1 INTRODUCTION

Why do stones form in human kidneys? The answer to this basic question remains elusive as currently we still do not fully understand the fundamental pathophysiology of urinary stone formation. In 1937, when Alexander Randall postulated that papillary "plaques" composed of calcium phosphate represented the nidus for future stone formation, he described such plaques to be "invading and replacing interstitial tissue." (Randall, 1937, 1940) While currently we know that Randall's plaques are present in the majority of calcium kidney stone formers, there is still more to understand with regard to the cascade of events leading to kidney stone formation. It is theorized that ectopic biomineralization in the proximal medullo-papillary complex precedes interstitial Randall

plaque in the distal papilla that ultimately culminates in urinary stone formation. We still have a limited understanding of the genetic and environmental reasons that lead to the early ectopic biomineralization process. The only way to fully understand the temporal evolution/process by which stones form will be to develop reliable animal models. There is a great need for *standardized* nephrolithiasis animal models to better understand the temporal sequence of stone growth and thus allow researchers around the world to share data from similar animal models. It is with this goal in mind that the current animal models to study urolithiasis are reviewed.

Urinary stone disease remains a prevalent disease with approximately 1 of 11 people affected in the United States (Scales et al., 2012). Multiple studies have shown that up to 50% of patients who develop a kidney stone will experience another stone episode within 5 years (Ljunghall, 1987). Acute renal colic associated with passage of a urinary stone is a major source of patient morbidity and mortality, with over 50% of these patients requiring surgical intervention and an average estimated 19 productive work hours lost each year (Pearle et al., 2005; Saigal et al., 2005). Previously an estimated $2.1 billion annual cost was linked to urolithiasis in the year 2000 (Pearle et al., 2005). The associated health costs of urolithiasis continue to rise and recently this number has risen to an estimated $10 billion annually (Scales et al., 2016). While major advancements in technique and technology have been made in the surgical treatment of kidney stones, our understanding of the fundamental mechanisms of stone formation remain limited.

A reliable and reproducible animal model for urinary stone disease is not widely accepted or used, and as such researchers frequently have resorted to studying stone specimens at the extreme ends of the spectrum (from early papillary Randall plaques, to deep sampling of the medullo-papillary complex at time of nephrectomy, and surgically excised calculi). Endoscopic papillary biopsies limit study to the tip of the renal papilla while excised medullo-papillary complexes from surgically removed kidneys reveal potential upstream development of biomineralization. Many surgically removed kidneys are removed due to infection or chronic obstruction and may not represent pristine specimens to study early elements of stone formation. As a community of clinicians and basic scientists trying to unfold the mysteries of biomineralization, there is an urgent need to develop a reliable animal model to study the pathogenesis of urinary stone disease.

Reflecting back on the last 50 years, there have been relatively few breakthroughs with respect to stone prevention. The lack of a reliable animal model has limited innovations in medicinal prophylaxis. Most urologists perform a metabolic evaluation that consists of laboratory testing including targeted 24-h urine collections and blood chemistries to try to identify risk factors for future stone formation. This metabolic evaluation has remained the same for nearly half a century, yet both the incidence and recurrence of stones continue to rise. An animal model is needed to better understand the mechanisms by which stones form to allow us to decrease future stone formation and provide a roadmap to develop new prophylactic regimens.

Currently no single animal model system can be thought of as perfect, yet valuable insight can be gained from reviewing those animals that have been utilized thus far. For each animal, the anatomic similarities and differences compared to humans will be highlighted. The methods by which investigators induce stone formation will be summarized, focusing on the advantages and disadvantages researchers have encountered to date. Each model has limitations and these will also be highlighted within each section. It is with these concepts in mind that hopefully the reader will gain an appreciation of the importance of animal models for urinary stone disease.

2 RAT MODEL

Similar to other fields in medicine, urinary stone disease has utilized the rat to attempt to systematically study the pathogenesis of urinary stone disease. Rats represent a well-established, relatively economical model that scientists have utilized since the 19th century. At the beginning of the 21st century, rats and mice accounted for over 90% of animals used in research (CCPA, 2000). For urinary stone disease, studies utilizing the rat have predominantly focused on reproducing both hypercalciuria and hyperoxaluria, two of the most common pathophysiologic changes associated with urinary stone disease.

2.1 Anatomic/Physiologic Comparison Between Rat and Humans

There are inherent differences between the kidneys of the rat and those of humans, the biggest of which is that rat kidneys are unipapillary compared to the multipapillary kidneys of humans. Average rat kidney measurements are $1.6 \times 1.0 \times 0.9$ cm, and their usual weight is 0.75–1.2 g (Khan, 2013). Despite having fewer urinary tubules and an overall smaller collecting system, rat kidneys have a similar cortex-medulla ratio (2:1) compared with humans. In general, rat kidneys are usually comprised of approximately 30,000 nephrons, compared to nearly 1,000,000 in humans (Khan, 2013). The rat bladder is different from humans in that it is considered to be more of an abdominal organ given that the shape of the rat pelvis lacks a true (lesser) cavity (DeSesso, 1995). Rat bladders generally have a pear-shape and have been

noted to have a maximum volume of 2.5 mL, with average urine output ranging between 10 and 25 mL/day (DeSesso, 1995).

2.2 Hypercalciuria

2.2.1 Cross-Breeding Model

Hypercalciuria has been established as one of the most common risk factors for the development of urinary stone disease (Bushinsky et al., 1995; Coe et al., 1992). For the rat, researchers have established a strain of multigeneration inbred Sprague-Dawley rats to produce hypercalciuric progeny (Bushinsky and Favus, 1988). While initially thought to be solely secondary to increased calcium absorption in the gut, multiple studies have since established that an increased number of vitamin D receptors in the GI tract, kidneys, and bone lead to increased calcium absorption in these genetically hypercalciuric stone-forming (GHS) rats (Krieger et al., 1996; Li et al., 1993; Yao et al., 1998). With each successive generation, these GHS rats have been shown to excrete multiple-fold times the amount of calcium compared to controls (Evan et al., 2004). While most of these studies have utilized female rats, male GHS rats have been shown to excrete a higher daily oxalate content compared to their female counterparts (Bushinsky et al., 1994).

2.2.1.1 SUPERSATURATION

While these GHS rats have been used to investigate multiple aspects of stone formation pathophysiology, one of their most important contributions has been related to stone formation and urine supersaturation. Since the development and use of the EQUIL2 equation, researchers have had a reliable program for calculating the urinary supersaturation of common stone components (Werness et al., 1985). Classic work has shown that supersaturation by itself does not necessarily equate to crystallization; compared to simple solutions, human urine contains an upper limit of metastability due to inhibitors of stone growth (Pak and Holt, 1976).

Asplin et al. (1997) demonstrated that compared to controls, GHS rats had higher calcium oxalate (CaOx) and calcium phosphate (CaP) supersaturation values, regardless of whether they were fed a low- or high-calcium diet. These increases in supersaturation were accompanied by a higher upper limit of metastability for CaOx but not so for brushite (CaP), reflecting that urine can have higher concentrations of CaOx without precipitating when under certain conditions. Meanwhile, the supersaturation level of CaP is elevated and near its upper limit of metastability, which is thought to be the main reason this GHS rat model results in CaP crystals instead of CaOx. Bushinsky et al. (2000) subsequently demonstrated that lowering dietary phosphorous in these GHS

rats resulted in decreased urinary phosphorous excretion and reduced supersaturation of calcium phosphate, with none of these rats producing CaP crystals.

As will be discussed later, Bushinsky et al. (2002) also demonstrated the ability to have these GHS rats produce calcium oxalate crystals through the addition of hydroxyl-L-proline.

2.2.1.2 APPLICABILITY

The GHS model has provided important contributions to the overall understanding of hypercalciuria and the role of supersaturation in the formation of urinary stones. Yet it remains unclear how this hypercalciuria model fits in translation to what is known regarding human hypercalciuria and stone formation. Our current classification of human hypercalciuria is not homogeneous. Classically, humans have been thought to have hypercalciuria etiologies ranging from absorptive—diet independent (type 1), diet dependent (type 2), renal urinary phosphate leak (type 3), to primary hyperparathyroidism (Stoller and Meng, 2007). All of these conditions result in large amounts of calcium present in the urine, similar to what has been created in the GHS rat model. Yet the question remains, which type of human hypercalciuria does this GHS rat model represent? Most patients with primary hyperparathyroidism should theoretically develop urinary stones, yet only about 10% of these patients will actually develop one. There must be critical factors other than serum and urinary calcium that contribute to stone formation. Therefore, this GHS rat model remains limited as it does not account for the heterogeneity that is found in clinical practice.

2.3 Hyperoxaluria

2.3.1 Exogenous Induction

A number of rat models for hyperoxaluria have relied on exogenous administration of lithogenic materials including sodium oxalate, glycolic acid, ethylene glycol (EG), and hydroxy-L-proline (HLP) (Khan, 1991; Khan and Hackett, 1993b; Khan et al., 1979a, 1982, 1992; Ogawa et al., 1990). The methods by which these materials have been delivered to the rat range from enriched chow, drinking water modification, gavage instillation, intraperitoneal injection, and even subcutaneous implantation of oxalate-containing osmotic minipumps (Khan, 2013). This section reviews how each lithogenic agent has been studied in the rat and shown to culminate in stone induction. For a summary of hyperoxaluria induction, see Table 17.1.

2.3.1.1 SODIUM OXALATE

As Khan et al. (1979a) illustrated, predictable calcium oxalate crystal formation in different areas of the nephron depends on elapsed time after intraperitoneal

TABLE 17.1　Rat Models Related to Hyperoxaluria

Type of approach	Lithogenic agent (references)	Diet/administration	Effects
Cross-breeding	Inbreeding hypercalciuric progeny (Asplin et al., 1997; Bushinsky and Favus, 1988; Bushinsky et al., 1994, 2000, 2002; Evan et al., 2004; Krieger et al., 1996; Li et al., 1993; Yao et al., 1998)	• Multiple-generation inbred • Multiple diets/agents applied	• Hypercalciuria • Hyperoxaluria • CaOx crystals • CaP crystals
Exogenous induction	Sodium oxalate (Khan and Hackett, 1993b; Khan et al., 1979a, 1982, 1991, 1992)	• Intraperitoneal injection of 10 mg/kg sodium oxalate	• Prompt CaOx crystal deposits • Crystal aggregation in the ducts of Bellini
	Glycolic acid (Ogawa et al., 1990)	• Free drinking of water with powdered 3% glycolic acid	• Hyperoxaluria • Hypocitraturia • CaOx crystal deposits
	Ethylene glycol (EG) (de Bruijn et al., 1994; de Water et al., 1996; Eder et al., 1998; Green et al., 2005; Huang et al., 2002; Khan et al., 1992, 2002a; Robinson et al., 1990; Thamilselvan et al., 1997; Yamaguchi et al., 2005)	• 0.75% EG in water with/without ammonium chloride, vitamin D, calcium chloride	• Hyperoxaluria • CaOx crystalluria • CaOx crystal deposits • Renal toxicity
	Hydroxy-L-proline (HLP) (Khan et al., 1989, 2006; Tawashi et al., 1980)	• Intraperitoneal injection of 2.5 kg/kg HLP • Mixed in chow of 5% HLP	• Hyperoxaluria • CaOx crystal deposits • Less toxic compared to other agents
Dietary manipulation	Potassium oxalate supplement (Wiessner et al., 2011)	• 5% level of potassium oxalate	• CaOx crystal deposits
	Magnesium (Mg) deficiency (Li et al., 1985; Rushton and Spector, 1982)	• Dietary Mg deprivation	• Increase of CaP crystal deposits
	Vitamin B6 (pyridoxine) deficiency (Andrus et al., 1960; Gershoff and Andrus, 1961; Gershoff and Faragalla, 1959)	• Dietary intentional deficiency of pyridoxine	• Hyperoxaluria • Hypocitraturia • CaOx crystal deposits
Surgery	Intestinal resection (O'Connor et al., 2005; Smith et al., 1972; Worcester et al., 2005)	• Resection of distal 40–45 cm of the terminal ileum • Combination diet of high oxalate/low calcium/high lipid fat	• Hyperoxaluria • Hypocitraturia • CaOx, CaP, CaCO$_3$ crystal deposits
	Gastric bypass surgery (Canales et al., 2013)	• Roux-en-Y gastric bypass • 40% fat and 1.5% sodium oxalate diet	• Hyperoxaluria • CaOx crystal deposits

injection of sodium oxalate. Male Sprague-Dawley rats receiving varied doses (3, 5, 7, 9, and 10 mg/kg) of sodium oxalate demonstrated persistent hyperoxaluria and crystals in a dose-dependent fashion (Khan, 1991; Khan and Hackett, 1993b; Khan et al., 1992). Rats receiving the highest dose of 10 mg/kg had over 500% more oxalate excreted compared to controls. Moreover, these rats demonstrated persistent crystals that remained present up to 7 days after injection. These studies also demonstrated how quickly crystals could be detected within the rat kidney, as investigators identified calcium oxalate crystals within 15 min of injection. By 6 h there was noticeable crystal aggregation in the ducts of Bellini (Khan et al., 1982). While this demonstrated the ability to induce urinary crystalluria relatively quickly, one should keep in mind that this does not necessarily equate to urinary stone development.

2.3.1.2 GLYCOLIC ACID

Through the administration of powdered 3% glycolic acid dissolved in drinking water, Ogawa et al. (1990) demonstrated the ability of male Wistar-strain rats to produce high levels of 24-h urinary oxalate and subsequent calcium oxalate calculi. Interestingly, this study also demonstrated how adding certain magnesium (Mg) salts to a diet high in glycolic acid resulted in increased urinary citrate levels despite relatively high levels of urinary oxalate excretion. Specific magnesium agents (Mg hydroxide, Mg silicate, and Mg citrate) were associated with significantly lower mean

renal tissue urinary oxalate concentrations (Ogawa et al., 1990). When compared with rats on a strict glycolic acid diet, rats who received additional Mg salt supplementation had decreased evidence of stone formation.

2.3.1.3 ETHYLENE GLYCOL

The administration of EG in drinking water has been shown to result in consistent induction of hyperoxaluria, crystalluria, and calcium oxalate nephrolithiasis (Khan et al., 2002a). Studies have shown that administering solely 0.75% EG to male rats eventually gave rise to persistent crystalluria at 12 days and renal crystal deposits at approximately 3 weeks (de Bruijn et al., 1994). To enhance the development of crystal deposition, EG often has been combined with other agents, such as ammonium chloride (AC) to reduce urinary pH, as well as vitamin D or calcium chloride to result in subsequent hypercalcemia and hypercalciuria (de Bruijn et al., 1994; de Water et al., 1996; Khan et al., 1992). The amount of calcium oxalate deposition in kidneys was found to be dependent on the concentration of both EG and AC. This lithogenic combination decreased the time for crystalluria from 12 to 3 days, and detectable calcium oxalate nephrolithiasis from 3 weeks down to 1 week (Khan et al., 1992).

A major limitation with the administration of EG is that it has been shown to be a toxic agent that can cause multiorgan failure (Eder et al., 1998). Multiple studies have shown it causes renal toxicity. Yamaguchi et al. (2005) demonstrated that the combination of EG and AC can have a significant detriment on rat health—as shown by those rats who received higher EG concentrations subsequently had increased urinary N-acetyl-β-D-glucosaminidase (NAG), an indicator of renal toxicity. These rats were found to have lower weights and worsening renal function as estimated by creatinine clearance. Other studies have also found that lipid peroxidation, increased free radicals, and metabolic acidosis also take place as a result of EG (Eder et al., 1998; Huang et al., 2002; Robinson et al., 1990; Thamilselvan et al., 1997). Even with evidence that a limited (<0.75%) dose of EG can bypass the usual resultant metabolic acidosis (Green et al., 2005), recognition of EG's toxic effects has since led to studies utilizing alternative, less toxic lithogenic agents.

2.3.1.4 HYDROXY-L-PROLINE

Hydroxy-L-proline (HLP) is a common ingredient in Western diets and has been shown to be less toxic than other lithogenic agents. It is derived from the amino acid proline and is a component of collagen that is metabolized to both pyruvate and glyoxalate, primarily in the renal proximal tubule and hepatocyte mitochondria (Knight and Holmes, 2005).

Earlier studies used intraperitoneal injection of HLP to successfully demonstrate the presence of calcium oxalate crystals within the rat kidney (Tawashi et al., 1980). This study utilized a large dose of 4-HLP (2.5 g/kg) and subsequently found a doubling of kidney volume and weight compared to controls. Using scanning electron microscopy, both calcium oxalate dihydrate (Weddellite) and calcium oxalate monohydrate (Whewellite) crystals were identified.

Initial attempts at administering HLP in chow at a dose of 5.2% for 10 days failed to produce calcium oxalate crystals despite demonstrating hyperoxaluria (Khan et al., 1989). Eventually Khan et al. (2006) provided 5% HLP (weight/weight HLP/chow) to male Sprague-Dawley rats and compared treated versus controls at 4, 6, and 9 weeks. At 4 weeks, all treated rats were found to have CaOx crystals throughout the regions of the kidney, with a majority present in the tubular lumens of the distal tubules and collecting ducts. Interestingly by 9 weeks these crystals were mainly located at the tips of the renal papillae.

2.3.1.5 DIETARY MANIPULATION

Investigators have also examined dietary administration of potassium oxalate as an alternative method compared to HLP. Wiessner et al. (2011) found that a 5% level of potassium oxalate was required to produce calcium oxalate crystals in both Dahl salt-sensitive and Brown Norway male rats. Furthermore, 2% supplemental dietary oxalate was all that was needed to result in an increased urine oxalate in control rats.

Magnesium (Mg), classically, was thought to be an inhibitor of calcium oxalate stone formation. Previous in vitro studies demonstrated the ability of Mg to decrease both calcium oxalate and calcium phosphate growth and nucleation (Li et al., 1985). Subsequently, investigators examined the effect of dietary Mg deprivation in hyperoxaluric rats, demonstrating the increased production of calcium phosphate (apatite) stones (Rushton and Spector, 1982).

Meanwhile, endogenous oxalate excretion has been shown to be inversely related to the amount of dietary vitamin B6 (pyridoxine) (Gershoff and Faragalla, 1959). The intentional deficiency of vitamin B6 can be employed in rats to enhance hyperoxaluria, hypocitraturia, and subsequent calcium oxalate crystal formation (Andrus et al., 1960). Studies exposing these pyridoxine deficient rats to supplemental Mg demonstrated the ability to counteract the hypocitraturia and effectively prevent calcium oxalate crystal formation (Gershoff and Andrus, 1961). This occurred despite these rats displaying persistent hyperoxaluria, confirming that the solvent characteristics had changed and that simply having high urinary oxalate was not the sole reason for the calcium oxalate stone formation.

2.3.2 *Intestinal Resection*

Small bowel resection has historically been associated with an increased risk of nephrolithiasis dating back to Smith et al. (1972). O'Connor et al. (2005) developed a rat model in which the distal 40–45 cm of the terminal ileum was resected and these rats were compared to sham controls that underwent transection of the distal ileum followed by reanastamosis without any intestine removal. After surgery these rats were then given either a normal versus a combination high oxalate (1% sodium oxalate)/low calcium (0.02%)/high lipids (18%) fat diet, before eventually being euthanized at 4, 5, 6, and 7 months postsurgery; 24-h urine samples demonstrated that those resected rats on the high oxalate/low calcium diet, developed hyperoxaluria, hypocitraturia, and crystals throughout the cortex, medulla, and renal papilla (Worcester et al., 2005). These crystals were comprised of a mixture of calcium oxalate, hydroxyapatite (calcium phosphate), and calcium carbonate. Meanwhile, none of the sham animals subsequently developed crystals, even those on the high oxalate diet, highlighting the importance of the bowel resection on crystal formation.

2.3.3 *Gastric Bypass Surgery*

Multiple previous studies have suggested an association between gastric-bypass surgery and an increased risk of kidney stone development (Duffey et al., 2010; Maalouf et al., 2010; Matlaga et al., 2009; Park et al., 2009; Patel et al., 2009). Patients undergoing Roux-en-Y gastric bypass (RYGB) have been shown to have significant hyperoxaluria and hypocitraturia (Maalouf et al., 2010; Patel et al., 2009). Epidemiologic studies have shown that patients post-RYGB have a increase in stone development: a twofold increase in nonstone formers and a fourfold increase in previous stone formers (Chen et al., 2013).

The pathophysiologic mechanism for this increased urinary oxalate is thought to be from a saponification process with excess fatty acids and bile salts binding to calcium, thereby leaving excess unbound oxalate free to be more easily absorbed by the enteric system (Canales and Hatch, 2014; Hofmann et al., 1983). Prospective studies have shown this hyperoxaluria to be a predictor of developing stones after RYGB, with an 8% incidence at 1-year postop reported, as well as a higher likelihood of stone formation as more time elapsed after surgery (Duffey et al., 2010; Valezi et al., 2013). Recent innovative work has delved into this process further by utilizing the rat as a successful animal model.

To investigate the mechanism by which post-RYGB hyperoxaluria takes place, Canales et al. (2013) utilized a diet-induced obesity (DIO) model in male Sprague-Dawley rats followed by subsequent intervention randomized to either sham surgery (controls) or RYGB. As shown in Fig. 17.1, this study examined stool and urine for respective fecal fat content and 24-h urine volume,

pH, oxalate and calcium levels. Results demonstrated that post-RYGB rats on a high (40%) fat and supplemental potassium oxalate had significantly less dietary fat absorption and excreted an eightfold higher amount of fecal fat compared to controls. Moreover, those post-RYGB rats with oxalate supplementation had a fivefold increase in urinary oxalate excretion, while those without supplemental oxalate had a twofold increase in urine calcium excretion.

Interestingly, this study also found that all RYGB rats had a significant 250% increase in water consumption and a twofold increase in urine volume excretion, regardless of dietary oxalate or fat content. While this finding has been postulated to be due to altered thirst mechanisms (Canales et al., 2013), it highlights a major difference compared to results from previous human studies that have shown significant decreases in urine volume post-RYGB (Agrawal et al., 2013; Hofmann et al., 1983; Wu et al., 2013). No doubt future studies will look to further elucidate the impact of RYGB and urinary volume production.

2.4 Predominant Stone Type

As mentioned previously, the GHS rat model has consistently demonstrated that those rats consuming a standard (1.2% Ca) diet for 18 weeks produce solely calcium phosphate calculi (Bushinsky et al., 1995). Bushinsky et al. (2002) examined how the addition of 1, 3, and 5% *trans*-4-HLP to GHS rats altered urine calcium and stone type. This study demonstrated that those rats receiving 5% HLP had decreased urine calcium excretion and also had consistent calcium oxalate calculi composition.

Given that the vast majority of rat studies utilizing exogenous induction have relied on oxalate precursors as the lithogenic agent, the resulting stones have been composed of calcium oxalate. There remains a void of studies that have been able to reproduce uric acid stones in the rat. Moreover, the potential role of heavy metals within rat models is an area of future research.

2.5 Limitations

While the rat model has been the most studied of all animal models for urinary stone disease, it does have some limitations. Like other vertebrates it requires formal approval for animal experimentation and lately the costs of rats has been increasing (CCPA, 2000). Rats are also corphagic (they eat their own stool) therefore they can consume elements that are not necessarily accounted for in their routine diets.

The majority of these models have focused on producing hyperoxaluria. It should be noted that the majority of human kidney stone patients do not suffer from hyperoxaluria, therefore, this modeling as limited
FIGURE 17.1 Diet-induced obesity *(DIO)* rat model followed by either sham or RYGB surgery. Following surgery, rats were randomized to high (40%) fat chow or 1.5% potassium oxalate for 5 weeks, followed by 2 weeks of a normal (10%) fat diet with or without 1.5% potassium oxalate. *Source: Reprinted with permission from Canales, B.K., Ellen, J., Khan, S.R., Hatch, M., 2013. Steatorrhea and hyperoxaluria occur after gastric bypass surgery in obese rats regardless of dietary fat or oxalate. J. Urol. 190, 1102–1109.*

applicability. As will be discussed later, modified gene expression studies have mainly been performed in other animal models besides the rat. While there are resources available for rat transgenic studies (Rat Genome Database, http://rgd.mcw.edu), comparatively there are considerably fewer for this application, which represents a limitation in the future use of this animal model.

3 MOUSE MODEL

Since the completion of the human genome project in 2003 (Collins et al., 2003), the mouse has been the most studied of all animals with respect to transgenic and gene-targeting research. Investigators have used the mouse model as a vehicle for genetic modification to examine both physiological and genomic features that are similar to humans. Applying molecular and genomic science to the mouse has helped unveil some of the intricacies involved in the pathogenesis of urinary stone disease.

3.1 Anatomic/Physiologic/Genomic Comparison Between Mice and Humans

The respective genomes of mice and humans are comparably similar as both genomes contain approximately 3.1 billion base pairs. Mice and human genomes are ~85% identical on an average; with some greater than 95% identical. Only about 5% of the sequence consists of protein-coding regions.

Mice generally weigh between 25 and 35 g, which is approximately 1/2500 the size of humans (Liebelt, 1998). Yet as the mean weight of an individual mouse kidney generally comprises 0.5%–0.8% of their body weight, mice kidneys are relatively denser compared to the average human kidney that comprises only 0.2% of a person's body weight (Meneton et al., 2000). Meanwhile, the maximal urine concentration (mice 4000 mOsm/kg H_2O vs. human 1200 mOsm/kg H_2O) is higher in mice than in humans (Meneton et al., 2000; Molina and DiMaio, 2012; Sands and Layton, 2009).

Like rats, the main difference in mice kidneys compared to humans is that they are unipapillary, therefore each kidney has a single papilla surrounded by the pelvis. Microscopic features show similar cortex and medullary components including a glomerular unit, tubule structures, and vascular framework (Liebelt, 1998).

3.2 Hyperoxaluria

3.2.1 Exogenous Induction

Similar to what has been performed in the rat, multiple researchers have experimented with inducing hyperoxaluria in mice by administering lithogenic agents,

such as ethylene glycol, hydroxyl-L-proline, and glyoxylate (Khan and Glenton, 2010; Okada et al., 2007). Despite successfully inducing hyperoxaluria, exogenous administration of these agents alone has demonstrated only a short duration of relatively few CaOx crystals in mice (Khan and Glenton, 2010; Okada et al., 2007). Okada et al. treated male C57BL/6 mice with either free drinking or daily intraperitoneal injections of EG, glycolate, and glyoxylate and observed crystal formation. Only the 80 mg/kg administration of glyoxalate produced detectable renal CaOx crystals after 3 days, with a peak on day 6 (Okada et al., 2007). However, a subsequent significant decline in stone presence ensued such that by day 15 hardly any stones remained. Meanwhile, Khan et al. also demonstrated that glyoxalate could produce crystalluria, however, there were significantly increased levels of lactate dehydrogenase (LDH), which has been shown to reflect renal toxicity (Khan and Glenton, 2010).

3.2.2 Genetic Modification

Given that dispensing solely lithogenic agents yielded minimal stone formation in mice, researchers have instead focused on utilizing genomic engineering using transgenic mice to help with inducing stone formation. Historically, in vitro studies demonstrated the importance of macromolecules, such as osteopontin (OPN) and Tamm–Horsfall protein (THP) as potential inhibitors of stone formation (Shiraga et al., 1992; Worcester, 1994). Employing the mouse to perform selective knockout (KO) of OPN and THP, investigators have established their critical role as inhibitors of stone formation.

OPN is an acid-rich phosphoglycoprotein that is expressed in inflammatory and wound-healing cascades, mineralized tissue like bone and teeth, as well as vascular and renal tubular cells (Giachelli and Steitz, 2000). It has also been shown to modulate ectopic calcification and bone mineralization, with OPN binding tightly to the calcium phosphate mineral, hydroxyapatite (Hunter et al., 1996). Wesson et al. (2003) were the first to demonstrate that an in vivo model of OPN KO mice could produce CaOx crystals. This study induced hyperoxaluria in both wild-type and KO mice by adding 1% ethylene glycol (EG) to drinking water for 4 weeks. Hyperoxaluric KO mice demonstrated renal tubular deposits of exclusively CaOx crystals. Wild-type hyperoxaluric mice also experienced a two- to four-fold upregulation of renal OPN expression, suggesting evidence of the renoprotective effects of this macromolecule (Wesson et al., 2003).

Meanwhile, THP, also known as uromodulin, is the most abundant urinary protein among all placental animals (Serafini-Cessi et al., 2003). Similar to OPN, THP is expressed by renal epithelial cells; however, unlike OPN, THP is kidney-specific as it is expressed only in the thick ascending loop of Henle (Kumar and Muchmore, 1990). Mo et al. (2004) compared wild-type versus THP KO

mice receiving 4 weeks of drinking water containing both 1% EG and 4 IU/mL vitamin D3. Results showed that 76% of THP KO mice produced calcium crystals while none were observed in wild-type mice.

Comparing these studies in which either THP or OPN was knocked out (Mo et al., 2004; Wesson et al., 2003), once these mice were given a hyperoxaluric load there was a compensatory increased expression of the remaining macromolecule. Yet this response was not enough to prevent crystallization, suggesting that the potential renoprotective effects of each might be based on a synergistic relationship. A subsequent study demonstrated this nicely, as a higher percentage (~39%) of double-null mice spontaneously developed renal papillary calcium deposits compared to 14% of THP–null and 10% OPN–null mice (Mo et al., 2007).

3.2.3 Metabolic Syndrome

A recent investigation looked at mice with *Leptin* gene deficiencies and metabolic syndrome (Ob/Ob) compared to wild-type (lean) mice, and how a high-fat diet in combination with hyperoxaluria induction impacted crystal production (Taguchi et al., 2015). The lithogenic agent was 1% EG in drinking water and diets consisted of either standard fat (10%) or high fat (62%). Results demonstrated those Ob/Ob mice on both EG and a high-fat diet demonstrated not only hypercalciuria and hyperoxaluria, but diffuse CaOx renal crystal deposits in the intratubular spaces of the renal cortex-medulla (Taguchi et al., 2015). This study also found a higher number of macrophages associated with these Ob/Ob mice, reinforcing findings of previous studies that found renal macrophages associated with crystal formation in the mouse (Okada et al., 2009). The true nature of this relationship between macrophages and crystal formation remains an area of future study.

3.3 Transporter Knockout Model

In addition to exogenous induction of hyperoxaluria, researchers have also performed solely transporter knockout in the mouse to induce hyperoxaluria, hypercalciuria, hyperuricosuria, and cystinuria.

3.3.1 Oxalate Transporter

Sulfate anion transporter-1 (Sat1) also known as Slc26a1, and Slc26a6 are both anion exchangers expressed on the apical membrane in renal epithelial cells that help mediate oxalate exchange (Dawson et al., 2010; Jiang et al., 2006). Both Sat1-null and Slc26a6-null mice have demonstrated abnormal oxalate homeostasis. Compared to wild-type mice, knockout mice demonstrated 2–3.5 times and 1.5–2 times higher oxalate concentrations in urine and plasma, respectively (Dawson et al., 2010; Jiang et al., 2006). Comparing Slc26a1and Slc26a6 knockout mice, 26 and 88%,

respectively had visibly detectable bladder stones, as well as CaOx crystal deposits in renal tubules and collecting ducts (Dawson et al., 2010; Jiang et al., 2006).

3.3.2 Na⁺-Phosphate Transporter

The sodium-hydrogen exchanger regulator factor-1 (NHERF-1) binds renal tubular transporters including the Na⁺-phosphate cotransporter 2a (Npt2a). NHERF-1 knockout mice have shown increased urinary calcium, phosphate, and uric acid excretion, resulting in tubulo-interstitial crystal deposits in the kidney (Weinman et al., 2006). Similar to NHEFR-1 mice, Npt2a knockout mice demonstrated hypercalciuria and renal crystal deposits in the kidney (Khan and Glenton, 2010). Both NHERF-1 and Npt2a knockout mice had calcium phosphate crystals in their kidney.

3.3.3 Cystine Transporter

A knockout transporter model has also been demonstrated for cystinuria, an autosomal-recessive disease of proximal tubular reabsorption of cystine and dibasic amino acids that results in cystine stones. Currently, there are two cystinuria phenotypes that are described, based on the heterozygosity of cystine and dibasic amino aciduria. Type I refers to the first cystinuria gene, *SLC3A1*, that is located on chromosome 2 (2p21) and encodes the rBAT transporter in both intestinal and renal epithelial cells (Biyani and Cartledge, 2006). Nontype I involves a second cystinuria gene, *SLC7A9*, that has been found on chromosome 19 (19q13) and encodes the light chain $b^{0,+}AT$ protein (Dello Strologo et al., 2002). Investigators have demonstrated that *Slc7a9* knockout mice experienced cystinuria, cystine crystalluria, and cystine urolithiasis (Fig. 17.2) (Feliubadaló et al., 2003).

Previous work by Peters et al. (2003) established a reliable *Slc3a1* murine knockout model that produces cystine stones. Recently a study by Zee et al. (2017) demonstrated the remarkable finding that oral administration of alpha-lipoic acid (ALA) significantly reduced or eliminated cystine stone development in $Slc3a1^{-/-}$ mice. ALA also dramatically reduced stone growth in those KO mice with existing stone burden. Interestingly ALA did not change the urinary pH or reduce quantitative urinary cystine levels. Furthermore, ALA tested in-vitro did not change crystallization, suggesting that it is likely one of its metabolites that alters crystal structure and thereby interferes with cystine stone pathogenesis. Future work on this exciting new pharmacologic intervention is currently underway.

3.4 Histology/Pathology/Stone Composition

CaOx crystals in hyperoxaluric mice have been shown with the use of von Kossa, Yasue, and Pizzolato stains (Mo et al., 2004, 2007; Taguchi et al., 2015; Wesson
FIGURE 17.2 Cystine stones of urinary tract in *Slc7a9* knockout mice. (A) Comparison between urinary tract anatomy of a normal mouse (Slc7a9⁺/⁺) versus nontype I knockout (Slc7a9⁻/⁻) mouse. (B) Radiograph view of the same mice urinary systems—wild type (+/+, left) and homozygous (−/−, right). *Arrowheads*, kidney stones; *arrows*, bladder stones. *Source: Reproduced with permission from Feliubadaló, L., Arbonés, M.L., Mañas, S., et al., 2003. Slc7a9-deficient mice develop cystinuria non-I and cystine urolithiasis. Hum. Mol. Genet. 12, 2097–2108.*

et al., 2003). In those mice who received intraperitoneal glyoxalate injections, X-ray diffraction analysis demonstrated that crystals were composed of calcium, phosphate, and oxalate (Okada et al., 2007). This same analysis was performed in OPN null mice, finding that the predominant crystal type was composed exclusively of calcium oxalate monohydrate (Wesson et al., 2003).

OPN and NHERF-1 knockout mice mainly developed interstitial crystals in the papilla whereas Slc26a6, Npt2a knockout mice, and normal mice with intraperitoneal glyoxylate injection showed impacted crystals in dilated papillary tubular lumens (Jiang et al., 2006; Khan and

TABLE 17.2 Summary of Mice Models of Nephrocalcinosis

Author (references)	Mouse	Exogenous method	Urinary features	Nephrocalcinosis
Feliubadaló et al. (2003)	Slc7a9 KO	Normal diet	Cystinuria, cystine crystalluria	Cystine stone in pelvis and bladder
Wesson et al. (2003)	OPN KO	Four weeks administration of 1% EG in drinking water	Hyperoxaluria, COD/COM crystalluria	Intratubular COM crystals
Mo et al. (2004, 2007)	THP KO	Normal diet or 4 weeks administration of 1% EG and 4 IU/mL vit. D3 in drinking water	Not described	Intratubular and interstitial CaOx crystals
Weinman et al. (2006)	NHERF-1 KO	Normal diet	Hypercalciuria, hyperphosphosuria, hyperuricosuria	Interstitial CaOx crystals

Okada et al. (2007)	C57BL/6	Daily 80 mg/kg GOX intraperitoneal injection	Hyperoxaluria, high CaO_x index	Intratubular COM crystals
Khan and Glenton (2010)	Npt2a KO	Four weeks administration of 1.5% GOX or 5% HLP in chow	COD/COM crystalluria	Intratubular/interstitial CaOx crystals and interstitial CaP crystals
Dawson et al. (2010)	Sat1 (Slc26a1) KO	Normal diet	Hyperoxaluria	Intratubular CaOx crystals and bladder stone
Taguchi et al. (2015)	MetS model	Two weeks administration of 1% EG in drinking water and high-fat diet	Hyperoxaluria, hypercalciuria	Intratubular CaOx crystals

CaOx, Calcium Oxalate; CaP, Calcium phosphate; COD, calcium oxalate dihydrate; COM, calcium oxalate monohydrate; EG, ethylene glycol; GOX, glyoxalate; HLP, hydroxy-L-proline; KO, knockout; MetS, metabolic syndrome; THP, Tamm–Horsfall protein.

Glenton, 2010; Okada et al., 2007; Weinman et al., 2006; Wesson et al., 2003; Wu, 2015).

In comparison to the hyperoxaluria-induced mice model, CaO_x stones of Slc26a6 knockout mice and cystine stones of Slc7a9 knockout mice were actual stones found in the renal pelvis and bladder (Feliubadaló et al., 2003; Jiang et al., 2006). These urinary stones were clinically consistent with human kidney stones, not just nephrocalcinosis as in other mice models (Table 17.2).

Inflammation and renal tubular cell damage were shown in intraperitoneal glyoxylate injected mice, metabolic syndrome model mice, and Slc7a9 knockout cystinuria mice kidneys. As described earlier, intraperitoneal glyoxylate injected mice develop intratubular CaOx crystals in 6 days; however, this acute crystal formation is accompanied with severe tubular cell damage caused by oxidative stress and immune cell infiltration (Okada et al., 2009). These inflammatory changes were facilitated by immune and/or metabolic disorders, such as obesity, hyperlipidemia, and antiinflammation disorders (Taguchi et al., 2014, 2015).

3.5 Limitations

Based on its similar anatomical, physiological, and genomic features, mice theoretically would be an ideal model for nephrolithiasis. Given its history with genomic engineering, the mouse has a clear advantage over other animal models. Yet despite several transgenic tools, its accuracy and consistency in relation to human kidney stone disease remain controversial among researchers.

An important point is that the pathogenesis of crystal formation in mice is different compared to humans. Human kidney stones are believed to originate from interstitial calcifications—Randall's plaque (Randall, 1940; Stoller and Meng, 2007). While some mice models have similar interstitial calcifications; these are gradually ingested and removed by inflammatory cells, eventually appearing as intratubular crystals. These crystals were not consistent with Randall's plaque (Khan and Canales, 2011). Furthermore, the presence of severe inflammation and cellular damage in many mice models represents significant renal injury, which is significantly different from most human kidneys with urolithiasis.

Similar to other animal models that focus on hyperoxaluria, the majority of mice models rely on induction of hyperoxaluria. Except for primary hyperoxaluria patients, relatively few human kidney stone patients have hyperoxaluria. In addition, the prevalence of cystinuria is rare (less than 1% of urolithiasis patients), therefore these mice models are not representative of the majority of humans who suffer from urinary stone disease.

4 FLY MODEL

Drosophila melanogaster has been studied as a research model across multiple organ systems for over a century (Jennings, 2011). It was through his work with *Drosophila*

in the 1920s that Dr. Herman Muller won the Nobel prize for discovering the impact of radiation on gene mutation (Muller, 1928). Since then, investigators have looked to the fruit fly as a model given that it has numerous advantages over other vertebrate animal models.

As an invertebrate, the fly requires no formal animal experimentation review to initiate a research protocol. Compared to other animal models, the lack of ethical and safety concerns makes it much easier to obtain and implement a study protocol. Meanwhile, with a short life cycle under standard laboratory conditions (typically <60 days), researchers can not only observe a disease process over the animal's entire lifespan, but also screen the effectiveness of medical drugs much more rapidly. Additionally, female flies are capable of producing hundreds of offspring in a matter of days, thereby studies can have large numbers of specimens prepared in a short amount of time. As their use is associated with relatively low-cost dietary and lab spatial requirements, it is dramatically less expensive to start and maintain a fly lab (Stocker and Gallant, 2008).

From a genetic standpoint, *Drosophila* have a fewer number of chromosome pairs—only 4—compared to 23 in humans (Chien et al., 2002). The fly genome has been completely sequenced and there is a well-established, free fly database—FlyBase (http://flybase.org)—dedicated to cataloging homology between human and fly genes (Tweedie et al., 2009). Approximately 75% of human disease genes have correlates in *D. melanogaster*, with nearly 80% of human renal transporters found in the fly Malpighian tubule (Reiter et al., 2001). With such an abundance of *Drosophila* resources available, targeted

animal gene manipulation has become a much more feasible endeavor. As a result, researchers have started applying this powerful translational model in the study of urinary stone disease.

4.1 Anatomic/Physiologic Comparison Between Fly and Humans

Initially one would not necessarily think of *Drosophila* as a model for stone disease given the inherent differences between human and fly anatomy. As an invertebrate, flies lack a bony skeleton. They also go through four distinct phases of life—starting first as an egg, then larva, pupa, and finally an adult fly. Instead of a mammalian vascular system, flies have a fluid-filled hemocoel cavity. This open circulatory system uses hemolymph in a similar fashion to how human blood vessels carry blood. This cavity contains two sets of free-floating Malpighian renal tubules, as well as an aglomerular renal system (Dow and Romero, 2010). The Malpighian tubule is homologous to human renal tubules and function to filter the fly hemolymph in a manner similar to how human tubules filter blood. Recent work has elucidated that these remarkable similarities between human and fly systems suggest an evolutionary relationship (Fig. 17.3) (Weavers et al., 2009).

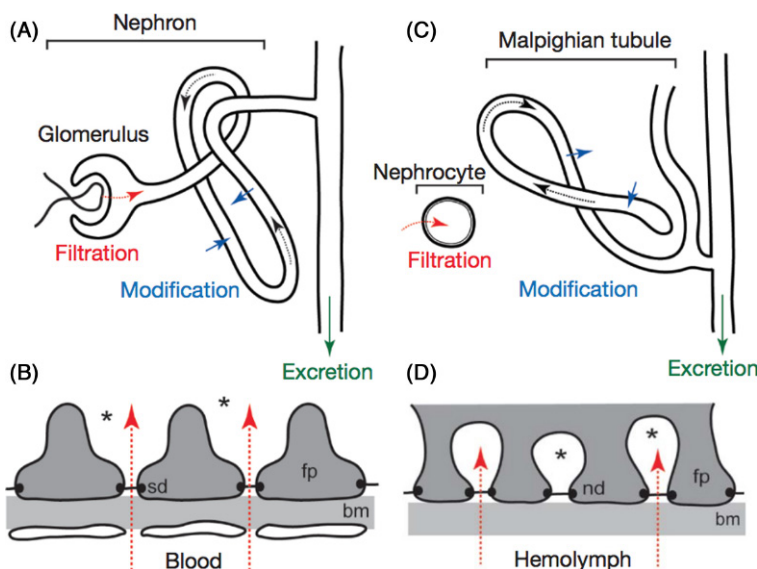
Drosophila have two anatomically separate organs that comprise their renal system—nephrocytes and Malpighian tubules. Nephrocytes filter the hemolymph and remove waste in a manner similar to podocytes in the human glomerulus (Weavers et al., 2009). Meanwhile, the anterior and posterior pairs of Malpighian tubules represent the functional equivalent of a human nephron.


FIGURE 17.3 **Comparison of glomerular and insect renal systems.** The human glomerular (A) and podocyte slit diaphragm (B) are similar to that of insect nephrocyte renal systems (C) and their basal labyrinth (D). *bm*, Basement membrane; *fp*, foot process; *nd*, nephrocyte diaphragm. *Source: Reprinted with permission from Weavers, H., Prieto-Sanchez, S., Grawe, F., et al., 2009. The insect nephrocyte is a podocyte-like cell with a filtration slit diaphragm. Nature 457, 322–326.*
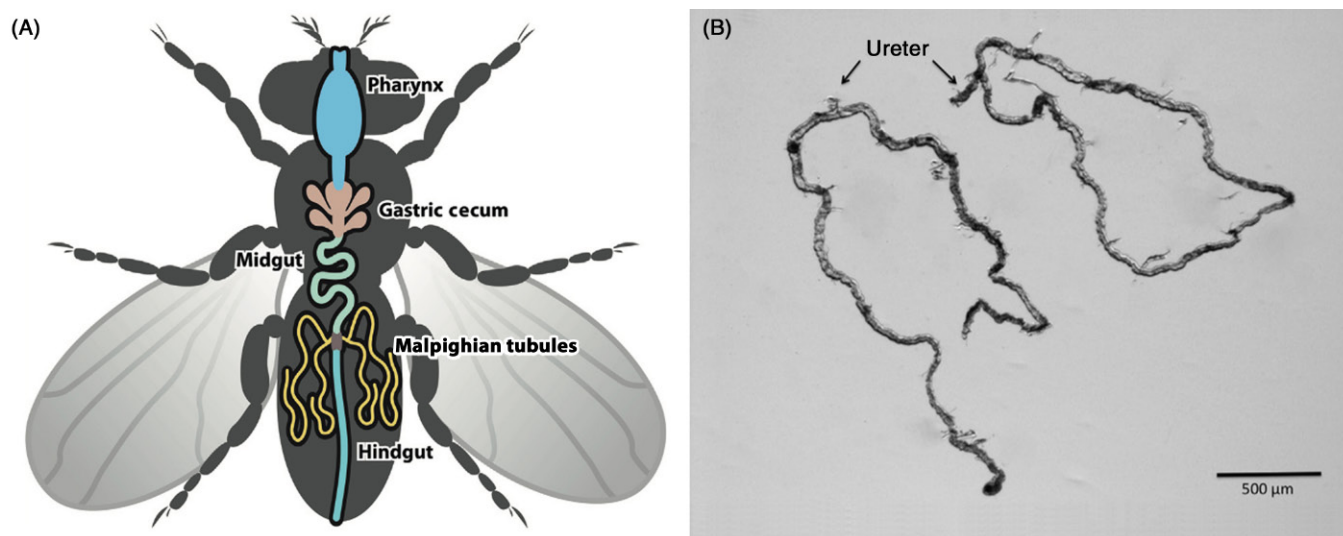

FIGURE 17.4 **Anatomy of *D. melanogaster*.** (A) Schematic of *D. melanogaster* excretory tract: two pairs of Malpighian tubules, one anterior and one posterior, each combine into a short common ureter that then joins the hindgut. (B) Example of anterior and posterior pairs of Malpighian tubules dissected free from adult *D. melanogaster*. *Arrows* represent common ureter. *Source: Reprinted with permission from Miller J., Chi T., Kapahi P., et al., 2013.* Drosophila melanogaster *as an emerging translational model of human nephrolithiasis*, J. Urol. *190, 1648–1656.*

The anterior Malpighian tubules consist of four distinct domains: the initial (distal), transitional, main and lower (proximal) segments (Rheault and O'Donnell, 2004; Sözen et al., 1997). The posterior Malpighian tubules do not possess the initial segment. The main domain segment is comprised of two main cell types—principal cells and stellate cells—both of which help control the active transport and excretion of solutes including calcium, uric acid, and phosphorous (Weavers et al., 2009). The anterior and posterior tubule pairs combine to form a common ureter (Fig. 17.4), that then joins the gastrointestinal tract at the junction of the midgut and hindgut.

Previous work has shown that *Drosophila* physiology involves the production of two types of luminal concretions (Wessing et al., 1992). Type I is composed of mainly calcium, magnesium, and a matrix of proteoglycans in the anterior Malpighian tubules. Type II is composed predominantly of potassium and phosphorous and is located in both the anterior and posterior Malpighian tubules. While these concretions appear to be a normal means by which the fly eliminates urine waste, studies have since shown that these concretions can be likened to human kidney stones (Chen et al., 2011; Chi et al., 2015; Dube et al., 2000; Hirata et al., 2012a). As a result, these concretions in *Drosophila* Malpighian tubules have been used as a functional in vivo model of kidney stones.

4.2 Diet-Induced Model

4.2.1 Hyperoxaluria

Similar to what has been done in rodent models, induction of hyperoxaluria in the fly can be accomplished with the administration of ethylene glycol or oxalate. Chen et al. (2011) found that supplementing adult *Drosophila*

with ethylene glycol produced calcium oxalate (CaOx) concretions in as little as 6 h. Feeding *Drosophila* larvae with a diet of sodium oxalate dissolved in standard growth media resulted in CaOx microliths within 2 days (Hirata et al., 2012a). As seen in Fig. 17.5, polarized light applied to dissected Malpighian tubules demonstrates the characteristic birefringence of CaOx crystals. These CaOx crystals have also been clearly visualized on microcomputed tomography (CT) (Fig. 17.6).

4.3 Genetic Models of Stone Disease

With the previously established GAL4 driver/UAS (upstream activation sequence) transgenic system (Brand and Perrimon, 1993), researchers are equipped with the ability to perform targeted gene expression in *Drosophila* and specifically knockdown those genes believed to play a role in stone formation. With the resources available for *Drosophila*, investigators can simply order their desired driver to express or silence specific
FIGURE 17.5 **Comparison of Malpighian tubules of *D. melanogaster* fed high oxalate versus control low oxalate diet.** Polarized light demonstrates birefringence of calcium oxalate concretions in high oxalate tubules. *Source: Reprinted with permission from Hirata, T., Cabrero, P., Berkholz, D.S., et al., 2012. FIGURE 17.6 **3D computed tomography reconstruction of *D. melanogaster*.** *Arrow* represents calcium oxalate concretions present in *Drosophila* Malpighian tubules. Note the *white* biominerals/stones *(blue arrow)* developing in the Malpighian tubules in this invertebrate animal model.

gene end-products. This allows for studies to examine the effects of individual genes very quickly. What would take a minimum of 3–6 months to accomplish for genetic manipulation in the mouse model can take 2–3 weeks in the fly model (Dow and Romero, 2010).

4.3.1 Hyperoxaluria

As discussed previously in the mouse section, the anion exchanger SlC26A6 has been shown to be important in oxalate transport in both mice and humans (Jiang et al., 2006; Monico et al., 2008). Experiments have since shown that the *D. melanogaster* genome contains 9 homologs of the 11 human Slc26 transporters (Hirata et al., 2012b). A SLc26a5 homolog, *dPrestin*, can be considered the *Drosophila* equivalent of SLC26A6 (Hirata et al., 2009).

After administering a dietary load of sodium oxalate, researchers have demonstrated the ability to visualize real-time nucleation and growth of oxalate crystals within the relatively transparent dissected Malpighian tubules (Hirata et al., 2010). Hirata et al. (2012a) subsequently performed knockdown of *dPrestin*, and decreased mRNA levels by 50%–70%. This knockdown took place mainly in the principal cells of the initial and main segments of the Anterior Malpighian tubules, producing markedly reduced CaOx concretions (Hirata et al., 2012a). This study illustrates how the genetic capabilities of the *Drosophila* model can further our understanding of kidney stone formation.

4.3.2 Xanthinuria

Another genetically based kidney stone model mimics one of the human-inherited errors of metabolism, xanthinuria. Xanthinuria types I and II are secondary to an autosomal recessive defect in purine metabolism, resulting in increased total body levels and subsequent excretion of xanthine (Ichida et al., 2001; Levartovsky et al., 2000). Xanthine dehydrogenase (XDH) is the enzyme that normally converts hypoxanthine to xanthine as well as xanthine to uric acid. XDH is deficient in xanthinuria type Iand the responsible gene for type I has been localized to chromosome 2p22-23 (Ichida et al., 1997).

Utilizing a GAL4/UAS, Chi et al. performed *Drosophila* gene silencing of *Xdh*, the fly equivalent gene producing xanthine dehydrogenase. This resulted in the formation of large, obstructing stones in the Malphighian tubules (Fig. 17.7) (Chi et al., 2015). This study also found that pharmacologic inhibition of XDH with allopurinol demonstrated similar tubule concretions. Moreover, when these *Xdh* silenced flies were fed a high yeast diet, their survival plummeted down to a median lifespan of 3 days, compared to controls which averaged 60 days.

4.4 Stone Composition

4.4.1 Calcium oxalate

Similar to what has been shown in the rat model, the administration of lithogenic agents such as ethylene glycol and hydroxyl-L-apatite also results in reproducible calcium oxalate crystals within the *D. melanogaster* Malpighian tubules (Chen et al., 2011; Hirata et al., 2012a). Studies have utilized both scanning electron microscopy (SEM) and energy-dispersive X-ray spectroscopy (EDS) to identify crystal deposition and composition, respectively.
FIGURE 17.7 **Comparison of Malpighian tubules in *D. melanogaster*.** (A) Control flies. (B) *Xdh* knockdown flies. *Source: Courtesy of Chi, T., Kim, M.S., Lang, S., et al., 2015. A* Drosophila *model identifies a critical role for zinc in mineralization for kidney stone disease. PLoS One 10 (5), e0124150.*

4.4.2 Hydroxyapatite

Fourier Transform Infrared Spectroscopy (FTIR), the conventional method to determine stone composition, demonstrated that the *Xdh* knockdown fly stones indeed contained xanthine (Chi et al., 2015). However, using targeted metabolomics, these stones were also found to contain hypoxanthine. Micro X-ray absorption near edge spectroscopy (µXANES), a technique that allows for interrogation of the chemical environment within a sample point of interest with submicron resolution, confirmed the presence of hydroxyapatite. Given that noncalcium based human stone formation may still be generated from a hydroxyapatite nidus (Evan, 2010), this finding highlights potential similarities between *Drosophila* fly stone concretions and human stones.

4.4.3 Zinc

The fly model has also enabled investigators to unearth the role of other minerals in the formation of stones. While the majority of stones are still comprised of calcium oxalate, other minerals have been shown to be part of the stone composition. Zinc, an essential mineral, has been identified to play a role in the formation of both human stones and *Drosophila* Malpighian tubule concretions (Chi et al., 2015). An analysis of the mineral components of these fly concretions, human Randall's plaques, and human xanthine stones demonstrated that calcium (Ca), magnesium (Mg), and zinc (Zn) were the major metal components within each specimen (Fig. 17.8). This was determined by using inductively coupled plasma optical emission spectroscopy (ICP-OES), which showed that the relative amount of each of these metals was consistent across stone source (Fig. 17.8).

This study also found that the concentration of zinc was dependent on the amount of yeast present in a standard *Drosophila* diet (Fig. 17.9) (Chi et al., 2015). A high yeast diet—the equivalent of a high protein diet in humans—caused a high rate of stone formation, while a low yeast diet resulted in limited stone formation. Supplementing flies on a low yeast diet with zinc increased the amount of concretions present, to a level close to those flies on the high yeast diet. The importance of zinc was further shown when it was inhibited with a known zinc chelator, TPEN, resulting in a decreased amount of concretions (Chi et al., 2015). These findings reinforce the importance of an animal model for stone disease, as without this discovery one might not have recognized the presence and importance of heavy metals in urinary stones.

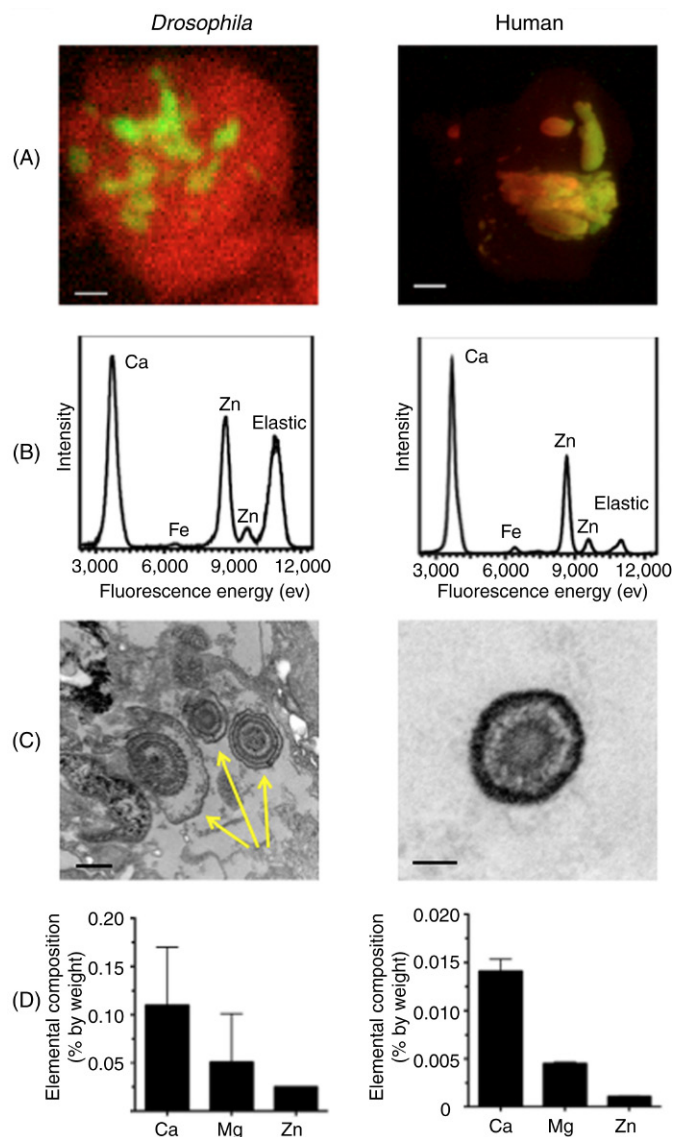
These two previously mentioned examples represent the first genetically based invertebrate models of kidney stones. Given the number of genetic homologs related to


FIGURE 17.8 **Comparison of zinc in *D. Melanogaster* concretions, human Randall plaques, and human kidney stones.** (A) Micro-X-ray fluorescence *(µXRF)* maps of knockdown *Da-GAL4, UAS-Xdh RNAi/+* concretions (left panel, scale bar: 10 µm) versus human Randall's plaques (right panel, scale bar: 100 µm). Zinc shown in *red* and calcium in *green*. (B) µXRF elemental analysis demonstrates similar elemental composition for both *Da-GAL4, UAS-Xdh RNAi/+* concretions (left panel) and human Randall's plaques (right panel), including the presence of calcium *(Ca)*, iron *(Fe)*, and zinc *(Zn)*. (C) Transmission electron microscopy of concretions in the lumen of the Malpighian tubule shows the presence of ring-like structures, as indicated by the *yellow arrows* (left panel, scale bar: 500 µm). Ring structures with homologous appearance are seen in Randall's plaques taken from a human renal papilla biopsy material (right panel, scale bar: 100 µm) when imaged in a similar fashion. (D) ICP-OES analysis of fly concretion samples (left) versus human xanthine stone samples (right) shows the presence of calcium (Ca), magnesium *(Mg)*, and zinc (Zn). Data shown are the mean ± SEM. *Source: Courtesy of Chi, T., Kim, M.S., Lang, S., et al., 2015. A* Drosophila *model identifies a critical role for zinc in mineralization for kidney stone disease. PLoS One 10 (5), e0124150.*
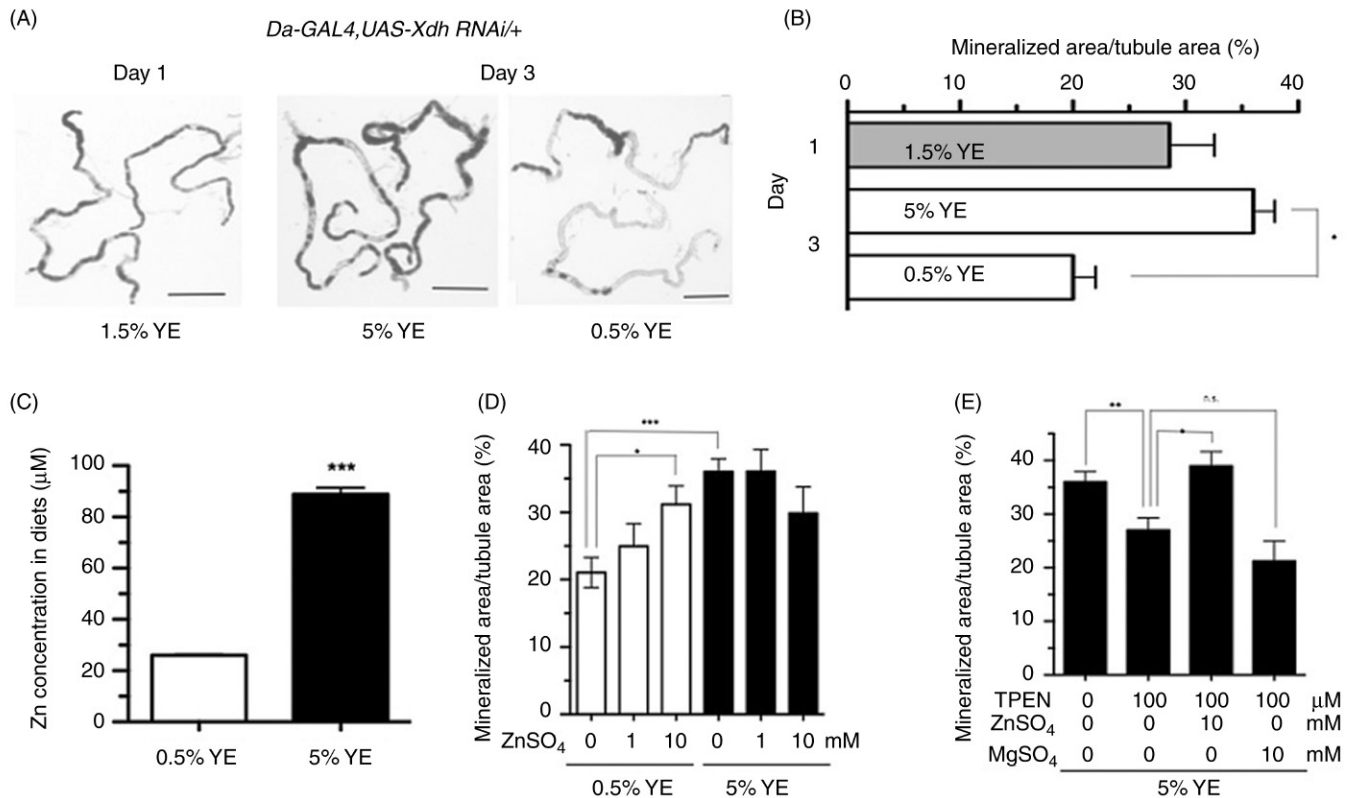

FIGURE 17.9 (A) Tubule images of Da-GAL4, UAS-Xdh-RNAi/+ flies: Day 1, 1.5% YE and after 2 days on high yeast (Day 3, 5% YE) or low yeast (Day 3, 0.5% YE) diets. (B) The mean percentage of the tubule lumen occupied by mineralized material (*$P < 0.001$, Student's t-test, $n = 14$–48). Scale bars: 500 µm. (C) The amount of Zinc (Zn) in the components of a standard *Drosophila* diet (corn meal, yeast, sugar, and agar) was measured with ICP-OES for both 0.5% YE and 5% YE diets. 0.5% YE is comprised of corn meal 8.5 g, yeast 0.5 g, sugar 5 g, and agar 0.46 g in 100 mL deionized distilled water. 5% YE is composed of the same components as 0.5% YE with the exception of 5 g yeast added instead of 0.5 g yeast (***$P < 0.001$, student t-test, $n = 3$). (D) Da-GAL4, UAS-Xdh RNAi/+ flies fed on 0.5% YE and 5% YE diets were supplemented with different doses of Zn. This led to a dose-dependent increase in accumulation of concretions on 0.5% YE feeding (*$P < 0.05$, ***$P < 0.001$, one way ANOVA with Bonferroni posthoc test, $n = 10$–48). Zn supplementation had no effect on altering concretion formation in 5% YE-fed animals, which may reflect a saturation of the calcification process under these conditions. (E) Supplementation of 5% YE diet with the zinc chelator TPEN reduced concretion formation. This effect could be reversed with the addition of 10 mM Zn but not 10 mM Mg (*$P < 0.05$, **$P < 0.01$, one way ANOVA with Bonferroni posthoc test, $n = 10$–43). Data shown are the mean ± SEM. *Source: Courtesy of Chi, T., Kim, M.S., Lang, S., et al., 2015. A* Drosophila *model identifies a critical role for zinc in mineralization for kidney stone disease. PLoS One 10 (5), e0124150.*

other stone types in flies, more model development may be expected in the future.

4.5 Limitations

While *Drosophila* represents a reliable, fast, cost-effective model system, there are some limitations to its use and applicability. First and foremost the fly is an invertebrate. Lacking a bony skeleton, it has no bone reservoir and its calcium metabolism may be fundamentally different compared to vertebrates. Next, the fly is not an ambulatory model and relies on a different feeding cycle compared to humans.

Another limitation is that it can be difficult to measure how much food and medication that *Drosophila* ingest.

Moreover, while direct injection of medication into the fly is possible, this requires specialized equipment that can be cumbersome.

Classically cited anatomic differences were addressed previously and instead should be considered more as an opportunity to study single tissue modeling of diseases that affect analogous vertebrate structures (Miller et al., 2013). Another cited limitation is that since the fly's Malpighian tubules drain into the hindgut, there is a combination of waste products in a single elimination chamber and the GI tract can contribute to the elimination of electrolyte and water waste (Assimos, 2012). Current dissection techniques allow for the Malpighian tubules and ureters to be isolated prior to their junction with the GI tract. These dissected tubules can then be

mounted and submerged in a desired medium, where they will continue to secrete fluid for several hours (Dow and Romero, 2010). Subsequent collection of this fluid can then be examined in a fashion similar to a 24-h urine analysis.

5 PORCINE MODEL

The oretically the porcine model would be an excellent model from both an anatomic structure and physiologic standpoint, as pig kidneys resemble those in humans. This has led multiple investigators to test new endourologic surgical modalities by placing human kidney stones within porcine kidneys. Moreover, in general there is not as much emotional attachment to the pig as compared to other animals that are used as domestic pets. The studies conducted thus far in the porcine model demonstrate a promising, reproducible model for inducing hyperoxaluria and calcium oxalate nephrolithiasis.

5.1 Anatomic/Physiologic Comparison Between Pigs and Humans

Comparing porcine and human kidneys, anatomic similarities include an undivided renal cortex, multiple medullary pyramids that each form a separate papilla or occasionally a complex papilla, especially in the upper pole (Thomsen et al., 1983). Pigs in general have 8–12 papillae compared to humans who usually have 4–18 (Cullen-McEwen et al., 2015). Moreover, as Kirkman showed, porcine renal physiology parallels that of humans with respect to maximal urine concentration (porcine 1080 vs. human 1160 mOsm/L), glomerular filtration rate (porcine 130 vs. human 126–175 mL/min

per 70 kg), and total renal blood flow (porcine 4.0 vs. human 3.0–4.4 mL/min·g) (Sachs, 1994). Meanwhile, other studies have noticed anatomic differences, centering around the pig kidney containing very little perinephric fat, being hypermobile, having a more spacious renal pelvis, and also tortuous, large diameter ureters (Paterson et al., 2002).

5.2 Induction of Hyperoxaluria

To date, previous porcine models have focused on replicating a hyperoxaluric state by administering hydroxyproline (HP) (Kaplon et al., 2010; Knight and Holmes, 2005; Mandel et al., 2004; Patel et al., 2012). As stated previously, hydroxyproline is derived from the amino acid proline and is a component of collagen that gets metabolized to both pyruvate and glyoxalate, primarily in the renal proximal tubule and hepatocyte mitochondria (Knight and Holmes, 2005) (Table 17.3).

As Mandel et al. (2004) showed in young pigs, delivering 10% weight per weight of *trans*-4-hydroxy-L-proline/food resulted in a maximum increased urinary oxalate concentration by day 6 in all HP-fed pigs. While the urinary oxalate levels in these young pigs did not decline until HP was removed from their diet, a noteworthy finding was that increasing the HP/food concentration up to 20% failed to result in an increased level of hyperoxaluria. This study demonstrated calcium oxalate monohydrate and dihydrate crystalline deposits in the papillary tips of the longitudinally sectioned kidneys.

Meanwhile, Kaplon et al. (2010) demonstrated that gravid sows in either a traditional or acidified diet experienced hyperoxaluria and hyperglycoluria when fed 10% HP. This study utilized 24-h urine collections via a 20-French Foley catheter attached to Tygon tubing that

TABLE 17.3   Porcine Models Related to Hyperoxaluria

Study references (year)	Porcine animal selected	Diet/intervention	Effects
Mandel et al. (2004)	Young male Yorkshire-Durox pigs	• Enriched diet: 10% HP days 1–5; 15% HP days 6–13; 20% HP days 14–21	• Hyperoxaluria • CaOx crystalluria • CaOx crystal deposition in collecting ducts nephrolithiasias at papillary tips
Kaplon et al. (2010)	Multiparous adult gestating sows	• Acidogenic diet versus control diet × 5 days • All fed diet with 10% HP for days 3–5	• Hyperoxaluria • Hyperglycoluria
Patel et al. (2012)	Gravid crossbred sows	• 5% HP diet • 10% HP diet • gelatin (12% HP + 20% glycine)	• 10% HP and gelatin diets induce hyperoxaluria • Gelatin more cost effective
Sivalingam et al. (2013)	Gravid and nongravid sows	• 5% HP diet	• Hyperoxaluria • CaOx crystals present in proximal tubule and collecting ducts • Lack of Randall plaques

FIGURE 17.10 **Photograph of porcine model arrangement.** Gravid sows with indwelling 20-French Foley catheters attached to Tygon tubing that then drains into a 20 L collection pail. *Source: Reprinted with permission from Patel, S.R., Penniston, K.L., Iwicki, L., et al., 2012. Dietary induction of long-term hyperoxaluria in the porcine model. J. Endourol. 26, 433–438.*

drained into the cap of a 20 L collection pail (Fig. 17.10). Results showed that the level of hyperoxaluria and hyperglycoluria peaked on the first day of feeding and subsequently declined despite continued HP administration. Likely this was the result of the pigs acquiring an aversion to the HP diets, as the study noted sows consuming less of their meals on days when HP was added.

Expanding on the model of the gravid sow, Patel et al. (2012) compared the effectiveness of different diet compositions of HP. The study provided pigs with a baseline 2 kg basal diet before subjecting to either 100 g L-HP (5% HP), 200 g L-HP (10% HP), or 1000 g of gelatin that consisted of high HP (12%) and glycine (20%) content. Results demonstrated that both HP and gelatin induced similar short-term (5 days) and long-term (21 days) hyperoxaluria effects (Patel et al., 2012). Interestingly, this study also highlighted some of the financial concerns associated with a HP-induced hyperoxaluria model, as they found that gelatin was significantly more cost effective than HP; $7.32 per kg for 150 Bloom gelatin versus $185.00 per kg for hydroxy-L-proline (Patel et al., 2012).

In humans, hydroxyproline ingestion can occur via either animal protein containing collagen or gelatin containing foods. Similar to these experiments in the porcine model, a study investigated whether hydroxyproline has similar effects in humans. Comparing the ingestion of different gelatin loads to whey protein, researchers found that 5 and 10 g gelatin loads were associated with significant changes in plasma hydroxyproline, urinary oxalate and glycolate (Knight and Holmes, 2005). From these results, it was inferred that the metabolism of hydroxyproline provides approximately 20%–50% of urine glycolate excretion, with a subsequent 5%–20% of urinary oxalate derived from endogenous synthesis (Knight and Holmes, 2005).

5.3 Histology/Pathology/Stone Composition

Mandel et al. (2004) demonstrated calcium oxalate monohydrate and dihydrate crystalline deposits in the papillary tips of longitudinally sectioned kidneys in young male Yorkshire-Durox pigs. Meanwhile, Sivalingam et al. (2013) demonstrated the presence of crystals in proximal tubules and at the renal papillary tips, with concomitant crystals that appeared to be embedded within the interstitium. There was widening of the interstitial spaces, presence of giant multinucleated cells surrounding these crystals, and noticeable inflammation with surrounding fibrotic changes (Fig. 17.11).

5.4 Treatment Simulation in Porcine Model

Given its similarities to human kidneys, many researchers have chosen porcine kidneys to test and evaluate new surgical techniques for the treatment of nephrolithiasis. This has centered on placing artificial or human kidney stones within swine kidneys, via ureteroscopic and percutaneous approaches, and then studying the effectiveness of these treatments in both in vivo and ex vivo models. To establish the effectiveness of different settings for shock wave lithotripsy (SWL), studies like Paterson et al. (2002) have used upper pole percutaneous access to place gypsum model stones into mainly the lower pole of female pigs, followed by treatment with extracorporeal SWL. This demonstrated superior breakup of stones treated with a slower rate (30 shocks/min) compared to a faster rate (120 shocks/min), which has helped guide practice for performing SWL at a slower, more effective rate in humans. This porcine model has been replicated to investigate the differences in focal width among shock wave lithotripter machines and their corresponding damaging effects on porcine kidneys (Connors et al., 2009, 2012).

Meanwhile, others have obtained porcine urinary tracts from slaughterhouses and used these as a model for teaching ureteroscopy (Hu et al., 2015; Strohmaier and Giese, 2001). Using mini-pigs given that they repre-
FIGURE 17.11 **Histopathology of crystal formation in porcine kidney.** (Cortical section, 21 days, H and E 20.) (A) Control kidney with normal glomerulus. Dietary hydroxyproline induced calcium oxalate lithiasis and associated renal injury in the porcine model. J. Endourol. 27, 1493–1498.*

sent a more manageable sized model compared to large adult pigs, Sorensen et al. (2010) tested the performance of a novel ultrasound probe in porcine kidneys to test the effectiveness of estimating stone size during ureteroscopy.

5.5 Limitations

With anatomy and physiology resembling humans, it is unfortunate that limitations of the porcine model reduce its ability to be widely adopted. First and foremost, adult pigs generally require a lot of space and eat substantial amounts of costly food. As previously seen in Fig. 17.10, a large facility is required to maintain a porcine model and this by itself limits its reproducibility. Meanwhile similar to all vertebrate animals, experimentation with pigs requires formal animal study review. In particular to pigs however, is that their eventual sacrifice must adhere to very specific US Department of Agriculture methods.

These limitations explain the relatively low numbers that have been seen in the porcine studies performed thus far. In addition, it also appears that obtaining urine and accurately measuring urine output can be a challenge in this animal model. An important aspect of their

initial study, Kaplon et al. (2010) noted that only 50% of the pigs were ultimately included as 6 of the 12 pigs did not make it to day 6 of the study due to infection or catheter-related problems. Nearly 1/3 of the pigs in another study also had to be excluded due to urinary tract infection or catheter-related problems (Patel et al., 2012). These results highlight the challenges associated with obtaining multiple 24-h urine collections from the pig model over an extended study duration.

Similar to other models that focus on hyperoxaluria, there is a relatively narrow application of this model given that it relates mainly to human primary hyperoxaluria. As the majority of humans with nephrolithiasis suffer from some aspect of hypercalciuria, a model in pigs replicating this physiologic state has yet to be developed.

6 OTHER ANIMAL MODELS

One should not forget that urinary stone disease remains a problem in veterinary medicine. Urinary stone disease has been shown to affect a wide variety of animals, ranging from land mammals like dogs, cats, horses, raccoons, goats, sheep, and kangaroos, to

water-based mammals, such as whales, seals, dolphins, otters, and even reptiles, such as turtles and fish like the zebrafish (Elizondo et al., 2005; Robinson et al., 2008). Of note, these animals are all protected under the Animal Welfare Act of 1966 and its subsequent provisions (US Department of Agriculture, https://www.nal.usda.gov/awic/animal-welfare-act). Therefore, the vast majority of research in these animals has been observational and epidemiologic in nature. While most studies have investigated canines and felines, there is value to reviewing the literature to help gain insight into the pathophysiology of stones in other animals and humans.

7 CANINE MODEL

7.1 Types of Stones

The dog has generated research interest because it spontaneously forms urinary stones that physically and chemically resemble those found in humans. In an effort to characterize the types of calculi formed by canines, large databases have been compiled of uroliths submitted by veterinarians in the United States since 1985 and in Canada since 1998 (Houston and Moore, 2009; Low et al., 2010). In the United States, through 2006, over 25,000 uroliths have been collected from both the upper and lower urinary tract, providing an incredible resource for research. Analysis revealed that the most common stone compositions were 53% struvite (magnesium ammonium phosphate) and 42% calcium oxalate (CaOx), with CaOx being the leading stone type collected since 1997 (Ling et al., 2003). A similar trend was noted in over 40,000 canine uroliths submitted in Canada, with ~85% of submissions being either struvite or CaOx (Houston and Moore, 2009). Meanwhile apatite, urate, silica, and cysteine were other common minerals identified in these uroliths, and over 73% of these samples contained a combination of two or more minerals (Low et al., 2010).

Interestingly, this study also found that a significantly higher proportion of CaOx-containing calculi were found in males compared to females, 69% vs. 31%, respectively (Low et al., 2010). Both cysteine and silica stones were also found more often in male dogs, while a higher percentage of struvite and apatite calculi were found for female dogs. Urate stones have been reported in a much higher percentage in male (93%) versus female (7%) Dalmatians (Houston and Moore, 2009).

7.2 Stone Risk Association With Breed

Historically, canine breeds have been associated with specific disease and stone types, such as the UK Cava-

lier King Charles Spaniels who were noted to experience xanthinuria and experience xanthine stones (Jacinto et al., 2013). Meanwhile, the Keeshond breed has been shown to be predisposed to primary hyperparathyroidism, resulting in hypercalciuria and higher risk of forming calcium oxalate calculi (Goldstein et al., 2007). Given that over the years, many canine species have been created for phenotypic characteristics—this has resulted in some breeds being more predisposed to developing stones compared to others. Based on Low et al. (2010), specific breeds have been associated with a higher and lower risk for specific types of urinary stones (Table 17.4).

In examining those breeds associated with a higher risk of forming stones, overall smaller dogs tended to be the ones associated with higher risk. While this could be secondary to a variety of reasons, investigators have suggested lower urine volumes, potential changes in diet composition, and rising obesity as possible etiologies (Low et al., 2010; Speakman et al., 2008). These smaller dogs are popular breeds with over half of the 9 breeds predisposed to CaOx-containing uroliths (Miniature Schnauzer, Shih Tzu, Pomeranian, Yorkshire Terrier, and Maltese) ranked in the top 20 of the most common dog breeds in the United States (American Kennel Club, 2009; Low et al., 2010). Intuitively, smaller dogs tend to be more popular in metropolitan areas and potentially could have less ability to exercise, contributing to rising obesity rates (Speakman et al., 2008). Further investigations are needed to establish this as a potential etiology for these breeds' increased risk of stone disease.

The Dalmatian represents a unique example of breed-specific calculi. Besides human and great apes, Dalmatians are the only other example of a mammal that excretes uric acid instead of allantoin (Kuster et al., 1972). In humans, high levels of uric acid can accumulate in blood and urine, leading to diseases such as gout. Meanwhile in Dalmatians, recent work involving interbreed backcrossing has shown that Dalmatians have a defect of the SLC2A9 gene, resulting in defective uric acid transport in the kidneys and liver (Bannasch and Henthorn, 2009; Bannasch et al., 2008; Giesecke and Tiemeyer, 1984). These dogs are homozygous for this autosomal recessive trait, with the end result being hyperuricosuria and hyperuricemia (Bannasch and Henthorn, 2009). This hyperuricosuria can be easily identified as Dalmatian urine forms a precipitate when cooled (Fig. 17.12) (Bannasch et al., 2008). Therefore, this breed is at high risk for urate stone development, as shown in the study by Low et al. (2010) where 80% of Dalmatian urate containing uroliths contained 100% urate. Interestingly, this study also found that nearly 69% of English Bulldog urate containing uroliths contained 100% urate, suggesting this breed may have a similar pathophysiologic condition.

TABLE 17.4 Canine Stone Risk Association With Breed—Based on Results Reported in Low et al. (2010)

Stone type (%)	Breeds at higher risk	Breeds at lower risk	Comments
Struvite (53.4%)	• Bichon Frise • Miniature Schnauzer • Shih Tzu • Pekingese	• Australian Cattle Dog • Rottweiler • Boxer • Border Collie • Standard Poodle	• Most commonly in bladder • Decreasing incidence • More in younger dogs • Female versus male: 76% versus 22%
Calcium oxalate (42.0%)	• Bichon Frise • Miniature Schnauzer • Shih Tzu • Lhasa Apso • Pomeranian • Cairn Terrier • Yorkshire Terrier • Maltese • Keeshond	• German Shorthair Pointer • Great Dane • Rottweiler • Australian Cattle Dog • Labrador Retriever • Boxer • German Shepherd Dog • Border Collie • Bull Mastiff	• Most commonly in bladder • Most common type of upper urinary tract stone • More often found in older dogs
Apatite (38.0%)	• Bichon Frise • Miniature Schnauzer • Shih Tzu • Pekingese • Lhasa Apso	• Rottweiler • Dalmatian • Great Dane • Boxer • German Shorthair Pointer • Golden Retriever	• 78% female versus 22% male • No changes in trends over time
Urate (23.8%)	• Dalmatian • Miniature Schnauzer • English Bulldog • Bichon Frise • Pekingese • Scottish Terrier	• Australian Cattle Dog • German Shorthair Pointer • Great Dane • Border Collie • Doberman Pinscher	• 80% of Dalmatian urate containing uroliths were 100% urate • More often in younger dogs
Silica (6.7%)	• Miniature Schnauzer • Lhasa Apso • Samoyed • Bichon Frise • Pekingese	• Australian Cattle Dog • German Shorthair Pointer • Great Dane	• Distribution: 89% male versus 11% female
Cysteine (1.3%)	• English Bulldog • Newfoundland • Dachshund • Chihuahua • Miniature Pinscher • Welsh Corgi	• Labrador Retriever • Cocker Spaniel	• 97.8% male versus 2.2% female • 77% in dogs <7 years old

7.3 Effect of Diet on Stone Risk

In 2004, there was an outbreak in Asia where over 6000 dogs and some cats experienced pet-food associated renal failure (Brown et al., 2007; Jeong et al., 2006). Reviewing the pathology demonstrated that these dogs experienced renal tubular necrosis, calcification, and green–yellow calculi (Jeong et al., 2006). Further investigation revealed that certain brands of commercial pet food were the culprit, stemming back to contamination of raw materials at a pet-food manufacturing plant in Thailand (Honnold, 2005; Thompson et al., 2008).

History repeated itself in North America in 2007, when a Canadian manufacturer of pet food issued a large-scale recall due to multiple reported deaths of both dogs and cats. The pathologic features were similar, acute renal failure with green–yellow calculi reported (Jeong et al., 2006). An analysis of the crystals associated with both outbreaks revealed predominantly birefringent melamine–cyanuric acid complexes, as well as a lesser number of calcium oxalate monohydrate crystals (Thompson et al., 2008). The FDA eventually announced that cyanuric acid and melamine had contaminated ingredients from China that subsequently entered the pet food (Thompson et al., 2008).

The knowledge gained from these canine intoxications helped with the identification of infant formula being contaminated with melamine in 2008. Ultimately there were 6 deaths, over 50,000 children hospitalized, and several hundred thousand affected (Gossner et al., 2009). Subsequent research has shown that melamine exposure measured by urinary melamine levels has an association
FIGURE 17.12 (A) Classic phenotype of Dalmatian with spotting. (B) Example of Dalmatian urine in crystallized precipitate (far left), compared to heterozygous backcross dog (middle) and dog from an unaffected breed (right). (C) Urinary urate calculi. *Source: Courtesy of Bannasch, D., Safra, N., Young, A., et al., 2008. Mutations in the SLC2A9 gene cause hyperuricosuria and hyperuricemia in the dog. PLoS Genet. 4, e1000246.*

with increased calcium-based stone formation in adults (Lu et al., 2011). These events provide a reminder of how veterinary medicine can help further the understanding of urinary stone disease.

8 FELINE MODEL

8.1 Types of Stones

For the other animal models presented thus far, the predominant discussion has focused on upper-tract stone formation. Yet for the sake of completeness, a discussion on bladder stones should be mentioned, as this brings attention to how environment contributes to and plays a role in stone formation. The bladder represents another environment where stone formation takes place that could be helpful to compare to the medullo-papillary complex, thought to be the main location of kidney stones.

Cats represent an example of an animal model where the vast majority of stones (98%) submitted for analysis are lower urinary tract (bladder) stones (Cannon et al., 2007). While recent reports have cited that the number of ureteral stone submissions has increased over the past 15 years (Cannon et al., 2007; Kyles et al., 2005a; Palm and Westropp, 2011), upper urinary tract stones still represent a minority of stones found in cats. Male cats are also anatomically set up for urethral obstruction given their narrow distal urethra (Cooper et al., 2010). Previous studies have cited that almost all (98%) of feline upper urinary tract calculi are calcium oxalate (Kyles et al., 1998, 2005b).

Similar to the dog, centers have collected large numbers of feline uroliths and been able to analyze trends in stone types. The same centers in the United States and Canada that collected the large number of dog uroliths have also collected over 5,200 and 11,000 feline bladder calculi, respectively (Cannon et al., 2007; Houston and Moore, 2009). As in dogs, the vast majority of feline urinary stones are composed of calcium oxalate and struvite, and there has been a significantly lower amount of struvite calculi since the late 1990s (Cannon et al., 2007; Lekcharoensuk et al., 2000).

8.2 Stone Risk Association With Breed

Similar to the dog, specific breeds of cats have been reported to have increased risks of certain types of uroliths. Persian and Himalayan (Colourpoint Persian) cats were found to have significantly increased risk for CaOx calculi, while Birman, Abyssinian, and Siamese were found to be at lower risk (Cannon et al., 2007). Compared to humans where studies have shown >50% patients have a stone recurrence within 5 years (Ljunghall, 1987), a similar figure has been reported for CaOx producing cats with 6.8% having another stone submitted within 2 years (Albasan et al., 2009).

9 CONCLUSIONS

The sequence of events that leads to urinary stone formation remains unclear. As discussed here, there are multiple animal models that have been used to date in an

effort to better understand the pathophysiologic chain of events that ultimately leads to the formation of a urinary calculus.

When one assesses most of these animal models, the surrogate endpoints used were the development of crystals seen either in the urine or with histologic examination of the renal papilla rather than documentation of a true stone. As appreciated in our clinical practices, crystalluria does not necessarily equate with future stone formation. Crystals may be an early form of eventual aggregation and stone fragmentation; or they may reflect a process of nucleation that may or may not be critical to stone formation. Future research is needed to determine whether the process of crystallization is independent of stone formation.

The eventual goal of these animal models is to help understand the temporal development of urinary stone formation. Translating these animal models to humans, one needs to appreciate the subtle differences in renal anatomy (unipapillary versus multiple renal papilla), as well as potential pathophysiologic differences between quadrupeds versus bipeds. Ultimately, it would be ideal for the urology and nephrology communities to agree on a few selected animal models such that results could be complimentary and comparable. It is only with such animal models that novel new interventions can be undertaken to help reduce the incidence and recurrence of urinary stone disease.

1 INTRODUCTION

Renal tumors account for 3.9% of the new cancer diagnosis in the United States, which represents more than 57,000 new cases and more than 12,000 deaths, being on the 10 more common tumors in humans (Jemal et al., 2009). According to Russo, the patients with renal tumors can be divided in two groups. In the first group are symptomatic patients, with large tumors which require radical nephrectomy. In the second group, representing 70% of the cases, are patients who had an incidental diagnosis. The tumors of these patients are discovered during abdominal ultrasound, computed tomography, or nuclear magnetic resonance, with indication not related to the renal tumor (e.g., spinal column diseases) (Russo and Huang, 2008). Frequently, in these patients, small tumors are found and radical nephrectomy may not be necessary for most cases.

Conservative renal surgery (partial nephrectomy) is indicated for patients with bilateral tumors, compromised renal function, or single kidney (Lane and Novick, 2007). It has been recently included as primary indication for patients with T1a tumors (masses smaller than 4 cm, restrained to the kidney) and electively indicated for T1b tumors (masses larger than 4 cm but smaller than 7 cm, restrained to the kidney) (Campbell et al., 2009; Ljungberg et al., 2015).

Partial nephrectomy is still considered a challenging procedure, and underutilized. Only 8% of surgeries for treating renal tumors in the United States, between 1988 and 2002, were partial nephrectomies (Hollenbeck et al., 2006). In the United Kingdom, only 4% of renal surgeries were partial nephrectomies in the year 2002 (Nuttall et al., 2005).

It is thought that this surgery involves technically difficult aspects, especially when performed with laparoscopic or robotic access, the use of radical nephrectomy is favored despite the size of the tumor. It has been reported that patients treated in large hospitals, university hospitals, or urban centers are more commonly submitted to partial surgery than in other medical institutions (Hollenbeck et al., 2006).

Clearly, partial nephrectomy has been underutilized because of its technical difficulties. One of the most

difficult aspects of this surgery is the closure of the collecting system. This step involves suturing the renal calices and/or pelvis, which is considered an advanced skill, especially when performing laparoscopically. It has already been shown that the intracorporeal collecting system closure increases the surgical time and requires longer warm ischemia time (Zorn et al., 2007), which is associated with postoperative renal function prejudice (de Souza et al., 2012). Therefore, there have been research efforts for simplifying and accelerating this step (Bishoff et al., 2003; Hacker et al., 2007; Kouba et al., 2004; Orvieto et al., 2007; Shikanov et al., 2009).

Several types of surgical glues or hemostatic agents (Bernie et al., 2005; Bishoff et al., 2003; Johnston et al., 2006; Kouba et al., 2004; L'Esperance et al., 2005; Margulis et al., 2005a; Murat et al., 2004, 2006b; Rouach et al., 2009), surgical bolsters (Abou-Elela et al., 2009; Johnston et al., 2006; Sabino et al., 2007; Xie et al., 2008a,b), lasers (and other types of energy) (Anderson et al., 2007; Bui et al., 2007; Collyer et al., 2002; Eret et al., 2009; Hindley et al., 2006; Honeck et al., 2008; Lafon et al., 2007; Lucioni et al., 2008; Murat et al., 2005, 2006a; Ogan et al., 2002; Sprunger and Herrell, 2005; Zeltser et al., 2008), and suturing methods (Orvieto et al., 2007; Shikanov et al., 2009) have been studied for developing an easier technique for the collecting system closure. Moreover, models simulating a renal tumor have been proposed for training purposes (Eun et al., 2008; Hidalgo et al., 2005; Taylor and Cadeddu, 2006; Taylor et al., 2004; Yang et al., 2009), which is associated with a reduction on the learning curve for performing partial nephrectomy (Rouach et al., 2008).

As the number of training programs for partial nephrectomy (both for open and minimally invasive access) increases, the utilization of conservative renal surgery would increase. Furthermore, the advent of the techniques for renal closure, which makes the procedure easier, would favor the utilization of partial nephrectomy, with potential benefits for several patients.

In this regard, the utilization of a good animal model is of great importance, both for the development and testing of new techniques and equipments, and for surgical training programs. This animal model should reproduce not only human renal anatomy (size, shape, and internal anatomy), but also the healing after the surgical aggression.

Other aspects, such as handling characteristics, cost, and necessary infrastructure should be also taken into account for deciding which animals would be the most adequate for experimentation and/or training.

For a long time, the pig was considered the best animal model for studying renal procedures due to its anatomical and physiological resemblances to human kidneys. Unlike the kidneys of dogs, rabbits, and rats, the swine kidneys are multipyramidal, and have length, weight, and shape similar to human kidneys (Sampaio et al., 1998).

Vascular intrarenal anatomy is very similar between humans and pigs, although some differences exist in the dorsal arteries (Pereira-Sampaio et al., 2004a), the proportional area of the arterial segments (Pereira-Sampaio et al., 2007), and the venous arrangement on dorsal renal surface has been described (Bagetti Filho et al., 2008).

For all these reasons, the pig has been largely used for the development and improvement of surgical methods applicable to conventional, laparoscopic, and robotic partial nephrectomy. However, we will observe that this species has some important differences from humans concerning renal healing after partial nephrectomy.

Thus, the present chapter presents the characteristics of some species that has been investigated as models for healing studies after partial nephrectomy.

