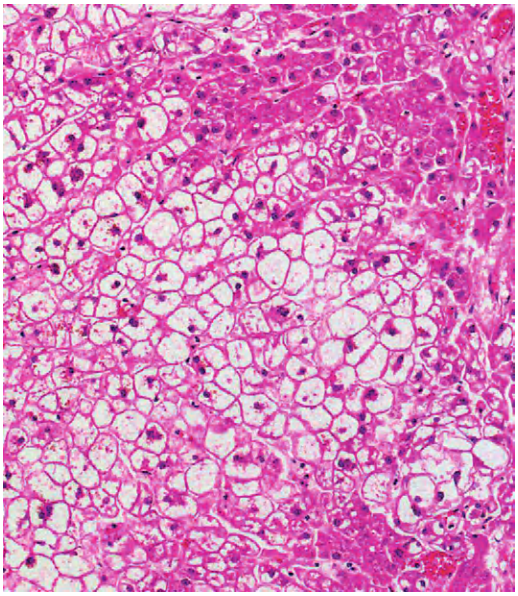

Figure 29-82 Excessive hepatocellular glycogen accumulation occurs most often in the presence of excess exogenous or endogenous corticosteroids, although there are other causes. Affected hepatocytes have ballooned profiles with empty cytoplasm or just wispy strands of eosinophilic cytoplasm evident.

In man and rodents microvesicular lipidosis is associated with injury to mitochondria and more severe liver dysfunction than macrovesicular lipidosis, but this has not been thoroughly investigated in dogs or cats. Microvesicular steatosis is seen most often in uncontrolled diabetes mellitus in dogs and in juvenile hypoglycemia of small-breed dogs in which the vacuoles are very small and may be diffuse or centrilobular. Mixed microvesicular and microvesicular lipidosis is common in the syndrome of feline hepatic lipidosis.

In paraffin wax–embedded and H&E-stained sections, lipid appears as a clear space because lipids are removed during processing. Other substances (e.g., glycogen and products of some storage disorders) can also appear as clear vacuoles, so it is desirable to identify the contents of clear vacuoles. Lipid can be identified by staining frozen tissue with lipid stains (see Table 29-4).

The lobular distribution of lipid vacuoles can vary from centrilobular to periportal, or, in extreme cases, the pattern is termed *massive*, involving all hepatocytes within the lobule. In mild cases, lipids may only accumulate in specific portions of each lobule, typically the centrilobular regions, leading to an enhanced lobular pattern. Lipid within hepatocytes should be distinguished from lipid between hepatocytes, as hepatic stellate cells can accumulate lipids, particularly in cats, and appear as cells with large single clear vacuoles that bulge into the sinusoidal space. Focal lipid accumulations, usually with foamy macrophages that also contain pigment are common in older dogs and are termed lipogranulomas.

Lipid accumulation in hepatocytes is often nonspecific; however, evaluation should include the lobular distribution and possible contributing factors, as well as the type of lipid vacuoles.

Glycogen Accumulation

Glucose is normally stored within hepatocytes as glycogen and is often present in large amounts after eating. Abnormal hepatic accumulation of glycogen is most often encountered in dogs as a result of glucocorticoid hepatopathy; however, other metabolic perturbations involving glucose regulation, including diabetes mellitus and the glycogen storage diseases, can produce similar changes. Disturbances of adrenocortical function involving steroids other than glucocorticoids, excessive progestins, and treatment with D-penicillamine are also reported to cause glycogen vacuolation.

Glucocorticoid-induced hepatocellular degeneration is a specific disorder of dogs characterized by excessive hepatic accumulation of glycogen. Excessive amounts of endogenous or exogenous glucocorticoids cause extensive swelling of hepatocytes from the accumulation of glycogen. In severe cases of glucocorticoid hepatopathy, the liver is enlarged and pale. Hepatocytes are prominently swollen with clear cytoplasm and diaphanous strands of eosinophilic cytoplasm with a central nucleus (Fig. 29-82). The distribution can be diffuse, zonal, or involve individual cells. Glycogen is notoriously difficult to detect in such livers, but PAS staining with or without diastase (which digests glycogen and distinguishes glycogen from nonglycogen carbohydrates) may be used. Special stains may help to identify glycogen accumulation in mild cases but, should it be necessary, frozen sections collected immediately at the time of biopsy are more useful. Other hepatic changes associated with glycogen accumulation are margination of neutrophils in sinusoids and occasional foci of extramedullary hematopoiesis.

Glycogen storage diseases type Ia and type II also lead to glycogen accumulation within hepatocytes, and such disease generally presents in young dogs.

Storage Diseases

A variety of inherited metabolic disorders, usually enzyme deficiencies, lead to excessive retention of storage of materials in hepatocytes and Kupffer cells. These materials often produce clear vacuoles, although they can have many morphologic appearances. Vacuoles can, alternatively, contain granular or hyaline material or, in some instances, cytoplasmic yellow-brown material (Fig. 29-83). The appearance varies with the type of substances retained. These changes are usually nonspecific, and water- or lipid-soluble materials are often lost in routine tissue processing. In such cases the liver can be evaluated using frozen sections, plastic-embedded sections, or electron microscopy. The histologic appearance of the vacuoles is generally insufficient to make a definitive diagnosis. Identification of the storage product, the enzyme deficiency, or the defective gene

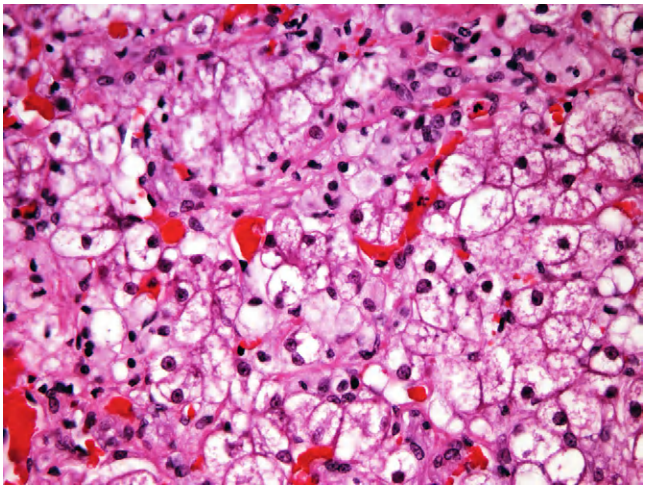

Figure 29-83 Inherited storage disorders can lead to hepatocellular and/or Kupffer cell vacuolation. In some disorders the vacuoles may appear clear, as in this kitten.

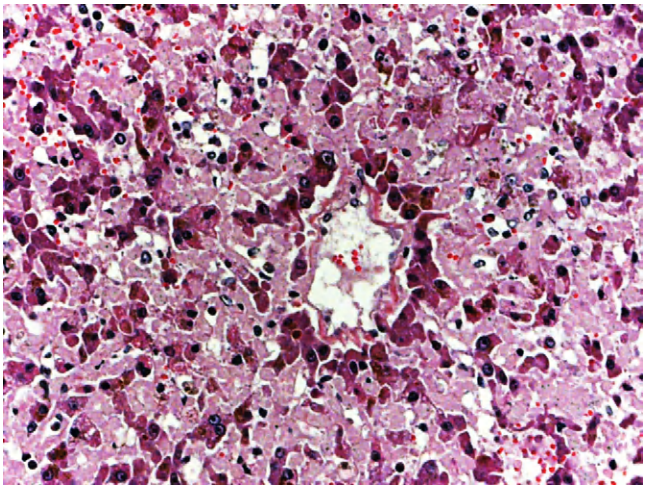

Figure 29-84 Amyloidosis. Amyloid can be recognized by its uniform pale and eosinophilic appearance. It can be deposited in the sinusoidal spaces, as seen in the left of this image, and is associated with hepatocellular atrophy.

is required. Some storage disorders (e.g., copper and cholesterol esters) may lead to necrosis, inflammation, and cirrhosis.

Amyloidosis

Hepatic amyloidosis occurs in dogs and cats. Amyloidosis is not a single disease entity, but a term used for various diseases that lead to the deposition of proteins that are composed of β-pleated sheets of nonbranching fibrils. Secondary or reactive amyloidosis is most common in dogs and cats and occurs as a consequence of prolonged inflammation. Inherited or familiar amyloidosis occurs in Shar Pei dogs and Abyssinian, Siamese, and other oriental breeds of cats. Histologically, all forms of amyloid appear as bright eosinophilic amorphous deposits that are usually found along the sinusoids in the space of Disse, but can be found in the portal tracts and within blood vessel walls (Fig. 29-84). The diagnosis can be confirmed with Congo red staining, which imparts an apple-green fluorescence when viewed under polarized light. As amyloid impairs blood flow or the access of hepatocytes to blood, hepatocellular atrophy is common, although affected livers are often enlarged as a result of the accumulation of amyloid.

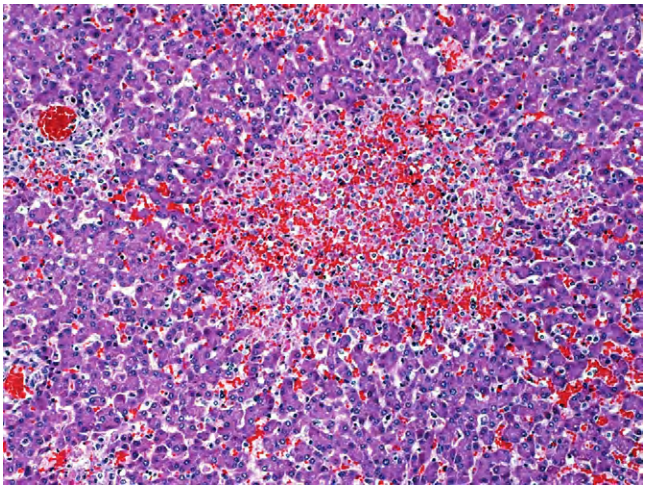

Figure 29-85 Neonatal puppies are susceptible to herpes virus infections that cause multifocal random necrosis, but little inflammation in the liver and other organs.

Inflammatory Disorders of the Liver

Acute Hepatitis

Regardless of the cause, acute hepatitis is characterized by hepatocellular necrosis or apoptosis, inflammation, and possibly regeneration. The pathologist should communicate the pattern and extent of necrosis and describe the type of inflammation present. If possible, the etiology and the age of the lesion should be identified.

Acute Viral Hepatitis

Viral infections of the liver typically occur in conjunction with systemic involvement. The most clinically significant hepatic infections are discussed next.

α-Herpes Viruses

Herpes virus infections in dogs and cats typically affect neonatal animals. Hepatic lesions are multifocal necrosis with scant inflammation. Necrosis may involve the portal tracts and the connective tissue surrounding the central and sublobular veins (Fig. 29-85). Infrequent intranuclear inclusions of hepatocytes and biliary epithelium, which are small and eosinophilic, are diagnostic but difficult to identify.