2 THE PIG AS ANIMAL MODEL

As previously stated, the pig kidney has been largely used as animal model for studying renal surgery and other urological procedures. In the early 1990s, there was a considerable increase in the use of swine kidneys as models for different surgical purposes. Not only partial nephrectomy (McDougall et al., 1993; Valdivia Uria et al., 1992) was studied in this animal model, but also renal transplant (Yanaga et al., 1991), lithotripsy (Evan et al., 1991; van Dongen et al., 1993), and hidronephrosis (Kelleher et al., 1992) were investigated using the pig as an experimental model. More recently, this species remained in use for the development of new surgical technologies, such as ureterorenoscopy (Ptashnyk et al., 2002), use of biologic glues (Hick et al., 2005), cryoablation (Collyer et al., 2004; Janzen et al., 2005), and radiofrequency ablation (Janzen et al., 2005; Margulis et al., 2005b). Furthermore, the pig kidney also plays an important role as a training model, being the most used animal in hands-on courses for surgical procedures and training with new surgical equipment and instruments (Earp, 2003; Hammond et al., 2004; Katz et al., 2003; Rassweiler et al., 1993; Strohmaier and Giese, 2005).

The pig kidney is considered the best animal model for studying human surgical procedures due to its anatomical resemblance to the human kidney (Bagetti Filho et al., 2008; Pereira-Sampaio et al., 2004a,b; Sampaio et al., 1998, 2001). As in humans, the swine kidney is a bean-shaped bilateral organ, localized in the retroperitoneal space. Notably, unlike what is seen in humans, the pig kidney is not involved by a renal fascia (called Gerota's fascia). Furthermore, for most animals, a small amount of whitish fatty tissue is found in the retroperitoneal space, instead of the yellowish and abundant fatty tissue found in the human's retroperitoneum. Despite these differences, the pig kidney has a mean length of 11.79 cm and mean weight of 98 g (Sampaio et al., 1998),
FIGURE 18.1 **Dorsal view of endocast (pelvicaliceal system and arteries) of pig right kidney, showing the primary division of the renal artery into cranial *(CR)* and caudal *(CD)* segmental arteries.**

FIGURE 18.2 **Dorsal view of pig kidney with two arterial segments.** Cranial segment *(red)* and caudal segment *(yellow). Source: Obtained from Pereira-Sampaio, M., Favorito, L.A., Henry, R., Sampaio, F.J., 2007. Proportional analysis of pig kidney arterial segments: differences from the human kidney. J. Endourol. 21 (7), 784–788.*

which is very similar to human kidneys (Sampaio and Mandarim-de-Lacerda, 1989). As in human kidneys, the mean width of the cranial renal pole is slightly superior to the caudal pole (Sampaio and Mandarim-de-Lacerda, 1989; Sampaio et al., 1998).

Internally, the renal collecting system of pigs is especially similar to the corresponding human system. The swine is one of the few animals that have a complex collecting system, with major and minor calyces. All kidneys of pigs show two major calyces (one cranial and one caudal), with 4–19 minor calyces (9 in mean). Thus, despite a great variation in the number of minor calyces, this is very similar to what is observed in human kidneys, in 62% of organs 5–14 minor calyces and 2 major calyces are found (38% of human kidneys show 3 major calyces) (Sampaio, 1993; Sampaio and Mandarim-de-Lacerda, 1988). Thus, pig's kidneys have the most similar collecting system to what is found in humans.

In 93% of kidneys, the renal artery of pigs is always single and divides into two branches (one cranial and one caudal) (Fig. 18.1). Only in 7% of kidneys, the renal artery gives a dorsal and a ventral branch (as seen in humans) (Pereira-Sampaio et al., 2004a). As in human kidneys, the swine renal artery splits into segmental arteries. However, instead of what is seen in humans where most kidneys have five segments, the most common division in swine kidneys (accounting for 42% of organs) is two segments, one cranial and another caudal (Fig. 18.2),

while three, four, or five segments can be found in 24%, 23%, and 3%, respectively (Pereira-Sampaio et al., 2007). The renal venous system of pigs is quite similar to that found in humans. Common to those species, and of surgical importance, is the occurrence of free venous anastomosis on different levels (Bagetti Filho et al., 2008; Sampaio and Aragao, 1990) (Fig. 18.3).

Despite these anatomical similarities and differences, we must say that the pig kidney is the most useful model when anatomical aspects are of interest. However, this is not what is observed when we desire to study the kidney healing after laparoscopic partial nephrectomy.

Several authors used the pig for studying novel techniques and technologies for hemostasis and collecting system closure during laparoscopic partial nephrectomy. However, this was performed without validating this model for this purpose. Moreover, most studies did not use control groups. Ames et al. (2005) published a study that investigated if the porcine kidney would be an appropriate model for experimental evaluation of renal collecting system closure during laparoscopic partial nephrectomy. In this experiment, eight pigs were submitted to heminephrectomy, exposing the collecting system, which was left opened. The authors visualized the opened collecting system by transoperatory retrograde ureteropyelogram, and performed renal hemostasis with a monopolar energy source, applied only on renal parenchyma, and taking care to avoid the collecting system. Contrary to what was expected, none of the animals
FIGURE 18.3   **Ventral view of endocast (pelvicaliceal system and renal veins) of pig right kidney, showing transverse anastomoses (arrows).**

showed urinary leakage after 1 or 3 weeks. Furthermore, these authors operated six pigs, which were also submitted to partial nephrectomy without collecting system closure, but their ureters were dissected, and after placement of an 8-french catheter in its lumen, a suture ligature was tied around it and left postoperatively. This intended to create a high-pressure renal collecting system porcine model, which was more prone to develop urinary leakage. All these six high-pressure renal collecting system animals had moderate hydronephrosis to the level of the tie obstruction, as documented by visual inspection on autopsy, on the eighth postoperative day. Even so, only one pig showed an urinoma. The conclusion of this study was that the porcine model (both with normal and high-pressure renal collecting system) is inadequate for evaluating the renal collecting system closure after partial nephrectomy.

After the publication of this study, our group decided to further investigate the subject. We performed a similar experiment in which 14 male domestic pigs were submitted to left partial laparoscopic nephrectomy, with the removal of 25% of the kidney total length at the caudal pole ($n = 7$) or at the cranial pole ($n = 7$) (de Souza et al., 2011). According to previous anatomical literature (Pereira-Sampaio et al., 2007), this would expose the caudal or the cranial major calices in all animals. During the surgery, the collecting system entering was determined when the surgeon felt a more dense structure to incise, and after complete removal of the renal pole region, the opening of the collecting system was confirmed by direct visualization (Fig. 18.4). In the same manner as
FIGURE 18.4   **Intraoperatory view of the opened collecting system (arrow) after the cranial pole resection of a pig kidney.**
FIGURE 18.5 **Serum levels of urea and creatinine during the postoperative period of the experiment with pigs.** *Source: Obtained from de Souza, D.B., Abilio, E.J., Costa, W.S., Sampaio, M.A., Sampaio, F.J., 2011. Kidney healing after laparoscopic partial nephrectomy without collecting system closure in pigs. Urology 77 (2), 508.e5–508.e9.*

performed by Ames et al. (2005), monopolar energy was applied for hemostasis only in the parenchyma, avoiding coagulation near the collecting system. Once again, after complete hemostasis, the collecting system opening was verified and no internal collecting system drainage catheter was inserted. The animals were clinically evaluated during 14 days after surgery, and afterward, they were submitted to euthanasia by anesthetic overdose. At the 13th postoperative day, the animals were transferred to individual stalls. Methylene blue was diluted in the drinking water for staining the urine to demonstrate any urinary leakage, which would stain the tissue around the kidney. Furthermore, serum levels of urea and creatinine were assessed prior to surgery and at postoperative days 2, 6, 10, and 14, to assess the renal function and any possible peritoneal absorption due to intracavitary urinary leakage.

We observed that all animals recovered well after surgery, presenting normal functions (ambulation, food and water intake, urination, and defecation) within the first 24 postoperative hours. Although serum levels of urea and creatinine showed a slight increase in the second postoperative day, these levels gradually decreased to preoperative levels until the end of the experiment period. Even so, these levels remained far below the upper limit of reference levels for pigs. At necropsy, the abdominal cavity was normal, with normal quantity and aspect of peritoneal liquid. Moreover, the peritoneal fluid levels of urea and creatinine were similar to the normal serum levels (Fig. 18.5).

During necropsy, the peritoneal fluid was collected for urea and creatinine analysis. The abdominal cavity and retroperitonium were evaluated for any evidence of urinary leakage around the operated kidney. Special attention was paid for identification of urinomas, urinary fistulae, peritonitis, and methylene blue extravasation. The operated kidney was removed, and the ureter was catheterized for performing an ex vivo retrograde

pyelogram, to evaluate any leakage of the contrast medium. Then, the organ was fixed in 4% formaldehyde, and the operated pole was cleaved to obtain a fragment of renal tissue together with adhered adjacent tissues. This fragment was processed for histological analyses.

In all animals, the operated pole was completely covered by fibrous tissue, which hindered the identification of the collecting system (Fig. 18.6). We also observed several adherences of the operated pole to adjacent organs (spleen, colon, and pancreas). The urinary bladder was filled with blue-colored urine; nevertheless, no blue stained tissue was observed around the kidney. No
FIGURE 18.6 **Longitudinal section of a left pig kidney submitted to a caudal pole partial nephrectomy.** It is noted a fibrosis in the operated renal pole sealing the collecting system that was sectioned *(arrow)*. It is also depicted the presence of fat firmly adhered to the fibrotic tissue *(asterisk)*. *Source: Obtained from de Souza, D.B., Abilio, E.J., Costa, W.S., Sampaio, M.A., Sampaio, F.J., 2011. Kidney healing after laparoscopic partial nephrectomy without collecting system closure in pigs. Urology 77 (2), 508.e5–508.e9.*
FIGURE 18.7   Ex vivo swine retrograde pyelograms performed 14 days after left kidney laparoscopic partial nephrectomy without closure of the collecting system in the cranial pole (A–B) and in the caudal pole (C–D) show the absence of contrast medium leakage at the operated poles *(arrows). Source: Obtained from de Souza, D.B., Abilio, E.J., Costa, W.S., Sampaio, M.A., Sampaio, F.J., 2011. Kidney healing after laparoscopic partial nephrectomy without collecting system closure in pigs. urinomas, fistulae, or any other signs of urine leakage were found in any animal; moreover, no abnormalities were found in the nonoperated (right) kidney.

The retrograde pyelograms depicted the collecting system anatomy without evidence of any contrast medium extravasation. In some kidneys, submitted to pyelograms with injection under high pressure, the contrast medium penetrated the renal parenchyma (collecting ducts) and still did not present any leakage in the operated pole (Fig. 18.7). Interestingly, we have some cases of high pressure pyelograms, in which we observed a rupture of collecting ducts and extravasation in the nonoperated pole, while the operated pole remained without leakage.

As observed in the histological analysis, the operated pole healed with a connective fibrotic tissue completely covering the renal tissue in all analyzed fields. Several adherences between the operated pole and adjacent organs were also observed under microscopy. The connective tissue presented great density of fibroblasts, which were more commonly seen around the blood vessels. As depicted by Sirius red staining method, observed under polarized light, the connective tissue covering the operated pole was bright red, indicating a predominance of type I collagen (Fig. 18.8).

Therefore, this study showed that the pig collecting system healing is quite different from that of humans. Although in pigs, the kidney heals after partial nephrectomy without any attempt for collecting system closure or internal drainage, with great deposition of collagen and firm adherences to adjacent organs; in humans, urinary leakage after this kind of surgery is considered a common and major complication (Breda et al., 2009), and is observed in 1.9%–5.5% of patients, even after suturing of the collecting system and applying sealant agents (Stephenson et al., 2004; Zorn et al., 2007).

Ames et al. (2005), in their study, postulated that the absence of Gerota's fascia and diminished renal adipose capsule in pigs would allow urine to flow into the peritoneal cavity and be absorbed. Nevertheless, the findings of our study (de Souza et al., 2011) are not in agreement with this theory because our analysis showed no significant alterations in the levels of urea and creatinine both in serum and peritoneal fluid.

The deposit of firm connective tissue over operated kidney is a common finding in several studies, which applied different methods of hemostasis and collecting system repair after partial nephrectomies in pigs (Anderson et al., 2007; Eret et al., 2009; Sabino et al., 2007; Sprunger and Herrell, 2005), although local adherences, as seen in our study, were not reported. The great amount of fibroblasts in tissue examined 14 days after surgery, especially around blood vessels, indicates that synthesis and degradation of collagen may still be occurring.

At the time of the publication of our study, although it was not exactly known how the swine collecting system spontaneously heals after partial nephrectomy, we suggested that the swine has an abundant muscular coat on its renal pelvis and calyces, as noted on our gross examinations. Thus, this musculature would contract and temporarily close the opened collecting system until connective tissue is deposited over the kidney wound. Then, we further investigated, and objectively compared, the human and pig's histological aspects of the collecting system by using histomorphometric methods (Simoes et al., 2016).

For this purpose, ten control kidneys from each species were obtained and fixed in 4% formaldehyde. Fragments containing the renal collecting system were collected from each kidney, routinely processed for paraffin embedding, and used for the histomorphometric analysis.

Gosling et al. (1983) described the collecting system wall, including renal calyces and pelvis, with three distinct subepithelial layers: a mucosal connective tissue (which we referred as superficial layer), a submucosal muscular layer (which we referred as middle layer), and an adventitial connective tissue (which we referred as inner layer). In our study, we analyzed the thickness and the surface density of smooth muscle fibers, elastic system fibers, and cellular density of each of the three layers. We also analyzed the blood vessel surface density in the inner layer, where there is a higher concentration of blood vessels.

In both species, as described by Gosling et al. (1983), the superficial layer was found immediately under the urothelium and was composed mainly of connective tissue. Under this layer, there was a middle layer, where an aggregation of smooth muscle fibers was observed. Finally, the inner layer connective tissue with a high concentration of blood vessels was observed.

We found that the swine kidney superficial layer was 43% thinner than that in humans; the thickness of the middle layer was similar in human and swine samples; and the thickness of the inner layer of swine was 53% higher than those of the human samples (Fig. 18.9).

FIGURE 18.10 Photomicrographs (of sections immunolabeled with anti alpha-actin antibodies and captured under 1000× magnification) illustrating the smooth muscle fibers (seen in *brown*) in the inner layer of (A) human kidneys and (B) swine kidneys. The swine sections have a much higher density of muscle fibers than do sections from humans. Image (C) shows the differences in muscle fiber densities in the three layers among the species. Scale bar represents 20 μm. *Source: Modified from Simoes, M., de Souza, D.B., Gallo, C.B., Pereira-Sampaio, M.A., Costa, W.S., Sampaio, F.J., 2016. Histomorphometric comparison of the human, swine, and ovine collecting systems. Anat. Rec. (Hoboken) 299 (7), 967–972.*

With regard to the surface density of the smooth muscle fibers, in the superficial layer, swine samples had 58% less muscle than humans; in the middle layer, swine samples showed 49% less density than human tissue; however, as for the inner layer, swine samples had values 82% higher than those observed in the human samples (Fig. 18.10).

No difference was observed on the surface density of elastic fibers in the superficial layer between human and swine samples; however, in the middle layer, pig kidney had values 87% higher than those of the human samples; a 15% lower density of elastic fibers in the inner layer was also present in human samples, as compared with swine samples.

The surface density of blood vessels in swine samples (which was analyzed only in the inner layer) was 59% higher than that in the human samples (Fig. 18.11).

The cellular density of the superficial layer in human samples was 19% lower than those of the swine; in the middle layer, the human samples had 46% lower density than the swine; and in the inner layer human samples was 59% higher than that in the swine samples.

With these results we demonstrated that the swine collecting system has a rich vasculature in its inner layer, which is also thicker than that in humans. Thus, it is possible that after the surgical opening, the blood vessels of the inner layer of the swine kidney deposit a clot that covers the collecting system (Fogelson and Neeves, 2015). This would temporarily seal the opening until the collagen that was reported on our previous study (de Souza et al., 2011) is deposited. In addition, this rich vascularization can facilitate chemotaxis, improving the inflammatory response and fibroblast migration to the local area.

A higher density of elastic fibers in the middle layer of the swine collecting system was also observed. It is well known that these elastic fibers are the source of elasticity in the tissue, increasing its resistance to mechanical pressures (Gallo et al., 2012). Therefore, the large amount of elastic fibers found in the swine kidney could cause contraction of the injured collecting system, contributing to its temporary sealing. Furthermore, in the thicker inner layer, swine have a massive density of smooth muscle. Contraction of the smooth muscle could help
FIGURE 18.11 Photomicrographs (of sections immunolabeled with anti-CD31 antibodies and captured under 1000× magnification) illustrating the blood vessels (seen in *brown*) in the inner layer of (A) human kidneys and (B) swine kidneys. Image (C) shows the differences in blood vessels density in the inner layer among the species. Scale bar represents 20 μm.

in temporarily sealing the collecting system, which may explain the absence of urinary leakage in swine.

The results of this study suggested some links between the histology of the collecting system and its healing. Even so, other mechanisms must be involved. As we previously hypothesized (de Souza et al., 2011), the anatomical differences may play a role in the unusual kidney healing mechanism observed in swine. As the collecting system of this animal is narrower than that of humans, it could be sealed more easily. We also suggested that the swine kidney may have a more muscular collecting system than does the human kidney. However, the histological study of the collecting system showed that only the inner layer of the swine collecting system is more muscular than that of humans.

Other possible involved aspect that may explain the differences on collecting system healing after partial nephrectomy is the absence of renal fascia (Gerota's fascia) and the low amount of perinephric fat observed in swine. According to Ames et al. (2005), these structures could contribute to the closure of the collecting system in pigs. Future studies are still necessary to fully understand the differences and similarities among kidney healing processes in these species. It is possible that these differences and similarities may relate not only to the histological characteristics, but also to anatomical, physiological, and molecular aspects.

Even so, the morphological features of the human and swine collecting systems may partially explain the different healing processes following partial nephrectomy. The highly vascular, thicker, and more muscular inner layer (adventitial connective tissue) of the swine kidney, as well as the higher density of elastic fibers in the middle layer (submucosal muscular), may be important factors in elucidating the unique collecting system healing process seen in this animal. This reinforces our previous conclusion that the pig kidney is not an adequate experimental model for research on which collecting system healing is an important aspect to be considered.

3 THE SHEEP AS ANIMAL MODEL

After reporting the pig as an inadequate model for research on collecting system healing after partial nephrectomy, one major concern arose. Which other animal should be used for this purpose, instead of the traditional swine model? Until early 2016 no other animal has been suggested to be a more suitable model for research on collecting system repair (de Souza et al., 2016). Therefore, even knowing that the pig model shows major limitations, this species continued to be used for this purpose (Duchene, 2011; Shikanov et al., 2009). We started then to investigate an alternative animal model that may show a collecting system healing more similar to that seen in human clinical settings.

The sheep has been used as a model for healing studies since 1960 (Lascelles and Claringbold, 1960), and is currently widely used for studying bone healing (Christou et al., 2014; James et al., 2016; Liu et al., 2016; Malhotra et al., 2014; Martini et al., 2001). It was shown that ovine show a comparable bone healing rate to that of humans and have been previously established as a useful model for human bone turnover and remodeling activity (Malhotra et al., 2014; Martini et al., 2001; Pearce et al., 2007). Thus, we supposed that as this species shows similar aspects on bone healing, it may also be a suitable model for studying kidney healing. Sheep have been used for some studies on renal denervation, radiofrequency, and hydronephrosis (Alexander et al., 2014; Booth et al., 2015; Haghighi et al., 2006; Springer et al., 2015; Tanaka et al., 2014); however, the kidney healing after laparoscopic partial resection was not reported. With the objective of investigating the kidney healing in sheep after laparoscopic partial nephrectomy without closure of the collecting system, we performed a study very similar to that previously done in pigs (de Souza et al., 2011).

Eight adult female domestic sheep were subjected to laparoscopic partial nephrectomy. The caudal pole of the left kidney was removed, and the renal pelvis was

purposefully left open to assess the animal's spontaneous healing. As in pigs, a more dense structure was felt during the incision of the collecting system. After completely removing the renal pole region, the opened collecting system was confirmed by direct visualization, and monopolar cautery was applied for hemostasis only in the parenchyma. The opened collecting system was once again verified after hemostasis, and no internal collecting system drainage catheter was inserted.

The animals were evaluated daily for 14 days after surgery and, after this period, were euthanized by anesthetic overdose. Serum levels of urea and creatinine were drawn before surgery and on postoperative days 2, 6, 10, and 14, to assess renal function and any possible peritoneal absorption due to intracavital urinary leakage.

During necropsy, peritoneal fluid was collected for urea and creatinine analysis. The peritoneal cavity and retroperitoneal space were evaluated for evidence of urinary leakage around the operated kidney. Special attention was given to identifying any urinomas, urinary fistulae, or peritonitis and visceral adhesions.

The operated kidney was removed, and the ureter was catheterized. To evaluate any leakage of contrast medium, an ex vivo retrograde pyelogram was performed, and after the pyelogram, the kidney was injected with methylene blue ink through the ureter to directly distinguish the area of urinary leakage onto the kidney. The kidneys were then fixed in 4% formaldehyde, and the operated pole was sectioned to obtain renal tissue together with adhered adjacent tissues for histological analyses.

As in the experiment with pigs, all animals had a normal postoperative recovery with a return to normal functioning (ambulation, food and water intake, urination, and defecation) within the first 24 h. Serum levels of urea and creatinine increased on postoperative day 2, but both levels gradually decreased from their early postoperative levels on the following days (Fig. 18.12).

FIGURE 18.13 Urea and creatinine levels in serum samples collected preoperatively (A) and postmortem (B) and in peritoneal fluid samples (C) of sheep subjected to laparoscopic partial nephrectomy without collecting system closure, indicating some urine leakage to the peritoneal cavity. †, Different from A; ‡, different from B. *Source: Obtained from de Souza, D.B., Abilio, E.J., Costa, W.S., Sampaio, M.A., Sampaio, F.J., 2011. Kidney healing after laparoscopic partial nephrectomy without collecting system closure in pigs. Urology 77 (2), 508.e5–508.e9.*

Peritoneal fluid collected during necropsy contained higher urea levels than serum samples collected both preoperatively and postoperatively. Necropsy-obtained creatinine peritoneal fluid levels were also higher than preoperative serum levels (Fig. 18.13).

During the postmortem gross examination, it was possible to note an urinoma surrounding the caudal pole in one animal. In this animal, the levels of urea and creatinine in the peritoneal liquid were 7.6 and 18.9 times higher, respectively, than its previous serum levels. No other macroscopic signs of urine leakage were found in the other animals. Moreover, several adhesions were observed connecting the operated pole with adjacent organs (rumen, omentum, and colon) and perirenal adipose tissue.

The retrograde pyelograms demonstrated contrast-medium extravasation through the operated pole in all kidneys. Usually, the contrast medium was observed in sinus tracts in the perirenal tissue. Injection of methylene blue ink through the ureter also confirmed that the collecting system was still open, as the contrast was easily observed extravasating into the perirenal area (Fig. 18.14).

Histological analysis confirmed the adhesions to adjacent organs in which connective tissue with fibroblasts covered the operated pole. The analysis of Sirius red–stained slides under polarized light indicated that this connective tissue had areas with different amounts of collagen fibers, which were characterized as types I and III (Fig. 18.15).

The deposit of firm connective tissue over the operated kidney has been a common finding after partial nephrectomies in pigs (Anderson et al., 2007; Eret et al., 2009; Sabino et al., 2007; Sprunger and Herrell, 2005), and we have also reported and described the histological aspects of this connective tissue (de Souza et al., 2011).

This tissue is mainly composed by type I collagen in pigs, while in sheep, type III collagen was also present in the connective tissue deposited over the resection area. This indicates that the healing process is histologically different between pigs and sheep, and may help to understand why urinary leakage occurs in one but not in other species.

With these results, we figured out that the sheep's collecting system does not heal as it does in pigs (de Souza et al., 2011), rather behaves similarly to what is seen clinically in humans in which urinary leakage is a common complication after partial nephrectomies (Breda et al., 2009; Zorn et al., 2007). Thus, we concluded that the sheep, instead of the pig, should be considered as an adequate experimental model for research on collecting system healing after partial nephrectomy.

Furthermore, many studies advocating different methods for collecting system closure were performed in pigs (Bishoff et al., 2003; Ogan et al., 2003; Orvieto et al., 2007; Shikanov et al., 2009), which is an inadequate model for studying kidney healing (closing spontaneously within 14 days). These methods should be evaluated in the sheep model before clinical usage.

Ames et al. (2005), in their study, postulated one possible explanation for the absence of urinoma formation in pigs as the inexistence of Gerota's fascia, and that the diminished renal adipose capsule in pigs would allow urine to flow into the peritoneal cavity and be absorbed. Although we refuted this theory in our study performed in pigs (de Souza et al., 2011), we reevaluated this hypothesis after the sheep experiment. Interestingly, some sheep specimens showed extravasation running around the kidney toward the cranial pole during retrograde pyelogram and methylene blue injection, suggesting the presence of a renal fascia similar to Gerota's fascia in humans. If confirmed, this anatomical feature might
FIGURE 18.16 Photomicrographs (of sections stained with Masson's trichrome and captured under 100× magnification) illustrating the three different layers observed under the urothelium: (A) human and (B) ovine. Image (C) shows the differences in layer thickness between the species. Scale bar represents 200 μm. *Source: Modified from Simoes, M., de Souza, D.B., Gallo, C.B., Pereira-Sampaio, M.A., Costa, W.S., Sampaio, F.J., 2016. help explain the similarity between kidney healing in sheep and humans. This question highlights the importance of knowing the anatomy of the experimental model used. After reviewing the literature regarding the theme, we realized that the anatomy of the sheep kidney and retroperitoneum has been little described, specially referring to renal surgery. Thus, we decided to deeply study and describe the renal anatomy of sheep (Buys-Goncalves et al., 2016).

The sheep kidneys are retroperitoneal and bean-shaped, but unlike the human and pig kidneys, they are asymmetric. The right kidney is most cranial and extends from the first to the third lumbar vertebrae, while the left kidney extends from the second to the fourth lumbar vertebrae. Concerning the volume, sheep kidney is smaller than the human and porcine kidney. The kidney length in an adult animal ranges from 5.5 to 7 cm, while the renal weight ranges from 100 to 160 g (Nickel et al., 1979). The lower kidney volume can interfere with healing and injury caused by less invasive procedures, such as cryoablation and radiofrequency ablation. Thus, sheep kidney does not seem to be a good model for renal

procedures in which the volume and position of the kidneys are relevant points to be considered.

We have also studied the sheep collecting system normal histology, and compared it with human and pigs' samples (Simoes et al., 2016). As we hypothesized, the collecting system of sheep is much more similar to that in humans than the pig's is, although differences are still present.

The superficial and middle layer of the ovine collecting system is 43% and 57% thinner than humans, respectively. However, the inner layer thickness of human and ovine is similar (Fig. 18.16).

The surface density of the smooth muscle fibers in superficial and middle layers also showed differences between humans and sheep. In the superficial layer, sheep had 36% less smooth muscle fibers than humans, and in the middle layer, ovine samples were 18% lower than that in human samples. However, in the inner layer, ovine samples had 39% less smooth muscle than that in human samples (Fig. 18.17).

With regard to the surface density of elastic fibers in the superficial layer, no difference was observed between
FIGURE 18.17 Photomicrographs (of sections immunolabeled with anti alpha-actin antibodies and captured under 1000× magnification) illustrating the smooth muscle fibers (seen in *brown*) in the inner layer of (A) human kidneys and (B) ovine kidneys. Scale bar represents 20 μm. *Source: Modified from Simoes, M., de Souza, D.B., Gallo, C.B., Pereira-Sampaio, M.A., Costa, W.S., Sampaio, F.J., 2016. Histomorphometric comparison of the human, swine, and ovine collecting systems. Anat. Rec. (Hoboken) 299 (7), 967–972.*
FIGURE 18.18 Photomicrographs (of sections immunolabeled with anti-CD31 antibodies and captured under 1000× magnification) illustrating the blood vessels (seen in *brown*) in the inner layer of (A) human kidneys and (B) ovine kidneys. Image (C) shows the differences in blood vessels density in the inner layer among the species. Scale bar represents 20 μm.

humans and sheep. As for the middle and inner layers, ovine samples had 46% and 15% more fibers than humans samples, respectively. However, the surface density of blood vessels (which was analyzed only in the inner layer) was statistically similar among these species (Fig. 18.18).

The cellular density of human superficial layer was 18% lower than those of ovine values. With regard to the middle and inner layers, no difference was observed between the human and ovine sample cellular densities.

This histological study depicted similarities between the ovine and human collecting systems, which supports our previous findings that the sheep's collecting system heals more similarly to what is seen clinically in humans, and this species should be considered an adequate experimental model for research on collecting system healing after partial nephrectomy. Specifically, it seems that the densities of blood vessels and elastic fibers are quite similar between these two species. Furthermore, the muscle fibers and cellular densities in the middle and inner layers of ovine samples resemble those of humans.

We then concluded that the comparable vascular and elastic fiber densities observed in all layers of the human and ovine kidneys, as well as the similar cellular and muscular densities of the middle and inner layers, may be the reasons for the similarities observed between human and ovine kidney healing (Simoes et al., 2016).

In addition to the histology, detailed anatomical study was recently published on the kidney collecting system and the branching pattern of the renal artery in ovine (Buys-Goncalves et al., 2016). We analyzed 38 ovine kidneys using three-dimensional endocasts of the collecting system together with the intrarenal arteries. The endocasts were prepared injecting a yellow and red polyester resin into the ureter and renal artery, respectively, and further digesting all tissue by immersion in hydrochloric acid baths.

The casts of the renal collecting system demonstrated a renal pelvis with several recesses. Thus, instead of a calyceal system as in human and pig kidneys (Barcellos

Sampaio and Mandarim-de-Lacerda, 1988; Sampaio et al., 1998), the collecting system consists only of a renal pelvis with several recesses on its edge. The recesses of the renal pelvis are expansions of the renal pelvis cavity, surrounding the renal pyramids. Researchers, who are familiar with the human calyceal system, may confuse the recesses of the renal pelvis with the minor calyces in urograms. Recesses were observed on both dorsal and ventral surfaces of the renal pelvis, varying from 11 to 19 (mean of 16) in each kidney. Due to lack of renal calices, the sheep kidney is not considered an adequate model for humans if the collecting system anatomy is the main point. Nevertheless, understanding its anatomy is important because we demonstrated that sheep could be a better model than pig for studies on collecting system healing.

In all endocasts, the renal artery was singular and divided into dorsal and ventral primary branches. These branches of the renal artery gave rise to different segmental branches that ran along the dorsal and ventral surface of the renal pelvis, which passed into the space between the recesses of the renal pelvis as interlobar arteries to reach the renal cortex (Fig. 18.19). This primary division of the renal artery is similar to humans (Sampaio and Aragao, 1990).

The cranial pole of all casts was supplied by two segmental arteries originating from the cranial segmental arteries from both dorsal and ventral branches of the renal artery. Interlobar arteries originated from these cranial segmental arteries and passed throughout the grooves between the recesses of the renal pelvis to reach the cortex (Fig. 18.20). This relationship between the arteries and the collecting system at the cranial pole is very similar to that of human (Sampaio and Aragao, 1990). However, the sheep does not have the retropelvic artery related to the upper infundibulum as humans. This artery, when present in humans (57% of cases), irrigates the posterior region of the kidney and, when injured during partial nephrectomy of the upper pole, can promote important bleeding and a large damage of the remaining
FIGURE 18.19 **Ventral view of endocast of sheep left kidney, showing ventral branch *(v)* of the renal artery divided into cranial *(cr)* middle *(m)*, and caudal *(cd)* segmental arteries.** Ventral mid zone is supplied only by the middle segmental artery. parenchyma (Sampaio, 1992). Consequently, the cranial pole of the sheep kidney should not be considered as an adequate model for experimental procedures in which the retropelvic artery is the main point to be considered. In this case, the damage of the remaining parenchyma could form a fistula, which can cause an impairment in the kidney healing.

In 71% of the kidneys, the caudal segmental artery from the dorsal branch of the renal artery supplied the entire or part of the dorsal mid zone (Fig. 18.21). This relationship between the arterial branching pattern and the collecting system is different from humans, where the dorsal mid zone is irrigated by the posterior segmental artery (Sampaio and Aragao, 1990).

The ventral mid zone of the sheep kidney was also mostly supplied by the caudal segmental artery from the ventral branch of the renal artery. In 71% of the kidneys, the blood supply of the ventral mid zone was partial or entirely provided by the caudal segmental artery. This is different from humans, where the ventral mid zone is vascularized by horizontal branches from the anterior segmental artery (Sampaio and Aragao, 1990).

The caudal pole of the sheep kidney was supplied by the interlobar branches from the caudal segmental arteries of the dorsal and ventral primary branches of the renal artery in all cases. In humans (62%), the caudal pole is vascularized by inferior segmental arteries, which divide into anterior and posterior branches, sending interlobar arteries on both ventral and dorsal surfaces of the caudal pole (Sampaio and Aragao, 1990). Although the branching pattern of the intrarenal arteries into the caudal pole of the sheep kidney is not exactly the same, the relationship between the intrarenal arteries and the collecting system in the caudal pole is similar to humans, showing one artery on each side, which originated in the interlobar branches. Therefore, the sheep kidney can be considered a good model for urological procedures when the caudal pole arterial branching pattern is an important topic to be considered.

Despite the different anatomy of the sheep kidney collecting system from the human kidney, without a calyceal system, it does not preclude its use as a model for urologic procedures in which the anatomy of the collecting system is not the main point. Due to the similarities of the arterial branching pattern in the caudal renal pole between human and sheep, the sheep kidney could serve as an experimental model. However, the lack of a retropelvic artery discourages the use of the cranial renal pole in experiments in which arterial branches are an important aspect to be considered.
FIGURE 18.21 **Dorsal view of endocast of sheep right kidney, showing the dorsal mid zone irrigated only by branches (asterisk) from the caudal segmental artery (cd).** The cranial pole is supplied by the cranial (cr) and the middle (m) segmental arteries. *Source: Obtained from Buys-Goncalves, G.F., De Souza, D.B., Sampaio, F.J., Pereira-Sampaio, M.A., 2016. Anatomical relationship between the kidney collecting system and the intrarenal arteries in the sheep: contribution for a new urological model. Anat. Rec. 299 (4), 405–411.*

The sheep has other advantages as an experimental model over a pig. Sheep are very docile animals. Handling these animals is much easier than handling pigs; they offer a very calibrous external jugular vein for blood retrieval. Other beneficial aspects that should be pointed out are the more hygienic ovine stall, instead of the (almost always) malodorous swine facility, and the quietness ambient during restraint (instead of the screaming pigs). These factors make sheep handling for experimental purposes much less stressful than handling pigs, and this should also be considered when choosing the experimental model to be used.

4 THE RABBIT AS ANIMAL MODEL

Simultaneous to the experiment performed in sheep, we investigated the rabbit as a model for kidney healing studies after partial nephrectomy. Rabbits are widely used as animal models for studying different surgical and nonsurgical conditions (Abdullahi et al., 2014; Deponti et al., 2015; Kim et al., 2015; Lossi et al., 2016). This species is especially important as a kidney transplantation
FIGURE 18.22 **Appearance of the abdominal cavity (dorsal region) of a rabbit, 14 days after laparoscopic partial nephrectomy without collecting system closure.** Note the adherence of a intestinal loop (arrowhead) to the renal adipose capsule (arrow).

model (He et al., 2015; Vera-Donoso et al., 2015; Yazici et al., 2015). Thus, we performed a similar experiment, as conducted in pigs and sheep, to evaluate if the rabbit would be an adequate model for kidney healing studies.

We studied eight rabbits that were submitted to left partial nephrectomy under laparoscopic access. The collecting system was left opened and the animals were submitted to euthanasia after 14 days. Kidneys were collected, and the same evaluation performed in sheep (necropsy, retrograde pyelogram, and retrograde injection of methylene blue ink) was conducted in rabbits.

During gross necroscopic examination, no evidence of urinary leakage or urinoma was observed, but adhesions of the operated pole to surrounding organs (mainly intestinal loops) were present (Fig. 18.22). The retrograde pyelogram depicted contrast-medium extravasation through the operated pole in six kidneys (75% of the eight operated) (Fig. 18.23). The other two kidneys did not present any extravasation, even after the collecting system being fulfilled with the contrast medium. In addition, the injection of methylene blue through the ureter confirmed that the collecting system was opened in 75% of the kidneys after 14 days from partial nephrectomy.

As seen in humans, the collecting system of rabbits does not heal spontaneously after being left opened in a partial nephrectomy. Thus, based only on these findings, we may conclude that the rabbit could be a good model for studying kidney healing after partial nephrectomy. However, other factors should be taken into account.

The kidney of an adult rabbit has a length of 3.5 cm (right kidney) and 3.9 cm (left kidney), a width of 2.5 cm (right kidney) and 2.6 cm (left kidney), and a thickness of 1.8 cm (right kidney) and 1.7 cm (left kidney) (Dimitrov
FIGURE 18.23 **Ex vivo retrograde pyelograms of rabbit kidneys removed 14 days after laparoscopic partial nephrectomy without collecting system closure.** The images demonstrated leakage of the opened collecting system.

et al., 2012). This is much inferior to the human kidney, which has a mean length of 10.97 cm (Sampaio and Mandarim-de-Lacerda, 1989), and this is an important aspect to be considered when considering a surgical model.

The size of the kidney is not the only embarrassment for considering it as an adequate model for studying partial nephrectomy healing. We must consider the small size and weight of rabbits (somehow) as a negative factor. These animals have small abdominal cavities that make it difficult for laparoscopic manipulation, as the instruments hit each other inside the cavity. Furthermore, as they have a high superficial area (in proportion to their weight), they easily develop hypothermia during surgical procedures. This is especially important when performing longer surgical procedures (such as partial nephrectomy) and when using cold carbon dioxide for intraabdominal insufflation during laparoscopic procedures. On the contrary, the small size of rabbits makes the handling and housing of these animals much easier than the other studied species (sheep or pigs).

With regard to the intrarenal anatomy, the rabbit kidney collecting system is very similar to those of sheep. It consists of a renal pelvis with 8–12 recesses on its edge, with more recesses on the dorsal surface than in the ventral surface (Shalgum et al., 2012). This demonstrates that as sheep, the rabbit is not a good model for experiments anatomy being an important factor to be considered.

The renal artery of rabbits divides into one dorsal and one ventral branch (Shalgum et al., 2012). This division of the renal artery is similar to what is found in humans (Sampaio et al., 1993) and in sheep (Buys-Goncalves et al., 2016), but different to that of swine (Pereira-Sampaio et al., 2007). This is an important aspect to be considered in favor of rabbits. However, there is a report of a dorsal and a ventral polar branch in 42% of the kidneys (Sindel et al., 1990).
FIGURE 18.24 **Cranial view of endocast of rabbit left kidney showing the collecting system involved by a dorsal (d) and ventral (v) division of the renal artery (r).** *Source: Obtained from Shalgum, A., Marques-Sampaio, B.P., Dafalla, A., Pereira-Sampaio, M.A., 2012. Anatomical relationship between the collecting system and the intrarenal arteries in the rabbit: contribution for an experimental model. Anat. Histol. Embryol. 41 (2), 130–138.*

Two main arteries, cranial branches of the dorsal and ventral division of the renal artery, involve the rabbit kidney cranial pole in 56% of cases (Fig. 18.24). This relationship between intrarenal arteries and the collecting system of the cranial pole is similar to that in human, sheep, and pig (Buys-Goncalves et al., 2016; Pereira-Sampaio et al., 2004a; Sampaio and Aragao, 1990). Therefore, this similarity supports the use of the rabbit as an animal model for urologic procedures in the cranial pole.

The caudal pole receives caudal branches from both dorsal and ventral divisions of the renal artery in all cases (100%), and the collecting system of the caudal pole was supplied by branches of these two arteries (Fig. 18.25). This differs from man, where the inferior pole is irrigated only by the inferior segmental artery of the ventral division of renal artery in 62% of kidneys (Sampaio and Aragao, 1990).

Overall, we feel that rabbits can be used as an alternative animal model to sheep when studying the collecting system healing after partial nephrectomy. As sheep and humans, they are prone to urinary extravasation if no attempt of closing the collecting system is performed. Rabbits present advantages on handling and housing; as it is a more commonly used experimental model, most

research centers have animal facilities for providing rabbits. Furthermore, most experimental surgical units should be adequate for operating rabbits (while operating pigs or sheep implies having special facilities). On the contrary, rabbits have an important disadvantage in comparison to sheep, as their body and kidneys are much smaller than humans.

5 THE DOG AS ANIMAL MODEL

Although there is little information regarding the use of dogs as model for studying kidney healing after partial nephrectomy, we should briefly comment on this species. First of all, we must note that scientists have made great efforts to replace dogs with other models to the extent possible. Even so, this species is still used in experimental surgical studies (Davari et al., 2016; Goudie et al., 2016; Yamada et al., 2016; Zou et al., 2016).

In 2005, when Ames et al. published their experiments with pigs, they also reported a small study with two beagle dogs. In these animals, they performed laparoscopic heminephrectomy (in the superior pole in one animal and in the inferior pole in the other). The hemostasis was achieved by a wet monopolar cautery with meticulous care to avoid the collecting system (Ames et al., 2005).

They found, after 1 week from surgery, that none of the animals developed urinoma, sepsis, or renal failure. Instead, an intense fibrotic response was observed around the site of heminephrectomy, similar to what had been observed in their swine (Ames et al., 2005), and in all species that we studied (pigs, sheep, and rabbits). Thus, they concluded that canine models cannot be used to evaluate collecting system closure because they do not manifest the same propensity for leakage as is seen clinically.

We further studied the canine renal anatomy in 110 kidneys from mongrel dogs (Pereira-Sampaio et al., 2009). The canine kidney has a great variance in size as a dog's size is significantly variable too. The smaller kidney length was of 4 cm, from a dog with 4.6 kg body weight and 41.5 cm height (measured at the withers, i.e., from the forehand to the highest point of the vertebral column of the thoracic segment), while the higher kidney length was of 9 cm, from a dog with 32.7 kg body weight and 73 cm height. This high variation should be taken into account when thinking of using a dog as an animal model. Dogs taller than 70 cm had a renal length of 9 cm, which is similar to adult human data (Sampaio and Mandarim-de-Lacerda, 1989). Therefore, kidneys from this size dog (which is not very common) might be useful as a model in experimental studies in which renal volume is an important aspect.

Furthermore, similar to sheep and rabbits (and different from pigs and humans), the dog's kidney does not present renal calices. The collecting system has only a renal pelvis with 9–17 (median 14) recesses in its margin (Figs. 18.26 and 18.27) (Pereira-Sampaio et al., 2009).

Thus, the dog kidney is not a good model for studying renal healing after partial nephrectomy, and to any

FIGURE 18.27 **Lateral view of a dog kidney's collecting system endocast, showing the ureter (u).** *Arrow* points to the groove made by the renal crest in the renal pelvis cast. *Source: Obtained from Pereira-Sampaio, M.A., Marques-Sampaio, B.P., Henry, R.W., Favorito, L.A., Sampaio, F.J., 2009. The dog kidney as experimental model in endourology: anatomic contribution. J. Endourol. 23 (6), 989–993.*

experimental studies in which collecting system morphology is an important factor to be considered. Kidneys of dogs that are taller than 70 cm at the withers might be useful as a model in experimental studies in which renal volume is an important aspect. However, other species that present renal volume similar to humans' should be preferred because of ethical considerations.

6 CONCLUDING REMARKS

After studying pigs, sheep, dogs, and rabbits, and comparing the results obtained in these species with the literature of humans in clinical conditions, several lessons were learned. The pig has the most similar renal anatomy with humans, especially in regards to renal size and collecting system anatomy. However, the pig kidney collecting system healed well without any kind of suture or internal drainage after partial nephrectomy. As this is much different from human kidney healing, we must say that the pig kidney is not an adequate experimental model for research on which collecting system healing is an important aspect to be considered.

Although limited data are disponible regarding the use of dogs as models for studying kidney healing. This species, as well as pigs, did not present the expected urinary leakage after partial nephrectomy. Furthermore, collecting system anatomy, and ethical considerations regarding the experimental use of dogs, precludes its indication as model for studying kidney healing after partial nephrectomy.

Sheep and rabbits showed signs that their kidneys' collecting system does not heal without surgical maneuvers for its closure. This is more similar to what is found in human clinical settings, and thus these animals should be preferred when studying the collecting system healing after partial nephrectomy. It should be considered that the collecting system anatomy of these species, without minor renal calices, is very different from humans. Thus, the pig should be preferred for studies in which the collecting system anatomy is important. On the contrary, the division of the renal artery of sheep and rabbits, in one anterior and one posterior branch, is more similar to humans; therefore for studies in which this vascularization is of importance, these species should be preferred.

It should be considered that sheep are animals with a renal size more similar to humans than rabbits. Moreover, the abdominal cavity's limited volume of rabbits sometimes makes it difficult for the execution of surgical maneuvers; this is especially important when performing laparoscopic surgery. Thus, sheep should be considered the best animal model for studying kidney healing after partial nephrectomy. Rabbits may be considered as an alternative when the experimental facility does not permit studies with sheep.

Animal Models of Inflammatory Bowel Disease

Sumit Jamwal, Puneet Kumar

I.S.F College of Pharmacy, Moga, Punjab, India

1 INTRODUCTION

Inflammatory bowel disease (IBD) is a group of idiopathic, chronic, and relapsing inflammatory conditions mainly affecting colon and small intestine and characterized by severe abdominal pain and diarrhea. IBD mainly covers Crohn's disease (CD) and ulcerative colitis (UC). CD and UC are chronic and progressive inflammatory conditions that may affect the entire GI tract and the colonic mucosa and might be associated with an increased risk for colon cancer (Arthur et al., 2010). Most of the pathological and clinical characteristics of CD and UC are similar, but they differ in some features, that is, regions of the GI tract affected and depth of inflammation. The GI tract is responsible for digestion of food, absorption of nutrients, and elimination of waste. Chronic inflammation impairs the ability of GI organs to function properly, leading to symptoms, such as persistent diarrhea, abdominal pain, rectal bleeding, weight loss and fatigue. It may result in significant morbidity and mortality, with compromised quality of life and life expectancy (Goyal et al., 2014).

CD may affect any part of the GI tract from mouth to anus most but commonly affects the end of the small intestine (the ileum) near the beginning of the colon. It mainly causes abdominal pain, diarrhea, vomiting, and weight loss. CD may appear in "patches," affecting some areas of the GI tract while leaving other sections completely untouched. In CD, the inflammation may extend through the entire thickness of the bowel wall. On the other hand, UC is mainly confined to the colon, and may involve the rectum. The inflammation occurs only in the innermost layer of the lining of the intestine and usually starts from lower colon, but may involve the entire colon. It is primarily manifested as continuous areas of inflammation, ulceration, edema, and hemorrhage along

the length of the colon. The most observational feature of UC is the presence of blood in stool and is associated with lower abdominal cramping during the bowel movements (Ordas et al., 2012).

In Western Europe and USA, CD and UC have an incidence of approximately 6–8 cases per 100,000 populations and an estimated prevalence of approximately 70–150 per 100,000 populations. The peak occurrence is between ages 15 and 35. Both sexes are equally affected in case of these diseases (Burisch, 2014).

The pathophysiology is not fully understood but is thought to be caused by a complex interplay between gut microbiota, dysregulation of the host's immune system, genetic susceptibility, and environmental factors. To study these different etiological factors, various experimental models are available in the scientific research, which includes chemical-induced, spontaneous, genetically engineered and transgenic models. These models represent a major source of information about biological systems and pathogenesis of the disease and are clinically relevant to both human UC, as well as CD. Though there is less information available in literature about all the models, in this chapter we have collected and presented systematically arranged data on pathophysiology involved in the disease and various types of animal models of IBD and other disease-related complications.

2 HISTORICAL PERSPECTIVES

UC was first described by two English physicians, Wilks and Moxon in 1875, who distinguished it from diarrheal diseases caused by bacterial and viral agents. There are reports of a disease with similar symptoms to UC in 16th and 17th century but it was not named as a distinct disease until 1875. CD was first described in 1932 by three doctors—Burrill Crohn, Leon Ginzberg, and Gordon D. Oppenheimer. During that period, any disease affecting small intestine was thought to be intestinal tuberculosis. These doctors collected data with symptoms of abdominal cramps, diarrhea, fever, and weight loss from 14 patients and revealed that the symptoms were not due to intestinal tuberculosis or any other known disease. Therefore, they described a new disease entity, which was first called regional ileitis and later on CD.

3 PATHOPHYSIOLOGY OF IBD

Although the exact cause of IBD remains unclear it but molecular assessment during IBD progression shows alteration in immune system, gut microbiota, disruption in mucosal barrier, increase in level of proinflammatory cytokines and oxidative stress.

3.1 Innate and Adaptive Immunity

The immune system is the collection of cells and macromolecules that protects the body from numerous pathogenic microbes and toxins in our environment. This defense against microbes involves two types of reactions: reactions of innate immunity and reactions of adaptive immunity. Innate and adaptive immunity are two equally important aspects of the immune system in which innate immune response acts as a first line of defense and provides nonspecific protection whereas adaptive immune response is highly specific in nature and gets activated by the innate immunity.

Innate immunity is formed by epithelial barrier, neutrophils, macrophages, dendritic cells, natural killer cells (NK cells) and others. It is activated by the toxin and microbial agents which are recognized by the specific recognition receptors, such as toll-like receptors (TLRs) and NOD-like receptors. Neutrophils along with other cells start the process of inflammation by releasing proinflammatory cytokines, such as TNF-α, IL-1, IL-6, and IL-8, which further activate the adaptive immune response (Wallace et al. 2014).

Adaptive immune system is composed of T-lymphocytes and B-cells, which on activation releases cytokines and antibodies. T cells have been reported to be the main contributor to IBD due to the increased production and release of proinflammatory cytokines and interferons (IFNs) in lower GI tract. IL-12 activates Th1 cells to produce large amount of IFNs and mainly responsible for inflammation in CD patients. Th2 cells increase the production and release of IL-4, IL-5, and IL-13 and are responsible for inflammation in UC patients. Recently, a third type of T-helper cell has been reported to involved in IBD pathogenesis, that is, Th17 cells. These cells cause the release of IL-17 and IL-22 and play role in destruction of local tissue (Siegmund and Zeitz, 2011). Further, reports are available that proinflammatory cytokines disrupts epithelial barrier and increases gut permeability; thereby accounts for an uncontrolled inflammation.

3.2 Gut Microbiota

The impairment in gut bacterial flora is well implicated in the pathophysiology of IBD. Alteration in the intestinal mucosa layer in IBD results in increased association of gut bacteria to innermost lining of mucosa. This association of bacteria is recognized as hapten and results in activation of the inflammatory process by binding on antigen-presenting cells (APC) and ultimately causing damage to mucosal layer (Wallace et al., 2014). Though the clear role of gut bacterial flora in the pathogenesis of IBD is unclear, but some of investigators have showed that some bacterial species like *Bacteroides* or *Clostridium* spp. and aerobic E. increases in IBD mucosa (Beisner et al., 2010).

3.3 Disruption of Mucosal Barrier

Mucosal surfaces are composed of epithelial cells and these cells form a barrier between hostile external environments and the internal milieu. Mucosal surfaces have selective permeability barrier and are responsible for nutrient absorption and waste secretion. Variations of the intestinal mucus layer concerning its thickness, continuity and composition, as well as the mucin-structure have been reported in IBD patients, especially in UC. These changes are thought to adversely affect the protective properties of the gel layer and consequently might cause an increased vulnerability of the epithelium to bacterial invasion. Disruption of this barrier results in dysregulated gut epithelial permeability, which can induce an overactive mucosal immune response and chronic intestinal inflammation. The exact mechanism of the loss of barrier is not known, but several studies have reported that cytokines, TNF-α, interleukins, etc. involved in the pathogenesis of UC and CD may attribute to the increased epithelial permeability and alteration of tight junctions resulting into barrier disruption (McGuckin et al., 2009).

3.4 Inflammatory Mediators

IBD is a chronic inflammatory condition in which several genetic, environmental, and biological factors trigger inappropriate immune responses, that is, overproduction of different proinflammatory mediators, such as TNF-α, ILs, cytokines, and chemokines. The concentration of these mediators is highly elevated in blood, stool, and intestinal mucosa of IBD patients. Inflammatory mediator profile of CD and UC is different, such as IL-2 and IFN-γ are responsible for the inflammation in CD whereas IL-4, IL-5, and IL-10 are involved in UC pathogenesis. The release of these inflammatory cells is regulated by different pathways involved in inflammation, that is, nuclear factor-κB (NF-κB) and mitogen-activated protein kinases (MAPK) and JAK/STAT pathway. NF-κB and MAPK are activated by the TLR-4 which further stimulates the release of TNF-α, IL-6, and IL-12 through macrophages, and thereby exacerbating the inflammatory response (Goyal et al., 2014). In addition to this, cytokines exert their signaling by activating JAK/STAT pathway and involved in the production of a number of interleukins. The proinflammatory mediators release is major factor involved in the progression of IBD.

3.5 Oxidative Stress

Oxidative stress has been well documented in IBD patients with increased ROS levels and decreased antioxidant levels in the inflamed mucosal layer, which ultimately contribute to tissue damage. A significant infiltration by neutrophils and increase in MPO levels was observed in the inflamed lamina propria of humans with UC. In IBD patients, an imbalance has been reported between oxidative species, such as superoxide ions, peroxynitrite ions, and hydrogen peroxide, and endogenous antioxidant levels, such as glutathione (GSH), catalase, and superoxide dismutase (SOD), resulting in the oxidative stress. These ROS are generated by the activated neutrophils and macrophages, and can be assessed by examining the amount of 8-hydroxy-20-deoxyguanosine (8-OHdG) in blood or malondialdehyde (MDA) in colonic biopsies, which are well-established biomarker for oxidative damage. These various factors are interlinked and functions in a viscous cycle, which contributes to the progression of disease leading to uncontrolled inflammation (Goyal et al., 2014). Various pathways involve in the pathogenesis of IBD as shown in Fig. 19.1.

4 ANIMAL MODELS OF INFLAMMATORY BOWEL DISEASES

Over the past 2–3 decades, several animal models of IBD have been developed which helped out in identification of novel drug targets and drug treatments, as well as helped to clarify a mechanism for abortive and prophylactic drugs. These animal models have provided translational knowledge and a framework to think about the impact of hormones, genes, and various environmental factors like sound, light, and so forth, on IBD pathophysiology. Although most of researchers have suggested that these animal models have lot of shortcomings but still some promising new drugs have been developed by utilization of these preclinical models. IBD has recently become of one of major interest to researchers. Various models for studying IBD mechanisms have been developed and exploited efficiently, leading to better understanding of the pathophysiology of the disorder. Since the exact etiology of IBD is not known yet, a number of animal models have been developed over past decades to study the possible mechanism involved in pathogenesis of disease and new therapeutic targets. The different types of animal models are developed for the study of IBD, which are discussed here, emphasizing on their clinical and histological features showing relevance to human IBD (Fig. 19.2).

4.1 Chemically Induced Model

4.1.1 Dinitrobenzene Sulfonic Acid

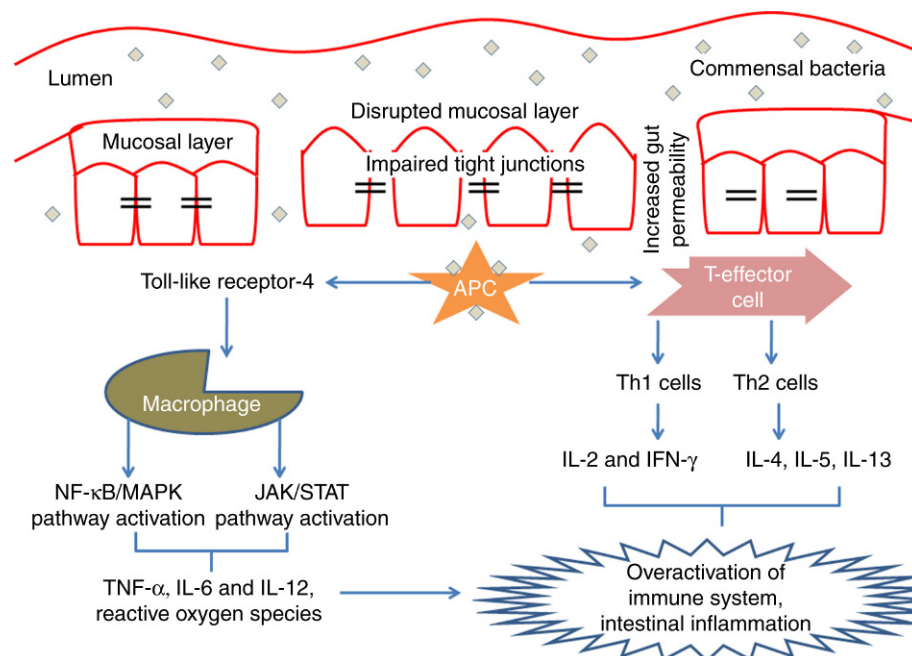
Dinitrobenzene sulfonic acid (DNBS) is a hapten, which induces the colonic inflammation and features of colitis. DNBS consist of additional active nitro group and binds more readily at lower concentrations. DNBS binds to the e-amino group of lysine is more selectively


FIGURE 19.1   **Various pathways involved in the pathophysiology of inflammatory bowel disease.** *APC*, Antigen-presenting cell; *JAK/STAT*, Janus kinase/signal transducers and activators of transcription; *IFN-γ*, interferon-gamma; *IL-2*, interleukin-2; *IL-4*, interleukin-4; *IL-5*, interleukin-5; *IL-6*, interleukin-6; *IL-12*, interleukin-12; *IL-13*, interleukin-13; *NF-κB*, nuclear factor-kappa B; *Th1*, T-helper cells type 1; *Th2*, T-helper cells type 2.
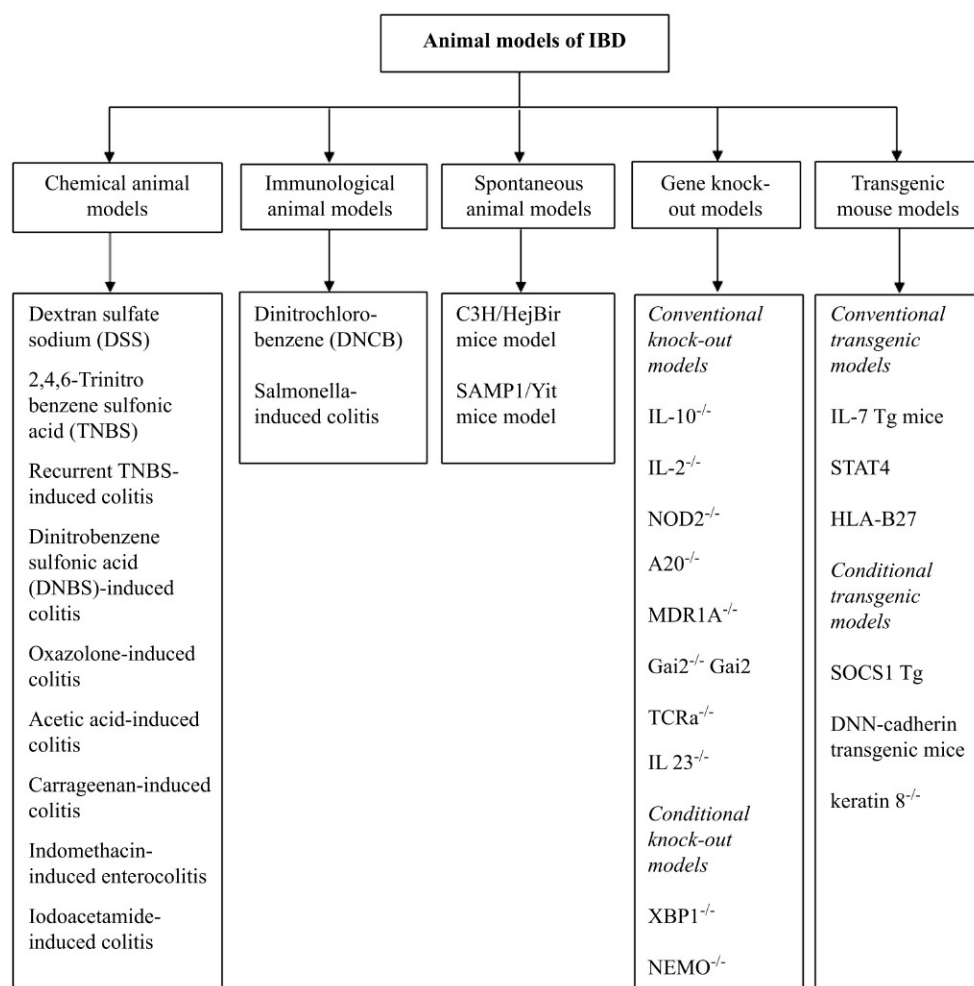

FIGURE 19.2   **Classification of animal models of inflammatory bowel disease.**

and used to induce colonic inflammation. The clinical features of colitis are presented in this model with bloody diarrhea and significant loss of body weight. DNBS administration (intrarectally) results in decreased food intake, increased colon weight, and changed stool consistency. DNBS causes overproduction of nitric oxide (NO) due to induction of inducible nitric oxide synthase (iNOS) and contribute to inflammatory processes. This model features transmural necrosis along with extensive morphological disorientation, edema, and immune cell infiltration in the submucosa of colon section.

4.1.1.1 PROCEDURE

Animals are on fasting overnight and on next day fasted rats are lightly anesthetized with ether. DNBS (3 mg in 100 mL of 50% ethanol) is administered to lightly anesthetized mice by an intrarectal injection with the help of a polyethylene catheter. Thereafter, animals were kept in trendelenburg position for 15 min to avoid reflux.

4.1.1.2 CLINICAL FEATURES

Decreased food intake, body weight, increased colon weight, and changed stool consistency are the common symptoms.

4.1.1.3 MOLECULAR CHANGES

- Overproduction of NO due to induction of iNOS
- Significant increase in myeloperoxidase (MPO) activity
- Elevated levels of MDA and decreased levels of SOD and GSH

4.1.1.4 HISTOLOGICAL FEATURES

- Transmural necrosis along with extensive morphological disorientation, edema and a diffuse leukocyte cellular infiltrate, as well as lymphocyte in the submucosa of colon section (Joshi et al., 2011)

4.1.2 Dextran Sulfate Sodium

Dextran sulfate sodium (DSS) is a synthetic sulfated polysaccharide composed of dextran and sulfated anhydroglucose unit and has highly water solubility. The colitogenic potential of DSS depends on its molecular weight. In general laboratory practice, a molecular weight of 36–50 kDa is used for inducing colitis. The low molecular weight DSS (5 kDa) results in milder colitis while higher weight DSS (500 kDa) does not cause colonic injury. DSS has high negative charge due to presence of sulfate group and is toxic to colonic epithelia and induces erosions that ultimately compromise barrier integrity resulting in increased colonic epithelial permeability. The anticoagulant property also aggravates intestinal bleeding. The mechanism by which DSS entry into mucosa remains unclear, but it has been suggested

that DSS forms nanolipocomplexes with medium-chain-length fatty acids in the colon.

4.1.2.1 PROCEDURE

DSS is commonly administered in a dose range of 3%–10% for 7–10 days to induce an acute inflammation depending on the type of the species used (Balb/c mice are more susceptible) or the molecular weight of DSS. For chronic colitis, DSS can be administered in three to five cycles with a 1- to 2-week rest between cycles (Mitrovic et al., 2010).

4.1.2.2 CLINICAL FEATURES

Weight loss, diarrhea and occult blood in stools, piloerection, anemia, and eventually death whereas in chronic phase of colitis usually do not reflect severity of inflammation or histological features found in large bowel

4.1.2.3 MOLECULAR CHANGES

1. Upregulation of cytokines, chemokines, NO, and iNOS levels
2. Increased activation of NF-κB
3. Increased expression of inflammatory cytokines genes (IL-1, TNF-α, IL-6, and IL-8), and some adhesion molecules genes [endothelial leukocyte adhesion molecule-1 (ELAM-1) and ICAM-1]

4.1.2.4 HISTOLOGICAL FEATURE

- Mucin depletion, epithelial degeneration, and necrosis leading to disappearance of epithelial cells which further leads to the formation of cryptitis and crypt abscesses.
- Chronic phase includes mononuclear leukocytes infiltration, crypt architectural disarray, increasing the distance (widening of the gap) between crypt bases and muscularis mucosa, deep mucosal lymphocytosis, and transmural inflammation.
- Increased apoptosis and decreased proliferation of epithelium that takes place in the acute phase of DSS further causing relevant leaks in the epithelial barrier.

4.1.3 2,4,6-Trinitrobenzene Sulfonic Acid

2,4,6-Trinitrobenzene sulfonic acid (TNBS) is a hapten, which when binds to tissue protein turns into an antigen and elicits number of immunologic responses. TNBS-induced colitis is a delayed-type hypersensitivity reaction to haptenized proteins, whereas DSS colitis is the result of a disruption in epithelial barrier. The major inflammatory mediators involved in this TNBS-induced colitis are leukotriene B4 (LTB4) and the monhydroxyl fatty acids 5-HETE, 12-HETE and 15-HETE. Ethanol is used in high concentration as a vehicle for the TNBS administration. Ethanol acts as a mucosal barrier breaker so

that TNBS can enter the mucosa to induce colitis where it binds to the amino group of lysine and modify cell surface proteins.

4.1.3.1 PROCEDURE

TNBS is administered using a trocar needle along with rubber catheter via the anus. TNBS is used in dose range of 0.5–4.0 mg in 45%–50% ethanol intrarectally. The dose varies between different mouse strains, such as SJL and BALB/c mice are highly susceptible, whereas C57Bl/6 and 10 mice are resistant (Kawada et al., 2007).

4.1.3.2 CLINICAL FEATURES

This model showed features, such as progressive weight loss, bloody diarrhea, rectal prolaspe, and large bowel wall thickening.

4.1.3.3 MOLECULAR CHANGES

- Increased level of various inflammatory mediators, such as prostaglandin E_2, thromboxane B_2, leukotriene B_4, 6-keto-prostaglandin F_{1a}, leukotriene C_4
- Increased colonic MPO activity and level of PAF

4.1.3.4 HISTOLOGICAL EXAMINATIONS

- Severe and intense transmural inflammation and/or necrosis, inflammatory granulomas, and submucosal neutrophils infiltration in mucosal and submucosal layers
- Cryptitis and architectural distortion are seen in endoscopic biopsies

4.1.3.5 ADVANTAGES AND DISADVANTAGES

This model has many advantages, which include (1) simple protocol, (2) reproducible colonic injury, (3) short length of the experiment, and (4) chronic damage accompanied by inflammatory cell infiltration and ulcers as seen clinically.

This model also suffers from some disadvantages like the absence of spontaneous relapse, which is the hallmark of human IBD. Also, ethanol itself causes severe inflammation in the intestinal mucosa, which makes it difficult to distinguish between the ethanol-induced inflammation and hapten-induced inflammation.

4.1.4 Recurrent TNBS-Induced Colitis

In this model, colitis is induced by repeated intrarectal administration of TNBS leading to the development of chronic intestinal inflammation. The inflamed colon shows increased weight and increased thickness, especially in the distal part. Histopathologically, it is associated with increased inflammatory cellular infiltration, which consists of $CD4^+$ and $CD8^+$ T cells, macrophages, granulocytes and mast cells, irregular crypts, and loss of Goblet cells (Goyal et al., 2014).

4.1.5 Oxazolone

Oxazolone when administered intrarectally with ethanol induces Th2-mediated acute colitis. Unlike TNBS-induced colitis, this model resembles only UC and is limited to the distal part of the colon only. Oxazolone-induced colitis has been suggested to be dependent on the presence of IL-13 producing invariant NK-T cells.

4.1.5.1 PROCEDURE

Colitis can be induced by applying 1% oxazolone (100 mL) dissolved in a mixture of four parts acetone and one part olive oil to the shaved abdominal skin of male C57BL/6CrSlc mice under pentobarbital anesthesia. Then, 1 week later, 100 mL of 50% ethanol solution with 1% oxazolone is administered intra rectally under pentobarbital and atropine anesthesia. Recently, oxazolone-induced colitis is used as a chronic model in Balb/c mice via repeated intrarectal administration of oxazolone in ethanol (Goyal et al., 2014).

4.1.5.2 CLINICAL FEATURES

The clinical manifestations of this model are weight loss, thin stool with pus and blood, bowel wall thickening, erosion, edema, and small patches of ulcer on colon.

4.1.5.3 MOLECULAR CHANGES

- Increased production of IL-4 and IL-5
- Rapid increase in the production of IL-13 in the lamina propria and the appearance of NK-T cells, both of which are immunologic features of acute oxazolone-induced colitis

4.1.5.4 HISTOLOGICAL FEATURES

- Neutrophil infiltration, fibrin deposition, submucosal neutrophil migration, submucosal edema, epithelial necrosis, and epithelial ulceration with loss of epithelial villi in the colon section
- Increase in MPO activity and decrease in number of goblet cells (Patel et al., 2012)

4.1.6 Acetic Acid

Acetic acid induces acute inflammation confined to the colon and produces characteristic features of UC. The colonic injury depends on the concentrations and length of exposure of acetic acid and is related to the necrosis and edema in epithelial cells mainly confined to the gastric mucosal layers. Mucosa and submucosal inflammation in this model is associated with activation of NF-κB and other inflammatory mediators. The transient local ischemia might contribute to the acute injury in this model.

4.1.6.1 PROCEDURE

Colitis is induced by intrarectal administration of 0.5 mL of 10%–50% acetic acid diluted with water in male Wistar rats. After 10 s of surface contact, the

acidic solution was withdrawn, and the lumen is flushed 3 times with 0.5 mL saline (Low et al., 2013).

Recently, this method is modified in which 1.5 mL of 4% acetic acid (pH 2.3) was slowly infused 8 cm into the colon through anus with a rubber cannula of a lightly anesthetized rat. After a 30-s exposure, excess fluid was withdrawn, and the colon was flushed with 1.5 mL PBS (Sotnikova et al., 2013).

Moreover, number of modifications has been made and now most of study used intrarectal administration of 2 mL of 4% acetic acid solution with the help of 2.7-mm soft pediatric catheter under light ether anesthesia. Animal is to be held horizontally for 2 min to avoid AA solution leakage because higher concentrations induced frequent perforations.

4.1.6.2 CLINICAL FEATURES

Weight loss, decreased mucous production, and increased colonic weight are the common manifestations of this model. Extensive hemorrhage, occasional ulceration, and bowel wall thickening were also observed in some studies.

4.1.6.3 MOLECULAR CHANGES

- Massive intracellular acidification resulting in massive epithelial damage
- Influx of acute inflammatory cells

4.1.6.4 HISTOLOGICAL FEATURES

- Eroded mucosa with ulceration and necrosis
- Edema, goblet cell depletion, lymphoid follicular hyperplasia, and heavy infiltration of inflammatory cells

4.1.6.5 ADVANTAGES AND DISADVANTAGES

The advantages of acetic acid-induced colitis are its low cost and the ease of administration.

The disadvantage of this model is that the epithelial injury observed within the first 24 h of acetic acid induction is not immunologic in nature. Thus, designing drugs that target immune responses should be tested at a time point after 24 h postinduction.

4.1.7 Carrageenan

Carrageenan is a proinflammatory agent and high molecular weight sulfated polygalactan, derived from several species of red seaweeds (Rhodophyceae), including *Gigartina*, *Chondrus*, and *Eucheuma*. Carrageenan triggers innate immune pathways of inflammation that resembles UC in which TLR-4 and BCL10 play critical role (Bhattacharyya et al., 2011).

4.1.7.1 PROCEDURE

The administration of 10% carrageen for 10 days in the drinking water of CF1 mice induces colitis exhibiting similar macro- and microscopic features as seen in UC.

4.1.7.2 CLINICAL FEATURES

Bloody diarrhea, colon length shortening, and pericryptal inflammation, with marked dilatation of the cecum and ascending colon, are the clinical features observed in this model (Tran et al., 2012).

4.1.7.3 MOLECULAR CHANGES

- Activation of NF-κB in the intestinal cells following carrageenan exposure
- Increase in Bcl-10 and TLR-4

4.1.7.4 HISTOLOGICAL FEATURES

- Mucosal ulceration with distorted crypt architecture, inflammatory infiltration of the lamina propria and hyperplastic epithelium, conditions are more pronounced in the proximal colon but also present in the distal colon.

4.1.8 Indomethacin-Induced Enterocolitis

Indomethacin is NSAID and induces small intestinal and colonic ulceration in a dose-dependent manner in rodents. Although small bowel ulceration and transmural inflammation have some similarity to CD, the chronic ulcerations are located in the mid-small intestine rather than the ileum. It involves small and large intestines and is associated with extraintestinal lesions (Stadnicki and Colman 2003).

4.1.8.1 PROCEDURE

Indomethacin is subcutaneously administered at dose of 7.5 mg/kg solubilized in 100% alcohol to fasted male Wistar rats, resulting in an acute inflammation. This acute response reaches its maximum intensity at 24 h and reversed within 7 days, whereas two daily subcutaneous injections of indomethacin induce a chronic inflammation that lasts for at least 2 weeks.

4.1.8.2 CLINICAL FEATURES

Acute intestinal inflammation, characterized by a thickening of the bowel wall, mesenteric hemorrhage, mesentery adhesion, and multiple mucosal ulcers of small intestine and colon.

4.1.8.3 MOLECULAR CHANGES

- Synthesis inhibition of the protective prostaglandins PGE1, PGE2, and prostacyclin
- Luminal bacteria and bacterial products contribute to the exacerbation and perpetuation of the chronic phase of indomethacin-induced inflammation

4.1.8.4 HISTOLOGICAL FEATURES

- Lymphoid hyperplasia, neutrophilic infiltration, crypt damage, and submucosal inflammation

4.1.9 Iodoacetamide

Iodoacetamide is a blocker of enzymes that contain SH-group (sulfhydryl) in the colon area. GSH contains SH-group and plays an important role in the protection of gastric mucosa; blockade of GSH by the iodoacetamide induces UC and produces injury to the mucosa by decreasing the amount of defensive SH compounds (Jurjus et al., 2004).

4.1.9.1 PROCEDURE

Single dose intrarectal (7 cm from anus) administration of 0.1 mL of 6% iodoacetamide dissolved in 1% methylcellulose via a rubber catheter induces reproducible colonic lesions in female Sprague Dawley rats after 1–2 h, leading to erosions and ulcers formation at 6–12 h. This is followed by extensive acute and chronic inflammation on 7–14 days.

4.1.9.2 CLINICAL FEATURES

The different clinical alterations in this model include diarrhea, dilatation, adhesion, mucosal damage, increased colon wet weight, and inhibition of body weight gain.

4.1.9.3 HISTOLOGICAL EXAMINATION

- Deep mucosal and submucosal ulcerations associated with an inflammatory infiltrate consisting mainly of lymphocytes and macrophages

4.2 Immunologic Model of Colitis

4.2.1 Dinitrochlorobenzene

Dinitrochlorobenzene (DNCB) is a hapten and is capable of inducing a cell-mediated (T-lymphocyte dependent) immune response with significant elevation in levels of CD4$^+$ and CD29$^+$ cells. First, animals are made sensitive to DNCB by placing it on their skin. Then, reapplication of DNCB induces an immune response at the same site.

Clinical and histological features of DNCB:
- crypt abscesses, superficial mucosal ulcerations, and depletion of mucus in the cells lining the crypts;
- edema in mucosa and submucosa, and infiltration of the lamina propria with plasma cells, lymphocytes and polymorphonuclear leukocytes, including eosinophils.

However, due to self-limited course of 2 weeks of DNCB, it is too short to be utilized as an ideal model for UC. To overcome these shortcomings, a new chronic UC model was established, that is, by using DNCB and AA in combination because of the following advantages: (1) like human UC, it manifests mucus in stools, bloody diarrhea, and weight loss; (2) it reflects the pathologic characteristics of UC, such as continuous superficial colonic inflammation. Microscopically, there exist mucosal edema and congestion, infiltration of lymphocytes, plasma cells and polymorphonuclear cells, crypt abscesses and ulceration; (3) also, it is an immune response model; immunology is well studied in UC (Goyal et al., 2014).

4.2.2 Bacterial Induction of Colitis (Salmonella-Induced Colitis)

The Gram-negative *Salmonella typhimurium* and *Salmonella dublin* are bacterial pathogens that can cause systemic infection and intestinal inflammation. The inflammation is very similar to human UC, including epithelial crypt loss, erosion, and neutrophilic infiltration. The colitis is induced by these pathogenic microbes usually after 5–7 days of systemic infection in C57BL/6 mice. Therefore, it is apparent that *S. typhimurium* infection is a important tool to study the acute phase of colitis (Low et al., 2013).

4.3 Spontaneous Model

Spontaneous models are one of the most effective, efficient, and attractive animal model systems for studying pathogenesis of IBD because they develop similar clinical features to human disease, intestinal inflammation without any apparent exogenous manipulations. Spontaneous models are broadly classified into two subcategories: (1) animals that spontaneously develop intestinal inflammation and (2) models in which a gene knockout results in an inappropriate mucosal immune response. For example, C3H/HeJBir murine model of colitis is characterized by spontaneous and chronic focal inflammation localized to the right colon and cecal region.

4.3.1 C3H/HejBir Mice Model

C3H/HejBir mice are produced by selective breeding of C3H/Hej mice with colitis known to develop ulcers and colitis. The intestinal inflammation in this model is limited to ileum and the right side of the colon and occurs spontaneously at age of 1 month of life and then completely disappears after 1 year of age. This model is also used in combination with other inducible colitis models and has proven to be effective tool for studying and identifying genetic factors underlying pathophysiology of IBD (Jurjus et al., 2004).

4.3.1.1 HISTOLOGICAL CHANGES

- Crypt abscesses and regeneration of epithelium
- Thickening of the intestinal wall and granulomas is not observed

4.3.1.2 MOLECULAR CHANGES

- Increased levels of IFN-c and IL-2 in the lamina propria lymphocyte, which shows that colitis in this model is a Th type-1 response, and thus represents CD.

4.3.2 SAMP1/Yit Mice Model

This model system develops spontaneously and presents itself as one of best is experimental system to study disease mechanisms of CD. It is characterized by severe inflammation in the last part of ileum, the primary location of CD lesions. The mucosal injury in this model system is characterized by presence by transmural inflammation, granuloma formation, and alterations in epithelial morphology. Increased epithelial permeability precedes the onset of inflammation, and epithelial cell dysfunction is primarily responsible for the disease progression. Ileitis develops at 10 weeks of age and the incidence of skin lesions inversely correlated with the occurrence of intestinal inflammation (Rivera-Nieves et al., 2003).

4.4 Conventional Gene Knockout Models

4.4.1 IL-10[−/−]

IL-10 are proinflammatory cytokine and play important role in the pathophysiology of IBD. IL-10-deficient mice spontaneously develop a transmural pancolitis and cecal inflammation at the age of 2–4 months and symptoms completely resembles CD in humans. The inflammation is confined the whole intestine, mainly in the duodenum, proximal jejunum, and ascending colon (Modi, 2012).

4.4.2 TGF-β[−/−]

TGF-$\beta^{-/-}$ is mainly produced by number macrophages and develops multiorgan dysfunction due to macrophage hyperactivation and reduced regulatory T cell activity, including severe colitis. These mice die within 4–5 weeks. The exact role of TGF-β in the intestine remains unclear, but it has been suggested to increase the production and release of IL-10 and downregulates the receptor expression of IL-12 (Boismenu and Chen, 2000).

4.4.3 IL-2[−/−]

IL-2 is a four-bundled a-helical regulatory cytokine mainly produced by activated T lymphocytes, and its synthesis is highly regulated at the mRNA level by signals from the TCR and CD28[+]. The small intestine of IL-2$^{-/-}$ mice remains intact, whereas the colon (from rectum to cecum) was severely affected with ulcers and wall thickening (Modi, 2012). Mice deficient in the cytokine IL-2 develop a chronic inflammation of the colonic mucosa/submucosa at 8–9 weeks of age that resembles UC.

4.4.4 NOD2[−/−]

Nucleotide-binding oligomerization domain 2 (NOD2) that is also known as caspase recruitment domain-containing protein 15 (CARD15) has been shown to be expressed in myeloid cell line, including macrophages, monocytes, Paneth cells, and dendritic cells, and is induced by the proinflammatory cytokines, such as TNF-α and IFN-γ, exhibiting features of CD. Mutations of NOD2 result in an alteration in the ability of NOD2 to activate NF-kB (Rosenstiel et al., 2003).

4.4.5 A20[−/−]

A20 is an ubiquitin-modifying enzyme in mice induced by TNF R, IL-1 R, and even NOD2. A20 is an inducible and broadly expressed cytoplasmic protein that inhibits TNF-induced NF-κB activity. A20-deficient mice develop spontaneous inflammation, cachexia, and premature death due to failure of A20 deficient cells to terminate TNF-α induced NF-κB responses. Thus, mice deficient in A20 develop spontaneous colitis indicating that NOD2 signaling alone is not sufficient to cause colitis (Hammer et al., 2011).

4.4.6 MDR1A[−/−]

MDR1A gene is an ATP-binding transporter limited to intestinal epithelial cells and mucosal lymphocytes. Knockout of this gene induces a severe spontaneous colitis via Th1-type inflammation. MDR1A$^{-/-}$ knockout mice are devoid of the proper ability to dispose off the bacterial breakdown products in epithelial cells which increases abnormal antigen presentation to T cells, leads to a marked T cell activation and inflammation. Histology includes pancolitis with enlarged crypts, immune cell infiltration, crypt abscesses, and ulceration similar to the pathology of UC in humans (Wilk et al., 2005).

4.4.7 Gai2[−/−]

Gai2 protein is a member of signal transduction molecules mainly expressed in intestinal epithelial cells, myofibroblasts, and intestinal T and B lymphocytes. Knockout of Gai2 in mice results in a development of spontaneous colitis at 8–12 weeks of age. Gai2-deficient colitis resembles UC, with the most severe inflammation occurring in the distal colon. The clinical and histopathological features include colonic thickening, lymphocyte and neutrophilic infiltrations, crypt and goblet loss, and crypt abscesses (Goyal et al., 2014).

4.4.8 TCRa[−/−]

T-cell receptor a (TCRa) chain knockout mice spontaneously developed chronic colitis, mediated by Th2-type immune response. It closely resembles the human UC with an inflammatory pattern restricted mainly confined to the colonic mucosa. TCRa$^{-/-}$ mice develop colitis at the age of 12–16 weeks of age. It is characterized with soft stools, associated with loss of goblet cells, and a mixed cellular infiltration mainly consisting of lymphocytes and neutrophils (Nagatani et al., 2012).

4.4.9 IL 23⁻/⁻

IL-23 belongs to IL-12 family of heterodimeric cytokines and is specific to mucosal inflammation rather than systemic inflammation. IL-23 is an important cytokine required for the initiation, generation, and development of Th17 cytokines, such as IL-17 (Lees et al., 2011).

4.5 Conditional Knockout Models (Cell Type-Specific Gene Alteration)

4.5.1 XBP1⁻/⁻

Xbp1 is a protein essential for the development of secretory cells, such as goblet and Paneth cells which are involved in mucus secretion in the gut. Deletion of this protein from small intestinal epithelium results in total loss of Paneth cells and reduced size and number of goblet cells, which make it susceptible to UC (Kaser et al., 2008).

4.5.2 NEMO⁻/⁻

NEMO (IKKc) is a regulatory unit of the IKK complex. NEMO⁻/⁻ model exhibits T cell-mediated immune response. Targeted deletion of this gene leads to the intestinal epithelial integrity. The characteristic histopathological features of this model are severe transmural pancolitis with enlargement of crypts, goblet cell ablation, and mononuclear cell infiltration into the mucosa, similar to that observed in IBD (Nenci et al., 2007).

4.6 Transgenic Mouse Models of Colitis

Unlike knockout mice, transgenic mouse models of colitis express one or more copies of the gene of interest resulting in over expression of that particular gene. However, similar to genetically engineered mice, the transgenic mice can be either conventional or cell-specific targeted conditional transgenic animals.

4.7 Conventional Transgenic Mouse Models

4.7.1 IL-7 Tg Mice

IL-7 is synthesized in intestinal epithelial cells and regulates the proliferation and differentiation of lymphocytes within the mucosal layers. IL-7 has been found to be upregulated in case of patients with UC. The overexpression of IL-7 in the colonic mucosa of IL-7 transgenic mice is associated with chronic colitis caused by infiltration of CD4⁺ T cells with overexpression of IL-7 mRNA. An IL-7 Tg mouse model is valuable tool to understand T cell-mediated pathogenesis of colitis for therapeutic interventions targeting mainly T cell functions. Therefore, this is a chronic colitis model that closely resembles human UC (Watanabe et al., 1998).

4.7.2 STAT4

STAT4 is an important transcription factor involved in the development and regulation of Th1 cells that regulates the IL-12 pathway, which in turn is responsible for the regulation of Th1 cytokines, such as the proinflammatory interferon gamma (IFN-γ). STAT4 transgenic mice develop weight loss, diarrhea, and severe colitis resembling human CD.

4.7.3 HLA-B27

Human MHC class I allele HLA-B27 overexpression in both mice and rats results in intestinal inflammation. Rats transgenic for human HLA-B27 develops a spontaneous IBD which affects the stomach, ileum, and in particular the entire colon. Crypt hyperplasia and mucosal infiltration of mostly mononuclear inflammatory cells are characteristic features of the disease. This model has been used extensively to study the effect of resident intestinal bacteria for acute and chronic stages of gastrointestinal inflammation (Rath et al., 1999).

4.8 Conditional (Cell-Specific) Transgenic Mouse Models

4.8.1 SOCS1 Tg Mice

Transgenic (Tg) mouse models of intestinal significance with cell-specific deletions include T cell-specific SOCS1 Tg in which CTLA-4 mediated control of T cell proliferation resulted in spontaneous colitis (Inagaki-Ohara et al., 2006).

4.8.2 DNN-Cadherin Transgenic Mice/Keratin 8⁻/⁻ Mice

Keratin 8 is one of the major intermediate filament proteins present in intestinal enterocytes of patients with IBD. So, mice deficient for Keratin 8 develop colonic hyperplasia and colitis due to a primary epithelial rather than immune cell defect. This model provides direct evidence for the importance of an intact epithelial barrier for mucosal homeostasis, expressing a dominant negative mutation of the cell adhesion molecule N-cadherin in intestinal epithelial cells along the crypt villus axis (Owens et al., 2004).

5 CONCLUSIONS

IBD is a chronic inflammatory disorder of unknown etiology and characterized by chronic intestinal mucosal inflammation. Different drugs are available to treat IBD but need for novel effective therapy is insistent. Different animal models described in this chapter can be used to explore the pathophysiology of IBD and to test novel drugs. Every model described reflects some particular

pathological features of the IBD like chronic inflammation, mucosal layer disruption, increased gut permeability, and immune system overactivation. A specific model can be picked to induce the disease on the basis of expected mechanism of action of new drug.

OUTLINE

1 INTRODUCTION

The drug development paradigm postulates that treatments are tested for safety and efficacy in animal disease models, and then carried through to clinical trial. Results from the clinical trial then generate hypotheses, which are used to guide and inform subsequent animal testing. The reality for stroke medicine is quite different.

Clinical evidence currently supports the use of five acute stroke therapies (Donnan et al., 2008): hemicraniectomy (Vahedi et al., 2007); aspirin (CAST, 1997; ISTC, 1997); specialist care in hospital stroke units (Langhorne et al., 1993, 1995; Seenan et al., 2007), and the reestablishment of blood flow to the ischemic brain using tissue plasminogen activator (tPA) (NIND, 1995; Hacke et al., 2004) or by mechanical clot removal (Goyal et al., 2016). Of these treatments, only tPA has a legacy in experimental medicine, and this has largely been grounded in the field of cardiology.

Critiques of the merits or otherwise of animal models of stroke have been made in a number of comprehensive, lucid and insightful essays (Alonso de Lecinana et al., 2001; Carmichael, 2005; Dirnagl, 2006; Dirnagl et al., 1999; Durukan and Tatlisumak, 2007; Fukuda and del Zoppo, 2003; Ginsberg and Busto, 1989; Green et al., 2003; Hainsworth and Markus, 2008; Hossmann, 1998; Hossmann and Traystman, 2008; Hunter et al., 1998; Karpiak et al., 1989; Small and Buchan, 2000; Traystman, 2003). We sought to extend this work by directly comparing animal models of cerebral ischemia with the clinical disease they purport to model. By explicitly contrasting animal models with the clinical manifestation of stroke, we hoped to bridge the gap between the experimental and the clinical, and to examine the contribution of animal models to the understanding and management of stroke.

To this end, we undertook a wide ranging and detailed systematic review and metaanalysis of studies reporting—in clinical trials or animal experiments—the effect of acute stroke treatments. The analysis was restricted to those studies reporting infarct size—the amount of brain damage following stroke—as an outcome measure (endpoint). Although clinical outcomes, such as death, disability, and quality of life are the most important measures in the appraisal of a patient's health, infarct size has several advantages as an outcome measure: it is relatively free from bias (NINDS, 2000), it is routinely used in animal research and has been used more frequently in clinical trials in recent years. Consequently, measures of brain damage are useful for translational medicine research and enable a quantitative comparison of two key parameters, the size of a stroke and the efficacy of a treatment. The flipside of the focus on the amount of brain damage rather than behavioral or neurological scales is that it is still largely used as a surrogate or secondary outcome measure in clinical trials, so the relevance of infarct size to patient outcomes has yet to be fully established, a factor which will be discussed in further detail later.

After reporting on the methods of systematic review and analysis used herein, the results of the review are presented commencing with the general characteristics of the animal experiments and clinical trials, including: reasons for exclusion; sample size, quality of experimental design and reporting, comorbidities and species tested. Following this, results relating to infarct size in human trials and animal experiments are presented, together with analyses of factors moderating infarct size. Factors considered included a comparison of the cause, location, timing, and treatment of stroke in animal models and in clinical trials. The analysis of clinical trials is very much biased toward the perspective of the animal experimental paradigm and the underlying pathophysiology of stroke.

2 SYSTEMATIC REVIEW AND METAANALYSIS METHOD

2.1 Definitions and Scope

Stroke is a heterogeneous group of cerebrovascular conditions caused by the interruption of blood supply to the brain, usually due to the blockage of a vessel by a clot or due to a burst blood vessel. The World Health Organization defined stroke as "rapidly developing clinical signs of focal (or global) disturbance of cerebral function lasting more than 24 h (unless interrupted by surgery or death) with no apparent cause other than a vascular origin" (WHO-MONICA, 1988). While this definition is commonly acknowledged, it is not without controversy (Saver, 2008) as it excludes shorter ischemic episodes (transient ischemic attacks), subarachnoid hemorrhages, and the diagnosis of stroke using modern imaging methods.

Stroke is typically accompanied by impairment in movement, sensation, or cognition as measured against various clinical and neurological scales. The amount of brain damage caused by the stroke may also be quantified with brain imaging or after death (histologically) as the volume of infarction. For smaller mammals, brain damage is usually in the order of 10s–100s mm^3, while in humans it is typically in the order of 10s–100s cm^3.

The term neuroprotection is used to denote the average percentage reduction in infarct size in the treatment group compared to the control group. A negative level of neuroprotection would suggest that the treatment is damaging as it increases infarct size. The terms neuroprotection and efficacy are used interchangeably here, as are infarct size, stroke size, and infarct volume (unless

otherwise specified). Reperfusion refers to the reestablishment of perfusion to the ischemic area in the brain. Similarly, recanalization refers to the reestablishment of the patency of the blood vessels. Comorbidities are other diseases, such as hypertension that a patient may have in conjunction with stroke.

The scope of this review is limited to controlled studies. A controlled animal experiment or clinical trial is one which measures the effect of a treatment by comparing the outcome in one cohort given the experimental treatment, to another cohort which does not receive the intervention, the control group. Selection was not limited to studies where subjects were randomly allocated to treatment groups; however, this was taken into account in the analysis and interpretation of results.

Animal experiments included in this review are restricted to those employing focal models of cerebral ischemia. Focal models purport to induce a circumscribed region of damage in the brain, as occurs when the middle cerebral artery (MCA) is occluded. Focal models are typically distinguished from global models of ischemia which induce a reduction of blood flow to the whole brain, such as via the occlusion of both common carotid and vertebral arteries Focal models of cerebral ischemia are believed to be more relevant to stroke than global models (Molinari, 1979), while global models may be more representative of cardiac arrest.

2.2 Search Strategy

2.2.1 Animal Search Strategy

Animal data was collected prior to the clinical data and was initially collected for the purpose of identifying potential neuroprotective agents (O'Collins et al., 2006). Drugs or treatments used in experimental stroke were identified by: (1) PubMed search for "neuroprotection"; (2) PubMed search for "cerebral ischemia" from 1960 to 1980 (to capture agents tested prior to the use of the keyword "neuroprotection"); (3) from the reference lists of articles identified by (1) and (2). For each drug identified, a separate PubMed search was undertaken using the criteria "(drug name) AND (cerebral ischemia OR stroke OR neuroprotection)." Where no results were found, the search was repeated using only the drug name as the search term.

Since the initial identification of animal experiments was performed prior to the search for clinical trials (date: December 2004), additional searches were again undertaken for the therapies also tested in acute stroke clinical trials. A PubMed search (date: December 2007) using the criteria "(drug name) AND (cerebral ischemia OR stroke OR neuroprotection)" was again carried out, and if no results were found, the search was repeated using only the drug name.

2.2.2 Clinical Search Strategy

Clinical data was collected using a top-down and bottom-up search strategy (search date: December 2007). The top-down strategy involved searching clinical trial databases for trials listing infarction or brain imaging as an endpoint. The databases searched included the Washington University Stroke Trials Registry (Goldberg, 2007), the Cochrane Controlled Trials Register (Cochrane, 2007), and the National Institute of Health Trials Database (NIH, 2007). Once candidate trials were identified, the original papers documenting the results were sought using the reference provided in the trial database or by searching PubMed or Web of Science under the trial or drug name.

The bottom-up search strategy involved a PubMed scan using the search terms: (1) [(infarct volume OR infarct size OR lesion volume OR lesion size) AND (randomized controlled trial OR randomized controlled trial) AND (human)]; (2) (acute stroke AND human) cross-referenced with the terms (imaging OR infarct volume) and (neuroprotection OR thrombolysis). An additional search was undertaken in the Cochrane Controlled Trials Register and Review databases using the search terms [(infarct volume AND acute stroke) OR (imaging AND acute stroke) OR (infarct volume AND randomized controlled trial AND human)].

2.3 Study Selection and Data Extraction

2.3.1 Animal Data

Controlled focal cerebral ischemia experiments measuring the effect of treatment on the infarct size, and reporting this effect as the mean and standard error or deviation, as well as the sample size for each group, were retained for further analysis. Gene-knockout technology was not deemed a "treatment" for the purpose of the analysis. Where available, the following type of information was extracted for each experiment: animal characteristics (species, strain, sex, age, comorbidities), stroke model (method of induction, vessels occluded, hemisphere damaged), intervention (mode of delivery, control condition), outcome (imaging/histology method, percentage/absolute measure of infarct), and study quality (randomization and blinded assessment of outcome).

2.3.2 Clinical Data

Controlled clinical trials reporting the effect of an acute stroke therapy infarct size were included. Data were extracted for the sample size, the average outcome, and the standard deviation or error in the control and treatment groups. In a subset of trials, the results were presented as medians and ranges, usually without reporting whether the data was normally distributed. The method of metaanalysis applied here assumes the use

of a normally distributed population, so the presence of median data raises a conundrum. The approach adopted here was based on the methods canvassed by Hozo et al. (2005): (1) exclude trials reporting data only as medians, (2) include trials with median data as reported, and (3) use an estimate of the mean and variance values. For estimates of overall effect size, all three methods were used to gain a better insight into how data reporting may affect outcome.

Estimates of the mean value derived from the median were calculated using formulas (1) and (2). Using sample data-sets with known median and mean values, these formulas yielded estimated means within 3%–4.5% of the true value. Interquartile range was substituted if the range was not available.

1   Mean = Median

$$+ \sqrt{(\text{Maximum} - \text{Median}) - (\text{Median} - \text{Minimum})} :$$
Positively skewed data

2   Mean = Median

$$- \sqrt{(\text{Median} - \text{Minimum}) - (\text{Maximum} - \text{Median})} :$$
Negatively skewed data

Where standard deviation or error data was not available it was estimated as one quarter of the range. For sample sizes of 15–70 (the typical size of clinical trial groups), Hozo reports that this formula for standard deviation is a good approximation to the variance (Hozo et al., 2005).

Where available, information about the following variables was also extracted: pretreatment infarct volumes, patient characteristics (age, sex, comorbidities), cause of stroke, location of stroke, reperfusion/recanalization (proportion of patients), treatment (treatment type, control condition), method of evaluation of outcome, and quality of study.

The quality of the clinical trials was calculated using a scale adapted from previous preclinical analyses (Macleod et al., 2005a). One point was assigned for each of the following criterion met by the trial: (1) publication in a peer reviewed journal; (2) inclusion of a conflict of interest statement; (3) testing in aged, hypertensive, or diabetic patients; (4) inclusion of an ethics statement; (5) measurement of temperature; (6) patients blinded to the treatment; (7) outcome assessed by a person blinded to the treatment group; (8) patients randomly assigned to different treatment groups; (9) sample size calculations performed before trial commencement, and (10) placebo or vehicle administered to the patients in the control group.

2.4 Data Analysis of Infarct Size and Treatment Effects

Metaanalysis is the statistical method for combining the results of different studies to obtain an overall measure of the effect of the treatment. Different weights are accorded to each study based on the sample size and the amount of variance in the outcome. Data were analyzed to yield two main parameters: (1) treatment efficacy (neuroprotection) and (2) infarct size. Stratified analyses were also conducted to investigate whether the characteristics of the subject, the study or the treatment had an effect on the level of therapeutic efficacy and the infarct size.

2.5 Metaanalysis of Treatment Effects

Within each study, the average size of the infarct in the control group was designated as equal to 100%. The average infarct volume in the treatment group and the standard deviations were then expressed as a percentage of the control infarct volume. The treatment effect size for each study was then estimated as the difference between control and treatment groups:

$$\% \text{ Treatment effect} = \frac{\text{Mean control infarct volume} - \text{Mean treatment infarct volume}}{\text{Mean control infarct volume}} \times 100$$

Across all studies, an overall estimate of treatment effect was calculated using the random effects metaanalysis method of DerSimonian and Laird (1986) as described in other publications (Macleod et al., 2004, 2005a,b). To account for median data, the analysis of clinical trials was repeated 3 times: first, with only those trials reporting the mean and standard deviation. second, using both the means and the medians as reported, and last, using the means and an estimated mean value derived from the median as described previously.

Studies were then partitioned into categories based on factors, such as the cause of stroke to determine whether the treatment differentially affected subjects in those categories. Since the number of clinical trials using infarct volume as an endpoint is small, stratified analyses were based on the full data-set including those results with means estimated from median values.

2.6 Infarct size

Reported results were also used to obtain the estimated infarct size or infarct volume in the untreated patients or animals. The mean infarct size across studies was weighted according to the number of subjects in the control group, adjusting for the number of treatment arms. To facilitate the comparison of strokes across species differing by up to three orders of magnitude in their brain size, mean infarct size was expressed as a percentage of brain volume. Where values were reported as an absolute volumetric level, they were converted to a

TABLE 20.1   Hemispheric Volumes Used to Convert Results from Absolute to Percentage Values

[a]Hemispheric volumes were taken as half the value of total brain volumes. Where edematous effects are large, this may underestimate hemispheric volume.

percentage of the hemisphere infarcted using the brain volumes given in Table 20.1. Where results were given only as areas, these values were taken into account in calculating the putative level of neuroprotection, but not in estimating the infarct size. Infarct size estimation was derived only from volumetric measurements. Partitioned analyses were also conducted to investigate the effects of subject characteristics, the stroke model or subtype, the intervention, and the outcome measurement on the infarct size.

2.7 Comparison of Human and Experimental Data

Results from the metaanalyses were then used to compare the human and the experimental findings. Regression analysis was used to evaluate the extent to which animal experimental results predicted clinical trial findings. The proportion of variance in clinical trial results predicted by the experimental results can be estimated using the adjusted R^2 statistic.

Cohen's Kappa was used measure of concordance between the results of the metaanalyses for each drug tested in animals and taken to clinical trial, and the results of each clinical outcome themselves ($N_T = 39$). In particular, Cohen's Kappa was used to measure the concordance between the direction (positive/negative) of efficacy for each drug in animal experiments and the direction prespecified hypothesis outcome in the clinical trial and the direction of the infarct size outcome in the treated versus control group. This measure takes into account agreement, which may occur due to random chance.

2.8 Effect of Pretreatment Infarct Size on Final Outcome

Those studies, which recorded pretreatment infarct size (in addition to final infarct outcome) were identified and selected for further analysis. Regression modeling was used to determine the extent to which pretreatment infarct size could predict the final infarct volume.

Unless otherwise stated, values are reported as means and standard errors. N_T refers to the number of animal experiments or clinical trials and N_P refers to the number of patients or animals. Mean is abbreviated to M, and standard deviation and standard error to SD and SE, respectively. CI denotes 95% confidence intervals.

3 RESULTS

3.1 Inclusions and Exclusions

Three-hundred and ninety-six acute stroke clinical trials were identified, 330 of which had been completed at the time of analysis. Although many trials ($N_T = 204$, 52%) reported using imaging as part of their inclusion/exclusion criteria or some other part of the protocol, only 13% ($N_T = 44$) of all completed trials used imaging parameters as an endpoint. In ongoing trials, the proportion was higher, with 21% ($N_T = 14$) of ongoing trials expecting to report infarct volume measures derived from brain imaging.

The top-down search of clinical trials databases was combined with a bottom-up search strategy of using prespecified criteria to yield a total of 177 clinical papers containing 188 controlled trials of experiential

TABLE 20.2   Included and Excluded Clinical Trials

Features	Clinical trials
CLINICAL TRIALS IDENTIFIED	
Number of trials	396
Ongoing trials	66
Completed	330
Number of trials with imaging as an inclusion/exclusion	204
Ongoing trials with imaging as an endpoint	14 (21% of all ongoing trials)
Completed/halted trials with imaging as an endpoint	44 (13% of completed trials)
CLINICAL TRIALS REVIEWED	
Number of clinical papers	177
Clinical trial controlled comparisons[a]	184
REASONS FOR EXCLUSION	
Review paper	17 (9%)
Not acute stroke	7 (4%)
No treatment	15 (8%)
No control group	29 (15%)
No separate analysis of treatment versus control groups	23 (9%)
No imaging outcome	22 (12%)
No infarct size measurement	34 (9%)
Unable to source paper	2 (1%)
CLINICAL TRIALS INCLUDED	
Number of clinical papers	30
Controlled trial comparisons[b]	35

[a]*A single paper sometimes contained a comparison between a control group and more than one treatment group, hence the number of papers is less than the number of comparisons.*
[b]*This value refers to 35 unique treatment-control group comparisons coming from 30 papers.*

treatments potentially relevant to the review. Of these, 155 trials were excluded for the reasons detailed in Table 20.2. Thus, 35 controlled comparisons from 30 papers met the criteria for inclusion in the meta-analysis (Table 20.3) (ASSI, 1994; RANTTAS, 1996; Berrouschot et al., 2000; Blanco et al., 2007; Clark et al., 2000, 2001; Emsley et al., 2005; Fiehler et al., 2002; Fogelholm et al., 2000; Hillis et al., 2003; Horstmann et al., 2003; Infeld et al., 1996, 1999; Loh et al., 2005; Martin et al., 1985; Molina et al., 2001; Obrig et al., 2000; Ogawa et al., 1999; Parsons et al., 2002; Roberts et al., 2002; Rother et al., 2002; Seitz et al., 2004, 2005; Selim et al., 2005; Shi et al., 2000; Thomalla et al., 2003; van der Worp et al., 2002; Warach et al., 2000, 2006; Wu et al., 2006; Yasaka et al., 1998).

Fourteen unique treatments were tested in these 35 trial comparisons, with a large proportion testing the efficacy of tPA (N_T = 14 trials and 16 comparisons). Several studies also reported results for a combination of treatment types.

The initial search for animal experiments identified 8516 results extracted from approximately 3500 papers (O'Collins et al., 2006). Of these, 3867 experimental results were conducted in the focal ischemia model. A follow-up search for testing in animal experiments of treatments identified as having been tested in clinical trial yielded an additional 110 experimental results. Studies were excluded if there was not sufficient information regarding means, variance, and sample size to warrant inclusion (N_T = 832). Included in the final analysis were a total of 3145 experimental results testing 492 different treatment types in animal models of focal cerebral ischemia published between 1978 and 2007.

3.2 Sample Size

One reason frequently given for the apparent failure of neuroprotection studies is that their small size leaves them without the statistical power to detect any real changes in outcome. On average, we found that clinical

study group sizes were 10 times larger than experimental groups. The 39 clinical trial comparisons of infarct volume included comparisons in 5532 patients, an average of 142 patients per clinical trial or $N_P = 71$ patients per treatment group. In contrast, the 3,145 experimental studies were undertaken on 45,476 animals, yielding an average of 14 animals per comparison or 7 animals per treatment group.

While sample sizes were larger in the clinical trials, so was the variance. In the 26 clinical trial results stating raw variance data as a standard deviation, the average standard deviation per trial equalled 99% in the control group and 105% in the treatment group (normalized with the mean control group infarct volume as 100%). In contrast, the animal studies showed an average standard deviation per experiment of 30% in the control group and 29% in the treatment group.

Overall, both animal and clinical studies tended to be underpowered. Estimates of sample size for a planned comparison of two independent means using a two-tailed test was undertaken using an online calculator (Brant, 2008) and in STATA v.10. To detect a 25% reduction in infarct volume in animals receiving treatment relative to animals in the control group and assuming a standard deviation of 30% of the control infarct volume (the average experimental variance reported previously), then the recommended sample size is 23 per group (powered at 80%, $\alpha = 0.05$, two-sided test). Based on these estimates, animal experiments were only 30% of the size needed to detect this level of difference. There is a prevailing dogma in animal research because animal experiments are controlled; there is less variance, so sample sizes can be small. Variance is indeed less than found in clinical trials, and sample sizes can be smaller, but not quite so small.

A similar calculation performed on the clinical data using a standard deviation of 99% yields a recommended sample size of 247 patients per treatment group (powered at 80%, $\alpha = 0.05$, two-sided test to detect a 25% difference in infarct size). Thus, on average, clinical trials were about only 28% of the size needed to detect a difference in infarct size. By clinical standards an effect size of 25% is large, so the degree to which clinical trials are underpowered would be much larger when trying to detect a smaller difference in independent groups.

The preceding analysis is of course just an estimate: Different animals, strains, models of stroke induction, and laboratories are associated with different degrees of variance, hence different required sample sizes. Similarly, using different types of analyses yields different estimates of group sizes, so smaller sample sizes may be required when looking at the effect of the treatments effect on the proportion of patients with expanding infarcts within each group (Phan et al., 2006), rather than comparing the treatment and control groups as two independent means (as is typically done in animal studies). Nevertheless, these rough estimates suggest both clinical trials and animal experiments were powered—or underpowered—to about the same extent.

3.3 Subject Characteristics

A frequent criticism of laboratory work is that animal studies are largely conducted in young, healthy male rats (Millikan, 1992). This criticism is supported by the findings of this review (Table 20.4): the vast majority of animal experiments were conducted in male animals ($N_T = 94\%$) while the clinical studies were undertaken in mixed sex patient groups ($N_T = 64\%$), or the sex was not specified ($N_T = 36\%$). Similarly, hypertension was the only risk factor for stroke that was represented in any sizable proportion of the animal experiments ($N_T = 14\%$), although still less than the prevalence in patients (66% of patients). Diabetes was underrepresented in animals (1.3% of animals vs. 26% of patients), and despite heart disease being major comorbidity in the clinical cohort (57% of patients), it was not modeled in animal experiments. Atherosclerotic animal models have been developed using modified genotypes or atherogenic diets (Moghadasian, 2002); however, these too are rarely used in neuroprotection research.

Animal experiments were almost exclusively conducted in the rat. Eighty percent of experiments employed rats ($N_T = 2506$), with 32% of all experiments ($N_T = 1016$) being undertaken in the Sprague Dawley strain. Previous meetings of the Stroke Therapy Academic and Industry Roundtable (STAIR) recommended that neuroprotection be explored in larger species, notably primates (STAIR, 1999). Only a handful of experiments in this data-set were conducted in primates ($N_T = 22$ experiments).

3.4 Study Quality

Clinical stroke medicine has been setting the pace for experimental stroke medicine in terms of its understanding of the need to maintain adequate standards of reporting results (Bath et al., 1998) and to minimize the potential for bias in experimental design through measures, such as blinding and randomization (Kidwell, 2001). While these issues are now more widely considered in animal experimentation (Fisher et al., 2009; Macleod et al., 2008), it was not surprising to find that clinical trial standards tend to surpass experimental standards, when assessed on the same scale.

The average quality score in the clinical trials was 6.2 points out of 10 (Table 20.5). Clinical quality was not related to the level of efficacy, as measured by a lower level of infarction in the treatment group ($r = 0.1$, $P > .05$, $N_T = 38$). Blinding of patients to treatment condition was

TABLE 20.4　Animal and Patient Comorbidities and Characteristics

undertaken in 50% of trials and in 84% of trials the outcome assessment was undertaken blind to the treatment condition. Sixty-three percent of trials randomized patients to treatment groups and in 16% temperature was monitored. The level of blinding and randomization in clinical trials was somewhat lower than that reported by Kidwell and coworkers (71% double-blinded and 93% randomized) (Kidwell, 2001), which may be due to the high proportion of thrombolytic reports in this data-set which were not yet complete at the time of Kidwell's analysis.

Study quality data was recorded in 80% of the animal experiment data. On average, about 38% of animal experimentation was randomized and in 32% the outcome was measured blind to the treatment group. These values are comparable to what has been found in earlier metaanalyses for individual drugs and are consistently below the levels of blinding and randomization for clinical trials (Table 20.5).

Over 10 years ago, quality in the design and implementation of animal studies was addressed by a consortium of researchers under the banner of the STAIR (STAIR, 1999). Since the initial STAIR recommendations were made, reporting standards have improved but there is still room for further gains. In the subset of animal experiments for which quality data was available, randomization was undertaken in 33% of studies published after STAIR (2000 onward) as opposed to 31% of studies published prior to STAIR, a 2% improvement. Blinded assessment of outcome has been raised from 34% pre-STAIR to 41% post-STAIR.

3.5 Infarct size

3.5.1 Background

Being a vascular disease, hemodynamic factors critically influence stroke size: blood pressure (Castillo et al., 2004), collateral flow (Toni et al., 1994), the

duration of occlusion (Arenillas et al., 2002), and the time to reperfusion (Molina et al., 2001) are all documented correlates or predictors of infarct development. Physiological factors, such as temperature (Leira et al., 2006; Reith et al., 1996), glycemic levels (Toni et al., 1994), and acidification (Smith et al., 1990; Wagner et al., 1992) have also been demonstrated to have a significant impact on infarct size.

Defining the volume of infarction is no trivial matter. Early computed tomography (CT) technology did not readily lend itself to infarct delineation, and the issue of what measure to use and where to threshold it remains open. Conventions in infarct measurement, analysis, and reporting also differ between the clinical and animal literature, hindering translational work. Clinical trial outcomes are often summarized using medians and ranges by virtue of having skewed data-sets and hence requiring different tests, such as the Wilcoxon rank sum test or Kruskal–Wallis test (Roberts et al., 2002). In contrast, animal findings are almost exclusively reported as a mean and standard deviation or error without regard to skewing of the data.

While clinical symptoms remain the gold standard in terms of patient assessment, imaging data is taking on a more prominent role in the management of the disease (Cramer et al., 2007; Selim et al., 2002). For instance, in order to minimize the risk of hemorrhagic transformation after thrombolytic therapy, imaging has been used to identify target patients with infarcts occupying less than one third of their MCA territory (Hacke et al., 1995; Pexman et al., 2001; Selim et al., 2002).

The size of a stroke is also of some importance in prognosis (Derex et al., 2004a). CT lesion volumes of less than 10 cm^3 have been associated with a favorable outcome (Saver et al., 1999), and clinical outcome has been shown to be better where diffusion weighted imaging (DWI) lesion size falls below 70 cm^3 (Sanak et al., 2006). DWI lesions larger than 89 cm^3 have been shown to predict early neurological deterioration (Arenillas et al., 2002). Similarly, CT lesions greater than 100 cm^3 have also predicted unfavorable outcomes (Saver et al., 1999). Malignant infarcts (massive hemispheric infarcts with a high mortality rate) were predicted by DWI volumes of greater than 145 cm^3 (Oppenheim et al., 2000), and patients with malignant infarcts occupying greater than 39% of the hemisphere are said to have little chance of responding to treatment (Carmichael, 2005) (Fig. 20.1).

3.5.2 Infarct Size in Different Species

The average infarct size in the control group of patients across all clinical trials included in this review was found to be 47.4 ± 28.3 cm^3, equivalent to 8.0% of one hemisphere (note, variance represents standard

Clinical outcome associated with infarct size

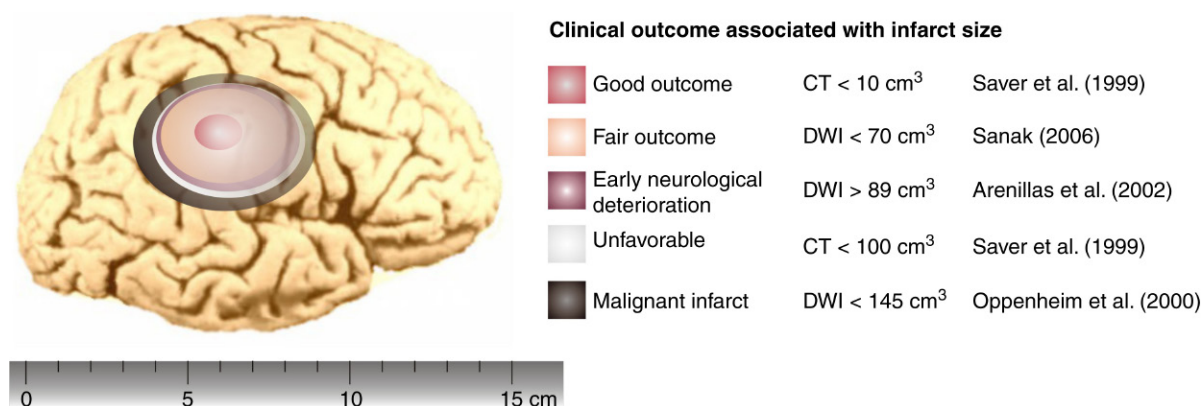
	Good outcome	CT < 10 cm^3	Saver et al. (1999)
	Fair outcome	DWI < 70 cm^3	Sanak (2006)
	Early neurological deterioration	DWI > 89 cm^3	Arenillas et al. (2002)
	Unfavorable	CT < 100 cm^3	Saver et al. (1999)
	Malignant infarct	DWI < 145 cm^3	Oppenheim et al. (2000)


FIGURE 20.1   **Infarct size and clinical outcome.** Note: infarct volumes are presented roughly to scale assuming they may be modeled as prolate spheroids.

deviation of mean outcomes). The mean stroke volumes from individual clinical trials ranged from 5.3 (0.9% of the hemisphere) to 124.8 cm^3 (21.1% of the hemisphere), with a median of 51.4 cm^3 (IQR: 34.0–70.0 cm^3, 5.7%–11.8% of the hemisphere). This is comparable with the findings of Brott et al. (1989) where infarct size averaged 55 cm^3 at 1 week using CT, though smaller than the volumes reported by Caviness et al. (2002) where infarct volumes ranged from 3.1 to 256 cm^3 with a mean of 103.3 cm^3.

The average infarct size in control animals across all studies was 30.7% ± 16.3% of the hemisphere (median: 29.6%, IQR: 19.0%–40.6%, note, variance represents standard deviation of mean outcomes). When the weighting is adjusted for the number of animals in the control group of each study and the number of treatment groups compared to the control, the mean size of animal stroke averaged 26.6% of the hemisphere. Relative to brain volume, the brain damage caused by animal strokes was on average about 4 times larger than for human strokes. While clinical cases have been reported with infarcts of up to 47% of the brain volume (Brott et al., 1989), strokes occupying most of the MCA territory in humans are a minority of about 7%–10% of all strokes (Caviness et al., 2002; Heinsius et al., 1998).

In the subset of studies which presented infarct size as an absolute volume rather than percentages, average stroke size ranged across species from 53.6 mm^3 in the mouse to 47.4 cm^3 in the human (Table 20.6). Within different rat strains, stroke size ranged from an average of 112.5 mm^3 in Long Evans rats to 197.6 mm^3 in Hooded Listar rats (Fig. 20.2). The pattern of differences shifted somewhat when looking at relative (percentage) stroke sizes, due to different brain volumes. Note, diabetic rats are not a strain as diabetes has been induced in a number of different strains but they are included for sake of comparison.
FIGURE 20.2   **Absolute infarct sizes in different rat strains or groups.** Consistent with the findings of Brint et al. (1988), stroke in the SHR rat was the tightest model in terms of having the lowest variance (average SD per experiment = 19%). In contrast to the results of Duverger and MacKenzie (1988), the Fisher produced the most variable infarct size models (average SD per experiment = 35%). Other rats tended to have experimental standard deviations averaging around 30%: Sprague Dawley (29%), Wistar (31%), Long Evans (27%), Lewis (30%), and diabetic (33%).

TABLE 20.6   Absolute Infarct Size in Control Cohorts

Primate	9	3,760 ± 1220
Human	35	47,366 ± 5,231

SHR, Spontaneous hypertensive rat.
[a]*Variance reflects average standard deviation per experiment.*

Relative infarct size across species ranged from an average of 4% to 28% of the hemisphere (Table 20.7 and Fig. 20.3A). (Note: estimates were derived from data reported as percentages of hemisphere infarct, together with absolute volume data converted to a percentage using brain volumes). Of all the animal models, the rat (28%) and cat (27%) gave the largest average stroke volume and the hamster (4%), gerbil (8%), and primate (9%) the smallest. Within the rat genus, the spontaneous hypertensive rat (SHR) had the largest volume of damage (35%). This was expected on the basis of strain comparison data from individual studies (Brint et al., 1988; Duverger and MacKenzie, 1988; Gratton et al., 1998). In contrast, Lewis rats had comparatively small strokes (17% of the hemisphere), while Fischer 344 rats (23%), Long Evans (26%), Sprague Dawley (26%), diabetic rats (27%), and Wistar rats (32%) had intermediate infarct volumes (Fig. 20.3B).

The greatest variability in infarct size was seen in the human population, where the average standard deviation per trial was 99% of the infarct volume in the control group (Table 20.7 and Fig. 20.4). Among the stroke models, the greatest variability in infarct size (average SD per experiment) was seen in the cat (48%), the guinea pig (52%), and the rabbit models (58%), perhaps owing to greater variability in collateral flow in the embolic and proximal MCA occlusion models typically used in the rabbit and cat, respectively. The least variable stroke was seen in the gerbil (20%), while mice and rats had an average experimental standard deviation of 24% and 29%, respectively.

Consistent with the findings of Brint (Brint et al., 1988), stroke in the SHR rat was the tightest model in terms of having the lowest variance (average SD per experiment = 20%). In contrast to the results of Duverger (Duverger and MacKenzie, 1988), the Fisher produced the most variable infarct size models (average SD per experiment = 35%). Other rats tended to have experimental standard deviations averaging around 30%: Sprague Dawley (29%), Wistar (32%), Long Evans (27%), Lewis (30%), and diabetic (33%).

3.5.3 Acute Stroke Treatment Effects and Reporting Standards

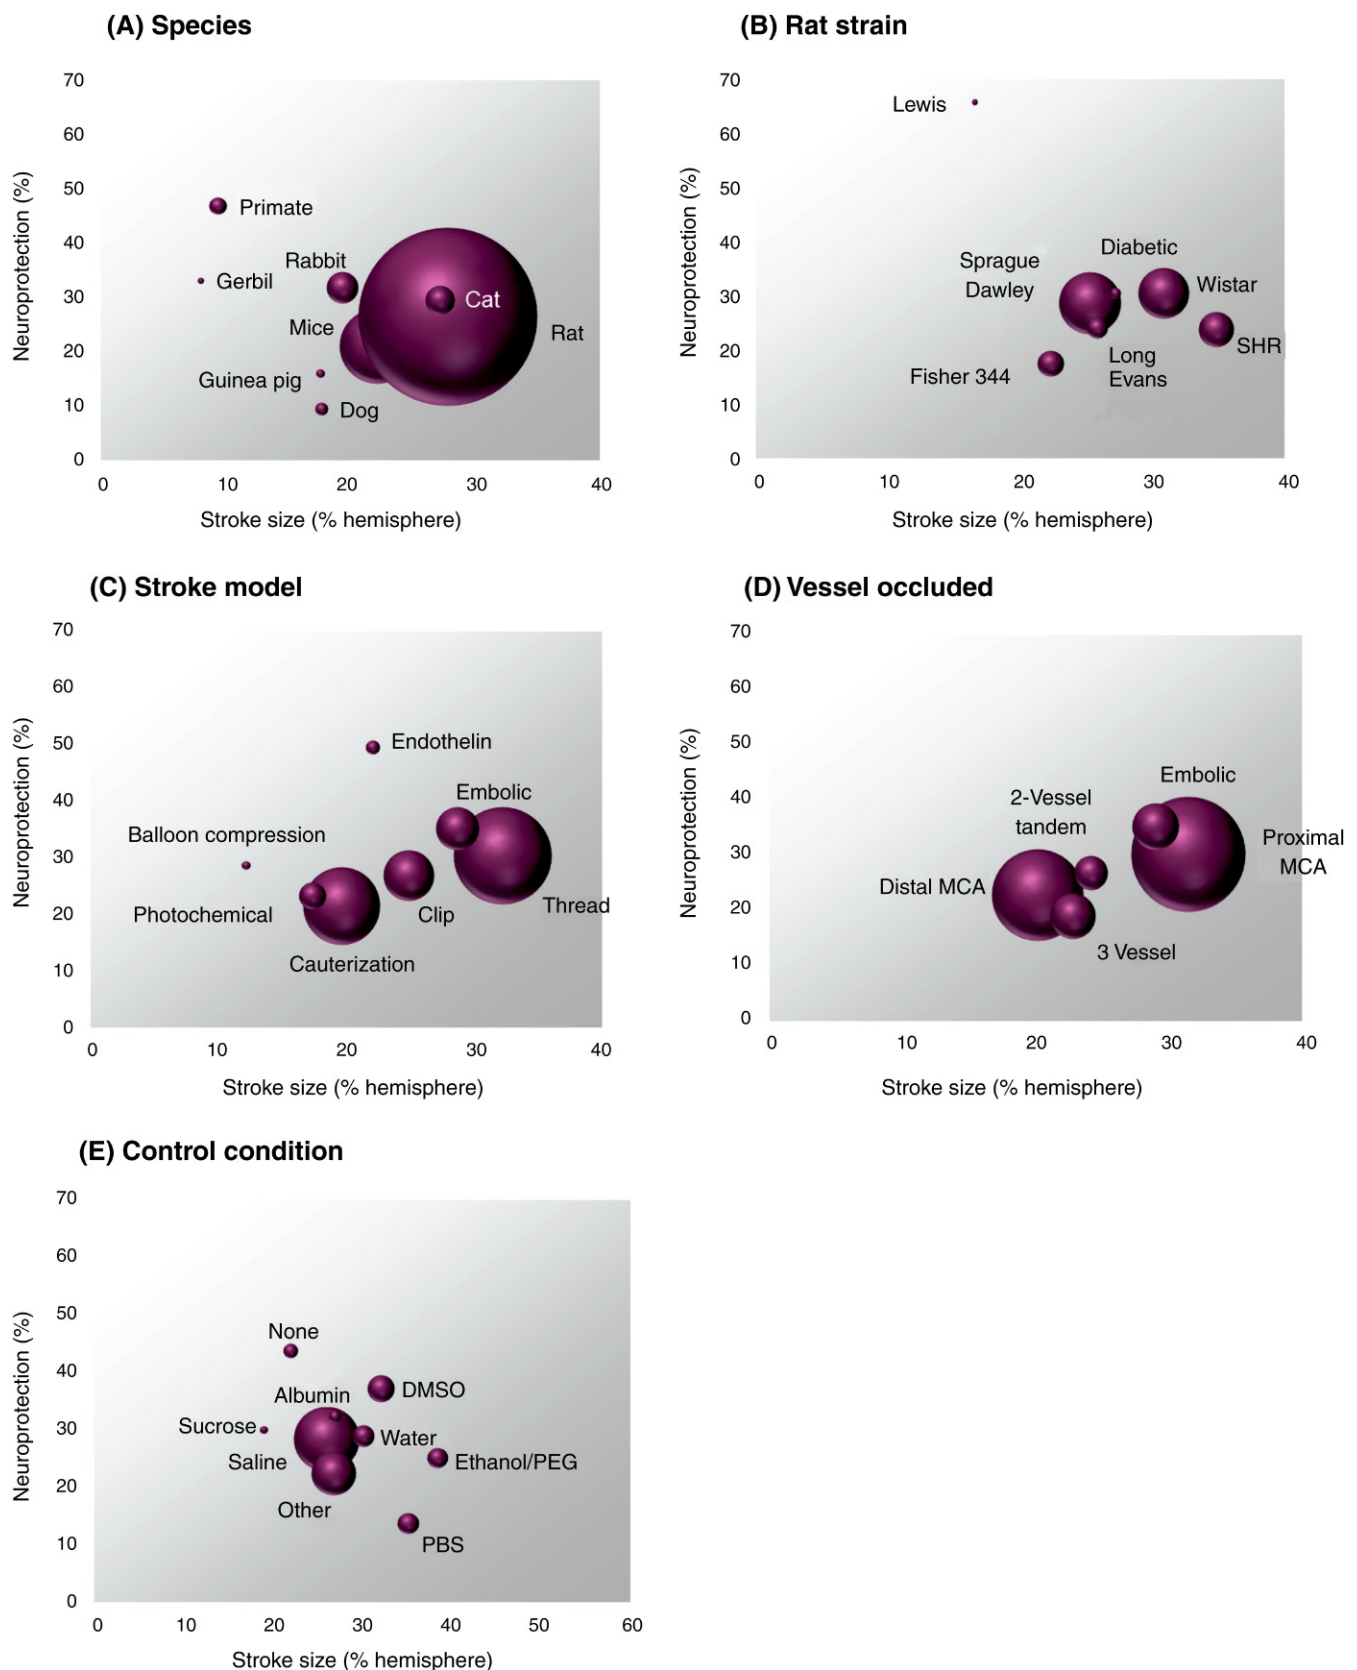
Overall, both animal and human studies suggest that acute stroke treatment reduces infarct size when the comparison is based upon the treatment group relative to an untreated control cohort. Using the Der Simonian and Laird metaanalytic method, animals receiving treatment had infarct volumes 25.5% smaller than those in the control group (M ± SE: 25.5 ± 0.2%, 95% CI = 25.2–25.8, N_P = 45, 476, N_T = 3145). A similar level of benefit was


FIGURE 20.3 **Infarct size and neuroprotection in animal models of stroke.** Size of the bubble is proportional to the number of subjects in each category. The infarct size represents an average infarct volume, expressed as a percentage of the hemisphere, for each category. Where the data was not reported as a percentage, then the absolute value was transformed into an average using the values described in the methods section. Panels A–E display the results for species, rat strain, stroke model type, the vessels occluded, and different control conditions, respectively. So for instance, in subplot (A) species, the size of the bubbles indicates that the greatest number of experiments by far was conducted in the rat. Further, the plotting along the *x*-axis indicates that infarct size as a percentage of the hemisphere was greatest in the rat, closely followed by the cat, while along the *y*-axis, the treated primates tended to show the greatest level of recovery compared with the control group, while guinea pigs did not respond greatly to treatment. The percentage neuroprotection represents the difference in infarct volume between the control group and the treatment group, with values above 100% suggesting that the treatment is damaging and values below 100% suggesting that the treatment is able to reduce the amount of brain damage. Data relating to rat strains also includes diabetic rats, not technically a strain, but a disease state usually induced in Wistar rats.

Ratios of baseline (pretreatment) infarct volume are depicted on the *x*-axis and final infarct volumes on the *y*-axis.

found for patients receiving treatment, with the treatment group having a stroke volume of 18%–29% smaller than the control group, depending on the method of reporting results (Table 20.8).

Where the effect size in clinical trials was based on the pooled estimate of data reported as means and raw or untransformed medians, the putative effect size was 31% (M ± SE: 30.7 ± 2.1%, 95% CI = 26.5%–34.9%, N_P = 5532 patients, N_T = 39 trial comparisons). For the effect size based on means and means estimated from median values, the effect size was 27% (M ± SE: 27.0 ± 1.9%, 95% CI = 23.3%–30.8%, N_P = 5532, N_T = 39). Looking at the subgroups, in those trials where the outcome was given as a mean (M ± SE: 18.3 ± 4.4%, N_P = 3432, N_T = 26) the estimated reduction was smaller than where it was given as a median and transformed into a mean (M ± SE: 29.1 ± 2.1%, 95% CI = 9.7%–26.9%, N_P = 2100, N_T = 13). There was significant statistical heterogeneity in the trial results based

TABLE 20.8   Method of Reporting and Outcome Measures

Reporting	Infarct volume (hemisphere %)	Neuroprotection ($M \pm SE$%)	Number of experimental contrasts
ANIMAL			
Absolute volume	30	25 ± 0.2	2107
Percentage of hemisphere	29	30 ± 0.4	755
Area of infarction	—	19 ± 0.7	145
Other/not known	—	30 ± 0.9	138
CLINICAL			
Mean	10	18 ± 4	26
Median	7	29 ± 2	13

Note: Infarct size—mean hemispheric volume in the control group. Neuroprotection—the percentage reduction in infarct volume in the treated group versus the control group.

on means and estimated means [$\chi^2(38) = 156$, $P < 3E^{-16}$] and means and medians [$\chi^2(38) = 155$, $P < 5E^{-16}$], though the heterogeneity was reduced when only the studies reporting means were included [$\chi^2(25) = 59$, $P < .0005$].

The effect of reporting method on the pooled estimate of efficacy may be a consequence of distortion of the data, with the conversion to a mean overstating the effect of the treatment. However, clinical trials reporting a median value tended to have smaller infarcts (*median*: 7.0% of hemisphere, *mean*: 9.8% of hemisphere) and thus their higher associated level of neuroprotection may have occurred as a consequence of the smaller infarct, irrespective of the reporting method.

Animal experiments also differed in their method of reporting results. Sixty-seven percent of experimental comparisons reported findings with an absolute value of brain damage, 24% as a percentage of hemispheric volume, with 9% of experiments recording damage as percentage hemispheric area, another geometric measure or measure unknown. Reports stating animal infarct volumes as an absolute value were associated with lower levels of neuroprotection than where volumes were reported as a percentage of the hemisphere (Table 20.8). However, the estimates of infarct size were similar, suggesting that some of the effect may be attributable to their effect on edema. A correlation of 0.97 has been found between edema volume and infarct volume in a tandem MCA model in rats (Kaplan et al., 1991), so a proportion of what is detected in the stroke neuroprotection literature may be due to the effect on the fluid balance in the brain and the molecules regulating it, such as aquaporins (Chen et al., 2007). Though not investigated here, treatment and postfixation tissue shrinkage may also differentially affect fluid balance within the ischemic and nonischemic brain tissues.

Of all the animals, the primate was associated with the highest level of neuroprotection ($M \pm SE$: 46.9 ± 3.0%, 95% CI = 40.9%–52.9%, N_P = 229 primates, N_T = 22 experiments). This was in spite of having the smallest infarct size. Conversely, the rat studies yielded a similar estimate of neuroprotection to that produced in clinical trials using the Der Simonian and Laird method ($M \pm SE$: 26.3 ± 0.2%, 95% CI = 26.1%–26.8%, N_P = 35,751 rats, N_T = 2,506 animal experiments), but their infarct size was much larger than seen in patients (when expressed relative to brain volume). The lowest level of neuroprotection was found in the hamster (Table 20.7), but this was found in a small sample ($M \pm SE$: 82.7 ± 11.42%, 95% CI = −104.9% to −60.4%, N_P = 128 hamsters, N_T = 2 papers and 15 experimental comparisons).

The more common strains of rats were associated with levels of neuroprotection in the order of 18%–31%. Neuroprotection was hardest to establish in the Fisher 344 strain ($M = 17.5\%$) and was most readily demonstrated in the Lewis rat ($M = 65.9\%$) (Table 20.7). This difference is of interest as the Lewis and Fisher strains are closely related, and it may have arisen due to differences in their corticosterone and hypothalamic–pituitary–adrenal axis mediated immune responses. Evidence indicates that the Lewis rat does not produce normal corticosterone responses (Sternberg et al., 1989a,b), and is highly susceptible to arthritis, while the Fisher is highly resistant and will withstand many attempts at inducing an inflammatory response (Lovallo, 2005). This suggests that the immune response greatly influences neuroprotective response. An alternate explanation might be found in differences in the vasculature. For instance, Dittmar has stated that the F344 rats are unsuitable for MCA occlusion due to vascular anatomy of their internal carotid artery (ICA), the ICA being heavily kinked (Dittmar et al., 2006), hence it
FIGURE 20.5   Pretreatment and final infarct size in treated patients and animals.

is conceivable that the F344 rat is less able to reperfuse and drugs which assist reperfusion might be associated with a lower associated level of efficacy.

3.5.4 Pretreatment Infarct Size and Relationship With Stroke Treatment

Early last century, Garrison wrote "Primitive man... tried to treat the disease rather than the patient, not realizing... that the dynamic effect of a drug upon the patients' body depends as much upon the delicate chemical adjustments of that body as upon the composition of the drug itself (Garrison, 1929)." The importance of individual variability of patients has been studied in a number of clinical trials, with the finding that pretreatment characteristics including site of arterial lesion, hypoperfusion volume, and clinical scores are predictive of therapeutic response (Adams et al., 1999; NINDS, 2000; Saqqur et al., 2007; Seitz et al., 2004; Warach et al., 2000).

Previous work has demonstrated that clinical outcome in stroke patients may be related to various pretreatment factors, including brain image characteristics (von Kummer et al., 1997), fibrinolytic profile (Ribo et al., 2004), and NIHSS scores (Adams et al., 1999; Uchino et al., 2001). Pretreatment measurement of infarct volume does not typically form part of the protocol in animal studies. This data is much more readily available clinically, as early imaging data is needed for diagnosis and treatment selection. But the issue is an important one, for if the treatment and control groups are not balanced—if they have different infarct sizes prior to treatment—it may affect the interpretation of results.

In the data collected for this review, pre- and posttreatment infarct volumes were available for 15 of the animal experiments (out of 3145 experiments) and 16 of 35 clinical trials (Fig. 20.5). The average infarct volume in the groups receiving treatment were expressed as a percentage of the control, with 100% indicating that on average the groups had the same size lesion, and values less than 100% expressing that the mean infarct volume in the treatment group was smaller than the control group. For each study, the ratios of treatment to control group were calculated pretreatment and at the final outcome assessment. A linear regression was then undertaken us-

ing the ratio of pretreatment stroke volume ratio as the independent variable and the outcome infarct size ratio as the dependent variable. Overall, pretreatment stroke volume significantly predicted outcome size ($b = 0.559$, $t(31) = 3.7$, $P < .01$). Pretreatment stroke volumes also explained a significant amount of variance in the outcome size ($R^2 = 0.312$, $F(1, 31) = 13.6$, $P < .0124$). Thus, pretreatment infarct sizes explained 31% of the heterogeneity in the model.

Interestingly, in two thirds of the clinical trials, the treatment groups had larger pretreatment stroke volumes, while in only 1 of the 16 animal studies was infarct volume larger in the treatment group prior to therapy (Fig. 20.5). Consequently, adding a variable to explain whether the results came from a clinical trial or animal experiment explained a greater amount of the variance in the outcome, and the cohort type (human or animal) was a significant predator of outcome (*adjusted $R^2 = 0.39$*, $b = 55.8$, $t(31) = 4.4$, $P < .001$). Given that pretreatment infarct size is an important predictor of outcome, an imbalance in infarct size at the outset may introduce bias into the results, with an underestimation of treatment effects in the case of clinical trials, and an overstatement of the effect of treatments in animal experiments. However, only a small subset of animal experiments acquired data on pretreatment lesion size so this may not be representative of the general experimental results. On the other hand, pretreatment conditions in animals are typically measured using a neurological score and/or the level of change in blood flow measured over a single point of the brain. Perhaps these measures are not sensitive enough to establish the equivalence of control and treatment groups prior to treatment administration and should be supplemented with subtler measures?

3.6 Temporal Factors in Stroke

3.6.1 Length of Occlusion

The criticality of reestablishing blood flow to ischemic tissue has been known at least since Harvey (Harvey, 2001). Through experimentation, Harvey demonstrated that ligation of a vessel may "induce sloughing and more extensive mortification in extremities" and

that upon reperfusion "all things immediately return to their natural state." Skip forward 380 years, and extensive clinical evidence has been furnished to support this point: where recanalization occurs, patients generally fare better (Rha and Saver, 2007). This is so even if some of the influx of blood is "nonnutritional" or "luxury" perfusion, that is, blood flow in excess of what is required to meet the metabolic demands of the surviving tissue (Barber et al., 1998). Reperfusion may be induced mechanically with specially crafted clot retrieval devices (Goyal et al., 2016), with antithrombolytic drugs, such as tPA, or it may occur spontaneously. Spontaneous reperfusion may lead to an improvement in clinical function (Barber et al., 1998), but evidence suggests that it must occur early to benefit a patient (Lees et al., 2010).

The perspective of experimentalists and clinicians diverge when looking at the duration of ischemia. Instead of asking how early the reperfusion must occur to benefit patients, experimentalists tend to emphasize the duration of ischemia needed to produce a reproducible infarct. To achieve this, Durukan recommended a minimum of 90–120 min of ischemia (Durukan and Tatlisumak, 2007). Prolonged periods of ischemia and reperfusion have been found to influence infarct volume, with both increasing it (Vosko et al., 2006).

The duration of occlusion in animals (N_P = 45,512) commonly spanned less than 6 h (N_P = 45%) or 1–3 days (N_P = 27%) and stroke of 6–24 h tended to be underrepresented compared with the clinical prevalence of stroke (N_P = 2% vs. 46%, respectively: Table 20.9). This comparison is limited by the paucity of included clinical trials in the review reporting this information, N_T = 1 (Molina et al., 2001). This trial, in particular, has relatively high levels of 24 h recanalization: 90% in the treated group and 61% in the untreated group. By way of contrast, Rha and Saver's metaanalysis of 53 studies placed the esti-

mated rate of recanalization at 55.1% after revascularization therapy, and 24.1% without treatment, measured at 24 h (Rha and Saver, 2007).

Trials documenting recanalization time, typically using transcranial Doppler, are bedeviled by considerable variability: failure to reperfuse occurs in untreated patients at a rate of 29%–88% (Molina et al., 2004; Poncyljusz et al., 2007; Vang et al., 1999); in treated populations, the range is lower at 8%–35% (Molina et al., 2004; Poncyljusz et al., 2007; Ringelstein et al., 1992). The juxtaposition of clinical and animal data is further hampered by the inability to accurately record of the number of patients who reperfuse before the first scan, typically in the first 6 h after onset of symptoms.

Data on the time of recanalization and infarct size was shown in only one clinical study reviewed here (Molina et al., 2001). This study demonstrated a clear positive relationship between time of recanalization after stroke onset and the subsequent size of the stroke: with recanalization earlier than 6 h, infarct size averaged around 25 cm³. Where recanalization took place at 6–12 h strokes were larger at around 90 cm³, and where blood flow restoration occurred at 12–24 h or 24–48 h patients had the largest infarcts of around 150 cm³. Failure to reperfuse leads to infarct volumes reaching almost 240 cm³.

Postponing reperfusion has a considerable impact on the progression of ischemia in animal models. The largest deficit was seen in animals with durations of ischemia of 90 min to 2 h (Table 20.10). Somewhat paradoxically, temporary ischemia of both under 30 min and over 3 h yielded smaller strokes, although this finding makes more sense when examining the trend within a single type of model. The inflatable balloon cuff model with its smaller lesion size was frequently conducted for over 3 h. Both thread occlusion models and models involving the placement of an external clip or ligature,

TABLE 20.9 Time of Recanalization

Length of occlusion	Number of animals	Number of tPA-treated patients	Number of untreated patients
0 up to 6 h	20,405 (45%)	16 (66%)	7 (15%)
6 and <12 h	587 (1%)	5 (20%)	15 (31%)
12 to <24 h	412 (1%)	1 (4%)	7 (15%)

N_T, Number of trials. Infarct size represents infarct size in the control group as a percentage of the hemisphere. Duration—duration of ischemia.

generally exhibited larger infarct sizes with longer occlusion times, but with exceptions. For the thread occlusion model, the largest occlusion time was seen with temporary occlusions greater than 3 h, compared with 90–120 min for the clip models. This time point is not without physiological significance: After 90 min of ischemia, edema increases and its imaging correlate—the ADC lesion volume on MRI imaging—eclipses the CBF lesion (Dzialowski et al., 2007; Meng et al., 2004). This length occlusion has also been associated with a peak in pCO_2, blood glucose and scalp temperature, and with the nadir in blood pressure (Memezawa et al., 1992).

At what time point is it no longer beneficial to restore blood flow, and can it be harmful? The injury said to arise from late restitution of blood flow, reperfusion injury, is typically imputed in animal studies when the infarct volume caused by temporary ischemia exceeds that in permanent ischemia. Supporting the idea of reperfusion injury, the thread occlusion models tended to show larger damage in the temporary models (48% of the hemisphere) than the permanent models with occlusion lengths greater than 3 h (42% of the hemisphere) (Table 20.10). Curiously, this pattern was not demonstrated in the clip and ligature models, with both occlusion lengths demonstrating stroke volumes of around 28%. This suggests that reperfusion injury may be more likely to arise in the filament models, perhaps due to greater damage to the endothelium or perhaps as a consequence of the larger infarct size.

These findings are generally concordant with individual studies looking at the outcome with different lengths of occlusion. Studies supporting the notion of reperfusion injury tend to come from filament or thread occlusion models (Yang and Betz, 1994) but not always (Memezawa et al., 1992). Those studies using microvascular clips or ligatures tend to refute the notion of reperfusion (Kaplan et al., 1991; Slivka et al., 1995; Young et al., 1997), but not always (Crowell et al., 1981).

A number of factors could account for a possible difference in susceptibility to reperfusion injury in different models. The discrepancy may have occurred by chance, but there also exist plausible physiological explanations, including edema, vessel damage, locus of occlusion, and differential effects of temperature, and anesthesia. Reperfusion after long periods in the thread occlusion model is associated with vasogenic edema (Neumann-Haefelin et al., 2000). Edema may have a reduced effect on some extravascular clip or ligature models because these models frequently involve removal of a small portion of the skull or the drilling of a hole—in order to reach distal MCA branches. This may mimic some of the effects of decompressive craniectomy, a procedure which has been found clinically to be useful in the treatment of malignant infarcts where edema and intracranial pressure management is critical (Vahedi et al., 2007).

Removal of the intravascular filament to allow reperfusion may also cause damage to the inner lining of the vessel, the endothelial cells and pericytes, instigating a pernicious response, a response exacerbated by the tendency of the filament model toward spontaneous hyperthermia associated with hypothalamic damage (Li et al., 1999). A complex interaction exists between the locus of occlusion and length of anesthesia (Hashimoto et al., 2008). A differential susceptibility of basal ganglia and cortical tissue to damage (Neumann-Haefelin et al., 2000) may also play a role. The basal ganglia may be more sensitive to ischemic damage than in the clip models, especially where the clip or ligature is placed prior to the origin of the lenticulostriate arteries. But this brings us back to the problem of experimental design; it is insufficient to imply reperfusion injury without first having established that blood flow did indeed return. Laser Doppler probes placed on the cortical surface measure only blood velocity in the surrounding 1 mm^3 and it would be insufficient to impute the return of blood flow to subcortical regions. The question of reperfusion injury therefore remains open.

Blood perfusion status is also an important mediator and indicator of treatment efficacy. The metaanalysis of Rha and Saver suggests that active revascularization

treatment raises the level of reperfusion to 55.1%, compared 24.1% with patients who receive no treatment (Rha and Saver, 2007). They found that the degree of reperfusion is moderated by stroke type, with occlusions of the ICA having the lowest rate of recanalization (49.1%) compared with the MCA/ACA occlusion (61%) and the vertebral and basilar arteries (66.2%) (Bamford et al., 1988).

The timing and effect of recanalization was reported in only two clinical studies, but there was greater neuroprotection ($M \pm SE$: $59.8 \pm 5.0\%$, $N_T = 1$) where the median reperfusion time was 3–6 h, compared with 6–12 h, where there was a 12% increase in damage ($M \pm SE$: $-11.8 \pm 35.4\%$, $N_T = 1$).

3.6.2 Time of Treatment Administration

Much effort over the preceding decades has been directed toward promoting the recognition of stroke as a medical emergency requiring immediate action. This urgency has been underwritten by several large thrombolysis trials finding benefit when treatment has been administered within the first four and half hours following stroke.

About one third of clinical trials included in this review involved the administration of drugs within 3 h or less ($N_T = 12$, 31%) and two thirds within 6 h or less ($N_T = 26$, 67%). This is exceptionally early, by standards of clinical trials, and accounts for the relatively early mean time of drug administration of 7 h after stroke onset ($M \pm SD$: 7.0 ± 9.0 h, median = 4.1 h, range: 1.1–48 h, $N_T = 34$, $N_P = 5299$). By contrast, in Kidwell's review of clinical trials before 2000, the median time to treatment was 24 h (range 3–360 h) (Molina et al., 2001). Treatment time is nevertheless protracted in clinical trials compared with the experimental counterparts. In experiments, the mean time of drug delivery is 10 h prior to stroke onset, with a median of 5 min poststroke ($M \pm SD$: -10.0 ± 67.2 h, median = 5.0 min poststroke, range: -84 to -15 days, $N_T = 3,048$, $N_P = 44,028$).

3.6.3 Time of Measurement

Study of the infarction as it develops over time is often referred to as the natural history of stroke. As time progresses after stroke onset, the amount of brain damage increases to reach a maximum at about day 2–3 poststroke (Lansberg et al., 2001; Schwamm et al., 1998), after which some patients plateau and some decline (Brott et al., 1989; Schwamm et al., 1998) contingent upon the recanalization status (Schellinger et al., 2001).

This pattern of infarct development is consistent with the findings in this study, with clinical trials tending to show a declining stroke volume in the control group as the time after stroke onset increased. For those studies looking in the acute phase, infarct size tended to be larger, perhaps reflecting the effect of edema or different types of measurands. The average infarct size occupied 11.6% of the hemisphere on day 1 ($N_T = 2$) and 9.3% at day 3–7 ($N_T = 3$). Most clinical trials ($N_T = 15$) measured infarct volume between week 1 and week 2, and at this time point, the average infarct size was 8.6%. After week 2, average size measured 7.8% of the hemisphere ($N_T = 13$).

Animal studies also followed this pattern. When measured less than 24 h after stroke induction, infarct volume in animals averaged 23.8% of the hemisphere ($N_T = 330$) and reached a maximum at 24–48 h, occupying 30.8% of the hemisphere ($N_T = 1353$). After 2–3 days, the stroke volume was 25.4% ($N_T = 513$), and at 3–7 days 24.4% ($N_T = 383$). During week 1–2 the infarct size was 23.7% ($N_T = 340$) and was smallest when measured after 14 days (19.8%, $N_T = 107$).

A frequent criticism leveled at animal studies is that outcome measurement is somewhat myopic, and that given enough time any differences between treatment groups may resolve. The median time of measurement was 8 days after stroke onset for patients and 1 day for animals (clinical: median = 8 days, range = 1–82 days; animal: median = 1 day, range: 20 min to 120 days). Twenty-six percent of clinical trials ($N_T = 10$) were measured at 4 weeks or beyond, compared to 1.7% of animal experiments ($N_T = 52$).

3.7 Cause of Stroke

3.7.1 Clinical Etiology of Stroke

The etiology of clinical stroke is commonly assigned using the TOAST classification system (Adams et al., 1993). According to this system, stroke is attributable to one of five conditions: (1) large vessel atherosclerosis, (2) cardioembolism, (3) small vessel occlusion/lacunar stroke, (4) stroke of other determined etiology, and (5) stroke of unknown etiology. In this review, 12 clinical trials with 2219 patients reported the cause of stroke (ASSI, 1994; Blanco et al., 2007; Clark et al., 2001; Fogelholm et al., 2000; Hillis et al., 2003; Obrig et al., 2000; Roberts et al., 2002; Selim et al., 2005; Shi et al., 2000; Thomalla et al., 2003; Yasaka et al., 1998). The most common attributable causes of stroke were large vessel disease ($N_P = 39\%$ of patients) and cardioembolism ($N_P = 39\%$ of patients). Small vessel disease was reported in 13% of patients, and 9% of patients had a stroke of unknown or some other etiology (Fig. 20.6). This population is less representative of small vessel stroke than has been found in other stroke studies (Salerno et al., 1996), perhaps because lacunar stroke patients are less likely to be included in imaging trials or receive thrombolytic therapy.

3.7.2 Method of Stroke Induction in Animals

The most common mechanism of stroke induction in animals involved the insertion of a filament into the common carotid artery, and threaded up to the point of origin of the MCA (N_T = 47%). This model has been variously called the thread occlusion model, the filament occlusion model, and the suture model. Ischemia by cauterization or thermocoagulation of the MCA was also popular (N_T = 28% of experiments). Occlusion of a vessel with a clip or by ligation was less common

(N_T = 12% of experiments), as were embolic models of stroke (N_T = 9% of experiments), and infarction induced by the laser activation of a photosensitive dye (N_T = 3% of experiments) or by application the vasoconstrictor endothelin-1 (N_T = 1% of experiments).

Methods of experimental stroke induction do not easily find parity with their clinical counterparts; nevertheless, it could be argued that the majority of animal models represent a nonatherosclerotic form of large vessel occlusion or a noncardiac form of cardioembolic stroke.

Although, the photochemical model of stroke may also mimic features of lacunae (Futrell et al., 1989), it is thought that no specific model captures all aspects of small vessel disease (Hainsworth and Markus, 2008): chronic models of hypertension have been suggested to be the best approximation (Hainsworth and Markus, 2008). Nevertheless, small vessel disease has been underrepresented in experimental stroke compared with its clinical prevalence.

Previous work has found that stroke of different etiologies may be associated with different sized infarcts (Brott et al., 1989). In the present review, the infarct occupied 15% of the hemisphere in control patients from trials only including cardioembolic strokes (N_T = 5). In trials of patients with stroke of mixed etiology, infarct size amounted to 6.5% of the hemisphere (N_T = 10), and where the cause was not reported, to 9.5% of the hemisphere (N_T = 24). Only one trial reported infarct volumes for the control patients grouped by causation, the NINDS tPA trial (Obrig et al., 2000). In this trial, the median CT volumes at 1 week were 40 cm^3 for cardioembolic, 32 cm^3 for large vessel stroke, and 4 cm^3 for small vessel stroke.

In animal experiments, establishing a relationship between infarct size and cause is aided by the fact that stroke may be tied to a single causal factor (Fig. 20.3C). The filament model induced the largest stroke (32% of the hemisphere), and the inflatable balloon cuff model the smallest (12% of the hemisphere). However, the balloon cuff model was also applied in larger species, perhaps accounting for the small infarct size. Similarly, the extensive nature of the damage caused by the filament occlusion model may be due to the location of the vessel involved—the origin of the MCA, a factor explored in the next section.

3.7.3 Cause of Stroke and Neuroprotection

Different stroke types may require different treatments and show different degrees of recovery (Murat Sumer and Erturk, 2002). For instance, Molina found that treatment efficacy depends on the cause of stroke with superior outcomes in cardioembolic strokes versus large artery disease, or other etiologies (Molina et al., 2004).

Establishing a relationship between stroke subtype and therapeutic efficacy in this review was hampered by the fact that clinical trials tend to include patients of multiple stroke typologies. In the five trial results including only cardioembolic strokes, the level of efficacy tended to be smaller (M ± SE: 4.4 ± 5.3%, N_T = 5) than where the cause of stroke was mixed (M ± SE: 32.8 ± 2.5%, N_T = 10) or not stated (M ± SE: 25.0 ± 4.0%, N_T = 24). However, the infarct sizes in these cardioembolic groups also tended to be larger occupying 14.5% of the hemisphere.

For animals, the relationship between the features of the stroke and level of neuroprotection was easier to ascertain, as the populations tend to be more homogenous

by design. In general, the relationship between type of stroke model and level of treatment efficacy may be explained by reperfusion. Models which permit reperfusion, such as the endothelin model (M ± SE: 49.6 ± 2.4%, 95% CI = 44.8%–54.3%, N_T = 25) and the embolic model (M ± SE: 35.3 ± 0.8%, 95% CI = 33.7%–26.9%, N_T = 253) tend to be associated with a higher level of efficacy. Models which permanently stop blood flow, such as the cauterization models tend to be associated with the lowest level of efficacy (M ± SE: 21.4 ± 0.2%, 95% CI = 21.0%–21.9%, N_T = 797). Clip and thread occlusion models which sometimes temporarily and sometimes permanently occlude the vessels had levels of efficacy in between. The relationship between treatment efficacy and infarct size for each type of model is depicted in Fig. 20.3C.

3.8 Location of Stroke

3.8.1 Background

In humans, the principal sources of arterial blood supply to the brain are the vertebrobasilar system or the carotid system (Fig. 20.6). The common carotid artery bifurcates or divides into the external carotid artery (supplying the external parts of the head), and the ICA (supplying the brain). The point of intracranial bifurcation of the internal carotid is often called the carotid T intersection, and beyond the carotid T, blood flows through to the MCA or anterior cerebral artery (if it has not already been diverted along one of the many other branches off the carotid arteries).

The branches of the MCA have been labeled M1 (the horizontal segment supplying the anterior MCA cortex), M2 (the sylvian segment supplying the cortex lateral to the insular ribbon), M3 (the cortical segment supplying the posterior MCA cortex), and M4–6 (the anterior, lateral, and posterior cortical segments supplying the anterior, lateral, and posterior cortical territories 2 cm superior to M1–3) (Kim et al., 2004; Pexman et al., 2001).

The rat brain is also supplied by the carotid and vertebrobasilar systems, but a different nomenclature is used to describe the vessels (Fig. 20.6). The major cortical branches of the MCA fan out across the cortical surface and have been called the frontal, parietal, temporal, and pyriform branches (from the frontal to posterior orientation, respectively) (Fox et al., 1993; Rubino and Young, 1988; Yamori et al., 1976). The lenticulostriate branches originate along the MCA and turn inward to supply the subcortical regions of the brain, notably, the basal ganglia.

An adjunctive classification of the MCA describes the proximal MCA as the portion of the MCA as it branches off the Circle of Willis and transcends anteriorly giving off the lateral and medial lenticulostriate arteries, up to the point of the olfactory tract (Fox et al., 1993; Yamori

et al., 1976). The distal MCA is then the portion of the MCA as it proceeds dorsally and traverses the inferior cerebral vein (ICV), the vein running with the rhinal fissure (Fox et al., 1993).

Differences in brain vasculature have been found both within and across species. Major variations have been found in the branching pattern of the Sprague Dawley, the most commonly used animal in stroke experiments (Fox et al., 1993; Niiro et al., 1996). Other species may exhibit features of the vasculature not found in people, notably, the carotid rete mirabilis, a fine web of vessels found in the neck of birds, ox, cats, sheep, swine, and to some extent in dogs (Daniel et al., 1953; Jewell, 1952; Scremin, 2004). Dogs may also have extensive intraextra cranial anastomoses (Jewell, 1952), as discovered in the 19th century by Astley Cooper. In his seminal ischemia experiments, Cooper and others who replicated his experiments were surprised to find that many dogs survived the occlusion of all carotid and vertebral arteries (Whisnant et al., 1956), a feat probably achieved by the diversion of extracranial blood supply to the brain regions critical for survival.

The location of a stroke may be defined either by the vessel occluded or by the territory affected. Each vessel is said to supply blood to a certain amount of brain tissue, its vascular territory. Estimates place the MCA territory at about 280 cm^3 or about 50% of the hemisphere (van der Zwan et al., 1993). By contrast, the anterior cerebral artery supplies about 138 cm^3 (23%) and the posterior about 119 cm^3 (20% of the hemisphere) (van der Zwan et al., 1993). However, the vascular territories of major vessels may be quite variable (van der Zwan and Hillen, 1991; van der Zwan et al., 1992, 1993), and the territory normally perfused by a certain vessel may not match the territory vulnerable to ischemia by occlusion of the same vessel (Phan et al., 2005). For instance, collateral blood supply from vertebrobasilar arteries may flow into the territory normally supplied by the MCA (van Laar et al., 2007). Thus, the effective area of the MCA territory may vary 34%–64% of the hemisphere (Provenzale et al., 2003).

The locus of the occlusion prejudices the final infarct size and the rate of recanalization of blood flow. Occlusions of larger vessels closer to the heart are frequently termed proximal lesions, while infarcts in smaller vessels further from the heart may be termed distal lesions. Distal MCA lesions tend to be smaller than proximal MCA lesions because they are less likely to involve the subcortical blood supply, the lenticulostriate arteries (Fig. 20.7 for the occlusion sites in the rat). However, distal lesions may also be smaller in size because they reperfuse more readily after stroke or respond better to thrombolytic therapy or because they receive more cortical collateral flow (Christoforidis et al., 2005; Rother et al., 2002). Collateral flow may alter this pattern, with occlusion of M1

resulting in more damage than an ICA occlusion where the ICA occlusion is accompanied by collateral flow to M1 (Liu et al., 2004).

Multifocal infarcts occur in 15% of patients with MCA territory lesions (Caviness et al., 2002) and in 10% of posterior territory lesions (Bernasconi et al., 1996). Multifocal lesions may occur in more proximal occlusions or where there are multiple embolic sources (Fiehler et al., 2005). Lesions may also occur bilaterally in patients, with around 10%–20% of patients showing signs of damage spanning both hemispheres (Arakawa et al., 2003; Castaigne et al., 1970). This is mirrored in rat embolic models, where Kaneko found that one third of rats (N_T = 12) had exhibited signs of a contralateral lesion (Kaneko et al., 1985). Multihemispheric infarcts may suggest a hemodynamic origin of stroke, but may also be due to the MCA or ACA vessels supplying both hemispheres, as occurs in a sizeable minority of patients (Provenzale et al., 2003).

3.8.2 Location of Stroke in Patients

Identifying the location of an infarct prior to the availability of brain imaging was the high-art of stroke diagnosis; careful clinicians, such as C. Miller Fisher wrote extensively on the subject (Miller Fisher, 1975). He listed the sites of predilection of large vessel or atherosclerotic stroke as the origin of the internal carotid in the neck, at the lower basilar and upper vertebral arteries at or near their junction and at the MCA stem (Miller Fisher, 1975). This description does not include embolic stroke or lacunar stroke, but with the exception of vertebral basilar artery territory stroke, this description largely characterizes the findings of the six trials in this review which documented the location of the stroke according to site of arterial obstruction (Fiehler et al., 2002; Hillis et al., 2003; Ogawa et al., 1999; Parsons et al., 2002; Roberts et al., 2002; Rother et al., 2002).

In the data from 470 patients included in these trials, 13% of strokes were located at the origin of the ICA, 2% were at the carotid T, 56% involved occlusion of M1 or M1 and extensions and 24% were occlusions of the M2 or distal branches of the MCA (Fig. 20.6). These findings are similar to those of Brott who found occlusion of the MCA in 82% of patients and of the ICA in 8% of patients (Brott et al., 1989). They are also congruent with the findings of Arnold, who found that the site of occlusion was more common in the larger M1 segment of the MCA (57 patients), compared with the smaller MCA branches (M2: 21 patients; M3 or M4 22 patients) (Arnold et al., 2002). In sum, the occlusion may occur anywhere along the carotid pathway, but it was most commonly found near the M1 segment of the MCA.

An alternate clinical stroke classification system is the Bamford or Oxford Classification System (IST Trial) (Bamford et al., 1988). Using this schema, clinical

FIGURE 20.7 **Location of occlusion in rat models of stroke.** (1) The photothrombotic model may be applied by shining a laser on the MCA above the rhinal fissure (Yao et al., 1996). The actual location of the point of occlusion may vary (Cai et al., 1998). (2) Distal MCA occlusions have been induced by thermocoagulation, electrocauterization, or with a clip (Bederson et al., 1986; Coert et al., 1999). It has also been achieved in tandem with occlusion of the ipsilateral CCA or both CCA (Aronowski et al., 1996, 1997). The success of the model depends on the both the location of the occlusion and the length of vessel occluded (Bederson et al., 1986). (3) The proximal MCA model typically involves cauterizing or clipping the MCA proximal to the lenticulostriate arteries yields a model of cortical and caudate damage (Davis et al., 1995; Tamura et al., 1986). (4) Endothelin-1 is commonly applied close to the origin of the MCA to obtain drops in blood flow to the caudate nucleus and cortex. However, it may also be applied more distally, or on the cortical surface to obtain smaller lesions (Sharkey et al., 1993; Windle et al., 2006; Macrae et al., 1993). (5) The filament or thread occlusion model of Zea Longa uses a heat-blunted filament inserted up to the base of the MCA (Longa et al., 1989). (6) The thread or filament model of Koizumi uses a silicon-coated thread (Koizumi et al., 1986). Depending on the length of the silicon tip on the thread, this has the potential to also occlude other branches off the internal carotid, including the hypothalamic arteries. (7) Embolic models involve injecting a material (typically an autologous clot, macrospheres, or microspheres) into the circulation near the origin of the MCA. *Source: Modified from Bremer, A.M., Yamada, K., West, C.R., 1978. G. STROKE AND NEUROMUSCULAR

symptoms define the stroke type as a total anterior circulation syndrome (TACS), a partial anterior circulation syndrome (PACS), a posterior circulation syndrome (POCS), or a lacunar syndrome (LACS). This classification system was reported in only one clinical trial paper included in this review (Emsley et al., 2005) and the patients were overwhelmingly of the anterior or partial anterior type (71%, N_P = 24 of 34).

The location of an infarct may prejudice the ability of blood flow to return to the dying tissue, and as a general rule, the more proximal the stroke the poorer the reperfusion. In the recanalization metaanalysis of Rha and Saver (2007), occlusion of the ICA had lower rates of recanalization (49.1%) compared with the MCA/ACA (61%) and the vertebral and basilar arteries (66.2%). Similar results were found here, with the four studies reporting data on the rate of recanalization and occlusion location (Derex et al., 2004b; Fiehler et al., 2005; Poncyljusz et al., 2007; Rother et al., 2002). Those patients with occlusion of the MCA segment M2 recanalized on average more readily (N_P = 69%) than M1 (N_P = 57%), which in turn fared better than occlusions at the carotid T (N_P = 22%) or origin of the ICA (N_P = 24%) (Table 20.11).

Infarct location influences not only recanalization, but also the size of the stroke. Clinical trials including only MCA infarcts had an average infarct size of 10.5%

of the hemisphere (N_T = 15), larger than where strokes were of mixed loci (6.6%, N_T = 4) or where the site of occlusion was not stated (6.8%, N_T = 20). Where infarct data was broken down by occlusion location, patients with M2 or smaller MCA branch lesions had stroke volumes of 56.6 cm^3 (9.6% of the hemisphere, N_P = 79); lesions of the M1 segment, M1 and extensions, or the MCA trunk were larger (89.3 cm^3, 15.1% of the hemisphere, N_P = 97) and those blocking the carotid T, ICA, or both ICA and MCA spanned an average of 113.7 cm^3 (19.2% of the hemisphere, N_P = 42). Predictably, the larger the vessel occluded, the larger the resulting infarct.

3.8.3 Location of Stroke in Animals

Information about the infarct in animal models is typically given as a total volume, sometimes supplemented with data on cortical and subcortical volumes. It is rare to find more detailed delineations of the location of damage, except in the early experimental work, or in papers establishing the methodology. Excellent and extensive descriptions of the locus of damage caused by different stroke models have been given by Ginsberg and Busto (1989) and Carmichael (2005). A précis of their work, together with descriptions from the original papers is given next in Table 20.12 (Fig. 20.8).

Time—time measured. N_P, number of patients. Numbers indicate the percentage of patients recanalized in relation to the total number of patients in each group.
[a]Not all results reported in paper.
[b]Identified in the search, but excluded from the metaanalysis because no infarct data or no control group. M1—M1 branch of the MCA. M2—M2 branch of the MCA. Proximal—proximal MCA. Distal—distal MCA. Rother—partial or full recanalization. Fiehler—reported as reperfusion or no reperfusion. Derex—reported as no recanalization or recanalization.

Animal experiments versus clinical trials

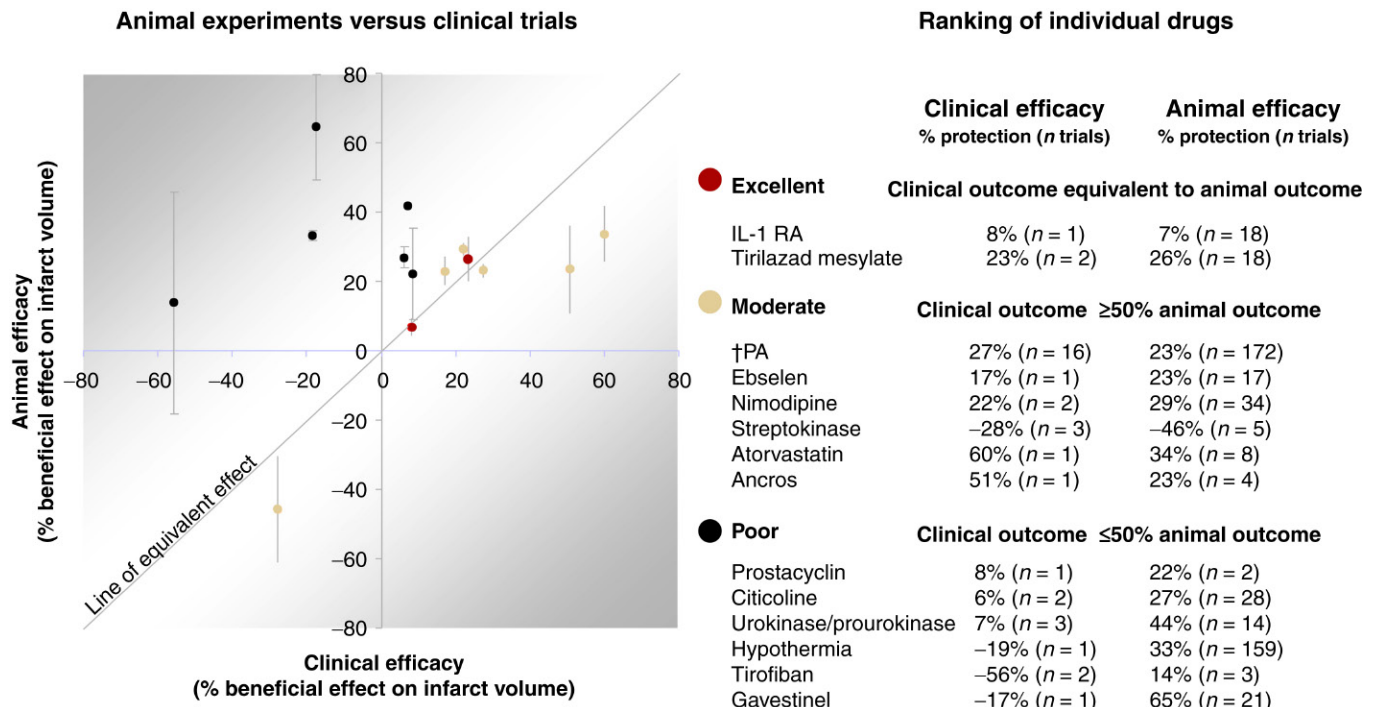
Ranking of individual drugs


FIGURE 20.8   **Treatment efficacy in animal versus clinical trials.** Each point on the graph represents the effect size for a single intervention in clinical trials *(horizontal axis)* versus animal experiments *(vertical axis)*. Efficacy estimates are derived from metaanalyses of differences in infarct volume in control versus treated groups. Higher estimates in efficacy represent a smaller infarct volume in the treated group. The correspondence between animal and clinical efficacy ratings for the same intervention were described as excellent if the confidence intervals overlapped; moderate, if the clinical outcome was at least half as effective as animal estimates predicted (on this scale); poor, if the clinical estimate of efficacy was less than 50% of the animal estimate.

In the analysis of animal data, the location of stroke was approximated by virtue of the model used. Experiments were deemed to fall into one of five categories: (1) MCA branch occlusions—occlusion of a branch of the MCA via cauterization, clips, ligation, endothelin-1, or a photochemical dye; (2) MCA origin occlusions—occlusion of origin of the MCA with a filament; (3) tandem occlusions—occlusion of the MCA and CCA; (4) three-vessel occlusion—occlusion of both common carotid arteries and the MCA, and (5) undefined—embolic models where the final place of lodgment of the clot or clot substitute is not controlled.

The largest strokes were induced by occlusion at the origin of the MCA with 32% of the hemisphere damaged ($N_T = 1497$) (Fig. 20.3D). The smallest strokes were found in the MCA branch occlusions, with 20% of the hemisphere damaged ($N_T = 936$). In spite of having the larger common carotid artery occluded, tandem and three-vessel occlusions were only slightly larger on average than the distal MCA models (24% $N_T = 130$ vs. 23% $N_T = 236$, respectively).

The relationship between the location of occlusion and the degree of neuroprotection is given in Table 20.7. The greatest neuroprotection was seen where the location of the infarct was not specified (embolic models: $M \pm SE = 35.9 \pm 0.8\%$, 95% CI = 33.7%–36.9%,

$N_T = 250$) and the smallest with the occlusion of both common carotid arteries and the MCA (3-vessel occlusion: $M \pm SE = 18.9 \pm 0.7\%$, 95% CI = 17.7%–20.3%, $N_T = 236$). Occlusions at the origin of the MCA ($M \pm SE = 29.5 \pm 0.3\%$, 95% CI = 29.0%–30.0%, $N_T = 1497$) showed greater neuroprotection than in an MCA branch occlusion ($M \pm SE = 22.9 \pm 0.2\%$, 95% CI = 22.5%–23.4%, $N_T = 936$).

Thus while animal models tend to correctly represent the proportion of different types of carotid pathway lesions, they tend to show a different pattern of protection to the clinical disease. In animal models, distal occlusions are linked with lower neuroprotection while clinically they are more likely to be associated with a positive outcome. This difference is probably due to an interaction of the type of model and the location of the occlusion, with occlusions of an MCA branch more likely to be induced by thermocoagulation or cauterization and hence more likely to permanently prevent the return of blood flow.

3.9 Study Design

3.9.1 Outcome Measures

The choice of outcome measure has a profound effect on the findings, as pointedly illustrated by a recent

TABLE 20.12 Location of Damage in Stroke Models

Models	Location of damage	Figure ID	References
Photothrombotic	Variable, as it can be manipulated stereotaxically. Typically confined to the cortex.	1	Cai et al. (1998), Futrell (1991)
Distal MCA	Cortex, hippocampus, caudoputamen. Depends both on the size and location of the segment occluded.	2	Bederson et al. (1986), Brint et al. (1988), Flaumenhaft and Lo (2006)
Proximal MCA	Sensorimotor and auditory cortex (75% of rats), occipital (25%), lateral caudate nucleus (100%), medial caudate nucleus (38%). No damage to hypothalamus, globus pallidus, thalamus, hippocampus, subthalamic nuclei, cerebellum, or pons. Sometimes undertaken in tandem with CCA occlusion to reduce variability of infarction.	3	Aronowski et al. (1996), Davis et al. (1995), Tamura et al. (1981)
3-Vessel MCA and CCA	Frontal and parietal cortex, temporal, and cingulate cortex. Dorsolateral striatum.	NS	Aronowski et al. (1997)
Endothelin-1	Variable as it can be manipulated stereotaxically. Typically cortical or cortical and striatal.	4	Macrae et al. (1993), Sharkey et al. (1993), Windle et al. (2006)
Filament (thread occlusion)	Cortex (frontal, parietal, temporal, occipital) and striatum. May also occlude the thalamus, cervicomedullary junction, substantia nigra and hypothalamus, typically with a longer thread and a longer occlusion.	5 + 6	Koizumi et al. (1986), Longa et al. (1989)
Embolic/clot[a]	Clot dependent. Large clots induce widespread cortical and subcortical damage. Microspheres produce smaller, distal, multifocal infarcts.	7	Bremer et al. (1978), Busch et al. (1997), Gerriets et al. (2003), Kudo et al. (1982), Zivin et al. (1987)

Figure ID refers to the numbers used in Fig. 20.7. Proximal and distal MCA occlusions are grouped together as MCA branch occlusions.

[a]Clot may be composed of blood from a different animal [homologous (Kudo et al., 1982)], from the same animal (Busch et al., 1997), or of nonbiological material (macrospheres or microspheres). NS—not shown [typically involves occlusion at distal MCA (location 2)] + CCA (not shown on diagram).

comparison of 10 different MRI perfusion measures (Kane et al., 2007). In this study, the smallest and largest measures differed in their estimation of the volume of perfusion volume deficit by a factor of 13 (Kane et al., 2007).

In animal studies, the histological damage delineated with the hematoxylin and eosin (H + E) is a common outcome measure following the focal ischemia mode. However, immunohistochemical markers may be more sensitive to postischemic changes. Carmichael found that histological damage was only a fraction of the metabolic deficit in a model of distal MCA occlusion (Carmichael et al., 2004). While metabolic and histological markers may vary in their delineation of the lesion, histology, and MR imaging used in animal experiments have been found to have good correlations at the same time point (Bochelen et al., 1999; Sauer et al., 1995).

In clinical trials, the most commonly used measure of outcome was CT imaging (N_T = 15). This gave a mean infarct size of 6.2% of the hemisphere and was associated with neuroprotection of 18 ± 3% ($M ± SE$). The second most common measure was T2-weighted magnetic resonance imaging (N_T = 10). T2-weighted imaging was associated with a mean infarct size of 12.5% of the hemisphere, and a higher but more variable level of neuroprotection 31 ± 9%. DWI weighted imaging yielded an average infarct size of 5% (N_T = 2) probably reflecting the use of this modality in the acute or early phase of stroke. DWI imaging was similarly associated with a more variable level of neuroprotection ($M ± SE$: 12 ± 17%). Stroke volumes were 17.8% for clinical trials reporting ADC measures (N_T = 1), and the putative level of neuroprotection was high ($M ± SE$: 67 ± 17%). The average stroke volume for a SPECT study was 7% and the treatment group fared worse than the control patients ($M ± SE$: −36% ± 50%, N_T = 1).

In the animal experiments for which data on the endpoint was available, 55% of animal infarcts were measured with the mitochondrial stain TTC. TTC was associated with a 28% level of neuroprotection ($M ± SE$ = 28.1 ± 0.2%, 95% CI = 27.7–28.6, N_T = 1609) and a stroke covering on average 33% of the hemisphere. This value was very similar to that found for MRI measures of infarction, with an infarct size of 34% and a

level of neuroprotection of 31% ($M \pm SE = 31.3 \pm 0.7\%$, 95% CI = 33.1%–73.0%, $N_T = 199$). Hematoxylin and eosin (H&E) was used in 612 experiments and yielded a slightly smaller infarct size (27% of the hemisphere), probably reflecting the fact that H&E would be used as later time points than TTC (TTC: median time of use 24 h, IQR = 24–48 h. H&E: median time of use 72 h, mean time, IQR = 24–168 h). Nevertheless, the estimates of neuroprotection with H&E were similar to those obtained with TTC ($M \pm SE = 28.0 \pm 0.4\%$, 95% CI = 27.3%–28.8%, $N_T = 612$). Smaller estimates of infarct size and neuroprotection were found with the stain neutral red ($M \pm SE = 11.3 \pm 0.9\%$, 95% CI = 9.6%–13.0%, $N_T = 51$), but these were undertaken almost exclusively in a single model of permanent occlusion in a mouse. Unusual results were also found with the ballistic light method of measuring output: the infarct size was comparable at 32% of the hemisphere, but the level of neuroprotection was high ($M \pm SE = 53.1 \pm 10.1\%$, 95% CI = 33.1%–73.0%, $N_T = 4$).

3.9.2 Control Conditions

Just over one third of the clinical trials were placebo controlled (31%, $N_T = 11$), a number administered heparin to all of the control patients (20%, $N_T = 7$), several reported giving aspirin (6%, $N_T = 2$) or saline (3%, $N_T = 1$), and several used an historical control group (11%, $N_T = 4$). In a number of trials, the control condition was not stated (29%, $N_T = 10$). The nature of the placebo treatment, whether it was a drug vehicle or some other substance, was rarely reported.

Due to small number of clinical trials, interpreting the effect of the control group on outcome must proceed with caution. However, where the control group received a drug known to have some effect, then neuroprotection was less readily demonstrated, as occurred with heparin ($M \pm SE$: $-12.2 \pm 5.8\%$, $N_T = 8$) and aspirin ($M \pm SE$: -8.4%, $N_T = 2$). Where the control group received saline ($M \pm SE$: $50.8 \pm 26.2\%$, $N_T = 1$), a historical control ($M \pm SE$: $49.3 \pm 7.6\%$, $N_T = 4$), placebo ($M \pm SE$: $24.5 \pm 3\%$, $N_T = 14$) or the control was not stated ($M \pm SE$: $45.2 \pm 4\%$, $N_T = 9$), then the level of neuroprotection was much higher.

The control condition in animals was related to both infarct size and the estimated outcome effect (Fig. 20.3E). Animal experiments most commonly used saline as a control, with an average effect size of 28% ($M \pm SE = 28.3 \pm 0.3\%$, 95% CI = 27.8%–28.9%, $N_T = 1091$) and an infarct size of 25.9%. Greater neuroprotection was found when treatment was combined with DMSO (($M \pm SE = 37.2 \pm 0.75\%$, 95% CI = 35.7%–38.7%, $N_T = 185$) and was reduced when using PBS ($M \pm SE$: $13.7 \pm 0.9\%$, 95% CI = 11.9%–15.5%, $N_T = 110$). With DMSO, the infarct volume was also much greater in the

control group (32.7% of the hemisphere), as it was with PBS (35% of the hemisphere). Where sucrose was used, the infarct size was smaller (14.5% of the hemisphere), but this was used in only a small number of animals ($N_T = 10$, $N_P = 46$).

Intriguingly, where animals were fasted the night before the experiment, neuroprotection was 10% higher (fasted: $M \pm SE$: $29.1 \pm 1.3\%$, 95% CI = 26.5–31.8, $N_T = 72$) than where they were not given free access to food or it was not stated if food was restricted (nonfasted: $M \pm SE$: $18.1 \pm 0.57\%$, 95% CI = 17.0–19.2, $N_T = 178$). Infarct size was also slightly smaller in the nonfasted control group (nonfasted: 25.1%, fasted 22.7%). This factor was only included in latter studies, but these initial findings suggest a possible benefit of fasting on stroke outcome, perhaps attributable to an upregulation of the ketogenic metabolism.

3.10 Translation of Animal Results to Clinical Trial

Fourteen interventions were tested individually in clinical trial. The direction of outcome in the trial was assessed using both animal experiment criteria (difference in infarct size between treatment groups) and using the hypothesis relating to imaging outcome prespecified in the study. Where a positive effect was reported in clinical trials, it was frequently on a measure of a reduction in infarct volume expansion, as opposed to an absolute overall difference between treatment groups. Where a hypothesis was tested, 44% of tPA results ($N_T = 7$) were positive and 30% of non-tPA results ($N_T = 7$) provided a significant improvement in the specified hypothesis. The overall number of clinical results demonstrating an improvement in the specified hypothesis was 14 trials, 36% of all results or 41% of all results specifying hypotheses. Applying the criteria used to assess animal studies (i.e., difference in infarct size between treatment groups) the putative positive outcomes in clinical trials was marginally higher (Table 20.13).

To gauge how well the results of the animal metaanalyses predicted the overall outcome in clinical trial metaanalyses results for each drug, the partitioned effect sizes of these interventions on the infarct volume in clinical trial were mapped against their partitioned effect size in animal stroke studies (Fig. 20.8). The overall effect for 11 of the 14 interventions was congruent (in the same direction in both animal and clinical trials). The exceptions were the antiplatelet tirofiban, the glycine antagonist gavestinel and hypothermia, where for each of these treatments infarct volume in animals was reduced, whereas in human trials it was increased. Apart from streptokinase, the mean efficacy of animal experiments was positive for all drugs taken to clinical

TABLE 20.13 Clinical and Animal Outcomes With Different Therapies

Features	tPA therapy	Other therapy (clinically tested)	Other therapy (not tested clinically)	All therapies
Clinical trials				
Improvement in specified hypothesis[a]				
Yes	7 (44%)	7 (30%)	—	14 (36%)
No	7 (44%)	13 (57%)	—	20 (51%)
No hypothesis testing	2	3 (13%)	—	5 (13%)
Total	16 (100%)	23 (100%)		39 (100%)
Improvement in infarct size[b]				
Yes	9 (56%)	12 (52%)	—	21 (54%)
No	7 (44%)	11 (48%)	—	18 (46%)
Total	16 (100%)	23 (100%)		39 (100%)
Animal experiments				
Improvement in infarct size[b]				
Yes	122 (71%)	328 (91%)	2244 (86%)	2694 (86%)
No	50 (29%)	33 (9%)	368 (14%)	451 (14%)
Total	172 (100%)	361 (100%)	2612 (100%)	3145 (100%)
Infarct volume average reduction				
Animal—overall reduction in meta-analysis	22.8 ± 1.0%	26.5 ± 0.5%	25.5 ± 0.1%	25.5 ± 0.2%
Clinical—overall reduction in meta-analysis	27.4 ± 2.7%	26.3 ± 2.7%	—	27.0 ± 1.9%
Difference—average difference in volume per drug as determined by partitioned analysis for each drug	−4.7%	8.1%	—	7.2%
Animal versus clinical outcomes				
Infarct volume in same direction[a]	N_T = 9/16 (56%)	N_T = 15/23 (65%)	—	N_T = 24/39 (62%)
Outcome in same direction[c]	N_T = 7/14 (50%)	N_T = 10/20 (50%)		N_T = 17/34 (50%)

tPA therapy group includes trials which administered tPA as well as other drugs. Clinical trials single time point—number of trials with a single endpoint. Multiple time points—number of clinical endpoints including multiple time-points form a single trial. N_T—number of experimental contrasts.

[a]*Refers to the infarct volume in the control group versus the treatment group. When outcome was measured multiple times, the latest time point was taken (Berrouschot et al., 2000; NINDS, 2000; Roberts et al., 2002).*

[b]*Reduction in infarct volume refers to a smaller infarct volume in the treatment group compared with the control group measured after treatment.*

[c]*Outcome in animal experiments refers to the control group versus the treatment group, but in clinical trials may differ. Some defined a positive result as less growth in infarct volume in the treatment group versus the control group. Five comparisons not included because no hypothesis was tested, and three were not included because tested at multiple time points. Percentages are calculated not on the total number of clinical trials or animal experiments but as a percentage of the numbers where tested.*

trial, as opposed to human trials, which showed both positive and negative effects. The performance of only two drugs (IL-1 receptor antagonist and tirilizad mesylate) had equivalent levels of neuroprotection in that the confidence intervals of the effect sizes in animals and humans overlapped. On average, the effect size as determined by the partitioned analyses for each drug were 7% higher in animal studies than in clinical trials, although for tPA the putative effect size was 4.7% higher in clinical trials.