Infectious Canine Hepatitis

Infection with canine adenovirus 1 (CAV-1) is the exception to the typical pattern of random distribution of lesions with infectious disease. The virus kills endothelial cells as well as hepatocytes and it may be that this vascular component produces local ischemia and the generalized centrilobular injury and necrosis superimposed on the random foci of hepatocellular necrosis (Fig. 29-86). The diagnostic feature associated with infection is the presence of prominent basophilic intranuclear inclusions with a clear rim of marginated chromatin in infected hepatocytes and endothelial cells, and, occasionally, in biliary epithelial cells (Fig. 29-87). Foci of necrosis are acute and coagulative, rimmed with apoptotic hepatocytes. Inflammation in the parenchyma and the portal tracts is typically minimal.

Coronavirus (Feline Infectious Peritonitis)

FIP can affect the liver and other tissue sites. In the liver there is a characteristic vasculitis, as well as a perivenular and subcapsular inflammatory lesion that may consist of pyogranulomatous

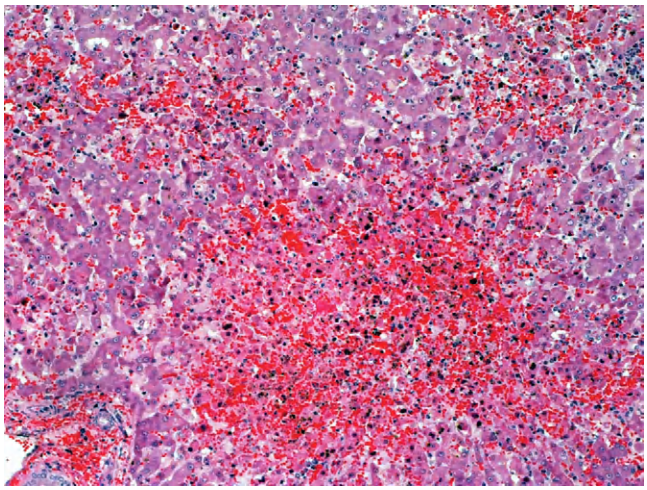

Figure 29-86 Infectious canine hepatitis. Typically, infection with canine adenovirus I produces foci of necrosis with a centrilobular to bridging distribution and variable inflammation.

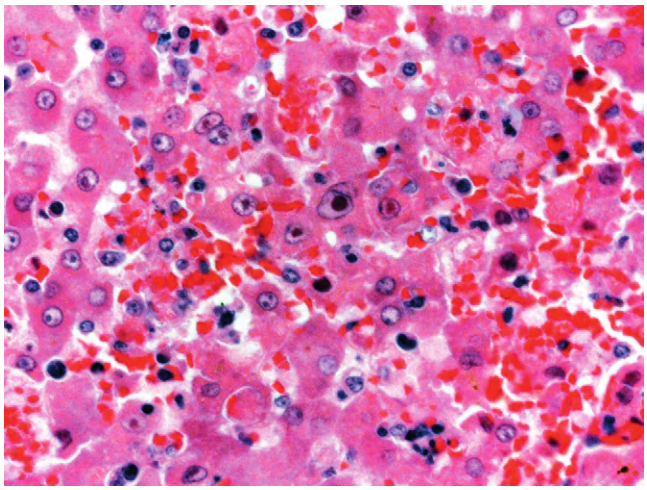

Figure 29-87 Infectious canine hepatitis. Prominent basophilic intranuclear inclusions are readily found within hepatocytes.

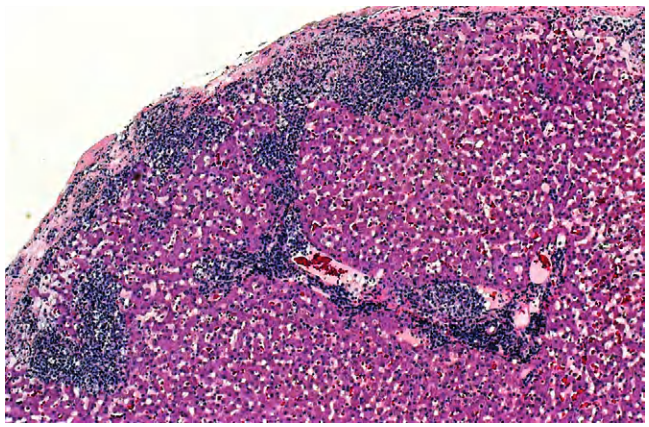

Figure 29-88 Feline infectious peritonitis. The characteristic lesion of this disease is perivascular inflammation composed of lymphocytes, macrophages, and neutrophils in varying proportions. Capsular injury and fibrin accumulation are also typical.

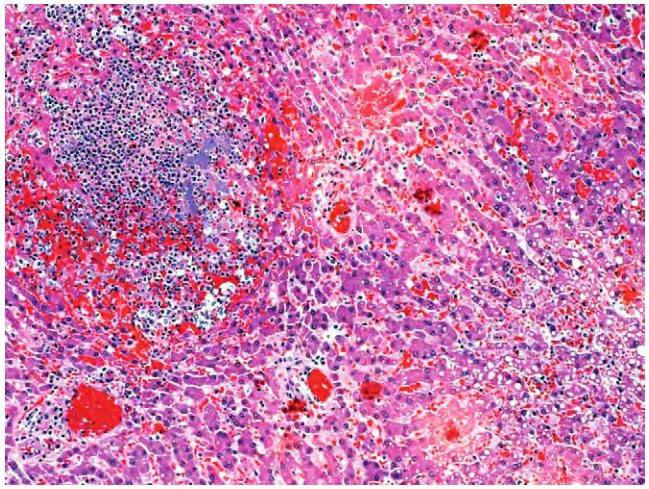

Figure 29-89 Various bacteria that can cause bacteremia may shower the liver and produce a random distribution of hepatocellular necrosis and associated inflammation, usually with neutrophils predominating.

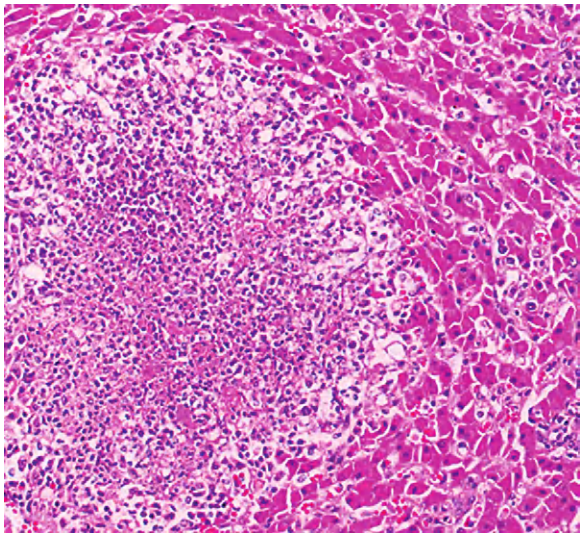

Figure 29-90 *Yersinia pseudotuberculosis* infection in a cat. Bacterial infections that produce septicemia often produce multiple, randomly distributed foci of necrosis and suppuration.

inflammation composed of foci of necrosis and infiltration of macrophages and degenerate neutrophils rimmed with lymphocytes, although in other cases lymphocytes and plasma cells may predominate (Fig. 29-88). Inflammation and necrosis usually also involve the liver capsule, which has prominent adherent fibrin with infiltrations of neutrophils and macrophages. The hepatic lesions can be similar in the effusive and the noneffusive forms of the disease.

Acute Bacterial Hepatitis

Most bacteremias involve the liver, and the range of bacteria that can produce septicemia and hepatic disease in dogs and cats includes *Salmonella* spp., *Leptospira* spp., *Clostridium piliforme*, *Francisella tularensis*, *Nocardia asteroides*, *Streptococcus* spp., and various mycobacteria and enteric organisms such as *E. coli*. Acute infections can produce random multifocal areas of necrosis with neutrophilic infiltration (Figs. 29-89 and 29-90). Culture is usually needed to distinguish the etiology. Some bacterial infections have somewhat distinctive changes. *Leptospira* infections, depending on the serotype, can produce prominent cholestasis, individualization of

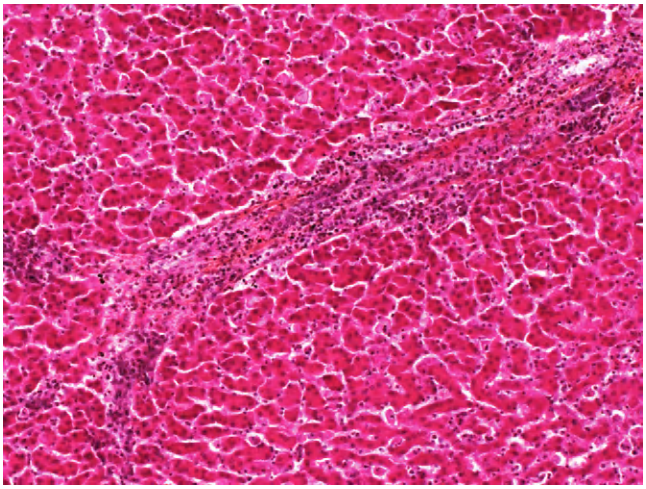

Figure 29-91 Leptospirosis can produce a pattern of hepatocyte individualization with mild lymphocytic portal infiltration.

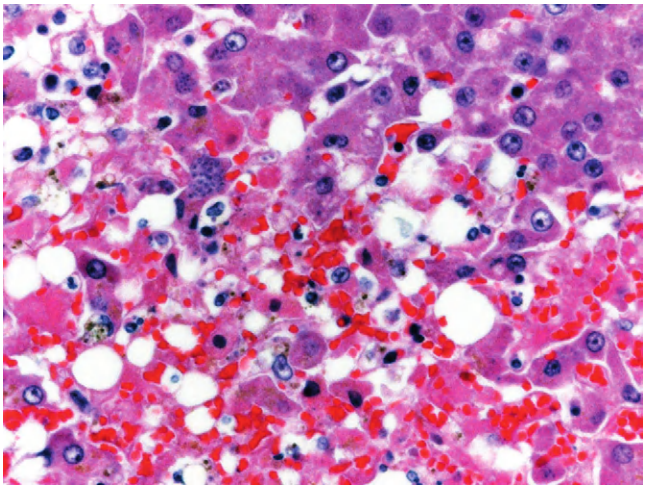

Figure 29-92 *Toxoplasma gondii* infection in a cat. Infection with *Toxoplasma* spp. and other protozoa typically produce multiple, randomly distributed foci of necrosis and a mixed inflammatory infiltrate. The presence of cysts with 1- to 2-μm basophilic merozoites is characteristic.

hepatocytes, increased hepatocellular proliferation, mixed inflammatory reactions in portal tracts, and scattered individual necrotic hepatocytes (Fig. 29-91). *C. piliforme* infections have slender elongated bacilli arranged in tangles within the cytoplasm of viable hepatocytes at the margins of the foci of random necrosis. The organisms are readily identified with silver stains. Mycobacterial infections are generally more chronic and produce granulomatous inflammation. Acid-fast bacilli within the lesion, although several forms of acid-fast stain may be required, are diagnostic. Infection with *Helicobacter canis* has been associated with multiple foci of necrosis and mixed inflammatory infiltrates in one young dog.[18] Silver stains are necessary to identify the organisms in the tissue. *Bartonella* spp. have been described in a variety of inflammatory hepatic lesions, including granulomatous hepatitis.[19]

Acute Protozoal Hepatitis

Apicomplexa protozoa, including *Toxoplasma gondii*, *Neospora caninum*, *Sarcocystis canis*, and *Sarcocystis neurona*, can infect the liver of dogs, usually as part of a neurologic or systemic disease process.[20] As in most infectious diseases, there is a random pattern of lesions in the liver. Hepatic infection with *T. gondii* is characterized by a random, diffuse to confluent pattern of lesions with a central area of necrosis surrounded by in a modest mixed inflammatory infiltration of neutrophils, macrophages, and other mononuclear cells (Fig. 29-92). Cysts containing bradyzoites and free tachyzoites may be found within and adjacent to these lesions. Hepatic lesions caused by *S. canis* do not occur in all infections, but include multifocal and portal inflammation, which may involve the limiting plate, with neutrophils, mononuclear cells, giant cells, and foci of necrosis within which intrahistiocytic schizonts and free merozoites can be found.

Hepatic Toxicity

As the recipient of all of the blood flow from the digestive tract, the liver is centrally positioned to protect the body from endogenous and ingested injurious substances. Consequently, it is also the most common site of toxic injury. Such injury often produces a characteristic distribution of acute coagulative necrosis within the hepatic lobule, most often centrilobular (Fig. 29-93). This pattern of toxin-induced injury is attributed to the higher content of cytochrome P450 enzymes in this area of the lobule. Hepatic metabolism of

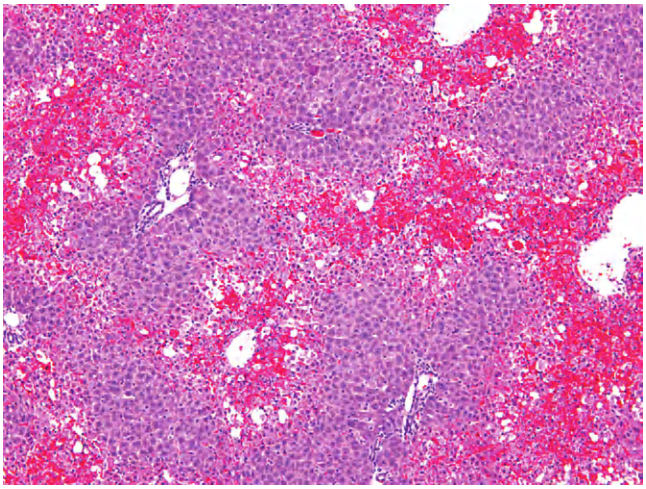

Figure 29-93 Acute centrilobular necrosis is characterized by extravasated blood cells and necrotic hepatocytes. This is a very common pattern for acute hepatic toxicities of many types and is also seen with acute hemolysis, blood loss, or cardiac decompensation.

many molecules destined for excretion usually goes through a three step process that involves oxidation of the parent molecule, conjugation with a polar molecule (often glutathione), and transport across the canalicular membrane into the bile. Hepatocellular injury can arise when the initial oxidation step leads to an excess of the oxidized (or bioactive) parent molecule. This bioactive form can bind to cellular proteins, RNA, and cell membrane lipids, causing acute toxicity, and in other circumstances bind to DNA and lead to carcinogenicity. Many naturally occurring and therapeutic hepatotoxins (e.g., acetaminophen, xylitol, aflatoxin B_1) produce centrilobular to massive necrosis, depending on the dose.[21-23] Cats are particularly sensitive to hepatic toxins such as acetaminophen and this is likely because of less robust antioxidant defenses and hepatic drug conjugation pathways compared with the dog.[24] Other types of toxins do not need hepatic metabolic activation and can cause injury directly, often producing random or periportal patterns of necrosis. However, drug- or chemical-induced acute necrosis in the

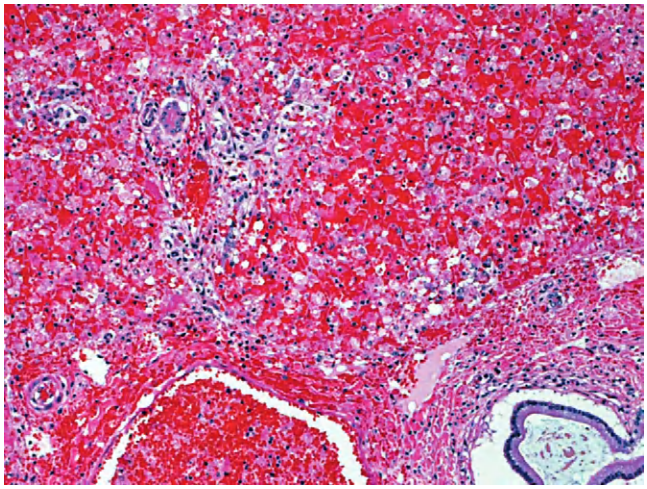

Figure 29-94 Massive necrosis involves the loss of all hepatocytes within a lobule. Several toxins, particularly in high doses, can produce this lesion.

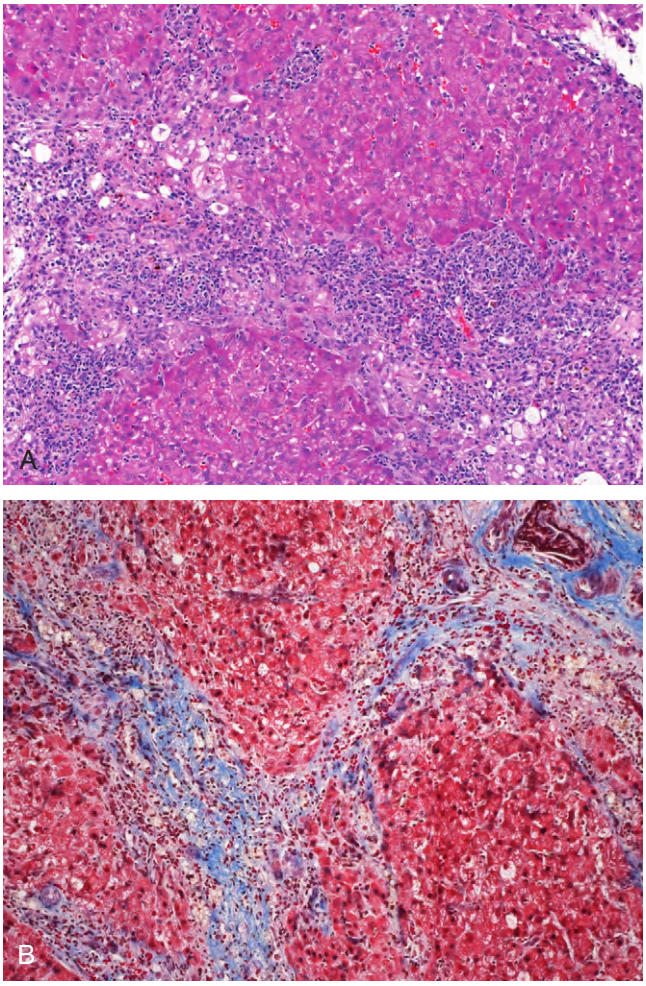

Figure 29-95 **A**, Chronic hepatitis. The hallmarks of chronic hepatitis are hepatocellular degeneration and death, fibrosis, usually in bridging bands with variable amounts of biliary hyperplasia and inflammation. Evidence of hepatocellular regeneration may be present. **B**, The connective tissue can be viewed more easily with special stains such as Mallory's trichrome that stains collagen blue.

periportal or midzone of the hepatic lobule is uncommon in dogs and cats.

Because the lobular model does not fully account for the three-dimensional anatomy of the liver, the pattern of acute necrosis more often irregularly bridges central areas with thick zones of necrosis. The degree and extent of necrosis can vary considerably from lobe to lobe and within lobes. Inflammation may be seen, but this is typically a nonspecific response to cell injury and death. The histologic appearance of acute toxic injury is heavily dependent on time, as a single insult can be nearly resolved in 3 to 4 days, depending on the severity of the initial insult. As a result, biopsies may fail to show significant lesions if the biopsy is obtained several days after a single exposure to a toxin, even though liver enzymes may still remain elevated. Centrilobular necrosis of the liver can also be caused by vascular disease, hypoxia, and some viruses, and must be distinguished from necrosis caused by toxins.

Massive acute necrosis is the most severe form of hepatic injury and affects all hepatocytes within the lobule (Fig. 29-94). This pattern can occur in dogs that have ingested toxic mushrooms such as *Amanita phalloides*,[25] blue-green algae, or as severe, possibly idiosyncratic, toxicities following drugs such as sulfonamides or trimethoprim sulfonamide in dogs and benzodiazepine in cats.[26,27] Chronic drug toxicity can produce lesions typical of chronic hepatitis with fibrosis, possibly bridging, and mononuclear cell inflammation.

Chronic Hepatitis

Chronic hepatitis is common in dogs, but rare in the cat. The pathogenesis remains unclear. Some cases have been associated with leptospirosis, *Bartonella* spp., and experimental and spontaneous CAV-1 infection, but this is a minority of cases.[7] Chronic hepatitis has also been reported in dogs treated with anticonvulsant drugs such as primidone, phenytoin, and phenobarbital, and in aflatoxicosis.[28] Approximately half of the cases of chronic hepatitis are linked to intrahepatic copper excess, but many cases are idiopathic.[29]

Histologically, chronic hepatitis is characterized by an inflammatory infiltration of mononuclear cells, lymphocytes, and macrophages, but other cell types, plasma cells, neutrophils, and eosinophils can be present in varying proportions (Fig. 29-95).[30] Other features include apoptosis or necrosis, regeneration, and fibrosis. The proportion and distribution of these components vary widely and it is appropriate for the pathologist to include in the diagnosis the activity and stage of the disease as well as the possible cause. The activity of the disease is determined by the amount of inflammation and extent of hepatocellular apoptosis and necrosis. The stage of the disease and the prognosis may be determined by the extent and pattern of fibrosis and the presence of architectural distortion. Early fibrosis may be seen as fine septa penetrating the parenchyma from the portal tracts or along the sinusoids. This is common in association with interface hepatitis (inflammation at the limiting plate). Fibrosis is usually the result of direct activation of hepatic stellate cells that are positioned in the space of Disse or related cells in the portal tract and connective tissue around the central vein. Increased connective tissue may be present or the collapse and condensation of the reticulin network because of hepatocyte injury and loss may give the appearance of increased fibrosis. The more advanced patterns of fibrosis may include portal-to-portal, portal-to-central and central-to-central bridging, or it may dissect the lobule. Other changes seen in chronic hepatic injury or hepatitis include regeneration and regenerative nodules of hepatic parenchyma, and proliferation of ductular structures at the periphery of the parenchymal

nodules and within fibrous septa. These ductular structures may represent biliary hyperplasia or, in cases of severe injury, proliferation of bipotential hepatic progenitor cells. Histochemical stains for connective tissue may be helpful in detecting the amount and pattern of fibrosis, particularly in early and mild disease.