Statistically, the extent to which the effect of drugs in animal experiments was related to the effect of the same drugs in clinical trial (as estimated by portioned effect sizes) was assessed in four ways: (1) simple linear correlation, and (2) simple linear regression models based on the average effect sizes from the metaanalyses of clinical and animal data, (3) hierarchical linear regression models, and (4) measures of agreement using Cohen's Kappa. While the overall pooled response to any treatment was similar between animal and humans (25.5% vs. 27.0%),

using simple linear correlation the response to individual treatments did not correlate well between animal and human studies ($r = 0.25$, $P > .05$, $N_{Drugs} = 14$). Similarly, the results from the regression analyses suggest that the average levels of neuroprotection from animal studies did not predict the average drug response in stroke trials [$b = 0.20$, $t(1,13) = 1.1$, $P > .05$]. Animal results failed to explain any significant amount of variance in the outcome [$R^2 = .02$, $F(1, 12) = 1.3$, $P > .05$]. A hierarchical regression was then conducted to determine whether animal experimental data predicted outcome, after taking into account the average time to treatment in the clinical trials, and whether clinical trials were placebo controlled. After controlling for these factors, the estimated treatment efficacy in animal models explained an additional 9.4% of the variance in clinical trials results, but this result was not significant. The measure of agreement between partitioned analyses of animal experiments for each drug and the partitioned analyses for each drug used in clinical trial results (with infarct volume between control and treated group as the outcome measure) was assessed using Cohen's Kappa. There was fair agreement between the direction of the effect sizes for each drug derived from animal studies and from clinical trial ($\kappa = 0.32$, $N_{Drugs} = 14$).

The measure of agreement between metaanalyses of animal experiments for each drug and the individual clinical trial results (with infarct volume between control and treated group as the outcome measure) was assessed using Cohen's Kappa. There was agreement between the direction of the trial result and the animal metaanalysis result for that drug in 24 out of 39 clinical trial results (62%). Taking into account the probability of random agreement using Cohen's Kappa, there was only a slight agreement between animal metaanalysis results and clinical trial outcomes ($\kappa = 0.18$, $N_T = 39$). For the 21 clinical trial results, which showed a smaller infarct volume in the treated group, the animal metaanalyses also yielded a positive effect size in all cases (100%). For the 15 negative clinical trial outcomes in which there was a larger infarct volume in the treated group, the animal metaanalyses yielded a negative effect size in only three of these cases (17%).

Where there was a prespecified hypothesis in the clinical trial, there was agreement between the direction of the trial result and the animal metaanalysis result for that drug in 17 out of 34 clinical trial results (50%). For the 14 positive clinical trial outcomes, the animal metaanalyses also yielded a positive effect size (100%). For the 17 negative clinical trial outcomes, the animal metaanalyses yielded a negative effect size in only three of these cases (18%). Taking into account the probability of random agreement using Cohen's Kappa, there was found to be none or only slight agreement between animal metaanalyses and clinical trial results ($\kappa = 0.00$, $N_T = 34$).

In general, the portioned estimates of treatment effect from metaanalyses were 7.2% higher in animal studies compared with clinical trial results for the same drugs. For treatments other than tPA, outcome in animal experiments was 8.1% higher than in clinical trials; for tPA studies outcome was better in humans by 4.7%.

4 DISCUSSION

4.1 What is the Legacy of Stroke Models?

How do you gauge the success or failure of a model? A successful animal model of stroke might be one that enables insights into the disease process or which predicts the therapeutic response to experimental treatments. How much have animal models contributed to stroke research, according to these criteria?

Experiments in cerebral ischemia have been integral in defining the mechanics of blood flow, especially circulation. Circulation is a cornerstone of modern medicine. Many aspects of stroke medicine from hypertension to intravenous drug delivery presuppose the existence of a closed circulatory system. The existence of such a system was articulated in the *Nei Jing* attributed to Huang Ti, the Yellow Emperor of China (2697 BC) but probably written during the Warring States Period (475–221 BC) (Fung, 1997). In the *Nei Jing*, it was written that blood "circulate(s) without stopping. In 50 steps they return to the starting point…like a circle without end" (p. 15) (Fung, 1997). Claims to the historical precedence of the discovery of circulation have also been made by Islamic and Italian historians on account of the work of Ibn An-Nafîs (1210–88) and Andrea Cesalpino (1524–1603) (Garrison, 1929; Meyerhof, 1935), but it was the ischemia experiments of William Harvey, which really embedded the concept of circulation in the scientific consciousness.

And what of the role of animal experiments in the development of acute stroke treatments? Generally speaking, animal models have helped define the rationale for therapeutic intervention, so that the choice of treatments is taken out of the realm of folklore, custom, and guess work. The thrombolysis story is a good case in point (and arguably the only solid case to date). Thrombolysis therapy with tPA did not begin with the NINDS trial in 1995 (NIND, 1995): its genesis can be traced back over the centuries to the work of John Hunter and Taag Astrup (Jaques, 1988) and the many less-lauded individuals who nevertheless played important roles in elucidating the details of the coagulation process without passing into the footnotes of history.

The success of stroke models for the evaluation of treatment efficacy (rather than safety or mechanism) is less clear. On the one hand, metaanalysis of data from animals and patients has yielded similar pooled levels of efficacy for acute stroke treatments measured in terms of infarct volumes in the control versus the treatment groups. On the other hand, the considerable heterogeneity in the findings suggest a need for exercising caution before extrapolating from pooled estimates of treatment effects (Thompson, 2001). A number of ongoing clinical trials have included volumetric measures as endpoints, and will be of considerable help in fleshing out this analysis when published. However, on the data analyzed here (summarized in Table 20.14), doubt remains over the role of animal models of stroke—in their present form—as tools for anticipating the effect of drugs in clinical trial, except perhaps at the most general level (agreement between the general direction of overall estimates of clinical and animal results for each drug). This challenge in translation is not unique to stroke research. Important work by Hackam and Redelmeier found that where drugs tested or developed in animal disease models were taken to clinical trial (57% of treatments in trial), only two thirds of those trials replicated the findings of animal studies (Hackam and Redelmeier, 2006).

4.2 Scope and Limitations of this Review

Recent critiques of animal models have highlighted the shortcomings of laboratory experiments when judged by clinical trial standards (STAIR, 1999). The purpose of this review was instead to evaluate clinical stroke from the perspective of the laboratory bench in order to evaluate the concordance of animal and human stroke. As most animal experiments tend to rely heavily on histological outcomes for assessment, the principle comparator used in this review was infarct size. However, when judged from a clinical perspective, there are several shortcomings to this approach: imaging outcomes are included in only a minority of clinical trials and where they are included they tend to be a surrogate outcome rather than a primary endpoint (although this is beginning to change).

By virtue of being imaging trials, the clinical trials included here also tend to be recent, to have short time windows and to be more likely to deploy thrombolytics compared with earlier trials (Kidwell, 2001). For instance, compared with the excellent review of pre-2000 clinical trials, tended to use thrombolytics (N = 13) compared with agents targeting excitotoxicity, calcium influx, oxidative stress, and other mechanisms which formed the basis of trials in the 1980s and 1990s (Kidwell, 2001). Imaging trials may also differ in design from stroke trials in general: By definition, imaging outcome studies would tend to be either Phase II trials or substudies of Phase III trials. Although an attempt was made to peer behind the "clinical trial veil" to investigate not the intent of the trial but the outcomes, the intentions of the investigators are paramount to both the design of the trial and the interpretation of the results.

A further suggestion that the clinical trials included here may not be representative of trials in general comes from the high proportion of positive findings: here, using the surrogate marker of infarct size, with 54% showing a smaller infarct size in the treated group compared with the control group and with 41% showing an improvement in the researchers' prespecified imaging hypothesis. Nevertheless, a similar finding was reported by Kidwell in the review of pre-2000 clinical stroke trials. Kidwell reported that 23% of trials had a beneficial outcome as defined by the authors, with 50% showing a beneficial trend or subgroup benefit. This was in spite of less than 2% of trials meeting strict criteria for a positive outcome.

Using outcome measures common in animal experiments may introduce bias from the clinical perspective. Clinical trials may use other imaging endpoints than absolute infarct volume (e.g., lesion growth). To some extent, investigators' trial design and hypotheses were acknowledged here when comparisons were made about whether the stated clinical imaging hypotheses were substantiated. But even if there is agreement between different types of imaging outcomes, the use of imaging outcomes may not show a uniformly high level of concordance with clinical outcome. If functional measures show no treatment effect in patients where an improvement in infarct size or growth has been observed, then it would suggest that volumetric analyses are flawed and the design of animal and human studies needs to be reassessed.

Adapting the metaanalysis to accommodate the many different endpoints in this comparison is the next logical step in this analysis. A broader and more balanced picture about the equivalence of animal and human trials will be achieved by extending this analysis to incorporate not only heterogeneity in imaging endpoints, but also the functional clinical scales and the primary clinical hypotheses. This project is currently underway and will enable questions to be addressed, which escaped the scope of the present review. For instance, is the variability the same with the NIHSS and infarct volume? How robust are the effect sizes? What was the primary clinical outcome and how did this change in outcome relate to changes in infarct volume? Is the variability the same with the NIHSS and infarct volume and how robust are the effect sizes? It seems logical that outcomes combining volume and measures of damaged tissue function will ultimately be required.

TABLE 20.14 Summary of Key Findings

Features		Findings
Studies	Exclusions	Clinical trials that lacked a control group (15%, N_T = 29/188 trials), lacked volumetric analysis of imaging data (18%, N_T = 34/188 trials), or failed to report treatment effects (12%, N_T = 23/188 trials) were excluded.
	Sample size	Clinical trials were 10 times the size of animal studies (N_P = 71 per clinical treatment cohort versus N_P = 7 per animal treatment group) but variance was substantially greater in clinical trials (average SD = 99% vs. 30%), so both were underpowered to the same extent.
	Quality	Random allocation to groups was done in 63% of clinical trials and 38% of animal experiments. Outcome was blinded in 84% of clinical trials and 32% of animal experiments. Mean quality in trials was 6.2/10 and ranged from 3.3 to 4.9/10 in past estimates of study quality in experimental metaanalyses.
Subjects	Sex	Ninety-four percent of animal studies were undertaken in male animals while clinical trials were conducted in both sexes (64% mixed, 26% sex not stated).
	Diabetes	Diabetes was 19 times more common in the clinical population than the animal population (26% vs. 1.3%).
	Hypertension	Hypertension was present in 66% of patients and 14% of animals.
	Age	Average age of patients was 66 years. Less than 1% of experiments (0.6%) used middle-aged or old animals.
	Species	Eighty percent of animal experiments were conducted in the rat, and of these 41% were in Sprague Dawley rats (32% of all experiments).
Infarct Size	Human stroke	The average infarct size was 47.4 cm³ (range: 5.3 cm³ (0.9% of the hemisphere) to 124.8 cm³ (21.1% of the hemisphere). *Median*: 51.4 cm³ (IQR: 34.0–70.0 cm³, 5.7%–11.8% of the hemisphere).
	Animal stroke	The average infarct size was 31% of the hemisphere (*median*: 29%, IQR: 19%–41% of the hemisphere).
	Comparative size	Animal strokes were on average 4 times larger than human stroke, measured as a percentage of the hemisphere (31% vs. 8%).
	Variability	Humans produced a more variable stroke (average SD = 99%) compared with animals (average SD = 30%). Of the animals, the rabbit (SD = 59%), guinea pig (SD = 52%), and cat (SD = 48%) produced the most variable infarct size and the gerbil (SD = 20%) and mice (SD = 24%) the least. Rats produced an average variability of 29%, with the SHR having the tightest model (average SD = 19%) and the Fisher 344 the most variable (average SD = 35%).
	Species	The rat (28%) and cat (27%) gave the largest average infarct volume and the hamster (4%), gerbil (8%), and primate (9%) the smallest. Where infarct sizes were reported in absolute terms, the infarcts were: mouse (M ± SD: 53.6 ± 12.9 mm³, N_T = 332), Gerbil (M ± SD: 57.9.1 ± 10.3 mm³, N_T = 3), rat (M ± SD: 172.4 ± 43.7 mm³, N_T = 1716), hamster (M ± SD: 14.4 ± 5.9 mm³, N_T = 14), rabbit (M ± SD: 525.7 ± 384.5 mm³, N_T = 24), cat (M ± SD: 2394 ± 4047 mm³, N_T = 23), primate (M ± SD: 3.76 ± 1.2 cm³ N_T = 9), and human (M ± SD: 47.36 ± 12.9 cm³, N_T = 39).
	Strain	The Hooded Listar (44%) and the SHR had the largest stroke (35%), and the Lewis the smallest (17%). Sprague Dawley rats (26%), diabetic rats (27%), and Wistar rats (32%) had intermediate volumes.
Cause of stroke	Animals	Forty-seven percent of animal experiments used the thread occlusion model (suture model) and 28% the cauterization model. Embolic models were less common (N_T = 9). Filament occlusion resulted in the largest infarct size expressed as a proportion of the hemisphere (32%) and the balloon or compression model the smallest (12%). Photochemical models (17%), endothelin-1 (22%), coagulation (20%), clip/ligation (25%), and embolic models (29%) had intermediate stroke sizes. Greatest protection was in the endothelin model (50% neuroprotection) and the embolic model (35% neuroprotection), and the lowest was observed in the permanent cauterization model (21% neuroprotection).
	Clinical	Etiology (TOAST criteria) was reported in 12 trials, with large vessel disease (N_P= 29%) and cardioembolism the most common (N_P 39%) and small vessel disease less common (N_P = 13%).
Location	Animals	Infarct volume was largest with occlusions of the MCA origin (32% hemispheric damage) versus MCA branch occlusions (20% hemispheric damage) or two-vessel (24%) or three-vessel occlusion models (23%). The three-vessel occlusion model (30% variability per experiment) and the two-vessel occlusion model MCA/CCA (36% variability) were no less variable than the distal MCA occlusions (25% variability) or proximal MCA occlusions (29% variability).

(Continued)

TABLE 20.14   Summary of Key Findings (*cont.*)

Features		Findings
	Clinical	Occlusion was most common at the M1 branch or M1 and extensions (N_P = 56%) and 24% at M2 or distal branches (N_P = 56%), with 13% at the ICA origin and 2% at the carotid T (N_T = 6, N_P = 470).
	Recanalization	Recanalization rates for clinical trials were (N_T = 4, N_P = 283): ICA origin occlusion (24%), carotid T occlusion (22%), M1 or proximal MCA occlusion (57%), and M2 or distal MCA/ACA occlusion (69%) with an overall rate of 48%.
	Reperfusion	Reperfusion injury is suggested in the thread models but not the clip/ligation models, possibly due to differences in basal ganglia and cortical susceptibility to this injury type (via edema, FRS, or collateral flow effects).
Temporal	Duration of occlusion	In animals, 45% of occlusions lasted less than 6 h, while 27% of animals had occlusions of 24 to 72 h. Durations of 6–24 h were conducted in 2% of animals, but may arise more frequently clinically. Infarct size in control animals reached a maximum value with occlusions of 1.5–2 h in the clip/ligation model and in temporary occlusions of greater than 3 h using the thread model. Permanent occlusion in the thread model leads to an infarct size 6% smaller than temporary ischemia, while there was no difference in the clip/ligation model.
	Treatment time	Treatment was administered within 3 h in 31% of trials and in 84% of animal experiments (where recorded N_T = 2982). Average time to treatment was 7 h (median = 4.1 h post stroke) for clinical trials, and 10 h prior to stroke onset (median = 5 min poststroke) for animal experiments.
	Outcome	The median time of outcome assessment was 1 day for animals and 8 days for patients. Average stroke volume for patients was 11.6% (day 1), 9.3% (day 3–7), 8.6% (week 1–2), and 7.8% (after week 2). Infarct volume for animals was 23.8% (<day 1), 30.8% day 1–2, 25.4% (day 2–3), 24.4% (day 3–7), 23.7% (week 1–2), 19.8% (after week 2).
Treatment	Animal versus clinical	Acute stroke interventions were associated with a 26% smaller infarct volume in animals receiving treatment, and an 18%–31% smaller volume in humans receiving treatment compared to the control group. However, there was no correlation between the overall performance of individual drugs in animal experiments and clinical trials. There was no agreement between the general direction of the estimated effect sizes of drugs from portioned metaanalyses of animal studies and individual trial results using the same drugs. However, there was fair agreement between the direction of the overall estimates from animal experiments and the overall estimates from clinical trials using the same drugs. Animal experiments underestimated the effect of tPA by 4.7% and overestimated the effect of other treatments on infarct volume by 8.13% (average 7.2%).
	Reporting method	Animal experiments were associated with a 25% reduction in infarct where reported as an absolute level, and a 30% reduction where reported as a percentage of the hemisphere (stroke volume did not differ). When results where reported as areas, the average reduction was 19%. Clinical trials were associated with a 29% reduction where reported as a mean and 18% reduction where reported as a median value.
	Species	The greatest level of neuroprotection was seen in the nonhuman primate (47%, N_T = 22 experiments) and the least in the hamster (−83%, N_T = 15 experiments).
	Strain	Efficacy was lowest in the F344 (18%) and highest in the Lewis rat (66%) and Hooded Listar (60%) perhaps because of differences in the inflammatory response.
	Pretreatment effect	Pretreatment differences in infarct volumes explained 31% of the variance in the final outcome (N_T = 31). Animal studies rarely had smaller infarcts in the control group prior to treatment, suggesting a selection bias for the treatment groups may be operating.
	Positive results	Animal experiments were more likely to show a reduction in infarct volume (86% experiments) than clinical trials (54% trials). Improvement in the prespecified imaging hypothesis was 41% in clinical trials.
	tPA versus other	Where a hypothesis was tested, 50% of tPA clinical trials were beneficial and 56% showed a reduction in infarct volume in the treated group compared with control. In animal experiments this was 71%. In drugs other than tPA tested in clinical trial, 35% met the prespecified imaging hypotheses and 52% showed a reduction in infarct volume (compared with 91% of animal experiments using the same drugs).

In addition to the theoretical validity of the review process, other prominent limitations of this review pertain to the search strategy and the method of analysis. The search strategy was limited, restricted only to PubMed, trial databases, cross-referencing and hand searching. Calculations of stroke size (as a percentage of hemisphere) relied upon assumptions—in many cases—about hemispheric volumes. Estimates of infarct size were also adjusted for the number of animals in each group, but not for the variance. Further, there was no easy method of how to deal with data presented as medians. We tried to get around this by presenting the pooled estimate of drug efficacy using three different methods, but in the future, the investigation of nonparametric metaanalysis methods may assist. Further, any hypotheses generated about factors relevant to clinical outcomes are hampered by the small number of clinical trials reporting subject and stroke characteristics or by the homogeneity of these populations. To obtain this kind of information, analysis of data from individual patients pooled across a number of trials would be more appropriate. Alternatively, clinical trials might provide more meaningful data if restricted to patients with similar characteristics—such as angiographic criteria—as suggested 20 years ago by Molinari (1988).

At the broadest level the adequacy of the statistical approach in drug trials is open to question, particularly with its neglect of individual differences (Hildebrandt, 2004). "Drug testing, as legally required today, has only arisen in modem times and is the result of an exchange between rational physiological medicine with its long-standing empirical therapeutics and the traditional natural historical school of the seventeenth and nineteenth centuries" (p. 847). Individual differences may be overlooked when gathering the information to generate information about efficacy, but this neglect may be replicated if these results are then reapplied to new patient groups without taking into account differences in this population.

It is also difficult to place a value on the contribution of animal models to something, which cannot be readily quantified—an idea, a theory, and an inspiration—something, such as circulation. Qualitative criteria—as largely used here—are not the only ones that matter. Nevertheless, they might provide some insight into factors important to experimental design, such as the choice of animal species in experiments and how to improve the translation of experimental results—factors discussed in the final part of this paper.

4.3 Findings From This Review

4.3.1 Mouse or Monkey

The choice of animal species is often influenced by practical considerations, such as the cost and availability of animals, access to appropriate housing, and what species can be squeezed into a brain-imaging scanner. Though these concerns are important, they are subordinate to the issue of ethics and concordance of the models with the human disease.

Primate research has been favored by some researchers because of the apparent face validity of these models. Although the infarct size generated in the primate model was similar to the humans (about 8% of the hemisphere), the level of neuroprotection was substantially higher ($M \pm SE$: primates: $47 \pm 3\%$, humans: $27 \pm 1.9\%$). By contrast, infarction in the rat occupies a larger proportion of the hemisphere than in patients (28% vs. 8%), but exhibits a similar level of neuroprotection ($M \pm SE$: rats: $26 \pm 0.2\%$, humans: $27 \pm 1.9\%$).

If rats are to be used to model stroke, and if the choice is determined by the need to obtain the most consistent infarct, then this study supports the use of SHRs. On the basis of similarity in infarct size to humans (as a percentage of the brain infarcted), then the results favor the use of the Lewis rat, as it has the smallest size stroke. However, on the basis of an equivalent level of neuroprotection to clinical findings, results would support the use of either the Sprague Dawley or the SHR. Other factors will, of course, guide decisions determining strain choice—especially genetics—as researchers attempt to model subtypes of patients and comorbidities and other individual differences.

4.3.2 Individual Characteristics and Initial Differences

Early last century, Garrison wrote "Primitive man... tried to treat the disease rather than the patient, not realizing... that the dynamic effect of a drug upon the patient's body depends as much upon the delicate chemical adjustments of that body as upon the composition of the drug itself (Garrison, 1929)." The importance of individual variability of patients has been studied in a number of clinical trials, with the finding that baseline characteristics including site of arterial lesion, hypoperfusion volume and clinical scores are predictive of therapeutic response (Adams et al., 1999; NINDS, 2000; Saqqur et al., 2007; Warach et al., 2000). For instance, in the citicoline trial smaller pretreatment lesions in the treatment group were associated with a positive outcome (Warach et al., 2000), while the converse was found in a tPA combination therapy trial (Seitz et al., 2004). Other researchers have focused on the interactions of preexisting inflammatory conditions and hyperglycemia (Kent et al., 2001).

Due to comparatively small sample size in animal experiments, initial differences have the potential to skew experimental results. In this review, in the few studies, which measured pretreatment stroke size, baseline

infarction explained a large portion of the variance in outcome. Characterization of pretreatment stroke size and use of outcome measures which reflect pretreatment stroke size—such as infarct growth—may reduce the possibility for this bias. More sensitive tools than neurological score or a laser Doppler reading may be necessary to rate the size of strokes in animals prior to treatment administration.

4.3.3 Mechanisms of Ischemic Damage

Can anything be adumbrated from this analysis regarding the mechanisms of stroke damage? All aspects of stroke models allude to the importance of blood flow in determining the outcome of ischemia. All factors that reduce blood flow tend to increase brain damage, including permanent occlusion in animals, failure to reperfuse in patients, and delayed reperfusion in animals.

A role for edema is also imputed by the differences between percentage and absolute measures of infarct volume in the animals. The importance of metabolic factors is suggested by data demonstrating that fasted animals have a smaller infarct volume and by the utility of hypothermia as a protective treatment in animals. Additionally, the influence of the choice of vehicle and the different response of those given glucose or cellulose-loaded vehicles also attest to the impact of metabolism on outcome.

A potential role for the inflammatory response comes from an observation about stroke volumes. Interestingly, there is a suggestion that brain volumes from stroke patients tended to be larger than brain volumes from cohorts of a similar age and sex but without a history of stroke (Janssen et al., 2007; Tupler et al., 2007). These differences persisted even after several months. Edematous changes are believed to resolve within the 1st week or so after stroke, suggesting that a persistent residual level of brain inflammation may contribute to the larger size of stroke brains. A recent study of brain sizes has found that of the inflammatory markers tested, only the CD40 ligand was associated—albeit nonsignificantly—with increasing brain size (Jefferson et al., 2007). Interestingly, the plasma CD40 ligand has been linked to stroke (Duygu et al., 2008; Ferro et al., 2007). Given the incidence of asymptomatic stroke in the population, brain volume may be a useful marker for identification of patients at risk of stroke.

4.3.4 Framework for Translational Research

Much effort has been directed toward trying to explain the failure of animal models to predict clinical trial results (Green et al., 2003; Millikan, 1992; Molinari, 1988; Zivin and Grotta, 1990; Wiebers et al., 1990). The most easily remedied outcome would be if the failure was attributable to insufficient rigor in experimental design,

both on the part of scientists through a failure to tame potential sources of bias with blinding, randomization and adjustments for pretreatment levels of damage, and on the part of the clinical personnel, in attempting to apply treatments to heterogeneous populations in time frames beyond which they have been shown to be effective and without using comparable control groups.

Failing that, the next best outcome would be if the experimental parameters and endpoints themselves require modification. The validity of animal models may be compromised by experimental factors, such as the control of respiration, the use of anesthesia, the artificiality of the occlusion device and the failure to provide adequate social and environmental stimulation for normal neuronal network development. Such a scenario would require adaptation of existing models.

A more challenging scenario would be if the failure were attributable to a lack of resemblance in the physiological processes of different species, perhaps due to scaling and vascular dissimilarities. Smaller brains have different patterns of fluid and heat transport, and network connectivity: the importance of these factors has not yet been fully evaluated. Qualitatively different types of tissue might also be destroyed in brains of a different scale. For instance, the hypothalamus is commonly damaged in longer occlusions using the suture model in rodents (Li et al., 1999). This may result in disturbances in temperature homeostasis, osmotic regulation, and the hypothalamic–pituitary axis stress response. This type of damage might not be evident if the results are given as a total infarct volume or if hypothalamic damage is subsumed as "subcortical" damage. Similarly, amygdaloid nuclei are sometimes demarcated as "cortical" tissue in rat models. Standardized terminology and the development of software for automated morphing of images into brain atlases may overcome some of these problems.

A new challenge to the relevance of animal models comes from the intriguing work of Garosi and coworkers documenting the imaging of spontaneous strokes in dogs. Dogs are one of the few species where strokes have been documented to occur spontaneously in nature (or at least, to occur in urban areas near veterinary surgeons with animal MRI equipment). A remarkable thing about the location of infarcts in these dogs is that it differs markedly from that induced in animal models of stroke. The location of the infarct typically occurs more posteriorly, with a greater preponderance of occlusion in the rostral cerebellar artery (15 of 33 dogs) (Garosi et al., 2006). Few dogs had MCA occlusions (4 of 33 dogs) (Garosi et al., 2006). The dog does have some peculiar vascular features, which may prevent MCA occlusions, such as a well-developed set of extraintracranial arterial anastomoses, which would facilitate blood flow to the brain in the event of occlusion (Daniel et al., 1953;

TABLE 20.15 Recommendations

Features	Finding
Reporting	All studies report mean, SD, median and range
	Report statistics for individual drugs, even if not statistically significant and even if the focus of the paper is not the treatment but some other factors, such as imaging algorithms
Pretreatment	Evaluate measures of brain damage before treatment (whether imaging or blood flow)
Control group	Use historical controls with caution
	Report drugs given in the human control group
	Consider the use of a tPA, best medical care, or other positive control in animal experiments
Endpoints	Develop scale independent endpoints or methods to assist in translation of results between animal and clinical fields

Jewell, 1952). Even so, surgically inducing a stroke in tissue not usually the target of stroke in humans does raise the issue of the realism and generalizability of such an animal model.

"Natural" stroke has also been studied in rats, in the genetically modified strain stroke-prone spontaneous hypertensive rat (SPSHR) model. In this model, infarcts tend to occur in the medial cortex (in regions sometimes called "border zones") (Yamori et al., 1976), rather than laterally as it does when stroke is surgically induced. One third of occlusions occur occipitally, again somewhat differently from the typical MCA lesion pattern in animal models

Establishing the equivalence in the progression of the infarct in animals and humans, and a methodology to scale and transform the experimental results to accurately predict clinical outcomes is a necessary prerequisite for the use of animals as drug-screening tools. Failure to establish equivalence in physiology may sound the death knell for use of existing animal models for efficacy testing, though not necessarily for generating and testing hypotheses about the pathophysiology of ischemia. Nevertheless, more studies are needed to assess the vascular, neuronal, and genetic differences in humans and animals used in stroke research if we are to determine their relevance.

For the purpose of evaluating translational research, it would be useful if both animal and clinical trials reported data for all relevant summary statistics (including means and medians), together with inclusion and exclusion criteria (Table 20.15). This is especially so in the case of clinical trials where data may be archived, as was the case for several clinical trials in this review. The development of novel, reproducible, and scale-independent endpoints will also assist with the measurements of treatment effects. Algorithms for the adjustment of endpoints for scale and pretreatment characteristics, and alternative measures, such as combined efficacy and safety data may also be useful (Dawson et al., 2001). Animal

experimentalists might consider also using best medical care as a positive control group. All such factors are easily remedied by exercising adequate control over the experimental design phase.

5 CONCLUSIONS

"Whenever many different remedies are proposed for a disease, it usually means that we know very little about treating the disease, which is also true of a drug when it is vaunted as a panacea or cure-all for many disease" Garrison (1929), p. 25. And so it is for stroke: many drugs have been tested in animal models of stroke, and by and large we've been short changed. But is it reasonable to expect that libraries of compounds or treatments imported from other areas of medicine will serendipitously toss up the next "penicillin" for stroke? May be, may be not. Adherence to this course of action is more than likely fuelled by underfunding of stroke research than by the belief that this is the optimal course of action. But the risk of second-hand science is the prospect of second-class results. Arguably, it is not the animal models, which have failed, but the neuroprotection research strategy.

The future landscape of stroke medicine may be very different. Effective primary prevention strategies may reduce the need for acute stroke treatments or change the nature of the disease itself, as might the aging of the population. Human imaging and genetics promise to reduce the historical reliance on animal models. Nevertheless, current costs provide hurdles to wholesale introduction of these technologies in the immediate future, so in the interim, treatments should ideally be tailored to fit the disease, not the disease-model or the budget. This may necessitate a return to first principles and greater emphasis on understanding the fundamentals of stroke pathophysiology (Dirnagl et al., 1999; Lo et al., 2003).

ACRONYMS

M	Mean
SD	Standard deviation
N_T	Number of clinical trials or experiments
N_P	Number of patients or animals
IV	Infarct volume
MCA	Middle cerebral artery
ECA	External carotid artery
ICA	Internal carotid artery
M1-6	Categorization of the branches of the MCA used for the description of the human cerebrovasculature
STAIR	Stroke Therapy Academic and Industry Roundtable

The Importance of Olfactory and Motor Endpoints for Zebrafish Models of Neurodegenerative Disease

Angela L. Shamchuk, W. Ted Allison, Keith B. Tierney

University of Alberta, Edmonton, AB, Canada

1 INTRODUCTION

1.1 The Function and Importance of Olfaction

Olfaction or the sense of smell is the process of odorant reception and interpretation by neuronal tissue. This aspect of the sensory system is important to animal survival because odorants provide cues for essential behaviors such as foraging, mating, and predator evasion. Outwardly, humans do not have the same dependence on the olfactory system for survival; however, they do retain similar capabilities. Although often overlooked, the sense of smell has a significant effect on human behavior and emotions (Stevenson, 2010). Not only can we recognize certain odors and interpret them accordingly, but we also learn to associate certain odors with memories and positive or negative experiences (Table 21.1).

Due to the emotional associations with certain odors, the olfactory system is considered important for quality of psychological life and its impairment has thus been associated with cases of depression (Pause et al., 2001). The decrease in quality of life associated with individuals who have olfactory deficits is largely due to paralleled impairments in eating, safety, personal hygiene, and sex life (Hummel and Nordin, 2005).

Deficits in olfaction also represent accessible symptoms to aid in clinical diagnosis of neurodegenerative disease. Diagnosis of neurodegenerative disease is a key challenge because discriminating between similar diseases is critical to proper disease management, early diagnosis is believed to be central to effective intervention, and accurate measures of disease progression remain a fundamental challenge in assessing treatments in experimental trials.

Although chemosensation is not essential to survival, specific odors will stimulate behaviors that can be considered attractive or aversive. The same is true for animals, and while sensitivity thresholds, specific odorants, and behaviors vary across vertebrates, the major anatomical and neurophysiological components that make up the olfactory system are conserved across many species (Ache and Young, 2005; Tierney, 2015). In general, the process of olfaction involves three stages: (1) odorant binding to a specific receptor on an olfactory sensory neuron (OSN); (2) a cascade of intracellular events leading to neuron depolarization; and (3) signal relay to the olfactory bulb for interpretation via comparison of OSN depolarizations. To facilitate odorant–receptor interaction, OSNs are exposed to the external environment, typically as part olfactory epithelia in the nasal pit or cavity. Odorants are believed to bind or otherwise interact with OSN receptors in a manner ranging from the specific (lock and key) to the general (Amoore, 1964; Brookes, 2011; Doty, 2010). Some receptors are believed to exhibit steric interaction with multiple odorants that are structurally similar, but bind to them with different affinities. Following this theory, receptors on OSNs are odorant specific to varying degrees and receptor expression is variable across species. Most commonly, the receptors in question are G-protein coupled, and upon odorant binding, G-protein activation results in one of two known signaling cascades (adenylyl cyclase/cyclic-AMP or phosphoinositide/IP_3) resulting in a neuron depolarization. If the signal from the activated neuron is sufficiently strong, an action potential may be conducted along an axon to the olfactory bulb in the brain. At the level of the brain, the odorant is interpreted and physiological or behavioral responses may ensue. A more detailed explanation of anatomy and neuronal process is beyond the scope of this chapter, but is reviewed in Ache and Young (2005) and Firestein (2001).

1.2 Olfactory Dysfunction

Deficits in olfactory function can occur at several levels of the olfactory system and to varying degrees. Typically, olfactory distortions present in one of three ways (Leopold, 2002). The first type refers to a decreased ability to perceive odors from partial (hyposmic) to complete (anosmic) loss of olfactory sensitivity. The two remaining types of dysfunction involve a change in odorant perception (dysosmia). The two known types of change refer to either odorant perception in an odorless environment (phantosmia) or a change in odorant perception, that is, odors are perceived incorrectly (troposmia). These conditions represent the main problems associated with olfactory dysfunction in general: detection, identification, and distinction. The etiologies for each dysfunction are variable, and documented cases suggest potential malformation, damage, or degeneration of the chemosensory tissues (Table 21.2). To investigate the relative frequencies of causes, a study examined 278 patients with olfactory dysfunction and found the proportions of causes to be posttraumatic (17%), postviral (39%) sinonasal disease (21%), congenital (3%), sporadic (18%), and other (3%) (Temmel et al., 2002). Congenital olfactory disorders (a relatively small proportion of cases) are unique in that they are typically the result of genetic defects that prevent either partial or entire olfactory tract or bulb development (Yousem et al., 1996). These disorders are usually part of congenital syndromes and thus accompany other major physiological abnormalities such as hypogonadism in Kallmann's and Bardet-Biedl syndromes (Hummel et al., 1991; Iannaccone et al., 2005). The other potential causes are related to damage inflicted upon the olfactory system. For example, case studies have demonstrated associations between exposure to metals, industrial agents, and pesticides and morphological and functional damage

(Smith et al., 2009; Sunderman, 2001; Upadhyay and Holbrook, 2004). Despite the rarity, it is important to note the permanence of damage-induced olfactory loss in cases where the tissue cannot fully recover. As an example, there is a case study of a head trauma patient who experienced anosmia following injury with an eventual shift to dysosmia (phantosmia) and reported the consistent detection of a "rotting garbage" odor (Kern et al., 2000). Tissue samples from this case indicated incomplete regeneration of the olfactory tissue following damage. There are also anecdotes that a change in smell or perception of "burning toast" indicates a stroke or heart attack, although this is not substantiated, but is not without some logic.

Natural aging and degeneration of sensory tissue is also a common source of olfactory loss. Whether or not increased damage over time or decreased ability to repair damage is the route of olfactory senescence has not been determined. Nevertheless, it has been documented that with increased age there is a higher incidence of olfactory dysfunction which supports a natural loss of sensory skill with an aging brain (Robinson et al., 2002; Wong et al., 2010). Functionally, elderly people show a reduction in abilities related to odor identification, memory, and sensitivity (Lehrner et al., 1999). In terms of pathological changes, little is known about neuronal modifications in healthy human aging and even less that is specific to the olfactory system (Dickstein et al., 2007). However, it is well known that older cohorts of individuals are more likely to be diagnosed with several neurodegenerative diseases that are also associated with, and likely causative of, olfactory dysfunction. Pervasive challenges in early diagnosis of neurodegenerative disease make it difficult to discriminate whether olfactory dysfunction in elderly populations represents healthy aging versus undetected early stage neurodegeneration.

1.3 Neurodegenerative Diseases and Loss of Olfaction

Prior to association with neurodegenerative diseases, little was published concerning olfactory inconsistency and disease. Investigations began in the industrial world as early as 1947 in relation to olfactory loss in varnishing industry workers, and following this work, subsequent industry related studies followed (Joyner, 1963). Along the same lines as chemical disturbances and olfaction, smoking and effects on olfactory deficit were also investigated (Joyner, 1964). Surprisingly, the first published association between olfactory dysfunction and neurodegenerative disease did not appear until 1975, and it described the symptom in patients suffering from Parkinson's disease (PD) (Ansari and Johnson, 1975). Since then, researchers have shown many cases of correlation between olfactory deficiency and neurodegenerative disease with varying severity (Table 21.3).

Olfaction–disease associations have resulted in a multitude of theories concerning not only the route and targets in the pathogenesis, but also the validity in identifying hyposmia and anosmia as disease precursors. Alzheimer's disease (AD), PD, Huntington's disease (HD), multiple system atrophy (MSA), and amyotrophic lateral sclerosis (ALS) all have associated olfactory loss in conjunction with cognitive symptoms and neuropathological markers. Interestingly, the diseases in question, perhaps excluding AD, also exhibit varying degrees and types of defective motor skills. The diseases also have specific cognitive and neuropathological markers (Table 21.4). Each condition is associated with the development of unique neuronal protein aggregates as well selective neuron loss. By investigating both the similarities and differences between these diseases, researchers are beginning to provide insight into their acquisition and progression (Leighton and Allison, 2016).

1.4 Disease Models and Olfactory Focus

Despite all the challenges, uncertainty and complexity of assessing patients for externally manifested symptoms such as cognitive, olfactory, and motor performance, such tests are relatively simple in contrast to those that define causality of disease progression and etiology, which is limited to biomarkers, noninvasive imaging, and postmortem histological analysis. As a result, researchers rely heavily on simulating these diseases in animal models to gain an understanding of pathogenesis, as well as to establish platforms for testing of potential treatments. Classically, studies have relied heavily on rodents due to their genetic and physiological similarities to humans. However, recent developments in zebrafish (*Danio rerio*) have allowed them to emerge as a viable complementary model of human neurodegenerative diseases. The zebrafish genome has been fully sequenced, being the most thoroughly annotated genome available after human and mouse. Many methods of genetic modifications are evolving quickly in zebrafish. Despite being nonmammalian, zebrafish have general vertebrate anatomical structures and many human genes have high sequence similarity and are functionally conserved. In addition, their relatively modest cost, high fecundity, and ability to breed throughout the year enable high throughput in vivo screening of phenotypes, which is invaluable to forward genetic and pharmaceutical studies. To facilitate their application, the scientific community has developed resources such as ZFIN: The Zebrafish Model Organism Database and

Zebrafish International Resource Center for information sharing concerning zebrafish research to enhance knowledge and future discovery. For these reasons, zebrafish represent an alternative for fast and economical investigatory and therapeutic studies of neurodegenerative disease. The use of zebrafish continues to grow, with expanding examples of neurodegenerative disease models (Benedetti et al., 2016; Das and Rajanikant, 2014; Lattante et al., 2015; Li et al., 2015; Liu et al., 2015; Newman et al. 2014a; Sarath Babu et al., 2016; Schmid et al., 2013; Veldman et al., 2015; Yu et al., 2015). Through studies applying "omics" and systems biology approaches, rich information can be produced about how treatments of interest impact upon the diseases in question, allowing zebrafish studies to contribute to future modeling and serve as an effective comparator to mouse models.

Intriguingly, for the zebrafish models that exist, behavioral and physiological assays using olfaction are rare. However, this can also be said of rodent models; despite the prevalence of loss of olfaction in neurodegenerative diseases (Table 21.3), olfactory endpoints are also rare (Glasl et al., 2012; Ubhi et al., 2010). The techniques established for sensory assessment therefore hold a great deal of unexplored potential. This chapter describes the current methods used to model certain neurodegenerative characteristics in zebrafish and suggests novel applications for established techniques to enhance future studies.

2 BUILDING RELEVANT MODELS

In modeling human disease in animal models, the goal is to create a condition that recapitulates the symptoms, pathology, and/or molecular events of the disease as closely as possible. Techniques typically used in zebrafish exist in two distinct categories: genetic and nongenetic.

2.1 Genetic

As defects in genes or gene products are common contributors to the development of disease, studying the phenotypes that result from induced gain and loss of function can help elucidate normal gene activity and pathogenic events. Typically, genetic engineering to create animal models of disease has a necessary focus on familial forms of disease that are the minority of patient cases; the so-called "sporadic" forms of disease, that is, those with no clear genetic link or insult to begin the disease progress, are prominent in patients and remain very challenging to model in any animal system because they cannot (almost by definition) be predictably induced.

Here we describe methods for gene knockdown and overexpression in zebrafish, allowing tractable in vivo

assessment of disease-related outcomes. In the diseases of interest herein, the causal mutations typically lead to misfolding and aggregation of proteins, and animal modeling has focused on overexpression of aggregating disease-related gene variants. However, such protein misfolding also results in at least partial loss or subversion of protein function (Leighton and Allison, 2016), such that gene knockdown and mutagenesis approaches can inform disease etiology. We begin by discussing methods of transient gene knockdown and overexpression in zebrafish that are suitable for assessing embryos and larvae, and subsequently review methods enabling long-term and progressive genetic impacts.

Although many tools are currently available to zebrafish, not all of them have been applied to modeling the diseases in question, but in future will serve as novel approaches to existing problems [Skromne and Prince (2008) provides a review of genetic manipulation tools in zebrafish]. It is also noteworthy that the diseases in question are generally associated with aging, and are late-onset progressive diseases, whereas much of the technological innovation surrounding zebrafish genetics and drug screening has centered on early development as a natural consequence to zebrafish being originally introduced as a model of vertebrate development rather than degeneration. Thus, disease modeling in zebrafish may, in some instances, be most powerful when it is designed to represent in vivo modeling of physiological or molecular aspects of disease etiology, rather than end-stage degeneration and process that generally occur only in aged patients. Despite this history of zebrafish technologies having a focus on early development, several instances of modeling and measuring disease progression exist (DuVal et al., 2014; McGown et al., 2013; Ramesh et al., 2010), enabled by transgenesis and adapting the techniques from comparative fish physiology used to asses adults of other fish species.

2.1.1 Morpholinos

The use of antisense morpholino oligonucleotides (morpholinos) in embryonic zebrafish was first demonstrated to be an effective method of transient loss-of-function in 2000 (Nasevicius and Ekker, 2000). Morpholinos, as modified oligonucleotides, bind target mRNA and block translation, thereby knocking down gene expression; alternatively, morpholinos can induce abnormal intron inclusion or skipping and thus modify (abrogate) protein production. Embryos are injected at the one cell to four stage, and efficacy can last for up to 5 days but may vary with dose or transcript and/or protein kinetics (Bill et al., 2009). Along with established controls for efficacy, microinjection of synthetic target mRNA is coinjected to show phenotype rescue and control for morpholino specificity (Bedell et al., 2011; Bill et al., 2009), whereas delivery of null mutant mRNA should fail to

rescue the same phenotypes (Bedell and Ekker, 2015a). With the recent advent of practical targeted mutagenesis (see later), additional controls may be advisable such as demonstrating that the morpholino has no effect in zebrafish carrying null mutations in the target gene. However, this latter control requires fulfilling the rarely met assumption that phenotypes resulting from acute partial loss of function (via morpholino) will be similar to phenotypes resulting from long-term loss of function; in the latter, breeding strategies to recover mutants are obliged to select for individuals that compensate for lack of the gene product (Rossi et al., 2015). The temporary nature of this microinjection knockdown typically limits observations to early life stages, which can be challenging when attempting to model an adult-onset disease. Furthermore, genes of interest often have multiple roles in development, resulting in off-target effects presenting as lethality or physical abnormalities. Nevertheless, morpholinos provide insight into gene function through temporary deficiency. Studies discussed further on in this chapter have already used morpholinos to target certain genes related to neurodegenerative diseases and have been able to induce the desired phenotypes in zebrafish. However, a recent advancement in this method called a photomorpholino or photo-caging remains rarely applied to disease target genes. Photomorpholinos (sense and antisense) are a novel technique that allows gene function to be manipulated when desired through ultraviolet light exposure (Deiters et al., 2010; Tallafuss et al., 2012). Photomorpholinos can be controlled temporally and spatially and be as specific as single-cell activation (Shestopalov et al., 2007; Tallafuss et al., 2012). The targeting and temporal control available with a photomorpholino could provide interesting results if applied to specific brain structures such as the olfactory bulb. Another recent way to control spatial and temporal morpholino action is through electroporation (Cerda et al., 2006; Thummel et al., 2006). With this technique, targeted electrical current temporarily changed the permeability of cells, which allowed for the entrance of morpholinos into the organism. Although photo-caging and electroporation have not yet been widely applied to disease modeling, they have potential for future application. Until then morpholino-mediated knockdown in general is the most common approach of initiating loss-of-function in zebrafish.

An alternative to morpholinos that is on the horizon for gene knockdown in zebrafish is CRISPRi (CRISPR Interference). This requires delivery of guide RNA designed to bind the transcript of interest, along with CRISPR/Cas9 as per emerging methods targeted mutagenesis (see later), except that the Cas9 is catalytically inactive and instead of cutting DNA remains bound and represses translation (Larson et al., 2013; Long et al., 2015). This approach has potential to be an effective complement to morpholinos, as it will be an independent method to assess the effects of acute gene knockdown, though it will certainly require the thorough controls for efficacy and specificity that have come to be expected for assessing outcomes of morpholino delivery in zebrafish (Long et al., 2015).

2.1.2 mRNA Injection

In addition to being used as a rescue control for morpholino work, mRNA can be injected into embryos to investigate the transient effects of overexpression (Kelly et al., 1995). Gain-of-function is an effective approach for studying gene function by inducing expression spatially and/or temporally where it would otherwise not be present or be present at lower levels. Methods remain limited to microinjection, and as with morpholinos, the use of photo-caging and electroporation may be applied to enhance the spatiotemproal specificity of expression (Ando et al., 2001; Cerda et al., 2006; Skromne and Prince, 2008). This technique may also be used to investigate loss-of-function by comparing results of wild-type versus mutant or nonfunctional mRNA, or can be used to overwhelm endogenous gene expression via production of a dominant-negative protein (Koos and Ho, 1998). Both types of construct injection have been integral in the existing studies of neurodegenerative disease.

2.1.3 Transgenics

Animal modeling in neurodegenerative disease has frequently utilized overexpression of human disease-related gene variants. Transgenic zebrafish can be used in this fashion, and have essentially had exogenous genes added to their genome, and as such can be used for many different experimental applications such stable overexpression, dominant-negative mutation expression, and general analysis of gene regulation. Another common use is the expression of fluorescent proteins in cells of interest to allow monitoring of the health of specific cells or tissues following genetic or chemical treatment. Fluorescent reporters deployed in zebrafish can report a myriad of gene functions and cell states, such as abundance of intracellular signaling [retinoic acid abundance (Schilling et al., 2016) or Wnt signalling (Dorsky et al., 2002)], cell death (McCutcheon et al., 2016; van Ham et al., 2010), or genetically encoded calcium imaging to reveal neuronal activity (Fosque et al., 2015; Kim et al., 2014). Transgenesis can be induced in a variety of ways and manipulated for temporal and tissue specific expression; however, this chapter will not go into the specific mechanisms of action (Skromne and Prince, 2008). The three established methods for transgenic generation in zebrafish use microinjection or electroporation of either linearized DNA, meganuclease, or a transposon into single-cell embryos (Sager et al., 2010). The most commonly used method in zebrafish involves

microinjection of embryos with a plasmid DNA (construct) composed of the transposase mRNA and transposon (often Tol2) (Clark et al., 2011; Kawakami, 2004; Kawakami et al., 2004). The insertion can then be passed on to approximately 50% of the progeny. In the last few years, transposon-mediated transgenesis has allowed for effective use of Cre/lox constructs which is a critical technique in mice (Hans et al., 2009). Transgenesis has become a common method for disease model creation and several models currently exist pertaining to neurodegenerative conditions (Sager et al., 2010).

2.1.4 Zinc-Finger Nucleases and TALENs to Induce Mutations

Zinc-finger nuclease (ZFN)-mutagenesis is currently one of the few methods to create a genetic knockout or permanent mutation in zebrafish. The lack of an effective method is a significant disadvantage in comparison to rodent models, especially in relation to disease modeling where long-term mutation is relevant; however, ZFN is a potential technique in development. Embryos are injected mRNA which encodes DNA-binding proteins fused to endonucleases that cut DNA (Bandmann and Burton, 2010; Fleisch et al., 2013; Gupta et al., 2011; Meng et al., 2008). The proteins then create double strain breaks in the gene of interest to which they have been targeted. Cellular repair of the induced break is prone to error leading to a stable mutation (often a small insertion or deletion that causes a frame shift and truncated protein) in the appropriate gene. An alternative to ZFNs in zebrafish is TALENs (transcription activator-like effector nucleases) that work on a similar principle of creating DNA-binding domains to target a gene of interest, fused to endonuclease domains to cut the target DNA (Sun and Zhao, 2013). Both ZFNs and TALENs require substantial expertise and time to construct prior to delivery to zebrafish. Researchers worked to perfect and enhance the success rate of these costly method to expand its use (Foley et al., 2009; McCammon et al., 2011; Pillay et al., 2013); however, the technology has been supplanted by CRISPR/Cas9 which is easier to deploy and more efficient.

2.1.5 CRISPR/Cas9 to Induce Mutations

The approach to targeted mutagenesis in zebrafish using CRISPR/Cas9 can be very similar clustered regularly interspaced short palindromic repeats (CRISPR)/ CRISPR.

CRISPR-associated protein 9 type II (Cas9) system (Armstrong et al., 2016) can be very similar to that described earlier using ZFN or TALENs. In each instance one can target a gene of interest to induce a cut in that DNA sequence, and repair of said cut is error-prone, thus leading to frame shifts and nonfunctional protein products. The CRISPR/Cas9 protein complex is directed to the target DNA by a guide RNA (gRNA) that is complementary to the DNA of interest, enabling cutting of the target DNA. The appeal of CRISPR/Cas9 is that, once operational in a laboratory, it is rather straightforward to generate gRNAs designed to cut the target DNA, and several sites can simultaneously be targeted within many genes to increase success rates and/or produce larger mutations such as exon deletions and clear null alleles. Although producing gRNAs is straightforward for molecular biologists accustomed to such work, it should be noted that the effort to generate a stable mutant line remains resource-intensive with respect to time, husbandry space, and technical work. Regardless, the CRISPR/Cas9 system has already produced intriguing mutants in zebrafish (Hruscha et al., 2013; Hwang et al., 2013; Jao et al., 2013). Caution is warranted with respect to whether mutations produced are null alleles, as in some instances insertions or deletions created in the target gene may not disrupt the gene in a straightforward manner; downstream translational start sites, phantom exons, and copy number variants all have the potential to confound the approach. Furthermore, specificity of the mutagenesis methods must be assumed to be imperfect and creating other mutations throughout the genome, such that any phenotypes observed must be proven to be causally linked to the engineered mutation of interest. Finally, genetic compensation for mutations may be substantial in zebrafish (Bedell and Ekker, 2015b), wherein acute gene knockdown produces phenotypes that are demonstrably specific, yet mutations in the same gene produce no overt phenotype and confound analysis.

2.1.6 Zebrafish Knock-In

Until recently a major limitation to disease modeling in zebrafish was the inability to edit DNA as is done to successfully model disease genetics in other model systems. The introduction of targeted mutagenesis to zebrafish, especially the efficient CRISPR/Cas9 system, promises to enable genome editing in zebrafish. Briefly, one delivers CRISPR/Cas9 with targeted gRNA as described earlier to induce cuts in a target gene; alongside this one delivers a synthetic section of DNA with high percent identity to the region being altered, to serve as a template that is used to repair the DNA. The synthetic donor DNA template can be manipulated to encode various disease-related mutations or other genetic elements, promising great flexibility in how diseases are modeling in zebrafish. The approach has already allowed engineering of several unique zebrafish strains (Armstrong et al., 2016; Auer et al., 2014; Bedell and Ekker, 2015b; Irion et al., 2014; Kimura et al., 2014).

2.1.7 Gene Targeting

Due to the current limitations of morpholinos and ZFNs, another method has been developed in an attempt to obtain a stable genetic knockout in zebrafish. A strategy

called TILLING (Targeting Induced Local Lesions in Genomes) combines chemical mutagenesis (e.g., N-ethyl-N-nitrosourea) with high throughput genetic screening to identify animals with the mutations of interest (Wienholds et al., 2003). This protocol has successfully created genetic knockouts in zebrafish modeling fragile X-syndrome and its success hints at application to neurodegenerative genes of interest (den Broeder et al., 2009). TILLING provides an attractive knockout alternative to ZFNs.

2.2 Nongenetic

Although genetic manipulation is very effective at inducing the appropriate defects, there are certain compounds that mimic the neurological loss and the locomotion phenotypes specific to the diseases in question. Further merit to this method is supported by reported instances of neurodegenerative disease correlated with toxic exposure (Gorell et al., 1998; Li et al., 2014; Smith et al., 2009). Treatments that evoke responses can be carried out via environmental contact (aqueous solution), ingestion, or injection. The methods of treatment can potentially yield different or off-target results, and therefore the likely mode of exposure for humans as well as the most relevant induced phenotype must be taken into consideration when evaluating these models. The neurological disorders discussed in this chapter are commonly modeled in this fashion and successfully express appropriate disease characteristics (Anichtchik et al., 2004; Bretaud et al., 2004; Lee and Freeman, 2016; McKinley et al., 2005; Pinho et al., 2016). Even so, there are some compounds that have been tested in rodents that have yet to be tested on zebrafish (Beal et al., 1991).

2.3 Genetic and Nongenetic Summary

By attempting both genetic and chemical types of models separately or in concert, researchers gain not only more information about pathogenesis, but also potential therapeutic and preventative measures. The methods described here have been applied in some capacity to investigate zebrafish olfactory and neuromuscular systems. For example, transgenic expression of fluorescent proteins has been used to visualize motor and olfactory neurons (Higashijima et al., 2000; Yanicostas et al., 2009). Direct modification of these systems helps elucidate functional and developmental aspects that may be relevant to disease pathogenesis. However, in terms of modeling neurodegenerative diseases, studies tend to target already suspected genetic and chemical links to replicate the symptoms observed in humans. As motor and olfactory deficits are characteristic symptoms of the diseases discussed here, it is important to examine related endpoints in animal models.

3 OLFACTORY–NEUROMUSCULAR DISEASES

3.1 Parkinson's Disease

The first official documented study on PD was described as a shaking palsy and is accredited to James Parkinson's essay in 1817, which described several case studies (Parkinson, 2002). Over time, closer examination of symptomatic and postmortem patients led to an array of recognizable disease characteristics. PD is now classified as a progressive disease largely affecting the motor system with generally middle-age onset, although incidence increases with age (Dauer and Przedborski, 2003). Currently, PD is the second most common neurodegenerative disease.

The hallmark physical manifestation of PD is tremor or shaking palsy. Although it is easy to identify when present, clinical expression between patients is variable and may or may not appear in conjunction with bradykinesia (slowness of movement), rigidity, and postural difficulties. As a result, a PD-specific tremor is classified as such only when associated with a positive neurologically based diagnosis (Dauer and Przedborski, 2003; Deuschl et al., 1998). The neurological traits primarily involve loss of nigrostriatal dopaminergic (DA) neurons in the substantia nigra leading to dopamine depletion in the striatum and the development Lewy bodies (abnormal intraneuronal protein aggregates). Although DA neuron loss is considered the hallmark of PD, neurodegeneration and Lewy bodies affect other parts of the brain including the amygdala and the olfactory tract and bulb (Braak et al., 2003). Mitochondrial dysfunction, with respect to complex I in particular, in the affected neuronal areas has also been linked to PD and may be linked to both sporadic and familial causes of PD (Büeler, 2009).

Olfactory impairment in PD patients was first noted in 1975, and it has been shown repeatedly that defects in sense of smell can be severe, stable, and may occur in PD cases as frequently as tremor (Ansari and Johnson, 1975). Those affected have impairments in odor detection (thresholds), discrimination, and identification, although it is important to note that with reduced detection ability, discrimination and identification also prove more challenging (Boesveldt et al., 2008; Tissingh et al., 2001). Since discovering the link between compromised olfaction and PD, impaired smell has been used as an early indicator of PD, and has been suggested as a valuable screening tool because it can predate clinical PD by approximately 4 years in men (Ross et al., 2008, 2012). First-degree relatives of individuals with PD that had idiopathic olfactory dysfunction had 10% increased chance of developing the disease (Ponsen et al., 2004, 2009). Postmortem studies of olfactory bulb and tract in patients showed Lewy bodies to be most numerous in the anterior olfactory nucleus (AON), which is an essential brain structure for odor processing (Hawkes et al., 1997).

PD patients may also have an olfactory bulb volume ~70% of normal (Brodoehl et al., 2012). Lewy bodies localized to olfactory tissue in presymptomatic cases of PD further support olfactory function as a preliminary test for diagnosis (Dickson et al., 2008; Ross et al., 2006).

The etiology of PD can be case specific, and as with most diseases, there are idiopathic and familial examples (Dauer and Przedborski, 2003). Numerous genetic mutations have been found in PD patients, which have led to focused genetic investigation. Furthermore, certain pesticides such as 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), paraquat, and rotenone have been shown to induce PD-like phenotypes in humans and animal models, although evidence is insufficient to conclude that exposure is the definitive cause of sporadic PD. Even so, several studies suggest that people living in rural environments with increased exposures to such chemicals have a greater chance of developing PD (Gorell et al., 1998; Priyadarshi et al., 2001). The suspected etiologies have led to studies pertaining to disease-related genes, toxins, and these routes in combination (Table 21.5).

TABLE 21.5 Zebrafish Models of Parkinson's

Target	Method	Phenotype	References
PARKIN	Morpholino/gripNA™ knockdown	Increased cell death post proteotoxic stress (heat shock) Conflicting evidence concerning mitochondrial dysfunction and DA neuron loss	Fett et al. (2010); Flinn et al. (2009)
	Transgenic	Human Parkin overexpression increases resistance to proteotoxic stress (heat shock)	Fett et al. (2010)
	Morpholino knockdown and MPP+ treatment	Increased damage/susceptibility to MPP+	Flinn et al. (2009)
PINK1	Morpholino knockdown	Changes in DA neuron axonal projections and expression in ventral diencephalon; TH positive (DA) diencephalic neuron loss; reduced locomotion behavior; mitochondrial dysfunction and increased ROS	Anichtchik et al. (2008); Sallinen et al. (2010); Xi et al. (2010)
	Morpholino knockdown and MPTP treatment	Increased damage/susceptibility to MPTP neurologically and behaviorally	Sallinen et al. (2010)
PARLa	Morpholino knockdown	Decreased survival; altered DA neurons	Noble et al. (2012)
PARLb	Morpholino knockdown	Decreased survival; altered DA neurons	Noble et al. (2012)
DJ-1	Morpholino knockdown	DA neuron loss with cellular stress (H_2O_2 and MG132)	Bretaud et al. (2007)
LRRK2	Morpholino knockdown	Conflicting evidence for DA neuron loss and reduced locomotion response	Ren et al. (2011); Sheng et al. (2010)
UCH-L1	Transgenesis	UCH-L1 promoter driven GFP expression	Son et al. (2003)
SNCA	Transgenesis	Overexpression of human α-syn induces deformity, lethality, and aggregates	Prabhudesai et al. (2012)
DA neurons	MPTP	Loss of DAT positive cells; reduced DA neurons; decreased locomotion behavior; increased ventilation; increased pigmentation	Bretaud et al. (2004)
	MPTP with DAT morpholino knockdown	Reduced toxin induced damage	McKinley et al. (2005)
	MPTP with DAT inhibitors	Reduced toxin induced damage	McKinley et al. (2005)
	MPP+	Loss of DAT positive cells	Lam et al. (2005)
	Paraquat	No effect	Bretaud et al. (2004)
	Rotenone	No effect (low dose); increased morphological changes and lethality (high dose)	Bretaud et al. (2004)
	Paraquat and rotenone	No effect (low dose); increased morphological changes and cardiovascular defects (high dose)	Bretaud et al. (2004)
	6-ODHA	Decreased DA and noradrenaline concentrations in brain; decreased locomotion	Anichtchik et al. (2004)

3.1.1 PD Genetic Models

Attempts to create a genetic PD model have been centered on functional investigations of mutations found in patients. The genes of interest include Parkin, phosphatase and tensin homolog-induced kinase1 (PINK1), presenilins-associated rhomboid-like (PARL), DJ-1, leucine-rich repeat kinase 2 (LRRK2), Ubiquitin C-Terminal Hydrolase-L1 (UCH-L1), and α-synuclein (SNCA/α-syn). There have been several attempts to modify expression of these genes in an effort to induce classical PD symptoms such as DA neuronal loss, formation of Lewy bodies, mitochondrial dysfunction, and locomotion abnormalities. Olfactory function has not yet been tested in the existing zebrafish models, but may serve as an important endpoint in future experiments.

3.1.1.1 PARKIN

Parkin mutations have been linked to both early and late-stage onset of PD with greater frequency in young cases (approximately 20 years of age) (Lücking et al., 2000). In vitro, Parkin functions as an E3 ubiquitin protein ligase contributing to protein degradation and when mutated is potentially involved in protein aggregation (Büeler, 2009; Periquet et al., 2005; Shimura et al., 2000). The current model predicts disruption of Parkin-mediated protein degradation either by genetic mutation or cellular stress, which leads to accumulation of Parkin substrates, impaired presynaptic function in DA neurons, increased dopamine levels and subsequent neurodegeneration (Imai and Takahashi, 2004). Parkin has also been shown to play a role in mitochondrial protection from oxidative stress and Parkin-deficient mice have had decreased expression of mitochondrial Complex I and reduced mitochondrial function (Büeler, 2009; Palacino et al., 2004). The three studies involving modification of *Parkin* expression in zebrafish have provided conflicting results. Zebrafish express a *Parkin* ortholog which has 62% sequence identity to human *Parkin* and up to 87% identity in functional domains (Fett et al., 2010; Flinn et al., 2009). One study reported that morpholino-induced blockage of *Parkin* in zebrafish was not associated with any effect on gross morphology, number of DA neurons, tyrosine hydroxylase positive (TH+) cells (a conversion enzyme for the dopamine precursor) or mitochondrial integrity (morphology or membrane potential). Despite the lack of physical change, embryos were more susceptible to cell death induced by proteotoxic stress (heat shock). In support of this finding, it was also observed that when heat shock was applied to transgenic zebrafish expressing human *Parkin*, embryos showed greater resistance to cellular stress (Fett et al., 2010). A separate morpholino investigation conflicted with the aforementioned study and found Parkin knockdown decreased mitochondrial Complex I activity and potentially causing

loss of diencephalic DA neurons. Differences between the studies may be attributed to morpholino specificity and effectiveness because the experiment with negative results used gripNAs antisense oligonucleotides as opposed to classical morpholinos (Fett et al., 2010). Further studies will need to be conducted to clarify Parkin deficiency in zebrafish.

3.1.1.2 PINK1

PINK1 encodes a mitochondrial serine/threonine protein kinase expressed not only in many brain regions, including the substantia nigra, but other tissue as well (Gandhi et al., 2006). Mutations in this gene have been associated with early-onset parkinsonism in humans (Bonifati et al., 2005). PINK1 has an established link with mitochondrial function, and its deficiency in both drosophila and mice has led to mitochondrial dysfunction and specific reduction of Complex I activity (Morais et al., 2009). In addition, in mouse cell cultures, PINK1 deficiency affects mitochondrial membrane potential and fragmentation, and increases the reactive oxygen species (ROS) in substantia nigra DA neurons (Wang et al., 2011). A study in PINK1 knockout did not yield the expected deficiencies in mitochondria and DA neurons; however, mice did exhibit classical PD precursor symptoms including impaired olfaction (Glasl et al., 2012). In zebrafish PINK1 protein has only 57.8% identity with humans, but the known functional domains are highly conserved (Sallinen et al., 2010). Morpholino knockdown of PINK1 in zebrafish was associated with alterations in DA neuron axonal projections and expression patterns in the ventral diencephalon paired with reduction in locomotion behavior and response (Xi et al., 2010). Other PINK1 knockdown studies also showed reduced number of DA TH+ neurons in the diencephalon (Anichtchik et al., 2008; Sallinen et al., 2010). Partial phenotypic rescue in knockdown fish with human PINK1 mRNA further validates zebrafish as an appropriate model by way of functional overlap between species (Anichtchik et al., 2008). Transient PINK1 knockdown caused a decrease in mitochondrial potential and increased ROS levels. Successful induction of DA neuron loss, locomotion deficits, and mitochondrial dysfunction supports the use of zebrafish models of PINK1-deficient PD. Nevertheless, the model can be improved by additional testing particularly by assessing olfactory function due to its importance as a symptom and marked impairment in the mouse model.

3.1.1.3 PARL

The PARL gene is more recently associated with PD and therefore less commonly studied to date (Shi et al., 2011). Whole organism experiments with PARL have been limited, but the use of cell lines has established a link between PARL, PINK1, and Parkin. It is

proposed that PARL is required for proper localization of PINK1 which, in turn, is necessary for Parkin recruitment for mitophagy (Shi et al., 2011). If true, it implies that PARL silencing may result in PINK1- and Parkin-related dysfunction in PD. Zebrafish have two PARL orthologs, Parla and Parlb, with 67 and 55% amino acid sequence identity compared to humans (Noble et al., 2012). When blocked with morpholinos, Parla- and Parlb-deficient larvae have reduced survival, increased cell death, and altered DA neuron phenotypes. Of note is that this study made effective use of a dopamine transporter (DAT)-driven green fluorescent protein transgenic line Tg(dat:EGFP) to mark DA neurons and effectively observe induced phenotypes. Both neuronal and lethality effects were rescued by coinjection of human PARL and zebrafish PINK1 mRNA separately. These results support functional overlap between human and zebrafish PARL and also the projected associations between PINK1 and PARL (Noble et al., 2012).

3.1.1.4 DJ-1

DJ-1 mutations and downregulation of DJ-1 mRNA and protein have been found in brain tissue from several PD cases (Bonifati et al., 2003; Kumaran et al., 2009). The normal function of the DJ-1 gene is not well. It was originally found as an oncogene, but in PD it is suspected to be critical to oxidative stress response (Kumaran et al., 2009). DJ-1 knockout mice showed progressive hypoactivity and gait abnormalities with age but no DA abnormalities (Chandran et al., 2008). Zebrafish DJ-1 is 83% identical and 89% similar to humans and colocalizes with TH+ neurons (Bai et al., 2006). A single study concerning DJ-1 deficiency in zebrafish showed that morpholino knockdown does not affect DA neuron numbers, but does cause upregulation of apoptosis regulator genes and increased embryo sensitivity to oxidative stress (H_2O_2 exposure and proteasome inhibition). With oxidative stress, there was an observed DA neuronal loss. Despite positive results, these studies have yet to be replicated and future studies should endeavor to include motor and olfactory assays to evaluate this model.

3.1.1.5 LRRK2

Since 2004, studies have found PD patients with mutations in the LRRK2 gene, with mutation frequencies ranging from 1.6% to 40%, depending on the type of mutation and the demographic analyzed (Gilks et al., 2005; Sharma et al., 2011). LRRK2 function is not fully understood; however, it has ubiquitous neuronal expression and known associations with cellular stress and neuronal maintenance by regulating neurite growth (Iaccarino et al., 2007; MacLeod et al., 2006; Sharma et al., 2011). In vivo models for these mutations are limited; however, in the few mouse studies conducted, there have been no DA neuron loss or protein aggregation (Yue, 2009). There

is reasonable amino acid sequence identity between zebrafish and humans with the highest conservation in the kinase domain (71%). Studies in zebrafish conflict as to whether LRRK2 knockdown results in loss of DA neurons and movement deficits (Ren et al., 2011; Sheng et al., 2010). One study demonstrated loss of TH+ neurons and severe defects with LRRK2 morpholino knockdown (Sheng et al., 2010). In addition, when morpholinos targeted the WD40 domain of LRRK2 specifically, survival was improved and larvae showed DA neuron loss, disorganization of axonal tracts, and locomotion irregularities. Functional overlap was suggested to be conserved due to phenotypic rescue by human LRRK2. Despite these promising results, another more recent study used the same methods and failed to replicate the neurological and behavioral phenotypes (Ren et al., 2011). Nevertheless, the potential for the creation of PD-like characteristics encourages further investigation.

3.1.1.6 UCH-L1

UCH-L1, another source of PD mutations, is involved in the ubiquitin-dependent proteolytic pathway and has been identified as a component of Lewy bodies in PD patients (Leroy et al., 1998). Its role in pathogenesis is proposed to be improper function of protein processing and degradation as well as suspected interaction with α-synuclein, another major component of neuronal aggregates (Leroy et al., 1998; Yasuda et al., 2009), and Parkin (McKeon et al., 2015). The function of UCH-L1 is not fully understood in vivo, but is a neuronal deubiquitinating enzyme (McKeon et al., 2015). Mice lacking UCH-L1 have demonstrated loss of DA neurons and have movement defects reminiscent of PD (Setsuie et al., 2007). There is a UCH-L1 homolog in zebrafish which encodes a protein that has 79% similarity with humans and is coexpressed with TH+ cells in the ventral diencephalon during embryonic development (Son et al., 2003). Experiments on gain or loss of function in zebrafish have not yet been performed, but they have been able to confirm expression and have developed a tool for future studies. Researchers have isolated a promoter containing region of UCH-L1 and combined it with a transgene encoding GFP (Son et al., 2003). The result was fluorescent marking of UCH-L1's neuron-specific expression. Effective transgenesis with this tissue-specific promoter will be of benefit for investigation of UCH-L1 and other coexpressed PD genes.

3.1.1.7 α-SYN

The α-syn gene (SNCA) encodes for a presynaptic protein involved in synaptic plasticity and has found to be mutated in some PD cases (Polymeropoulos et al., 1997). As previously mentioned, α-syn protein is a major component of Lewy bodies in PD patients (Spillantini et al., 1998). Transgenic mice overexpressing

human α-syn had α-syn containing inclusions along with DA neuron loss and motor defects, which indicates α-syn is an important target in modeling and therapeutics (Masliah et al., 2000). Investigations of the protein in zebrafish have been limited. Zebrafish express their own family of synucleins *sncga*, *sncgb*, and *sncb*, which each have different embryonic spatial and temporal expression (Sun and Gitler, 2008). To date these synucleins have not been investigated further. Instead, fish have been modeled to overexpress human α-syn resulting in high frequencies of mortality and deformity (Prabhudesai et al., 2012). Gain and loss of function of α-syn in zebrafish is needed to fully evaluate this organism to model this gene. Modification of endogenous synucleins may prove more effective.

3.1.2 PD Toxin-Induced Models

There are several toxins that due to their correlation between exposure and development of PD have been used in attempts to mimic PD characteristics. The most common ones are as follows: rotenone, paraquat, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), and 6-hydroxydopamine (6-ODHA). These compounds are used to induce DA neuronal loss and their efficacy has been demonstrated in rodent models. Application of these toxins to zebrafish is relatively novel; however, there have been some published results.

Rotenone, commonly used as a pesticide, is toxic to humans and animals by way of mitochondrial disruption. In rats and mice, it has been shown to selectively bind mitochondrial Complex I and induce nigrostriatal DA neuron loss and neuronal cytoplasmic inclusions (NCIs) (Alam and Schmidt, 2002; Betarbet et al., 2000; Sherer et al., 2003). Treated animals also developed poor posture, rigidity, and demonstrated hypokinetic behavior paw shaking resembling a tremor, akin to PD patients. Unfortunately, in adult zebrafish a 4-week exposure to rotenone did not replicate these neurological and behavioral defects (Bretaud et al., 2004). Negative results were also seen in larval fish raised in rotenone solutions although higher doses (50 μg/L) did increase morphological abnormalities and lethality (Bretaud et al., 2004). Increased exposure length in future investigations may successfully induce PD-like symptoms. Alternately, perhaps fish will need to be exposed using a different route such as via intraperitoneal injections.

Similar to rotenone, paraquat acts via inducing oxidative to stress and is normally used as a herbicide. In mice paraquat treatment has caused nigral DA neuron loss as well as upregulation and aggregation of α-synuclein (Manning-Bog et al., 2002; McCormack et al., 2002). Despite the effective modeling in mice, in both adult and larval zebrafish paraquat exposures have not resulted in any locomotion or DA neuron loss (Bretaud et al., 2004). However, this investigation did

not examine α-synuclein expression levels or protein aggregation, so some effects may have been overlooked. The joint exposure of larval fish to high concentrations of paraquat and rotenone did increase incidence of morphological abnormalities and cardiovascular defects (Bretaud et al., 2004).

MPTP is a neurotoxin that when converted to MPP+ via monoamine oxidase B (MAO-B) has direct toxic effects on mitochondria that leads to cell death. In zebrafish MAO activity has been observed in general in the telencephalon and the diencephalon with weak action in the olfactory bulb (Anichtchik et al., 2006). MPTP exposure in adult zebrafish was able to reduce locomotion and cause increases in both ventilation and pigmentation; however, DA neurons were unaffected which is potentially due to the length of exposure (Bretaud et al., 2004). In contrast, larval fish, however, with exposure both during and after DA neuron development showed DA-specific neuron loss, decreased mobility, and diminished touch response (Bretaud et al., 2004; Lam et al., 2005). In adult zebrafish, exposure was associated with decreased movement and changes in a suite of genes and proteins (Sarath Babu et al., 2016). MPTP damage was prevented in the presence of a MAO-B inhibitor, while MPP+ effectively reduced DA neurons, suggesting that the precursor is metabolized to MPP+ in zebrafish by a mechanism similar to mammals (Lam et al., 2005). Recently, it was shown that melatonin can also counteract the effects of MPTP in the olfactory bulb (Díaz-Casado et al., 2016). The confirmed reduction of DA neurons in the olfactory bulb supports investigation into olfactory dysfunction in this model. MPTP uptake via DAT as in mammals was confirmed in zebrafish with reduced MPTP neurotoxicity when paired with DAT pharmaceutical inhibition or morpholino-mediated knockdown (McKinley et al., 2005). MPTP is currently the most effective method of inducing DA neuron loss in zebrafish and consequently it has been paired with genetic models to test for increased susceptibility to the toxin. Morpholino knockdown of both Parkin and PINK1 paired with MPTP exposure demonstrated enhanced neuronal loss and decreased movement behavior (Flinn et al., 2009; Sallinen et al., 2010).

6-ODHA is a neurotoxin that accumulates in neuron terminals after being taken up by DATs or noradrenaline transporters and causes DA and noradrenergic neuronal damage. Compared to MPTP, 6-ODHA causes less specific damage and is not used as frequently in models. Nevertheless, it has been tested in zebrafish. Intramuscular injections of the compound cause decrease in DA and noradrenaline concentrations in the brain, but no changes in TH levels or patterning of TH+ cells. 6-ODHA was also correlated with changes in locomotion activity, including decreased swimming distance and increased turn angle (Anichtchik et al., 2004).

Overall, genetic, toxic, and combination of zebrafish models are arguably still in the early stages for PD; however, results are promising. In most cases researchers have effectively analyzed neuron condition and locomotion defects. There remains a great deal of potential in future studies for electrophysiology and olfactory response. For example, a study may examine changes in odorant activation of neurons at the levels of the olfactory epithelium and bulb following exposure to chemical compounds. In the same respect, if olfactory tissue is found to be functional, behavioral analysis of odorant responses can determine whether fish have impaired capacities for odor identification and interpretation.

3.2 Amyotrophic Lateral Sclerosis

ALS, also known as Lou Gehrig's disease, involves progressive loss of both upper and lower motor neurons, and manifests as a subsequent impaired capacity to move and perform basic functions such as swallowing and breathing. The disease was first described in scientific literature by Jean-Martin Charcot in 1869. ALS is a devastating disease that limits survival to 5 years for 80% of diagnosed patients; 90% of classical ALS cases can be attributed to sporadic acquisition (Kiernan et al., 2011). Diagnosis can be a challenge, not only due to the variation between individual patients, but also due to the subtypes of ALS. ALS not only exhibits in its classical form, but also exists with dementia (ALS-D) and as a Guam-specific ALS-Parkinsonism-Dementia Complex (ALS-PDC). The latter subtype involves Parkinsonian tremors and Alzheimer's-like cognitive dysfunction along with the motor neuron degeneration (Ikemoto et al., 2000).

Pathologically, there are several types of inclusions linked to ALS, but the most specific is known as the Bunina body (small eosinophilic granular inclusions) found within cytoplasm or dendrites (Kato, 2008; Okamoto et al., 2008). Skein- and Lewy body-like inclusions that stain positively for ubiquitin have also been identified in some ALS patients that had severe neuronal loss in the spine and medulla (Ikemoto et al., 2000; Shibata et al., 1994; van Welsem et al., 2002). Other neuronal aggregates of basophilic and hyaline bodies have also been observed, but these are less specific to ALS (Ikemoto et al., 2000; Kato, 2008; Wood et al., 2003). In some cases, neurofibrillary tangles (NFTs) have been noted in patients with ALS-PDC (Ikemoto et al., 2000).

There is some controversy over symptomatic olfactory loss in ALS. Although ALS-PDC has confirmed association with olfactory impairment, the link to classical ALS patients is an area of contention (Doty, 1995). Although there have been studies that find no correlation, many studies argue that chemosensory function is affected; however, it is mild in comparison to other neurodegenerative diseases (Ahlskog et al., 1998; Doty, 1995;

Elian, 1991; Hawkes and Shephard, 1998; Sajjadian et al., 1994). The variation in results could be due to variation between cases in terms of severity and perhaps even the type of ALS. Few studies have endeavored to investigate it as a disease marker of the symptom in terms of disease time course. Long-term case studies in conjunction with postmortem olfactory structure analysis and testing in ALS models will need to be conducted to confirm associations.

The animal models for ALS to date have attempted to replicate ALS phenotypes by manipulating genes found to be mutated in diseased patients. Specific mutations in ALS2, the gene encoding aslin, led to juvenile onset of ALS, which will not be discussed in this chapter (Chandran et al., 2007). Within adult cases of ALS, three main genes have been identified: superoxide dismutase (SOD1), TAR DNA-binding protein (TARDBP), and fused in sarcoma (FUS) (Rosen et al., 1993). C9orf72 is a gene more recently found to be causal of ALS (DeJesus-Hernandez et al., 2011; Renton et al., 2011), and bone morphogenetic protein (bmp) signaling pathway genes may act as modifiers on disease severity (DuVal et al., 2014). There is little evidence to suggest that exposure to chemicals enhances the risk of developing ALS and therefore it is not generally used in modeling (Weisskopf et al., 2009). However in ALS-PDC, there is a dominating theory that neurotoxin beta-methylamino-L-alanine (BMAA), from the local cycad seed, induces the disease (Cheng and Banack, 2009; Wilson et al., 2004). As a result there have been specific models that use it to induce disease-like symptoms (Ahlskog et al., 1998; Wilson et al., 2002, 2004).

3.2.1 SOD1

Many different missense mutations in SOD1 occur in ALS patients (Gamez et al., 2006; Rosen et al., 1993). SOD1 has also been found within Lewy body-like inclusions of ALS patients (Shibata et al., 1994). In transgenic mice expressing mutations in SOD1, it was shown that SOD1 was crucial to mitochondrial function and that ubiquitous but not neuron specific dysfunction leads to ALS-like phenotypes (Mattiazzi et al., 2002). Zebrafish SOD1 has a 77% sequence identity to humans and has already been examined in several models. Overexpression of mutant SOD1 in zebrafish through construct injection can induce abnormal motor neuron axonal branching and length (Lemmens et al., 2007; Pramatarova et al., 2001). Another study generated fish that expressed mutant zebrafish SOD1 along with fluorescent protein DsRed driven by heat shock protein 70 (to show transgene expression) (Ramesh et al., 2010). Both larval and adult fish from this transgenic line had abnormal neuromuscular junctions and spinal cord motor neuron loss in adults (Ramesh et al., 2010. This study is of particular interest because of its use of a swimming tunnel to test motor abilities at several different ages

in transgenic fish. Swim tunnels are used to assess the physical endurance of a fish by monitoring its capacity to swim against applied water currents (Brett, 1964; Gilbert et al., 2014; Tierney, 2011). Remarkably, these fish showed progressive decline in swim performance with increased age. Mutant models also displayed serious decreases in movement and some instances of paralysis in late stages, with overall exhibiting a shorter lifespan. In this model, the worsened performance correlative with aging best replicates the progressive trait of ALS. Additional models of ALS have identified SOD1 mutants using the TILLING strategy or transient transgenesis, and they also assessed swimming though using less traditional measures of fish swim physiology (Da Costa et al., 2014; Sakowski et al., 2012). Other models of neuromuscular degeneration would benefit from following this example of longitudinal testing of motor endurance.

3.2.2 TARDBP and FUS

Both the TDP-43 protein, encoded by TARDBP, and FUS mutations have been reported in ALS patients (Kabashi et al., 2008; Kwiatkowski et al., 2009; Neumann et al., 2006; Vance et al., 2009). These proteins have also been identified as components of ALS aggregates (Arai et al., 2006; Deng et al., 2010). Overexpression of mutant human TDP-43 in rats led to motor neuron loss and reduced movement capacity; however, TDP-43 inclusions were not observed, which indicates the aggregates are not essential for neuron death (Huang et al., 2012). Similar to TDP-43 mutants, rats overexpressing mutant human FUS had motor neuron degeneration accompanied by progressive paralysis and ubiquitin accumulation (Huang et al., 2011). In terms of modeling in zebrafish, there are already several examples of successful functional disruption. Overexpression of several different mutant human TARDBP (and therefore TP-43) in larvae resulted in deficits in swimming response as well as decreased motor neuron length and increased branching (Kabashi et al., 2010). Morpholino-induced knockdown of TARDBP resulted in the same motor neuron phenotype and defective swim response which suggests potential pathogenesis via toxic gain of function and as TARDBP deficiency (Kabashi et al., 2010). Knockdown of FUS also resulted in abnormal motor behavior and reduced outgrowth of motor neuron axons (Kabashi et al., 2011). Both FUS-deficient phenotypes were rescued by human FUS mRNA (Armstrong and Drapeau, 2013). Targeted mutagenesis to induce FUS or TARDBP mutations have exhibited some ALS-related phenotypes (Armstrong et al., 2016). CRISPR/Cas9 knockins into zebrafish SOD1 have been remarkably effective in modeling disease-related mutations and will be intriguing models for determining what phenotypes, if any, these mutations cause in zebrafish (Armstrong et al., 2016).

To investigate the potential interactions between SOD1, TARDBP, and FUS, a study used zebrafish to conduct a multigenetic analysis (Kabashi et al., 2011). FUS mRNA coinjection rescued TARDBP knockdown; however, the inverse rescue was not observed, indicating an in vivo interaction in which FUS is the downstream effector. A particularly intriguing finding was the enhanced neurological phenotypes and locomotion deficits observed in both double mutant mRNA expression and double knockdown experiments with SOD1 and either FUS or TARDBP. Although ALS-like symptoms were worsened by doubled genetic defects, it was suggested that SOD1 acts independently from FUS and TARDBP through lack of phenotypic rescue.

Although SOD1, TARDBP, and FUS remain the main focus for investigations, a study on mutations in elongator protein 3 (ELP3) in ALS patients and subsequent examination of EPL3 knockdown zebrafish had unique findings (Simpson et al., 2009). EPL3 has a 91.3% identity to humans, which strongly supports the model validity for investigation of this protein. Morpholino injection resulted in abnormal branching and length of motor axons reminiscent of the SOD1-, TARDBP-, and FUS-deficient phenotypes. Future EPL3 studies may find it has an important if not multigene interactive role in ALS pathogenesis.

Genetic ALS modeling in zebrafish thus far has been exploratory out of necessity, but has effectively used the tools available to zebrafish. Not only have they used overexpression, transgenic and transient knockdown, but they have performed multigenetic experiments to elucidate pathogenic interactions. Zebrafish models were also routinely tested for motion defects, and a swim tunnel provided an appropriate measure for muscle strength and endurance.

The lack of olfactory-based endpoints in ALS models may be in part due to the dispute on sensory loss association with the disease. In terms of rodent studies, only one particular study examined olfactory structure, but not function, in a cycad ingestion-induced ALS-PDC-specific model. Notably, these mice demonstrated reduced size in PD-related structures such as the striatum, substantia nigra, and the olfactory bulb (Wilson et al., 2004). BMAA, the putative toxic element in cycad seeds, has been tested in larval zebrafish where exposure during development caused pericardial and spinal defects, increased mortality, and convulsions (Purdie et al., 2009). Further investigations including exposure from ingestion may cause appropriate ALS-PDC phenotypes to complement mammalian models.

3.3 Alzheimer's Disease

The behavioral symptoms and basic neuropathology of a single affected patient with AD was first described in 1906 by Alois Alzheimer (Small and Cappai, 2006).

Today, AD is the most commonly acquired neurodegenerative disease in the elderly and is notorious for the devastating effects on cognition and memory (Selkoe, 2001). As noted in the original patient, AD cases involve not only the progressive loss of memory, but also changes in behavior that may cause episodic paranoia, delusion, and social inappropriateness (Galton et al., 2000; Selkoe, 2001; Stopford et al., 2007). Although AD is associated with extensive cognitive decline, there is no evidence to support major motor dysfunction excepting perhaps the increased risk of seizures (Born, 2015). Conversely, severe olfactory impairment has been reported in AD patients and is considered a potential preclinical marker (Albers et al., 2015; Devanand et al., 2000; Wang et al., 2010). AD subjects have demonstrated a correlation between impaired sense of smell and decreased volume of the olfactory bulb and tract (Thomann et al., 2009).

Pathologically, there are two markers for AD: amyloid-β (Aβ) plaques and NFTs. Aβ plaques are named after the Aβ protein which comprises the majority of the deposit (Masters et al., 1985). In terms of areas of the brain affected, most AD brains show amyloid deposits in the cerebral cortex and subcortical regions, particularly in the isocortex (Braak and Braak, 1991). One of the primary theories for Alzheimer's pathogenesis called the "Amyloid Hypothesis" is based on the formation of these plaques (Hardy and Selkoe, 2002). Essentially, the theory details missense mutations in known disease-related genes that result in increased or aberrant production and accumulation of Aβ. Aβ proteins then oligomerize and deposit as plaques in certain regions of the brain (Della Bianca et al., 1999; Takahashi et al., 2004). These plaques may either cause direct damage to neurons and synaptic function or indirect destruction through microglia activation (Della Bianca et al., 1999), although the causality of plaques in AD has been scrutinized often in recent years (Albers et al., 2015), and it may be that oligomeric forms of Aβ (presumed to be a precursor of plaque formation) are causal of disease. There is also evidence to suggest that misfolded proteins such as α-syn and tau can propagate aggregation within a diseased subject (Polymenidou and Cleveland, 2012; Sydow and Mandelkow, 2010). Aβ oligomers, or its parent protein APP, may effect some of their action through binding to the prion protein (Kaiser et al., 2012; Nelson et al., 2012), which is known to be critical for neuroprotection. Ultimately, Aβ presence is proposed to cause neuronal damage leading to cell death and eventual cognitive impairment. There is evidence to suggest that plaque deposition is involved in the development of the second AD neurological marker, NFTs. NFTs are bundles of abnormal fibers composed of hyperphosphorylated tau proteins (Grundke-Iqbal et al., 1986; Selkoe, 2001). Many kinases may be capable of initiating development; however, whether it is one or a combination of many has yet to be established. NFTs

are also found in the isocortex and are most identifiable in the later stages of the disease, particularly in the entorhinal and transentorhinal regions of the brain. Most studies identify a typical trend of degeneration beginning in the transentorhinal (or perirhinal) region before spreading to the temporal lobe (particularly the hippocampus complex) and the basal forebrain; however, there have been documented cases of patients who vary from this pattern (Galton et al., 2000). Notably, while Aβ aggregates are less frequently observed in the olfactory system, tau pathology has been seen to severely affect the olfactory bulb and nerves in *postmortem* analysis of AD patients (Attems et al., 2005; Kovacs et al., 1999).

Although causes and potential therapies for AD are heavily researched areas, the underlying causes for the disease remain unknown. The observed pathological changes are often believed to be secondary to changes in gene expression. The genetics behind AD are difficult to interpret and model because there is no singular mutation behind the syndrome. The complexity stems from the variety of genetic mutations linked to early-onset familial cases versus those related to late onset. Pathways and interacting components continue to be investigated, but there are several genes that seem to play a significant role and consequently have been the focus in most animal models. Mutations in amyloid β-protein precursor (APP), presenilin 1 (Psen1), presenilin 2 (Psen2), tau, and Apolipoprotein E4 (ApoE) have been reported in AD patients and correlated with one of the two cerebral pathological markers.

3.3.1 APP

The amyloid hypothesis has made APP, the precursor protein to Aβ, a focal point in AD research. APP has several suspected roles in vivo, but perhaps the most relevant to AD is the production of the Aβ protein upon cleavage (see APP functions review in Zheng and Koo, 2011). Mutations in APP have been found in AD patients and shown to enhance Aβ production, thereby contributing to its aggregation and cerebral plaque deposition (Goate et al., 1991; Scheuner et al., 1996). There have been many variations of APP transgenic mutation models in mice, but the overall endpoints and observed phenotypes are generally conserved (Ashe, 2001; Dodart et al., 2002; Lalonde et al., 2012). Mice with defective APP function show progressive increases in plaque formation, plasma β-amyloid levels, and deficits in learning and memory, but generally fail to recapitulate the hallmark neuronal death (Moechars et al., 1999; Rustay et al., 2010). Importantly, transgenic mice with increased Aβ deposition have shown a variety of olfactory deficits such as atypical odor responses, failure to habituate to repetitive odorant exposure, and reduced ability to discriminate between odors (Wesson et al., 2010).

Zebrafish have two APP orthologs, APPa and APPb, each showing developmental expression in the nervous system and relatively high (63%–66%) sequence identity to mice and humans (Joshi et al., 2009; Liao et al., 2012; Musa et al., 2001). It has been suggested that morpholino knockdown of APPa and APPb together and APPb alone results in shortened body, curly tail, and convergent-extension defects (Joshi et al., 2009), though further controls for MO specificity are warranted. Larvae lacking APPb also had impaired motor neuron axonal outgrowth providing another clue in its role during embryonic development. Although typical AD model endpoints were not examined, human APP695 was shown in rescue of the APPb-deficient phenotypes, which does suggest some functional conservation across species (Joshi et al., 2009; Song and Pimplikar, 2012). Combinations of morpholino knockdown and concerted recovery using mRNA variants demonstrated that human APP interacts with human prion protein (Kaiser et al., 2012), in a niche interaction required for neuroprotection. Early studies using targeted mutagenesis in zebrafish support a role for prion protein in neurodevelopment, neuroprotection, and regulation of NMDA receptors, further supporting a role in AD (Huc-Brandt et al., 2014). A few studies involving APP and zebrafish focused on the creation of transgenic lines for future investigations. These studies exemplify the typical approach to transgenic models by inducing RFP or GFP expression under the control of APPa and APPb, respectively, to locate secreted soluble forms of the proteins (Lee and Cole, 2007; Liao et al., 2012). The use of the transgenic models will be critical to future AD investigations.

3.3.2 Presenilins

Presenilins are transmembrane proteins that encode the catalytic component of the γ-secretase complex (GSC) suspected to play a role in proteolysis regulation of APP. Mutations in Psen1 and Psen2 have both been identified in early-onset familial cases of AD (Janssen et al., 2003; Sherrington et al., 1995; Żekanowski et al., 2003). Through studies in mice it has been established that mutations in Psen1 and Psen 2 can result in characteristic loss of learning and memory functions, NFT-like structure, tau pathology, Aβ deposition, and neuron degeneration (Chen et al., 2008; Elder et al., 2010). Compared with human presenilin, zebrafish express orthologs of Psen1 and Psen2 (Groth et al., 2002) that are highly similar. Investigations into presenilin dysfunction in zebrafish thus far have been limited, and did not examine the expected AD-like phenotypes (Moussavi Nik et al., 2015; Newman et al., 2014a,b). Overexpression of Psen2 in zebrafish through mRNA construct injection does not affect transcription or protein levels of Psen1 perhaps indicating differential regulation (Nornes et al., 2003). In addition, overexpression of a truncated form of Psen2 led to an increased number of dorsal longitudinal ascending (DoLA)

interneurons (Nornes et al., 2009). However, there remains some interaction between the two presenilins, as loss of Psen1 reduces the DoLA phenotype, that is, Psen1 and Psen2 may regulate each other. Basic morphology and development were also observed for separate morpholino knockdown of Psen1 and Psen2, with each leading to impaired somite formation, reduced melanocytes, and hydrocephalus, suggesting functional overlaps (Nornes et al., 2003, 2009). More related to AD, one of these studies also examined morpholino knockdown of presenilin enhancer 2 (PEN-2), which is another component of the GSC. PEN-2 deficiency resulted in reduced Notch signaling and caused a loss of islet-1 positive neurons through what was proposed to be increased apoptosis (Campbell et al., 2006). Caution must be used in interpreting the various studies applying GSC inhibitors as models of AD because GSC has at least several dozens of substrates, including those fundamental to neuron development and maintenance such as Notch (Jurisch-Yaksi et al., 2013). Although Notch's direct role in AD pathogenesis has not been elucidated, Notch may be an influencing factor because of its role in memory deficits and associated neuronal degeneration (Woo et al., 2009). Verification of a relationship between PEN-2 and Notch in zebrafish in conjunction with observation for other AD markers is of potential interest and disease relevance.

3.3.3 ApoE

ApoE was identified in the 1990s as associated with plaques found in AD patients (Dickson et al., 1997). Since then it has become an important area of investigation for sporadic AD cases due to its proposed roles in amyloid deposition and neurodegeneration (DeMattos, 2004; Holtzman et al., 2000). A point of particular interest is that mice deficient in ApoE demonstrated deficits in olfactory functionality (Nathan et al., 2004). A gene homologous to mammalian ApoE with low amino acid sequence identity (27.5%) has been identified in zebrafish (Babin et al., 1997; Durliat et al., 2000). Functionally, there has been an observed expression in the yolk syncytial layer, brain, and eyes during development (Babin et al., 1997). There has also been marked expression during morphogenesis and regeneration of fins (Monnot et al., 1999). Future investigations will need to determine functional overlap with humans if zebrafish are to be used as model for ApoE-related AD.

3.3.4 MAPT/tau

Impaired function of microtubule-associated protein tau (MAPT) is another hallmark of AD. As previously mentioned, NFTs are composed of altered MAPT that have formed aggregates similar to Aβ plaques. The steps that lead to the modification of tau via hyperphosphorylation are not wholly understood, but several kinases, including GSK3β, have been implicated

(Grundke-Iqbal et al., 1986; Hanger et al., 1992). Transgenic mouse models overexpressing or expressing mutant tau have displayed phenotypes reflective of AD, including NFTs, memory deficits, neuronal degeneration, and, importantly, olfactory deficits (Lewis et al., 2000; Macknin et al., 2004; Tatebayashi et al., 2002). Within zebrafish, two orthologous candidates to human MAPT, MAPTa and MAPTb, have been identified, but they have not been examined for loss or gain of function (Chen et al., 2009). Instead, taupathies in zebrafish have been replicated using a transgenic approach. A study used a Tol2 transposon and Gal4/UAS system to generate a transgenic model expressing mutant human tau. This model has proven extremely effective as fish develop hyperphosphorylized tau aggregates or NFTs, and show increased cell death and neuron motor neuron disruption in the spinal cord. Neuronal defects were paired with reduced movement and defective touch response. Interestingly, the application of GSK3β inhibitors can reduce the hyperphosphorylation seen in this model (Paquet et al., 2009). Another transgenic model used an enolase-2 (*eno2*) to drive overexpression of human tau in the CNS (Bai et al., 2007). Antibody staining for tau revealed dense labeling resembling possible deposition of NFTs in the adult brains. Zebrafish models of tauopathy have been used to examine the contribution of autophagy to pathogenesis (Moreau et al., 2014). Replication of human histology for AD in these transgenic models is encouraging and should now be paired with the testing of cognitive and olfactory capacities.

3.3.5 Chemical Modeling of AD

There is some evidence to suggest that nitrosamine-related compounds typically found in foods are related to sporadic cases of AD, as cognitive impairment and neuronal degeneration postexposure have been found in several rodent studies (de la Monte et al., 2009). Chemical modeling in AD in zebrafish largely pertains to the impairment of memory or learning through the use pharmaceuticals. For example, scopolamine, a muscarinic receptor inhibitor that reduces memory function in zebrafish, permits testing of pharmaceuticals for attempted recovery or improvement (Kim et al., 2010; Lester-Coll et al., 2006; Richetti et al., 2011) The mechanisms and methods behind memory and learning testing are not within the focus of this chapter; however, these endpoints may be invaluable for modeling neurodegenerative diseases and could be applied to genetically modified models (Table 21.6).

3.4 Multiple System Atrophy

The disease now referred to as MSA was documented as early as the 1891, but due to overlapping pathologies with PD, the current name was not suggested until 1969 by Graham and Oppenheimer (Burn and Jaros, 2001;

Rehman, 2001; Ubhi et al., 2011). MSA has sporadic onset in adults aged 50 and older and is pathologically associated with neuron loss and neuronal inclusions. Generally, the areas of the brain that suffer from neurodegeneration vary in severity between MSA patients; however, they have included the cerebellum, basal ganglia, pons, and inferior olivary nuclei (Ubhi et al., 2011). Symptoms can manifest as any combination of ataxia, parkinsonism, or autonomic dysfunction, which typically can be designated as one of the specific MSA subtypes: parkinsonian (MSA-P) or the less common cerebellar (MSA-C). MSA-P is usually associated with the striatonigral (basal ganglia) region, and MSA-C cases refer to olivopontocerebellar regions (Rockenstein et al., 2007). The observed symptoms of the two subtypes do differ slightly. In terms of cognitive impairment, MSA-P tends to involve deficiencies in visuospatial, construction, verbal fluency (retrieval), and executive functions, whereas MSA-C patients have difficulties with attention, learning verbal information, as well as visuospatial and constructional functions, but to a lesser degree (Balas et al., 2010; Kawai et al., 2008). Some studies of MSA patients indicate differences in specific autonomic subsystem dysfunctions; however, results are variable (Schmidt et al., 2008). Although it may present with degeneration and movement akin to PD, MSA is distinguished by several features including irresponsiveness to levodopa treatment, autonomic failure, and cerebellar signs (Rehman, 2001).

In addition to neuron loss, MSA is accompanied by several types of inclusions: glial cytoplasmic inclusions (GCIs), glial nuclear inclusions (GNIs), NCIs, and neuronal nuclear inclusions (NNIs). The most commonly identified aggregates in MSA patients are the GCIs found in oligodendrocytes (Ubhi et al., 2011). The mechanisms underlying inclusion formation in MSA have yet to be determined; however, α-syn protein has been identified as a major component of these aggregates, which draws yet another interesting parallel to PD (Burn and Jaros, 2001; Nakazato and Suzuki, 1996; Wakabayashi et al., 1998).

In terms of olfactory dysfunction, postmortem examinations of MSA patients showed positive α-syn stained GCIs in olfactory bulbs and tracts. Within the olfactory bulb, GCIs were mainly in the superficial layers and rarely in AON (Kovács et al., 2003). Despite a lack of inclusions, the number of AON neurons in MSA cases was significantly reduced (Kovács et al., 2003). Considering this pathology, it is not surprising that MSA patients have difficulties processing odor-related information (Abele et al., 2003).

MSA cases suggest the disease to be sporadic and therefore underlying causes are not well known. There are is little evidence supporting certain genetic polymorphisms and mutations are associated with the condition. Candidates found in MSA patients include ApoE allele, α-syn, and ZNF231 (Cairns et al., 1997; Hashida et al., 1998). In terms of specific MSA modeling, there has been no

further research on ApoE4 or ZNF31. The sporadic nature of this disease has spurred investigation of environmental toxins as a potential cause. A study in humans documented a strong correlation between toxic exposure and MSA development, and toxic modeling in animals has had some success (Hanna et al., 1999). Interestingly, the use of zebrafish in establishing an MSA-specific model has yet to be achieved. However, due to the symptomatic and pathogenic overlap with PD, some basic genetic investigations carried out on both mice and zebrafish have potential application for zebrafish MDA models.

Genetic studies have focused mainly on α-syn overexpression due to its association with GCIs. As previously described, the overexpression of α-syn in zebrafish leads to increased lethality and deformity, and the endogenous synucleins have yet to be modified (Prabhudesai et al., 2012; Sun and Gitler, 2008). To best model the disease, targeted α-syn upregulation is ideal and could be achieved by using transgenesis and tissue-specific promoters. Mouse models have taken advantage of this strategy to overexpress α-syn using the oligodendrocytic-specific promoters myelin basic protein (MBP) and proteolipid protein (PLP). The MBP model had the desired α-syn accumulations in oligodendrocytes and decreased motor capacity (Shults et al., 2005). Of particular interest was a potential olfactory deficit, as transgenic mice took longer to find their food source (Ubhi et al., 2010). A PLP-α syn model was used to investigate the hypothesis that microglial activation (glial CNS macrophage) has a prominent role in MSA neurodegeneration (Ishizawa et al., 2004; Stefanova et al., 2007). The results showed oligodendroglial α-syn accumulation was paralleled with progressive and regional microglial build-up. Several neuronal structures including the MSA targets of the substantia nigra and striatum in particular were affected, which provides another avenue for future MSA research. Although these models have not yet been attempted in zebrafish, there have been transgenic lines developed that utilize zebrafish P0, MBP, and mouse PLP promoters to drive oligodendrocyte-specific enhanced GFP expression (Jung et al., 2010; Yoshida and Macklin, 2005). Using these tools, MSA α-synucleinopathy could be replicated in zebrafish.

Rodent studies have also attempted to model MSA with toxin exposure such as MPTP, ODHA, quinolinic acid (QA), and 3-nitropropionic acid (3NP) (Fernagut and Tison, 2012; Ubhi et al., 2011). 3NP and QA have yet to be applied to zebrafish, but they have been successfully modeled in certain mice phenotypes. For example, 3NP enhanced the motor function and neuronal loss seen in the α-syn transgenic models (Stefanova et al., 2005). MPTP and ODHA have already been used in zebrafish PD models without compromising lethality or deformity, and therefore future studies could be adapted to look for MSA-specific degeneration.

MSA modeling remains relatively new and will expand as associated mutations and toxins continue to be discovered. Although an MSA model in zebrafish has not yet been published, the genetic and toxic experiments performed in mice can be theoretically be applied to zebrafish in the future.

3.5 Huntington's Disease

HD is another example of a neurodegenerative disease associated with olfactory loss and motor dysfunction. The trademark symptom of HD involves a condition of irregular involuntary movements called chorea. Since its original description from the observation of a patient by George Huntington in 1872, HD diagnosis and research have uncovered not only unique neuropathology but also a genetic link. Presently, HD is known as an autosomal dominant largely identified by the trinucleotide (CAG) repeat expansion in the *hd* gene (IT15) that translates as an abnormally long polyglutamine (polyQ) insertion in the huntingtin protein (Htt). The mutation results subsequent dysfunction and degeneration (Walker, 2007).

Interestingly, HD patients can develop symptoms at any life stage, but there is a proposed inverse relationship between the length of polyQ insertions and age of onset (Duyao et al., 1993). Apart from chorea, HD patients have exhibited degeneration of executive functions including planning and organising as and may have certain psychiatric symptoms such as depression, anxiety, and ideas of suicidal thoughts (Gómez-Tortosa et al., 1998; Lemiere et al., 2004; Montoya et al., 2006). In terms of neuropathology, HD is marked by severe neuron loss and atrophy in the neostriatum (caudate nucleus and putamen) and cortex. Htt neuronal inclusions have also been reported in these affected brain regions (DiFiglia et al., 1997; Gómez-Tortosa et al., 1998; Gutekunst et al., 1999). Olfactory dysfunction was recognized early in the disease history as a marker prior to the onset of motor and cognitive symptoms, as patients have difficulties in odorant detection, identification, and discrimination (Hamilton et al., 1999; Nordin et al., 1995).

Despite the strong correlation between dysfunction and disease, the neuronal reasons underlying observed olfactory dysfunction are not fully understood. There are, however, reported correlates of degeneration of cerebral regions involved in olfaction such as the entorhinal cortex, the thalamus, the parahippocampal gyrus, and the caudate nucleus with olfactory loss (Barrios et al., 2007).

3.5.1 Htt

Wild-type Htt function is not fully understood; however, the protein has been demonstrated to have ubiquitous tissue expression with highest levels in the brain. Expression in the brain is not restricted to HD-affected striatum, but is also apparent in the cerebellar cortex, hippocampus, and neocortex. At the cellular level, Htt may associate with proteins in the cytosol and nucleus, which suggests roles in cell signaling, transport, and gene transcription (Borrell-Pagès et al., 2006; Harjes and Wanker, 2003; Kegel et al., 2002). It is accepted that both wild-type and mutant Htt undergo caspase-mediated cleavage; however, mutated Htt fragments are neurotoxic and form aggregates in striatal neurons, neurites, and axonal terminals (Li et al., 2000; Wellington et al., 2002). The formation of these intranuclear inclusions was not correlated with mutant Htt's induction of neurodegeneration through apoptotic pathways (Saudou et al., 1998).

The established genetic link between HD and Htt has led to research on the creation of animal models to elucidate the mechanism by which mutant Htt results in neurodegeneration. Many experiments have been executed in mice, while zebrafish models are just beginning to emerge and their use has tended to focus on testing potential therapies. Zebrafish have a homolog for the HD gene that has 70% amino acid identity with humans (Karlovich et al., 1998). Several genetics techniques have been used to replicate HD symptoms in zebrafish (Table 21.7).

One study conducted morpholino knockdown of *hd* and found it may play a role in iron uptake; researchers did not test for neuron loss and motor defects (Lumsden et al., 2007). Building on this study, a more recent

TABLE 21.7 Examples of Current Zebrafish Models of Huntington's Disease

Target	Method	Phenotype	References
hd	Morpholino knockdown	Small eye, lower jaw and swim bladder defects; symptoms of cellular iron deficiency; increased cell death in midbrain, hindbrain; reduced cell death in the olfactory placode and lateral line neuromasts; upregulated caspase activity; reduced BDNF	Diekmann et al. (2009); Henshall et al. (2009); Lumsden et al. (2007)
BDNF	Morpholino knockdown	Small eye, lower jaw and swim bladder defects; increased cell death in midbrain and hindbrain; upregulated caspase activity	Diekmann et al. (2009)
PolyQ proteins	Overexpression construct injection	Inclusion formation; morphological abnormalities; cell death	Miller et al. (2005)

investigation showed that Htt knockdown resulted in minor morphological abnormalities and desired neuronal loss in the midbrain and hindbrain (Diekmann et al., 2009). Htt-deficient larvae also had elevated caspase and decreased levels of brain-derived neurotrophic factor (BDNF), which have both been previously implicated in HD (Hermel et al., 2004; Zuccato et al., 2001). To determine BDNF's role in the observed phenotype, fish were injected with a BDNF morpholino. BDNF-deficient fish expressed the same phenotypes as the Htt knockdowns. In addition, BDNF treatment rescued Htt knockdown fish further supporting the idea that BDNF is a contributing factor in HD pathology. Transient knockdown has also shown that Htt is required for the development of the olfactory and lateral line systems in zebrafish. Specifically, knockdown showed reduced apoptosis at the within lateral line neuromasts and olfactory placode along with the absence of mature OSNs (Henshall et al., 2009). The phenotypes noted of the olfactory tissue suggest a link between Htt dysfunction and olfactory impairment in humans.

Zebrafish models for HD have also been created by injecting embryos with plasmids that encoded normal or expanded polyQ tracts fused with GFP. Plasmids that encoded longer polyQ repeats were correlated with the formation of insoluble polyQ inclusions as well as increased morphological abnormalities and cell death (Henshall et al., 2009). Ideally, a zebrafish model for HD should not only replicate the polyQ inclusions and isolated neurodegeneration, but also display motor and olfactory defects. The abnormalities observed in zebrafish and mouse olfactory tissue within HD models merit investigation of sensory function (Kohl et al., 2010; Menalled et al., 2003; Petrasch-Parwez et al., 2007). Adding olfactory and movement endpoints to model evaluation will strengthen any results obtained from therapeutic testing.

Toxin-induced HD models have not yet been published with zebrafish subjects; however, there are existing rodent models that have used QA to induce lesions and cell loss in the striatum of the brain (Beal et al., 1991; Tattersfield et al., 2004). Furthermore, chronic treatment with 3NP mimics the striatal damage and similar movement abnormalities observed in HD (Guyot et al., 1997). Toxic exposures conducted in mice could easily be applied to zebrafish to complement current genetic investigations.

4 CONCLUSIONS

4.1 Therapeutic Potential

For the diseases discussed in this chapter, the majority of therapeutic investigations have involved pharmaceutical application to genetic or toxin-induced models in an attempt to recover the disease-like phenotypes. Although many potential drugs prove effective in vitro, it is necessary to test these compounds in vivo, not only

to confirm functionality, but also to rule out any unforeseen toxicity. Zebrafish have been shown to be excellent models for identifying potential neuroprotectants, antioxidants, and drug screens in vivo (Parng et al., 2006; Zon and Peterson, 2005). They are the optimal choice for early chemical screens for several reasons. First, treatment or exposure is simple and fast compared to other vertebrate tests, at least partly because zebrafish can absorb the compound in question from the aqueous environment through their skin and gills. Second, compared to rodent studies, zebrafish can be tested faster and in higher volumes. This owes to their high fecundity, small size, and low cost. Even the creation of genetic models prior to testing can be completed comparatively quickly because of their short life cycle. Third, despite being a nonmammalian vertebrate, disease-related targets are often functionally conserved.

4.2 Future Motion and Olfactory Endpoints

It is important to note that the enthusiasm concerning the use of zebrafish in genetic modeling is not meant to suggest substitution for mammalian models. On the contrary, zebrafish should be used for complementation, comparison, and prescreening of results in relation to mammalian studies. In terms of the diseases discussed in this chapter, many of the existing models are still in the development phase. With the advancement of effective knockout methods and continued creation of transgenic lines, the amount of information gained from zebrafish is expected to increase dramatically. For the models described in this chapter, applied endpoints encompass neuronal abnormalities, cell death, and basic touch response. Monitoring of activity has been applied to some disease models discussed such as PD and ALS, but it has not been given the same level of importance as it is in mammalian studies (Table 21.8). High throughput automated analysis of larval and adult fish motion is currently available through video tracking software (Cachat et al., 2011; Cario et al., 2011; Kane et al., 2004). Not only can basal movement be assessed, but behavioral responses can also be evaluated (Bhinder and Tierney, 2012; Shamchuk and Tierney, 2012). As mentioned in AD models, the testing of fish in a T-maze provides a learning and memory-based assay for the measurement of dementia. In the case of ALS, testing motors skills using a swim tunnel was uniquely applied (DuVal et al., 2014; McGown et al., 2013; Ramesh et al., 2010), providing novel information in longitudinal study design that increased the relevance of the model to human study and created another point of measure for therapeutic analysis. Similar longitudinal observations of neuromuscular deficits during normal aging have also been reported in zebrafish (Gilbert et al., 2014), providing context for endpoints in these disease models.

TABLE 21.8 Motion Endpoints Applied to Zebrafish Models of Neurodegenerative Disease

Disease	Endpoints applied	Potential endpoints[a]	References
Parkinson's disease	Larval touch response; larval and adult basal activity	Adult escape response; swimming performance	Anichtchik et al. (2008); Anichtchik et al. (2004); Bretaud et al. (2004); Ren et al. (2011); Sallinen et al. (2010); Sheng et al. (2010); Xi et al. (2010)
Alzheimer's disease	Larval touch response	Larval and adult basal activity[b]	Paquet et al. (2009)
Huntington's disease	—	Larval touch response; adult escape response; larval and adult basal activity; swimming performance	—
Multiple system atrophy	—	Larval touch response; adult escape response; larval and adult basal activity; swimming performance	—
Amyotrophic lateral sclerosis	Swimming performance; larval touch response	Adult escape response; larval and adult basal activity	DuVal et al. (2014); Kabashi et al. (2011); Kabashi et al. (2010); McGown et al. (2013); Ramesh et al. (2010)

[a] Olfactory endpoints pertaining to odor evoked behavior, tissue analysis, and electrophysiology can be applied to larval and adult zebrafish models of these diseases.
[b] AD is not considered a neuromuscular disease; however, measuring basal activity will contribute to assessments of overall heath.

Although the study of movement is making its way into zebrafish disease models, there has been no indication that olfactory testing will gain popularity. It is interesting that the olfactory symptoms so frequently remarked upon in diseased humans are rarely applied to animal models. Zebrafish olfaction can be tested in several different capacities. Electrophysiological recordings can be taken at the level of the olfactory bulb and epithelium to detect neuronal activity following odorant exposure (Friedrich et al., 2004; Michel et al., 2003). Using electrophysiology, the impairments in olfaction can be isolated to a particular structure, or olfactory neuron class. The characterization of odor-evoked activities in zebrafish could also provide an interesting parameter of analysis (Lindsay and Vogt, 2004; Speedie and Gerlai, 2008; Vitebsky et al., 2005). By combining the results of behavior with electrophysiology, it could help elucidate whether olfactory loss is due to physical damage or the inability to interpret the odor. With the latter result also comes the prospect of inappropriate responses to established odors, thereby replicating cases of dysosmia. Loss of odorant sensitivity can also be tested using various odorant concentrations. As support for using olfaction assays in neurodegenerative studies with zebrafish grows, there is an interesting theory on disease acquisition called the "Olfactory Vector Hypothesis" (OVH) (Prediger et al., 2012). The general principle of the theory concerns the transfer of exogenous agents, be they metals, toxins, or viruses, across the olfactory epithelium and through the olfactory nerve to the brain (Doty, 2008; Prediger et al., 2012). In his review, Doty (2008) also discusses the idea of an "olfactory damage hypothesis" that suggests damage to the olfactory system may in fact enhance the risk factor for genetically susceptible patients for developing AD and PD. In other words, individuals that have a genetic or physiological predisposition for neurodegenerative disease may have such conditions arise after olfactory damage. There has yet to be a substantial amount of evidence to support the OVH; however, zebrafish could be an effective model to test isolated olfactory exposures and damage. In sum, increased integration of motor and olfactory systems toward understanding neurodegenerative etiology and early diagnosis is warranted, and the promise of such approaches is gaining recognition (Albers et al., 2015). Overall, the inclusion of olfactory endpoints in future zebrafish studies of neurodegenerative diseases should increase both study relevance and the potential to elucidate characteristics of dysfunction and causation.

Animal Models for Studying Substance Use Disorder: Place and Taste Conditioning

Catherine M. Davis

Johns Hopkins University School of Medicine, Baltimore, MD, United States

1 WHAT IS SUBSTANCE USE DISORDER AND WHY SHOULD WE STUDY IT?

With the release of the *Diagnostic and Statistical Manual*, Version 5 (DSM-5, 2013), the terminology and criteria for additive disorders underwent a substantial revision. Terms commonly used in the literature, including "abuse" and "dependence," were replaced by the phrase "substance use disorder." Substance use disorder (SUD) is now subdivided into mild, moderate, or severe forms of the disease. While many of the features that previously defined "drug addiction" are still included, tolerance and withdrawal in the DSM-5 are specific to nonprescription drug use, and these effects when associated with the cessation of prescribed medications, no longer fall into the SUD category. The most severe form of SUD, however, is often still referred to as addiction and is still considered a chronically relapsing disorder, characterized by the compulsion to seek out and take the drug and a loss of control in limiting drug intake, despite a desire to stop using the drug (Koob and Volkow, 2010; Volkow et al., 2016). Use of licit (e.g., alcohol, nicotine) and illicit (e.g., marijuana, cocaine, heroin) substances are pervasive societal problems resulting in severe emotional, financial, and physical cost to the substance abusing individual, the individual's family, and the community (Nicholson and Ator, 2011). The economic cost (e.g., healthcare costs, crime-related costs, loss of productivity) of SUD in the United States exceeds $700 billion annually, with approximately 70% of these costs associated with abuse of alcohol and tobacco (CDC, 2014; US Department of Health and Human Services, 2014; US Department of Justice, 2011). Substance use and abuse is also associated with other

public health issues, including the spread of infectious diseases (e.g., HIV, hepatitis C) and impaired driving (CDC, 2005a,b). Despite the myriad costs to individuals and society, justifying the need for animal models of SUD can be a difficult task for researchers given that drug addiction is perceived by a large portion of the general public to result from moral weakness, a lack of will power, and/or self-discipline (Leshner, 1997; Nicholson and Ator, 2011).

In the scientific community, however, SUD is viewed as a disease of the brain that warrants the same type of investments in research and treatment strategies as those given to diseases, such as autism, schizophrenia, and Alzheimer's and Parkinson's disease (Leshner, 1997). Further, researchers studying SUD employ the same strategies as researchers investigating these other diseases: animal models are developed to represent some characteristic of the disorder and then studied, with the understanding that every detail of the disorder is most often not completely reproducible in a laboratory animal, but that a better understanding of the factors that contribute to the disease-process can be gained. For example, "schizophrenic" or "autistic" rats and mice do not exist (Baker, 2011), although there are rats and mice that exhibit behaviors characteristic of schizophrenia, autism, or even obsessive-compulsive disorder (Peca et al., 2011; Welch et al., 2007); these animal models are used to further our understanding of the molecular, cellular, and genetic components of a specific disorder and how these deficiencies translate into quantifiable behavioral symptoms.

Similar to many of these other human disease states, SUD is a uniquely human phenomenon, thus any attempt to study it in the laboratory inevitably constrains it reproducibility. Investigators must keep this in mind when designing and employing animal models of drug addiction. Some models have very good face validity, such as the drug self-administration procedure in which an animal emits a response (e.g., lever press) to receive a drug injection reinforcer. Elegant experiments using the self-administration procedure to study in rats the diagnostic criteria of addiction (outlined in a previous version of the *Diagnostic and Statistical Manual of Mental Disorders*; DSM-IV-TR) have been reported and arguably provide new approaches to study the neurobiology of addiction (Belin et al., 2008; Deroche-Gamonet et al., 2004; Robinson, 2004; Vanderschuren and Everitt, 2004). For other methods, the connection to the human drug user is not as evident, but the procedure nonetheless allows researchers to examine some aspect of addiction that is important to its overall etiology. Thus, the specific question under investigation influences the methodology and procedure employed. Great care must be taken to understand each procedure's strengths and limitations and how these factors impact

the interpretation of the results of the study. Even with these caveats, preclinical animal models have been instrumental in furthering our understanding of the neurobiological and behavioral characteristics of addiction, including drug-taking, physical dependence, tolerance, drug craving, and the factors that might increase the likelihood of relapse; however there is still much to learn and numerous reasons to continue refining our current models, in addition to developing new models as various techniques become even more sophisticated (Lobo et al., 2010; Tsai et al., 2009).

In the current review, two popular methods used to study SUD, place conditioning (primarily focused on conditioned place preference or CPP) and conditioned taste aversion (CTA) will be discussed. Both procedures have been used extensively to study the rewarding and aversive effects associated with drug exposure. With each of these procedures comes a rather large literature base that includes, but is not limited to, variations in procedural details, equipment, and study design, debates on data analysis and interpretation, and excellent reviews commenting on the strengths, weaknesses, and controversies surrounding each procedure. Although many of these factors will be discussed in the current review, readers are encouraged to access these resources for additional information (Bardo and Bevins, 2000; Bardo et al., 1995; Huston et al., 2013; Liu et al., 2008; Mueller and de Wit, 2011; Riley et al., 2012; Schechter and Calcagnetti, 1993, 1998; Tzschentke, 1998, 2007; van der Kooy, 1987).

2 REWARD AND REINFORCEMENT

When beginning any discussion of animal models of drug addiction, the distinction between reward and reinforcement should be made and include what these terms mean in the context of drug addiction research. Drugs of abuse are considered reinforcers and, in a Skinnerian view, are received as a consequence of an instrumental response and influence the probability of that response occurring in future. Regardless of the valence (i.e., positive or negative), reinforcement will increase the probability of behavioral output in an organism, in order for the organism to earn an appetitive reinforcer or to avoid experiencing an aversive one. At different stages in the addiction process, drugs of abuse are thought to differently reinforce drug-taking behavior with positive reinforcement occurring in the early stages of drug use (i.e., binge and intoxication, Volkow et al., 2016), and negative reinforcement involved predominantly following more chronic drug taking (e.g., to decrease or obtain relief from a dysphoric state). Sanchis-Segura and Spanagel (2006) argue that in this context drugs of abuse serve as reinforcers

in three distinct ways: (1) Drugs serve as primary motivators (i.e, positive reinforcement) where behavioral contingencies are positively reinforced, that is, they serve as appetitive stimuli that increase the emission of the instrumental response; stimuli associated with drug intake in these situations can also become "conditioned reinforcers," a process by which they acquire incentive-motivational properties (which are considered to become pathological in addiction), and when these stimuli are presented in the absence of drug, elicit "wanting" or craving responses (Robinson and Berridge, 1993, 2000, 2001, 2008). (2) Drugs acting as reinforcers increase the associative strength of specific stimulus-response contingencies, which results in an increased probability of the instrumental response occurring; reinforcers thus serve to enhance information storage about the situations in which they occur, a process that can bias response choice when those situations occur in the future. (3) Acting as a negative reinforcer, drugs can reduce specific needs/drives or eliminate/prevent the occurrence of a negative state; this process is most important after prolonged drug taking when abstinence can result in withdrawal symptoms that are alleviated following drug intake (Koob and Le Moal, 2006; Sanchis-Segura and Spanagel, 2006).

Although negative reinforcement by drugs of abuse is an important aspect of the addiction process (Koob and Le Moal, 2006), drugs have traditionally been viewed as appetitive stimuli, for which responding is thought to be due to positive reinforcement. Another common term used to describe positive reinforcement in this regard is reward. This term is often mistakenly used as a synonym for reinforcement, without any distinction between the valences used to distinguish the type of reinforcement. When describing positive reinforcement, rewards are those appetitive reinforcers that increase the probability of emission of the instrumental response. Reward is also used to describe hedonia, which is defined as a hypothetical internal state of pleasure associated with acquiring, using, and/or consuming appetitive stimuli (Everitt and Robbins, 2005; Sanchis-Segura and Spanagel, 2006). Given these definitions of reward, it is clear that this term can be used to describe positive reinforcement contingencies or appetitive stimuli, but is distinct from that of the broader concept of reinforcement.

3 AVERSIVE DRUG EFFECTS

Although drugs of abuse are typically viewed as appetitive stimuli, it is argued that these compounds have multiple behavioral effects, including aversive properties that might impact the overall acceptability of a drug and its subsequent self-administration (Davis

and Riley, 2010; Hunt and Amit, 1987; Riley, 2011; Stolerman and D'Mello, 1981; Verendeev and Riley, 2012, 2013; White et al., 1977; Wise et al., 1976). For example, Riley (2011) argues that the "overall hedonic effect of a drug" and the likelihood of its use and abuse, is dependent on the balance of a drug's rewarding and aversive effects. When examining patterns of self-administration an inverted U-shaped function typically emerges, such that drug intake increases with dose until some asymptotic level is achieved; as the dose continues to increase, self-administration begins to decrease.

A drug's rewarding effects are hypothesized to increase with dose until some maximal level is achieved, where fewer self-injections are needed to attain the desired effect, in addition to possible receptor saturation (Lynch and Carroll, 2001). As the drug dose is increasing, a drug's aversive effects are also hypothesized to be increasing and the overall balance of these effects presumably results in the observed pattern of drug intake (Riley, 2011; Verendeev and Riley, 2013). Describing use and abuse as a balance of these affective properties suggests that reward and aversion are on a continuum where a drug with robust rewarding effects must also be weakly aversive (or the opposite, an aversive drug must be weakly rewarding). It is more likely, however, that each of these effects is mediated independently, such that a drug has some level of rewarding and/or aversive effects (Verendeev and Riley, 2011). The perceived balance of these effects then dictates drug intake, where a drug perceived as "more aversive" is theoretically self-administered less than a drug that is perceived as "more rewarding." Importantly, these aversive drug effects are considered distinct from those that negatively reinforce drug-taking following withdrawal; aversive drug effects in this context are experienced following acute administration and could serve a protective function by limiting (or eliminating) future intake. Thus, aversive drug effects could decrease the likelihood that drug use would lead to misuse of that drug. Interestingly, the two procedures reviewed in this chapter have been used independently and in combination to demonstrate that a drug's rewarding and aversive effects are measurable simultaneously in individual subjects following a single drug administration. Further, these procedures have shown that not all manipulations and subject variables, including drug history, strain, and other genetic differences, sex, and stress, alter these effects in the same manner (e.g., decreased aversion and increased reward), which makes these procedures useful for continued investigations focused on understanding the factors that impact substance use disorder (Bahi et al., 2013; Cunningham, 2014; Davis and Riley, 2010; Riley, 2011; Riley et al., 2009).

4 THE PLACE CONDITIONING PROCEDURE

4.1 What are Conditioned Place Preferences?

Place conditioning is a simple procedure used to assess the positive (rewarding) or negative (aversive) motivational effects of exposure to various stimuli, including, but not limited to, drugs of abuse, food, sexual behavior, novel environments, social reward, music, or footshock, and in many species, including rodents, zebrafish, birds, and humans (Astur et al., 2014, 2016; Childs and de Wit, 2009; Collier and Echevarria, 2013; Cunningham et al., 2006; Dixon et al., 2013; Lahvis et al., 2015; Molet et al., 2013). Conditioned place preference or CPP is a procedure commonly used to assess the rewarding effects of a stimulus by measuring increased approach and contact behaviors to a certain location or place, whereas conditioned place aversion (CPA) measures increased avoidance and/or escape behaviors indicative of the aversive effects of a specific stimulus. Although these procedures are simple and effective methods for assessing the motivational effects of various stimuli in different species, the CPP procedure is most commonly used in rodents (rats and mice) as an indirect assessment of the rewarding effects of various classes of drugs, especially drugs of abuse. In a standard CPP experiment, subjects undergo conditioning sessions, in which a drug injection is paired with specific cues (e.g., tactile, visual, olfactory) while the subject is confined to one compartment of a conditioning apparatus, typically a shuttle box-like apparatus (Fig. 22.2); subjects experience different cues paired with a saline injection while confined to the opposite compartment. After several drug-environment and saline-environment pairings (i.e., conditioning trials), subjects are tested for the expression of a CPP during a drug-free test session in which subjects are given access to the entire apparatus and can move freely between the conditioning compartments for a specified timeperiod (typically 15–30 min). Subjects that spend significantly more time in the compartment paired with drug administration are said to express a conditioned preference. In contrast, avoidance of the drug-paired compartment, by spending more time in the saline-paired side, is often interpreted as a CPA (Cunningham et al., 2006; Mueller and de Wit, 2011).

This procedure is based on principles of Pavlovian classical conditioning, where the drug administered serves as the unconditioned stimulus (US) and is paired with the initially neutral environmental cues of the shuttle box compartment—after several pairings as stated earlier, these neutral environmental cues become associated with the rewarding effects of the drug and acquire secondary motivational properties. The drug-paired compartment then becomes the positive conditioned stimulus (CS+) that evokes a conditioned motivational response and elicits approach and contact behavior during the subsequent drug-free test session. The other shuttle box compartment, which is usually paired with saline injections (or no injection at all), contains different cues from those of the CS+. These environmental cues remain neutral in that they do not become associated with the drug's effects (US) and thus become the negative conditioned stimulus (CS−). The fact that an animal will approach and/or contact stimuli that have been previously paired with rewarding drug effects is fundamental to the CPP procedure. When an animal receives these drug-environment pairings and subsequently approaches and spends time in contact with the drug-paired side of the conditioning apparatus, it is inferred that the drug administered had rewarding effects and these effects have become associated with the specific compartment in which the conditioning trials occurred. In a similar manner, avoidance and/or escape behaviors elicited by a CS+ paired with an aversive stimulus are essential to the CPA procedure as well. Although most drugs of abuse result in conditioned preferences for the CS+, these same drugs can result in a CPA in different strains of rodents or following variations in the route of drug administration or temporal parameters used when pairing the drug's effects with the environmental cues available in the conditioning apparatus (see later). An understanding of the procedure and careful selection of the parameters used will help to reduce many of these confounding factors and provide for an easier, more straightforward interpretation of the results.

While place preference is most often described in terms of Pavlovian conditioning as detailed earlier, Huston et al. (2013) have argued that this interpretation of CPP might oversimplify a procedure that includes multiple learning processes, memory retrieval, and various neurobiological mechanisms. In an operant conditioning account of place conditioning, for example, drug effects that are typically perceived and expressed during and after place conditioning sessions could elicit behaviors that are inadvertently reinforced by drug exposure. In this context, the cues (e.g., floor texture, wall pattern, etc.) in the drug-paired chamber would arguably serve as discriminative stimuli (SD); thus, the behavior(s) previously reinforced in this compartment would then be under stimulus control and increase the probability that the subject would remain in the presence of the SD upon subsequent encounters. These behaviors are argued to be similar to "superstitious behaviors" in pigeons previously reported by Skinner (1948) (Staddon, 1992), where spontaneous behaviors were inadvertently reinforced by delivery of a food reinforcer.

Huston et al. (2013) argue that conditioned treatment effects induced by the pharmacological agent used during CPP conditioning are a third theoretical explanation

of preference for the drug-paired chamber. Given that the various behavioral effects induced by psychoactive drug administration can be conditioned to environmental cues (Banasikowski and Beninger, 2010), these effects could increase or decrease the probability that a subject will remain in the chamber associated with drug administration. For example, conditioned drug effects that prevent a subject from leaving the drug-paired chamber would increase the likelihood of a CPP and would arguably be independent of the rewarding effects of the drug. Thus, CPP induced by some classes of psychoactive drugs could simply indicate that due to the conditioned drug effects, the subject was less likely to leave the drug-paired chamber and explore the entire apparatus (Meyer et al., 2012). In this context, a false positive CPP could result from a psychoactive drug that is due to these conditioned drug effects and not rewarding drug effects per se; this interpretation is especially important for assessing the rewarding effects of novel therapeutic compounds. In a similar vein, psychoactive drugs that increase movement or activity during conditioning sessions could result in conditioned hyperactivity. During the CPP test session, the conditioned hyperactivity would be elicited by exposure to the drug-paired chamber, which could weaken the overall "preference" for the drug-paired cues because the subject is moving around the entire conditioning apparatus; Huston et al. (2013) argue that these effects could impact cocaine-induced CPP (Bardo et al., 1995). Empirical evaluation of these alternative interpretations is needed and could be accomplished by altering the place conditioning apparatus (White et al., 2005) and comparing spontaneous behaviors during the CPP test to the CPP pretest, although this second suggestion requires recording and scoring the various behaviors emitted by each subject during all phases of the CPP procedure, including (and arguably most importantly) during the CPP conditioning sessions (Cunningham, 2014).

4.2 A Brief History of Place Conditioning

Garcia et al. (1957) first used the place conditioning procedure to assess the motivational effects of whole-body gamma (γ) or X-ray irradiation in male rats. A two-compartment apparatus was employed, which included one compartment that was painted black and contained a grid floor; the opposite compartment was painted white and contained a wire mesh floor. Rats experienced four irradiation-compartment pairings in either the black or the white compartment; the radiation-paired compartment (or sham-irradiation) was divided across subjects such that baseline preference for the black compartment was used to divide rats into groups with comparable baselines (i.e., time spent in the black compartment). Half of the rats were irradiated in the

black compartment and half received the exposures in the white compartment. Following conditioning, all animals displayed significant *decreases* in the amount of time spent in the compartment paired with irradiation, indicating a *conditioned place aversion*. Although the groups conditioned with γ irradiation in the black compartment initially spent more time there during the pretest session compared to rats conditioned in the white compartment, there were no significant differences in the radiation-induced conditioned place aversion between the groups.

Although this initial study was assessing aversion induced by irradiation, Garcia et al. (1957) employed several techniques that are currently used in place conditioning studies with drugs of abuse. For instance, the baseline preference for each conditioning compartment was determined on the day prior to the first conditioning session during a pretest session, which consisted of a test period (150-min) where the rats could freely explore both the black and white compartments. This study was one of the first to use the pretest session in order to determine each subject's baseline preference for the compartment subsequently paired with the US (in this case, irradiation). In this way, these investigators compared the shift in the amount of time spent in this compartment during the pretest to the amount of time spent in the same compartment following the conditioning sessions for each subject. Although the rats conditioned with irradiation in the black or white compartment were treated as separate experimental groups, a procedure similar to this is commonly used in place conditioning with drugs of abuse to specifically assign the CS-US pairings across the experimental groups (see Section 4.5). Garcia et al. (1957) conditioned some rats to their naturally preferred sides (i.e., groups receiving γ irradiation-black compartment pairings) and others to their naturally less-preferred side (i.e., groups receiving γ irradiation-white compartment pairings); the former procedure is more common in place aversion work in order to avoid a floor effect, that is, an aversive stimulus is paired with the naturally preferred side of the conditioning apparatus because subjects are most likely to decrease the amount of time spent in the compartment paired with an aversive stimulus. Both groups conditioned with X-ray irradiation paired with the white or black compartment were conditioned to their naturally preferred side (e.g., the group of rats receiving irradiation-black compartment pairings preferred the black compartment during the pretest and the group of rats receiving irradiation-white compartment pairings preferred the white compartment during the pretest). Interestingly, the irradiation-induced aversions were similar in strength regardless of what compartment the animals received the exposures. This is not always the case when assessing drugs of abuse in the CPP design and the choice of the drug-paired compartment is an important one (Bardo et al., 1995).

While Garcia and colleagues were interested in examining the effects of irradiation in the place conditioning procedure, Beach (1957) published the first paper assessing a drug-induced CPP in rats. Beach hypothesized that rats would associate a specific place with the drug's effects, if they were confined to this place *after* each drug administration and remained in this place long enough to adequately experience the drug's effects. This work was to demonstrate that rats could learn to associate a specific environment with a drug's effects and would subsequently prefer this environment when tested while "needing" morphine (tested 2–4 h following saline administration) or while morphine "sated" (tested 2–4 h after being injected with morphine; Beach, 1957). Rats were chosen as subjects for this study to determine if this species could learn drug effect-environment associations in a manner similar to the morphine-environment associations displayed by morphine-dependent chimpanzees in an earlier report by Spragg (1940). Beach successfully demonstrated that morphine-dependent and nondependent rats both learned to associate the effects of morphine administration with a specific environment and subsequently preferred this environment to the one in which the rats received saline injections (or no injection at all).

This study is not only the first report of a drug-induced CPP, but also is an example of simple changes to the place conditioning procedure and apparatus from those reported by Garcia and colleagues. For example, Beach employed a Y-shaped discrimination box in which two distinct arms connected a starting box to two separate "goal boxes" (i.e., conditioning compartments) (Fig. 22.1).

The start box, left goal box, and right goal box were each painted a different color and each contained additional visual and tactile cues. The left goal box had grey walls with square black insets and a flyscreen-covered floor. The right goal box had black walls with circular white insets and a wood floor. Additionally, the Y-shaped discrimination box had four doors that could be used to close off the start box or either of the goal boxes. In 16 pretest choice sessions, rats were placed in the start box and allowed to access either of the goal boxes. Once the rats reached a goal box, a choice for that goal box was recorded; after 5 s in the chosen goal box, rats were removed to prevent them from moving back down the arm and into the start box and/or the other goal box. From these pretest choice sessions, preferred and nonpreferred goal boxes were determined for each rat. Rats were subsequently conditioned to their nonpreferred goal box, that is, rats were injected with morphine, placed in the start box, and run to the goal box that was chosen *less* during the pretest sessions. In this way, some of the rats experienced morphine in the gray goal box and others experienced morphine in the black goal box, but all rats
FIGURE 22.1   **Various place conditioning apparatuses have been reported in the literature, including two- and three-compartment designs with additional alleys and/or goal boxes.** (A) Barr et al., 1985; Garcia et al., 1957; Cunningham et al., 2006; (B) Mucha and Iversen, 1984; Parker, 1992; (C) Carr and White, 1983; (D) Davis et al., 2007; Mueller and de Wit, 2011; Roma and Riley, 2005; Spyraki et al., 1982; (E) Beach, 1957. *Source: Some examples have been redrawn from Carr, G.D., Fibiger, H.C., Phillips, A.G., 1989. Conditioned place preference as a measure of drug reward. In: Liebman, J.M., Cooper, S.J. (Eds.), The Neuropharmacological Basis of Reward. New York, Oxford, pp. 264–319.*

were conditioned to the nonpreferred goal box. This study can be considered the first use of the "biased" design in place conditioning with drugs of abuse, a technique where subjects are conditioned to their initially nonpreferred side. A significant change in the amount of time subjects spend in the nonpreferred side following conditioning with morphine, for example, indicates a preference for the drug-paired side. This is in contrast with the "unbiased" design in which the drug-paired compartment is counterbalanced across subjects regardless of initial compartment preference (see later for more details on biased vs. unbiased designs).

Following Beach's report of morphine CPP in morphine-dependent and nondependent rats, Kumar reported conditioned preferences for morphine-paired environments in morphine-dependent rats tested during withdrawal (i.e., 48 h after the last morphine injection) using a two-compartment apparatus. Further, two additional studies included interesting changes to the CPP procedure that have since received considerable attention in the CPP literature (Reicher and Holman, 1977; Rossi and Reid, 1976). More specifically, Rossi and Reid reported "acquisition" of a morphine CPP by conditioning and testing rats over a 4-day cycle where

rats received morphine- or saline-environment pairings over 3 days and were then tested for CPP on the 4th day of the cycle; four conditioning cycles were completed which allowed for analysis of the CPP after additional morphine-environment pairings. Although initial side preferences influenced the results, morphine did condition a significant CPP, however a clear increase in the conditioned preference over test trials was not evident (for a more recent study of morphine CPP acquisition, Davis et al., 2007). In the study by Reicher and Holman (1977), CPP procedures were combined with the conditioned taste aversion (CTA) procedure to simultaneously test the rewarding and aversive effects of amphetamine administration. In this combined CTA/CPP procedure, Reicher and Holman reported amphetamine-induced taste aversions and place preferences conditioned in rats that consumed a distinctively flavored solution in one shuttle box compartment and a different flavored solution on the other side (Simpson and Riley, 2005; Verendeev and Riley, 2011).

Since these initial studies, the use of the place conditioning procedure has become widespread in the field of SUD research and has amassed an extensive literature containing the use of different species, classes of drug, procedures, and methodologies. For example, drug-induced place conditioning has been reported in rats and mice, hamsters, birds, zebrafish, nonhuman primates, and humans (Borges et al., 2015; Childs and de Wit, 2009; Collier and Echevarria, 2013; Cunningham et al., 2006). These studies have also demonstrated that most drugs serving as reinforcers in self-administration procedures also condition place preferences, including cocaine, amphetamine, nicotine, morphine, and ethanol. Numerous variations in the place conditioning procedure exist in literature, including the experimental design used, shape and layout of the conditioning apparatus, and environmental cues employed; further, the procedure has evolved considerably since these early studies. Thus, it is not surprising that no single method for conducting place-conditioning studies exists. Nonetheless, generalities among most studies are apparent, but substantial variability still exists in these items throughout the place conditioning literature. While many of these variations impact the interpretation of the results of place conditioning studies, others have demonstrated interesting interactions between route and timing of drug administration, strain of animals employed, and strength of preference or aversion conditioning (Bardo et al., 1995; Cunningham et al., 2002). For example, intraperitoneal or intravenous injection of ethanol in mice results in a CPP, whereas a 5-min delay following drug administration and prior to placement into the ethanol-paired compartment is needed for intragastric ethanol administration to condition a place preference. Intraperitoneal or intragastric ethanol administration interestingly results

in place *aversions* when exposure to the conditioning compartment (i.e., CS+) occurs immediately prior to or immediately following ethanol administration, respectively (Cunningham et al., 2002).

Recently, the CPP procedure has been used in the pain field to investigate motivated behaviors associated with analgesic administration and pain relief (Gerber et al., 2014; Navratilova and Porreca, 2014). Pain relief in humans is rewarding (Leknes et al., 2008, 2011) and recent work employing CPP has demonstrated this effect in laboratory animals (Andreatta et al., 2012; Becerra et al., 2013; Gerber et al., 2014; Navratilova et al., 2012). In most of these studies, relief of ongoing pain is paired with one compartment of the CPP apparatus (CS+). In the subsequent test session, subjects prefer this context over the CS− that was paired with vehicle administration (i.e., no pain relief). Significant preferences for the pain-relief paired context have been shown in rodents following postsurgical pain, neuropathic pain, inflammation, osteoarthritic pain, cephalic pain, and bladder and bone cancer pain models (Davoody et al., 2011; De Felice et al., 2013; Hung et al., 2015; Navratilova et al., 2012, 2015; Okun et al., 2012; Park et al., 2013, 2016; Qu et al., 2011; Remeniuk et al., 2015; Roughan et al., 2014; Sufka, 1994; Wei et al., 2013). Further, many of these studies demonstrate pain relief-induced CPPs with analgesic agents that are not rewarding in the absence of pain. For example, intrathecal clonidine administration conditions a significant CPP only in rats with spinal nerve ligation, but not sham-operated rats (King et al., 2009), further supporting the hypothesis that pain relief is rewarding and when paired with distinct contextual cues, will elicit approach behaviors following conditioning. While the positive reinforcing effects of other analgesic compounds (e.g., opioids) can confound interpretation of pain relief-induced CPPs, these effects appear to be dose-dependent, given that morphine doses that do not condition a CPP in control or sham-operated subjects, condition significant pain relief-induced CPPs in certain animal models (Hung et al., 2015; Navratilova et al., 2015; Roughan et al., 2014).

4.3 Advantages of the Place Conditioning Procedure

Place conditioning is a methodologically simple and relatively inexpensive procedure: Place conditioning is a popular method in the drug addiction field because it provides numerous advantages compared to other methods used to assess the conditioned motivational effects of drugs. First, the procedure is methodologically simple in terms of (1) experimenter training and (2) expensiveness of the necessary experimental equipment. More specifically, extensive training in survival surgery, jugular catheter implantation, and proper anesthesia/analgesia

procedures needed for intravenous self-administration protocols are not required for a general place conditioning study. Indeed, intraperitoneal (i.p.) or subcutaneous (s.c.) drug injections are the most widely used methods to administer drug in the place conditioning procedure, although oral gavage and intragastric cannulas have been used for ethanol administrations (Ciccocioppo et al., 1999; Cunningham et al., 2002). While intravenous (i.v.) drug administration via indwelling jugular catheters is not a requirement for a standard place conditioning study, this drug administration technique has been used in the CPP procedure for several different drugs of abuse, including amphetamine, morphine, and ethanol (Bardo and Neisewander, 1986; Bardo et al., 1999; Kelley et al., 1997; Mucha et al., 1982).

In terms of the equipment needed for a place conditioning study, the conditioning apparatus can be purchased from a commercial vendor (e.g., Med Associates, Harvard Apparatus, San Diego Instruments) or hand-made with some common materials found at home improvement stores, for example. While commercially available place conditioning systems commonly require the added expense of a computer and software package for data acquisition and analysis, these systems are fully automated in terms of data collection and result in immediate access to each animal's data once the test session has ended. For example, the rodents' movements are typically tracked by a series of infrared light sources and detectors (i.e., photobeams) located on opposite sides of the apparatus that form a grid to monitor body positions in each chamber. Beam breaks that occur when an animal traverses the apparatus are recorded by a computer software package and are easily transformed into "time spent in compartment" measures. That is, the breaking of specific photobeams is used to determine the animal's position in the apparatus and to determine in what compartment the animal is located. Further, a break in one or several photobeams, in addition to photobeams in another area being released, is used to determine when the animal has entered a specific compartment. Some systems also monitor vertical movements (rearing) in addition to horizontal movement throughout the apparatus. Test sessions in an automated apparatus can be video recorded for later analysis, but this is not necessary for data acquisition like it is in a system without photobeams.

Although the commercially available systems confer many advantages in terms of ease of data collection, purchasing an expensive system is not required to do place conditioning studies because the place conditioning apparatus can be constructed of readily available materials, such as wood or Plexiglas sheets. Size measurements for rat or mouse place conditioning chambers are easily acquired through a brief literature search (Fig. 22.2), in addition to examples of visual and tactile cues used in
FIGURE 22.2　Illustration of a three-compartment apparatus used for place conditioning studies with rats. Each individual conditioning compartment measures 30 cm × 30 cm × 39 cm and the center compartment measures 10 cm × 30 cm × 39 cm (total size: 70 cm × 30 cm × 39 cm). The "white" compartment consists of a black-and-white striped floor and solid white walls (in addition to a textured floor surface, see Davis et al., 2007). The "black" compartment contains a solid-colored floor and walls (in addition to a smooth floor surface). During the pretest or the posttest, rats have free access to all three compartments. During the conditioning trials, however, guillotine doors are inserted at the border of the white and center compartments and at the border of the black and center compartments. *Source: Picture courtesy of Peter G. Roma.*

each compartment and variations in lighting schemes that can help to reduce bias for one compartment over another in experimental subjects.

When constructing an apparatus out of materials like wood, it is imperative that the apparatus can be sanitized easily so painting of the wood surface is necessary; this is not the case for materials, such as Plexiglas which will not absorb liquids on their surfaces (e.g., urine). Custom-made conditioning chambers allow the experimenter to fully control the appearance of each compartment of the apparatus and the ease with which a compartment's appearance can be altered, if necessary. In this way, an experimenter can design an apparatus with floor textures and/or wall patterns that are easily interchangeable (Cunningham et al., 2006; Roma and Riley, 2005). The advantage of an easily alterable apparatus is that the cues within each compartment of the apparatus can be changed to manipulate the initial side preference that is typically found in rodents. For example, one strain of rats or mice might show no bias when a wire mesh floor, grid floor, or different lighting conditions are used in the opposing compartments (Roma and Riley, 2005); however, this might not be the case for a different strain of rodent or for the opposite sex of the same strain of rodent.

In a handmade place conditioning apparatus, the infrared light sensors and detectors can be added to automate data collection during the test session(s) in a manner similar to that described earlier; this will require electronic circuits and computer software that can be made in the laboratory. If constructing these types of circuits and software is not possible, other methods are available for collecting data in this type of apparatus, and although they can be labor-intensive, most only require a video camera (or cameras depending on the number and/or placement of the apparatus in the laboratory), a stopwatch (or some other way to keep track of the time spent in each compartment), and an experimenter/technician (or several); additionally, experimenters can use computer-based event logging software (free software is available: JWatcher: http://www.jwatcher.ucla.edu/; Observational Data Recorder (Beta version): http://www.samuelpean.com/odrec/). When "scoring" place conditioning test sessions (e.g., pretest, posttest) in this manner, each shuttle box apparatus needs to be in full view of a video camera so that the entire apparatus can be seen easily on playback (Myers et al., 2012). To achieve this, the camera needs to be positioned above the apparatus, looking down at the conditioning compartments such that an animal's body position is easily discerned above the border for each compartment. Experimenters must consider rodent coat color and its contrast with the floor material/color in order to adequately determine each subject's movement during the test sessions (Myers et al., 2012). Further, all experimenters responsible for scoring the data need to be adequately trained on what criteria will be used to determine when an animal is one compartment of the shuttle box and what criteria will be used to determine when that animal is no longer considered to be in that specific compartment. These criteria should be determined ahead of time and reliability testing between experimenters should be conducted; use of an event logging software with experimenter training sessions and reliability testing can easily overcome any issues between experimenters (e.g., The Observer software by Noldus; http://www.noldus.com/animal-behavior-research/products/the-observer-xt). With reliably trained experimenters and consistent methodology in the laboratory, scoring video recorded place conditioning test sessions provides an inexpensive alternative to purchasing a fully automated system from a commercial vendor. Additionally, with a video recording set up in place, experimenters can easily record all sessions of the CPP procedure (e.g., conditioning sessions) for detailed behavioral analyses (Huston et al., 2013).

Place conditioning studies are short in duration and have the potential for high throughput of subjects: Another advantage to the standard place conditioning procedure is the large number of animals that can be conditioned and tested in a relatively short period of time. If no other experimental manipulations are required, a standard place conditioning study can run anywhere from 8–14 days. More specifically, the standard place conditioning procedure usually consists of a pretest session or a habituation day (day 1), four drug and four vehicle conditioning trials (days 2–9), and a test session (day 10). If all sessions occur on consecutive days, including on the weekends, then the procedure requires 10 days; if weekends are excluded, the procedure takes two 5-day weeks (or 12 total days), where week 1 would include days 1–5 (days 6–7 would be the weekend days where no sessions would occur) and week 2 would include days 8–12. Some investigators recommend inserting a 2-day break between the end of the conditioning trials and the place conditioning test (Mueller and de Wit, 2011) given that they have acquired a greater drug-induced CPP following this protocol compared to testing immediately after conditioning (i.e., the day following the last conditioning trial).

It should be noted that when conditioning with different drugs or routes of administration, only one or two CS+ drug trials are sometimes necessary to condition a preference, which subsequently results in a shorter experimental period. For example, Bardo et al. (1999) used a one-trial (a single exposure to the CS+ and CS−) place conditioning procedure in which rats received a single IV injection of amphetamine during one CS+ conditioning session; doses of 1 or 3 mg/kg amphetamine induced a significant CPP in this design (Bardo and Neisewander, 1986; Bardo et al., 1999; Mucha et al., 1982). Ethanol-induced place conditioning studies with a reduced number of conditioning sessions (i.e., two CS+ trials and two CS− trials) have been reported as well (Cunningham et al., 2002). While these shorter conditioning periods have been reported in other laboratories, adhering to a more common conditioning approach is beneficial to a laboratory that lacks substantial experience with the place conditioning procedure. Once the parameters within the laboratory are established and place conditioning produced with known drug(s) and doses, then alterations to this standard timeline can be made; these changes however, could require additional control groups to demonstrate reliability of the findings.

In a standard place conditioning experiment, a period of at least 24 h commonly separates the conditioning trials, and this results in either one CS+ or one CS− trial being run per day in each animal. The studies mentioned earlier decreased the total number of conditioning trials, but still maintained this 24-h interval (i.e., intertrial interval). Several investigators have reported place conditioning following two conditioning trials in 1 day (e.g., a drug trial in the AM followed by the vehicle trial in the PM). Use of an intertrial interval less than 24 h should be carefully considered (Bevins and Cunningham, 2006, for

a discussion of the advantages and disadvantages of this procedure).

Other advantages of the place conditioning procedure: In addition to the advantages discussed earlier, there are several additional items that make the place conditioning procedure an excellent preparation with which to study the conditioned motivational effects of drugs of abuse. First, test sessions in this procedure are drug-free, which eliminates the confounding effects of drug-induced motor and/or sensory impairments (or enhancements) that occur in other procedures where subjects are tested shortly following drug administration. Second, this procedure is sensitive to the effects of low drug doses and when a variety of doses are tested in separate groups of subjects within the procedure, monophasic dose-response curves have been reported. It is important to note that this is not always the case and a common criticism of the CPP design is the difficulty in obtaining well-defined dose-dependent responses (Ahsan et al., 2014; Bardo et al., 1995; Durazzo et al., 1994; Spyraki et al., 1985). Further, many studies report an "all-or-none" effect where after achieving a threshold dose and inducing CPP, no further increase in CPP occurs at higher doses (for discussions of this effect, see Carr et al., 1989; Mueller and de Wit, 2011).

The use of drug-naïve subjects is an additional advantage to the place conditioning procedure. Several different drugs of abuse induce CPP in a variety of drug-naïve subjects, which provides a reliable method to study the rewarding effects of a specific drug without the added effects of tolerance (or sensitization) from previous drug exposures (Cunningham, 2014; Meyer et al., 2012). Generally speaking, the fact that a lengthy drug history is not necessary to induce place conditioning and, as mentioned earlier, specific routes of administration can reduce the number of conditioning trials needed to induce CPP all add to this procedure's flexibility and adaptability. Although a drug history is most often not needed for drug-induced CPP, there are examples of rats needing previous drug exposures (with the US or a different drug) or stressful experiences to induce an ethanol CPP (Marglin et al., 1988; Matsuzawa et al., 1998, 2000). Thus experimenters should research extensively the specific species and/or strain to be used in the place conditioning procedure, understand these differences, and adapt the general procedure and/or interpretation of the results to account for these factors.

Finally, the neurobiological underpinnings of drug reward can be investigated in the place conditioning procedure and recent work in the SUD field demonstrates the utility of this procedure for these types of studies. This procedure has been used extensively to investigate differences in drug-induced reward among genetically modified rodents, different rodent strains, and even different animal species with the goal of understanding the neurobiological mechanisms responsible for the rewarding effects of abused drugs and how these effects are altered following chronic drug exposure or withdrawal. For instance, inhibition of the IRS2-Akt (protein kinase B) pathway, which is thought to mediate opiate-induced changes in dopaminergic neurons of the ventral tegmental area, results in a diminished morphine-induced CPP (Russo et al., 2007). Morphine CPP is dependent on certain brain regions (e.g., nucleus accumbens, amygdala), but only in the presence of certain conditioning cues or apparatus configurations (White et al., 2005). Cocaine CPP, interestingly, is apparent at a lower dose in fosB mutant mice compared to wildtype mice (Hiroi et al., 1997), which demonstrates the sensitivity of the place conditioning procedure to molecular changes related to chronic cocaine use as well.

4.4 Place Conditioning: Experimental Protocol and Conditioning Apparatus

Although the characteristics of a place conditioning study were mentioned briefly in the preceding text, the current section aims to describe the place conditioning study in detail, including a discussion of some general parameters and characteristics of the experimental design that should be taken into consideration when designing and executing a place conditioning experiment.

Phases of a place conditioning study: There are several general phases to a place conditioning study and these will be discussed here. These phases are included because they are commonly reported in place conditioning studies however, some can be altered or eliminated depending on the goals of the experiment and the extent to which the laboratory has experience with the procedure and/or apparatus.

The pretest: The pretest or preconditioning test is performed at least 1 day prior to the start of the place conditioning trials and consists of a drug-free test period (typically 15-min) where subjects are allowed to freely explore all parts of the apparatus. During this test, the amount of time spent in the to-be-conditioned compartments is recorded. This test is used to accomplish several important experimental goals, including (1) to determine whether the subjects have an inherent bias for one set of cues within one chamber over another, (2) to give the subjects a brief exposure to the novel environment of the place conditioning apparatus, and (3) provide a data point to which posttest changes in preference are compared. Following the pretest, the baseline preference score for each compartment for each individual animal is used to assign drug- and vehicle-paired environments. If an unconditioned preference for one of the compartments exists (i.e., an inherent or natural bias or side-preference), subjects then receive drug injections in their least-preferred compartment (i.e., the compartment

in which they spent the least amount of time) and this is termed a "biased procedure."

If no inherent side preferences exist, the drug-paired compartment is counterbalanced across animals, where half of the subjects receive drug in one compartment and the other half receive drug in the opposite compartment; this is termed the "unbiased procedure."

The pretest is not always necessary, and in laboratories where the place conditioning parameters have been optimized (Cunningham, 2014; Cunningham et al., 2006) for a specific procedure, drug, and/or rodent strain(s), the pretest is not regularly used. In these cases, a short (e.g., 5-min) habituation session is used to reduce the effect of novelty and stress. However, the pretest is recommended if the apparatus (or cues within either compartment) or rodent strain is new to the laboratory. In addition, acquiring the pretest data allows experimenters the opportunity to alter the cues within each compartment in order to eliminate any inherent side preferences and use the "unbiased procedure" (described later; see also Roma and Riley, 2005) and to compare activity or other behaviors across the conditioning and testing phases to this first exposure to the apparatus.

Conditioning trials: In a standard place conditioning study, there are typically four conditioning trials in which the drug is administered prior to placement into the CS+ compartment and four additional trials where vehicle (or no injection) is administered prior to placement into the CS− compartment (for a vehicle-only control group, vehicle injections are administered prior to placement into both the CS+ or CS− compartments). More specifically, for each drug conditioning trial, animals are removed from their home cages, injected with the appropriate dose of drug (or vehicle), and immediately placed into the CS+ compartment (or the CS− compartment if receiving vehicle). In order to counterbalance the drug and vehicle pairings across subjects on each conditioning trial, half of the experimental animals are injected with drug and the other half are injected with vehicle; this arrangement is reversed on the next conditioning trial. A vehicle-only control group is injected with vehicle prior to placement in either the CS+ or CS− compartments; these vehicle-compartment pairings should also be counterbalanced, such that half of the control group receives vehicle paired with the CS+ and the other received vehicle paired with the CS− on each conditioning trial.

Conditioning trials typically occur once every 24-h, with the same type of trial occurring at 48-h intervals, that is, a conditioning trial in which drug was administered is followed 24-h later by a conditioning trial in which vehicle is administered, for example. Thus, the conditioning period typically requires 8 days of altering drug and vehicle trials. As mentioned earlier, changes in route of drug administration or other parameters provide a means by which the number of conditioning trials is reduced or otherwise altered from this common arrangement (e.g., i.v. administration and one-trial conditioning, see earlier). Further, greater CPP has been reported for the same drug with an increasing number of conditioning trials, a finding that encourages the use of more than one or two conditioning trials. For example, morphine CPP increases with the number of conditioning trials and a significant CPP is apparent after three or four conditioning trials, but not after one or two (Mucha and Iversen, 1984; but see Parker, 1992). However, in strains that show differential sensitivity to opioids, a significant morphine-induced CPP is apparent after only two conditioning trials for a 1 mg/kg dose of morphine, but is not apparent after four conditioning trials with a higher 10 mg/kg dose (Davis et al., 2007; Grakalic et al., 2006).

While the duration of the conditioning trials is commonly 30 min, this parameter varies considerably across studies with reports of conditioning trials as short as 4 min and as long as 120 min (Cunningham et al., 2006; Parker et al., 1994; Reid et al., 1985). One of the most important factors used to determine the length of the conditioning sessions is the duration of the drug effect, such that longer conditioning trials are typically used for drugs with longer half-lives. For example, studies assessing cocaine-induced CPP in rats commonly report 20–30 min conditioning trials (Guitart et al., 1992; Isaac et al., 1989; Kosten et al., 1994; Mucha et al., 1982; Spyraki et al., 1982), whereas morphine conditioning trials are usually 30 min or longer (see also Bardo et al., 1995; up to 120 min, see Parker et al., 1994). Conditioning trial duration is also dependent on the strain of rodent used as subjects. More specifically, 60-min cocaine conditioning trials are most effective when DBA/2J mice are used as subjects, but in C57BL/6J inbred mice, cocaine-induced CPP occurs following conditioning trials between 15–60 min in length (Cunningham et al., 1999). Additionally, ethanol is most effective in the CPP procedure in various strains of mice when 5-min conditioning trials are used (Cunningham and Prather, 1992). These differences emphasize the importance of selecting the appropriate trial duration for the drug of interest and subjects used.

The posttest: Following the conditioning period, a CPP test is run to determine if subjects spend more time in the drug-paired compartment. The posttest is identical to the pretest: in a drug-free state, subjects are allowed to move through all compartments of the apparatus for a specific amount of time (usually 15-min). The amount of time spent in each compartment is recorded. A drug-induced CPP is apparent when a subject spends more time in the drug-paired compartment compared to the time spent in that same compartment during the pretest or compared to the time spent in the CS− compartment. Thus CPP data is expressed as either an increase in preference for the CS+ compartment from pretest to posttest

or as an increase in preference for the CS+ compartment compared to the CS− compartment (Carr et al., 1989). As mentioned previously, the posttest occurs at some point following the final conditioning trial, where some studies assess CPP 24 h following the last conditioning trial and others asses CPP 2 days following the last conditioning trial. In the latter instance, no drug injections and/or exposure to the compartments are given during these 2 "rest" days (Mueller and de Wit, 2011).

The place conditioning apparatus: The most common apparatus used in place conditioning studies is a two- or three-compartment shuttle box, but several different arrangements have been reported and are shown in Fig. 22.1 (Carr et al., 1989). While these shuttle boxes vary in size, lighting conditions, and environmental cues, there are several characteristics common to the experimental apparatuses of most place conditioning studies with rodents. For mice, a standard size conditioning apparatus is approximately 30 cm long, 15 cm high, and 15 cm deep (Cunningham et al., 2006); for rats, a commercially available apparatus from San Diego Instruments, for example, is approximately 68.5 cm long, 34.5 cm high, and 21 cm deep (Fig. 22.2); these sizes can vary slightly with the addition of a third compartment. Importantly, each compartment is distinct from the other, regardless of whether a two- or three-compartment apparatus is used. The differences most often include the type and texture of flooring material and the color and appearance of the walls of each compartment. The floors are typically made of various materials including wire mesh, steel panels with holes or rods, textured or smooth Plexiglas, textured or smooth Kydex plastic, or rodent bedding. If the floor cues (i.e., tactile cues) are the to-be-conditioned cues associated with the CS+ compartment, the walls of the apparatus do not necessarily need to include any visual cues. However, if visual cues, in addition to the tactile cues, are to be used, a common practice is for one compartment to be a solid color (e.g., black) and another compartment to contain some type of pattern (e.g., black and white stripes) or for both compartments to be solid colors (e.g., black or white) with different texture and/or colored floors (Davis et al., 2007). While most studies use opaque barriers between the conditioning chambers during training and no barriers during testing, White et al. (2005) used clear barriers and a tunnel to allow subjects to see the visual cues in the adjacent chamber during testing, which unmasked differential effects of brain lesions on morphine CPP. Regardless of the floor and/or wall materials chosen, it is imperative that all surfaces of the apparatus are constructed of materials that are easy to sanitize (in accordance with institutional animal care guidelines) during a place conditioning study in order to eliminate olfactory cues from each subject (Fig. 22.3).

The use of a two- or three-compartment apparatus has received some attention in the place conditioning literature as an important design characteristic that provides an advantage in terms of a control for novelty, but has been shown to impact the strength of conditioning with certain drugs. More specifically, a third compartment in the conditioning apparatus is typically situated in between each conditioning compartment and is only available for exploration during the test trials (e.g., pretest, posttest); since this compartment is not accessed during conditioning, it is considered a novel environment compared to the other compartments. However, the number of pretest sessions where subjects have access to this third compartment can impact the novelty of this area and the amount of time spent in this area during a test session (Myers et al., 2012; Parker, 1992) (Fig. 22.4).

Rats, for example, exhibit preferences for novel environments (Bardo et al., 1989; Carr et al., 1988; Hughes, 1968; Parker, 1992; Scoles and Siegel, 1986) and it has been argued that drug-induced place conditioning actually represents avoidance of the saline-paired compartment (Scoles and Siegel, 1986), since the effects of the drug could interfere with habituation to the drug-paired compartment and is perceived as the more novel compartment during the drug-free test session. In a series of studies, however, Parker (1992) demonstrated that for several drugs, including apomorphine, amphetamine, and morphine, rats displayed significant preferences for the drug-paired compartment compared to both the saline-paired and novel compartments of a three-compartment, Y-shaped apparatus. Interestingly, rats' preferences for the novel compartment were intermediate to those of the drug- and saline-paired compartments, with rats preferring the novel compartment more than the saline-paired compartment, but less than the drug-paired one (Parker, 1992). Further, in a meta-analysis by Bardo et al. (1995), a three-compartment apparatus was associated with a larger effect size in heroin and cocaine place conditioning studies, but no association was found when morphine or amphetamine was used. These authors argue further that drug-induced CPP might be enhanced in the three-compartment apparatus because the availability of the novel compartment during the test session reduces the amount of time spent in the saline-paired chamber (Bardo et al., 1995). Thus these data demonstrate that the choice of using a two- or three-compartment apparatus is an important one that can impact the results of the study and should only be made after careful consideration of these issues and the benefits (or limitations) associated with the use of each type of apparatus (Fig. 22.5).

General rodent place conditioning procedure:

Pretest session (day 1)

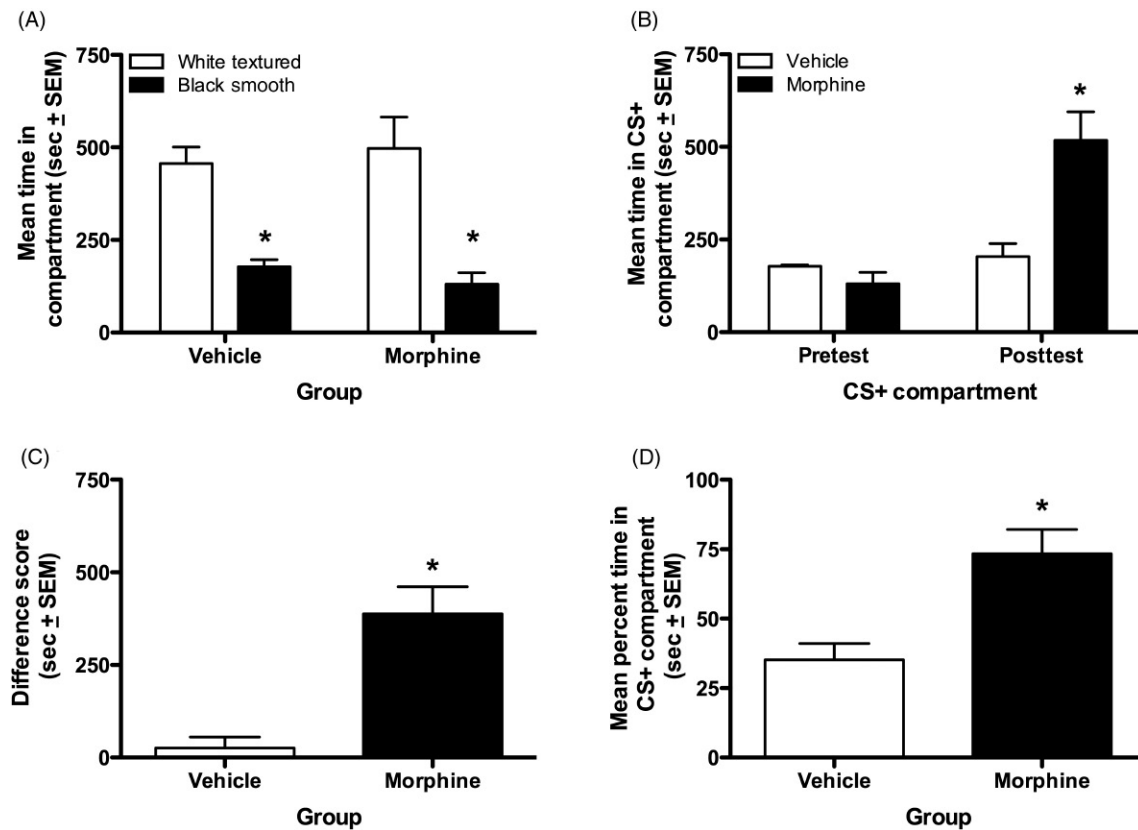
1. Clean all conditioning chambers thoroughly with soap and water; allow to air dry before beginning the pretest. If changing of floor materials is required, make certain that the appropriate


FIGURE 22.3 **Morphine-induced place preference in adult male Fisher 344 inbred rats.** (A) All rats received one 15-min pretest on the day prior to the start of the conditioning phase. There was a significant preference for the white textured side of the apparatus, thus a "biased-design" was used and rats were conditioned with morphine in the black smooth side (i.e., the least-preferred compartment was the CS+). Rats then received four morphine (5 mg/kg, SC)-CS+ pairings and four vehicle-CS− pairings. The control group received vehicle paired with both compartments. (B) Mean time in seconds spent in the CS+ compartment on the pretest and posttest by the vehicle-conditioned and morphine-conditioned rats. Morphine-conditioned rats displayed a significant preference for the CS+ compartment compared to rats conditioned with vehicle. (C) This figure presents the same data as a difference score (i.e., posttest seconds in CS+ minus pretest seconds in CS+) to demonstrate the significant morphine-induced CPP. (D) The same CPP data presented as mean percentage time spent in the CS+ compartment (i.e., CS+ compartment seconds divided by total time spent in both the CS+ and CS− compartments times 100). Although there was a pretest in this study, there are numerous ways to present the data and not all require a comparison to the pretest performance. *Source: Data redrawn from Davis, C.M., Riley, A.L., 2006. Drug preexposure in Fischer (F344) and Lewis (LEW) rats: effects on place and taste conditioning. Paper presented at the College on the Problems of Drug Dependence (CPDD) Annual Meeting, Scottsdale, AZ.*

conditioning floors/cues are inserted into the appropriate chambers. These cues will be the same ones used during conditioning and on the posttest.

2. Weigh rodents. Place each subject into the middle of the two-compartment apparatus and record movements for 15 min. If the apparatus has a third (middle) compartment, place the rodent into the middle compartment, remove the barriers, and allow the animal to freely explore all compartments for 15-min while recording the animal's movements.

    Note: If the home cage area and the conditioning apparatus are not located in the same location, some investigators recommend moving all

animals to a quiet area closer to the conditioning location for an hour prior to the start of the pretest (or conditioning sessions, posttest).

3. Using the pretest data, determine each subject's initial side preferences. If an unconditioned preference exists, the least-preferred compartment is the drug-paired compartment (CS+) and a biased procedure should be used. If there is no unconditioned preference, drug- and vehicle-paired compartments are counterbalanced across subjects, such that half receive drug (or vehicle) in one compartment and half receive drug (or vehicle) in the other compartment (i.e., an unbiased procedure). Once subjects are assigned a drug-paired compartment, the presentation of
FIGURE 22.4 **Median saccharin preference in rats conditioned with a single exposure to gamma irradiation at 30 or 57 rads.** The irradiation-induced CTA was apparent for approximately 30 days postirradiation and after that time, some extinction of the aversion was apparent. *Source: Redrawn from Garcia, J., Kimeldorf, D.J., Koelling, R.A., 1955. Conditioned aversion to saccharin resulting from exposure to gamma radiation. Science 122(3160), 157–158.*

CS+ and CS− trials must be counterbalanced as well. That is, half of the subjects receive drug-compartment pairings (or CS+ trials) on odd-numbered conditioning trials (i.e., drug on days 3, 5, 7, and 9) and half receive these pairings on even-numbered conditioning trials (i.e., drug on days 2, 4, 6, and 8).

4. Thoroughly clean all compartments between animals and at the end of the day.

Conditioning trials (days 2–9)

5. Twenty-four hours following the pretest, the conditioning trials commence. Begin by cleaning each compartment and placing the appropriate floor materials/cues in each conditioning compartment; insert barriers to keep animals confined to a specific compartment.
Note: Some laboratories use the entire conditioning apparatus during each conditioning trial, such that the floor material for the CS+ or CS− trial covers the entire apparatus. Others insert barriers between the two compartments such that the apparatus is split into its conditioning compartments and the barrier is present throughout the entire conditioning phase. Regardless of what option is used, the conditioning apparatus must contain both conditioning floors/cues during the posttest session.

6. Weigh each subject, inject with the appropriate solution (i.e., drug or vehicle), and immediately place the subject into the assigned compartment for a specified time period—a general duration is 30 min, however this parameter varies with different drug USs and should be chosen for the specific drug being studied. Subjects' activity can be recorded during the conditioning trials
FIGURE 22.5 (A) 50-mL Nalgene tube for fluid access during taste aversion conditioning. This volume of fluid is adequate for a 20–30 min fluid access period. The tube is inverted when it is attached to the rat's cage. (B) Curved steel sipper tube. If rats are housed in wire mesh cages, these curved sipper tubes are needed for fluid access. If rats are housed in polycarbonate cages with a wire top, curved or straight sipper tubes can be used. (C) Size #7 rubber stopper. This size fits snugly in the 50-mL Nalgene tube. When putting the stoppers into the tubes, wet the stopper and twist it once it has been inserted. This provides tight seal so that the stoppers are not easily knocked out of the tube. (D) The tube, with inserted stopper, inverted, and attached to a wire mesh rat cage.

for a more detailed behavioral analysis (Huston et al., 2013), but it is not required.

Note: Subjects should be run at the same time each day throughout the entire procedure (i.e., from pretest through conditioning and the posttest). Thus, drug solutions should be made in advance to allow enough time for the equipment set-up and syringe preparation each day. It is recommended that drug solutions are made fresh daily.

7. Once the trial is complete, remove the animal and return it to its home cage. Clean each compartment and prepare the equipment for conditioning trials with additional subjects, if necessary.

8. Twenty-four hours after the first conditioning trial, steps 5–7 are repeated. Animals receive an injection of the opposite solution, followed by confinement to the other compartment. More specifically, an animal that received a drug-compartment pairing (or CS+ trial) on day 2, now receives a vehicle-compartment pairing (or CS− trial) on day 3. This process is reversed for animals that received CS− trials on day 2. Conditioning trials continue in alternating manner every 24 h until day 9, which results in 4 CS+ trials and 4 CS− trials.

Posttest (preference test; day 10)

9. Twenty-four hours after the final conditioning trial, clean all compartments. Prepare each conditioning apparatus with the appropriate floor materials/cues. If using a two-compartment apparatus, remove the barrier between the compartments and place the animal in the middle of the apparatus. Record activity. If using a three-compartment apparatus, place the animal in the middle compartment of the apparatus; remove the barriers and record activity. Other barrier configurations can be used, such that clear or opaque barriers with a tunnel remain in place during the test session (White et al., 2005).

10. Once the test is complete, remove the animal from the conditioning apparatus and return it to its home cage. Clean each compartment thoroughly and prepare for additional animals, if necessary.

5 THE FLAVOR CONDITIONING PROCEDURE

5.1 What are Conditioned Taste Aversions?

Flavor conditioning is a simple procedure most commonly used to assess the positive (appetitive) or negative (aversive) effects of numerous compounds, including various nutrients, food sources, toxins, poisons, ionizing radiation, and drugs of abuse (Freeman and Riley, 2009). Conditioned flavor preference (CFP) is a procedure used to assess the positive effects of a stimulus by measuring increased consumption of a solution, whereas conditioned taste aversion (CTA) is used to assess the aversive effects of different stimuli by measuring decreases in consumption of a palatable solution. While CFP is a common procedure used to assess the positive effects of oral and postoral associations (Sclafani, 2004; Touzani et al., 2010), the current review will focus on the use of the taste aversion procedure in measuring the aversive effects of drugs of abuse. In a standard CTA experiment, subjects undergo conditioning trials in which consumption of a novel, palatable solution (typically saccharin) is paired with the injection of a drug. Interspersed between conditioning trials are water recovery days where subjects receive water (or a solution with another distinct flavor) to drink, but do not receive any drug injections. After several saccharin-drug pairings, subjects are tested for the expression of the CTA during a final test trial in which subjects are given access to the saccharin solution and consumption is recorded; no injections follow saccharin access on this test trial. Subjects that decrease consumption of the saccharin solution following the saccharin-drug pairings are said to express a conditioned taste aversion. While the methodology is slightly different, procedures similar to this that result in greater consumption of the novel fluid are indicative of conditioned flavor preferences.

Similar to the CPP procedure discussed earlier, the CTA procedure is also based on principles of Pavlovian classical conditioning, where the drug administered serves as the US and is subsequently paired with the novel saccharin solution—after several saccharin-drug pairings, decreases in consumption or avoidance (CR) of the saccharin solution (CS) are evident, due to its association with the aversive effects of drug administration. Interestingly, most drugs that serve as reinforcers in the self-administration procedure and that condition place preferences also induce taste aversions, which suggests that reinforcing drugs of abuse have both rewarding and aversive effects, and that the balance of these effects (i.e., reward and aversion; see earlier) could impact overall acceptability, which could influence subsequent misuse of these compounds (Davis and Riley, 2010; Verendeev and Riley, 2013).

5.2 A Brief History of Taste Aversion Learning

One of the first demonstrations of taste aversion learning was in 1951 when John Garcia and colleagues observed that rats decreased consumption of water from bottles that had been present during the irradiation (for a review of the history of CTA, see Davidson and Riley, 2015; Freeman and Riley, 2009; Verendeev

and Riley, 2012). Garcia argued that the decrease in consumption following exposure to radiation was due to the acquired association of the taste (imparted on the water from the plastic bottles in which it was contained) with the aversive effects of gamma irradiation. This explanation appeared to be valid, given that the same rats would ingest water from glass bottles in their home cage. In 1955, Garcia et al. (1955) sought to systematically test this hypothesis by pairing a novel saccharin solution with gamma irradiation. Consistent with his earlier findings, rats receiving saccharin-irradiation pairings decreased consumption of this palatable solution, whereas rats receiving saccharin paired with sham-irradiation displayed no change in saccharin consumption. Thus the effects of gamma radiation were causing a decrease in consumption of the novel fluid, demonstrating that radiation exposure had identifiable effects that could be readily associated with other stimuli, such as taste. Importantly, this effect was not simply a direct effect of radiation-induced damage impairing the ability of these animals to consume the sweetened solution, given that rats receiving exposure to gamma radiation that was not explicitly paired with the saccharin solution continued to consume the saccharin solution at control levels (Garcia et al., 1955, 1968). The effects of gamma irradiation were thus associated with the novel tasting saccharin solution, and this association created the decrease in consumption on successive saccharin presentations. Garcia and colleagues determined that irradiation could condition a decrease in saccharin consumption indicative of a taste aversion.

Following these initial studies, numerous reports from Garcia and his colleagues and other investigators detailed several important findings that now characterize the phenomenon of taste aversion learning as a "specialized form of learning." In their initial study, Garcia et al. (1955) demonstrated that radiation-induced taste aversion were evident following only one saccharin-radiation pairing. Further, these aversions were still evident at 30-days postirradiation (Garcia et al., 1955). Shortly following this report of one-trial learning of CTA, it was shown that taste aversions could be acquired over long time delays between consumption of the saccharin CS and presentation of the US, which in these early studies was ionizing radiation (McLaurin and Scarborough, 1963; Revusky, 1968; Smith and Roll, 1967), but has since been shown to occur with other compounds serving as the US, such as lithium chloride, an emetic, and cocaine, a drug of abuse (Etscorn and Stephens, 1973; Freeman and Riley, 2005; Nachman, 1963; Riley and Mastropaolo, 1989). Lastly, Garcia and Koelling (1966) reported that taste aversions appeared to be selectively acquired to gustatory stimuli, whereas stimuli like audiovisual cues did not serve as a CS in this design because they were not readily associated with the X-ray or lithium chloride USs

(see also Garcia and Ervin, 1968; McGowan et al., 1972). Taken together, one-trial learning, long-delay learning, and the selective associations of this procedure took aversion learning beyond an interesting radiation-induced effect to a learning example that was somewhat at odds with the traditional views of associative learning. More specifically, traditional associative models generally assumed that control could only be established after many conditioning trials with short-delay and/or trace conditioning techniques and that conditioning could be achieved equally well with most CS-US combinations (Klosterhalfen and Klosterhalfen, 1985; Rescorla and Wagner, 1972). Conditioned taste aversion learning was thus described as a specialized form of learning that facilitated specific associations imperative to an animal's survival, such as those between taste and the postingestive consequences of consumption (e.g., illness). These associations are argued to be highly adaptive because they provide an animal a means by which rapid acquisition of taste-illness associations can occur following consumption of natural toxins in the environment (e.g., those most likely found in food sources) followed sometime later (e.g., after the natural delay imposed by digestion) by illness.

After these initial assessments in which radiation and lithium chloride induced taste aversions to palatable saccharin solutions, investigations began to assess what other compounds could induce a CTA. Given that aversion learning is viewed as a unique form of learning that enables an animal to learn about and subsequently avoid food sources containing poisons or toxins, many of these early studies focused on assessing taste aversion learning induced by compounds or substances with known aversive effects, including poisons, classical toxins, and common emetics. One of the first emetic compounds examined in this context was apomorphine, a nonselective dopamine agonist. Apomorphine-induced aversions were robust, readily acquired after only one CS-US pairing, and could withstand long-delays during conditioning, much like the taste aversions reported earlier following irradiation (Brackbill et al., 1971; Garcia et al., 1966; Stolerman and D'Mello, 1979). Further, lithium chloride gained popularity as a tool to investigate how manipulations to the standard taste aversion procedure would impact acquisition of a taste aversion (Nachman and Ashe, 1973; Nachman et al., 1970). Work assessing other aversive compounds in the CTA design steadily increased throughout the 1970s and into the 1980s: various well-known toxins, including strychnine sulfate, acetaldehyde, sodium fluoride, paraquat, and physostigmine sulfate, all reportedly induced CTAs (for a review, see Riley and Tuck, 1985). Clearly taste aversion learning and the conditions under which it is acquired are not simply an effect of exposure to irradiation, but are common characteristics of a procedure that has general utility as a measure of drug toxicity; more specifically, the fact that

toxin- and poison-induced CTAs are acquired at doses much lower than those needed to adversely impact other behaviors, including food and water consumption, demonstrates the sensitivity of this procedure for measuring the aversive effects of various compounds.

While toxins, poisons, and emetics are common USs in the CTA procedure, drugs of abuse have received considerable attention in taste aversion experiments as well. Further, the taste aversion procedure was viewed as a sensitive assay with which to investigate the potential aversive effects of these drugs, given that these compounds were viewed as stimuli with numerous behavioral effects because they were reinforcers in self-administration and discriminative stimuli in drug discrimination studies and could alter learning and memory in other procedures (Colpaert et al., 1975; D'Mello and Stolerman, 1977; Schuster and Thompson, 1969). One of the first reports of drug-induced taste aversion learning was published in 1971, in which Cappell and LeBlanc assessed the aversive effects of amphetamine or mescaline in rats (Cappell and LeBlanc, 1971). In this study, both compounds induced dose-dependent aversions to the saccharin solution following one conditioning trial in which a drug administration was paired with saccharin to drink. These authors argued that the amphetamine- and mescaline-induced CTAs support the idea that these two drugs, at the doses used, had aversive effects that resulted in significant decreases in saccharin consumption of the test day. They argued further that the CTA results also support the lack of self-administration of mescaline in monkeys (Deneau et al., 1969) and the decrease in amphetamine self-administration in rats at 1 and 2 mg/kg (doses that conditioned a taste aversion; see Pickens and Harris, 1968; see also, Verendeev and Riley, 2011).

In a relatively short period of time, most major drugs of abuse were shown to induce CTAs, including alcohol, morphine, cocaine, Δ9-tetrahydrocannabinol (THC), and 3,4-methylenedioxypyrovaleron (MDPV), under the same parametric conditions as irradiation, emetics, and toxins, for example, one-trial learning, long-delay learning (Freeman and Riley, 2005; King et al., 2015). The fact that drugs of abuse were found to have aversive effects is not surprising since drug effects are generally dose-dependent, with toxicity occurring at greater drug doses. Yet the fact that these effects are evident at the same drug dose is less intuitive. In a combined CPP-CTA study, Reicher and Holman (1977) presented data demonstrating that the same injection of amphetamine could condition a taste aversion while conditioning a place preference to the environment in which the saccharin was consumed. More specifically, rats received an injection of amphetamine prior to placement into one compartment of a place conditioning apparatus. Within in this amphetamine-paired (CS+) compartment, rats had access to a distinctly flavored solution (almond or banana flavor). In the CS− compartment, rats had access to a different solution; if almond was the flavor used in the CS+ compartment, banana was the flavor used in the CS− compartment. Interestingly, amphetamine administration in this design conditioned a significant place preference while also conditioning a significant taste aversion. Further, these same results were evident after a 20-min delay between amphetamine administration and placement into the CS+ compartment. Reicher and Holman argued that amphetamine had rewarding and aversive effects that occurred simultaneously in the same animal and that each of these effects could condition different behaviors (i.e., approach and avoidance).

Since these initials studies with drugs of abuse in the taste aversion procedure, a wealth of literature has accumulated investigating drug-induced CTAs and factors that influence drug taking, including drug history, genetic manipulations (e.g., inbred rats and mice, genetically-modified animals), stress, age, and the maternal environment. In addition, the taste aversion procedure is used in behavioral pharmacology studies aimed at determining what receptor systems are responsible for drug-induced CTAs (Freeman et al., 2005; Serafine and Riley, 2010) and has been adapted for use as a procedure to assess the discriminative stimulus effects of various drugs, especially low doses of opioid antagonists in drug-naïve rats (Riley, 1997). Thus the CTA procedure is commonly used to assess the aversive effects of drugs of abuse and once the general procedure is instituted, adaptations to the procedure can be made to enable subsequent investigations in a manner similar to those mentioned earlier.