Copper-Associated Hepatitis

Copper accumulation occurs in dogs and occasionally in cats. Progressive hepatic copper storage leading to inflammation and necrosis is well recognized in Bedlington Terriers because of a mutation in the COMM-D gene. Other breeds can also have elevated liver copper levels, but the disease process is not as well characterized.[31] Affected breeds with apparently familial disease include the West Highland White Terrier,[32] Skye Terrier,[33] and Dalmatian.[34] Chronic hepatitis and elevated liver copper has also be described in the Doberman Pinscher,[35] Labrador Retriever,[36,37] and American and English Cocker Spaniel, and likely occurs in other breeds.

Histologically, the pattern is similar in all affected dogs. Hepatocellular copper accumulation is first evident in centrilobular hepatocytes as intracytoplasmic granules. With progressive accumulation retained copper results in hepatocellular necrosis, inflammation with copper-laden macrophages forming small aggregates, and, finally, chronic hepatitis and cirrhosis (Fig. 29-96). Healthy dogs with normal livers may have copper levels of 400 to 500 mg/g dry weight, but some dogs can have higher liver copper burdens without significant liver disease.

Canine Idiopathic Chronic Hepatitis

Chronic hepatitis that is not associated with excessive copper retention remains a conundrum. The histology is typical of that described previously for chronic inflammation of the liver. Suggestions of breed predispositions to chronic hepatitis have been reported.[31] Drug toxicity, immune-mediated disorders, α_1-antitrypsin deficiency, and chronic infections may play a role, but the majority of cases are idiopathic.[29,38]

Granulomatous Hepatitis

Granulomatous hepatitis can result from the presence of any persistent antigen, including infectious agents such as mycobacteria, parasites, and fungi. Some cases do not have a clear etiology and novel infectious agents such as *Bartonella* spp. or atypical inflammatory responses or drug reactions have been suggested.

End-Stage Liver (Cirrhosis)

The terms *end-stage liver* and *cirrhosis* each have their adherents, but debate on the proper terminology remains. The WSAVA Liver Study group recommends the use of the term *cirrhosis* and supports the following definition for cirrhosis: a diffuse process characterized by fibrosis with conversion of normal hepatic architecture into structurally abnormal nodules and the presence of portal-to-central vascular anastomoses.[7] Bridging fibrosis is a regular feature, but fibrosis within the space of Disse also occurs and disrupts the interface between hepatocytes and the sinusoidal plasma. The pathologist should communicate to the clinician the extent and pattern of the fibrosis, the activity of the disease and, if possible, the likely etiology.

There are two morphologic categories of cirrhosis: micronodular cirrhosis with nodules less than 3 mm and regular in size, and macronodular cirrhosis with nodules greater than 3 mm and irregular in size. It is believed that micronodular cirrhosis develops from regular and diffuse injury and fibrosis. In contrast, macronodular cirrhosis develops from larger irregularly distributed areas of necrosis with secondary collapse and scarring (Fig. 29-97). In dogs, the histologic features also include proliferation of ductular structures and varying degrees of inflammation, bile stasis, lipidosis, and glycogen accumulation. Ascites and multiple acquired portosystemic shunts may develop when hepatic fibrosis disrupts hepatic blood flow leading to portal hypertension. Diminished hepatic function interferes with albumin synthesis, which can accentuate the formation of ascites. An idiopathic syndrome of hepatic fibrosis, unrelated to chronic injury has been reported in dogs and should be distinguished from typical cirrhosis.[39]

Cirrhosis is uncommon in cats. Affected cats may have diffuse hepatic fibrosis and disruption of the normal lobular pattern, usually as the result of chronic biliary disease, but rarely have nodules of regeneration. These cats may also have inflammation and proliferation of ductular structures.

Hepatocutaneous Syndrome (Superficial Necrolytic Dermatitis)

Hepatocutaneous syndrome is a disorder of dogs in which there is a combination of abnormalities in the liver and the skin, except in less-common cases where the skin disease is related to a

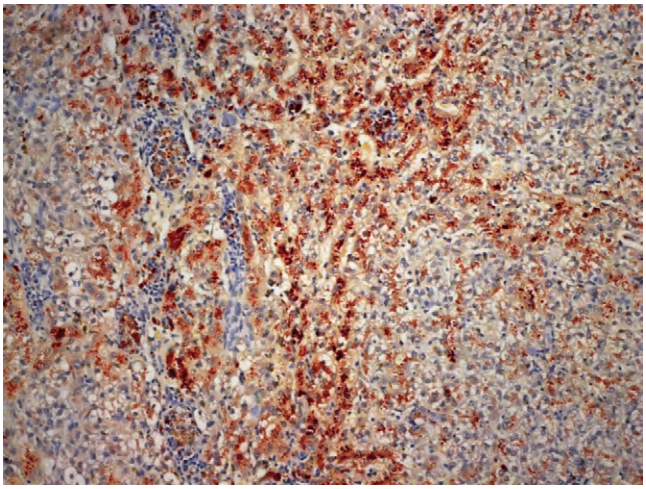

Figure 29-96 Retained hepatocellular copper can be seen more readily when special stains such as rhodanine are used, imparting an orange tint to the copper and associated binding proteins.

Figure 29-97 Macronodular cirrhosis. This condition is characterized by the formation of regenerative nodules that are greater than 3 mm in diameter. Irregular fibrosis is also evident.

glucagon-producing tumor of the pancreatic islet. Typically the hepatic lesion is a form of cirrhosis that has some atypical features. The liver, in this syndrome, is divided into multiple large confluent nodules, which are separated by prominent, enlarged hepatocytes containing clear vacuoles. Fibrous septa may be found between the nodules, although they may be less robust than in typical macronodular cirrhosis and in some cases nodules may only be separated by collapsed and condensed hepatic extracellular matrix. These septa usually contain proliferations of ductular structures and macrophages. Necrosis and inflammation are usually absent.

Lobular Dissecting Hepatitis

Lobular dissecting hepatitis occurs in young or young adult dogs as isolated cases or in groups of dogs from the same litter or kennel. Clinically, affected dogs deteriorate rapidly, but the histologic lesion is a form of cirrhosis. The liver usually has a normal size with a smooth capsular surface or may have some small nodules of regeneration. Microscopically, bands of fibroblasts (or myofibroblasts) and thin strands of extracellular matrix are seen between individual and small groups of hepatocytes that cause dissection of the original lobular architecture (Fig. 29-98).

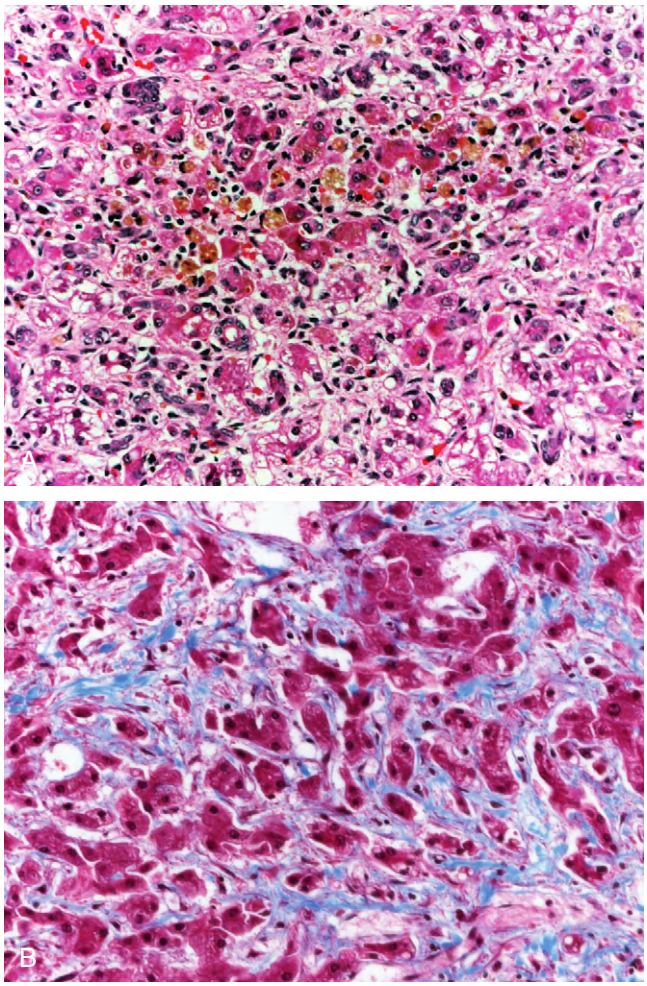

Figure 29-98 Lobular dissecting hepatitis. **A**, The normal lobular architecture is disrupted by the many fine fibrous septa that divide and distort hepatic plates. **B**, The presence of the fibrous septa can be more readily seen as blue linear material in this Mallory's trichrome stain.

Connective tissue stains demonstrate the pattern of connective tissue alterations. Inflammation is usually light and hepatocellular death is not a prominent feature. The cause is unknown.

Hepatic Abscesses

Hepatic abscesses can occur as single or multiple lesions in dogs and cats. Isolated organisms are predominately of enteric origin.[40,41] Abscesses contain central areas of suppuration and the surrounding hepatocytes may be necrotic, degenerate, or relatively normal, depending on the cause and maturation of the abscess.

Nonspecific Reactive Hepatitis

Nonspecific reactive hepatitis is not a disease, but is a recognizable response of the liver to a variety of extrahepatic disease processes, especially those involving the splanchnic bed or febrile illnesses. It may also be the residuum of an earlier hepatic disease. The importance of this diagnosis is the realization that the liver is responding to a systemic problem and that there is no primary liver disease, although there may be elevated liver-related enzymes and other clinical signs. The histologic pattern of nonspecific reactive hepatitis is characterized by an inflammatory infiltrate in portal areas and in the parenchyma. Hepatocellular necrosis is not usually evident (Fig. 29-99). Neutrophils may predominate in a proportion of the portal areas in acute extrahepatic diseases. There is slight to marked accumulation of inflammatory cells within the sinusoids and Kupffer cells may be prominent because of hyperplasia or hypertrophy. The central vein connective tissue may have similar changes to those in the portal tracts. The chronic form of nonspecific reactive hepatitis is characterized by infiltration of mononuclear cells, plasma cells and lymphocytes, and pigmented macrophages. The connective tissue around the central and sublobular veins, as in the case of acute disease, may mimic the changes in the portal tracts. This disorder has been termed *mild (neutrophilic* or *lymphocytic) cholangiohepatitis*, which is misleading, as the disease process does not involve the hepatic parenchyma or the biliary tree as a primary component of the disease process.

Eosinophilic Hepatitis

Eosinophilic hepatitis is of unknown cause. It can be regarded as a nonspecific reactive hepatitis particularly associated with allergic conditions and hypereosinophilic syndromes, and is more common in cats than dogs. Histologically, this condition may be present as part of a mixed inflammatory infiltrate in portal and perivenous areas and less frequently within the sinusoids. A distinct and less-common process of prominent eosinophilic hepatic inflammation is most likely associated with migrating nematode larvae or other parasitic infections. Rare drug reactions may involve an eosinophilic response, as can be seen in man.