5.3 Advantages of the Conditioned Taste Aversion Procedure

The advantages of the CTA procedure are similar to those listed earlier for the CPP procedure; nonetheless, this section will outline these advantages and focus on specific equipment and techniques that are useful for taste aversion studies.

The conditioned taste aversion procedure is methodologically simple and does not require special and/or expensive equipment. The taste aversion procedure is a popular method to study the aversive effects of drugs of abuse for several reasons including (1) the procedure's simplicity in terms of experimenter training and (2) the fact that little specialized equipment is needed; most CTA studies are conducted in an animal's home cage environment. Much like that described earlier for the place conditioning procedure, taste aversion conditioning does not require any specialized training like jugular catheter surgery for self-administration studies. For the CTA procedure, drug is most commonly administered via the intraperitoneal (IP) or subcutaneous (SC) route. While these drug administrations are relatively simple, the route of

administration used in taste aversion conditioning is an important factor and has been shown to differentially impact CTAs induced by different drugs of abuse. Cocaine-induced aversions, for instance, are weaker when drug administrations are IP compared to aversions induced by subcutaneously administered cocaine. Ferrari et al. (1991) demonstrated that IP cocaine induced weak dose-independent aversions, such that all three dose groups (18, 32, and 50 mg/kg) significantly decreased saccharin consumption on the final test trial when compared to consumption of the vehicle control group. In contrast, rats injected SC with cocaine exhibited robust taste aversions at 32 and 50 mg/kg doses; decreases in saccharin consumption in these two groups were evident on the second conditioning trial (Busse et al., 2005; Ferrari et al., 1991; Grigson et al., 2001; Mayer and Parker, 1993). In addition, intracerebroventricular (ICV) drug administrations are also used in taste aversion learning, primarily in studies interested in determining whether a drug's aversive effects are centrally- or peripherally-mediated or what brain areas are involved in a drug-induced CTA (Amit et al., 1977; Clegg et al., 2002; Greenshaw and Buresova, 1982; Liu and Sue Grigson, 2005).

The equipment needed for a taste aversion study is relatively simple and typically includes two different sets of water bottles with rubber stoppers and sipper tubes, in addition to some type of sweetener, which will be prepared as a solution in tap-water and paired with drug administrations. Two sets of water bottles are needed because one set is used to provide the animals with plain tap water (or plain filtered water) and the other set is used for the saccharin solution during the conditioning trials. The use of different water and saccharin water bottles helps to ensure that the taste of the saccharin remains novel and prohibits subjects' exposure to this taste on habituation and/or water recovery days. For this reason, two sets of rubber stoppers with sipper tubes are needed as well. Different types of drinking tubes are used in taste aversion studies and the type of tube chosen usually determines how fluid consumption is measured.

For example, graduated 50-mL Nalgene drinking tubes are commonly used for taste aversion studies with rats and fluid consumption is easily recorded in 0.5 mL increments. Fluid measurements are taken prior to placement of the drinking tube onto each subject's cage and are taken again after the drinking period has ended. Given that movement of the drinking tubes can lead to some fluid loss, care must be taken to place drinking tubes on the cages while minimizing dripping or spilling. To determine the amount of fluid loss that occurs during placement of the drinking tube, a full drinking tube can be placed on an empty cage and pre- and postfluid access measurements can be recorded. Nongraduated drinking bottles are commonly used as well, however, bottles are weighed prior to each subject's fluid access period and then weighed again immediately following the end of the drinking period.

A review of the taste aversion literature demonstrates the variety of gustatory stimuli that have been used in taste aversion studies. For example, numerous studies have used condensed milk or other flavored solutions, including Kool-aid, flavor extracts (e.g., almond, banana, coconut, orange), vanilla, sucrose, or polycose. One of the most common gustatory stimuli is a 0.1% sodium saccharin solution, a relatively inexpensive noncaloric sweetener dissolved in tap water. Noncaloric sweeteners are typically used to decrease the likelihood that changes in consumption result from the high caloric value of a solution, such as sucrose, glucose, or polycose (Gomez and Grigson, 1999); nonetheless, caloric sweeteners are used in drug-induced aversion learning (Grigson et al., 2001; McDonald et al., 1997; Parker and Brosseau, 1990) and to examine the specificity of the tastant-CS association (Nissenbaum and Sclafani, 1987). In addition, strain differences in preference for various gustatory stimuli exist, with most rats and mice displaying a preference for saccharin solutions over water; however, the amount of saccharin (or other flavored solution) consumed does differ between many of these strains and this can impact the results of a taste aversion study. For example, Tordoff et al. (2008) examined two-bottle choices tests (i.e., water vs. solutions containing sucrose, NaCl, saccharin, etc.) in 14 common laboratory rat strains that included 3 outbred and 11 inbred strains. All of these strains displayed a preference for various concentrations of saccharin, but the amount of saccharin consumed did differ among rat strains (Tordoff et al., 2008). Similar results have been reported for numerous strains of inbred mice as well, and most strains display a preference for at least one concentration of saccharin in solution (Bachmanov et al., 2001; Fuller, 1974; Kotlus and Blizard, 1998; Reed et al., 2004). Selection of the appropriate gustatory stimuli for aversion learning can depend up on the strain of rodent(s) used in the study, thus experimenters should be aware of any possible strain differences in tastant preferences prior to the start of conditioning. If strain differences are a focus of the aversion study, the US tastant chosen should be equally preferred between the strains. Finally, while drinking tubes/bottles and a novel tastant, such as saccharin are required for an aversion study, a specific conditioning apparatus is not necessary and most CTA studies condition subjects in their home cages when animals are housed individually; a conditioning apparatus, such as a test cage, has been used when taste aversion conditioning is done in animals that are group housed (Smith et al., 1998).

The conditioned taste aversion procedure is relatively short in duration and has the potential for high throughput of subjects. Another advantage to the conditioned taste

aversion procedure is the fact that large numbers of subjects can be conditioned in a relatively short period of time. For example, taste aversion studies commonly employ 4-day conditioning cycles that begin with a conditioning trial where 20-min access to saccharin is followed by an injection of a drug of abuse; 3 water recovery days follow in which subjects only have access to plain water during the 20-min fluid access period and do not receive postconsumption drug injections. This 4-day conditioning cycle is typically repeated 4 times and is then followed by a test day in which subjects receive access to saccharin, but do not receive any injections following the consumption period. When a taste aversion study is conducted using these common parameters, the entire conditioning period requires only 17 consecutive days (including weekends). The conditioning cycles are however preceded by a habituation phase in which subjects are given 20-min access to plain tap water at the same time each day. The length of this habituation phase is determined by the variability in water consumption: once subjects display stability in the amount of water consumed each day (e.g., for rats, amount consumed not differing by more than 2 mL for 3 consecutive days; Davis et al., 2010) and are approaching and drinking from the water bottle almost immediately after its placement on the cage (i.e., within 2 s of its presentation), the conditioning phase begins. While there is no standard method for determining stability, these criteria result in relatively stable levels of water consumption in approximately 7–14 days, depending on the strain of rodent (Fig. 22.6; see Davis et al., 2009). If no other manipulations are included, a taste aversion study requires a little more than a month (i.e., 31 consecutive days) to complete, assuming a 2-week habituation phase. Obviously, additional manipulations, such as a drug preexposure phase, increase the number of days needed to complete the taste aversion study (Berman and Cannon, 1974; Davis et al., 2010; Risinger and Cunningham, 1995).

Although the 4-day conditioning cycle is common in the taste aversion literature, shorter conditioning cycles have been reported, and depending on the manipulation, are necessary for the specific experimental protocol. For instance, in the combined conditioned taste aversion/conditioned place preference procedure (King et al., 2015; Pomfrey et al., 2015; Roma et al., 2006; Simpson and Riley, 2005; Verendeev and Riley, 2011; Wakeford et al., 2016), the taste aversion procedure is adapted to fit the conditioning phase of the CPP procedure, such that saccharin access occurs on the same day as the drug injection and placement into the CS+ compartment. Water access occurs on the intervening days when vehicle injections precede placement into the CS− compartment. In this combined design, the taste aversion conditioning cycles are 2 days and include a conditioning trial followed by 1 water recovery day, instead of the 3 water
FIGURE 22.6 Mean water consumption in three different rat strains during the habituation phase of six different taste aversion studies (A or B). Although some rat strains consume more water compared to others, all strains display the same pattern of water consumption during the habituation phase. More specifically, water consumption increases over the habituation period to an asymptotic volume from which most rats do not vary (note the errors bars are within the symbol for each point on the graph). The SD rats *(pink and yellow squares)* only needed a 12-day habituation phase, whereas the F344 and LEW rats required 12–15 days, depending on the study (A or B, respectively). *F344*, inbred Fischer 344; *inbred LEW*, Lewis; *SD*, outbred Sprague Dawley. *Source: Data redrawn from Davis, C.M., Riley, A.L., 2006. Drug preexposure in Fischer (F344) and Lewis (LEW) rats: effects on place and taste conditioning. Paper presented at the College on the Problems of Drug Dependence (CPDD) Annual Meeting, Scottsdale, AZ; Davis, C.M., Riley, A.L., 2007. Behav. 87(1), 198–202; and Davis, C.M., de Brugada, I., Riley, A.L., 2010. The role of injection cues in the production of the morphine preexposure effect in taste aversion learning. Learn. Behav. 38(2), 103–110.*

recovery days described earlier. The concern with this procedure is that subjects displaying a conditioned taste aversion will not be adequately rehydrated during the one water recovery day, which could negatively impact the subsequent conditioning trial. Using this combined design however Roma et al. (2006) demonstrated that inbred Fischer and Lewis rats both maintained relatively stable levels of fluid consumption on each water recovery day separating each saccharin-IP ethanol-CS+ conditioning trial, regardless of the strength of the ethanol-induced aversion. Further, body weights of both strains remained stable over the 13-day habituation phase and the 8-day CTA/CPP conditioning phase (Roma et al., 2006) in all rats, including those subjects displaying robust ethanol-induced aversions, that is, subjects that were only consuming water every other day due the to the aversion to the saccharin solution (for similar conditioning cycles with cocaine, see Davis and Riley, 2007). Regardless of the length of the conditioning phase, almost all drug-induced taste aversion studies report dose-response assessments in which different groups of subjects (8–10 per dose group) receive saccharin paired with a specific dose of the drug of interest, in addition to a control group that receives saccharin-vehicle injection pairings. Dose-response assessments typically include

two or more drug doses with separate groups of animals for each dose used; in this way, large numbers of animals can be conditioned in a relatively short period of time in a single taste aversion study.

Other advantages of the taste aversion procedure: In addition to the advantages described earlier, there are several additional advantages of the taste aversion procedure that add its utility and ease with which it can be performed in the laboratory. First, consumption of the fluid CS is always done under drug-free conditions. More specifically, subjects receive the fluid CS to drink for a specified amount of time (e.g., 20-min); once this period is over, subjects are then injected with the drug US. Any changes in consumption then are not simply a function of drug-induced motor impairments for example, because the subjects receive drug only after the fluid access period has ended. Similar to the drug-free posttest in the place conditioning procedure described earlier, the taste aversion test day (i.e., the day after the final conditioning cycle) is a drug-free test as well.

A second additional advantage is the fact that taste aversion studies routinely report dose-response functions where conditioning day saccharin consumption decreases over trials, such that increasing drug doses are typically associated with a more robust decrease in saccharin consumption. While these functions are common in taste aversion learning, floor effects (i.e., no saccharin consumption on subsequent conditioning days) do occur and are not only influenced by the conditioning dose, but also by other factors including baseline consumption of the novel fluid US and strain of rodent used as subjects. For this reason, choosing a novel fluid US that is readily consumed by the strain of rodent serving as subjects in a taste aversion study is important. Nonetheless, most drug-induced CTAs are conditioned at relatively low doses where toxicity is not an issue and conditioning of other behaviors is supported. For example, morphine CTAs are readily acquired at 5 mg/kg, a dose that also conditions a significant place preference in the same animals (Martin et al., 1988; Simpson and Riley, 2005; Verendeev and Riley, 2011). These findings are true for most drugs of abuse, such that the range of drug doses supporting taste aversion learning also support conditioned place preferences.

5.4 Conditioned Taste Aversion: Experimental Protocol and Conditioning Apparatus

Although the characteristics of a taste aversion study were mentioned briefly in the preceding text, the current section aims to describe taste aversion conditioning in detail, including a discussion of some general parameters and characteristics of the experimental design that should be taken into consideration when designing and executing a conditioned taste aversion experiment.

Phases of a conditioned taste aversion study: There are several general phases to a conditioned taste aversion study and these will be discussed in detail here. These phases are included because they are commonly reported in taste aversion studies however some can be altered depending on the goals of the experiment.

The habituation phase: When beginning a taste aversion study, subjects are typically water-restricted and habituated to drinking during a specified period (i.e., the fluid access period) each day. In order to achieve reliable drinking during this period, rats are presented with plain tap water following 23.5 h of water deprivation. More specifically, rats are maintained on *ad libitum* access to water up to the day prior to the start of the habituation phase. On this day, *ad libitum* water bottles are removed from the rats' home cages at a specified time (e.g., 1000 h). On the following day, which is the start of the habituation phase, subjects receive water bottles containing plain water to drink at this same time; rats are given 20-min access to these water bottles and consumption is recorded. If presentation of the drinking bottles occurs earlier or later than the predetermined fluid access period, the amount of water consumed can vary substantially between individual subjects. For this reason, the water bottles must be presented at the same time each day to maintain the subjects' level of fluid restriction throughout the study.

It is common for subjects to increase water consumption throughout the habituation period, thus this phase continues until all subjects display stable day-to-day consumption levels.

Using each subject's mean water consumption, stability is commonly defined as a subject consuming within 2 mL of its mean fluid consumption over 3 consecutive days (Davis et al., 2010). Beginning the conditioning phase after subjects' habituation water consumption has stabilized helps to ensure that changes in consumption are a function of conditioning and are not due to continued habituation to the fluid restriction procedure. Further, subjects should be weighed each day prior to the fluid access period and weights should be closely monitored throughout this phase and the conditioning phase described later.

Although a single, daily fluid access period is commonly used in taste aversion conditioning, some investigators also include an additional drinking period during which subjects only have access to water. For example, Grigson and Freet (2000) employed a 5-min fluid access period in the morning followed by an hour-long fluid access period in the afternoon (Grigson et al., 2001; Liu and Sue Grigson, 2005). During the habituation phase, rats had access to distilled water during the 5-min and 1-hour fluid access periods, but on conditioning trials saccharin was available during the 5-min period only; distilled water was always available during the 1-hour

afternoon fluid access period. This additional fluid access period is included because subjects were only given 5-min access to water or saccharin during conditioning and needed the afternoon period to rehydrate; conditioning trials in this study occurred every other day, instead of every 4th day (see later).

The conditioning phase: Once subjects are maintaining stable levels of fluid consumption during the habituation phase (approximately 10–14 days), the conditioning phase begins. On the conditioning days of this phase, subjects receive saccharin during their 20-min fluid access period and consumption is recorded. Following the fluid access period, subjects are removed from the home cage, injected with the appropriate drug dose or vehicle, and returned to the home cage. The water recovery days of this phase however are identical to the habituation phase: subjects receive plain water during the 20-min fluid access period and consumption is recorded. No drug injections occur on these days. Taken together, one conditioning cycle consists of a saccharin-conditioning day, in which saccharin consumption precedes an injection of drug or vehicle, followed by 3 water recovery days. This 4-day conditioning cycle is then repeated 4 times for a total of 4 conditioning days and 12 water recovery days.

The first day of the conditioning cycle is important for two reasons: (1) subjects are assigned to an experimental or control group based on their saccharin consumption and (2) the CS-US interval is determined at this time. While subjects can be grouped by mean water consumption on the 3–5 days prior to the 1st conditioning day, it is common for subjects to be assigned to a group based on total saccharin consumed on the 1st day of conditioning. More specifically, once the fluid access period is over, the consumption values are ranked from largest to smallest and subjects are assigned to an experimental or control group such that mean consumption is comparable across groups. By using this pseudorandom assignment technique, saccharin consumption on the first conditioning day is not significantly different between the various experimental (and control) groups, which provide a good baseline for subsequent saccharin consumption day comparisons. This comparable baseline also increases the likelihood that data can be presented as total milliliters consumed instead of having to be transformed to a percentage shift from or percentage of control consumption.

In addition to grouping subjects on this day, the CS-US interval is determined as well and this interval needs to be maintained on subsequent conditioning days. For example, each subject receives 20-min access to saccharin followed by an injection sometime after fluid consumption. The time between fluid consumption and the subsequent drug injection should be carefully timed on the 1st conditioning day and this CS-US interval should be maintained throughout the conditioning phase. Thus, if subjects are injected 5-min after saccharin consumption on the 1st conditioning day, subsequent injections should also occur 5-min after saccharin access as well.

The one-bottle final aversion test: Following the final water recovery day of the last conditioning cycle, the final aversion test is typically administered. This test consists of 20-min access to saccharin during the fluid access period following which no injections are administered. When done in this manner, this test is also referred to as a one-bottle aversion test. If the drug-induced taste aversions are robust—subjects are consuming little to no saccharin on this test—the one-bottle aversion test is typically the final day of a conditioned taste aversion study.

The two-bottle final aversion test: If the conditioned taste aversion is not robust, does not differ by dose, or is relatively weak, etc., a more sensitive two-bottle test is usually administered. This test is considered to be more sensitive than the one-bottle test described earlier because subjects have access to saccharin and water concurrently during the 20-min access period and can choose to drink the saccharin or water during this time. If a taste aversion has been conditioned, subjects consume a greater percentage of water compared to saccharin during this period, with similar levels of total fluid consumption (i.e., saccharin + water consumption) between experimental and control groups. If the two-bottle test will be run following the one-bottle aversion test, it is important to consider injecting the subjects following the one-bottle test and giving the subjects 3 water recovery days (i.e., running a 5th conditioning cycle). In this way, the subjects have always experienced saccharin paired with the drug effects and no extinction effects will be evident on the results of the two-bottle test.

In a recent paper examining taste aversions induced by opioid receptor agonists, Davis et al. (2009) demonstrated the sensitivity of the two-bottle aversion test following what appeared to be weak aversions induced by (-)-U50.488H, SNC80, kappa and delta opioid receptor agonists, respectively (Fig. 22.7).

Saccharin consumption in the experimental groups conditioned with either drug did not differ much from their control group's saccharin consumption over five conditioning trials. More specifically, only the subjects conditioned with the highest dose of the kappa agonist displayed significant decreases in saccharin consumption compared to control subjects; subjects conditioned with SNC80 displayed similar levels of saccharin consumption throughout conditioning that did not differ between the conditioning doses. However, robust and dose-dependent (for the kappa agonist only) drug-induced aversions were apparent in the two-bottle aversion test, which was administered following the one-bottle test and 3 water recovery days (i.e., a 5th conditioning cycle; Fig. 22.8). These results demonstrate the
FIGURE 22.7 **Morphine-induced conditioned taste aversion in adult male Fischer 344 rats.** Following the habituation phase on conditioning day 1, all rats received 20-min access to saccharin followed by an injection of morphine (5 mg/kg, SC) or vehicle. Consumption on this day is equivalent between the groups because group assignments were made based on the ranking procedure described in the text. Over the three subsequent Conditioning Days, rats receiving morphine display a significant decrease in saccharin consumption compared to vehicle-treated control rats, in addition to a significant decrease in saccharin intake on the one-bottle final aversion test. *Source: Redrawn from Davis, C.M., Riley, A.L., 2006. Drug preexposure in Fischer (F344) and Lewis (LEW) rats: effects on place and taste conditioning. Paper presented at the College on the Problems of Drug Dependence (CPDD) Annual Meeting, Scottsdale, AZ.*

usefulness of the two-bottle aversion test and while it is not required, administering this test is highly recommended, especially when aversions are weak over consecutive conditioning trials.

General rat taste aversion conditioning procedure:

Prehabituation (day 0):

1. Weigh rats. Remove *ad libitum* water bottles to provide 23.5 h of water deprivation prior to the start of the habituation phase on the following day.

Habituation phase (days 1–14):

2. Fill one set of 50-mL Nalgene tubes with plain water (e.g., distilled, filtered, tap) and allow the water to come to room temperature.
3. Weigh rats.
4. Once water has reached room temperature, invert the first Nalgene tube. Allow the air bubbles to escape and record the preconsumption volume. Attach this bottle to the cage of the first rat. Start

(-)-U50,488H one- and two-bottle aversion tests
SNC80 one- and two-bottle aversion tests
FIGURE 22.8 **Mean consumption during one- and two-bottle final aversion tests for Fischer 344 and Lewis conditioned with (-)-U50,488H, a kappa opioid receptor agonist, or SNC80, a delta opioid receptor agonist.** All rats received 4 saccharin-drug pairings and then received a one-bottle final aversion test (panels A and D). The drug-induced decreases in saccharin consumption were weak and did not differ by dose, thus a two-bottle aversion test followed a fifth conditioning cycle. On the two-bottle test, taste aversions following conditioning with (-)-U50,488H were robust and differed by dose but not by strain (panel B). Rats conditioned with 0.90 (#) or 1.6 mg/kg (^) consumed significantly less saccharin than rats receiving 0.0 or 0.28 mg/kg. For SNC80 conditioned rats, the two-bottle test revealed a more robust decrease in saccharin consumption that remained dose-independent (*denotes all groups consuming significantly less saccharin than rats receiving 0.0 mg/kg; panel E). Panels C and F depict total fluid consumption on the two-bottle test for both strains; no differences were evident in overall fluid consumption, even though significant aversions to the saccharin solution were apparent. *Source: Redrawn from Davis, C.M., Rice, K.C., Riley, A.L., 2009. Opiate-agonist induced taste aversion learning in the Fischer 344 and Lewis inbred rat strains: evidence for differential mu opioid receptor activation. Pharmacol. Biochem. Behav. 93(4), 397–405.*

stopwatch or timer. Invert the next Nalgene tube; allow air bubbles to escape, and record preconsumption volume.

5. Once 10–15 s has passed, attach the second water bottle to the second rat's cage. Continue in this manner until all rats have water bottles. Exit the drinking area with the stopwatch or timer.
Note: A standard time interval should occur between the placements of each water bottle, such that each subject receives a full 20-min consumption period. This is easily done by placing water bottles on individual cages at 10–15 s intervals. Depending on the number of subjects, the total experimental time could exceed 20 min due to the staggered drinking periods, however this technique ensures that each subject receives the full time to drink regardless of when the water bottle is placed on the cage.

6. Once 20 min has elapsed, return to the drinking area and gently remove the first Nalgene tube from the first rat's cage; avoid spilling/ dripping any saccharin from the tube. Record the postconsumption volume. Wait 10–15 s and remove the next bottle; record postconsumption volume. Repeat until all bottles have been removed.

7. Empty bottles and rinse with fresh tap water. Store bottles inverted and allow to air dry.

8. Repeat steps 2–7 on each day of the habituation phase. Monitor body weights and daily water intake.
Note: If any subject is not adapting to the habituation schedule and is showing signs of distress and/or illness, the animal should be removed from the study and given *ad libitum* access to water, in addition to softened food and any other necessary veterinary care.

9. After approximately 7 days, water consumption by most subjects will begin to stabilize. Acquire 3-day averages for each subject and compare them to that day's consumption values. When average daily consumption does not vary by more than ±2 mL, water consumption is stable.

Conditioning phase:

Conditioning cycle day 1 (day 15):

10. On the morning of the 1st conditioning day, dissolve saccharin in plain water—use the same type of water that was used during habituation, for example, distilled, filtered, tap. Fill the second set of Nalgene tubes with the saccharin; let the bottles sit to warm to room temperature.
Note: A different set of bottles and stoppers must be used for saccharin access to avoid exposing the subjects to the saccharin flavor on water

recovery days (or habituation days in a future study). Labeling the saccharin bottles prior to the start of conditioning should be done to avoid any cross-contamination. Further, once the saccharin bottles/stoppers have been used for saccharin access, they should never be used for plain tap water and should not be stored with the water-only bottles/stoppers.

11. Weigh rats; prepare drugs and syringes.

12. Similar to the habituation phase, invert the first Nalgene tube, allow the air bubbles to escape, record preconsumption volume, and place the bottle on the cage of the first rat. Start the stopwatch or timer.

13. Invert the second Nalgene tube and repeat, placing the second bottle on the next rat's cage 10–15 s after placement of the first bottle.

14. Continue until all rats have saccharin bottles on their cages. Exit the drinking area with the stopwatch or timer.

15. Return to the drinking area after 20 min and remove the first rat's saccharin bottle. Record the postconsumption volume. Wait 10–15 s and remove the next rat's saccharin bottle and record postconsumption volume. Repeat every 10–15 s to remove all bottles.

16. Rank subjects by saccharin consumption from greatest to least. Denoting each dose group by a different letter (e.g., high dose = 1, control = 0), assign each subject a dose value in ascending order (i.e., 0, 1, 2); after the last dose value, repeat the values in descending order (i.e., 2, 1, 0). In this way, average saccharin consumption across all groups on the first conditioning day will be similar.
Note: This ranking procedure typically takes about 3–5 min; use of a computer with Microsoft Excel is highly recommended. If an experimenter allots 5 min to this ranking procedure, drug injections will not begin until 5-min after the saccharin access period. It is important that this time interval be maintained on subsequent conditioning days when the ranking procedure is not completed (because group assignment has been completed), such that the CS-US interval is consistent across conditioning days. If an experimenter does not allot a specified period of time to ranking, it is recommended that the stopwatch or timer be used to time the ranking procedure and determine precisely when the first injection was administered following saccharin access.

17. After the last injection, dispose of needles/ syringes. Empty saccharin bottles, rinse with warm tap water, and invert to dry. Soap should *not* be used to clean the saccharin

bottles because this could impart a taste on the bottle and/or stopper that could influence conditioning.

Conditioning cycle 1 days 2–4 (days 16–18):

18. During the water recovery days, no saccharin is consumed and no injections are administered. Similar to the habituation phase, fill Nalgene tubes with plain water and let sit out to warm to room temperature.
19. Weigh rats.
20. Place Nalgene bottles on cages as described earlier; record pre- and postconsumption volumes. Empty and rinse bottles.

Conditioning cycles 2–4 (days 19–30):

21. The 2nd conditioning day is similar to the 1st in all respects except that there is no ranking procedure.
22. Prepare saccharin as stated earlier. Prepare drug and syringes.
23. Place saccharin on cages and record preconsumption volumes.
24. After 20 min, return to drinking area and remove saccharin.
25. Maintaining the same CS-US interval employed on conditioning day 1, inject subjects after the saccharin access period.
26. On the following 3 water recovery days, prepare Nalgene tubes with plain water, weigh rats, and record water consumption.

One-bottle final aversion test (day 31):

27. On the day following the last water recovery day of the final conditioning cycle, prepare saccharin in the morning and fill the Nalgene tubes.
28. Similar to the conditioning days, place saccharin bottles on the rats' cages at 10–15 s intervals. Record pre-and postconsumption volumes. If no two-bottle test will not be run, no injections are necessary and this is the last day of the taste aversion study.
29. If a two-bottle aversion test will be run, prepare drug and syringes. Inject subjects after saccharin access. Provide plain water during the fluid access period on the following 3 days—this constitutes a fifth conditioning cycle (days 31–34).

Two-bottle final aversion test (day 35):

30. Twenty-four hours following the last water recovery day dissolve saccharin in plain water and fill the Nalgene tubes. Additionally, fill the other set of Nalgene tubes with plain water. Let water in both sets of tubes warm to room temperature.

31. Invert the first saccharin Nalgene tube, allow bubbles to escape, and record preconsumption volume. Invert the first plain water Nalgene tube, allow bubbles to escape, and record preconsumption volume. Holding one bottle in each hand, present both sipper tubes to the first rat simultaneously. Attach both tubes to the first cage.
32. For the second rat, place the saccharin tube on the opposite side of the cage compared to the first rat. More specifically, if the saccharin tube is on the right side of the first rat's cage, place the saccharin tube on the left side of the second rat's cage. Repeat at 10–15 s intervals for the remaining subjects; continue to alter the location of the saccharin bottle from left to right. Exit the drinking area.
   Note: The two-bottle test is easier to administer if there are two experiments—one to invert and place the bottles on the cages and another person to record the consumption values and monitor the stopwatch or timer.
33. After 20 min, return to the drinking area and remove each rat's bottles at the same time. Record postconsumption volume for both bottles.
34. Rinse both sets of bottles and invert to air dry.

6 CONCLUSIONS

The conditioned place preference and conditioned taste aversion procedures are two common methods for assessing the rewarding and aversive, respectively, effects of drugs of abuse. Both of these procedures have numerous advantages, including the ease with which the procedures can be performed and the fact that both procedures require relatively inexpensive equipment. Further, the popularity of these procedures in the drug addiction field gives investigators a wealth of data that can be examined when designing new CPP and/or CTA studies to aid in the selection of parameters, methodology, and other important experimental variables. While these procedures might not represent every aspect of SUD or addiction, these procedures are valuable tools to enable researchers to gain a greater understanding of the effects of drugs on the brain and behavior and to enable discovery of pharmacotherapeutic strategies to treat SUD.

Modeling Schizophrenia in Animals

David Feifel, Paul D. Shilling

University of California, San Diego, La Jolla, CA, United States

1 OVERVIEW OF SCHIZOPHRENIA

1.1 Clinical Presentation

Schizophrenia is a chronic, debilitating disorder, which affects approximately 1% of the world's population. While there is a fair degree of heterogeneity in the clinical presentation of schizophrenia, the unifying thread among individuals stricken with this condition is psychosis, a profound disorder of perception and thinking that robs a person of the capability of reaching a culturally normative interpretation of the external world and thereby prevents him or her from participating in the collective perceptions of reality.

The first overt manifestations of schizophrenia typically emerge in late adolescence to early adulthood. Although men and women are affected in equal proportion, the emergence of symptoms occurs several years later, on average, in women (Sham et al., 1994). There is often a "prodromal" period, characterized by various subclinical features that precedes the first frank psychotic break that heralds the unequivocal onset of the disorder (Cadenhead, 2011; Hafner et al., 2004).

The current version of the *Diagnostic and Statistical Manual for Mental Disorders* (DSM-V) (American Psychiatric Association, 2013), the most widely accepted source for diagnostic criteria of mental disorders, delineates five potential clinical features of schizophrenia. It requires that, within a period of at least 6 months of continuous disturbance in function (that may include the prodromal period), an individual exhibit at least two of these features concurrently for at least 1 month without a remittance of symptoms Under certain circumstances, only one symptom need to be present (vide infra). Moreover, the symptoms also must not be better accounted for by another cause, such as substance use or a medical condition, such as Huntington's disease or a severe endocrine abnormality, such as thyrotoxicosis.

The first four diagnostic features listed in DSM-V, delusional thinking, hallucinations, disorganized speech, and disorganized behavior, are collectively referred to as "positive" symptoms. DSM-V recognizes the *sine-qua-non*

nature of these positive symptoms is that it is not possible to achieve the diagnostic criteria without at least the presence of two of them. The disorganized speech and behavior of schizophrenia are not the type that might be observed in a person suffering from a neurological disorder affecting speech output, such as a receptive aphasia, or motor output, such as the choreoathetotic movement associated with advanced Huntington's disease. Rather, the disorganized speech and behavior seen in schizophrenia are outward manifestations of disordered thinking and perception occurring internally. Qualified clinician's familiar with schizophrenia's clinical presentation are able to recognize its distinct disturbances of speech and behavior.

The fifth feature listed in DSM-V is, in fact, a collection of behavioral deficits collectively referred to as "negative" symptoms. Negative symptoms include poverty of speech (alogia), reduced or absent outward expression of emotions and reduced volitional, goal-directed behavior. As DSM-V acknowledges, negative symptoms are less characteristic in nature than positive symptoms and can, *prima facie*, be hard to distinguish from symptoms of other conditions, such as clinical depression or certain neurological disorders. For this reason, negative symptoms cannot, by themselves, warrant a schizophrenia diagnosis no matter how severe or pervasive they may be. Furthermore, genuine primary negative symptoms can be hard to distinguish clinically from the secondary effects of severe and overwhelming positive symptoms (e.g., a catatonic manifestation) or from side effects of some antipsychotic drugs used to treat them.

In addition to the positive and negative symptoms, people with schizophrenia typically exhibit broad impairments in formal cognitive functions. Several discrete and measurable domains of cognition have been identified as commonly deficient among people diagnosed with schizophrenia. These domains include: attention, learning and memory (including visual, verbal, and working memory), information processing speed, reasoning and problem solving, and social cognition. Although commonalities exist within these specific cognitive domains, the severity and extent (i.e., number of domains) of cognitive impairment vary substantially among individuals with schizophrenia. Furthermore, like negative symptoms, they do not appear to have a characteristic nature in schizophrenia, which would distinguish them from cognitive impairments occurring in other disorders. Also, like negative symptoms, impairments in cognitive performance can be secondary to the presence of strong positive symptoms or side effects of medication, making it hard to distinguish such secondary impairments from primary cognitive deficits emanating from the schizophrenia. Nevertheless, cognitive impairments are widely regarded as an additional core feature of schizophrenia even though they are not part of the formal DSM-V diagnostic criteria.

1.2 Etiology

The current consensus is that the etiology of schizophrenia is multifactorial, resulting from a combination of genetic and environmental factors. Genetic inheritance is believed to account for 50%–80% of the incidence of schizophrenia as evidenced by substantially higher concordance rates in monozygotic versus dizygotic twins (Lewis and Lieberman, 2000). It is manifestly clear that the genetic contribution, albeit a strong one, is complex. No single mutation or genetic variant has been found to be sufficient to cause this disorder. Although genome-wide and single-gene association studies have implicated a long list of candidate genes (Allen et al., 2008), only a small number among these candidate genes have shown to be associated with schizophrenia in many studies and/or to play a biological role that is likely to contribute to the development of this disorder. Genes on that short candidate list include DISC1, neuregulin, ErbB4, reelin, and dysbindin. In addition, recent evidence suggests the association of a small proportion of schizophrenia cases (5%–8%) with de novo copy number variants (CNVs) (Sebat et al., 2009). The lack of a strong association of identified gene candidates with the incidence of schizophrenia may suggest that multiple genes acting in combination through epistasis or synergistically with epigenetic effects may underlie manifestations of this disorder. Some investigators have suggested that the causative gene variants have not been identified at this time because this disease may be caused by rare variants with high penetrance having a large effect (Walsh et al., 2008). Discussion of the studies aimed at gaining a better understanding of the function of schizophrenia candidate genes and how they may contribute to this disorder have been published elsewhere (Jones et al., 2011; Powell et al., 2009).

A "two-hit" developmental model has been proposed in which a combination of environmental and genetic factors affecting early development is responsible for the emergence of the schizophrenia in adolescence/early adulthood (Lewis and Levitt, 2002). Among environmental contributors that have been implicated in the development of schizophrenia, those associated with the neonatal or perinatal period have the strongest scientific support. Prenatal risk factors for schizophrenia include maternal malnutrition and maternal infection. Risk factors associated with the perinatal period have been reported in the medical histories of approximately 20% of patients who suffer from schizophrenia include complication during labor and delivery (e.g., hypoxia) (Lewis and Levitt, 2002; Powell, 2010). Childhood abuse and psychological trauma have also been found to be

associated with the development of schizophrenia later in life and, therefore, may constitute risk factors for this disorder (Sideli et al., 2012).

Finally, there is compelling evidence that the use of certain drugs can trigger the onset of schizophrenia or a relapse. Drugs that have been strongly associated with this include stimulants, such as amphetamines, cannabis, and hallucinogens, such as lysergic acid diethylamide (LSD) or phencyclidine (PCP). However, it has been hard to establish a clear causal connection between drug use and schizophrenia as well as the extent that drug use can trigger schizophrenia because it is likely to occur only in people with an underlying biological predisposition for the disorder (Hermens et al., 2009; Yui et al., 1999).

1.3 Pathophysiology

Despite intense investigation for decades using the best available tools of neuroscience, the fundamental pathophysiological abnormality that underlies the clinical presentation of schizophrenia remains elusive. That is not to say that structural and functional abnormalities have not been found, but rather there does not appear to be a single set of consistent findings. This may be due to the fact that the clinical presentation that satisfies the diagnostic criteria for schizophrenia may not result from a single brain dysfunction but, rather, a large number of potential CNS malfunctions. Indeed many have suggested that schizophrenia is not a unitary disorder, even when taking into account its descriptive subtypes, but instead a heterogeneous collection of disorders with overlapping clinical manifestations (Lewis and Lieberman, 2000; Young et al., 2010). Adding to the challenge of parsing out the etiology of schizophrenia is that it has been hard to disentangle abnormalities that are causative or contributory to the symptoms from those that are a result of or perhaps an epiphenomenon of this chronic disorder (e.g., social isolation) and from the effects of medications used to treat it.

Originally proposed in the 1960s, the dopamine hypothesis (Carlsson, 1977), which posits that schizophrenia is the result of excess dopamine neurotransmission, still dominates the thinking regarding pathophysiology of schizophrenia. This hypothesis was primarily based on two observations. The first observation was that drugs that enhanced dopamine neurotransmission in the brain had a proclivity to transiently replicate the psychosis of schizophrenia in people that did not have this condition and to exacerbate it in people who did (Byne et al., 1999). The second observation was that all efficacious antipsychotics at the time inhibited dopamine transmission by binding and blocking activation of the dopamine-2 (D2) receptor. The potency of antipsychotics was correlated with their affinity for that receptor (Seeman, 1992, 1995). Over time the dopamine hypothesis has become more

nuanced, positing that excess dopamine transmission in subcortical limbic areas (mesolimbic pathway) produces positive symptoms (Howes and Kapur, 2009; Szekeres et al., 2002; Walter et al., 2009), while concurrent dopamine deficiency in the prefrontal cortical areas (mesocortical pathway) predisposes one to negative symptoms and cognitive deficits (Fusar-Poli et al., 2011; Szekeres et al., 2002).

Although the dopamine hypothesis remains the dominant pathophysiological theory of schizophrenia, direct evidence to support it has been surprisingly difficult to obtain and examination of the brains of people with schizophrenia have yielded inconsistent results. However, there currently exists reasonably good evidence for increased density of D2 receptors (Klaning et al., 2002; Onstad et al., 1991), increased presynaptic dopaminergic function (Howes et al., 2012) in the striatal regions, and decreased activation and dopamine tone in the prefrontal cortex in people with schizophrenia compared to controls (Fusar-Poli et al., 2011; Szekeres et al., 2002).

More recently the search for neurochemical perturbations underlying schizophrenia has shifted from an exclusive focus on dopamine to include other neurotransmitters. In this respect, dysregulation of the glutamate and gamma aminobutyric acid (GABA) neurotransmitter systems have been detected in people with schizophrenia (Kantrowitz and Javitt, 2010). For example, the loss of excitatory glutamatergic synapses leading to decreased dendritic density and reduced functional activity of GABAergic interneurons have been a consistent finding in people with schizophrenia (Beneyto et al., 2011). Expression of glutamate decarboxylase (GAD) 67, an enzyme that metabolizes glutamate into GABA, has been consistently found to be reduced in the brains of people afflicted with schizophrenia compared to people without any mental illness (Bullock et al., 2008).

Some of the more consistent alterations in brain structure associated with schizophrenia include lateral ventricle enlargement, decreased hippocampus volume, and decreased gray matter in a number of brain regions that modulate cognition, including the prefrontal, medial, temporal, and inferior parietal cortex (Nasrallah et al., 2011; Yeganeh-Doost et al., 2011). Although these differences in brain structure have been noted in relation to schizophrenia, it is not entirely clear if these pathophysiological abnormalities contribute to the development of the disorder or are the result of mechanisms associated with the underlying etiology.

1.4 Treatment

The mainstays of treatments for schizophrenia are medications and psychosocial interventions. The first member of today's antipsychotic drug family, chlorpromazine, was discovered by serendipity in the early

1950s. Between 1955 and 1990, approximately one dozen "typical" or first generation antipsychotics (FGAs) were approved in the United States for the treatment of schizophrenia. In the 1970s, investigators elucidated that all FGAs had a common mechanism of action, which was pharmacological antagonism of the dopamine-2 (D2) receptors in the brain. Later research localized the therapeutic mechanism to D2 blockade in the mesolimbic areas (Seeman, 1992, 1995). FGAs are generally efficacious in reducing positive symptoms when taken regularly. However, their efficacy against negative symptoms and cognitive deficits is poor. Furthermore, FGAs have a propensity to produce side effects related to their pharmacological actions at other brain receptor sites, such as histamine-1 (sedation, weight gain), acetylcholine-muscarinic (dry mouth, blurry vision, constipation, cognitive impairments), and alpha-1 (orthostatic dizziness, hypotension). They also have a tendency to antagonize D2 receptors in brain pathways, other than the mesolimbic pathway, which often causes muscle and movement abnormalities (extrapyramidal symptoms) as well as changes in libido and menstrual cycle due to increased release of the reproductive hormone prolactin (Tamminga, 2003).

The entry of the drug clozapine into the US marketplace in 1990 after a protracted FDA approval process, due to serious safety risks, marked the beginning of the atypical or second generation antipsychotics (SGAs). The FDA agreed to approve clozapine because of evidence that it benefited schizophrenia patients who did not respond to FGAs. Despite its efficacy, clozapine does not have a propensity to produce the extrapyramidal side effects or raise prolactin blood levels, which is something that had previously been considered inextricably connected with clinical efficacy (Tamminga, 1997).

It was not immediately clear why clozapine had these unique clinical benefits but the fact that it has a wider profile of receptor affinities than most FGAs was thought to underlie this clinical benefit. Clozapine's success spurred development of a family of SGAs with multireceptor affinities (Tamminga, 1997). SGAs are considered to generally produce less side effects related to blockade of D2 receptors and to have some therapeutic advantages over FGAs, namely with regards to negative symptoms and cognitive deficits. However, there is a substantial degree of controversy regarding the magnitude of their efficacy advantage over FGAs and clozapine remains the only SGA with strong evidence for a superior efficacy profile. Unfortunately, clozapine's prodigious side effect and safety burden limit its use. Furthermore, the precise mechanism responsible for clozapine's superior efficacy remains unknown.

To date all SGAs, like FGA, have clinically relevant affinity for D2 receptors and all, except for aripiprazole, act as D2 antagonists. Aripiprazole is a partial agonist at the D2 receptor. In addition to D2 affinity, SGAs have affinity for serotonin 2A (5-HT2A) receptors that is comparable and usually greater than their affinity for D2 receptors. It is this pharmacological property, which generally distinguishes SGAs from FGAs and which is considered by many investigators to underlie their clinical differences from the FGAs (Tamminga, 2003).

Despite the reasonable success of both FGAs and SGAs in attenuating positive symptoms, the lack of effective treatments for the cognitive deficits and negative symptoms has substantially contributed to the poor functional outcomes and long-term morbidity of this disorder. The long-term prognosis for schizophrenia has shown little if any improvement (Carpenter and Koenig, 2008) during the past nearly 60 years of drug development. Therefore, there remains a strong need for antipsychotic drugs with novel mechanisms that can deliver more efficacious benefits.

2 APPROACHES TO CREATE ANIMAL MODELS WITH RELEVANCE TO SCHIZOPHRENIA

Developing animal models that have validity for schizophrenia presents formidable challenges since the biological mechanisms underlying the clinical features of this disorder have thus far eluded discovery despite the identification of numerous neurobiological abnormalities associated with schizophrenia. Additionally, the most characteristic features of schizophrenia, auditory hallucinations and delusional thinking cannot be directly modeled in animals. We have reviewed these and other challenges encountered in developing animal models of schizophrenia in greater depth elsewhere (Feifel and Shilling, 2010). Despite these challenges animal models with relevance to schizophrenia continue to be developed and to play an important role in the effort to understand this disease and identify new treatments.

Several general approaches are available to investigators who are interested in using animals to study a disease related abnormality. The majority of well-characterized animal models considered to have relevance to schizophrenia involve manipulations that induce, usually in rodents, a homolog, or, if that is not achievable, a presumed analog of one or more of the abnormal features associated with the disorder. Table 23.1 displays examples of some of the more common approaches used to model schizophrenia in rodents. Commonly induced schizophrenia-like abnormalities in rodents are deficits in information gating, such as prepulse inhibition, latent inhibition, deficits in social interaction, and tasks that are thought to model human cognitive functions, such as working memory.

Model	Schizophrenia-like features		Effects of antipsychotics and other drugs	Strengths and limitations
	Behavioral	Pathophysiology		
Pharmacological Acute PCP injections Rodents are administered one-time dose of PCP, an antagonist of NMDA subtype, glutamate receptor	Increased locomotion analogous to positive symptoms of SCZ (Jentsch and Roth, 1999; Neill et al., 2016) Reduced social interaction homologous with negative symptoms (Neill et al., 2016; Mouri et al., 2007) PPI deficits homologous with PPI deficits in SCZ (Geyer et al., 2001) Reduced performance on animal cognitive tasks that are thought to be analogous to human cognitive tasks that SCZ patients perform poorly on (Mouri et al., 2007; Rajagopal et al., 2014)	Some evidence exists for glutamate hypofunction in brains of patients with SCZ, which is transiently induced by PCP in animal (Mouri et al., 2007)	Acute: SGAs but not HAL attenuate PPI deficits (Geyer et al., 2001; Barros et al., 2009; Fejgin et al., 2007; Pouzet et al., 2005) SGAs and HAL attenuate cognitive deficits (Neill et al., 2016; Mouri et al., 2007; Rajagopal et al., 2014; Grayson et al., 2007; Nagai et al., 2009; Snigdha et al., 2011; Didriksen et al., 2006; Terranova et al., 2005) Non-APDs: Citalopram, bupropion, and desipramine have no effect on PPI deficits (Pouzet et al., 2005). Diazepam, citalopram, methadone and naloxone have no effect on social interaction deficits (Sams-Dodd, 1998a) (3 days) Other: modafinil, and erythropoietin attenuate cognitive deficits (Goetghebeur and Dias, 2009; Goetghebeur et al., 2010) Subchronic (3 days): CLOZ but not HAL, reverse social and cognitive deficits (Jentsch and Roth, 1999; Mouri et al., 2007; Sams-Dodd, 1998a; Sams-Dodd, 1999; He et al., 2006) Chronic (21 days): Neither CLOZ, nor HAL, reverse social interaction deficits (Sams-Dodd, 1998b)	Strengths: Displays features relevant to positive and negative symptoms and cognitive deficits of SCZ Limitations: Induction of SCZ-like features is transient Acute administration of FGAs and SGAs reverse social interaction and cognitive deficits but these drugs produce, at best, a partial improvement in negative symptoms and cognitive deficits when given chronically to SCZ patients does not seem to model the therapeutic time course of APDs as chronic administration less efficacious than acute

(Continued)

TABLE 23.1 Comparison of Three Rodent Models Representing Different Inducing Strategies: Pharmacologic, Developmental and Genetic *(cont.)*

Model	Schizophrenia-like features		Effects of antipsychotics and other drugs	Strengths and limitations
	Behavioral	**Pathophysiology**		
Developmental Neonatal hippocampal lesions Rats are administered neurotoxin into the hippocampus during the neonatal period	Cognitive deficits and social deficits appear prior to puberty (Tseng et al., 2009) PPI deficits may appear after puberty (Tseng et al., 2009) or before it (Swerdlow et al., 2012)	Consistent with evidence of hippocampal atrophy in SCZ Consistent with theory that brain abnormalities exist long before people develop SCZ, as early as in utero or early childhood (Tandon et al., 2008)	Acute APDs: PPI deficits reversed by CLOZ, but not HAL (Le Pen and Moreau, 2002) Chronic APDs: CLOZ attenuates PPI deficits similar to acute administration but does not reverse cognitive or social deficits (Rueter et al., 2004; Levin and Christopher, 2006; Sams-Dodd et al., 1997) Chronic CLOZ reverses locomotor activation (Bringas et al., 2012) Non-APDs: No Reports	Strengths: Models the construct of an early brain pathology that remains latent until adolescence/early adulthood Limitations: No strong evidence yet that PPI deficits emerge late in development versus congenital Specificity for APD effects not reported
Genetic: Natural Vasopressin-deficient Brattleboro rat The result of a mutation in the vasopressin gene	Spontaneous hyperlocomotion—thought to be an analog of positive symptoms (van den Buuse, 2010) PPI (Demeter et al., 2016), LI and habituation deficits homologous with same deficits in SCZ patients (Feifel and Priebe, 2001) Cognitive deficits relevant to SCZ (Demeter et al., 2016; Laycock et al., 1983; Feifel et al., 2009) Polydipsia/polyuria similar to polydipsia seen in significant proportion of SCZ patients (de Leon, 2003)	Strong genetic component as in SCZ (Feifel and Priebe, 2007) Increased dopamine (Feenstra et al., 1990; Dawson et al., 1990) and D2 receptor brain density in striatum similar to several findings of postmortem SCZ (Shilling et al., 2006) Consistent with vasopressin system dysfunction reported in SCZ (Linkowski et al., 1984; Frederiksen et al., 1991; Krishnamurthy et al., 2012) H3 acetylation changes in prefrontal region and hippocampus (Demeter et al., 2016) Reduced brain GAD 67 consistent findings of reduced brain GAD 67 in SCZ (Akbarian and Huang, 2006)	Acute: SGAs and FGAs reverse PPI deficits (Feifel et al., 2007; Feifel et al., 2004) CLOZ reverses social recognition deficits (Feifel et al., 2009) Valproate, diazepam and imipramine had no effect on PPI (Feifel et al., 2011a) Putative APD, neurotensin-1 agonist produces effects similar to APDs (Feifel et al., 2004) Chronic: FGAs and SGAs produce stronger effect after chronic administration than after acute (Feifel et al., 2007)	Strengths: Does not require manipulation to induce SCZ-like features Good sensitivity and good specificity regarding responding only to drugs with known or putative APD efficacy Models therapeutic time course of APDs in which therapeutic effect begins after acute administration but grows stronger with repeat administration (Feifel et al., 2007) Limitation: No evidence for gene based vasopressin dysfunction in SCZ

APD, antipsychotic drug; CLOZ, clozapine; FGA, first generation antipsychotic; GAD67, glutamate decarboxylase isom; HAL, haloperidol; LI, latent inhibition; NMDA, *N*-methyl-D-aspartate; PCP, phencyclidine; PPI, prepulse inhibition; SGA, second generation antipsychotic; SCZ, schizophrenia; AVP, vasopressin

Some of these models are based on transient induction of schizophrenia-relevant features. Classic examples of these features are abnormalities produced by acute administration of psychotomimetic drugs (e.g., amphetamine, PCP), such as hyperactivity and reduced prepulse inhibition of the startle response. The duration of the induced changes is correlated with the pharmacokinetic properties of the administered psychotomimetic. Other experimental approaches produce more enduring abnormalities consistent with the chronic nature of schizophrenia. An example of enduring, induced, schizophrenia-like features are those produced by genetic engineering or by manipulations to the nervous system applied during the developmental period. Even among enduring abnormalities induced in rodents, there may be differences in the degree of robustness. For example, prepulse inhibition deficits produced in adult rats by chemical lesions of the hippocampus during the neonatal period are robust, whereas prepulse inhibition deficits induced by social isolation rearing of rats during early development can dissipate due to handling or changes in the home cage (Lipska et al., 1995; Powell et al., 2002).

Another approach has been to identify animals that spontaneously exhibit relevant abnormal features that are germane to schizophrenia. This is typically achieved by screening different strains of rats or mice, or by selecting individual animals that exhibit a certain schizophrenia-relevant feature from a normal colony (Ellenbroek et al., 1995). The selected individuals may then be interbred to produce a man-made strain of animals that spontaneously exhibit schizophrenia-relevant behaviors, for example, (Ellenbroek et al., 1995; Hitzemann et al., 2008; Schwabe et al., 2009).

Yet another approach foregoes both inducing schizophrenia-like abnormalities and identifying spontaneous abnormalities in favor of studying normal expression of an animal phenotype that is assumed to have some relevance to schizophrenia. These approaches are usually used for drug discovery rather than for identifying mechanisms underlying the disease, and are based on the concept that an abnormal behavior or physiological function exists on a continuum with normal levels of that behavior or function and share the same underlying biological mechanisms. It follows therefore that treatments that alter normal levels of a phenotype in a certain direction (e.g., enhance it) are likely to do the same thing to abnormal levels of that phenotype in people with schizophrenia. For example, enhancement of normal latent inhibition in rodents or their performance on animal tasks modeling human cognition have been used as a putative predictive test of drugs with efficacy for schizophrenia (Feldon and Weiner, 1991). Though these models may have reduced validity for the abnormal features in schizophrenia, they have the advantage of not requiring unique expensive animal strains or time-consuming special preparations to induce deficits. Other examples of normal behavior used as models to screen for antipsychotics include catalepsy (Greenblatt et al., 1980) and conditioned avoidance response (Wadenberg, 2010).

3 FEATURES OF SCHIZOPHRENIA THAT CAN BE MODELED IN ANIMALS

3.1 Clinical Time Course and Response to Treatment

Before describing the symptoms, biological perturbations, and other specific clinically-relevant features of schizophrenia that are able to be modeled in animals, it should be noted that there are secondary features related to these, namely the developmental timing and the response to antipsychotic medication, that can also be modeled in principal and when done so successfully, further enhance the animal model's validity.

With regards to developmental timing, the emergence of a clinically relevant phenotype sometime after puberty in an animal model is considered validity enhancing because it is viewed to reflect the typical temporal emergence of the core clinical features of schizophrenia in early adulthood. In reality, the onset of schizophrenia is clinically identified by the emergence of positive symptoms, with or without negative symptoms, and at present we do not know whether or not the emergence of other clinically relevant features, such as cognitive or information gating deficits, coincide with the emergence of positive and negative symptoms. Therefore, strictly speaking, until the timing of those other clinically relevant features is well established, only the postpubertal emergence of phenotypes directly relevant to positive and negative symptoms should be considered to enhance the validity of an animal model.

An animal model that measurably responds to treatments for the disease being modeled is said to have predictive validity. Predictive validity is most strongly demonstrated when an animal model of schizophrenia responds to all antipsychotic drugs with established efficacy for the symptoms of schizophrenia, but not does respond to drugs that lack efficacy for schizophrenia but are efficacious for other related disorders. For example, an animal model that responds consistently to all antipsychotics but not to any mood stabilizer or antidepressant would be considered to have very strong predictive validity. The predictive validity of an animal model is considered a major determinant

of its utility in identifying potential new treatments for the modeled disease. However, beyond that, predictive validity is often thought to enhance the overall validity of an animal model for the disease, especially, if the effect of antipsychotic medication is to normalize or ameliorate a clinically relevant, abnormal phenotype. Some have argued that predictive validity is the most important feature in assessing the validity of an animal model (Geyer and Markou, 1995). However, there are some vexing dilemmas related to the predictive validity of animal models of schizophrenia since antipsychotics display unequivocal efficacy only against positive symptoms but, as will be discussed later, there are no animal homologs for positive symptoms, only presumed analogs, such as motor hyperactivity. Additional challenges are presented by the fact that antipsychotic drugs are not highly efficacious against cognitive deficits or negative symptoms of schizophrenia and it is controversial whether they are completely without efficacy or have moderate efficacy against these clinical components of schizophrenia (Blin, 1999). As such, it is unclear whether the validity of a phenotypic abnormality in an animal that is proposed to represent negative symptoms, is enhanced or compromised, by the amelioration of the abnormality by antipsychotic drugs. The same applies to animal phenotypes that are proposed to represent schizophrenia's cognitive deficits. Despite these conceptual challenges, most animal models are evaluated for the effect of antipsychotic drugs on one or more of their clinically relevant phenotypes.

3.2 Positive Symptoms and Hyperdopaminergia

Though positive symptoms are the most characteristic clinical feature of schizophrenia and a requirement for making the diagnosis, they are the most challenging to model in humans. Clinicians ascertain the presence of hallucinations and delusional thinking in a schizophrenia candidate through his or her language, whether it is in response to directed questions or spontaneously generated speech. This approach is obviously not possible with animals and there is no reliable way for researchers to probe the internal mental state of animals. As such, there are no animal models, to date, that credibly replicate the phenomenology of positive symptoms although chronic administration of PCP, a psychogenic drug, in monkeys will cause them to exhibit behaviors suggestive of humans experiencing positive symptoms (see Section 4). The dopamine theory of schizophrenia, which is based upon strong but indirect evidence, posits that increased dopamine transmission in the subcortical mesolimbic brain pathway mediates positive symptoms. Despite limited direct evidence for increased dopamine transmission in the brains of people with schizophrenia,

the dopamine theory remains the dominant theory regarding the underlying pathophysiology of schizophrenia and, in particular, it's positive symptoms. It is not, therefore, surprising that much of the effort toward developing animal models of this disorder has historically been guided by this theory. Indeed, inducing hyperdopaminergia in rodents has been the basis of the earliest and most ubiquitous attempts to model schizophrenia and study antipsychotic drugs in animals. In the absence of the ability to replicate the phenomenology of positive symptoms, animal models of hyperdopaminergia have been largely considered to be animal models of positive symptoms.

The simplest and most common approach used to model hyperdopaminergia in animals has been to administrator prodopamine drugs to rodents. Apomorphine, a direct agonist at the D2/D3 dopamine receptors, and amphetamine, an indirect agonist that enhances synaptic levels of dopamine, are the most commonly used drugs for this purpose. Animals given systemic injections of these drugs display characteristic acute effects that can be measured quantitatively. The most apparent effect is increased locomotor behavior, however, increased cage climbing, stereotypic movements, and reduced PPI and latent inhibition are also induced. All of the established antipsychotics that have been tested are able to block these effects and therefore blockade of apomorphine- or amphetamine-induced behaviors is the most common preclinical screening test for putative antipsychotics and is considered predictive of efficacy to treat positive symptoms of psychosis.

While reduced PPI is an established feature of schizophrenia, increased motor activity is not considered one of its prominent features. Therefore, measuring the PPI effects of prodopamine drugs is preferable to measure their locomotor effects when using the hyperdopaminergia model.

People with schizophrenia have increased sensitivity to the psychosis inducing effects of prodopamine psychostimulants, such as amphetamine. This is thought to be due to an upregulation of their dopamine system. Increased sensitivity to the prodopamine drugs has been proposed as a validating feature of an animal model for schizophrenia. The APO-SUS rat (Wistar) strain was developed by selecting the individual rats from among a colony of rats that exhibited the strongest stereotypy response to apomorphine. These APO-SUS rats were then interbred to produce a strain of rats with a genetic sensitivity to apomorphine (Ellenbroek et al., 1995).

Similarly, there exists evidence for increased striatal presynaptic dopamine function (increased synthesis and release) and increased dopamine receptor density (Howes et al., 2012). Therefore the existence of similar findings occurring naturally in animals, or as a result

of specific preparations, is considered a validating feature for their relevance to schizophrenia. In this regard, rats raised in social isolation have been reported to exhibit elevated presynaptic DA levels (Powell, 2010) and Brattleboro rats, a strain of rats with deficient vasopressin, have increased striatal D2 receptor levels (Shilling et al., 2006). The presence of certain dopamine-regulated behaviors has also served as the presumed behavioral marker for increased brain dopamine "tone" and increased spontaneous hyperactivity has been suggested to be a schizophrenia-validating feature for an animal model despite the fact that people with schizophrenia do not exhibit prominent hyperactivity (Minassian et al., 2010). One study showed that rats exhibiting the lowest PPI among a colony were more sensitive to further reduction of their PPI by apomorphine than rats with naturally high PPI, suggesting that the low PPI exhibited by people with schizophrenia may be due to the increased central dopamine tone, which also makes them more sensitive to prodopamine drugs (Feifel, 1999).

3.3 Negative Symptoms

As mentioned previously, negative symptoms are one of the core features of schizophrenia and it is included in the DSM list of symptoms of schizophrenia that are included in the diagnostic criteria. There have been several attempts to model negative symptoms in animals. While some specifics manifestations of negative symptom, such as alogia (reduced speech) and affective flattening are difficult to model in animals, modeling reduced social interaction, one manifestation of negative symptoms is viable and a widely accepted paradigm. This is accomplished with the social interaction test, which measures the social interaction between individual members of species placed together in a test arena (Neill et al., 2016; Sams-Dodd, 1998b). Unlike control animals who freely explore the environment and interact frequently with the other members of their species, rodents that are treated with the NMDA receptor antagonist PCP for 3 consecutive days typically ambulate along the periphery of the arena and avoid contact with the other members of their species. This PCP-induced phenotype is considered to be analogous to the social avoidance displayed at times by some schizophrenia patients. FGA's and SGA's reverse the effects of PCP in the social interaction test when administered for 3 or 21 days in combination with PCP. However, the antipsychotics also increase social interaction in animals that did not receive PCP (Sams-Dodd, 1998b). Given the equivocal nature of the benefit of antipsychotics in treating negative symptoms, their distinct efficacy in the social interaction test may, arguably, weaken the predictive validity of this animal model of negative symptoms.

3.4 Information Processing Abnormalities Associated with Schizophrenia

Substantial evidence suggests that people with schizophrenia have deficiencies in processing information including a reduction in normal automatic filtering, or gating, of irrelevant internal and external stimuli, resulting in a greater intrusion of irrelevant stimuli on the conscious awareness in people with schizophrenia (Braff and Geyer, 1990; McGhie and Chapman, 1961). This abnormality may be fundamental to the disturbances of thought associated with schizophrenia (Braff and Geyer, 1990). Several cross-species operational measures of sensory and sensorimotor gating have been characterized and used to develop animal models of the gating deficits observed in schizophrenia. The abnormalities in these gating measures are considered "endophenotypes" of schizophrenia—phenotypic features that are not symptoms of the disorder but are likely to reflect the underlying neuropathology that contributes to the core symptoms. The endophenotypes of schizophrenia described later can be modeled in rodents in a manner homologous to their manifestation in people with schizophrenia.

3.4.1 Prepulse Inhibition (PPI)

The most researched schizophrenia endophenotype related to information gating is PPI. PPI refers the normal suppression of the reflexive startle response to a brief intense startling stimulus (pulse) when it is preceded by a barely detectable, nonstartling, lead stimulus (prepulse) that is presented 30–500 ms before the pulse (Swerdlow and Geyer, 1998). PPI is an operational measure of a phenomenon referred to as sensorimotor gating, which is an early stage (preattentional) perceptual filtering mechanism that allows some stimuli to proceed through for further processing while filtering out other stimuli. Weak sensorimotor gating can, in theory, allow higher order processing centers to become overwhelmed by irrelevant information. This can reduce the efficiency of cognitive processing and produce disordered thinking. The startle reflex is mediated by a monosynaptic circuit that transfers information from sensory receptors to motor neurons. PPI is mediated by a multisynaptic circuitry that modulates the startle circuit and overlaps substantially with circuits implicated in schizophrenia (Swerdlow and Geyer, 1998; Swerdlow et al., 1986, 2001). The suppression of the motor response to the startling stimulus occurs because the processing of the prepulse creates a time limited gating mechanism that inhibits processing of other stimuli (Fig. 23.1).

People with schizophrenia have decreased PPI compared to matched control subjects (Braff and Geyer, 1990). Though the precise clinical correlation of low PPI in schizophrenia has not been established,

(A)

Prepulse

FIGURE 23.1 **Diagram is representative of prepulse inhibition.** (A) The presentation of Stimulus A (pulse) results in a large startle response. (B) When a subthreshold prepulse is presented 50–500 ms prior to Stimulus B (pulse), the startle response is decreased. Prepulse inhibition is represented by the *grayed box* (Startle A–Startle B).

schizophrenia patients with maximal PPI deficits have been shown to have the greatest thought disorder (Perry and Braff, 1994). Several lines of evidence suggest that these PPI deficits represent a vulnerability trait. For example, first degree relatives of schizophrenia patients not afflicted with the disorder and people with schizotypal personality, a condition associated with milder forms of psychosis than schizophrenia, have been shown to have PPI that is intermediate between people with schizophrenia and healthy people who do not have first degree relatives with schizophrenia (Cadenhead et al., 1993). There is also evidence that low PPI may represent somewhat of a state marker for psychosis, as hospitalized bipolar patients in the midst of an acute manic episode with psychosis displayed reduced PPI whereas stable outpatient bipolar patients did not (Perry et al., 2001a).

PPI can also be measured in animals under parametric conditions similar to those used to measure it in humans. Some common parameters used to elicit PPI in both rodents and humans include a startling auditory stimulus (pulse) of approximately 120 dB, preceded by a much weaker stimuli (prepulse) ranging from 4–16 dB that is presented 50–500 ms before the pulse. A test session includes presentation of both startling pulses alone and prepulse-pulse pairs. In humans, the startling acoustic pulse and nonstartling stimulus are delivered through headphones and the startle response is measured by the strength of the involuntary eye blink, which is measured electromyographically via electrodes positioned below one eye on the ocular blink muscle (orbicularis oculi). To measure the startle response in rodents, mice or rats are placed in cylindrical enclosures housed within soundproof boxes. Acoustic stimuli are delivered via speakers and startle response is measured by mechanical transducers, which detect the downward displacement of the cylinders produced by the rodent's involuntary limb extension in response to the startling stimulus.

PPI is commonly calculated in each human or animal subject by comparing the average magnitude of the startle responses to the startling pulses presented alone with the magnitude of the startle response to the prepulse-pulse presentations. The most common way to report the attenuation in startle produced by the prepulses is as the average percentage reduction of the unmodified startle response.

$$[(1 - (\text{Startle}_{\text{prepulse}} - \text{Startle}_{\text{noprepulse}}) / \text{Startle}_{\text{noprepulse}})) \times 100)]$$

PPI deficits can be induced in animals by a variety of interventions. Psychostimulant drugs that have a proclivity to temporarily induce psychotic symptoms in humans, such as amphetamine, PCP, and LSD, produce transient PPI deficits in rodents. Nonpharmacological interventions can also produce PPI deficits in rodents and are often more enduring than those deficits produced by drugs. Examples of these interventions include lesions induced in the ventral hippocampus during the neonatal period, rearing rodents in social isolation, in-utero viral infections and certain genetic manipulations. In addition, some rodent strains, such as the Brattleboro rat and C57BL/6j mice exhibit naturally low PPI. Antipsychotic drugs, specifically SGAs, tend to reverse PPI deficits in people with schizophrenia (Braff, 2010). PPI deficits in rats and mice have been widely used as predictive test for drugs with therapeutic potential for schizophrenia (Braff, 2010; Geyer et al., 2001).

A limitation of PPI deficiency as a basis for modeling features of schizophrenia in animals is that PPI deficits are not specific to schizophrenia as people with other neuropsychiatric disorders have been shown to exhibit PPI deficits, including Huntington's disease (Swerdlow et al., 1995), obsessive compulsive disorder (Swerdlow et al., 1993), Tourette's disorder (Castellanos et al., 1996), and bipolar mania with psychosis (Perry et al., 2001a). These findings raise questions regarding the fundamental nature of the PPI deficiency in schizophrenia.

One of the advantages of using PPI as the basis for an animal model of relevance to schizophrenia is that the PPI measurement itself is highly automated and provides an objective quantitative output. Moreover, it does not require any physical preparation or training of animals.

3.4.2 P50/N40 Gating

Electroencephalographic (EEG) monitoring following presentation of a stimulus reveals electrical potentials that are generated at highly predictable times following the stimulus presentation. Evoked responses to auditory stimuli, termed auditory event related potentials (AERP), have been well studied in humans and animals. One well-characterized AERP occurs 50 ms after an auditory stimulus is presented and is called the P50 wave.
FIGURE 23.2   **N40 gating in sham and NVHL rats.** Grand average auditory ERPs in sham and lesion (NVHL) groups showing prominent reduction in S1 magnitude among NVHL group rats. *Source: Reprinted with Permissions from S. Karger, A.G., Basel; adapted from Swerdlow, N.R., Light, G.A., Breier, M.R. et al., 2012. Sensory and sensorimotor gating deficits after neonatal ventral hippocampal lesions in rats. Dev. Neurosci. 34(2–3), 240–249.*

When two auditory clicks are presented in sequence with an interstimulus interval of 0.5 ms or less, there is a marked attenuation of the P50 invoked by the second click (S2), compared to the one evoked by the first click (S1). This is thought to be an operational measure of sensory gating (versus sensorimotor gating, since P50 gating involves no motor response), which is a process by which the brain filters the flow of sensory information that is allowed to pass through to higher processing centers. It is presumed that sensory gating helps avoid flooding of those systems. In the paired click paradigm an inhibitory mechanism or sensory gate is activated by the first click (Swerdlow et al., 2006).

P50 gating is usually measured as a ratio of the amplitude of the P50 response to the second click to that of the first click (S2/S1) or as a percentage reduction similar to the formula for percentage PPI $(1-(S2/S1) \times 100)$ (Swerdlow et al., 2006). People with schizophrenia exhibit much smaller P50 gating compared to nonclinical control subjects. It has been suggested that PPI and P50 suppression measure complementary aspects of inhibitory neural circuitry (Braff et al., 2007) and are not correlated in patients with schizophrenia.

This abnormality in the P50 gating, which is genetically linked to the α-7 nicotinic receptor, can be transiently reversed in people with schizophrenia through acute nicotine administration (Martin and Freedman, 2007). However, investigations into the ability of antipsychotics to reverse P50 deficits have been inconsistent (Adler et al., 2005; Su et al., 2012) (Fig. 23.2).

Rodents do not exhibit a P50, but they exhibit a similar AERP, the N40. The N40 and its attenuation by a preceding auditory event are considered to be analogous to human P50 and P50 gating, respectively (Stevens et al., 1991). Similar to PPI, N40 gating deficits in rodents can be induced by psychotomimetic drugs including apomorphine and amphetamine (Swerdlow et al., 2006)

as well as NMDA receptor antagonists, such as PCP (Miller et al., 1992). Social isolation rearing (Stevens et al., 1997) and neurotoxic-induced lesions of the CNS (Stevens et al., 1998) also disrupt N40 gating in rodents. Measuring N40 gating requires implanting and securing electrodes in the brains of rodents, making this paradigm much less practical than PPI testing. Furthermore, studies have not yet found a strong association with the P50 deficits in schizophrenia and any of the clinical features of that disorder (Potter et al., 2006). Additionally, unlike the case with PPI deficits, P50 gating deficits are not remediated by antipsychotic medication. Studies of the antipsychotic effect on N40 gating deficits in rodents have produced mixed results. For example, haloperidol reverses N40 gating deficits in rats that are induced by neurotoxins (Stevens et al., 1998). However, social isolation induced N40 gating deficits are reversed by nicotine, which is consistent with findings in schizophrenia patients (Bickford-Wimer et al., 1990; Stevens et al., 1997, 1998). In DBA/2 mice, SGAs, but not FGAs improve, N40 gating (Simosky et al., 2003, 2008).

3.4.3 Habituation

Another measure of information processing plasticity based upon the startle response is habituation, which refers to the normal decrement in startle response when the startling stimulus is repeatedly presented. Habituation is considered the simplest form of learning and is considered essential for selective attention. Habituation is deficient in schizophrenia [see (Geyer et al., 1990; Hammer et al., 2011) for review] but was not found to be abnormal in patients with obsessive compulsive disorder (Swerdlow et al., 1993), Huntington's disease (Swerdlow et al., 1995), or autism (Perry et al., 2007) conditions that are associated with PPI deficits. These findings suggest that habituation and PPI are independent measures of startle plasticity and that habituation

deficits may be more specific to schizophrenia than PPI deficits.

Habituation can easily be measured concurrently with PPI testing in the same session by presenting a short series of consecutive pulse-alone stimuli at the very beginning of the startle session and at the end of the session. The average startle response to both series is calculated and the percentage decrease from the first to second series represents habituation. The clinical correlates of habituation have not been well studied.

Concerning modeling habituation deficits in rodents, the DBA/2 mouse (Brooks et al., 2004), the Maudsley Nonreactive rat (Commissaris et al., 1988) and the Brattleboro rat (Feifel and Priebe, 2001) show innate startle habituation deficits.

In regards to drug effects on habituation deficits in patients with schizophrenia, Perry et al. (2002) reported no difference in habituation deficits in acutely ill patients who were being treated with antipsychotics and those who were medication free.

3.4.4 Latent Inhibition

Latent inhibition is a normal modulation of associative learning. Specifically, latent inhibition refers to the reduced ability to learn the relevance of a stimulus that is paired with an aversive or positive condition through classic conditioning if there has been a previous exposure to the stimulus in a neutral context (Lubow, 1965; Swerdlow et al., 1996). In humans, associative learning is typically measured in a laboratory setting by pairing an initially neutral stimulus (e.g., image of a blue circle) with an aversive one, such as a mild shock to the hand until the previously neutral stimulus elicits a similar physiological response as the shock. For example, this learned association can be measured by the ability of the once neutral stimulus to potentiate the subject's startle response to a startling stimulus, such as a sudden brief sound. To measure latent inhibition, some subjects are exposed to the neutral stimulus on its own before the first pairing with mild shock. The preexposure to the neutral stimulus normally inhibits its ability to become associated with the shock as measured by a reduced ability to potentiate startle compared to a neutral stimulus that is not preexposed.

Both PPI and latent inhibition are considered measures of information gating and their underlying neural circuitry overlap (Bakshi et al., 1995). However, whereas PPI assesses early attentional or "preattentional" gating mechanisms, latent inhibition assesses later stages of information processing gating (Leumann et al., 2002). The degree to which PPI and latent inhibition are related within individual animals or humans is not well established. Latent inhibition, like PPI, is deficient in schizophrenia patients (Bakshi et al., 1995; Baruch et al., 1988; Gray et al., 1995) although there is some degree of

controversy (Swerdlow et al., 1996; Rascle et al., 2001). Latent inhibition is also deficient in a subgroup of Parkinson's patients (Lubow et al., 1999). However, in contrast to PPI deficits, latent inhibition deficits, like startle habituation deficits, are not found in patients with obsessive compulsive disorder (Swerdlow et al., 1999).

Latent inhibition can be measured in rodents using paradigms similar to those in humans. For example, a colored light can be used as the conditioned stimulus and an electric shock delivered through a grid in a cage floor can be used as the unconditioned stimulus (Weiner et al., 1996). Another approach to study latent inhibition has been to use a conditioned taste aversion paradigm (Simonyi et al., 2009) where a distinct gustatory stimulus, such as saccharin-sweetened water is presented to rodents just prior to administration of a substance, such as lithium chloride that induces malaise. Animals who are presented with the colored light or saccharin flavored water not paired with shock or malaise, respectively, will develop weaker potentiation of startle or aversion to drinking saccharin flavored water when those stimuli are later paired with the shock or lithium (Fig. 23.3).

In humans and rats, the indirect dopamine agonist amphetamine produces latent inhibition deficits (Russig et al., 2002; Thornton et al., 1996; Weiner et al., 1988). In addition, an injection of interleukin-6 (IL-6), which stimulates the immune system, in pregnant mice causes latent inhibition deficits in their adult offspring (Smith et al., 2007).

In rodents, antipsychotic drugs, such as haloperidol and clozapine reverse amphetamine-induced latent inhibition deficits (Thornton et al., 1996; Williams et al., 1996) and facilitate latent inhibition that is above baseline levels when given alone (Bethus et al., 2006; Feldon and Weiner, 1991). Additionally, compounds that lack antipsychotic activity are usually not active in this model (Moser et al., 2000). Based upon these findings, enhancement of baseline latent inhibition or reversal of amphetamine-induced reduction of latent inhibition, have been proposed as predictive tests of antipsychotic activity (Moser et al., 2000). In addition, some strains of rodents, such as the Brown Norway (Conti et al., 2001) and Brattleboro rat (Feifel et al., unpublished), as well as 29/SvJ, CBA, A/J, and C3H/Ibg mice (Gould and Wehner, 1999) exhibit spontaneous deficits in latent inhibition. In this regard, Feifel et al. (2015, 2016) recently reported that both oxytocin and a brain penetrating neurotensin-1 agonist, PD149163, modulate latent inhibition in a manner consistent with antipsychotic drugs in Brown Norway rats.

3.4.5 Other Cognitive Deficits

Cognitive deficits are highly prevalent in schizophrenia and are considered by many schizophrenia investigators to be a core feature of the disorder, despite

	Stage 1 (preexposure)	Stage 2 (conditioning)	Stage 3 (test)
Control group	Normal water +++ imbibed	Flavored water and saline +++ imbibed	Flavored water +++ imbibed (no conditioned taste aversion)
Non-preexposed group	Normal water +++ imbibed	Flavored water and LiCl* +++ imbibed	Flavored water + imbibed (conditioned taste aversion)
Preexposed group	Flavored water +++ imbibed	Flavored water and LiCl +++ imbibed	Flavored water ++ imbibed (latent inhibition of conditioned taste aversion)

FIGURE 23.3 **The three stages of the latent inhibition paradigm using a conditioned taste aversion procedure.** In stage 1, water-restricted animals are given a drinking session with either flavored water (e.g., 1% saccharin) (preexposed group) or regular drinking water (nonpreexposed group and control group). In the second stage, all animals are given a drinking session with flavored water. The nonpreexposed and preexposed groups are then injected immediately with LiCl, which induces malaise. The controls are injected with saline instead of LiCl. In the third stage (Test), conditioned taste aversion and latent inhibition are tested by exposing all animals to the flavored water (CS) alone. All animals except the controls exhibit conditioned taste aversion. Furthermore, the group that had experience with flavored water before it was paired with lithium-inducing malaise demonstrates less aversion to the flavored water on the test day, indicating that the preexposure to the flavored water produced a latent inhibition of the conditioned taste aversion. Thanks to Dr. Robert Lubow for assistance in preparing this figure. *LiCl is administered in doses that produce a rapid, but transient sensation of malaise in rodents.

that they are not counted among the DSM criteria for making the diagnosis of schizophrenia. The cognitive deficits experienced by people with schizophrenia are responsible for a substantial amount of the functional disabilities associated with this disorder. Moreover, as with negative symptoms, the beneficial effects of antipsychotic drugs on the cognitive deficits of schizophrenia are, at best, modest (Woodward et al., 2005). Due to these modest effects, there has been much effort recently to develop drugs that specifically address the cognitive deficits of schizophrenia (Young and Geyer, 2015). This has, in turn, energized efforts to develop and optimize animal models and animal tests that have validity for the cognitive deficits of schizophrenia. Several distinct domains of cognitive function have been identified to be perturbed in people with schizophrenia including attention, memory and learning (visual, verbal and working), reasoning and problem solving, processing speed, and social cognition (Hagan and Jones, 2005). There are established tests to assess each of these cognitive domains in humans and tests have also been developed to measure analogous cognitive functions in rodents and other animals. Researchers interested in studying the cognitive dysfunction associated with schizophrenia in animals have generally utilized those preclinical tests. Pharmacological, neuroanatomical lesion, neurodevelopmental intervention, and genetic approaches have been used to induce deficient performance in these animal tasks in order to create animal models for these cognitive deficits. For example, PCP, a noncompetitive NMDA antagonist, induces reduced performance in rats and mice on tests of

animal attention (Jentsch and Anzivino, 2004), working memory (Marrs et al., 2005), problem solving (Egerton et al., 2005), social cognition (Terranova et al., 2005), and novel object recognition (Neill et al., 2016).

Investigators have attempted to improve animal performance on cognitive tasks with a variety of compounds in the hope of identifying therapeutic treatments for the cognitive deficits exhibited by patients with schizophrenia. A major barrier to this effort is the lack of positive controls for establishing predictive validity for animal models of cognitive dysfunction since, at this time, there are no known drugs that have good efficacy against these cognitive abnormalities exhibited by people with schizophrenia. The human clinical batteries and their corresponding preclinical cognitive tests, for which performance is assumed to be analogous, are displayed in Table 23.2.

3.4.6 Genetic Abnormalities

A large number of genetic variants have been identified from various studies comparing the genome of people with schizophrenia to the general population, suggesting multiple susceptibility loci for schizophrenia (Allen et al., 2008) (Also see SZGene URL http://www.szgene.org/). For example, specific single nucleotide polymorphisms (SNP) variants have been detected significantly more often in people with schizophrenia in association studies. In addition, family studies have detected linkage to an array of chromosomal regions. Several knockout and transgenic approaches have been used to model some of these genetic abnormalities in animals.

TABLE 23.2   Cognitive Domains Impaired in Schizophrenia, Tests Used to Measure These Behaviors in Humans Animal Tests That Measure Analogous Cognitive Domains in Animals

Cognitive domain	Clinical battery	Animal tests
Working Memory	BACS, Spatial delayed response task, WMS-III spatial span WAIS-III letter-number sequence, UoM letter-number span	Operant or T-maze, delayed nonmatch to position/sample Radial arm maze
Attention/vigilance (preattentive processing)	3-7 CPT, Identical pairs CPT	Latent inhibition, 5-choice serial reaction time task
Visual learning and memory	NAB—Shape learning, BVMT—Revised	Novel object recognition, Social recognition
Speed of processing	5-choice serial reaction time task, simple reaction time tasks	Category fluency, Trail making A, WAIS-III digit symbol coding, BACS—Symbol coding
Reasoning and problem solving	WAIS-III Block design, BACS—Tower of London, NAB—Mazes	Attentional set-shifting, maze tasks
Social cognition	MSCEIT—Managing emotions, MSCEIT—Perceiving emotions	Social interaction, social recognition
Verbal learning and memory	NAB—Daily Living Memory, HVLT—Revised	Not applicable to animals

Characterization of these genetically engineered animal models has revealed inconsistent findings regarding the manifestation of schizophrenia relevant phenotypes, endophenotypes, or pathophysiological abnormalities. The effects of a single gene abnormality are not likely to be sufficient to cause schizophrenia and environmental risk factors also play an important role. Therefore, creating animal models that combine two or more candidate genetic abnormalities, or combine a candidate genetic abnormality with environmental factors in a "two-hit" model, may produce more valid animal models.

Table 23.3 displays examples of genetically engineered mouse models of the genetic alterations that have been found to be associated with schizophrenia in many studies.

4 SPECIFIC ANIMAL MODELS

4.1 Pharmacological Approaches

Animal models have primarily used psychotomimetics, such as dopamine agonists and noncompetitive NMDA (glutamate) receptor antagonists to produce deficits in behaviors that are analogous to phenotypes exhibited by people with schizophrenia, such as deficits in PPI, latent inhibition, cognitive task performance, and social interaction.

4.1.1 Administration of Prodopamine Drugs

Early efforts at modeling schizophrenia in animals relied on acute administration of indirect dopamine agonists, such as amphetamine or direct dopamine receptor

agonists, such as apomorphine to induce a transient central hyperdopaminergia. This approach remains highly utilized and it is driven by the prominence of the dopamine hypothesis of schizophrenia (Carlsson, 1977; Luchins, 1975; Willner, 1997) and the strong corpus of evidence linking hyperdopaminergia in the mesolimbic pathway to positive symptoms. The dependent measures usually studied are the well-known effects produced in rodents by prodopamine drugs, namely hyperlocomotion, stereotypy, and the disruption of PPI and latent inhibition (Geyer et al., 2001; Swerdlow et al., 1994). Typically, a single administration of 0.5–1.0 mg/kg of amphetamine is used to produce hyperlocomotion in rats, whereas higher doses (2.0–5.0 mg/kg) induce stereotypy and deficits in latent inhibition and PPI. Disrupted PPI is a well-established feature of schizophrenia and the evidence for a latent inhibition deficit in schizophrenia is also strong, with some inconsistent findings, but there is no strong evidence supporting increased locomotion in people with schizophrenia (Minassian et al., 2010) and stereotypy is exhibited by only a small percentage of them. As such, the rationale for studying hyperlocomotion and stereotypy induced by prodopamine drugs is that they are considered animal analogs of positive symptoms because they are reliably produced by increasing mesolimbic dopamine transmission. However, the ability to induce and measure a phenomenon that is actually associated with schizophrenia enhances the validity of the prodopamine pharmacological animal models and, not surprisingly, PPI has become the output of choice to measure in these hyperdopaminergia-based animal models as well as other animal models of relevance to schizophrenia. Unlike its deficit inducing

TABLE 23.3   Mouse Models Based on Some of the Most Promising Susceptibility Genes for Schizophrenia

Candidate gene and it's known function	Animal models	Schizophrenia-like features		Effects of antipsychotics (APDs)
		Phenotype	Pathophysiology	
Neuregulin 1 Growth factor involved in neuronal migration, synaptogenesis, and neuron glial interactions in brain development. (Harrison and Law, 2006)	Neuregulin 1 Knockout/hypomorph (Chen et al., 2008; Stefansson et al., 2002; O'Tuathaigh et al., 2008; Zhang et al., 2016)	PPI Deficits (Chen et al., 2008; Stefansson et al., 2002) Impaired performance on delayed alternation memory tasks, (Chen et al., 2008) Social Interaction deficits (O'Tuathaigh et al., 2008) Hyperactive in open field (O'Tuathaigh et al., 2008)	Larger lateral ventricles, decreased spine density (Chen et al., 2008) Reduced NMDA receptor activity (Stefansson et al., 2002)	Acute CLOZ reversed hyper-activity but not PPI deficits (Stefansson et al., 2002) Acute olanzapine prevented PCP-induced effects in normal neurons but not in neurons from KOs (Zhang et al., 2016) Non-APDs: Chronic Nicotine attenuated PPI deficits in HETs (Chen et al., 2008)
ERBB4 Neuregulin receptor	ERBB4 knockout (Barros et al., 2009; Golub et al., 2004; Roy et al., 2007) Specific to KO in excitatory pyramidal neurons (Cooper and Koleske, 2014)	PPI Deficits (Barros et al., 2009) HETS: Deficit in spatial learning (Golub et al., 2004) Hypoactive, social interaction deficits, enhanced AMPH sensitization (Roy et al., 2007)	Reduced spine density in hippocampus (Barros et al., 2009) Oligodendrocyte abnormalities (Roy et al., 2007)	Acute CLOZ reverses PPI deficits (Barros et al., 2009)
DISC1 Scaffolding protein critical role in neuron development, to cellular proliferation, intracellular signaling, migration and transport (Jaaro-Peled, 2009)	DISC1 L100P mutant (2nd exon) (Lipina et al., 2010)	Spontaneous hyperactivity and deficits in PPI and LI (Lipina et al., 2010) Facilitation of AMPH effect on locomotor activity and PPI (Lipina et al., 2010)	None reported	Acute HAL blocked hyper-activity, deficits in PPI and LI and blocked enhanced sensitivity to AMPH (Lipina et al., 2010)
	DISC1 KO/Knockdown (Clapcote et al., 2007; Niwa et al., 2010; Hikida et al., 2007; Umeda et al., 2016)	Deficits in PPI, working memory and LI (Clapcote et al., 2007) PPI and novel object recognition deficits after but not before puberty (Niwa et al., 2010) Increased sensitivity to MethAMPH induced disruption of PPI vs. WT (Niwa et al., 2010)	Less cortical parvalbumin containing cells (Hikida et al., 2007)	PPI deficits reversed by acute CLOZ and HAL (Clapcote et al., 2007; Niwa et al., 2010) Bupropion had no effect on PPI (Clapcote et al., 2007) LI deficits reversed by acute CLOZ (Clapcote et al., 2007)
	DISC1 (Truncated) (Shen et al., 2008)	Deficit in LI and social interaction (Shen et al., 2008)	Enlarged ventricles (Shen et al., 2008) Decreased paralbumin neurons in mPFC and hippocampus (Shen et al., 2008)	None reported
	DISC1 129S6/SvEv Naturally occurring mutant (termination codon at exon 7, abolishes production of the full-length protein) (Koike et al., 2006)	Working memory deficit (Koike et al., 2006)	Naturally occurring DISC1 truncated protein (Koike et al., 2006)	None reported

TABLE 23.3   Mouse Models Based on Some of the Most Promising Susceptibility Genes for Schizophrenia (cont.)

Candidate gene and it's known function	Animal models	Schizophrenia-like features		Effects of antipsychotics (APDs)
		Phenotype	Pathophysiology	
Dysbindin 1 Synaptic protein, regulates exocytosis and receptor trafficking in excitatory neurotransmission (Karlsgodt et al., 2011)	Sandy (sdy) Mouse Spontaneous mutation in dysbindin (Bhardwaj et al., 2009; Takao et al., 2008; Feng et al., 2008; Hattori et al., 2008; Murotani et al., 2007; Chen et al., 2017)	Working memory deficits (Takao et al., 2008) Social interaction deficits (Feng et al., 2008) Decreased basal locomotor (Hattori et al., 2008) Lack of locomotor habituation (Bhardwaj et al., 2009) Enhanced AMPH sensitization (Bhardwaj et al., 2009)	Decreased DA levels in cortex, HPC, hypothalamus (Hattori et al., 2008) DA turnover increased in specific regions of brain (Murotani et al., 2007)	None reported
Reelin Extracellular matrix protein essential for cell positioning and neuronal migration during development implicated in synaptic formation and cellular plasticity. (Cassidy et al., 2010)	Reeler Mouse, Heterozygous (Barr et al., 2008; Costa et al., 2002; Howell and Pillai, 2016)	Habituation and PPI deficits (Barr et al., 2008)	Reduced GAD 67 expression (Costa et al., 2002) Dendritic spine defects (Costa et al., 2002)	None reported

AMPH, amphetamine; APD, antipsychotic drug; CLOZ, clozapine; DA, dopamine; GAD, glutamate decarboxylase; HPC, hippocampus; HAL, haloperidol; PPI, prepulse inhibition; NMDA, N-methyl D-aspartate

effects on PPI and latent inhibition, acute administration of prodopamine drugs in animals does not consistently produce impairments in their performance on cognitive tasks that are considered analogs of those that people with schizophrenia perform poorly on. In fact, these drugs often enhance performance on these tasks (Menesses, 2011). Similarly, impairments in social interaction or other behaviors relevant to negative symptoms are not induced by acute administration of prodopamine drugs. Therefore, the acute administration of prodopamine drugs does not seem useful as an animal model of the cognitive deficits or negative symptoms associated with schizophrenia.

In addition to having some degree of validity based upon sharing the pathophysiological feature presumed to be an important mechanism underlying its clinical features (hyperdopaminergia) with schizophrenia and exhibiting a homolog of the information gating deficits (PPI and latent inhibition) exhibited in schizophrenia, the acute prodopamine pharmacological model also appears to exhibit predictive validity based upon its response to acute administration of antipsychotic drugs. FGAs and SGAs block the PPI effects of dopamine agonists and a strong correlation has been found between the potency of antipsychotics to block apomorphine-induced disruption of PPI in rodents and their clinical potency as well as their D2 receptor affinity (Swerdlow et al., 1994). Nevertheless, this finding is not surprising,

as it seems to reflect a "pharmacological tautology" since apomorphine acts as an agonist at D2 receptors and all antipsychotics tested have been D2 receptor antagonists. However, the efficacy of clozapine in the prodopamine drug animal model has been inconsistent, reducing the model's predictive validity, although strain differences across these studies may have contributed to this discrepancy (Swerdlow et al., 1998). Nonetheless, the predictive validity of this animal model is also reduced somewhat by an apparent lack of specificity for antipsychotic drugs. For example, the antidepressant desipramine, a noradrenergic reuptake inhibitor (Pouzet et al., 2005), the mood stabilizer lithium (Ong et al., 2005), and the anticonvulsant topiramate (Frau et al., 2007), none of which have any known antipsychotic efficacy, block amphetamine- or apomorphine-induced PPI deficits.

The prodopamine drug animal model also does not appear to be well suited for modeling the efficacy time course associated with antipsychotic drugs in schizophrenia. Whereas the therapeutic efficacy of antipsychotic drugs in schizophrenia patients reaches optimal levels after several weeks of continuous administration, the efficacy of single doses of antipsychotics to attenuate prodopamine drug-induced PPI deficits in rodents has been shown to weaken (Martinez et al., 2000) or disappear altogether (Andersen and Pouzet, 2001) after chronic administration.