Parasitic Helminths

The livers of dogs and cats can be infected with a variety of helminthes. Most cestode infections lead to cystic change grossly. There are no significant nematodes that infect the liver of dogs and cats, apart from *Calodium hepaticum* (formerly *Capillaria hepatica*) and these produce granulomatous reactions to the deposited eggs. Adults and eggs with typical polar caps can be seen within the lesions. Larval migration often produces tracts of acute necrosis at the early stages and encysted larvae provoke granulomas. Trematodes of clinical significance are discussed above under biliary disease.

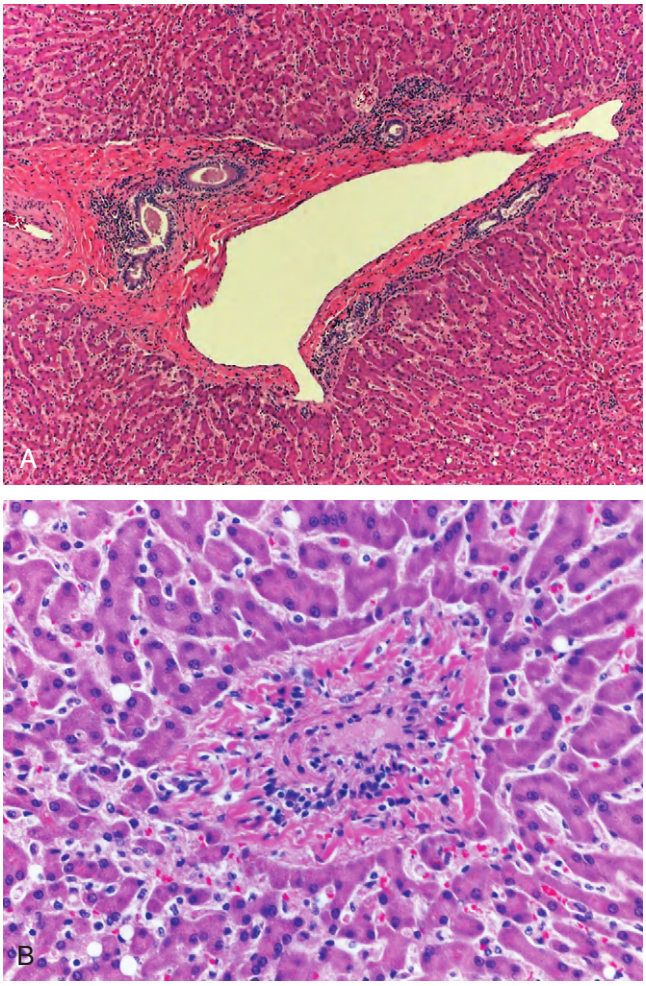

Figure 29-99 Nonspecific reactive hepatitis. This is a nonspecific response to extrahepatic inflammation or injury, usually in the gastrointestinal tract. **A**, Portal tracts contain a modest inflammatory infiltrate that may be composed of neutrophils or mononuclear cells (as in this case) depending on the type and duration of the condition. **B**, Similar changes can occur within the connective tissue surrounding the sublobular veins. Hepatocellular necrosis is not evident.

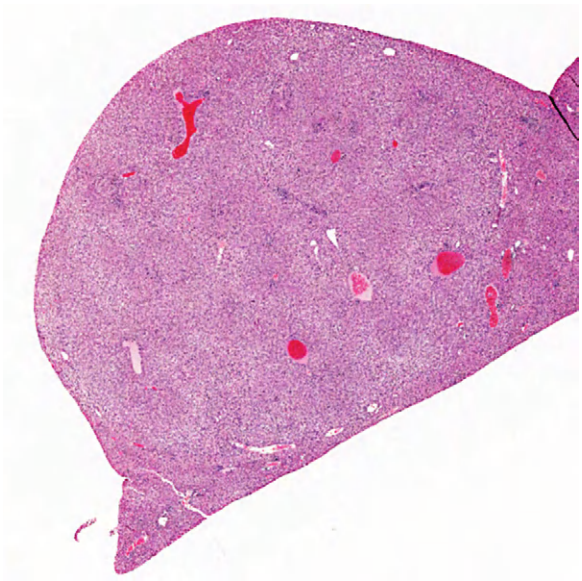

Figure 29-100 Nodular hyperplasia. Most older dogs have areas of nodular hyperplasia. Typically the remainder of the liver is completely normal and there are one or several expansile masses of well-differentiated hepatocytes present.

Proliferative Disorders of the Liver

Nonneoplastic Proliferative Lesions

Hepatocellular Nodular Hyperplasia

Hepatocellular nodular hyperplasia is common in older dogs, but rare in cats. The incidence of nodular hyperplasia in dogs is age-related, becoming evident at approximately 6 years of age, without predilection for either sex or breed.[42] The cause of these nodules is unknown. Nodular hyperplasia has no clinical impact, but because this change is readily detected with contemporary imaging techniques, the nodules should be distinguished from metastatic or primary hepatic neoplasms and regenerative nodules. Multiple hyperplastic nodules may occur, but often only a single mass is evident. Typically, the nodules are raised above the capsular surface and appear hemispherical. The color of the nodules can vary considerably, ranging from yellow to tan, to dark red when congested. The nodules vary in size with the smallest evident only microscopically and others as large as 3 cm in diameter. They are well demarcated from the normal parenchyma and usually compress adjacent parenchyma (Fig. 29-100). Hyperplastic nodules maintain a semblance of lobular architecture, but the lobular pattern is distorted, as portal tracts are separated by greater than normal and varying distances. Hepatocytes in nodular hyperplasia frequently contain lipid or glycogen vacuoles.

Regenerative Nodules

Regenerative nodules occur primarily in dogs and are not age related, but arise from the proliferation of hepatocytes in response to damage and loss. Often the source of the insult is unknown. They are typically multiple and often so numerous in macronodular cirrhosis that the affected liver resembles a cluster of grapes. The nodules can be smaller than 1 cm in diameter or up to several centimeters in diameter (see Fig. 29-97). Regenerative nodules are separated by septa of collapsed hepatic stroma, variable amounts of collagen and other newly synthesized extracellular matrix, proliferated bile ducts and variable inflammation, typically composed of mononuclear cells. Nodules are typically pale red-brown to darker mahogany, but may be pale when they contain lipid. Because these lesions result from the outgrowth of surviving hepatocytes, there is usually only a single portal tract apparent in sections. Hepatocytes in regenerative nodules are well differentiated. Regenerative nodules are readily distinguished from nodular hyperplasia since regenerative nodules occur in the presence of significant injury, fibrosis, and disruption of normal hepatic parenchymal architecture.

Neoplastic Lesions: Primary Hepatic Neoplasia

Primary liver tumors can arise from epithelial (e.g., hepatocytes, biliary epithelium of bile ducts or the gallbladder), neuroendocrine, or mesenchymal elements (e.g., connective tissue and blood vessels).

Hepatocellular Adenoma

Hepatocellular adenomas are benign neoplasms that are typically single, red or brown unencapsulated masses that compress adjacent parenchyma. They are usually spherical and can be less than 1 cm in diameter, or they may be quite large, involving the majority of a

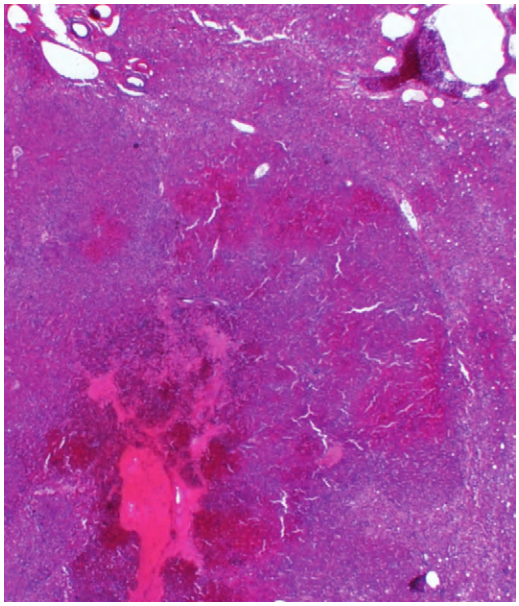

Figure 29-101 Hepatocellular adenomas are characterized by well-differentiated hepatocytes that form a uniformly expansile mass that compresses adjacent parenchyma. Central necrosis may occur, as it does in this case.

liver lobe. On occasion they may be pedunculated. Small to moderate areas of hemorrhage and necrosis may occur within the center of the tumor.

Macroscopic differential diagnoses for hepatocellular adenomas include nodular hyperplasia, regenerative nodules, hepatocellular carcinoma, and metastatic masses. Histologic examination is often needed to make a final determination. Histologically, hepatocellular adenomas are compressive masses composed of well-differentiated hepatocytes that form uniform plates up to two to three cells thick. Within the mass there is usually no more than a single portal tract (Fig. 29-101). Adenomatous hepatocytes tend to abut normal adjacent hepatocytes at right angles. Cystic areas of necrosis, hemorrhage, or serum, as well as foci of extramedullary hematopoiesis can be present. Hepatocellular adenomas can be difficult to distinguish from hepatocellular nodular hyperplasia in biopsies because of similarity between the level of differentiation of the hepatocytes in both lesions. Unlike adenomas, nodular hyperplasia retains normal lobular architectural elements, although the portal tracts are more separated than normal. In small biopsies it is nearly impossible to distinguish regenerative nodules from hepatocellular adenomas, as many microscopic features are identical, such as the degree of differentiation of the hepatocytes and the paucity of portal tracts. However, regenerative nodules arise in a background of hepatocellular injury and are typically multiple so an appropriate clinical history can aid in the correct interpretation. Hepatocellular adenomas are most likely underdiagnosed and often confused with well-differentiated hepatocellular carcinomas because diagnostic criteria have been imprecise but the advent of newer criteria should clarify this issue.[7]

Hepatocellular Carcinoma

Hepatocellular carcinomas are typically gray-white or yellow-brown masses that are subdivided into lobules by multiple fibrous bands. They are often quite friable. Hepatocellular carcinomas are often solitary, frequently involve an entire lobe, and are well demarcated, although these tumors can also form multiple nodules within the

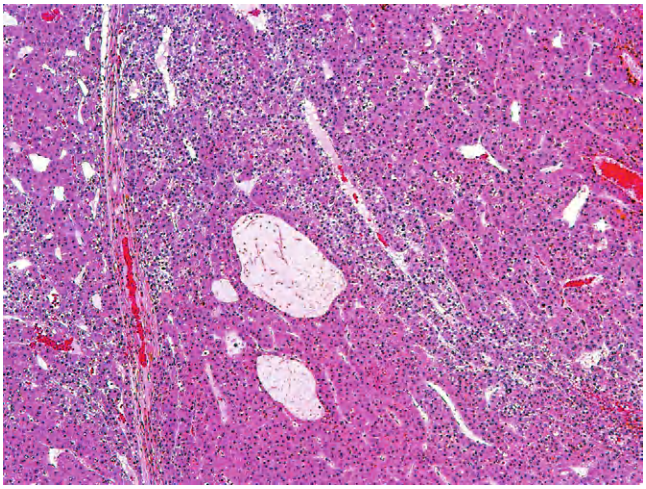

Figure 29-102 Hepatocellular carcinomas may have an irregular trabecular arrangement with intervening vascular channels.

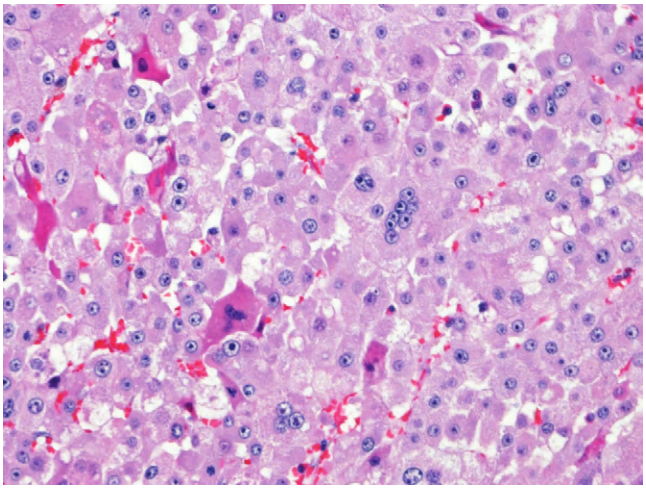

Figure 29-103 Varying sizes and shapes of neoplastic hepatocytes and their nuclei (pleomorphism) are a characteristic feature of hepatocellular carcinoma, as seen in this pulmonary metastasis of a primary hepatocellular carcinoma.

liver via intrahepatic metastasis or possibly multiple sites of origin.[43] Massive forms involving the entire liver can also occur.[43] Areas of necrosis and hemorrhage are common. Histologically, malignant hepatocytes can form trabecular, pseudoglandular, or solid patterns. All three patterns can be found in a single neoplasm. Trabeculae are variably thick with three or more cells forming a trabecula and there may be prominent vascular spaces between the trabeculae (Fig. 29-102). In the pseudoglandular pattern neoplastic cells line a space that may contain eosinophilic fluid. Solid variants are composed of sheets of neoplastic hepatocytes (Fig. 29-103). Neoplastic hepatocytes can range from well-differentiated to highly anaplastic spindle cells. Pleomorphic and giant cells can occur. Bile plugs may be found in canaliculi. Metastasis to a variety of sites may occur, particularly to lymph nodes within the anterior abdomen, lungs, and seeding into the tissues of the peritoneal cavity.[43,44] Intrahepatic metastasis is also possible. The rate of metastasis of hepatocellular carcinomas is an area of considerable debate. Early references suggest a relatively high rate of metastasis (more than 60%),[43] although most were reported to occur in the hepatic lymph node. Other reports

indicated a rate of metastasis half of this level.[44] More recent surveys are not available, but the conclusion of a consensus panel of veterinary hepatic pathologists was that metastasis of hepatocellular tumors to other organs was very uncommon. In the absence of metastasis, a clear indication of malignancy, the most useful criteria of malignancy are (a) invasion by malignant hepatocytes into local veins and through the interface between the tumor mass and the normal adjacent compressed normal hepatocytes; (b) prominent hepatocellular atypia, including pleomorphism, anisokaryosis, prominent nucleoli, and giant cells; and (c) increased mitotic index.

Cholangiocellular (Biliary) Adenoma

Cholangiocellular adenomas are benign tumors of biliary epithelium and are uncommon in dogs and cats. There is ongoing debate regarding the proper terminology for proliferative biliary lesions. In one new classification scheme[7] the majority of multicystic biliary lesions are interpreted as congenital biliary anomalies; however, there are pathologists who consider these lesions to be benign neoplasms. When multicystic disorders of the biliary and renal epithelium occur in the same animal, they are readily identified as developmental disorders. Given the similarity between lesions found only in the liver and those found in combination with renal cysts, it is likely that the majority of multicystic biliary lesions arise from congenital malformations. In keeping with the WSAVA classification, true adenomas of the biliary ducts are discrete, firm, gray or white masses comprised of well-differentiated biliary epithelium that forms narrow tubular or ductular structures lined with cuboidal epithelium and scant intervening connective tissue.[7]

Cholangiocellular (Biliary) Carcinoma

Cholangiocellular carcinomas occur in dogs and cats and usually arise from the intrahepatic ducts. Biliary epithelial malignancies may form a single mass or more often, multiple masses are scattered throughout the liver, possibly as a result of intraorgan metastasis. Tumor masses are pale gray to tan and unencapsulated. Cholangiocellular carcinomas can be distinguished from hepatocellular carcinomas by their firm texture, frequent presence of umbilication, and typically widespread distribution throughout the liver.

The tumors are composed of cells that retain a resemblance to biliary epithelium. Characteristically, well-differentiated carcinomas are organized into a tubules or acini lined by cuboidal to columnar epithelium. Well-differentiated tumors often contain mucin within the lumina of the tubules (Fig. 29-104). Bile pigment is not a feature of these tumors. In less-well-differentiated neoplasms some acinar arrangements can be detected among solid masses of neoplastic cells. Poorly differentiated carcinomas are composed of packets or cords and areas of squamous differentiation can occur. Tumor cells typically have a clear or pale eosinophilic cytoplasm. Nuclei remain round and mitotic figures are typically abundant. The epithelial components of the tumors are usually separated by abundant fibrous connective tissue (a scirrhous response) that is responsible for their firm texture. The growth pattern of this tumor is aggressive and the margins of cholangiocarcinomas are characterized by multiple sites of invasion into the surrounding hepatic parenchyma. Multiple sites of hepatic necrosis are also common in the adjacent parenchyma.

Metastasis to extrahepatic sites is common, particularly to the adjacent lymph nodes of the anterior abdomen, lungs, or by seeding into the abdominal cavity. Metastasis into the peritoneal cavity can produce variably sized nodules within the mesentery and on the serosal surface of the abdominal viscera.

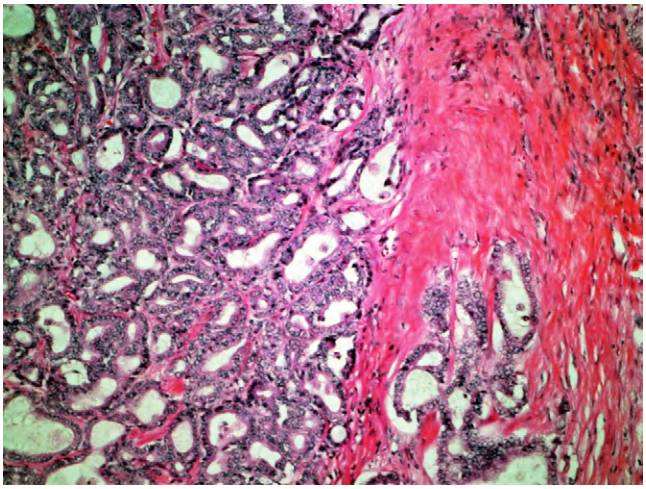

Figure 29-104 Biliary carcinoma is histologically typified by the presence of numerous small- to large-caliber tubular structures lined by cuboidal biliary epithelium. Dense connective tissue separates the tubular structures, imparting a firm texture to these masses.

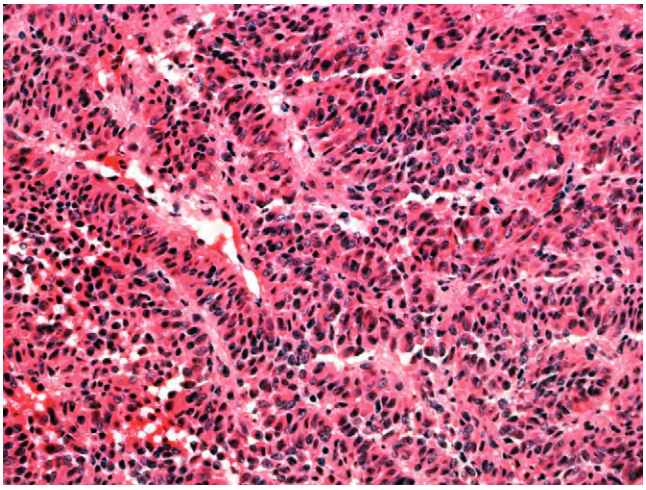

Figure 29-105 Hepatic carcinoid. These tumors are characterized by their ribbon or rosette conformation composed of small to elongated cells with dark basophilic nuclei.

Hepatic Carcinoids

Hepatic carcinoids are uncommon in dogs and cats, and most likely originate from neuroendocrine cells that lie within the hepatic parenchyma or biliary epithelium. These tumors have an aggressive course and frequently metastasize.[45,46] They may appear as a single mass, but multiple nodules can occur, probably secondary to intrahepatic metastasis. Cells tend to be small, oval to elongate or spindle-shaped, and form ribbons or rosettes. Neoplastic cells tend to be grouped into small islands separated by fine fibrovascular stoma (Fig. 29-105). Immunohistochemical detection of neuroendocrine markers such as chromogranin A or glucagon, among others, can be used to confirm the diagnosis.

Primary Hepatic Neoplasms of Mesenchymal Origin

Any of the cellular constituents of the liver can give rise to primary neoplasms. However, as a result of the relatively high frequency of metastatic spread of malignant tumors to the liver, a careful and

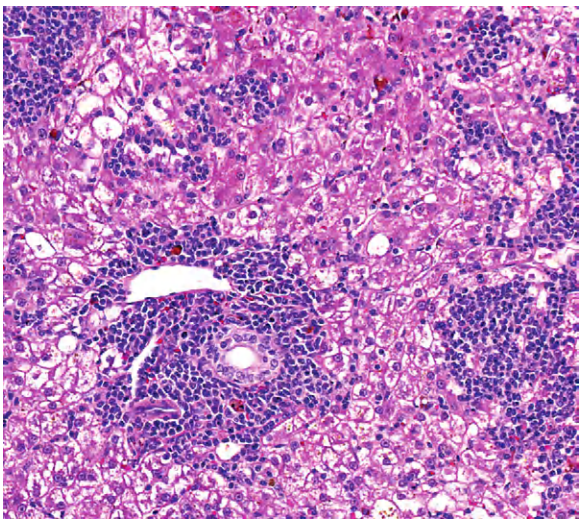

Figure 29-106 Lymphoma in the liver is manifested as dense lymphoid accumulations within and expanding the portal tracts, and occasionally involving the connective tissue around the central and sublobular veins. In advanced cases, neoplastic lymphocytes expand into the parenchyma.

thorough necropsy examination, as well as a thorough review of the history to check for, among other issues, the evidence of previous surgeries, must be performed to ensure that the tumor in question is indeed a primary mass. The most common primary mesenchymal neoplasm of the liver is hemangiosarcoma, but hemangioma, fibrosarcoma, leiomyosarcoma, and osteosarcomas are also recognized. Myelolipomas are discrete, nodular tumors with a thin capsule composed of lipocytes and myeloid elements that occur in cats.