However, the amphetamine model seems to have exhibited true predictive validity (i.e., to predict an aspect of schizophrenia not yet known) with at least one novel drug for schizophrenia. Oxytocin, a neuropeptide with no affinity for dopamine receptors, blocked amphetamine-induced PPI disruption in rats suggesting that it would be efficacious in schizophrenia before oxytocin had been systematically tested. Subsequently, oxytocin was found to be efficacious in reducing symptoms of schizophrenia (Feifel et al., 2010; Pedersen et al., 2011).

A single administration of a prodopamine drug produces only a short-lived hyperdopaminergia and related behavioral effects. In this respect, acute pharmacological animal models do not replicate the chronic hyperdopaminergia and chronic phenomenology associated with schizophrenia. Furthermore, the emergence of psychosis in people who do not have schizophrenia and take prodopamine drugs recreationally is typically exhibited after repetitive use over an extended period (Segal et al., 1981). Therefore many investigators have attempted to model psychosis in animals using chronic administration of prodopamine drugs. Some paradigms employ repeated administration of the same dose whereas others employ an escalating doses administered in binges to replicate the pattern of use in many amphetamine and cocaine addicts, which can lead to the development of stimulant-induced psychosis (Kreek et al., 2009; Segal and Kuczenski, 1999). This approach typically involves administering escalating doses of amphetamine over the course of several days (1.0–8.0 mg/kg), followed by 4 binges/day of a very high dose (8.0 mg/kg) for a variable number of days (Segal and Kuczenski, 1997). Both the steady dose and escalating dose paradigms of chronic administration induce a persistent sensitization in which rodents exhibit an amplified response to acute administration of the same drug or another pro-dopamine agent (Kalivas and Duffy, 1993a,b; Kuczenski and Segal, 1999; Segal and Kuczenski, 1992, 2006). This sensitization emulates the increased sensitivity that people with schizophrenia demonstrate to the psychotogenic effects of prodopamine drugs. Of particular interest, non-human primates administered a repeated single dose of amphetamine or an intermittent escalating dose regimen of amphetamine exhibited behaviors similar to people experiencing hallucinations including picking at imaginary parasites, orienting to nonexistent stimuli, swatting at imaginary objects and staring into empty space (Featherstone et al., 2007). Sensitized animals display persistent deficits in some cognitive tasks relevant to schizophrenia whereas others are not affected (Featherstone et al., 2007). In addition, chronic administration of prodopamine drugs seems no better than acute administration at inducing behaviors in animals that are reminiscent of the negative symptoms of schizophrenia. The findings regarding the PPI and latent inhibition effects of chronic regimens of amphetamine administration in rodents are inconsistent, as some studies have reported PPI and latent inhibition deficits in amphetamine-sensitized rodents (Featherstone et al., 2007). Although not well studied, PPI and latent inhibition deficits in sensitized rats have been reversed by FGAs and SGAs (Abekawa et al., 2008; Russig et al., 2002). Biochemical and structural changes are induced in the brain by chronic administration of amphetamine in animals, which may account for the persistent changes observed in behavioral and cognitive measures.

In conclusion, pharmacological induction of hyperdopaminergia by acute or chronic administration of prodopamine drugs in animals seems to have reasonable validity and utility as models to study positive symptoms of schizophrenia. The acute models have limitations as a valid predictive assay for efficacious treatments and the chronic model has not been studied sufficiently in this regard. Both acute and chronic models lack validity for the negative symptoms or cognitive deficits associated with schizophrenia.

4.1.2 NMDA Receptor Antagonists

Converging evidence supports the notion that, in addition to the dopamine system, dysfunction of the glutamate system contributes to the manifestation of schizophrenia (Geyer and Moghaddam, 2002; Tsai and Coyle, 2002). This evidence includes the observation that PCP and ketamine, drugs that block the N-methyl d-aspartate (NMDA) subtype of the glutamate receptor, can produce a transient psychosis similar to that experienced by people with schizophrenia. However, unlike the transient psychosis produced by prodopamine drugs, such as cocaine or amphetamine, these NMDA antagonists can induce a phenomenon that emulates both the negative and positive symptoms, as well as the cognitive deficits of schizophrenia (Krystal et al., 1994; Tamminga et al., 1995). PCP and ketamine can also exacerbate positive and negative symptoms in people with schizophrenia. Studies have provided support for reduced NMDA receptor function in the brains of people with schizophrenia (Coyle et al., 2003; Pilowsky et al., 2006). This body of converging evidence has led to the development of the glutamate hypothesis of schizophrenia, which posits that in addition to subcortical hyperdopaminergia, hypofunction of glutamate transmission through NMDA receptors, and possibly other glutamate receptor subtypes, contributes to clinical features of schizophrenia, especially the negative symptoms and cognitive deficits (Javitt, 2010).

In response to increasing recognition of the potential role of glutamate perturbation in schizophrenia, NMDA antagonists, such as PCP, ketamine, and dizocilpine (MK801) have been used to create pharmacological

animal models of schizophrenia in an attempt to better understand the role of glutamate hypofunction in this disorder and to screen for new treatments (Brown et al., 2014; Geyer et al., 2001; Jentsch and Roth, 1999; Mouri et al., 2007). A single administration of noncompetitive NMDA antagonists, such as PCP (0.1–10 mg/kg) produces a wide array of schizophrenia-relevant behaviors in rodents, such as hyperlocomotion, deficits in PPI and latent inhibition (Gaisler-Salomon and Weiner, 2003; Jentsch and Roth, 1999; Mansbach and Geyer, 1989; Neill et al., 2016), social withdrawal (Sams-Dodd et al., 1997) and impairment in performance on several animal cognition tasks including set shifting (Goetghebeur and Dias, 2009; Goetghebeur et al., 2010), novel object recognition (Grayson et al., 2007; Nagai et al., 2009; Neill et al., 2016; Rajagopal et al., 2014), spatial learning (Beraki et al., 2008), 5-choice serial reaction time tasks (Baviera et al., 2008), and latent visuospatial learning and memory (Wang et al., 2007).

Acute administration of FGAs and SGAs reverse the hyperlocomotion induced by acute administration of NMDA antagonists, whereas NMDA antagonist-induced disruption of PPI is blocked by acute administration of SGAs but not FGAs (Geyer et al., 2001; Jentsch and Roth, 1999). Several studies, however, have found that chronic administration of the FGA haloperidol is able to block the NMDA antagonist-induced PPI deficits (Feifel and Priebe, 1999; Martinez et al., 2000). NMDA antagonist-induced hypoglutamatergic models do not seem to be sensitive to drugs with no antipsychotic efficacy and, therefore, they seem to have greater specificity for drugs with antipsychotic efficacy than the animal models that utilize prodopamine drug administration (Pouzet et al., 2005). The neuropeptide oxytocin attenuated PPI deficits induced by an NMDA antagonist in rats as it did with PPI deficits induced by amphetamine (Feifel and Reza, 1999). Oxytocin was later found to improve positive and negative symptoms and cognitive performance in people with schizophrenia (Feifel, 2012; Feifel et al., 2010).

As with animal models based upon prodopamine drug administration, the desire to replicate the chronic nature of the hypoglutamatergia in schizophrenia has motivated the development of pharmacological animal models based upon chronic administration of NMDA antagonists (Mouri et al., 2007). Chronic PCP treatment results in sensitization to the locomotor-activating effects of a challenge dose of PCP (Jentsch and Roth, 1999) analogous to the effects of chronic amphetamine treatment. In some studies, chronic PCP administration produced more enduring social withdrawal and impairments in cognitive performance than single doses of PCP (Mouri et al., 2007). On the other hand, the duration of PPI deficits induced by acute and chronic PCP treatment seem to be comparable (Martinez et al., 1999).

Few studies have investigated effects of antipsychotics on repeated administration of NMDA antagonists, however, acute clozapine administration was found to potentiate PPI deficits induced by 12-days of PCP treatment (Schwabe et al., 2005). Repeated clozapine, seroquel and risperidone, but not haloperidol or olanzapine, blocked PPI deficits in mice subchronically treated with PCP (Li et al., 2011). Neither risperidone nor haloperidol reversed set shifting deficits induced by subchronic PCP (Goetghebeur and Dias, 2009). Both clozapine and risperidone, but not haloperidol, reversed PCP-induced visual learning and memory deficits (Grayson et al., 2007). SGAs were also superior to FGAs at improving social withdrawal behaviors reminiscent of negative symptoms that are induced by repeated injections of PCP in rats, (Sams-Dodd, 1997; Sams-Dodd et al., 1997) while nonantipsychotic drugs were without effect (Sams-Dodd, 1998a).

In conclusion, hypoglutamatergia induced in animals by acute and chronic administration of NMDA antagonists seem to model a wider spectrum of the clinical features of schizophrenia compared to models that induce hyperdopaminergia. Most notably, they induce features that are similar to negative symptoms and cognitive deficits. This model seems to be sensitive to the effects of drugs that have effects beyond D2 antagonism.

4.2 Neurodevelopmental Approach

The neurodevelopment hypothesis of schizophrenia posits that critical pathological perturbations in the brains of people with schizophrenia start well before the clinical onset of the disorder, beginning as early as in-utero or early childhood. For reasons not yet understood, these brain abnormalities give rise to characteristic symptoms in adolescence or early adulthood when brain areas underlying cognitive processing, such as the dorsal lateral prefrontal cortex, are not fully mature (Goldman-Rakic, 1994; Weinberger, 1987). In this regard, exposure to environmental insults during gestation and the perinatal period, including maternal malnutrition, infection and perinatal hypoxia, have been reported to increase the risk for developing schizophrenia (Lewis and Levitt, 2002).

Several efforts have been made to develop animal models of this neurodevelopmental hypothesis. These efforts typically involve inducing a deleterious biological effect, relevant to the known risk factors or pathophysiology of schizophrenia, during an animal's prenatal or perinatal period. Validity for these models is based upon the emergence of schizophrenia-relevant features after the rat reaches puberty. However, the timing of the emergence of many schizophrenia-relevant features, aside from positive and negative symptoms, that are commonly modeled in animals, such as gating deficits,

are not well known and may be congenital. Therefore, developmental models that rely heavily on the latent emergence of these features for validity may in fact lack validity.

4.2.1 The Social Isolation Rearing Model

Rats that are housed in cages by themselves immediately after weaning exhibit abnormalities in behavior relevant to schizophrenia when they are tested as adults (Geyer et al., 1993; Powell et al., 2002; Varty and Higgins, 1995). These abnormalities include locomotor hyperactivity, PPI deficits, and reduced performance on cognitive tasks, such as an object recognition task, T-maze (Li et al., 2007; Millan and Brocco, 2008), reversal (Powell et al., 2015), and probabilistic learning (Amitai et al., 2014). Single injections of both FGAs and SGAs reverse social isolation rearing-induced PPI deficits (Bakshi et al., 1998; Cilia et al., 2001; Geyer et al., 1993; Powell et al., 2002; Varty and Higgins, 1995), whereas several psychotropics that are devoid of antipsychotic efficacy, including the anxiolytics chlordiazepoxide and diazepam as well as the antidepressant amitriptyline, have no effect on PPI deficits (Powell, 2010; Powell et al., 2002) suggesting this animal model responds with good sensitivity and specificity to drugs with antipsychotic efficacy. Chronic administration of clozapine reverses learning deficits in a T-maze in social isolation reared rats (Li et al., 2007). A potential limitation of this model is related to the robustness of the induced deficits. Some studies have found that handing of social isolation reared rats or changes in the bedding of their home cages can eliminate the PPI deficits (Lipska et al., 1995; Powell et al., 2002).

4.2.2 The Methylazoxymethanol Acetate Model

Methylazoxymethanol acetate (MAM) is an antimitotic and proliferative compound toxin that targets neuroblast development (Moore et al., 2006; Penschuck et al., 2006). In the MAM developmental animal model, MAM is administered intraperitoneally to pregnant rats, either during midgestation (embryonic day 9–12) or late gestation (embryonic day 17–18), and through selective disturbance of proliferation and migration of neuronal precursor cells, MAM induces brain morphology and cytology changes in specific brain areas of their offspring (e.g., entorhinal cortices, frontal cortex, and hippocampus) that are similar to those observed in some patients with schizophrenia (Lodge and Grace, 2009). During adolescence, these offspring exhibit some features of schizophrenia including PPI deficits, increased sensitivity to prodopamine and NMDA inhibitory drugs (Moore et al., 2006; Le Pen et al., 2006), as well as schizophrenia-like glutamate transmission abnormalities in the hippocampus (Hradetzky et al., 2012). These offspring also exhibit social interaction deficits and cognitive

impairments including deficits in reversal learning (Le Pen et al., 2006; Moore et al., 2006) and spatial recognition memory (Le Pen et al., 2006). The most robust behavioral effects have been reported after late gestational MAM administration. To date, predictive validity has not been examined in this model.

4.2.3 The Neonatal Ventral Hippocampus Lesion Model

The neonatal ventral hippocampus lesion (NVHL) model is based on the convergent findings of disrupted hippocampus function in many people with schizophrenia (Jaaro-Peled et al., 2010; Whitworth et al., 1998) and is the best characterized neurodevelopmental animal model of schizophrenia (Lipska and Weinberger, 1993, 1994; Lipska et al., 1992, 1993). In this model, ibotenic acid is infused bilaterally into the hippocampus of 7-day old neonatal rats to disrupt hippocampal circuits. Rats prepared this way exhibit many schizophrenia-like features, which emerge during the rats' peripuberty period of development. Specifically, in the prepubertal period, NVHL rats begin to exhibit deficits in social interaction and grooming as well as impaired performance on cognitive tasks, such as those that measure working and spatial memory (Lipska and Weinberger, 2002; Lipska et al., 1993). These deficits are considered analogous to the emergence of negative symptoms and cognitive impairments that are part of a prodromal period before the presentation of full-blown positive symptoms. (Levin and Christopher, 2006; Sams-Dodd et al., 1997). The NVHL rat also exhibits behavioral changes believed to be associated with positive symptoms including locomotor hyperactivity and exaggerated behavioral response to amphetamine and NMDA antagonists as well as deficits in PPI and N40 gating (Lipska and Weinberger, 2000; Swerdlow et al., 2012; Tseng et al., 2009). NVHL rats also have reduced expression of glutamate decarboxylase-67 (GAD67) mRNA consist with reduced GAD67 in the brains of people with schizophrenia (Lipska and Weinberger, 2000).

Single doses of clozapine, risperidone, and olanzapine, but not haloperidol, reverse the hyperlocomotion and PPI deficits in the NVHL model (Le Pen and Moreau, 2002). Chronic (21 days) administration of clozapine and haloperidol reverses the hyperlocomotion, PPI deficits but not the social interaction deficit (Rueter et al., 2004; Sams-Dodd et al., 1997).

Unfortunately, there do not appear to be any reports on testing nonantipsychotic drugs to determine the specificity of this model for drugs with antipsychotic efficacy.

4.3 Genetic Models

Given the strong genetic contribution to schizophrenia and the many genetic variations identified in

people with schizophrenia, there is a strong impetus for developing genetically based animals models of this disorder. Two approaches have been used in the development of genetic animal models of schizophrenia. The first approach has employed genetic engineering to induce abnormalities in the expression of the mouse version of genes that are associated with patients with schizophrenia or that regulate neurotransmitter or other systems that are implicated in the pathophysiology of schizophrenia. The second approach involves identifying strains of rodents or individual rodents among the rodent population who exhibit schizophrenia-like abnormalities.

4.3.1 Models Created by Genetic Engineering

An abundance of genetically engineered mice have been created with the intention of modeling schizophrenia (Powell et al., 2009). Genetic manipulation models fall into two categories: those developed based on pathophysiological hypotheses of schizophrenia and those developed based upon empirically identified candidate genes for the disorder.

An example of the pathophysiology approach based on the dopamine hypothesis of schizophrenia is one in which mice are genetically engineered to lack dopamine transporters. The primary function of this protein is the transport of dopamine from the synaptic cleft back into presynaptic neuron. Reducing the dopamine transporter function increases dopamine in the synaptic cleft and thereby increases dopamine transmission. Mice that have been engineered to lack dopamine transporters (i.e., dopamine transporter knockout mice) exhibit disrupted PPI and increased locomotor activity (Rodriguiz et al., 2004). However, abnormalities in the dopamine transporter have not been identified in schizophrenia patients (Mazzoncini et al., 2009). Furthermore, the PPI deficits in the dopamine transporter mice are reversed by cocaine, methylphenidate, and amphetamine (Yamashita et al., 2006), greatly reducing the validity of this model for schizophrenia.

Of relevance to the glutamate hypothesis of schizophrenia, mice lacking the mGluR5 subtype of glutamate receptors exhibit deficits in PPI and short-term spatial memory. Single dose administration of antipsychotics, raclopride, and clozapine do not attenuate these deficits, whereas chronic clozapine administration mitigates them (Brody et al., 2003; Gray et al., 2009; Kinney et al., 2003). Because these mice seem more sensitive to chronic effects of antipsychotics than to acute effects, they may have the ability to model the time course of the therapeutic effects of antipsychotics. Testing single versus repeated administration of other antipsychotics will be necessary to determine if this notion is correct.

Over the past two decades, linkage and association studies comparing people with schizophrenia and schizophrenia-free people have identified a number of candidate genes (see SCZGENE website http://www.szgene.org/). To better understand the function of these candidate genes and their potential relevance to schizophrenia, investigators have used genetic engineering techniques in mice, which have resulted in either a loss or gain of function of the targeted protein, to assess whether these mice exhibit features associated with schizophrenia. Table 23.3 displays animal models based on some of the most promising susceptibility genes for schizophrenia.

This short list of candidate genes includes disrupted in schizophrenia 1 (DISC1) (Devon et al., 2001; Millar et al., 2001), neuregulin 1 (Stefansson et al., 2002), ERBB4 (Silberberg et al., 2006), dysbindin (Bhardwaj et al., 2009), and reelin (Chen et al., 2002). At this time, genetically engineered mouse models for these candidate genes have not been characterized well enough to determine if any of them would be useful to screen for novel antipsychotics. It will be necessary to test a wider array of antipsychotics for sensitivity and non-antipsychotic psychotropics for selectivity in these models.

While mice exhibiting abnormalities in the expression of schizophrenia candidate genes provide useful tools to better understand the biological role of those genes, including previously unknown roles in regulating specific animal behaviors, such as PPI, locomotor activity, latent inhibition, and social affiliation, they have limitations in regards to their validity as genetic models for schizophrenia since the perturbation of a schizophrenia candidate gene in mice is not likely to replicate the genetic perturbation of the gene that occurs in schizophrenia. The biological impact of any given candidate gene variation identified in schizophrenia is usually not well-known. For example, it is often not known whether the function of a schizophrenia-associated gene is enhanced or reduced (Mazzoncini et al., 2009). Therefore, knocking out a candidate gene in mice, one of the more common genetic engineering approaches used to study candidate genes, will not induce the same biological perturbation that is produced in a person with schizophrenia due to a function-reducing alteration in that candidate gene. For that matter, a knockout of a candidate gene may produce a qualitatively distinct biological impact than the impact of an alteration that reduces, but does not shut-off, the function of that gene in people with schizophrenia. Furthermore, it is almost certain that no single genetic perturbation is responsible for schizophrenia and thus, animal models based on alterations in the expression of a single gene, even if the functional change of that gene in schizophrenia is replicated, are unlikely to reliably model this disorder. Models based on interactions between multiple genetic variations or combinations of genetic and environmental alterations ("two-hit" models)

are potentially a more promising approach to modeling schizophrenia.

4.3.2 Models Based on Inherent Genetic Variation

Animal models have been developed by identifying certain strains of rodents that exhibit schizophrenia-relevant phenotypes or by generating new strains with these characteristics through selective breeding of selected animals from a larger population. The schizophrenia-like phenotypes in these models result from underlying genetic differences between strains, although the specific genetic differences responsible may not have been identified. One of the major strengths of these models is that they obviate the necessity to use an intervention, such as a drug, virus, lesion, or gene knockout to induce the deficits of interest. The complexity of models where a manipulation is required to induce impairments that are then reversed by antipsychotics produce additional variance that can be avoided by using rodents with natural deficits (Crawley et al., 1997). For example, mice strains exhibit a wide range of baseline PPI levels. In this respect, C57BL/6J (Chang et al., 2010; Lipina et al., 2005; Ouagazzal et al., 2001) and DBA/2 mice (Browman et al., 2004; Flood et al., 2011; Zhang et al., 2006) exhibit naturally low levels of PPI compared to other mice strains. These strains have undergone testing with antipsychotic drugs to varying degrees and those that have been tested display varying degrees of predictive validity. C57BL/6j and DBA/2 mice, for example, appear to have reasonably good predictive validity (Olivier et al., 2001; Ouagazzal et al., 2001).

Regarding other phenotypes relevant to modeling schizophrenia, while both C57BL/6j and DBA/2 mice exhibit low PPI, DBA/2 mice exhibit latent inhibition deficits compared to C57BL/6j mice (Singer et al., 2009). The effects of antipsychotics on latent inhibition deficits in DBA/2 mice have not been well-studied.

Strain differences in PPI and latent inhibition have also been reported in rats. Palmer et al. (2000) and Feifel and Priebe (2001) were the first to report naturally occurring PPI deficits in Brown Norway rats and Brattleboro rats, respectively. Furthermore, Brown Norway (Conti et al., 2001; Feifel et al., 2016) and Brattleboro HET rats (Feifel et al., 2015) also exhibit deficits in latent inhibition. The Brattleboro rat has been well-characterized and the behavioral phenotypes exhibited by this rat model, as well as the effects of antipsychotics and nonantipsychotic psychotropics on these impaired behaviors, are discussed in the following section of this chapter. There have been several reports on the effects of antipsychotics in Brown Norway rats. The earliest study found that neither haloperidol nor clozapine attenuated PPI deficits in Brown Norway rats (Conti et al., 2005), whereas a more recent study indicated that PPI in Brown Norway rats was increased by clozapine but not

haloperidol (Feifel et al., 2011b). Furthermore, oxytocin, a neuropeptide that has demonstrated clinical efficacy in patients with schizophrenia (Feifel et al., 2010; Pedersen et al., 2011), increased PPI in Brown Norway rats (Feifel et al., 2012). PD149163, an agonist of the neurotensin-1 receptor and a putative antipsychotic has also increased PPI in this rat strain (Feifel et al., 2011b).

Examples of models based upon selecting individual animals from a large population include apomorphine susceptible (APO-SUS) (Ellenbroek et al., 1995) and low-PPI rats (Schwabe et al., 2007) and mice (Hitzemann et al., 2008). In regards to the APO-SUS model, rats were selected for their response to apomorphine. High responders were used to create a colony of apomorphine susceptible (APO-SUS) rats and low responders were used to create a colony of apomorphine unsusceptible (APO-UNSUS) rats. Compared to APO-UNSUS, APO-SUS rats exhibited deficits in PPI and latent inhibition similar to those exhibited by patients with schizophrenia (Ellenbroek et al., 1995). Unfortunately, it does not appear that predictive validity of this model has been investigated.

Schwabe and coworkers were the first group to report that outbred rats could be selectively bred for PPI differences. PPI deficits in the PPI low group were reversed by haloperidol but not clozapine (Hadamitzky et al., 2007), which is not consistent with the predictive validity of this model. The effects of nonantipsychotic psychotropic drugs on this model have not been reported. Hitzemann et al. (2008) selectively bred low/high PPI mice and found that haloperidol increased PPI in a similar manner in low and high PPI mice. However, they did not test these mice in paradigms relevant to the cognitive or negative deficits seen in schizophrenia.

4.4 The Brattleboro Rat

The Brattleboro (BRAT) rat is a strain of rat derived from a single litter of Long Evans rats born in 1961 in a colony maintained by Dr. Henry Schroeder, a physiologist associated with Dartmouth medical school. It was observed that several pups among a litter displayed severe polydipsia and polyuria. Breeding of those pups produced a colony of rats exhibiting this phenotype and subsequent analysis revealed that the underlying cause of the polydipsia and polyuria was a lack of circulating vasopressin or antidiuretic hormone, due to a frameshift mutation in a single gene that resulted in deficient secretion of vasopressin in response to physiological stimulation (Birkett and Pickering, 1988; Valtin and Schroeder, 1964). The Brattleboro rat is the first natural knockout model in medical research and the forerunner of genetically engineered knockout animals that are widely studied today. As knockouts are almost exclusively created in mice, the Brattleboro rat

is unique in that it is a well-characterized, single gene deficient knockout rat. The Brattleboro rat has become a highly studied animal model for diabetes insipidus, which is the first such animal model for that condition. The polydipsia and polyuria in the Brattleboro rat is due to a lack of activation of the vasopressin-2 (V2) receptors located on the kidney, which stimulates concentration of urine (Bouby et al., 1999). Moreover, vasopressin acts as a neurotransmitter on the other two vasopressin receptor subtypes, V1a and V1b, which are primarily located in the brain (Hurbin et al., 1998), and also has a high affinity for the oxytocin receptor (Tahara et al., 2000). Vasopressin has been found to play an important role in a number of cognitive, emotional, and social functions (Bohus and de Wied, 1998; Reghunandanan et al., 1998) and, not surprisingly, the Brattleboro rat displays abnormalities in several of these domains including memory (Laycock et al., 1983), emotional reactivity (Williams et al., 1985), and social recognition (Engelmann and Landgraf, 1994). Additionally, Jentsch et al. (2003) found that Brattleboro rats displayed a complex pattern of abnormal attention.

Our laboratory has been investigating the Brattleboro rat specifically for potential to serve as a model for psychiatric disorders. We have found that these rats exhibit several features that are homologous or analogous to features observed in schizophrenia and some other neuropsychiatric disorders. For example, Brattleboro rats exhibit baseline PPI that is significantly lower than most strains including the Long Evans rat, their parental strain (Demeter et al., 2016; Feifel and Priebe, 2001; Feifel et al., 2004). This is a finding homologous with PPI deficits in schizophrenia. This is a highly robust and consistent finding that does not dissipate with repeat testing, which facilitates the use of this animal for experiments involving repeated testing on PPI (Feifel et al., 2007), such as investigating the chronic effects of drugs on PPI.

The PPI deficits in the Brattleboro rat appear to be related to their genetic abnormality rather than possible abnormalities in early development since Brattleboro pups removed from their mothers after weaning and raised by Long Evans foster mothers exhibit PPI deficits of similar magnitude to those raised by their biological Brattleboro mothers (Feifel and Priebe, 2007). Similarly, Long Evans pups raised by Brattleboro foster mothers exhibit intact PPI, ruling out the maternal behavior of Brattleboro mothers as a possible contributor to the PPI deficit in their offspring (Feifel and Priebe, 2007). This is consistent with the evidence for a strong genetic contribution and relatively inconsequential contribution of parenting factors to the manifestation of schizophrenia in individuals (Seeman, 2009; Neill, 1990). The onset of PPI deficits in Brattleboro rats can be seen early in

development, prior to puberty, which is consistent with some evidence that low PPI is a feature of schizophrenia that is expressed in childhood well before the manifestation of the overt symptoms of this disorder in early adulthood (Sobin et al., 2005) and thus may represent a vulnerability trait marker. Interestingly, separate lines of V1a and V1b knockout mice have been created and both lines exhibit PPI deficits (Egashira et al., 2009) compared to wild type mice suggesting that a lack of vasopressin activation of both receptors may contribute to the PPI deficits seen in Brattleboro rats.

Brattleboro rats have been shown to display reduced startle habituation (Feifel and Priebe, 2001) and Het-Brattleboro exhibit latent inhibition deficits (Feifel et al., 2015) compared to Long Evans rats, which are two additional features observed in schizophrenia. Brattleboro rats also exhibit increased spontaneous locomotor hyperactivity, which is considered to reflect central hyperdopaminergia and is a rodent analog of positive psychotic symptoms (van den Buuse, 2010); while they also exhibit cognitive-like deficits in novel object recognition (Demeter et al., 2016) and social recognition tasks (Demeter et al., 2016; Feifel et al., 2009), and attention as detected by the five-choice serial reaction time task (Berquist Ii et al., 2013).

Juvenile Brattleboro rats display social deficits as well as stereotypic movements causing some authors to suggest that, in addition to schizophrenia, they may be a valuable model of autism and autism spectrum disorders (Schank, 2009). In this regard, it is noteworthy that recent studies suggest autism spectrum disorders and schizophrenia may have an underlying relationship, which is in sharp contrast to the traditional view that they are distinct (Bevan Jones et al., 2012; Pelletier and Mittal, 2012).

Testing of Brattleboro rats in animal paradigms proposed to have validity for human anxiety and mood disorders, such as the elevated plus maze and the forced swim test, have not revealed evidence that Brattleboro rats have anxiety- and depression-like behaviors. In some cases, lower levels of these behaviors in Brattleboro rats have been found (Mlynarik et al., 2007; Williams et al., 1985). These findings indicate that although Brattleboro rats have a general psychopathology phenotype consistent with multiple psychiatric disorders, they may also represent an animal model with some specificity for schizophrenia and autism.

Brattleboro rats also exhibit certain pathophysiological similarities with schizophrenia. While abnormal VP function has not garnered as much attention as a possible biological mechanism underlying schizophrenia, such as the neurotransmitters dopamine or glutamate, abnormal central VP function has, nevertheless, been a consistent finding among studies that have investigated

this neurochemical system in people with schizophrenia. Several groups have found significantly lower peripheral (Elman et al., 2003; Kishimoto et al., 1989; Legros and Ansseau, 1992) and central (Frederiksen et al., 1991; Linkowski et al., 1984) levels of vasopressin or the vasopressin precursor peptide (Krishnamurthy et al., 2012) in people with schizophrenia. Furthermore, normal stimulation of vasopressin by the direct dopamine agonist, apomorphine, is significantly blunted in people with schizophrenia (Legros et al., 1992). Thus, downregulation of the vasopressin system appears to be a robust physiological abnormality associated with this disorder. Given the well-established role that it plays in cognitive, emotional, and social regulation (Engelmann and Landgraf, 1994; Laycock et al., 1983; Reghunandanan et al., 1998; Williams et al., 1983, 1985), vasopressin dysfunction is a viable mechanistic candidate for at least a subgroup of people with schizophrenia.

The polydipsia and polyuria exhibited by the Brattleboro rat is also analogous to observations of similar behavior in some people with schizophrenia. The association between disturbances in water balance and schizophrenia has been recognized for almost a century (Rowntree, 1973). Disordered water homeostasis is a well-recognized complication of schizophrenia and its prevalence is estimated to be 20% of chronic psychiatric inpatients (de Leon, 2003; de Leon et al., 1994).

In regards to other pathophysiological similarities with schizophrenia, Brattleboro rats have increased density of striatal D2 receptors (Shilling et al., 2006) and dopamine content in the ventral striatal region (Dawson et al., 1990; Feenstra et al., 1990) [but see (Cilia et al., 2010)], which is consistent with findings from several studies of people with schizophrenia (Keshavan et al., 2008). A highly consistent finding in postmortem studies of the brains of people with schizophrenia is reduced levels of GAD67 (Akbarian and Huang, 2006; Akbarian et al., 1995; Volk et al., 2000), an enzyme that catalyzes the decarboxylation of glutamate to GABA. Using a real time reverse polymerase chain reaction (RT-PCR), we have found similar reductions of GAD67 mRNA in the brains of Brattleboro rats (unpublished data). Although there are several brain regions of Brattleboro rats that exhibit abnormal development, the cerebellum is the most prominent (Boer et al., 1982). Cerebellum abnormalities have been reported in people with schizophrenia, including reduced overall volumes and correlations of psychopathological subscores with their cerebellar volume reduction. Evidence from positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) studies has shown decreased activation of the cerebellar subregions at rest and during certain cognitive tasks [see (Yeganeh-Doost et al., 2011) for review].

4.4.1 Heterozygous Brattleboro Rats

Most of the research in Brattleboro rats has focused on rats homozygous for the mutated VP allele. Our laboratory has recently begun to investigate Brattleboro rats that are heterozygous for the mutated allele (Het-Brattleboro). These animals have one normal allele and one mutated allele. Importantly, het-Brattleboros have normal peripheral levels of VP and do not display the polydipsia and polyuria that are seen in homozygous Brattleboro rats (Bohus and de Wied, 1998). Nevertheless, Het-Brattleboro rats have a robust deficiency of PPI (Feifel and Priebe, 2001) and latent inhibition (unpublished results), as do their homozygous counterparts. Het-Brattleboros have also been found to exhibit deficits in tasks modeling working memory in rodents (Aarde and Jentsch, 2004), which is highly relevant for schizophrenia as working memory deficits are a consistent finding among people with this disorder (Goldman-Rakic, 1994; Perry et al., 2001b). The finding that Het-Brattleboros display many of the schizophrenia-like features exhibited by homozygous Brattleboro rats indicates that these schizophrenia-like deficits are not secondary to possible CNS dysfunction caused by wide shifts in tissue hydration due to the abnormal fluid regulation occurring in homozygous Brattleboro rats.

4.4.2 Drug Effects on Brattleboro Rats

Several studies have tested the predictive validity of BRAT rats and most have focused on the effects of antipsychotic drugs on their PPI deficits. Single doses of peripherally (subcutaneous or intraperitoneally) administered FGAs and SGAs reverse the PPI deficits in Brattleboro rats, although there have been some inconsistent findings with single doses of haloperidol (Cilia et al., 2010; Feifel and Priebe, 2001). Repeated administration of FGAs and SGAs produce a greater increase in BRAT rat PPI (Feifel et al., 2007) than a single administration (Feifel et al., 2004, 2007), which indicates that the Brattleboro rat is able to model the efficacy time course of antipsychotic drugs in schizophrenia. Brattleboro rat PPI has also been increased by both single and chronic administration of putative antipsychotics that work via novel mechanisms, such as neurotensin receptor agonists (Feifel et al., 2004, 2007). In contrast, Brattleboro PPI was not significantly affected by a single injection of an antidepressant, an anticonvulsant mood stabilizer or a benzodiazepine (Feifel et al., 2011a), indicating that amelioration of Brattleboro PPI deficits is selective for drugs with antipsychotic efficacy. We have recently begun testing the predictive validity of het-Brattleboro rats and the preliminary results indicate that, like homozygous Brattleboro rats, their PPI deficits are reversed by single and repeated administration of antipsychotics but not psychotropic drugs devoid of antipsychotic efficacy (unpublished results).

1 INTRODUCTORY REMARKS

In 1942, a publication appeared reporting on a thus far unknown male disorder in which the patients revealed a combination of small firm testes, azoospermia, gynecomastia, low androgen levels, and elevated FSH. This pathology was described in a cohort of only nine patients. Nevertheless, it was the first definition of the clinical features of the most prevalent male chromosomal disorder, Klinefelter's syndrome (KS), named after the main author of the publication, Harry F. Klinefelter (Klinefelter et al., 1942). Seventeen years later, Jacobs and Strong (1959) revealed an extra X chromosome to be the underlying cause of this syndrome, hence exhibiting a karyotype of 47,XXY. This nonlethal chromosomal aberration, results from meiotic nondisjunction of the sex chromosomes, a segregation failure occurring during the differentiation of the gametes (Lanfranco et al., 2004). The 47,XXY karyotype is the most frequently seen in Klinefelter patients (9 out of 10 cases). The pure lineage is the classical variant, however there are other chromosomal aberrations that are also designated to KS which are either mosaic (e.g., 47,XXY/46,XY or 47,XXY/46,XY/45,X) or men with more than one supernumerary X chromosome (48,XXXY, 49,XXXXY, or 49,XXYY) that generally show more severe phenotypes (Bojesen et al., 2003; Pacenza et al., 2012).

Reviewing the literature of the past 7 decades, almost 4000 articles have been published on KS, a tremendous amount of clinical research describing the endocrine, genetic, metabolic, epidemiological, and behavioral aspects of the disorder (Nieschlag et al., 2014; Sokol, 2012). However, some of the most important questions, in particular the regulatory molecular mechanisms underlying the condition, remain unresolved (Nieschlag et al., 2016). To obtain this crucial knowledge, experimental access and manipulation is required, prerequisites which are practically and ethically impossible when dealing with patients. Understanding germ cell loss, endocrine disturbances or defects in cognitive function on a cellular or even molecular level, therefore needs the availability of animal models (Wistuba, 2010). Sporadically occurring in some mammalian species, males with a supernumerary X chromosome are naturally infertile. Consequently, they are unable to fulfil the most important requirement for an experimental model: the standardized production of a sufficient amount of subjects which would allow experiments to be designed that ensure statistical relevance. Almost 50 years after the discovery of KS, a mutated mouse line, the B6Ei.Lt-Y* strain, was described in which the Y chromosome acquired a new centromere. Following a complex breeding scheme, this strain regularly produces male mice with a supernumerary X chromosome (Eicher et al., 1991) which constitute the basis for the current mouse models of KS. To date, two such mouse models have been successfully established, both mimic human KS and can be expected by an animal model (Wistuba, 2010). In the approximately 25 articles that have appeared which make use of these KS mouse models, many open questions concerning the pathophysiology have been addressed. Apart from the two classical models, others with aberrant sex-chromosomal composition have been used to address more generally the impact of sex-chromosomes and sex-specificity on metabolic aspects (Chen et al., 2013a,b; Link et al., 2015; Ngun et al., 2014). Also these findings were of importance for our understanding of the effects of a supernumerary X-chromosome in the male. As a consequence mechanisms, which were previously only suggested have now been confirmed as regards X-inactivation, Leydig cell hyperplasia, and the putative contribution of X-linked genes on the phenotype (Poplinski et al., 2010; Swerdloff et al., 2011; Werler et al., 2011; Wistuba, 2010; Wistuba et al., 2010). Interestingly, findings from the mouse models, as the surprising fact that intratesticular testosterone (ITT) levels were found normal in 41,XX^{Y*} mice, were confirmed in the meantime in patients (Tüttelmann et al., 2014) as well as the different expression of X-linked genes escaping from silencing (escapees) observed in mice hold also true in patients (Zitzmann et al., 2015). Furthermore, these models have provided

the means to examine features of the KS not possible in a clinical setting, facets, such as the very early onset of germ cell loss, the general cognitive dysfunctions which are linked to the karyotype, and not to social or learning problems as well as the general disturbance in bone metabolism (Lewejohann et al., 2009a; Liu et al., 2010; Lue et al., 2010a; Mroz et al., 1998). "Retranslation" of the design and findings of the investigations utilizing the mouse models was performed that indicated the cognitive phenotype observed in the mice's memory recognition (Lewejohann et al., 2009a) paralleled the learning behavior seen in KS boys. The lessons garnered by this approach were not only useful in providing some understanding of the cognitive failure of young KS patients (Bruining et al., 2011) but also demonstrated how well designed investigations using the mouse models can examine and provide explanations for the clinically observed manifestations of the condition.

The following chapter summarizes the state of the art on animal models for KS and provides some perspectives for further research on the disorder.

2 KLINEFELTER'S SYNDROME—AN UNDERESTIMATED DISEASE

Klinefelter's syndrome consists of a broad spectrum of traits with no homogeneous phenotype or even a subset of features that occurs in every patient. As mentioned in the introductory remarks, KS is the most frequent male chromosomal disorder affecting approximately 0.2% of the male population (an incidence of 1 in 600–1000 new born boys (Aksglaede et al., 2006; Bojesen and Gravholt, 2011a; Bojesen et al., 2011b; Pacenza et al., 2012; Wikström and Dunkel, 2008). Despite this, screening studies indicate that only a quarter of all KS individuals are diagnosed during their lifetime (Bojesen and Gravholt, 2011a; Bojesen et al., 2003). As the main features associated with the syndrome are concealed, the disorder is often diagnosed only late in life, mostly after puberty. Although some aspects are visible in childhood, for example, Klinefelter boys have been found to be taller than matched healthy boys (Aksglaede et al., 2011), due to the heterogeneity and the diversity of the phenotype, a certain proportion of the men with milder forms of the symptoms are not diagnosed at all.

Interestingly, of all the features that are associated with KS, only two are found in almost every adult patient, namely infertility (due to azoospermia and small testes) and the endocrine disturbance of elevated gonadotropins (Aksglaede et al., 2011; Pacenza et al., 2012). In addition, other conditions, such as diabetes, osteoporosis, and various types of cancer (Aguirre et al., 2006; Aizenstein et al., 1997; Sokol, 2012; Swerdlow et al., 2005) have been associated with KS. It is not surprising therefore that the

morbidity and mortality risk for Klinefelter men is increased (Bojesen and Gravholt, 2011a).

Of equal importance are the varying degrees of cognitive impairment which affect language skills and learning behavior. As the condition is normally only diagnosed after puberty, this delay places the boys at a disadvantage as the opportunity to provide effective means of counteracting the impairments is usually missed. Additionally, due to the altered testicular and endocrine conditions, KS boys often suffer from delayed puberty, a factor which might further impair their mental development and can result in social isolation. Because of the socioeconomic trajectories that have been described to be associated with the disorder, a proper diagnosis of KS to the earliest time point possible would be in particular important. There are very few epidemiological studies on KS, almost all are from Denmark due to the excellent health registries which have been set up some decades ago (Aksglaede et al., 2011; Bojesen et al., 2003; Bojesen and Gravholt, 2011a). Significantly, these reports reveal that beyond the repercussions of the syndrome on the individual, the frequency and consequences of KS are greatly underestimated. Bojesen and coworkers evaluated data from more than 1000 KS patients which they matched with more than 100,000 control men. Among other parameters, they examined traits, such as partnership, educational level, income, and age at retirement as well as at mortality. They found that beyond infertility, endocrine and metabolic disturbances, which affected each individual, collectively KS patients presented with a poorer socioeconomic status compared to the control population (Bojesen et al., 2011b). KS men had significantly fewer partnerships, the time point when they entered a relationship was clearly later in life, and they possessed lower educational level, hence received lower income and retired earlier. More importantly, mortality risk in these men was significantly increased. These findings are consistent with those of Stochholm et al. (2012), who examined criminality in KS patients, specifically, the incidence of convictions for various criminal activities (e.g., arson, burglary sexual abuse, and drug related offenses). They found that KS patients did indeed have a higher proportion of convictions significantly though when the data was corrected for socioeconomic state, the differences disappeared indicating that the higher incidence for criminality was related to the poorer socioeconomic conditions the patients face (Stochholm et al., 2012). Such epidemiological analyses are important as they provide insights that cannot be obtained in experimental settings, by the animal models, or clinical reviews of patients. They expose the hitherto hidden effects of KS, which extend beyond the physical features of the condition and contribute to the lower quality of life experienced by these men. Taking into account the importance of early intervention for the circumvention

of many of the consequences identified by the epidemiological studies, the need for screening approaches capable of early diagnosis is obvious and there are ongoing attempts to provide simple, cheap, and—if possible—noninvasive tests (Hager et al., 2012; Mehta et al., 2012, 2014; Werler and Wistuba, 2014). If successfully implemented, these screenings may provide some therapeutic interventions and opportunities; however, for the development of novel and effective therapeutic options, which tackle the root consequences of the condition, a deeper understanding of the specific mechanisms by which the sex chromosomal imbalance instigates the detrimental milieu is needed.

In the following sections, we will examine what the X chromosome does in the male, what a supernumerary X chromosome means, and what clinical features associated with the disorder are caused in individual patients and the corollary of these features which animal models can help us to understand and to ideally solve.

3 THE X CHROMOSOME IN THE MALE

3.1 Sex Chromosomal Balance and Gender

In most animal species, sex is determined by an X chromosome to autosome ratio (X:autosome) usually of 0.5. In mammals, however, it is the presence of a Y chromosome that is the primary signal for male sexual determination, making mammalian sexual development more complex. For example, X0 containing fruit flies become male whereas mammals with the same X0 chromosomal complement are females. In mammals, sexual development is regulated by a cascade of gene expression beginning with the fetal activation of the *sry* (sex-determining region on the Y chromosome) gene which in turn causes the differentiation of the embryonic genital into a testis. The male gonad consists of two compartments: the seminiferous tubules where the somatic Sertoli cells provide nutritive and regulatory support for the spermatogonial stem cells, which constantly renew themselves while giving rise to daughter cells which undergo meiosis and differentiate to mature spermatozoa, and the interstitium responsible for blood supply, immunological responses, and containing the steroidogenic Leydig cells, which produce testosterone needed for normal androgenization and hence the formation of the male endocrine milieu.

Unlike all other chromosomes, only a small section of the Y chromosome (the pseudoautosomal region or PAR), undergoes recombination. Because of this, it has undergone evolutionary degeneration resulting in the loss of most of its functional genes (Hughes et al., 2012). In contrast, due to recombination events during cell division, the X chromosome has acquired new active genes in the course of evolution. Therefore, the heterosomes are

divergent with regard to the number of genes they carry; compared to the X chromosome, the Y chromosome bears only a few genes. As males possess only one copy for numerous X chromosomal genes (Hughes et al., 2012), but gene expression levels are strongly correlated in both males and females, a dosage-compensation has to occur to account for this sex-chromosomal divergence and the loss of genes on the Y chromosome (Dupont and Gribnau, 2013; Gribnau and Grootegoed, 2012). This compensation is achieved via the phenomenon of X chromosome inactivation (XCI) in females, a process which realigns the effective gene dosage and equilibrates the transcription rate in the two sexes.

In order to explain the remarkable impact of the instigation of X-inactivation must have had on the X:autosome ratio in females during chromosomal evolution, Ohno (1967) proposed a two-step process for the evolution of XCI and the dosage-compensation mechanism.

First, the global expression of the X chromosome genes must have doubled in both sexes, hence solving the X:autosome imbalance in males, then the XCI evolved resulting in the reduced output of X-linked genes back to the ancestral levels in females. Some credence to this meaning that the gene dosage X:AA was compensated (i.e. expression from one X chromosome vs expression from two autosomes is balanced to an approximately equal ratio, has been provided by microarray data which revealed the gene expression on the X-chromosome in mammals to be comparable with that expression from the autosomes (Gupta et al., 2006; Lin et al., 2007) and by RNA sequencing, which demonstrated that the expression level from both sex-chromosomes is only half that of the autosomes (Xiong et al., 2010). However, as the possibility cannot be excluded that the expression of testis-specific genes linked to the X chromosome affected these results, even though the purported combination still did not reach the expression level of the autosomes (Deng et al., 2011; Kharchenko et al., 2011), the origins of XCI and the dosage compensation mechanism remain contentious and the focus of ongoing debate (Casci, 2011). What is awaited are technical developments allowing more molecular explorations of the mechanisms of chromosomal regulation which can provide deeper insights into the dosage compensation between heterosomes.

The following section summarizes the current state of our understanding on the process of XCI.

3.2 X-Inactivation

Thus far, all available data indicates that in female cells, one of the two X-chromosomes is inactivated to achieve dosage equilibrium between the sexes (Lyon, 1961). This silencing is established in the early embryo and remains stable throughout life. The process of X-inactivation comprises several distinct steps:

X chromosome counting, the choice which copy is to be inactivated and finally, the initiation and maintenance of the chromosome silencing. An important player in the process is the noncoding RNA of the *Xist* gene. In early embryonic life, this RNA is only expressed from the X-chromosome that will later become inactive (Xi). Once transcribed, *Xist* RNA spreads over the entire chromosome exclusively *in cis*, that is, on the same chromosome on which *Xist* is transcribed. This leads to heterochromatization, the suppression of gene expression and thus chromosomal inactivation. Located within the X chromosome inactivation center (Xic), the *Xist* gene is in close proximity to several of its regulators, required for the initiation of silencing of the X chromosome, but not for the maintenance of the repression of other genes in differentiated cells (Brown and Willard, 1994; Csankovszki et al., 1999). Once *Xist* RNA is spread across the Xi, the transcription machinery becomes excluded from the *Xist* domain forming a repressive compartment (Brown and Willard, 1994; Csankovszki et al., 1999). The recruitment of the so called polycomb repressive complexes PRC1 and PRC2 induces chromosome wide histone modifications on the Xi, which together with other changes affecting the Xi result in a stable inactivation of genes which is subsequently maintained in differentiated cells independent of *Xist* (Plath et al., 2002).

Most but not all genes on the Xi are silenced; some "escape" inactivation and are responsible for the differing expression patterns found in males and females. In humans, approximately 15% of the X-chromosomal genes bypass inactivation, most of which are clustered together, and the majority is located in the pseudoautosomal region 1 of the long arm of the X chromosome (PAR 1 Xq; Carrel and Willard, 2005). Because of their relative high number, analysis of these so called X chromosomal "escapee" genes is highly complex in the human. In contrast, in the mouse only about 3% of the X-linked genes escape inactivation indicating that although inactivation is a general mechanism among mammals, it varies in a species-specific manner with mouse X-inactivation being more stringent than that of humans. Interestingly there is some overlap between species, in that most of the mouse escapee genes are also active in women. However, this is not all embracing as three mouse escapee genes are silent in humans (Yang et al., 2010). Furthermore, in contrast to the human, murine escapee genes are not clustered together and the manner of their escape from X-inactivation may be controlled on the level of individual genes. Recently, it was reported that, although most murine "escapee genes" are distributed along the entire X chromosome, four escapees (*Ddx3x*, *Eif2s3*, *Kdm5c*, and *Cxorf26)* are clustered in small domains with noncoding RNAs (ncRNA) which also escape inactivation. It seems plausible that these ncRNAs either directly or indirectly regulate the activation status of their

surrounding genes (Lopes et al., 2011). In combination, these attributes make the study of murine escapee genes easier than their human counterparts and enables genotype-phenotype correlations to be made which are not possible in the human.

Important factors enabling the escape from silencing are the LINE (long interspersed nuclear elements) repeat elements. On the X chromosome, LINE-1 repeats are overrepresented where it is suggested that they recruit and anchor *Xist* RNA (Chow et al., 2010; Lyon, 1998). As genes escaping from silencing contain fewer LINE-1 repeats than silenced ones (Carrel et al., 2006; Ross et al., 2006), it is likely that LINE-1 repeats are involved in the process.

Histone modifications are also thought to contribute to the silencing mechanisms. Transcriptional repressive marks, such as trimethylation of Lysine 27 on Histone 3 (H3K27me3) and trimethylation of Lysine 9 on histone (H3K9me3) are enriched on the Xi, while the histone variant macroH2A, which renders transcription factors unable to bind DNA sites, is depleted in escapee genes (Changolkar et al., 2010; Goto and Kimura, 2009). H3K4me3 and acetylated H3 and H4 which mark active chromatin portions are lost in the silenced parts of the X chromosome but remain in the escape gene sites (Goto and Kimura, 2009; Jeppesen and Turner, 1993; Khalil and Driscoll, 2007; Marks et al., 2009). It has been also suggested that the insulator protein CTCF, which blocks interactions between enhancers and promoters, may also act as a chromatin barrier, which prevents the spread of heterochromatin structures, thus prevents their spread to the genes that escape inactivation (Filippova, 2008; Goto and Kimura, 2009).

The relative expression of escapee genes from the inactive X-allele has been shown to be lower than their counterparts on the active allele (Carrel and Willard, 2005; Yang et al., 2010). This "partial" silencing may be due to RNA spreading over portions, but not all, of the gene domains thus hampering full expression. Interestingly, there appears to be some sort of "differential escape" mechanism that only functions during certain developmental phases. For example, the murine escapee gene *Kdm5c* escapes X-inactivation in adult tissue but is silenced in embryonic cells (Lingenfelter et al., 1998).

3.3 X-Inactivation in Klinefelter Patients

Whether the clinical features of KS result from the altered endocrine milieu, genetic effects due to altered X-linked gene expression or a combination of both is still a matter of contention. An indicator of whether altered X-chromosomal gene expression could be due to incorrect X-inactivation is the epigenetic status of the affected genes. If the cytosine-guanine rich regions (CpG islands) located in the promoter are methylated to totality (i.e.,

100%), the gene is silenced. In the case of *XIST*, such a methylation profile would show that expression of the gene is lacking and hence the X chromosome remains active. This is the situation observed in healthy males. In healthy females, where one of the two X chromosome remains active, the corresponding profile shows 50% methylation of the *XIST* promoter region. Examining blood samples in KS patients, Poplinski et al. (2010) found the *XIST* methylation pattern to be approximately 50% and comparable to healthy females and correct X-inactivation. In addition, the results also suggest the possible involvement of the Xi escapee genes in the KS phenotype. It is plausible that the enhanced expression of these genes is a normal component of the female cellular environment; however, in the male they constitute an aberration which has detrimental consequences (Nieschlag et al., 2014; Poplinski et al., 2010; Stabile et al., 2008; Zitzmann et al., 2015). Some credence to this proposition is the dosage effect on the extent of cognitive deficit in KS patients where the sequelae of the condition become more severe with increasing numbers of X chromosomes (i.e., 48,XXXY and 49,XXXY; Tüttelmann and Gromoll, 2010).

A further example of the influence of an Xi escapee is the *SHOX* (short stature homeobox) gene, whose increased expression is accommodated in females while in Klinefelter patients it results in increased height. This might be due to the escape of the *SHOX* gene in Klinefelter patients and an increased gene dosage compared to healthy male controls. To truly gauge the influence of genetic factors on KS, more sophisticated and comprehensive investigations need to be undertaken. The breadth of these studies and the amount of material required is only possible with the availability of suitable animal models.

4 CLINICAL FEATURES OF KLINEFELTER'S SYNDROME

The symptoms of this complex condition are so varied that only a fraction of sufferers are actually diagnosed; those with a mild phenotype may go through life never knowing they have the syndrome. The majority of patients that are diagnosed are identified either when they attend an infertility clinic seeking help to fulfil their wish for a child or when asking for the treatment of endocrine or psychological problems (often a combination of both). On rarer occasions, some KS prepubertal or pubertal boys are identified due to the development of social or learning problems. Nevertheless, underdiagnoses remains an issue due to the known increased mortality and morbidity and concerns the clinical community. Therefore, pros and cons of a neonatal screening program are currently intensively debated (Nieschlag et al., 2016).

KS was acknowledged as a disease of sexual development during the International Consensus Conference in 2006 (Hughes et al., 2006; Lee et al., 2006; Pacenza et al., 2012), a recognition that infertility is the feature of KS which is most ubiquitously exhibited. The reason for the infertility of KS patients is the massive loss of germ cells manifesting after puberty. However, beyond its association with disturbed karyotype and sex chromosomal imbalance, little is known about the causative mechanism responsible for the germ cells disappearance.

The presence of a supernumerary X chromosome is the most frequent genetic reason for male infertility, affecting 1 in 600–1000 men (Lanfranco et al., 2004). The detrimental influence of an additional copy(ies) of the X chromosome on male reproductive function is not unexpected when it is taken into account that approximately 10% of this chromosome's genes exhibit testis specific expression (Ross et al., 2006). Some of which are only expressed in spermatogonia, the undifferentiated germ cell type that is most severely affected by the syndrome and the one which is central for the maintenance of a residual germ cell population (Wang et al., 2001).

When the KS testicular phenotype is fully established after puberty, it is manifest not only in the loss of germ cells, but also in serious perturbations of the seminiferous tubules structure. First in the form of hyalinization which with time leads to tubules populated only by Sertoli cells (Sertoli cell only syndrome, SCO) and then finally the testes are composed of "ghost tubules" comprising of extracellular matrix components and Leydig cell hyperplasia (Aksglaede et al., 2006). As most of these features are not pronounced before the onset of puberty, the presence of KS is cloaked until later in life. Unfortunately, in terms of fertility, the time of diagnosis may already be too late, as most, if not all of the germ cells may already be gone (Wikström et al., 2006a).

Despite being the most common feature of KS, it is not uniform in its manifestation, in that, in a proportion of patients a few germ cells survive and differentiate for periods beyond puberty. Microscopic examination of testicular biopsies of KS men have found that in approximately 40% of patient's focal spermatogenesis can be detected (Fullerton et al., 2010). Although overall it is highly unlikely that these small areas with spermatogenic activity would be able to produce sufficient postmeiotic cells needed for a naturally derived pregnancy (Lanfranco et al., 2004), there have been two case reports demonstrating spontaneous paternity in KS (Laron et al., 1982; Terzoli et al., 1992). However, these successes are so few that until recently the perspective for KS patients to father a child seemed hopeless. However, novel methods of assisted reproductive techniques (ART), such as micro testicular sperm extraction (mTESE), revealed a substantial percentage of KS men to exhibit small foci of intact spermatogenesis from which testicular sperm could be harvested in approximately 50% of patients and used to father children by intracytoplasmatic sperm injection (ICSI). The adoption of this combination of techniques: TESE followed by ICSI, then normal IVF culture and finally embryo transfer has resulted in over 100 pregnancies and live births worldwide being reported for KS fathers (Fullerton et al., 2010; Lanfranco et al., 2004).

The second major group of KS patients who by seeking medical attention diagnosed with the syndrome are those with various metabolic or psychological conditions that are determined as being provoked by a disturbed male endocrine milieu. Considering KS's actions on the composition and structure of the testis, it is not surprising that it also detrimentally influences its function as a major endocrine organ. As a consequence, the majority of the adult Klinefelter men are described as having "hypergonadotropic hypogonadism" (Christiansen et al., 2003; De Braekeleer and Dao, 1991; Kamischke et al., 2003; Lanfranco et al., 2004; Nielsen and Wohlert, 1991; Simpson et al., 2003; Yoshida et al., 1997).

When the hypothalamic-pituitary-gonadal (HPG) axis works normally, the levels of androgens (i.e., testosterone) and gonadotropins [luteinizing hormone (LH) and follicle stimulating hormone (FSH)] are highly synchronized by a finely tuned feedback loop. Driven by the hypothalamic pulse generator, gonadotropin releasing hormone (GnRH), the pituitary produces LH and FSH which in turn induce the steroidogenic Leydig cells to produce T in the testis. FSH is necessary for the maintenance of the supportive functions of the Sertoli cells while T and FSH are required for full and complete spermatogenesis to occur. Beyond its testicular function, T is also pivotal for the maintenance of many aspects of the male phenotype, among others: muscle strength, deep voice, hair growth, and bone metabolism.

Hypergonadotropic hypogonadism is defined by lowered androgen levels (although serum T concentrations might be above the lower limit of the normal range) and significantly elevated levels of LH and FSH. To date, it is still contentious whether the endocrine phenotype is cause or consequence of the disturbed testicular situation, that is, whether it is a secondary effect of a dysfunctional gonad, due to sex chromosomal genetics, or a mixture of both. What is not debated is that the endocrine situation in KS influences metabolism and is associated with decreased life expectancy (Bojesen and Gravholt, 2011a; Bojesen et al., 2004, 2006; Swerdlow et al., 2005) due to altered insulin resistance, gynecomastia, and dyslipidemia. Additionally, also the risk for some types of cancer is elevated in 47,XXY patients, for example, non-Hodgkin lymphoma, some extragonadal germ cell tumors, and male breast cancer (Aizenstein et al., 1997; Aguirre et al., 2006; Sokol, 2012; Swerdlow et al., 2005).

Reduced diameters of arteries, cardiovascular problems, such as pulmonary embolism, peripheral vascular diseases, and altered QTc times have also been directly associated with the condition in a substantial proportion of KS men, contributing substantially to the increased morbidity and mortality (Foresta et al., 2012; Jørgensen et al., 2015; Nieschlag et al., 2014; Pasquali et al., 2013). Additionally, very recently, an association between an increased risk for thromboembolism was reported in a Swedish registry study (Zöller et al., 2016). We could recently demonstrate that KS men have increased insulin resistance, enhanced inflammatory, and procoagulatory status, higher waist circumference, clinical dyshomeostasis, and dyslipidemia (Zitzmann et al., 2015). As they possess more active *SHOX* gene copies due to the supernumerary X chromosome, the body proportions of KS men are altered. Specifically, they are taller in stature and as early as the prepubertal period, they have increased fat mass and a negative fat to muscle ratio, which may result in the aforementioned metabolic disturbances (Aksglaede et al., 2006; Kamischke et al., 2003; Lanfranco et al., 2004). These disturbances may in turn provoke lower bone mineral density and the increased risk for osteoporosis (Aksglaede et al., 2008) seen in KS men. However, these complications may also be linked to the enhanced expression of specific genes found on the X chromosome. These features are not present in all KS men; they rather affect only certain proportions of the patient population (Lanfranco et al., 2004; Sokol, 2012). Another novel aspect of KS has been recently reported by Foresta et al., 2012, who found morphological differences in the blood vessels, specifically nonmosaic Klinefelter men had arterial diameters significantly smaller than non-KS men but similar to those found in females. Although these alterations are yet to be verified, they do raise questions as to the possible consequences on the circulation of these patients (Foresta et al., 2012).

The third and only set of clinical indications that lead to the early diagnosis of KS are altered cognitive skills and behavior. Usually identified due the normal mild phenotype becoming manifest in learning problems or mild linguistic impairments around puberty, the severity of these sequelae is increased, up to complete retardation, depending upon the number of additional X chromosomes present (Bruining et al., 2011). X-chromosomal imbalance is known to affect brain function however it remains to be shown whether the cognitive deficits in KS are due to gene expression changes only or are induced or at least enhanced by the disturbed endocrine milieu (Itti et al., 2006; Temple and Sanfilippo, 2003; van Rijn et al., 2006). More details of the cognitive phenotype are discussed later.

5 SEX CHROMOSOMAL ABERRATIONS IN MALE MAMMALS

As mentioned earlier, in mammals, male gender is generally determined by the presence of two activated and different sex chromosomes, a Y and X, which together with the autosomes comprise the normal karyotype. During meiotic division errors, such as disturbed separation can occur which result in chromosomal aberrations forming in the gametes. When these malformed gametes fuse with their counterparts during fertilization, the zygotes formed contain aberrant karyotypes, most of which cause severe damage impairing developmental progression and result in embryonic lethality. Only the few, "mild" perturbations survive into adulthood. In humans the most prominent are trisomy 21 (Down syndrome) and the sex chromosomal aberrations, Turner Syndrome (45,X0), KS in its various forms (i.e., the pure lineage or the more severe variants with more than one supernumerary X chromosome), 46,XX men (where the decisive part of the Y chromosome is translocated to one of the X or an autosome), and 47,XYY syndrome (de la Chapelle, 1972; Hager et al., 2012; Lanfranco et al., 2004; Stochholm et al., 2010; Vorona et al., 2007; Yencilek and Baykal, 2005).

The XXY karyotype is not exclusive to KS humans, in some mammalian species similar sex chromosomal conditions have been reported and all have been found in a variety of animals, for example, experimental animals (e.g., monkeys), domestic pets (dogs, cats), zoo species (tiger), and farm animals (horse, cattle, pig, goat). All of which showed varying degrees of a disturbed male phenotype (Wistuba, 2010).

XXY tomcats were found to have testicular changes similar to the gonadal pathology of humans and also displayed reduced body and facial hair (Centerwall and Benirschke, 1975) and also a "canine Klinefelter syndrome" (karyotype 79,XXY, Nie et al., 1998) has been described. For the latter, mainly the mosaic form of the sex chromosomal aberration was observed; however, there have also been some reports of animals exhibiting the pure lineage. These dogs displayed several features associated with their chromosomal disorder, some of which resembled human KS. In all cases, testicular phenotype was altered and the testes were small, in one animal there was eunuchoidal stature, lowered T and a Sertoli cell tumor, another was found to have a congenital heart disease while a dog with 79,XXY/78XY mosaicism was cryptorchid (Clough et al., 1970; Goldschmidt et al., 2001; Meyers-Wallen, 1993; Reimann-Berg et al., 2008).

The 39,XXY karyotype in boars has been associated with azoospermia, small testes, and a complete loss of germ cells resulting in SCO syndrome. No data on the endocrine state of these animals is available, so it is impossible to discern whether they were also

hypogonadal. However, their testicular interstitium appeared to be normal (Hancock and Daker, 1981; Mäkinen et al., 1998). The first bovine counterpart of KS was described over 30 years ago, a Hereford bull with 61,XXY karyotype who had markedly reduced testes (approximately 10% of the normal size), degenerating tubules containing Sertoli cells only, and Leydig cell hyperplasia (Dunn et al., 1980). Two other bulls (Chianina) with the same karyotype showed similar features: testicular degeneration which was complete at 5 months of age, SCO syndrome, hyalinized tubular walls, and Leydig cell hyperplasia (Molteni et al., 1999). As animals related to these calves were found to be karyotypically and phenotypically normal, the origin of the disorder was attributed to de novo meiotic disjunction failure.

Also for cattle, apart from the classic cytogenetic Giemsa staining methods, more sophisticated sex chromosome painting methods have been developed (Słota et al., 2003) and a Klinefelter bull was one of the first azoospermic animals in which germ cell transplantation was applied in an attempt to experimentally rescue its fertility and determine the feasibility and utility of the technique (Joerg et al., 2003). However, all donor cells transferred into this bull were rejected after a few months and hence no donor-derived spermatogenesis could be induced.

Sex chromosomal abnormalities appear to be more frequent and better tolerated by horses as they comprised more than 90% of all chromosomal disorders (Chowdhary and Raudsepp, 2000). To date there have been at least three published cases of stallions with a pure lineage "KS"-like karyotype of 65,XXY (Iannuzzi et al., 2004; Kubień et al., 1993; Mäkinen et al., 2000). In one, the parental origin was examined but no chromosomal aberrations were found, thus suggesting that a de novo nondisjunction event caused the aberrant karyotype. All stallions were found to be infertile due to azoospermia and in those analyzed histologically, the testes were found to have a disturbed phenotype with Sertoli cells only and degenerating tubules. Two animals were taller than comparative breed and one was reported to have a relatively small penis (Iannuzzi et al., 2004; Mäkinen et al., 2000); features that have been well chronicled in human KS.

Of all the animals identified, one outstanding exotic case deserves mention, namely that of a 13-year-old "Klinefelter" Siberian tiger exhibiting a karyotype of 39,XXY. The chromosomal aberration was detected during a routine health check prior to the animals' registration in a breeding program. When the tiger had to be killed later due to an acute disease, the testicular histology revealed azoospermia and hyalinization typical for the presence of a supernumerary X chromosome (Suedmeyer et al., 2003).

As in humans, in other mammals, mosaic individuals occur presenting a mixture of cell lines containing different karyotypes. Generally, in mosaic humans, the sequelae are less severe. Interestingly, this is not the case in other species. For example, a case report on a male baboon (*Papio hamadryas*) with a 43,XXY/42,XY mosaic karyotype, found no spermatogonia in the testes despite the animal being examined at an early age, that is, 175 days of gestation, the late fetal stage. This is in contrast to human mosaic patients who are those with the best chances of possessing surviving germ cells beyond puberty (Lanfranco et al., 2004; Dudley et al., 2006) and suggests that unlike humans where mosaicism ameliorates the effects of the syndrome, no such action is present in other animals. This becomes particularly clear when examining the effects of sex chromosomal mosaicism in farm animals. Apart from pure XXY karyotypes, mosaic males (XX/XXY or XY/XXY, respectively) have been found in pigs, horses, and cattle, all of whom have exhibited phenotypes akin to pronounced "feminization" (Breeuwsma, 1968; Dain and Bridge, 1978; Iannuzzi et al., 2004; Pinton et al., 2011). Intersexuality and true hermaphroditism have been reported in sex chromosomal mosaic animals, for example, rams (XY/XXY mosaic with ovotestes but male like behavior; Bunch et al., 1991) and goats (XX/XY mosaic with male and female parts of the reproductive tract, a testis and an ovary; Bongso et al., 1982).

Considering the history and importance of domesticated and captive animals to humanity, it is not surprising that they have been studied more intensely and hence provide the bulk of our knowledge regarding the incidence and consequences of male sex chromosomal disorders, which are similar to human KS. The existence and prevalence of the syndrome however is not restricted to these species but a wide spread throughout the animal kingdom. Although admittedly few, there is evidence of these aberrations also in wild species. "KS" like rodents and insectivores have been described (Searle and Jones, 2002). In the shrew family (*Soricidae*), XXY males from two species (*Sorex araneus*, Searle, 1984; *Scuncus murinus*, Rogatcheva et al., 1998) have been found. Interestingly they possessed small testes, absence of germ cells and increased numbers of interstitial cells similar to the testicular phenotype present in other XXY male animals as well as to the features described for the human KS.

Hauffe et al., 2010 characterized wild house mouse populations in which they found two XXY males, who were phenotypically similar to the male mice generated experimentally (see later) and who had small testes devoid of all germ cells. Based on their findings and the data available from the literature, the authors calculated that the XXY karyotype in mice occurs with an incidence that is 5 times lower (0.04%) than that in humans.

Comparing the clinical features of human KS and manifestations seen in the various animal species where a similar sex chromosomal aberration has been found, it is obvious that the condition produces common sequelae. Specifically, a perturbed testicular structure, frequently with Leydig cell hyperplasia (and thus endocrine changes and hampered androgenization), massively impaired spermatogenesis, germ cell loss, and as a consequence, infertility is observed. The impact of supernumerary X chromosome genes that escape X-inactivation thus seem to have the same effect regardless of which male environment they are found.

Because of this commonality in cause and consequence, it is not surprising that most of the publications and case reports mentioned in the preceding section, suggested that the animal they describe could/should serve as the experimental model to study the principles and mechanisms underlying human KS. An experimental model is desperately needed to understand the complexities and difficulties of areas, such as the molecular underpinnings of the condition. However, despite the similarities, none of the cited examples can realistically fulfil the requirements of an experimental animal model for the following reasons:

- All animals reported were infertile.
- In such cases in which the parental generation was examined, the abnormalities were de novo in origin.
- XXY males occurred irregularly and only sporadically in the breedings.

In contrast, an animal model that can be useful for research has to fulfil certain criteria:

- The model animals and their matching controls have to be available (i.e., reproduce) in numbers that are sufficient for the design of experiments which are statistically robust.
- Animals with the target karyotype must be accessible on a regular basis in order to allow experimental designs and endpoints to being planned beforehand.
- Animals have to resemble not only the karyotype but also mirror as many features of the human phenotype as possible.

The main obstacle for the use of the animals previously described as experimental models for human KS is that they were "random" occurrences. Although the observations, descriptions, and analyses of these animals are helpful and interesting, they cannot form the basis for the types of investigation needed to truly understand and elucidate the human syndrome. As the condition is accompanied by infertility, generation of similar animals is unlikely, so the identification of similarly affected animal would depend upon happenstance. It is for this reason that the published information has been limited to descriptive studies of the condition, more systematic investigations of the mechanisms underlying the syndrome using the available examples have been impossible.

6 MOUSE MODELS FOR KLINEFELTER'S SYNDROME

Based on the observation that in many mammalian species, males carrying a supernumerary X chromosome occur and possess similar phenotypes, particularly anomalous testicular structure and function, as human KS, the possibility existed to obtain an animal model. The availability of such an animal would circumvent the limitations of experiments involving patients (e.g., ethical concerns, availability of material) and would provide the chance to investigate in detail pathophysiological consequences of the additional X chromosome.

When techniques for chromosomal manipulation became available, it was a logical extension to use the technique for the generation of chimeric mice for KS research. The concept being that by injecting embryonic stem cells with an extra X-chromosome into mouse blastocysts, the resultant male progeny would have an XXY karyotype. The approach proved to be of limited value, as the male animals born with a supernumerary X chromosome were difficult to obtain and few in number. The "KS"-like males did resemble the desired phenotype (Lue et al., 2001); however, the line could not be maintained as a permanent strain necessitating the constant generation of chimeric females. The XXY males derived from these approaches therefore only constituted a "transient" model, which, for the reasons mentioned previously, were unsuitable for involvement in complex experimental designs.

Twenty-five years ago, a fortuitous and remarkable breakthrough occurred, when male mice from the B6Ei. Lt-Y* strain were found to carry a spontaneous mutation of the Y chromosome (Y* which lost the normal centromere but acquired a new centromere distally; see later). These mice acted as progenitors in a complex, staggered, multigeneration breeding scheme that resulted in offspring with a karyotype containing a supernumerary X and a male phenotype (Eicher et al., 1991; Hunt and Eicher, 1991; Lue et al., 2005). The availability of this mouse line made possible the design and undertaking of more sophisticated experimental approaches, which promised to broaden the scope of investigations into the mechanisms of KS. It is not surprising that, to date, the only two mouse models that have been successfully utilized for animal research on KS have been derived from breedings of this certain strain.

In order to understand the rationale behind the development and research in the mouse models reported in the following paragraphs, one has to keep in mind

the major question arising from translational research, which uses animals to gain insights into human disease. Namely, what does an animal model have to provide in order to serve as an experimental surrogate of KS? For this condition, first of all, males with a supernumerary X chromosome but a full male phenotype must be obtainable on a regular base by a breeding protocol. Second, as we learnt from the clinical appearance of the disorder, such mice must present the whole gamut of features that we know from KS to be associated with the actions of a supernumerary X chromosome in a male environment. This is of importance, because the phenotype observed in patients is complex and reflects the effects of the sex chromosomal imbalance on different systemic levels in the organism. For example, T treatment on a KS adolescent patient might result in improved cognitive performance and may well treat their hypogonadism, but it will concurrently kill the few remaining testicular germ cells that the patient might have.

If such pathophysiological relationships are to be addressed experimentally, the animal model must resemble as many features of the human phenotype as possible so that the metabolic interactions and reactions of the entire organism due to experimental manipulation can be deciphered. So the question posed is which key features should an animal model for KS mimic? From the previously detailed descriptions we know that altered body proportions, an endocrinology of hypergonadotropic hypogonadism, infertility due to azoospermia, small firm testes in which all germ cells are lost after puberty at the latest, the presence of Leydig cell hyperplasia, cognitive deficits, disturbed bone, and/or carbohydrate metabolism are characteristic traits of the syndrome. In addition, considering the recent findings that KS patients have normal X-inactivation, thus raising suspicions that the expression of escapee genes could play a role in the induction of the pathophysiology, the candidate model should have a similar X-inactivation profile.

B6Ei.Lt-Y* males with the mutated Y* chromosome present a completely normal male phenotype (Wistuba, 2010). However, when these mice are mated to normal (40,XX) females, genetically aberrant offspring with a wide variety of differing karyotypes were obtained during subsequent generations. In the progeny, the sex chromosomal content was altered most probably due to the mutated Y* chromosome inducing meiotic non-disjunction because of its structural alterations (Eicher et al., 1991; Hunt and Eicher, 1991; Lue et al., 2005). This Y* chromosome exhibits a rearrangement at the distal part of the short arm and in the pseudoautosomal region where a functional centromere has been newly acquired and the entire region inverted in wide parts. Sex chromosomal recombination, albeit in an aberrant way, was successful in producing offspring that are able to survive. Resulting from the recombination processes,

an X^{Y*} chromosome, in which the X and substantial parts of the Y* are linked in close attachment or a Y^{*X} chromosome is transmitted to the next generation. Female 41 XY^{*X} are fertile while males with the X^{Y*} (41,XX^{Y*}) are sterile. The fertile 41,XY^{*X} females are used as founders for subsequent generations in which, by the fourth generation, the male offspring have a 41,XXY karyotype (Eicher et al., 1991; Wistuba, 2010). Karyotypes regularly derived from the various generations during the staggered breeding of this mouse strain include XXY, XX^{Y*}, XXY^{*Y}, XY^{*Y}, XYY^{*X}, XY^{Y*}, XY^{*X} (Wistuba, 2010).

When this phenomenon was reported in 1991, the importance of these 41,XXY male mice was immediately recognized due to their potential worth for the in depth exploration of KS. Although time consuming, expensive, and difficult via this strategy, for the first time it became possible to obtain sufficient numbers of 41,XXY male mice and matched controls on a regular basis which would enable complex experimental designs. Unfortunately, in these early animal experiments, karyotype could be only determined cytogenetically from dead males, thus making manipulative or behavioral experiments impossible and limiting studies to a descriptive level. Nevertheless, two key criteria for a true animal model were fulfilled: regular production and the access to numbers allowing robust statistical evaluation.

The first investigation showed that physiologically, histologically, and morphologically, the XXY mice had features that resembled the pathophysiology seen in KS patients, giving credence to the idea that a mouse model was now truly available. More specifically, early testis differentiation in XXY male mice followed the normal time course, testicular architecture is morphologically normal containing spermatogonia and showing intact migration, and colonization of the genital ridge by primordial germ cells. These germ cells follow the normal male developmental pathway in the testicular environment. They do not enter a stage of meiotic arrest which would be assumed if X chromosomal reactivation was independent of sex differentiation (Hunt et al., 1998; Mroz et al., 1998, 1999). From postcoital day 12.5, there is a progressive loss of germ cells (Hunt et al., 1998), indicating defects that impair early proliferation driving the mitotic spread (Hunt et al., 1998). Subsequently, germ cell loss continues in the postnatal period of life, resulting in aspermatogenic testis in adulthood with testicular tubules showing predominantly the SCO phenotype (Hunt et al., 1998). Interestingly, when cultured, these testicular cells could not only be maintained and propagated in vitro but also retained their normal morphology. Therefore, it has been suggested that a disturbed interaction between the somatic Sertoli cells and the undifferentiated germ cells might be the cause or at least enhance germ cell depletion in vivo (Hunt et al., 1998; Wang et al., 2001). The spermatogonial stem cells of XXY mice were found

to undergo apoptosis, while stem cells from mosaics (XXY/XY) survived but produced an increased number of aneuploid daughter cells. This indicates that XY germ cells exposed to a XXY testicular environment are subverted to a certain extent, that is, they are at higher risk of meiotic aberrations. This phenomenon suggests meiotic errors may not to be due to the XXY testicular environment alone, but may represent a more general mechanism in testes with reduced germ cell content. Against this background, the role of the Sertoli cells in the synchronous regulatory support was shown to be of equal importance for the germ cell fate in the disturbed testicular phenotype (Mroz et al., 1998). Our recently published data also indicate an early, intrauterine starting point of the germ cell loss. However, at least postnatally we could not confirm an apoptotic cause in vivo but rather found a lack of proliferation of the germ cells (Werler et al., 2014). As a consequence of these results, many questions have been posed and investigative paths opened, all of which rely on this animal model, for example, the elucidation of the interaction between the germ line and the somatic testicular environment by transplantation approaches (Mroz et al., 1999). However, as stated, the limitation posed by the inability to karyotype living animals made it impossible to conduct such studies. Thus, the development and availability of novel methods and tools, which were able to remove this impediment were of tantamount importance. This breakthrough was achieved when Lue et al., 2005, 2010b) developed a fluorescence in situ hybridization (FISH) method for their 41,XXY mouse model of detecting metaphase sex chromosomes from fibroblast cultures derived from tail tip biopsies, while Lewejohann et al. (2009a) used a similar approach utilizing interphase nuclei obtained from peripheral blood samples in the 41,XX^{Y*} mouse.

These methods allowed for the first time, the possibility to identify the "target" animal and thus opening the way for hitherto impossible experimental designs, for example, evaluation of the cognitive functions of the males with a supernumerary X-chromosome (Lewejohann et al., 2009a; Lue et al., 2005). Not surprisingly, this opportunity was readily accepted and a number of new studies were immediately undertaken.

From the earliest investigation of the 41,XXY males, it was recognized that during the breeding scheme another variant male karyotype occurred regularly even in the first generation, the 41,XX^{Y*}. Other than being reported as sterile (Eicher et al., 1991), little attention was paid to these animals. While searching for an animal model for XX male syndrome, these animals were reexamined due to their sex chromosomal constitution of two X and a part of the Y chromosome. As mentioned previously, in the rare 46,XX testicular disorder of sex development, the vast majority (>90%) of patients have two X chromosomes, which contain some Y chromosomal material,

harboring the *SRY* gene, which is essential for male sexual determination and induces the gonadal development during the embryonic life (de la Chapelle, 1972; de la Chapelle et al., 1964, 1990; Hughes et al., 2006; Kashimada and Koopman, 2010; Vorona et al., 2007).

Compared to KS patients, these XX men exhibit some similarity but also differ in certain phenotypical features, such as clinical appearance and epigenetics (Vorona et al., 2007). For example, while KS patients are in general tall, XX men are smaller than average and exhibit a higher incidence of gynecomastia and maldescended testes. The detailed analysis of the 41,XX^{Y*} males found them not to resemble the features of the XX males but rather they had characteristics that were almost identical to those of the 41,XXY mice and symptoms similar to human KS.

These two models (male 41,XXY and the 41,XX^{Y*}) have formed the basis for numerous investigations into the underlying mechanisms that provoke the disturbance of the male phenotype, for example, the endocrine, cognitive, gonadal, and metabolic changes. In the next part, we discuss the findings of these studies in detail and reveal why the male mice with a supernumerary X chromosome from the B6Ei.Lt-Y* strain are the most valid animal models available for KS (Wistuba, 2010).

7 LESSONS FROM ANIMAL EXPERIMENTS

With the availability of the earlier mentioned mice, the initial set of experiments that was conducted set out to establish their bonafides as true models for KS. Therefore, a complete characterization of the animals was the essential first step, before the design or performance of any novel approaches could be considered. Without these investigations research on the animal model would have been restricted to descriptive studies and no deeper insights into cellular and molecular mechanisms of the sex chromosomal imbalance due to the supernumerary X chromosome in a male environment could be gained.

7.1 X-Inactivation in the 41,XX^{Y*} Mouse Model

As noted previously, there are differences in the X-inactivation process between mice and humans. However, the relatively few genes which escape X-inactivation in the mouse make it an interesting model for providing some insights into the genotype-phenotype relation of KS. The caveat being that the X-inactivation process seen in the model reflects the findings obtained from patients, healthy men and women (Poplinski et al., 2010). Only then meaningful conclusions could be derived that would have relevance to the more complex human situation.

In line with the study previously conducted on human Klinefelter patients (Poplinski et al., 2010), the X-inactivation profile in the 41,XX^{Y*} mice was determined in peripheral blood samples by assessing the *Xist* promoter region methylation profile. As expected, female mice were found to possess a *Xist* methylation status of approximately 55% indicating that one of the two X chromosomes was inactive, while male 40,XY* mice had approximately 100% *Xist* methylation, indicative of a silenced *Xist* gene and hence an active X-chromosome. The 41,XX^{Y*} mice were found to possess 57% *Xist* methylation, significantly different from the male controls but consistent with the pattern seen in the healthy female mice (Wistuba et al., 2010). These results confirmed that in the 41,XX^{Y*} mouse, the *Xist* methylation pattern and as a consequence the X chromosomal inactivation status mimicked that seen in human KS patients. Hence, beyond the hormonal, phenotypic, and behavioral, these male mice could also provide comparable insights into the genetic underpinnings of the human condition.

In follow up experiments, genes escaping X-inactivation were analyzed in the animal model. It has been reported that in contrast to the approximately 15% of X-linked genes escaping silencing in the human, only about 13 genes do so in the mouse (Carrel and Willard, 2005). As only four, *Kdm6a*, *Kdm5c*, *Ddx3x*, and *Eif2s3*, are known to escape X-inactivation in both species, these were the most interesting to gauge the suitability of the 41,XX^{Y*} model. *Kdm6a* is a H3K27-demethylase, whose overexpression results in the decreased levels of di-and trimethylation of Lysine 27 on Histone 3 (Hong et al., 2007; Hosey et al., 2010). *Ddx3x*, ubiquitously expressed by all cells of the testis, has an autosomal homolog which has been suggested to play a role in spermatogenesis (Vong et al., 2006). *Eif2s3x* encodes a subunit of eukaryotic translation initiation factor 2. Its expression is coupled to brain function and has a Y-homolog which plays a role in spermatogonial proliferation (Mazeyrat et al., 2001; Xu et al., 2006). Finally, *Kdm5c*, a H3K4 demethylase, is ubiquitously expressed and has been associated with mental retardation (Iwase et al., 2007).

As it has been previously reported that the expression of "escapee genes" can vary among individuals as well as between tissues (Carrel and Willard, 2005), the expression pattern of the four genes was determined in various organs, namely in liver, kidney, and brain tissue.

In the liver and kidney, the mRNA transcript expression pattern in the 41,XX^{Y*} mice resembled that of the female mice and differed from that seen in the healthy males, proving that in both females and the KS model, the genes do escape X-inactivation while in the healthy males they do not (Werler et al., 2011). These findings have been recently corroborated in a study of sex differences in adiposity, which demonstrated that the number of X chromosomes and escapee gene expression may play a role (Chen et al., 2012).

In contrast, the expression pattern in the brains of healthy male (40,XY*) and female (40,XX) animals was similar—indicating that the gene expression in the brain is differently regulated compared to the other tissues—while, in the 41,XX^{Y*} mice, the "escapee genes" were found to be upregulated (Werler et al., 2011). This finding is of particular interest when considering the cognitive deficits observed in the 41,XX^{Y*} and 41,XXY mice and in Klinefelter patients (Bruining et al., 2011; Lewejohann et al., 2009a,b; Lue et al., 2005). So far, there has been no explanation as to whether or how X-linked gene expression in KS can be related to the cognitive phenotype. If, as previously shown, the X-inactivation pattern of KS males is similar to that of normal females yet healthy women do not exhibit cognitive changes. Why should this be the case in KS patients? For the first time, the gene expression data obtained from the 41,XX^{Y*} mouse model sheds some light on a possible mechanism explaining this phenomenon. The upregulation (or the missing downregulation) of these particular genes suggests their possible involvement or even direct contribution to the altered cognitive phenotype observed. For example, variation in the expression of *Kdm5*c has been shown to influence either directly or obliquely the regulation of other genes involved in brain development (Iwase et al., 2007).

We also examined the expression pattern of six more escapee genes (i.e., *Bgn*, *Cxorf26*, *Car5b*, *Mid1*, *Shroom4*, and *1810030O07Rik)* in the liver and brain of the 41,XX^{Y*} mouse. In humans, *Bgn* expression levels are reduced in patients with 45,X Turner Syndrome and elevated in patients with additional sex-chromosomes, such as KS. Interestingly this gene is subject to X-inactivation in humans, and only the murine form escapes inactivation (Geerkens et al., 1995). *Cxorf26* is expressed in most adult brain structures, most prominently in the cerebellum (Lopes et al., 2011). Like *Bgn*, the human ortholog does not escape X-inactivation (Carrel and Willard, 2005). Similarly, the *Mid1* gene, which encodes a protein that forms homodimers which associate with microtubules in the cytoplasm (Cainarca et al., 1999; Dal Zotto et al., 1998; Schweiger et al., 1999). *Shroom4*, a regulator of the cytoskeletal architecture, is associated with Stoco dos Santos like X-linked mental retardation (XLMR), where affected males have severe mental retardation (Hagens et al., 2006; Yoder and Hildebrand, 2007). The functions of *Car5b* and *1810030O07Rik* are thus far not completely assessed.

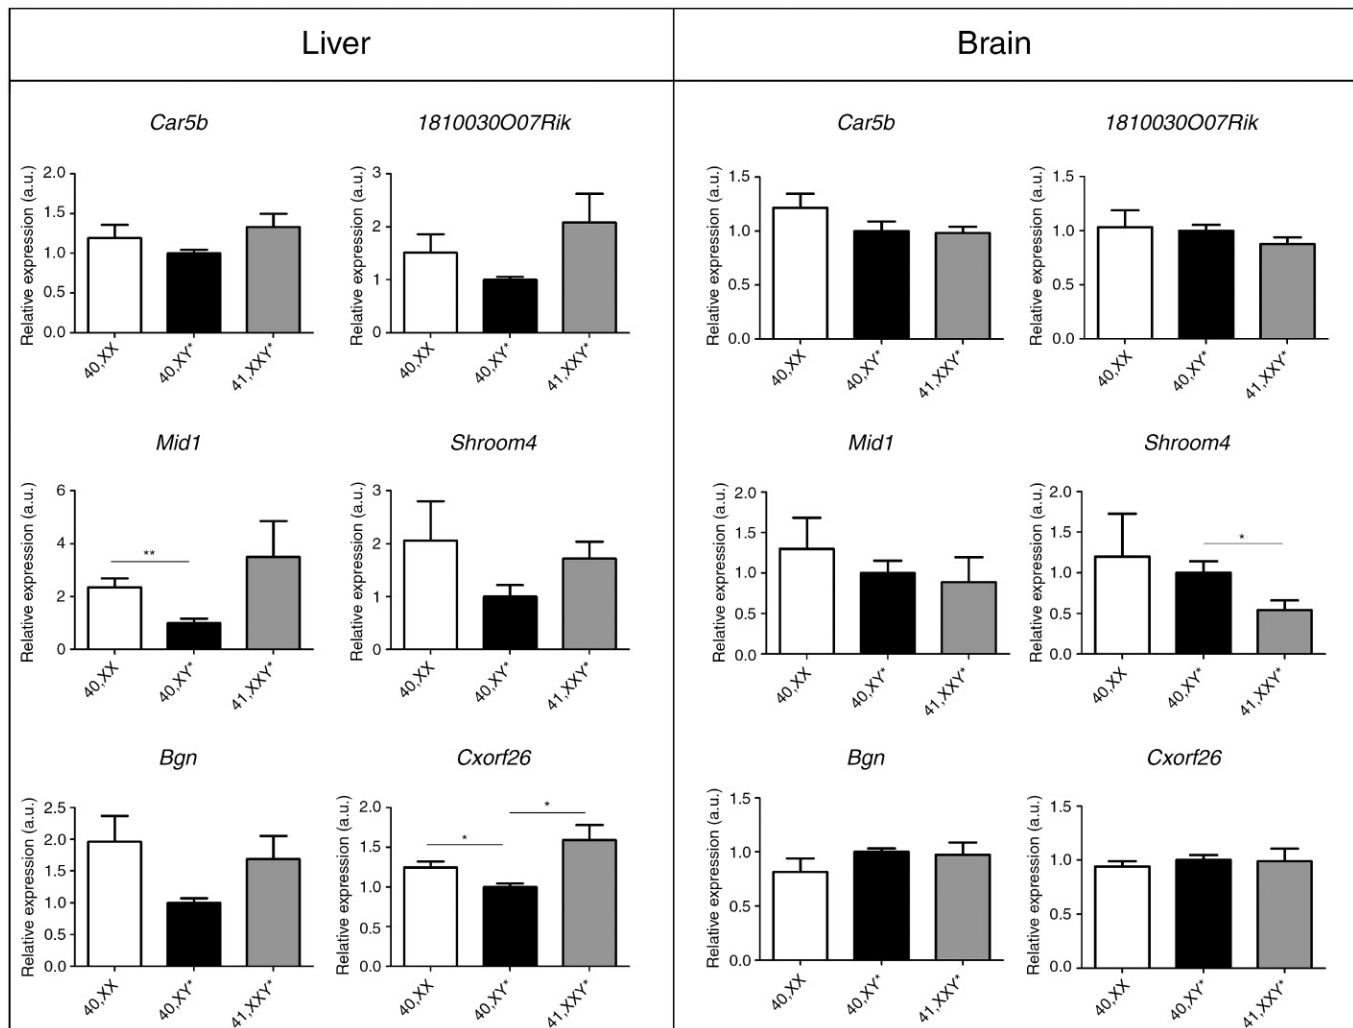
We found that for all six genes, the mRNA expression in the liver of 41,XX^{Y*} males to be akin to the four escapees previously reported, namely similar to that of the females and higher than in their healthy male littermates (Werler et al., 2011). Interestingly, unlike *Kdm6a*, *Kdm5c*, *Ddx3x*, and *Eif2s3x* for which increased mRNA expression was found in the brain (Werler et al., 2011), *Bgn*, *Cxorf26*, *Car5b*, *Mid1*, *Shroom4*, and *1810030O07Rik*


FIGURE 24.1 Relative expression of the genes *Car5b, 1810030O07Rik, Mid1, Shroom4, Bgn,* and *Cxorf26* in liver and brain of 40,XX (*n* = 3); 40,XY* (*n* = 6); and 41,XX^{Y*} (*n* = 6) mice; * *P* < 0.05, ** *P* < 0.001.

expression levels in the 41,XX^{Y*}, healthy males and female littermate controls were similar (Fig. 24.1). These new findings confirm the tissue and gene specificity of the escapee genes and show that the expression pattern is independent of the tissue environment in which the genes are transcribed, that is, in the brain some are over expressed and some are not. When taken overall, the results of the mouse model experiments show that although escapee genes probably contribute to the phenotypical alterations, a general mechanism, such as a simple over expression in the male cellular environment does not exist. In contrast every gene has to be examined independently and with regard to the target organ. These first findings on the genetic background of KS provide tantalizing clues as to the mechanisms causing the manifestations of the condition. Thus far the information available is restricted to the transcription level. To what extent the regulation of these genes' translation into the proteins is affected and if/how this is involved in the

sequelae of the syndrome remains to be clarified. The quest for answers to these questions will be aided by the mouse model which—unlike its human counterparts—presents a more homogeneous population where only 13 genes are affected.