Hematopoietic tumors, particularly lymphoma, occur in the liver. Lymphoma can infiltrate and enlarge the liver imparting a pale discoloration. Microscopically, lymphoma is characterized by infiltrates of neoplastic lymphocytes into the portal tract connective tissue and around the central and sublobular veins (Fig. 29-106). With advancing disease the neoplastic lymphocytes extend into the parenchyma. Usually there is no evidence of biliary proliferation in lymphoma that can help distinguish this tumor from feline lymphocytic cholangitis. Other hematopoietic neoplasms, including myeloid and erythroid neoplasia, malignant histiocytosis, and mast cell tumors can be found in the liver, although neoplastic cells are more likely to collect along the sinusoids, rather than within the portal tracts.

Metastatic Tumors

The liver is one of the two most common sites for metastasis for a large variety of malignant tumors. Distinguishing metastatic neoplasms from primary tumors can be difficult, particularly in the case of poorly differentiated epithelial tumors. For example, exocrine pancreatic and mammary tumors can resemble primary cholangiocarcinoma. It is important to ensure that a thorough postmortem examination is done, or when evaluating a biopsy, that the complete history is available to determine whether masses have been removed previously.

CHAPTER 30

Nutritional Assessment and Management

MALNUTRITION

Marjorie L. Chandler

Definition

Used broadly, the term *malnutrition* describes any nutritional disorder, including obesity caused by overnutrition, unbalanced nutrition as a consequence of one or more nutrient deficiencies, or cachexia caused by undernutrition.[1] Although there is no universally accepted definition for malnutrition, the World Health Organization describes it as "the cellular imbalance between supply of nutrients and energy, and the body's demand for them to ensure growth, maintenance, and specific function."[2] The term *undernutrition*, which is sometimes used interchangeably with malnutrition, is defined as "a state of energy, protein or other specific nutrient deficiency which produces a measurable change in body function, and is associated with a worse outcome from illness as well as being specifically reversible by nutritional support".[1] The terms *malnutrition* and *undernutrition* are used interchangeably in this chapter.

Isolated deficiencies of vitamins, minerals, and trace elements may occur in the absence of protein-energy malnutrition.[2] Suboptimal nutrition also occurs, in which an individual is not unhealthy, but will not function at his or her highest level. For example, it has been shown that an overnight preoperative fast in a healthy person results in postoperative insulin resistance and negative nitrogen balance.[3] Circumstances may also arise when an individual has an illness or trauma in which a substrate such as glutamate becomes limiting and is, therefore, a conditionally essential nutrient.[1]

Disease states may be accompanied by a loss of appetite or inability to eat, a decrease in the assimilation of nutrients, or nutrient losses that result in malnutrition. Malnutrition may also occur when an animal is being fed an insufficient amount of food for its energy needs, either because of poor feeding practices or a high energy requirement, such as in working dogs (Fig. 30-1). Feeding a poor-quality diet may result in energy deficiencies or specific nutrient deficiencies, such as thiamine. Animals fed homemade or vegetarian diets are known to be at higher risk for developing subclinical nutritional deficiencies or imbalances.[4]

Starvation in Healthy Animals

Starvation in an unstressed (i.e., not ill or injured) animal, also called *uncomplicated starvation*, initially results in utilization of the body's carbohydrate stores, especially hepatic glycogen. In dogs this reservoir may last for several days, compared with approximately 24 hours in humans.[5] Energy consumption then shifts primarily to fat and some protein metabolism. Both skeletal and visceral body proteins are used to provide gluconeogenic precursors, but liver structural proteins are used for gluconeogenesis before skeletal muscle.[6] As all body protein is functional, the primary adaptive shift is to fat utilization. Fatty acids are readily oxidized by the kidney and muscle tissues. Fatty acids are also converted to ketones in the liver which may then be used by the central nervous system. Several tissues, for example, adrenal medulla, red blood cells, and brain, have an obligate requirement for glucose, but the brain can adapt to ketone metabolism during periods of starvation. Glycerol resulting from the breakdown of triglycerides can be converted to glucose. Full adaptation to starvation with minimal protein oxidation can take up to 2 weeks in humans. At that time the respiratory quotient (RQ), a determination of the fuels being used by the body, is usually 0.6 to 0.7, indicating fat oxidation primarily.[7,8] If uncomplicated starvation lasts for longer than several days, metabolic rate is decreased as a consequence of a loss of tissue mass, a decreased metabolic rate of the remaining tissues, and decreased physical activity.[9]

Starvation in Ill or Injured Animals

Metabolism of the starved ill or injured animal is more complicated than in simple starvation (Table 30-1). Tumor necrosis factor (TNF) and interleukin-1 produced during injury or illness are associated with stimulation of proteolysis and inhibition of lipoprotein lipase activity. The counterregulatory hormones, cortisol and glucagon, and the catecholamines contribute to this process, eventually leading to insulin resistance and a tendency to develop hyperglycemia. Because of the metabolic shift, protein is catabolized at an increased rate and the adaptation to lipid metabolism is impaired.[7,8,10] The use of protein as an energy source often results in a persistent, marked nitrogen loss and net negative nitrogen balance. The increase in urinary nitrogen excretion can be approximately five times that of a patient in uncomplicated starvation. In humans, the RQ of 0.8 during this state indicates mixed fuel consumption, with

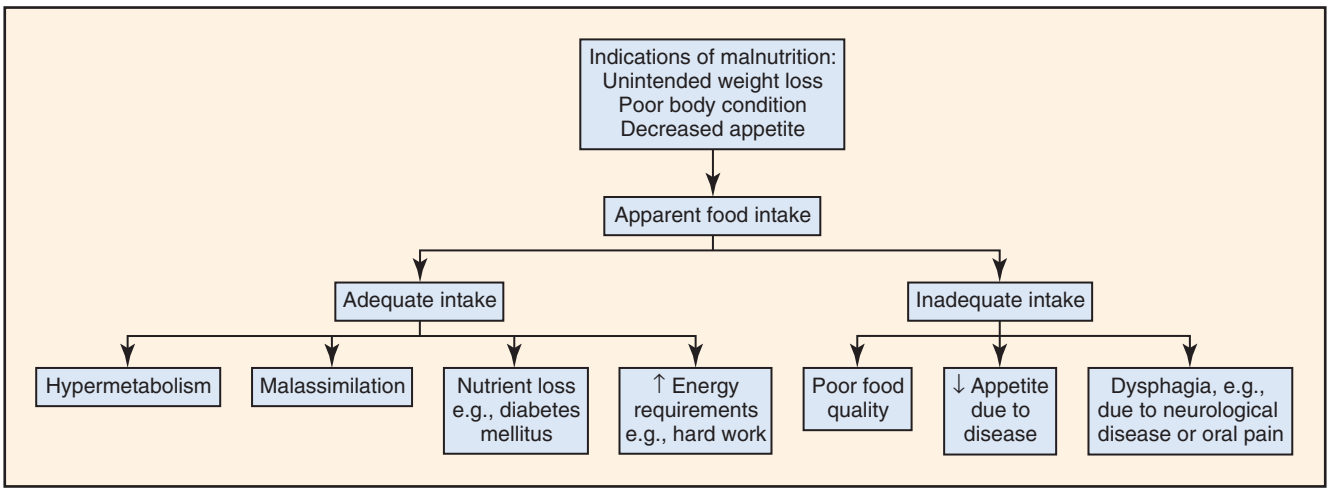

Figure 30-1 Causes of malnutrition.

Table 30-1 Comparison of the Metabolic Changes of Uncomplicated Starvation Versus Stressed Starvation of the Ill or Injured

Metabolic Parameter	Uncomplicated Starvation	Stressed Starvation
Inflammatory mediators	↑	↑↑↑
Primary energy sources	Glucose, fat	Glucose, amino acids, fat
Protein synthesis	↓	↓↓
Catabolism	↑ or ↓	↑↑↑

↑, increased; ↓, decreased.

Box 30-1 Complications of Malnutrition

Compromised wound healing
Immune suppression
Impaired muscle strength
Fatigue
Poor thermoregulation
Decreased respiratory function
Decreased gastrointestinal function
Decreased pancreatic function
Decreased water and sodium excretion
Increased tendency to develop edema
Increased morbidity and risk of secondary diseases
Increased risk of death

approximately 30% from amino acids, 40% from glucose, and 30% from fat.[7] It is the loss of body protein, not fat loss, that produces the complications of malnutrition during illness or injury.

Consequences of Malnutrition

Wound healing, which involves increased cellular activity and new protein synthesis, is compromised by malnutrition.[4] If the loss of lean body mass exceeds 10%, there may be decreased substrates for wound healing.[11] Specific micronutrients are also necessary for collagen synthesis and epithelialization, in particular, vitamins C and A, and zinc, copper, and manganese.[2] Malnutrition is also a predictor of postoperative complications after human abdominal surgery.[12]

Malnutrition affects the immune system in many ways, including decreases in the ratio of CD4:CD8 T cells, lymphokine and monokine production, complement C3, opsonic function, intracellular killing capacity of neutrophils, phagocyte dysfunction, antibody affinity, response of acute phase reactants to infectious challenge, and secretory immunoglobulin (Ig) A antibody response.[13,14] Seven days of starvation in cats results in immunosuppressive effects, including decreases in leukocyte and lymphocyte numbers.[15]

Other consequences of malnutrition include fatigue, impaired muscle strength and thermoregulation, and decreased respiratory, pancreatic, gastrointestinal, mental, endocrine, and cardiovascular functions.[1] As fat and lean components of the body are depleted, the extracellular fluid compartment stays the same or increases. The ability to excrete water and sodium may be reduced, increasing the tendency to develop edema.[1]

Morbidity and mortality rates are increased in malnourished patients. Postoperative mortality rates in human cancer patients approach 23% for the malnourished, but are only 4% in those in better nutritional condition.[16] Nutritional support in elderly patients reduces the mortality rate from 18.6% to 8.6% at 6 months.[17] Emaciated cats are significantly more likely to die within a year than those of optimal body condition.[18] Box 30-1 summarizes the consequences of malnutrition.

Assessment of Malnutrition

A number of methods have been used to assess nutritional status in humans, most of which include a combination of medical and dietary history, physical examination, anthropometric measurements, and laboratory data.[19] Many of the assessment protocols for humans use the body mass index (BMI), which is a ratio of weight in kilograms and the square of the height in meters, and anthropometric measurements such as mid-arm muscle circumference.[16] These methods are not practical in dogs because of extreme variations in body shape and size. A feline version of BMI has been developed for healthy cats and has been validated by dual-energy

X-ray absorptiometry for cats weighing between 3 and 9 kg of body weight.[20] The feline BMI uses the rib cage circumference in centimeters and the leg index measurement (LIM), which is the hind leg length from the middle of the patella to the dorsal tip of the calcaneal process in centimeters. The amount of body fat is then calculated using the equation:

$$\text{Percentage body fat} = [\text{rib cage}/0.762 - \text{LIM}] \div 0.9156$$

This measurement and calculation have not been validated in ill animals and feline BMI is not yet widely used in clinical practice.

The degree of weight loss can be difficult to assess if the animal's previous weight is unknown, and ascites may make weight loss assessment more difficult for the owner. Humans do not give reliable estimates of their own food intake[21]; the reliability of owners' assessment of the food intake of their pets has not been established.

Body condition scores (BCSs) provide a semiquantitative method for evaluating fat and lean body tissue percentages.[22,24] Scoring systems for dogs and cats have been developed using systems of 1 to 5 points, 1 to 6 points, and 1 to 9 points, with lower numbers representing thinner condition and higher numbers indicating obesity. In both dogs and cats, a BCS using a 9-point scale has shown good correlation (0.92 for dogs and 0.91 for cats) with percentage of body fat as determined by dual-absorption X-ray absorptiometry (DEXA).[23,24] This BCS system, using pictures and descriptions, shows good repeatability within and between observers. In dogs, a score of 4 or 5 out of 9 is optimal, depending upon the breed, and in cats a score of 5 is optimal. Unfortunately, the BCS systems do not take into account muscle wasting, and many ill animals may show loss of muscle that is disproportionate to the loss of fat because of the metabolic changes of stressed starvation. Consequently, a muscle mass scoring system has been developed that is based on palpation of skeletal muscle over the skull, scapulae, spine, and pelvis. Animals with no muscle wasting are scored as a 3, those with mild wasting are scored as 2, moderate wasting is scored as a 1, and a 0 score represents severe wasting.[25]

Multifrequency bioelectrical impedance has been used experimentally to assess body composition in healthy cats,[26] but has not yet been used in the clinical setting. Disturbances of water and electrolyte metabolism in the ill patient would limit the usefulness of this technique in the hospital setting.[16] Another method used in research settings for determination of body composition is DEXA, which has good accuracy but requires anesthesia and may not be practical for ill animals.[27]

Nutritional assessment in humans has included measurements of serum albumin and other proteins, including acute-phase reactants. These parameters may be affected by factors other than the metabolic changes of illness, including hydration status and changes in vascular permeability. Furthermore, normal serum albumin concentrations are maintained in starving people without stress, such as humans with anorexia nervosa,[16] and a study in elderly humans showed frequent discordance between serum albumin and clinical nutritional assessments. This may mean that changes in serum albumin seen in ill patients are more likely to be caused by the underlying disease.[28] Measurement of serum insulin-like growth factor 1 (IGF-1) concentrations in healthy dogs has shown correlation with nutritional restriction,[29] but IGF-1 is not yet performed in routine clinical practice and the association with nutritional restriction has not been examined in ill animals. Although there appears to be no reliable laboratory marker for assessment of nutritional status, the identification of specific nutrient deficiencies, such as folate, cobalamin, and iron, can be very useful. Box 30-2 summarizes the nutritional assessment for cats and dogs.

Box 30-2 History and Parameters for Initial Assessment of Undernutrition

Dietary history—type and amount, supplements
History of weight loss
History of decreased appetite
Body weight
Body condition score
Muscle mass score
Feline body mass index?
Possible disease causing malassimilation or nutrient loss?

Prevalence of Malnutrition

The prevalence of malnutrition in hospitalized human patients ranges from 13% to 78%.[30-32] The prevalence of malnutrition among cats and dogs is not as well documented. In a multicenter study of canine and feline BCSs using a 5-point scale, dogs had a mean BCS of 3.3 ± 0.7 and cats had a mean BCS of 3.2 ± 0.7.[33] The most commonly reported score for both species was 3, indicating ideal body weight. In another study of 276 hospitalized dogs that utilized a 9-point scale, the average BCS was 5.0 with a range of 1 to 9, and a normal distribution of scores.[34] Another study of small animal patients referred to an internal medicine service using the 9-point scale showed a median BCS for dogs of 6.5, although 20% of the dogs had a less-than-ideal BCS.[35] Of dogs, 34.7% had a history of decreased food intake and 45.8% had recent weight loss. Although many of the dogs had a good or even fat BCS, the history of weight loss and poor appetite was consistent with a risk of malnutrition and loss of functional lean body mass. For cats, the median BCS was 4.0, with 53.3% of the cats having a less-than-ideal BCS. Of cats, 53.3% had a decreased appetite and 56.7% had lost weight. In another study of canine cancer patients using a 9-point BCS scale, 55% of dogs were scored at 6 or higher, and only 4% were scored at 3 or less.[25] However, using the 3-point muscle-wasting score, 15% had moderate to severe muscle wasting and 20% had mild muscle wasting, consistent with the loss of lean body tissue.[25] The latter result emphasizes the importance of determining muscle mass scores in addition to BCSs.

Gastrointestinal Disease and Risk of Malnutrition

Human patients hospitalized with gastrointestinal disorders have among the highest rates of malnutrition.[2] The highest prevalence is in those people with inflammatory bowel disease (IBD), liver disease, and pancreatitis. The pathophysiologic mechanisms are manifold and include decreased intake, maldigestion, malabsorption, inflammation, increased nutritional requirements, and drug–nutrient interactions. Decreased appetite and reduced intake are obvious findings in many of the canine and feline gastrointestinal, pancreatic, and hepatobiliary disorders.

In humans it is noted that cobalamin is often deficient in cases of atrophic gastritis and disorders of the terminal ileum, and iron, folate, and magnesium deficiencies are common in patients with primary enteropathies.[16] Similarly, decreased cobalamin and folate have been reported in cats with gastrointestinal diseases,

including IBD, intestinal lymphoma, pancreatic inflammation, and cholangitis.[36,37] Iron-deficiency anemia may develop as a consequence of IBD in the dog.[38]

Reduced food intake and intestinal malabsorption may be present with many primary enteric diseases or secondary to cholestatic liver disease.[39] Fat malabsorption may result in deficiencies of fat-soluble vitamins A, D, E, and K, and zinc.[6,40] Pancreatic insufficiency classically presents with signs of malnutrition caused by maldigestion and decreased nutrient absorption. The reader is referred to Chapter 32 for more information on nutritional requirements in gastrointestinal, pancreatic, and hepatobiliary disorders.

Contribution of Hospital Practices to Worsening Nutritional Status

Ten percent to 60% of human patients lose weight during hospitalization.[16] Inadequate intake or fasting prior to anesthesia or diagnostic procedures may contribute to this weight loss. In one study, 20% of meals were missed, often because of fasting for investigative or therapeutic procedures.[41] In another study, estimated nutrient requirements were met in only 50% of patients because of inappropriate feeding instructions and failure to deliver prescribed nutrients.[42]

In a multicenter canine study it was found that a positive energy balance (>95% of calculated resting energy requirements) was achieved in only 220 (27%) of 821 "dog-days."[34] Reasons cited for patient negative-energy balance included poorly written feeding orders (22%), orders to withhold feed (34%), and, in many dogs (43%), a refusal to eat offered food. Anorexia in ill animals may arise as a consequence of the effects of cytokines such as pain and drug therapy. The reader is referred to Chapter 7 for more information on the mechanisms and management of anorexia.

In a study of enteral feeding prescribed by a nutrition support service, patients received 91% of their prescribed feedings.[43] Animals in this study received more than two-thirds of their goal calories on only 76 of 104 days, which may have resulted from continuous tube feedings rather than intermittent bolus feedings. The interruption of continuous feedings for procedures may have resulted in a smaller total intake than the use of intermittent bolus feedings.[43] Box 30-3 summarizes some of the causes of worsening nutritional status in hospitalized patients.

Box 30-3 Contributing Causes to Worsening Patient's Nutritional Status within the Hospital

- Animal's disease condition
  - Anorexia or decreased appetite
  - Nutrient malassimilation
  - Nutrient loss
- Hypermetabolism causing increased calorie requirements (uncommon)
- Lack of nutritional status assessment
- Delayed initiation of nutritional support
- Fasting for procedures
- Inappropriate diet, e.g., too low in calories or unpalatable
- Poorly written feeding orders or no feeding orders
- Incorrect calculation of caloric requirements
- Interruption of continuous feeding for procedures or to take animal out of cage

Management of Malnutrition

Management of malnutrition starts with appropriate assessment of the patient's nutritional status, including dietary history. Impairment of organ function occurs with starvation long before significant physical changes are observed, and nutritional deprivation is especially likely to be overlooked in the obese patient during hospitalization.[16] Initiation of nutritional support is indicated in patients meeting the criteria of acute weight loss of 5%; chronic weight loss of greater than 10%; anorexia for more than 3 days; or indications of decreased protein intake or malabsorption, poor body condition, weakness, or nonhealing wounds. Daily monitoring of the patient's nutritional status while hospitalized helps to ensure adequate intake. Patients should be weighed daily, although day-to-day fluctuations in weight may be greatly influenced by fluid balance. Energy requirements change as a consequence of illness, although in most patients requirements are not increased above resting energy requirements.[16]

Nutritional support in the starving and malnourished patient may induce a shift from the catabolic to the anabolic state. In the refeeding of a severely malnourished patient, a metabolic shift from endogenous to exogenous energy sources, particularly carbohydrates, may cause depletions in serum concentrations of phosphate, magnesium, and potassium, which move intracellularly under the influence of insulin. This is described as the refeeding syndrome,[44] and may be seen with either parenteral or enteral nutritional support. Hypophosphatemia resulting in hemolytic anemia has been described in cats during the provision of enteral nutrition.[45] Eight of these nine cats were in poor body condition prior to feeding, and the ninth, which was an obese cat, had a history of anorexia. Initiating feeding at less-than-resting energy requirements may help prevent refeeding syndrome. In another case of feline refeeding syndrome, the phosphorus, potassium, and magnesium were all deficient, and the cat showed concurrent cardiac abnormalities,[46] which have also been reported in human refeeding syndrome.[44]

Hypophosphatemia and red blood cell abnormalities have also been reported in dogs during feeding after nutrient deprivation.[44] Phosphorus should be monitored daily for the first week of nutritional support in malnourished animals. Decreased serum potassium and magnesium and hyperglycemia all play a role in refeeding syndrome and should be closely monitored. As thiamine plays a role in carbohydrate metabolism, and it may be depleted during starvation, provision of thiamine supplementation prior to nutrient supplementation has been recommended.[44]

Appropriate nutritional support should be initiated early in patients, following rehydration and stabilization, and ideally within 24 hours of hospitalization. Initial feeding protocols may be formulated at less-than-resting energy requirements, as even small amounts of nutritional support reverse the catabolism of endogenous protein for energy.[47]

Monitoring of the patient's food intake is important, as often records only note that "the patient ate," and do not describe the quantity or the type of food eaten. Supplemental nutritional support may be provided orally, enterally via feeding tubes, or parenterally via either central or peripheral vein. Enteral feeding stimulates the gut-associated immune system and provides nutrients such as glutamine to the intestinal mucosa.[48] Enteral nutrition is also generally safer and more economical than parenteral nutrition. The reader is referred to Chapter 33 for further information about enteral and parenteral nutritional support.