7.2 Testicular Architecture

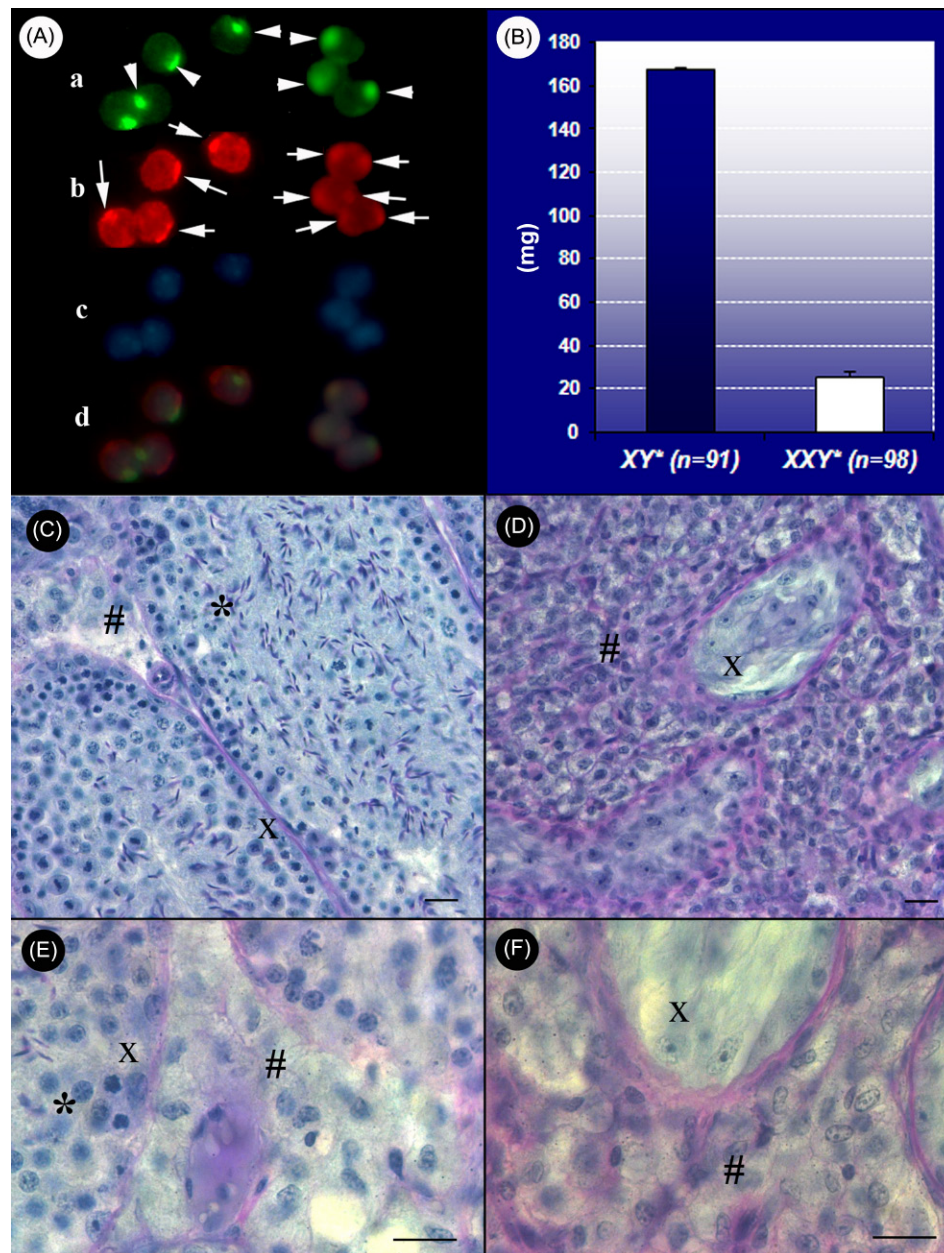
Lue et al. (2005, 2010a) reported that adult 41,XXY mice had small, firm testes containing SCO tubules of decreased diameter with increased numbers of Leydig cells in the interstitium. These findings are identical to those for the alternative KS model, the 41,XX^{Y*} mouse (Lewejohann et al., 2009a; Wistuba et al., 2010, Fig. 24.2) and resemble perfectly the testicular phenotype seen in the vast majority of adult KS men (Fig. 24.3). Additionally 41,XXY mice displayed an aberrant pattern of androgen receptor (AR) expression, not observed thus far in KS (Lue et al., 2005).


FIGURE 24.2   **Testicular phenotype of the 41,XX^{Y*} mouse model of KS.** (A) Fluorescence in situ hybridization (FISH) of sex chromosomes in interphase nuclei obtained from peripheral blood samples of male mice of the strain B6Ei.Lt-Y*. *Left side*: leucocyte nuclei from 40,XY*, *right side*: leucocyte nuclei from 41,XX^{Y*} male mice. (a) Y* chromosomes *(arrowheads)* detected by green fluorescent mouse specific probe; (b) X chromosome *(arrows)* detected by red fluorescent mouse specific probe; (c) DAPI nuclear stain; (d) overlay of a–c. Note the two X chromosome signals in 41,XX^{Y*} leucocytes. One X chromosome is always situated in close association to the Y* signal. Partial overlap of these chromosomes can be detected by the yellowish color. (B) Comparison of bitesticular weights between adult 41,XX^{Y*} males ($n = 98$) and their 40,XY* littermate controls ($n = 91$). The germ cell loss in males with a supernumerary X chromosome resulted in significantly reduced testis size. Values are mean ± SEM. (C and D) Representative micrographs of testicular histology of the seminiferous epithelium. (C) 40,XY* control mouse exhibiting full spermatogenesis. (D) 41,XX^{Y*} mouse testis. All germ cells were depleted from the seminiferous epithelium leaving Sertoli cell only syndrome. Sertoli cells show the beginning of vacuolization. (E and F) Representative micrographs of testicular histology of the interstitial space. (E) In the 40,XY* control mice Leydig cells are normally arranged in the interstitial spaces between the tubular walls. (F) In contrast in the 41,XX^{Y*} mice, Leydig Cell number is increased, forming a hyperplasia. Bars represents 20 μm. Symbols: *X*, Sertoli cells; *, differentiating germ cells; #, Leydig cells. Staining: Hematoxylin-Eosin.
FIGURE 24.3 **Histology of human testicular tissue: Comparison of normal spermatogenesis and SCO syndrome typically observed in Klinefelter patients.** (A, C, and E) Representative micrographs of the normal human testicular histology exhibiting full spermatogenesis. (B, D, and F) Representative micrographs of the testicular histology of a KS patient with SCO syndrome. (A and B) overview of tubular cross sections: while the control tissue shows normal distribution of interstitial and tubular areas, the SCO situation exhibits complete loss of germ cells and hyalinized tubular walls. The seminiferous tubules only contain Sertoli cells. (C and D) Detail of the seminiferous epithelium: In the control, all germ cell stages up to mature spermatozoa are present. Typically for adult KS men, all germ cells are lacking. Sertoli cells show the beginning of vacuolization. (E and F) Detail of the interstitial space. In the control testis, Leydig cells are normally arranged in the interstitial spaces between the tubular walls. In contrast in the tissue obtained from a KS patient, Leydig cell number is elevated showing typical hyperplasia. Bars represents 20 µm. Symbols: *X*, Sertoli cells; *, differentiating germ cells; #, Leydig cells. Staining: Hematoxylin-Eosin.

Sertoli cells are situated in the seminiferous tubules where they support spermatogenic differentiation by providing nourishment and mediation of endocrine signalling (Wistuba et al., 2007). As such any alterations in these essential cells profoundly influence testicular function. Evidence has been found for early apoptosis of Sertoli cells in KS, leading to the proposition that loss of support and communication between Sertoli cells and germ cells might be related to the germ cell depletion seen in the syndrome (Aksglaede et al., 2006; Wistuba et al., 2010). Sertoli cells express the androgen receptor (AR) and produce androgen binding protein and inhibin. Any perturbation of the cells therefore, might influence the amount of ITT in the interstitial spaces and, as a consequence, affect the endocrine feedback along the hypothalamic—pituitary gonadal axis. No empirically robust evidence on altered Sertoli cell presence, development, and/or function could be obtained until the first systematic findings from the experimental models became available. The findings of the first studies (Lue et al., 2005) were of particular interest and importance as they showed AR was expressed in the Sertoli cells of adult XY control mice but not in the XXY mice. This is despite both animals having a similar pattern up until day 20 postpartum (pp), indicating that the loss of AR expression in the XXY mice occurs around puberty and suggests that in these animals, the maturation of Sertoli cells may be altered indicating that they may influence or be influenced by abnormal germ cell development. Some credence to this notion was provided by a histological evaluation of the testes of the 41,XX^{Y*} model, which found the number of Sertoli cells to be decreased compared to controls.

The investigations performed thus far provide sufficient evidence to surmise that Sertoli cells are altered in males with a supernumerary X chromosome. To understand the underpinnings of Sertoli cell germ cell interaction, Sertoli cell apoptosis, maturation, and differentiation, more in depth evaluations are needed; studies that require substantial amounts of material and the chronicling of proliferation, differentiation, and maturation over an extensive timeperiod. These investigations are impossible to perform in humans. Only with the aid of the mouse models can any meaningful exploration of the changes in this crucial somatic testicular cell be undertaken.

It was reported that during testicular degeneration observed in KS also Sertoli cells degenerate over time (Aksglaede and Juul, 2013; Aksglaede et al., 2006), an observation which is in line with data in our mouse model demonstrating that Sertoli cell numbers are altered during postnatal development (Werler et al., 2014). Taken together, the altered Sertoli cell physiology needs more detailed analyses of this somatic cell type already during prenatal development. Germ line propagation

and differentiation is in particular affected by the consequences of the chromosomal aberration. Thus, major checkpoints and consequently processes occurring specifically in the germ line might be altered by the chromosomal imbalance, that is, the development of the primordial and the spermatogonial stem cell (PGC, SSC) system. As mentioned earlier, in vitro studies have shown that aneuploid undifferentiated germ cells died when isolated from embryonic gonads and only those with a randomly corrected karyotype survived in culture (Hunt et al., 1998; Mroz et al., 1999). Thus, SSCs with an aberrant karyotype must have entered a default pathway during the intrauterine phase but latest in the perinatal period. When only germ cells with a corrected karyotype survive in vitro after they were isolated from the embryonic gonad, while aberrant germ cells died over time, the question arises, why—in vivo—the germ cell loss progresses postnatally as shown recently (Werler et al., 2014). Even if a few aberrant germ cells are still present in the perinatal testis, a certain proportion of those present at the time point of birth should be of correct karyotype and the population of spermatogonial cells should at least stay stable if not propagating. From this in part contradictory observation and accepting the most plausible assumption that correction by random propulsion explains the survival of a reduced population of primordial germ cells (PGCs; Mroz et al., 1999; Sciurano et al., 2009) and subsequently gonocytes into the postnatal period, some of those survivors might lose their stem cell properties already before birth. Apparently they get lost during peripubertal differentiation while very few can occasionally survive, express all relevant markers correctly and drive foci of spermatogenesis. Systematic evaluation of the phenotypic changes during development in utero is per se only possible in a mouse model.

The disturbance of the HPG axis, which causes the hypergonadotropic hypogonadism commonly seen in KS patients together with the suggested increased numbers of Leydig cell in testicular biopsies has led to the hypothesis that Leydig cell function and/or maturation might be affected by the sex chromosomal imbalance. Leydig cells are steroidogenic being the source of testosterone which is essential for the development of the healthy male phenotype and crucial for the continuance and completion of normal spermatogenesis.

As with the other facets of KS, the restrictive factor for any in depth investigation is the limited access to testicular tissue. With the availability of the 41,XX^{Y*} male mice, studies on Leydig cells from males with a supernumerary X chromosome became feasible to investigate. Using this model we confirmed the presence of Leydig cell hyperplasia as determined by stereological microscopy and also found that ITT levels were similar to those in the control mice (Wistuba et al., 2010). This was surprising

considering the low serum T levels seen in KS patients and 41,XX^{Y*} mice alike (Lanfranco et al., 2004; Smyth and Bremner, 1998; Wistuba, 2010). In line with low circulating T levels was the finding that once Leydig cells from the KS model were taken out of the testicular environment, grown in vitro and normalized for cell number, their function was indeed altered. However, it was not impaired, as would first be thought, but hyperactivated. When the mRNA expression profiles of the marker genes *Tsp2* (thrombospondin 2: a matricellular protein of fetal origin which is predominantly expressed in juvenile Leydig cells), *Rlf* (relaxin-like factor: marker of mature Leydig cells), *Est* (estrogen sulfotransferase: marker of mature Leydig cells), and *LHR* (LH receptor: investigated for correlation with Leydig cell stimulation experiments, see later) were determined, the isolated XX^{Y*} Leydig cells showed a mature mRNA expression profile and significantly higher transcriptional activity compared to controls (Wistuba et al., 2010; O'Shaughnessy et al., 2002). The gene expression analysis revealed an overall increase in expression of XX^{Y*} Leydig cell specific genes with *Est* expressed approximately 20-fold, *Rlf* 8-fold, *Tsp2* 5-fold, and *LHR* 3-fold higher than wild-type Leydig cells. Stimulation of the XX^{Y*} Leydig cells in vitro indicated a mature LH receptor which responded even stronger to human Chorionic Gonadotropin (hCG, a surrogate for LH) stimulation than cells from controls. Furthermore, the steroidogenic activity of the XX^{Y*} Leydig cells was elevated, in that more T per cell was produced in response to hCG.

These exciting results not only lead to a new concept on the origin of hypergonadotropic hypogonadism but also demonstrate the validity of the KS mouse model, with its direct translational consequences for our understanding of KS patients. The results from the mouse model indicate that Leydig cell function is not impaired per se, hinting that other factors in the testicular environment are responsible for the disturbed androgen endocrinology seen in KS patients. In particular, as we could confirm also in patients that ITT values were not different from controls (Tüttelmann et al., 2014). Possibly the altered testicular architecture associated with the disorder may hamper endocrine transport into the circulation, a proposition which was supported by the findings that KS patients also have diminished blood vessel diameter (Foresta et al., 2012). Taking this into account, we set out to find a possible "vascular" explanation for the lack of T release into the testicular blood stream. In testis biopsies from patients, reliable analysis of the vessels is, however, not possible because of the bias resulting from the dissection technique requiring avoidance of larger blood vessels to prevent bleeding. Consequently, the blood vessel constitution was evaluated in whole testis sections from adult male 41,XX^{Y*} and 40,XY* mice. Indeed, the blood vessel/testes surface ratio correcting for the smaller

testes of XX^{Y*} mice was significantly lower in these mice compared with XY* controls. In conclusion, testicular T production does not seem to be impaired in men with KS. The data from the mouse model let us speculate that a reduced vascular supply might be involved in lower release of T into the bloodstream.

7.3 Infertility in KS—A Stem Cell Disease?

Beside hypergonadotropic hypogonadism, the clinical feature that is consistently present in KS is infertility. Caused by the degeneration of germ cells, their depletion from the seminiferous epithelium occurs in a process most likely beginning prenatally and progressing during infancy (Coerdt et al., 1985; Murken et al., 1974). The number of germ cells dramatically decreases by the onset of puberty and is often accompanied by a massive hyalinization of the seminiferous tubules (Aksglaede et al., 2006). As already mentioned, although the germ cell degeneration in patients, in general, leads to complete azoospermia, small foci of full spermatogenesis in the testicular tissue can be found in some Klinefelter men (Foresta et al., 1999; Schiff et al., 2005), which with the aid of assisted reproductive techniques make paternity possible (Denschlag et al., 2004; Kyono et al., 2007).

In patients with focal spermatogenesis, FISH evaluation has shown that the premeiotic and meiotic germ cells still undergoing differentiation and forming normal haploid gametes, possess a 46,XY karyotype while the nurturing somatic Sertoli cells have the aberrant 47,XXY karyotype (Sciurano et al., 2009). These results provide two useful pieces of information: First, germ cells that survive in the KS testis are karyotypically corrected and second, the somatic testicular environment despite being composed of aberrant cell types is able to support germ cell differentiation to some extent. Taken together, this indicates that the germ cell communication is able to overcome and/or to compensate the disturbances in the somatic testicular components (Sciurano et al., 2009).

Focal spermatogenesis is present in a substantial proportion of KS patients but was also observed to some extent in KS mice (Werler et al., 2014). Some 41,XX^{Y*} animals exhibited few tubules with differentiating germ cells up to late meiotic stages were observed (Fig. 24.4).

Again, the 41,XXY mouse model played an important role in the elucidation of these observations as it provided the experimental means which made the proof of principle possible. Specifically, transplantation assays in the mice allowed for the separate analysis of the germ cell line and the somatic testicular components by permitting the transplantation of germ cells from KS mice into healthy hosts and vice versa (Brinster, 2007; Wistuba and Schlatt, 2002). Lue et al. (2010a,b) transplanted healthy spermatogonial cells from donor mice into the germ cell depleted testes of 41,XXY recipient mice and
FIGURE 24.4 **Focal spermatogenesis in a testis obtained from a 41,XX^{Y*} male mouse.** Histology rarely exhibits foci of spermatogenic differentiation. In this testis of a 3-week-old 41, XX^{Y*} mouse a few tubular cross sections show differentiation of germ cells up to meiotic pachytene spermatocytes. Staining: Periodic Acid Schiff (PAS), the bar equals 100 μm.

found that normal mature spermatozoa could be derived. An experimental finding that supports the focal spermatogenesis observed in patients. In humans and mice alike, it appears that germ cells with an XXY karyotype are lost with only those that are corrected, very likely by random expulsion of one X chromosome, able to survive (Sciurano et al., 2009). Furthermore, despite the surrounding environment being altered, it is still capable of providing sufficient support to nurture the few surviving germ cells throughout the entire differentiating process and culminating in the successful production of mature gametes.

As material from immature and pubertal boys is extremely rare, the mouse models offer the only realistic means for studying the processes associated with the germ cell loss in KS in detail. In the 41,XXY mice, it was noted that at the early stages of testicular differentiation, when germ cell proliferation is underway, fewer germ cells are present compared to littermate controls. Chronicling testicular formation, development and content from day 10.5 postcoitum (pc) to day 6 pp, Hunt et al. (1998) noted that the numbers of germ cells present in the genital ridges of both XXY and XY animals were similar. However, perinatally, around the period when testicular differentiation begins a marked reduction in the quantity of germ cells in the tubular cross sections of XXY animals was found. It has been suggested, that the cause of this impaired proliferation might be the

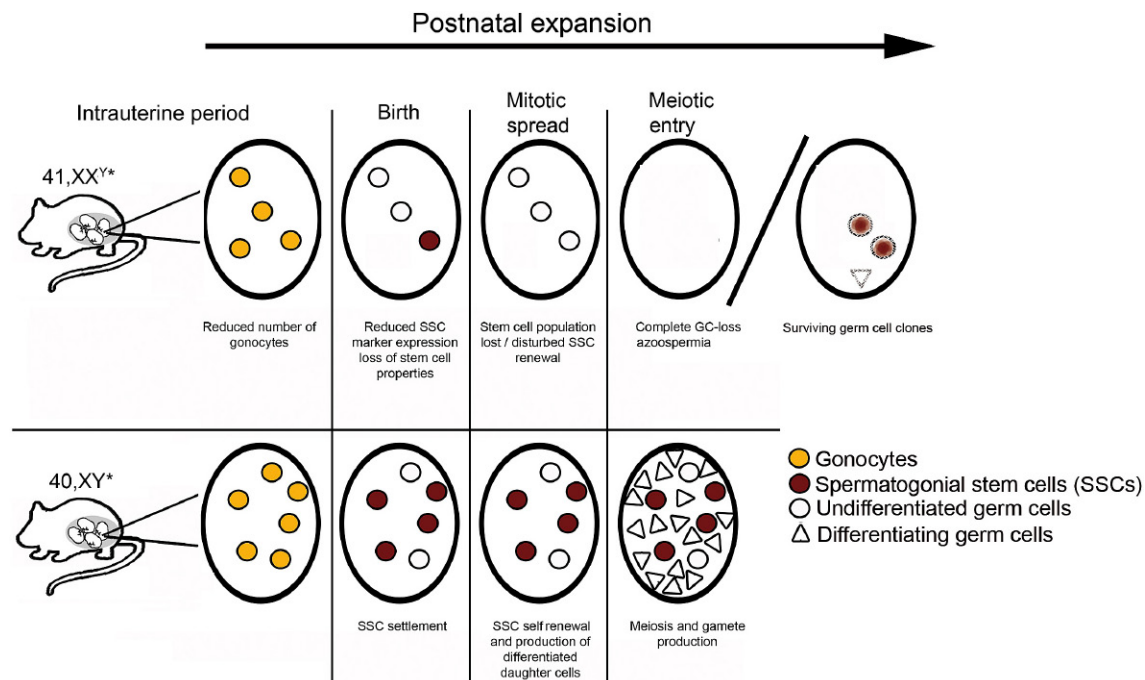
reactivation of the inactivated X chromosome when the XXY germ cells enter the genital ridge (Mroz et al., 1999). If the XXY cells are removed from their somatic environment they proliferate similarly to normal XY germ cells. This ability in vitro is suggestive of an error in germ cell-somatic cell communication (Hunt et al., 1998), a disturbance that afflicts spermatogonia at a very early undifferentiated stem cell level, possibly by interfering with the colonization of the stem cell niches. At present, the topic of germ cell loss is a matter of contention and debate. Hampered by the technical difficulties inherent in the handling of prenatal and neonatal experimental animals, together with the small quantity of tissue obtained from such young mice, only a few studies have been performed. Lue et al. (2005) found decreased germ cell numbers as early as day 3 pp but no differences in the number of gonocytes at day 1 pp; findings which are contrary to those of Hunt et al. (1998) who assessed the same mouse model. We have performed a systematic study by the postnatal time course of germ cell loss in vivo. When utilizing the 41,XX^{Y*} mice, we found the number of undifferentiated germ cells to be reduced already from the time point of birth onward and could link this to altered protein expression of spermatogonial stem cell markers: Lin28 and Pgp9.5 expression were not detected after day 3 pp and day 5 pp, respectively. Lin28 regulation implements a network of several miRNAs of which we analyzed miR-125b and miR-let7g. Both miRNAs are normally expressed in a complementary pattern in the healthy developing testis, in 41,XX^{Y*} mice we found this pattern to be completely disturbed (Werler et al., 2014). In tubules with germ cells, the expression of Lin28 and Pgp9.5 was corrected. Based on these findings, we developed a model for prenatal germ cell loss in our KS mouse model (Fig. 24.5). Preliminary evidence suggests that also in the human the germ cell loss starts earlier than thought so far (Davis et al., 2015). We hypothesize that a first wave of germ cell death occurs already in the early embryonic phase during colonization of the developing gonad, a second phase, when gonocytes propagate followed by a third phase, when germ cells that survived enter meiosis but fail to complete this process except of a few germ cells which eventually can undergo full spermatogenesis (Fig. 24.5, Werler et al., 2014). Apart from the evidence provided by our group that the only parameter correlating with the success of testicular sperm retrieval by mTESE in young KS patients is age (Rohayem et al., 2015), the scenario currently discussed in the clinical and scientific community is to offer a fertility preservation option already in infantile KS boys by cryopreservation and -storage of immature testicular tissue for later maturation of the spermatogonia in vitro by methods which however, are currently still on the experimental level (Stukenborg et al., 2009; Van Saen et al., 2012; Kossack et al., 2013).


FIGURE 24.5 **A revised model of germ cell loss in mouse models for Klinefelter Syndrome.** A reduced number of gonocytes is proposed already during the intrauterine period. Consequently, at birth, a reduced number of germ cells (GC) expressing SSC markers is present and the stem cell potential is lost during the mitotic propagation after birth. When the germ cells afterwards enter meiosis, they are finally depleted in the 41,XX^{Y}* testis whereas in normal 40,XY* control mice spermatogenic differentiation starts. The exception of the rule is seen in focal spermatogenesis were single germ cell clones can survive (dotted lines). *Source: Modified from Werler, S., Demond, H., Ehmcke, J., Damm, O.S., Middendorff, R., Gromoll, J., Wistuba, J., 2014. Early loss of germ cells is associated with fading expression of Lin28, a spermatogonial stem cell marker in the 41,XX^{Y}* mouse model for Klinefelter Syndrome. Reproduction 147, 253–264.*

Consequently, in the light of the most prominent features of KS, the testis has to be seen as the most severely affected organ, thus reflecting the genotype-phenotype relation of this condition most strongly. Both testicular functions, the maintenance of the male endocrine milieu as well as the production of gametes are the features of KS which are consistently affected. Therefore, the logical target for the exploration of gene dosage effects is the analysis of gene expression and the functional response of testicular cell types. The availability of mouse models, the option to analyze gene expression patterns and somatic cell responses offers the privileged situation not only to study aspects of the mechanisms by which, for example, escapee genes provoke a complex phenotype but also to directly translate those findings into a clinical context (Nieschlag et al., 2014; Rohayem et al., 2015; Tüttelmann et al., 2014; Zitzmann et al., 2015).

7.4 Behavior and Cognition

New technologies in molecular biology which allow for the selective manipulation of genomic sequences have dramatically reshaped biomedical research during the last decades. The extensive utilization of these techniques in mice together with the animals' high reproduction rate, small size, and low maintenance costs, have made it the most widely used mammalian model organism.

The rapid rise in the number of different mouse models available now has greatly outpaced the behavioral characterization of these animals as these analyses are complex and time-consuming. The KS mice are indicative of the situation as only a minority of publications deal with detailed investigation of this murine model and report any behavioral data.

The first examination of cognitive ability of XXY mice was undertaken by Lue et al. (2005) in order to determine if their murine model exhibits cognitive deficits comparable to those found in human Klinefelter patients. To test cognitive functions, they used a Pavlovian conditioning box located in a sound-attenuating chamber. The mice were trained to acquire a tone-food association by providing food rewards only while a 20-kHz tone was presented for 20 s. Pavlovian or classical conditioning is based on the famous experiments conducted by Ivan Petrovich Pavlov where food was presented to dogs and the amount of saliva they produced measured. Before presenting the food, he rang a bell (although it has been questioned whether or not it was a bell or some other sound in the original experiment) as a

conditioning stimulus. After several repetitions the dogs associated the sound of the bell with food and started salivating regardless of whether food was present or not (Pavlov, 1906).

In the experiments by Lue et al. (2005), in lieu of saliva, the latency to pick up a food pellet after a 20-kHz tone was measured. In this study a relatively low number of seven XXY and seven XY mice were tested owing to the experiments being designated as preliminary. The mice were adult but of varying ages ranging from 4 to 12 months. The tone-food association was repeated 10 times a day for 4 consecutive days. Pellets were presented in a magazine that automatically recorded head dips by means of an infrared beam. Prior to testing the mice were provided with 90% of the food that they would freely consume for 3 days in order to increase motivation for a food reward. Both, XY and XXY mice learned the association of the tone with the food reward, but the XY controls proved to be faster learners. On the first day XY mice obtained the reward on average 6 s after the tone was presented. XXY mice took 9 s on average—significantly longer—to pick up the pellets on day 1. The latencies of picking up the reward by the XXY mice were also significantly longer on day 2 and 3 but equilibrium was reached on day 4. The authors speculated that the delayed latency might be due to either decreased plasma T levels, a defect of the androgen receptor or increased X-linked gene expression in specific brain regions, such as the medial temporal lobe. We ourselves conducted similar experiments testing conditional learning in a pavlonian setting under the administration of testosterone enanthate (TE). Mice of both karyotypes (41,XX^{Y}* and 40,XY* littermates) were placed individually into cages which allowed for applying stimulants (acoustical signals) and rewards (food) in an automatized way. An animal with normal learning abilities should be able to respond the signal within a small timeframe and the more sessions applied; the better the animal should respond until habituation sets in. Animals with reduced learning abilities should respond worse, that is, the duration until the task has been successfully fulfilled should be longer. We aimed at investigating whether a T supplementation of 2 µg/g bodyweight prior to the experiments would improve the outcome of conditional learning. However, we found no change under TE treatment for both groups, neither for XY* nor for XX^{Y}* males. While the wild types show normal learning behavior with and without TE, XX^{Y}* mice did not benefit from the T administration, which was unable to compensate the worse performance of these animals in the setting chosen (Fig. 24.6). Thus learning behavior might be unaffected from rising androgen levels and thus rather due to genetic reasons, however other reasons as altered androgen receptor functionality has still to be fully excluded.
FIGURE 24.6   **Conditional learning after T supplementation.** Data points summarize ten trials each. TE administration does not improve conditional learning in 41,XX^{Y}* mice which are slower than their 40, XY* littermates. Response times of all groups remained stable under T supplementation indicating an underlying genetic mechanism likely not affected by androgen increase. *B*, Behavioral testing.

In another study (Liu et al., 2010) the social behavior and sex preference of the XXY mouse model was explored to determine if they mimicked the known peculiarities of KS patients' social skills. A series of tests was conducted using a "choice" apparatus which comprised three chambers, the mice could explore. Entrance into the apparatus was either from a left or right compartment where social partners or inanimate objects were presented. The preference was measured by the relative amount of time spent in the compartments. XXY mice preferred ovariectomized female mice or male mice over the inanimate objects. A finding that may appear inconspicuous until it is compared with that from the XY mice in this study (in contrast to the observations made by Ryan et al. (2008) who did not show such a preference). This test gauges whether the preference was based on social or sexual interest. When given the choice between an unknown male and an unknown ovariectomized female, XXY mice did not prefer the male. Furthermore, similar to XY mice, the XXY mice preferred the odor of intact females in oestrus over the odor of male conspecifics indicating that the preference for males over inanimate objects was socially rather than sexually motivated. In a second step, the authors investigated whether or not the observed differences in social preference were related to T. In order to match androgen exposure, castrated animals of both groups were tested before and after

T substitution. Neither castrated nor T substituted males of either group showed a specific preference for unknown males over an inanimate object. Castrated XXY mice preferred unknown males over unknown ovariectomized females in contrast to castrated XY mice that did not show any preference. When substituted with T neither group showed any partiality for unknown males or unknown ovariectomized females. Overall, the XXY mice exhibited increased rather than decreased social interest in these tests which is contradictory to the initial hypothesis derived from observations of disturbed social skills in KS patients. Nevertheless, the fact that differences in social behavior could be related to karyotypic differences is noteworthy and awaits further analysis.

The study by Lewejohann et al. (2009a) investigated the 41,XX^{Y*} mouse model with the intension of clarifying whether these mice can be used as an easier to obtain model to analyze the linkage between sex chromosomal imbalance and cognition processes. In contrast to the XXY model, the KS like mice were compared to XY* littermates, a group of animals that was deemed suitable to

act as controls based on their physiological and morphological similarities to XY mice.

The evaluations were based on a nonconditional test of recognition memory which uses an object recognition paradigm and measures the exploration of known versus unknown objects based on the tendency of mice to prefer novel objects over familiar objects. As it has been suggested that anxiety related behavior can bias the exploration in this test (Görtz et al., 2008), it was important to ensure that the preconditions for recognition memory were identical for both groups. Preceding the tests, a general health check and analysis of exploration and anxiety like behavior was conducted. The results of testing the preconditions could only be briefly presented in the paper. For the preparation of this chapter, we revisited the data in order to provide a more detailed picture of the XX^{Y*} model. The health check comprised the inspection of physical appearance and neurological testing including acoustic startle, visual placing, grip strength, and reflex functions. Mice of both groups appeared healthy and no differences were found (Fig. 24.7A). Spontaneous
FIGURE 24.7 **Behavioral phenotyping of 41,XX^{Y*} mice.** (A) Mice were subjected to a general health check including visual inspection of fur and whiskers as well as tests for eye sight, hearing, reflex functions, and basic motor skills. The maximal test score of 14 points was assigned as 100%. (B) Spontaneous exploration was measured as the latency to climb over a barrier of 3 cm height dividing the test cage into two compartments. (C) Percentage of arm entries into open arms of an elevated plus maze to measure anxiety related behavior. (D) Locomotor activity in a 30 by 30 cm open field box was measured using a video based animal tracking software.

exploratory behavior was measured by the barrier test using a standard cage, which was divided by a 3 cm high barrier into two equally sized compartments. Spontaneous exploration was measured for 5 min by the latency to climb over the barrier into the other compartment. No statistical difference was detectable between XX^{Y*} and XY* mice, indicating no difference in spontaneous exploratory behavior (Fig. 24.7B). There is evidence of a reduced volume of the amygdala of KS patients (Patwardhan et al., 2002; Shen et al., 2004). Since this region of the brain is strongly involved in emotional processing, it is tempting to speculate that there might also be differences regarding anxiety related behavior. We measured this aspect by calculating the proportion of open versus shielded arm entries in an elevated plus-maze test. This test is pharmacologically validated, showing that less anxious mice explore open arms more frequently (Lister, 1987). Mice of both groups explored the open arms similarly and often indicating no difference between the animals nor severe anxiety related disturbances (Fig. 24.7C). In the open field test, the mice were allowed to explore a 30×30 cm^2 arena for 3 min. This test assesses locomotor behavior by means of a video-based automated tracking system that calculates the path length travelled. The test was also included to habituate the mice to the arena where the object recognition task would be performed. Again both groups explored the arena to a similar extent and no significant differences were detectable (Fig. 24.7D). However, when the objects were provided, the XY* male mice significantly preferred the novel object indicating that they remembered the object that was presented 1 h before. In contrast, the XX^{Y*} males did not show a preference indicating poor recognition memory or less interest in novelty. For each mouse a recognition index was calculated by dividing the time spent exploring a novel object by the total time spent exploring objects. XY* male mice had significantly higher recognition indices than the XX^{Y*} males. Interestingly, T concentrations correlated significantly with object recognition memory in XY* mice but not in XX^{Y*}. These correlations are consistent with the findings that T substitution in human KS patients failed to bring about an increase in memory performance (DeLisi et al., 2005). We therefore propose that the T driven organizing effects which occur during adolescence play a vital role for memory performance later in life. Adolescence is not only a period where secondary and tertiary sexual characters develop but is also the period where the behavioral responses of individuals changes from the juvenile to the adult phenotype. This phenomenon is highly conserved in mammals and has been found in just about all species studied (Spear and Kulbok, 2004). The obvious changes in behavior are driven by processes of brain development and reorganization that are unique to the periadolescent phase of development. For example, the maturation of

brain regions with high numbers of androgen receptors has been shown to be dependent upon testosterone-by-sex interactions in humans (Bramen et al., 2012).

Determining the validity of the animal models for KS, 34 human KS patients were assessed for visual object memory (Bruining et al., 2011), a task directly comparable to tests undertaken in the study by Lewejohann et al. (2009a). Indeed, the human KS subjects were found to have difficulties in processing visual objects as well as visual pattern information especially when temporal information needed to be processed and reproduced. Seven of the participating patients were treated with androgens during the time of testing, although the treatment did not appear to improve cognitive performance, due to the low number of patients receiving androgens, an affect cannot be entirely excluded. Overall, the cross-species comparison of cognitive behavior in KS is an important step in understanding the full spectrum of KS sequelae.

The behavioral studies of the KS mouse models provide a valuable tool for understanding social as well as cognitive aspects of the syndrome. There is no doubt that we are still at the very beginning, and a plethora of questions remain to be solved. In most studies analyzing behavioral phenotypes of mice, the animals are housed in small standard sized cages, preventing them from showing a variety of species specific behavior (Lewejohann et al., 2010). For example, anxiety-related behavior is usually characterized outside the home-cage using artificial apparatuses which investigate the motivational differences between fear and exploration by subjecting the mice to a challenging situation. Although it is acknowledged that such tests are fundamental for the characterization of animal models, for these behavioral traits to be more comparable to the human condition, an in-depth characterization of how the day-to-day life of these mice is affected in their home environment is also needed. For example, considering the association of supernumerary X chromosome and social interactions, it would be interesting to see, whether or not, the social day-to-day behavior of these mice is affected including an analysis of social dominance hierarchies (Lewejohann et al., 2009b, 2010). The cognitive phenotyping of the murine KS models which also awaits further in depth analysis would possibly benefit from a similar approach namely tests conducted in the home cages of the mice (de Visser et al., 2006).

As with the previously detailed physical and physiological consequences of KS, the influence of the disturbed endocrine milieu, differential gene expression and/or the mixture of both on brain function need to be clarified. The murine models allow for the systematic study of the effect of T treatment on behavioral and cognitive skills, not only in adulthood, but just as importantly during the early stages of life when androgens play a significant role in the organization of the brain.

In addition, the behavioral phenotypes of individual mice are known to be affected by environmental factors as well as gene-environment interactions (Lewejohann et al., 2011). For example, cognitively stimulating environments may help to ameliorate observed cognitive deficits. Translational research which relates human phenotypes with the behavioral data obtained from the murine models will help to further facilitate the value of these models by increasing their face validity (Bruining et al., 2011).

7.5 Endocrinology and Metabolism

Beyond infertility, hypergonadotropic hypogonadism is the condition present in almost all KS patients. The disturbed hormonal milieu is supposed to cause, or at least is involved in, many of the metabolic features that can accompany KS (e.g., gynecomastia, disturbed bone metabolism, increased diabetic risk) (Lanfranco et al., 2004). Cognitive deficits are also influenced by endocrine alterations, although experimental work using the mouse KS models has revealed that the hormonal influence on brain function is complex and multifaceted and that altered gene expression may play an important role despite the lack of T.

The most common therapeutic strategy to deal with the hypergonadotropic hypogonadism of Klinefelter patients is by the administration of exogenous T. Beyond redressing the androgen imbalance, T administration has been reported to have other beneficial effects, such as treating delayed puberty (Richmond and Rogol, 2007), enhancing bone metabolism (KS patients have a significantly higher risk of developing osteoporosis), and circumventing the development of metabolic syndrome (Bojesen et al., 2010; Gravholt et al., 2011). At present one of the treatments suggested for KS boys suffering from behavioral deficits is to administer T, a strategy that is claimed to aid a portion of patients; however, the purported beneficial attributes of this approach have yet to be proven unequivocally. T treatment is not without risks; its use has been linked to psychiatric consequences (Rogol and Tartaglia, 2010) and it undermines the small foci of spermatogenesis that may persist in KS patients, in particular for pubertal boys that may have sperm, this treatment effectively subverts their fertility potential, as exogenous T administration results in lowered ITT levels and thereby jeopardizes spermatogenic progress, which requires sufficient levels of T in the surrounding testicular environment (Wistuba et al., 2007).

As both mouse models exhibit hypergonadotropic hypogonadism with low plasma T and high gonadotropin levels, they closely mimic the endocrine profile of patients. This makes them ideal to the study of the true worth and consequences of T treatment which in turn may open routes for the development of novel therapeutic strategies.

Two examples of such investigations illustrate the potential of this approach. First, the study by Liu et al. (2010) on androgen action and effect on adult 41,XXY mice where they analyzed the impact of T on the bone metabolism in order to separate endocrine from genetic effects. In an elegant experimental design they used castrated 40,XY males as hypogonadal controls to assess solely the influence androgens on the bone phenotype. They treated these animals with T via silastic implants and monitored bone volume, trabecular thickness, and trabecular separation, all of which are deficient in 41,XXY mice. Following castration the controls' bone metabolism was to such an extent altered that it was indistinguishable from condition seen in the 41,XXY animals, demonstrating the importance of normal androgenization for the maintenance of a normal bone metabolism. Interestingly, although treatment did return serum T to values similar to the controls, the bone volume in males with a supernumerary X chromosome remained reduced. Thus, the authors suggested that as well as disturbed endocrine regulation, genetic causes must contribute to the bone volume loss in 41,XXY mice. Meaning, that like disturbances in brain function, bone metabolism is also adversely affected by a combination of altered gene expression and endocrine changes. The clinical corollary of these findings is that although T replacement therapy can be helpful for dealing with some of the sequelae it is not a panacea for KS, as it is unable to overcome the contribution of the genetic component.

In a second study (Wistuba et al., 2010, described in detail earlier), our group demonstrated that Leydig cells from 41,XX[Y*] mice are not impaired but rather hyperactivated probably in a compensatory response to the hypergonadotropic hypogonadism. Taken together with the normal ITT values in these animals, we proposed that it is not the production of T but rather its transport to/in the circulation that is hampered, perhaps due to the altered testicular architecture. By supplementing these findings with an observation from a study of KS patients from the 1970s, we suggested a new hypothesis. Smals et al. (1974) proposed the presence of a so-called "steroidogenic reserve" in Klinefelter men in an attempt to explain their finding that these patients responded with increasing serum T levels after treatment with CG. At the first glance, such a treatment seems to be absurd, treating hypergonadotropic patients with a gonadotropin, and the response paradoxical. However, our recent experimental findings that the Leydig cells in the 41,XX[Y*] mouse are functionally normal provides a possible explanation for Smals et al. (1974) conundrum, in that rather than a "reserve" increasing gonadotropin levels might further enhance steroidogenic activity and hence result in the noted rise of serum androgen levels. This might open a new route for therapy, in that instead of treating—in particular boys—with exogenous T and placing

their remaining spermatogenesis at risk, CG administration might be considered as it also increases serum T but more importantly it does so via the production of the patient's own testis. This is the crucial aspect as endogenous T is not harmful to spermatogenic progression. By this tack, the patients still achieve the androgenization state that is desired but no longer risk the loss of their small fertility reserve. Experimental and clinical testing of this hypothesis is still to be performed.

8 PERSPECTIVES—WHAT CAN BE EXPECTED FROM FUTURE ANIMAL EXPERIMENTS AND HOW TO RETRANSLATE EXPERIMENTAL FINDINGS INTO CLINICAL ROUTINE—CONCLUSIVE REMARKS

The generation and availability of mouse models of KS have led to some remarkable progress in our knowledge of the molecular and cellular mechanisms that form the aberrant male phenotype associated with this chromosomal disorder. On the genetic level, research on the mouse model has shown that X-inactivation is seemingly normal providing credence to the hypothesis that it is the expression of "escapee" genes that differentiates the normal condition from that seen in male mice with a supernumerary X chromosome. The use of these animal models has allowed for the identification of this very basic molecular mechanism along which the affected phenotype may become manifest namely, female expression patterns of X chromosomal genes that escape silencing, when present in a male cellular environment, act either directly or along regulatory pathways to undermine fertility, endocrine status cognition, and bone metabolism (Nieschlag et al., 2014; Wistuba, 2010; Zitzmann et al., 2015).

Some studies have already been undertaken to investigate this hypothesis and although the findings broadly support the proposition (Werler et al., 2011; Zitzmann et al., 2015), it is equally apparent that the situation is far more complex than first thought as some of the candidate genes are expressed in a tissue and gene-specific way and also autosomal gene expression appears to be affected by the disorder, likely downstream of the escapee action (Zitzmann et al., 2015). Therefore, more information is needed before the idea of developing novel therapies targeting on the human homologs of these genes can become a reality. Such deeper insights can only be made possible with the use of the animal model as they require experimental manipulation and functional studies.

As mentioned earlier, infertility due to the SCO phenotype is one of the major problems caused by KS. Unfortunately, primarily due to the late diagnosis of the syndrome, other than the cases where TESE/ICSI can

be performed, there is little that can be done to treat or preserve the fertility of KS patients and as a consequence, the majority of these men will never have the chance to father a child. In the 41,XX^{Y*} mice, the time course of germ cell loss was shown to occur earlier than thought and some studies in patients confirm at least partly that this is also true in human (Davis et al., 2015; Rohayem et al., 2015). Thus germ cell loss has likely to be encountered early, be it during puberty or even during childhood. The mouse models might provide an experimental basis for the development of innovative approaches to rescue the germ line and by these possibly open new routes for fertility preservation. Already the mouse models have shown that the aberrant somatic cells of the testis are able to support spermatogenesis. The transplantation experiments performed by Lue et al. (2010b) demonstrated that germ cells can differentiate, as long as they have a corrected karyotype; an observation confirmed in patients with focal spermatogenesis by Sciurano et al. (2009).

Therefore, the target for novel approaches may well be the germ line. If it becomes possible to harvest germ cells and to provoke the expulsion of one X chromosome from the cells (e.g., by certain culture conditions) it might become possible to either differentiate the cells in some novel in vitro system or to retransplant them. At present, these suggestions remain speculative. However, in vitro differentiation of mouse germ cells in three-dimensional matrices has recently been shown to be able to produce morphologically mature spermatozoa in a culture dish (Abu Elhija et al., 2012; Stukenborg et al., 2008, 2009). For further proof of principle studies, the KS mouse models are the perfect model. As the in vitro differentiation protocols are available for murine germ cells, immature mice of the 41,XXY and 41,XX^{Y*} karyotype may provide undifferentiated spermatogonia which could be sorted for to identify those that by random expulsion have already corrected their karyotype or could be cultured under certain conditions that force high mitotic activity which provokes the loss of the supernumerary X chromosome. These corrected germ cells could then be brought together with somatic testicular cells and undergo in vitro differentiation. Once the proof of principle has been provided under such an experimental design, then protocols might be developed for future fertility preservation attempts in human patients.

Male mice with a supernumerary X chromosome will also be useful to improve endocrine treatments for hypergonadotropic hypogonadism. As both mouse models possess endocrine phenotypes which are regulated along the HPG axis similar to humans, experiments can be designed that aim at improving routine T treatment and as such provide greater choice, safety, and efficacy in the protocols devised at overcoming the hypogonadal state and impaired androgenization. However, as mentioned

earlier, T treatment also bears some risks, that is, for the maintenance of remaining spermatogenesis. As the analysis of the Leydig cell physiology of 41,XX^{Y}* mice has shown, there might be alternative treatments, that is, the administration of gonadotropins to improve the endocrine milieu in patients without augmenting some of the adverse features of KS further. The availability of the mouse models permits the systematic testing of such novel and alternative treatments.

Zebrafish: A Model System to Study the Architecture of Human Genetic Disease

Erica E. Davis, Nicholas Katsanis

Center for Human Disease Modeling, Duke University Medical Center, Durham, NC, United States

1 INTRODUCTION

The past decade has heralded an exponential growth in the number of human genomes and exomes, in large part due to the combination of improved technology and turnaround time with concomitant erosion in cost. For rare disorders, genes underlying >4000 Mendelian phenotypes have now been characterized, and account for the causal basis of as many as 50% of such conditions (Chong et al., 2015). Furthermore, genome-wide association studies (GWAS) have associated >2000 genomic loci with as many as 300 different complex traits (Manolio, 2013). For rare or common phenotypes, population-based evidence has been a consistent first-line argument supporting the implication of a locus in disease: rarity of a mutation in the general population supports the candidacy of novel Mendelian alleles (Bamshad et al., 2011), while replicated association of a locus with a measurable trait in well-powered

populations suggests a possible role in complex phenotype determinism (Altshuler et al., 2008). Although the community has excelled at increasing the size and ethnic diversity of human populations enrolled in genetic studies (Fu et al., 2013; Lek et al., 2016; Tennessen et al., 2012), such population genetic arguments often remain insufficient to explain causality. Furthermore, in silico tools that—in addition to population frequency—consider evolutionary constraint, protein structure, and other biochemical properties have only improved partially the predictive power of the genotype (Cooper and Shendure, 2011). Still, these computational approaches remain limited in their sensitivity and specificity (Castellana and Mazza, 2013), and provide a paucity of information about cellular and molecular basis of disease.

The overarching goals for genetic studies pertaining to human health can be subdivided into the following bench-to-bedside themes: (1) discover loci that underscore

pathology; (2) investigate the mechanistic basis of such genes or genomic regions as they pertain to disease; and (3) develop therapeutics to delay or ameliorate symptoms. Historically, animal studies have enhanced gene discovery, and have served critical roles in mechanistic investigation and therapeutic avenue development (Aitman et al., 2011). Gene modulation in animal models, either through knockout approaches or knock-in of human alleles, have improved our understanding of disease manifestation by offering a physiologically relevant system in which to study recapitulation of the human phenotype. Numerous laboratory models have been employed to understand the causal link between genotype and phenotypic trait. Each model system has its advantages and disadvantages including genomic conservation; anatomical and physiological similarity to humans; generation interval; versatility of the molecular toolkit; and operational cost (Table 25.1).

Although in vitro cell culture systems or biochemical assays have proven utility to inform human genetic disease (James and Parkinson, 2015; Tiscornia et al., 2011), a broad array of laboratory animal systems have been harnessed to diversify and expand the spatiotemporal study of novel disease genes and alleles. Mammalian models, such as the mouse (*Mus musculus*) or rat (*Rattus norvegicus*) traditionally have been attractive disease modeling platforms due to their high degree of genomic orthology with human [>80%; (Gibbs et al., 2004; Mouse Genome Sequencing et al., 2002)]; conserved organ structure and function; and a broad array of gene targeting or transgenesis approaches to induce disease phenotypes (for scholarly reviews see Capecchi, 2005; Devoy et al., 2012). However, in the context of modeling human genetic findings—especially for rapid clinical use—time, cost, and footprint represent major drawbacks for rodents and most other mammalian models. By contrast, invertebrate models, such as the fruit fly (*Drosophila melanogaster*) or nematode worm (*Caenorhabditis elegans*) are tractable and inexpensive alternatives. Through strong community efforts, these laboratory species have extensive availability of RNAi resources, transgenic reporters, and mutant lines (Antoshechkin and Sternberg, 2007; Ugur et al., 2016). Nevertheless, the obvious advantages of fly and worm systems are accompanied by diminished

homology with human genes [61 and 43% for fly and worm genomes, respectively; (Lander et al., 2001)]; and disparate anatomical features and molecular or cellular processes. The zebrafish (*Danio rerio*), however, is a compromise between mammals and invertebrates, and has emerged as a model system that is employed increasingly to model human disease.

Here, we will provide a comprehensive overview of zebrafish as a model of human disease phenotypes (Table 25.2). Although not the panacea to the continually compounded challenge of interpreting human genetic variation, we will discuss how in vivo complementation studies in zebrafish have accelerated gene discovery in rare and complex traits (Niederriter et al., 2013); and we will highlight successes in modeling multigene phenomena, such as copy number variants (CNVs) and oligogenic interactions. We will also summarize the current stateofthe art in terms of zebrafish model resources, molecular technologies, and phenotyping approaches. Driven by a dedicated community whose efforts have built substantial zebrafish resources over the past decades, the zebrafish has been adapted not only for research on human genetic disease, but also to toxicology (Garcia et al., 2016), aquatic physiology (Alestrom et al., 2006), and tissue regeneration studies (Gemberling et al., 2013).

TABLE 25.2 Anatomical Comparisons Between Zebrafish and Humans

Anatomy	Key similarities	Key differences
Embryology	• Cleavage, early patterning, gastrulation, somitogenesis, organogenesis are all represented	• Rapid • Influence of maternal transcripts • Nonplacental, involves hatching
Skeletal system	• Ossified skeleton comprising cartilage and bone	• Lack long bone, cancellous bone, and bone marrow • Joints are not weight-bearing
Muscle	• Axial and appendicular muscle groups • Skeletal, cardiac, and smooth muscle cell types, with similar cellular architecture and machinery • Fast and slow skeletal muscle fibers	• Fast- and slow-twitch muscle topographically separate • Tail-driven locomotion depends on alternating contraction of myotomal muscle • Appendicular muscle bulk is proportionately small
Nervous system and behavior	• Central nervous system anatomy: fore-, mid-, and hindbrain, including diencephalon, telencephalon, and cerebellum • Peripheral nervous system has motor and sensory components • Enteric and autonomic nervous systems • Specialized sensory organs, eye, olfactory system, and vestibular system, are well conserved • Complex behaviors and integrated neural function: memory, conditioned responses, and social behaviors (e.g., schooling)	• Telencephalon has only a rudimentary cortex • Fish-specific sensory organs, such as the lateral line • Fish behaviors and cognitive function are simplified compared with human behavior • Significant difference in population of dopaminergic neurons (telencephalic vs. midbrain) • Some immediate early genes and neuropeptides not conserved in zebrafish

(Continued)

TABLE 25.2　Anatomical Comparisons Between Zebrafish and Humans (*cont.*)

Anatomy	Key similarities	Key differences
Hematopoietic and lymphoid/immune systems	• Multiple hematopoietic cell types: erythrocytes, myeloid cells (neutrophils, eosinophils, monocytes, and macrophages), T- and B-lymphocytes • Coagulation cascade for hemostasis • Innate and adaptive humoral and cellular immunity	• Erythrocytes are nucleated • Possess thrombocytes rather than platelets • Kidney interstitium is the hematopoietic site
Cardiovascular system	• Multichamber heart with an atrium and ventricle • Circulation within arteries and veins • Separate lymphatic circulation • Cardiac differentiation occurs through similar signaling pathways (e.g., *nkx2.5*, *bmp2b*) • Similar electrical properties and conduction patterns (SA node, slow atrial conductance, AV node, fast ventricular conductance)	• Has left–right distinctions in cardiac anatomy, but does not have separate left–right circulations, that is, the heart has only two chambers • So far no evidence for secondary heart field derivatives • Lymph nodes have not been described • Embryos are not dependent on functioning CV system for larval development • Atria and ventricles express different myosin heavy chains during development (human hearts only later differentiate between atrial and ventricular mhc) • Heart has high regenerative capacity, even in adult animals
Respiratory system	• Cellular gas exchange • Oxygenation is dependent on circulation and hemoglobin carriage	• Respiration occurs in gills, not lungs • No pulmonary circulation • Endoderm-derived swim bladder (functioning as a variable buoyancy device), which corresponds embryologically but not functionally to the lungs
Gastrointestinal system	• Major organs: liver, exocrine and endocrine pancreas, gall bladder • Zonal specializations along the length of the absorptive alimentary tract • Immune cells in lamina propria	• Lack an acidified digestive organ • Have an intestinal bulb rather than stomach • Intestinal Paneth cell not present
Renal and urinary systems	• Glomerular anatomy and function	• Filtration occurs in anterior and posterior kidneys • Mesonephric rather than metanephric adult kidney • No bladder or prostate gland • No structure in zebrafish homologous to descending or ascending thin limb of nephron in mammals
Reproductive system	• Molecular and embryological biology of germ-cell development • Cellular anatomy of germ-cell organs, the testis and ovary	• No sex chromosomes; • Mechanism of sex determination is uncertain • Fertilization is ex vivo (no uterus or the related internal female reproductive organs) • Oocytes are surrounded by a chorion, not the zona pellucida, which must be penetrated by sperm • Nonlactating; no breast equivalent
Endocrine system	• Most endocrine systems represented, including hypothalamic/hypophyseal axis (glucocorticoids, growth hormone, thyroid hormone, prolactin), parathyroid hormone, insulin, and rennin	• Differences in anatomical distribution of glands, for example, discrete parathyroid glands do not seem to be present • Prolactin has a primary role in osmoregulation
Skin and appendages	• Ectodermal derivative • Pigmentation pattern is due to neural-crest-derived pigment cells including melanocytes	• Structures unique to fish that are specialized for the aquatic environment (including elasmoid scales, mucous cells) • Lack appendages (hair follicles, sebaceous glands) • Additional pigment cell types: xanthophores and iridophores

Table adapted with permission from Lieschke, G.J., Currie, P.D., 2007; Davis, E.E., Katsanis, N., 2014. Biochim. Biophys. Acta 1842, 1960–1970.

2 ZEBRAFISH IN THE LABORATORY: A HISTORICAL OVERVIEW

The zebrafish is a tropical teleost that has found its way from the freshwater rivers and streams of southeast Asia, to pet stores and home aquaria worldwide, and eventually to hundreds of research laboratories over the course of the past ~50 years (Fig. 25.1). One common zebrafish strain, AB, actually originates from a mating of strain A and strain B purchased on two different occasions from a pet store in Albany, Oregon (Chakrabarti et al., 1983; Streisinger et al., 1981; Wilson et al., 2014). Led in large part by University of Oregon researcher George Streisinger in the 1960s and 1970s, zebrafish transitioned from a household pet to a preeminent model of embryonic development because of a unique blend of attributes. First, one pair of zebrafish adults can produce several hundred embryos in a single mating, and can be mated repeatedly every 10–14 days for a sustained period of several months. Second, embryos develop synchronously ex vivo, enabling uninhibited visualization during early development; early organ formation is rapid, with major organ systems formed within the first few days postfertilization; and importantly, zebrafish embryos are optically transparent (Kimmel et al., 1995; Streisinger et al., 1981). Finally, zebrafish have modest diet, space, and water-quality requirements, and the emergence of husbandry standards has improved consistency and ease of care in the laboratory setting (Lawrence, 2016).

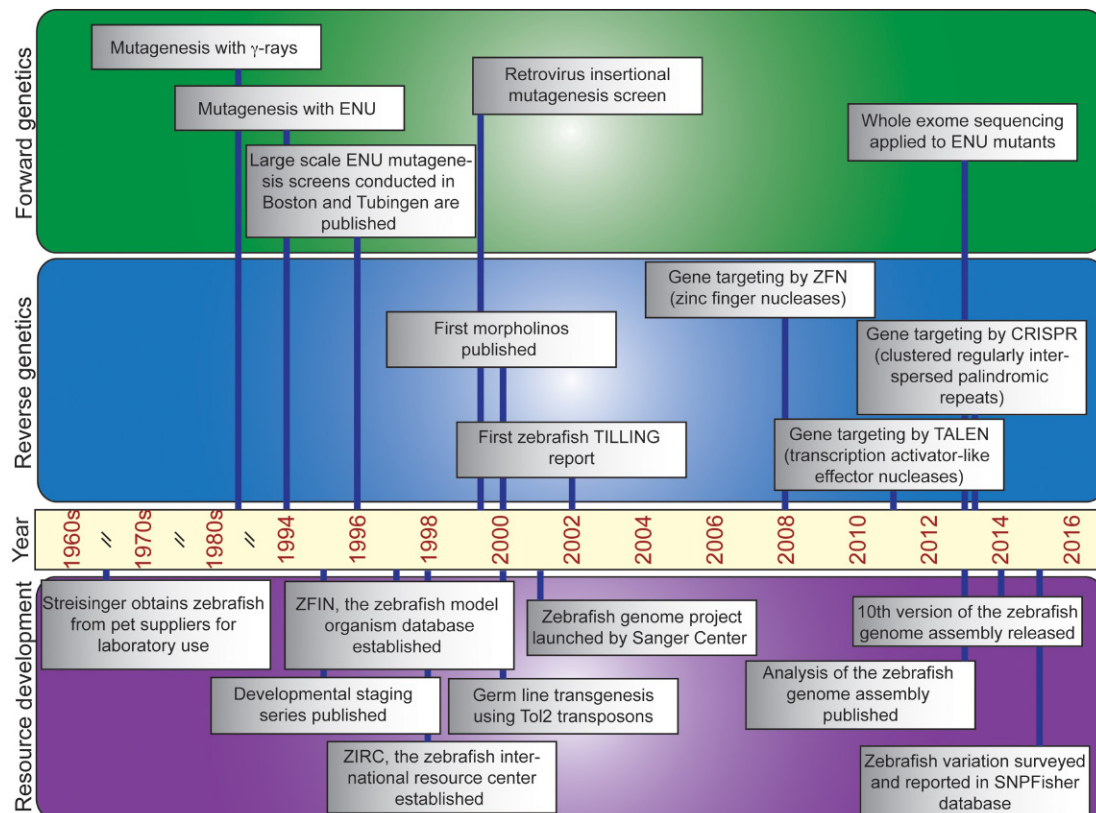
The zebrafish has a diploid genome for which the sequence is publicly available, and ~70% of human genes have at least one zebrafish ortholog (Howe et al., 2013b). The most notable structural difference of the zebrafish genome, and a major cause for the challenges of initial genome assembly, stems from the teleost specific duplication event (Amores et al., 1998; Meyer and Schartl, 1999; Postlethwait et al., 1998), which has resulted in an average of 2.28 zebrafish genes per human ortholog (Howe et al., 2013b). As a result of the genomic duplication, certain zebrafish gene pairs have acquired one of four different functional classifications: (1) redundant function; (2) neofunctionalization; (3) subfunctionalization; or (4) pseudogenization. The zebrafish orthologs of *NF1*, the genetic cause of neurofibromatosis in humans (Cawthon et al., 1990; Viskochil et al., 1990; Wallace et al., 1990), are an example of redundant function; loss of both orthologs is required to recapitulate *Ras* signaling defects


FIGURE 25.1 **Timeline summarizing landmarks in zebrafish model organism research.** Over the past ~50 years, numerous landmarks in resource development (bottom; *purple box*), forward genetic screening (top; *green box*), and reverse genetics approaches (middle; *blue box*) have improved our knowledge of vertebrate animal development, as well as human genetic disease through the use of zebrafish studies. *ENU*, *N*-ethyl-*N*-nitrosourea; *TILLING*, targeting-induced local lesions in genomes.

and relevant neuronal and tumorigenesis phenotypes observed in humans (Shin et al., 2012). Subfunctionalization is the phenomenon in which orthologous pairs of genes have the same function, but in discrete contexts. One example of subfunctionalization is the expression of the transcription factors *pax6a* and *pax6b* [orthologous to *PAX6*, the cause of multiple ocular disorders in humans (Jordan et al., 1992)]; the former is expressed primarily in the brain, and the latter has predominant expression in the pancreas (Kleinjan et al., 2008). Neofunctionalization, less frequently documented, is the phenomenon in which one of the two orthologs has acquired a distinct function from its cognate partner. However, in some instances, there is only one functional ortholog of the zebrafish pair of genes, termed pseudogenization (Force et al., 1999). In sum, the accurate characterization of the zebrafish genome has been critical to inform the development of models to mimic human phenotypes.

The zebrafish genome harbors extensive variation, and recent application of whole genome sequencing (WGS) and whole exome sequencing (WES) approaches have elucidated the differences within and across wild-type zebrafish strains (Leshchiner et al., 2012; Obholzer et al., 2012; Ryan et al., 2013). A recent WGS study comparing natural genetic variation across three laboratory-reared strains (Tupfel long fin [TL]; Wild India Kolkata [WIK]; and EkkWill [EK]) identified an average of 5.04 million single nucleotide polymorphisms (SNPs) per strain in comparison to the Zv9 reference genome, and uncovered population isolates that had arisen in the same strain maintained in independent laboratories. The SNP density in zebrafish, ~7 SNPs per 1 kb of unique sequence, is higher than that of any human population surveyed to date using WGS [2.6–4.4 SNPs per 1 kb; (Genomes Project et al., 2010)], and is publicly accessible through the SNPfisher website (Butler et al., 2015). This initial characterization of genetic variability and drift is not only a starting point toward understanding the buffering capacity of the zebrafish genome, but is also a valuable resource that will assist with the precise development of tools that depend on base complementarity to target the genome.

Extensive genomic characterization, in addition to systematic expression studies using primarily RNA in situ hybridization (Thisse and Thisse, 2008), have motivated the generation of a repertoire of zebrafish mutants and transgenic reporter lines. These data are curated in ZFIN (the Zebrafish Model Organism Database; www.zfin.org), a publicly available, searchable database (Howe et al., 2013a). Furthermore, zebrafish reagents have been centralized by ZFIN's sister organization, ZIRC (Zebrafish International Resource Center; www.zirc.org), a US-government supported center that maintains zebrafish lines, frozen sperm, and reagents for redistribution to the scientific community (Carmichael et al., 2009; Varga, 2011).

3 FORWARD GENETICS: PHENOTYPE-DRIVEN STUDIES OF VERTEBRATE DEVELOPMENT

Long before widespread access to databases or curated genomic sequencing data, zebrafish research was motivated primarily to answer questions about vertebrate embryonic development (Fig. 25.1). Initial genetic screens in any model organism were predated by the practice of enthusiasts to collect animals with unusual traits that likely arose spontaneously. This was a well-known practice for mice, and a series of spontaneous mutants with peculiar phenotypes were collected at major facilities, such as the Jackson Laboratory; however, a major drawback was the investigator's inability to generate a predetermined phenotype of interest for further genetic mapping (Kile and Hilton, 2005). Random mutagenesis revolutionized the ability to create mutant animals; although zebrafish became a laboratory model later than the mouse, the employment of mutagens to conduct efficient forward genetic screening occurred in parallel for both species. Reviewed extensively elsewhere (Lawson and Wolfe, 2011), this "phenotype-first" approach involves the following steps: (1) random, and evenly dispersed introduction of mutations throughout the genome; (2) generation of progeny who harbor recessive mutations using informative breeding schemes; (3) assessment of animals for measurable phenotypic readouts; and (4) identification of the gene and mutation underlying the phenotype. This approach involves significant time, space, and personnel but has served as an important platform to expand our understanding of embryonic development.

The first zebrafish screens were reported in the 1980s and used gamma rays to introduce recessive lethal mutations. However, this resulted in substantial chromosomal breaks and rendered the mapping to a single causal locus challenging (Chakrabarti et al., 1983; Streisinger, 1983). This approach was replaced with a more refined method, treatment of alkylating reagents including *N*-ethyl-*N*-nitrosourea (ENU), resulting in less severe genomic lesions than that of its predecessor through introduction of point mutations at the rate of approximately one mutation per genome (Mullins et al., 1994; Solnica-Krezel et al., 1994). The success of this approach motivated two large scale forward screening efforts in the 1990s; laboratories in Tübingen and Boston applied ENU to zebrafish, and within 2 years, their combined efforts led to the characterization of ~4000 embryonic lethal phenotypes affecting early patterning [e.g., gastrulation (Hammerschmidt et al., 1996; Solnica-Krezel et al., 1996); somitogenesis (van Eeden et al., 1996); notochord formation (Odenthal et al., 1996)]; organogenesis [e.g., brain (Brand et al., 1996; Jiang et al., 1996; Schier et al., 1996); cardiovascular system (Stainier et al., 1996)]; and the

craniofacial skeleton (Neuhauss et al., 1996; Piotrowski et al., 1996; Schilling et al., 1996).

How did the products of forward genetic screens inform genetic findings from humans? The initial torrent of zebrafish ENU screen publications from the December 1996 issue of *Development* (Driever et al., 1996; Haffter et al., 1996), and the ensuing characterization of such mutants contributed significantly to our knowledge of vertebrate development. However, the direct contribution as models of human disease was more modest. There are four primary reasons for this: First, because most forward screen mutants display embryonic lethal phenotypes, many postnatal or adult phenotypes would likely have been missed. Second, the breeding strategy of forward genetics paradigms mandates a recessive mode of inheritance and a loss-of-function effect, excluding the possibility of capturing dominant negative or gain-of-function alleles. Third, the randomness of chemical mutagens means that the chance of recapitulating human variants of interest, especially recurrent point mutations present in human cohorts, is low. Finally, the unique structure of the partially duplicated zebrafish genome is such that a null mutation in a zebrafish locus corresponding to an orthologous human disease gene may produce a negative phenotype. Among the genes for which there is an identifiable human ortholog, 47% have a reciprocal relationship with a human counterpart while the remainder of zebrafish genes have complex one-to-many or many-to-one orthology in comparison to the human gene (Howe et al., 2013b). Especially problematic are zebrafish genes with redundant function; the wild-type duplicate might mask the effects of a null mutation present in only one of the two orthologs. Furthermore, mutation in one of the two orthologous gene partners that have undergone neo- or subfunctionalization would have imperfect recapitulation of the human disease phenotype, thereby confounding mechanistic studies of genes underscoring such human pathologies.

Nonetheless, there are notable examples in which ENU mutants have been successful in drawing anatomical correlates for genes implicated in human disorders with anatomical defects. For instance, the *crusher*[m299] mutant was identified in a craniofacial phenotyping forward screen, and the causal nonsense mutation was mapped to *sec23a* (Lang et al., 2006). Coincident with this discovery, *SEC23A* mutations in humans were shown to cause a clinically relevant craniofacial dysmorphology, craniolenticulo-sutural dysplasia, bolstering the evidence of causality in both species (Boyadjiev et al., 2006). Importantly, the application of WGS (Obholzer et al., 2012) and WES (Ryan et al., 2013), and improved mapping strategies (Leshchiner et al., 2012) to zebrafish ENU mutants has accelerated the speed of gene discovery. As an example, this approach has also generated mechanistic hypotheses for complex traits, such as inflammatory bowel

disease (IBD). In a recent screen to identify mutants with defects in gut epithelium integrity (Ryan et al., 2013), WES of two different mutant larval progeny identified disruption of *uhrf1* and *dnmt1*, both of which have been associated previously in GWAS for IBD risk of onset in humans (Franke et al., 2010). Although infrequent, the intersection of a zebrafish mutant with a human disease locus provides functional information justifying the continued use of forward genetics approaches. Furthermore, forward screen models will maintain an important role in the context human genetics by generating hypotheses to test in human cohorts.

4 REVERSE GENETICS: TESTING CANDIDATE GENES IN ZEBRAFISH MODELS

Forward genetic screening is a powerful method that involves the grouping of phenotypic anomalies and subsequent dissection of the underlying gene and variant to inform aberrant development. However, this approach produces a random distribution of mutations and there is no certainty that targeting will occur in a specific locus of interest. To overcome this limitation, and to circumvent the cumbersome breeding strategy hallmarked by the approach, precise targeting of candidate genes and alleles can be achieved through several methods that have been developed (Fig. 25.1).

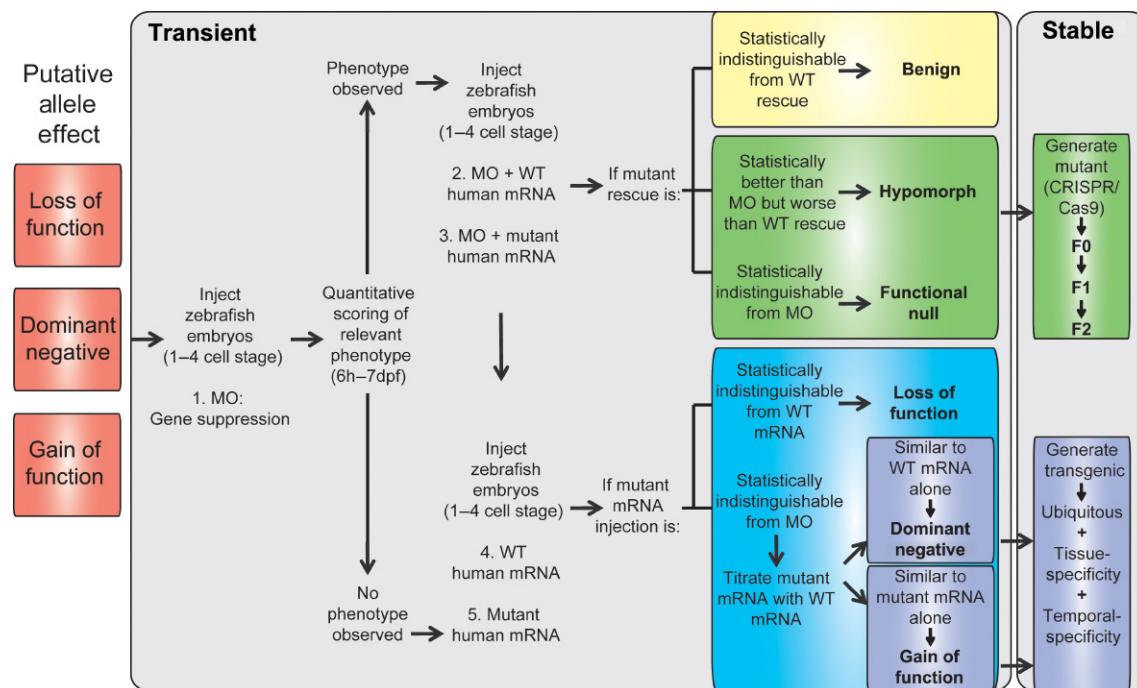
For early patterning and organogenesis phenotypes, transient gene manipulation can be achieved through the injection of either morpholino (MO) antisense oligonucleotides (gene suppression) or capped in vitro transcribed mRNA (ectopic expression) into zebrafish embryos. MOs are stable molecules that consist of a large, nonribose morpholine backbone with the four DNA bases pairing stably with mRNA at either the translation start site (to disrupt protein translation), or at exon–intron boundaries (to inhibit mRNA splicing) (Summerton and Weller, 1997). In 2000, Nasevicius and Ekker showed the first effective gene knockdown in zebrafish embryos; they injected MOs targeting five different genes shown previously through forward genetics to cause embryonic lethal phenotypes, and reproduced the mutant defects. Further, they suppressed *urod* and *shh* as a proof of concept to model the human genetic disorders hepatoerythropoietic porphyria and holoprosencephaly, respectively (Nasevicius and Ekker, 2000). Since this report, thousands of studies have used this technology to expand our knowledge of vertebrate developmental mechanisms and to mimic human pathologies. Additionally, in vivo complementation approaches—coinjection of MO and capped human mRNA harboring either wild-type or human mutant versions of a gene followed by statistical comparisons of rescue efficiency


FIGURE 25.2   **In vivo complementation assay to test variants of uncertain significance.** Nonsynonymous variants, in-frame insertion/deletions, or truncating mutations that are not subject to nonsense-mediated decay can be assessed in zebrafish using the following approach. Briefly, the assay begins with (1) suppression of a gene of interest using MOs, and subsequent quantitative scoring of a phenotype relevant to the human pathology. If a phenotype is observed, the assay proceeds to loss-of-function tests. If the knockdown results in a phenotype that can be rescued similarly with (2) wild type *(WT)* and with (3) mutant mRNA, the allele is likely a benign variant *(yellow box)*. If the mutant rescue is statistically improved from MO, but worse than WT, the allele is a hypomorph *(green box)*; and if the MO and mutant rescue are indistinguishable, the variant is a functional null *(green box)*. To recapitulate transient phenotypes, a genome-editing technology, such as CRISPR/Cas9 should be employed to generate founder (F0) and subsequent stable mutants (F1 and F2). For dominant tests, if the injection of (4) WT mRNA or (5) mutant mRNA do not yield a phenotype, this indicates that the variant is a loss-of-function or the assay may have failed *(blue box)*. If the mutant mRNA alone results in a phenotype that can be titrated with increasing doses of WT mRNA to rescue the phenotype, it is likely to be a dominant negative *(lavender box)*; if the titration of mutant mRNA with WT mRNA is indistinguishable from mutant mRNA alone, the allele is scored as a gain-of-function variant *(lavender box)*. Stable transgenesis can be used to induce ectopic expression of human genes harboring dominant negative or gain-of-function variants; if ubiquitous expression results in embryonic lethality, tissue-specific or temporal-specific approaches can be used to study variant effects. *Source: Figure adapted from Niederriter, A.R., Davis, E.E., Golzio, C., Oh, E.C., Tsai, I.C., Katsanis, N., 2013. In vivo modeling of the morbid human genome using* Danio rerio. *J. Vis. Exp. 78, e50338.*

(Fig. 25.2)—have been used to test variant pathogenicity (Niederriter et al., 2013); to determine direction of allele effect (loss-of-function, dominant negative, or gain-of-function) (Niederriter et al., 2013); to dissect isoform-specific effects on variant pathogenicity (Borck et al., 2015; Sarparanta et al., 2012; Schulte et al., 2014); to test evolutionary genomic hypotheses, such as *cis* compensation (Jordan et al., 2015); and to test whether pathway-specific modulation with small molecule compounds can ameliorate zebrafish phenotypes analogous to human pathologies (Bogershausen et al., 2015).

Some 15 years of broad MO use has propelled multiple discoveries, but it is not a panacea. There are multiple drawbacks to this reagent that include: (1) limited efficacy to the first 3–5 days postfertilization (Nasevicius and Ekker, 2000); (2) with few exceptions, injected MOs and mRNAs do not confer spatial or temporal specific activity (Shestopalov et al., 2007); and (3) MOs can produce nonspecific developmental phenotypes due to

off-target effects (Eisen and Smith, 2008). Still, for transient studies of early developmental phenotypes, the MO remains a valuable reagent that can enhance human genetic studies, provided that appropriate experimental controls are employed. Such controls include: (1) direct demonstration of efficient gene-specific knockdown; this can be accomplished through either immunoblot for translation blocking MOs (dependent upon antibody availability), or RT-PCR studies for splice-blocking MOs; (2) significant and reproducible rescue of MO phenotypes with coinjection of orthologous wild-type RNA; (3) observation of similar phenotypic outcomes when two or more MOs targeting different sites of the gene are injected independently; (4) phenotypic similarities with a stable mutant; and (5) when possible, demonstration that injection of MO into embryos harboring a null allele in the same target gene do not induce additional phenotypes (Eisen and Smith, 2008; Kok et al., 2015; Rossi et al., 2015).

Independently of MOs, the molecular techniques to develop germline zebrafish mutants for a gene of interest have evolved substantially. Iterative refinement of zebrafish mutant approaches have been motivated, in part, by some key limitations of MOs, including phenotypic variability and the restriction to anatomical assessment in early larval stages. Targeting-Induced Local Lesions in Genomes (TILLING) was the first reverse genetic approach to produce germline mutations (Wienholds et al., 2002). Similar to forward screens, TILLING harnesses the mutagenic properties of ENU to introduce mutations into male zebrafish sperm, and then generate F1 families. Sperm from F1 males is cryopreserved while genomic lesions are screened in target genes. This was accomplished initially by PCR amplicon screening in early exons or critical protein domains, and is now carried out by WES to augment mutant discovery rates; at the initial time of publication, TILLING mutants were reported for ~38% of all known zebrafish protein coding genes (Kettleborough et al., 2013). This corresponds to ~60% of orthologous genes associated with a human phenotype in the Online Mendelian Inheritance in Man (OMIM; http://www.omim.org) database and has expanded to >36,000 mutant alleles (www.sanger.ac.uk/Projects/D_rerio/zmp), although it is not clear how many of these are genuinely recoverable to propagate mutant lines. While the TILLING efforts have generated a comprehensive resource of putative loss-of-function or hypomorphic models of human genetic disorders, there is the possibility that ENU may have introduced lesions at multiple sites in the genome. Therefore, it remains critical to obtain multiple mutant alleles in a gene of interest for phenotypic characterization to ensure specificity of the pathology. These guidelines also apply to transposon (Sivasubbu et al., 2007) or retrovirus (Wang et al., 2007) insertional mutants developed using similar reverse genetics approaches.

Neither forward ENU screens nor reverse TILLING approaches are experimentally tractable; fortunately genome-editing techniques have propelled the utility of zebrafish further by enabling precise and germline transmittable gene targeting that does not require excessive downstream screening to identify mutations (Wijshake et al., 2014). One approach, zinc finger nucleases (ZFN), employs a zinc finger array to target specific genomic regions (usually in the early exon of a gene), and *FokI* endonuclease guides cleavage and repair at a target cleavage site (Urnov et al., 2010); this approach was first used to generate proof-of-principle models that altered pigment formation (*gol* locus); disrupted early embryogenesis (*ntl*), or resulted in aberrant vascular endothelial growth (*kdr*) (Doyon et al., 2008; Meng et al., 2008). Second, transcription activator-like TAL effector nucleases (TALEN) emerged as a locus-specific genome editing approach that has demonstrated improved

specificity and superior germline efficacy than that of ZFN, accompanied by reduced technical costs (Bedell et al., 2012). The most recently developed genome-editing technology involves clustered, regularly interspaced, short palindromic repeats (CRISPR), which are bacterial type II systems that guide RNAs unique to a target site in the genome to drive DNA cleavage by the Cas9 endonuclease (Hwang et al., 2013). Subsequent repair of this event will either induce small insertions or deletions, or accomplish knock-in of sequence with a repair template. In a short period of time, multiple human genetic studies have reported the use of MO alongside CRISPR/Cas9 models to support human-driven WES/WGS studies. Notable examples include CRISPR/Cas9 mutagenesis of the *gata5* locus mimicking the *faut^{m236a}* zebrafish mutant and humans with congenital heart defects (Chang et al., 2013; Reiter et al., 1999); recapitulation of the human macrocephaly and gut phenotypes in humans with *CHD8* mutations that were reproduced in one CRISPR/Cas9 founder mutant (F0) model and four different *chd8* MO models (Bernier et al., 2014); modeling of *mmp21* in a rare human laterality disorder with morphant and CRISPR/Cas9 F0s (Perles et al., 2015) (Fig. 25.3); and modeling of the vertebrate hedgehog effector *PTCH1* as a candidate microphthalmia locus in which two MO and one CRISPR/Cas9 F0 zebrafish models displayed eye size phenotypes reminiscent of the *leprechaun* mutant (Bibliowicz and Gross, 2009; Chassaing et al., 2016).

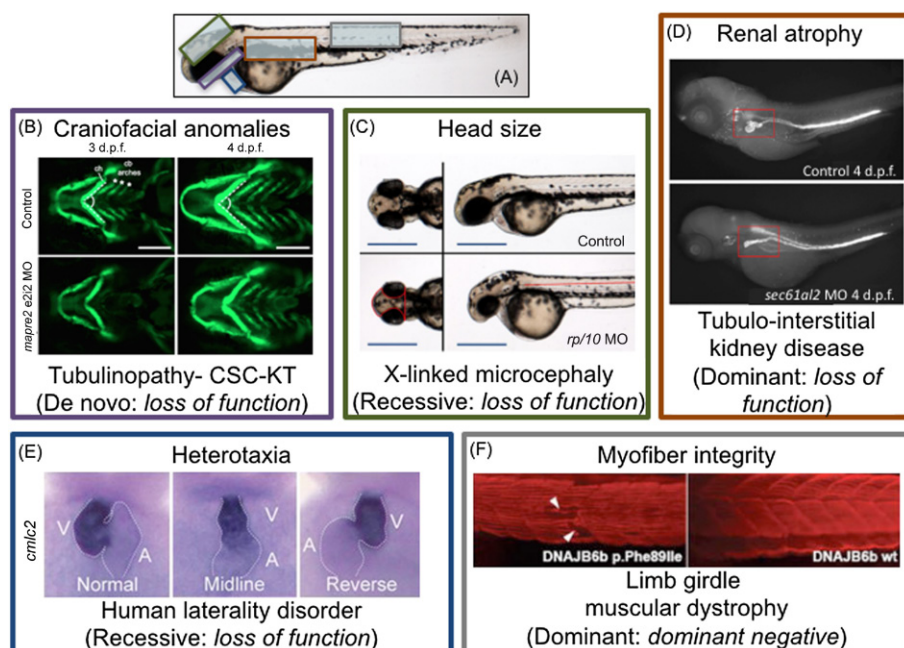
Although a multitude of studies have now shown that MOs and CRISPR/Cas9 often produce equivalent, or at least overlapping phenotypes, there have also been reports of discordance. Two publications in 2015 highlighted an absence of phenotype in mutant models of vascular development, which disagreed with clear phenotypes in MO-induced zebrafish models. First, Kok et al. (2015) selected more than 20 genes with previously published morphant phenotypes, and used ZFN, TALEN, or CRISPR/Cas9 to generate null mutations in each gene; they observed mutant phenotypes in only a minority of genes assessed and concluded that MOs produce a high false-positive rate. However, an independent study that probed the discrepant phenotypes of endothelial extracellular matrix gene morphants and mutants corresponding to *egfl7* and *vegfaa*, showed that compensatory networks can be activated in mutants (but not morphants) to buffer against phenotype-inducing thresholds (Rossi et al., 2015). While these studies have motivated the zebrafish community to assess critically the best practices for transient gene suppression approaches, they have also opened the tantalizing possibility that genetic compensation can account for phenotypic differences across different strains or species in the context of loss of orthologous gene function. Assessment of additional genes with diverse functions will


FIGURE 25.3 **Zebrafish models of human genetic disease.** In vivo assays in zebrafish can be applied to determine the physiological relevance of a candidate gene in various organ systems; these models can then be used to determine the direction of allele effect (i.e., loss-of-function or dominant negative) underlying diverse inheritance patterns. be required to determine whether or not this is a widespread phenomenon.

5 HUMANIZING ZEBRAFISH TO STUDY HUMAN GENETIC VARIATION

An expanding number of reports have demonstrated the ability of zebrafish to assist with the dissection of allele causality under Mendelian paradigms, as well as more complicated phenomena including oligogenic disorders and contiguous gene syndromes. Certainly, there are some experimental limitations, including a lack of orthology for ~30% of human genes in the zebrafish genome (Howe et al., 2013b), and the technical challenges

associated with in vitro transcription of mRNA >6 kb in length (Niederriter et al., 2013). Even so, the major benefits of zebrafish—experimental tractability and cross-species structural and functional conservation—have been harnessed to establish: (1) physiological relevance of gene alteration to human pathology; (2) variant pathogenicity, especially for nonsynonymous changes; and (3) direction of allele effect for a multifarious array of human genetic conditions with diverse modes of inheritance, phenotypes, and ages of onset.

5.1 Single Gene Effects in Mendelian Disease

Zebrafish have been instrumental in modeling disorders that segregate primarily under a recessive mode

of inheritance, especially congenital or childhood onset conditions with an orthologous anatomical structure. Through different strategies, zebrafish have provided layers of evidence to support the candidacy of a gene/allele in disease. Regardless of whether the genetic evidence is strong (multiple cases harboring unambiguous loss-of-function variants in the same gene); or exemplifies an "n-of-one" (ultra-rare condition in which a single case has rare variation that is predicted to impact protein function), a starting point in modeling recessive conditions is to recapitulate the disease phenotype in a zebrafish model. For instance, zebrafish have provided mechanistic insight into primary ciliary dyskinesia (PCD), a condition observed in 1/10,000 live births that is caused by almost exclusively null changes (nonsense, frameshift, or splice-site) (Praveen et al., 2015). Transient MO-based studies have shown that proteins of a priori unknown function including *CCDC39*, *ARMC4*, and *ZMYND10* give rise to left–right asymmetry defects in zebrafish that are consistent with the situs inversus phenotypes observed in affected humans (Hjeij et al., 2013; Merveille et al., 2011; Zariwala et al., 2013). A more poignant problem in clinical genetics, however, is the challenge of supporting the candidacy of ultra-rare alleles in isolated cases or pedigrees. Community efforts to identify multiple rare cases with mutations in the same gene (Sobreira et al., 2015) can be unfruitful, necessitating the use of an animal model (Hieter and Boycott, 2014). This can be especially challenging for the clinically heterogeneous neurodevelopmental defects that encompass microcephaly, intellectual disability, autism spectrum disorders, and structural anomalies of the brain. One example is the identification of a rare missense mutation in the 60S ribosomal protein component gene *RPL10* that segregated with microcephaly in three males of a single X-linked pedigree. Suppression of the gene in zebrafish embryos resulted in a significant reduction in larval head size (Fig. 25.3), and in vivo complementation with mutant mRNA failed to rescue the phenotype indicating that the p.K78E variant shared by affected individuals was a loss-of-function allele (Brooks et al., 2014). Clinical relevance and variant pathogenicity was also determined in a similar fashion for a candidate pontocerebellar hypoplasia locus, *EXOSC3*, encoding exosome component 3. Wan et al. (2012) identified nonsynonymous changes in four affected siblings through WES, and used zebrafish assays to demonstrate that the cerebellar phenotype could be mimicked in zebrafish *exosc3* morphants, and that coinjection of human mRNA harboring these changes failed to rescue the neuroanatomical defect. Finally, the use of complementation studies have uncovered apparent isoform-specific effects in recessive neurological disease, such as the observation that candidate missense changes present in both *BRF1* transcripts, encoding B-related factor involved in RNA transcription, are only deleterious in the short protein isoform implicating it specifically in cerebellar hypoplasia and intellectual disability (Borck et al., 2015).

Differing from recessive conditions, in which the variant is more likely to result in a loss of protein function, traits that segregate in an autosomal dominant paradigm could be the result of three mechanisms: (1) loss-of-function; (2) gain-of-function; or (3) dominant negative. A heterozygous null variant in some pediatric-onset dominant diseases that segregates in multiple affected individuals in a multigenerational pedigree is often sufficient to suggest a haploinsufficiency model; this has been confirmed in zebrafish through MO-induced gene suppression. For example, dilated cardiomyopathy is caused by ablation of the gene encoding heat shock protein cochaperone BCL2-associated athanogene 3 (*BAG3*), and knockdown studies in zebrafish reproduce the human cardiac defects (Norton et al., 2011). Likewise, autosomal dominant tubule-interstitial kidney disease (ADTKD) has been modeled in zebrafish to show both phenotypic relevance and loss-of-function effects of putative causal alleles. CRISPR/Cas9 F0 mutants and morphants of *sec61a1* displayed renal tubular atrophy consistent with the human phenotypes (Fig. 25.3); and assay of two different missense changes suggested that allelism at that locus was consistent with patient severity (a functional null in the syndromic ADTKD pedigree; a hypomorphic variant in the family with renal disease and anemia) (Bolar et al., 2016).

Not all dominant conditions are the result of insufficient dose, however, and injection of human mRNA bearing a mutation can uncover dominant negative effects in developing zebrafish. One example is the transient functional study of the cochaperone DNAJB6, mutations which cause adult-onset limb girdle muscular dystrophy (Sarparanta et al., 2012). Coinjection of mutant *DNAJB6* mRNA in the presence of equivalent amounts of wild-type transcript resulted in myofiber defects in zebrafish embryos (Fig. 25.3); injection of increasing amounts of wild-type mRNA with a fixed concentration of mutant transcript resulted in a phenotypic rescue, suggesting the dominant toxicity of the mutant alleles. Given the nature of dominant mutations (pathogenic in heterozygosity), the use of zebrafish to investigate such disorders will likely remain restricted to transient MO, CRISPR/Cas9 F0, or mRNA-based studies until the refinement of more tractable gene suppression/expression techniques in zebrafish has been achieved.

In addition to recessive or dominant inheritance, variants can arise de novo; these phenomena are significant contributors to the human mutational burden (Veltman and Brunner, 2012). Similar to dominant inherited disorders, de novo variants can either cause haploinsufficiency, novel allele function, or dominant negative effects. Therefore use of an unbiased approach to discern the

direction of allele effect is critical. For example, zebrafish were employed to study de novo missense mutations in *CACNA1C*, encoding the voltage-gated calcium channel Cav$_{1.2}$, in Timothy syndrome (TS), a pediatric disorder hallmarked by cardiac arrhythmias, syndactyly, and craniofacial dysmorphisms. Expression of mutant mRNA and suppression of *cacna1c* in zebrafish larvae not only showed that the mutation confers a gain-of-function effect, but also demonstrated a novel role for Cav1.2 in the nonexcitable cells of the developing mandible (Ramachandran et al., 2013). Taken together, these Mendelian examples demonstrate the diversity of zebrafish as a tool to characterize diverse pathomechanisms.

5.2 Second-Site Modifiers and Oligogenic Effects

Dissection of second-site phenotype modification in primarily recessive human genetic disorders is a challenge, primarily due to the power limitations of small cohorts. However, multiple modifier and oligogenic hypotheses have been tested successfully in zebrafish and the ciliopathies epitomize this approach. Underscored by the structural or functional defects of the primary cilium, the ciliopathies have been causally linked with >100 different loci and can give rise to a constellation of human phenotypes (Davis and Katsanis, 2012). Dissection of the genetic architecture of Bardet–Biedl syndrome (BBS), a ciliopathy characterized by retinal degeneration, truncal obesity, postaxial polydactyly, renal abnormalities and intellectual disability, using zebrafish models demonstrated: (1) the pathogenic potential of >100 alleles identified in cases, most of which are nonsynonymous changes; (2) revealed an unexpected contribution of dominant negative variants in oligogenic pedigrees with BBS; (3) provided sensitivity (98%) and specificity (82%) metrics for the in vivo complementation assay to predict allele pathogenicity; and (4) has suggested that as many as >50% of cases have one to four additional heterozygous deleterious variants in BBS genes outside of the primary causal locus that interact either additively or synergistically to aggravate phenotype (Lindstrand et al., 2016; Zaghloul et al., 2010). Transient zebrafish in vivo complementation assays have similarly been used to support the *RPGRIP1L* p.A229T as a modulator of retinal endophenotypes in ciliopathies (Khanna et al., 2009); *TTC21B* as a common contributor to mutational burden in ciliary disease (Davis et al., 2011); *RET* as a modifier of Hirschsprung phenotypes in BBS (de Pontual et al., 2009); and trans-heterozygous interaction between *DNAH5* and *DNAH6* as a likely molecular basis for the heterotaxy phenotypes of some PCD cases (Li et al., 2016). Increased genetic resolution of oligogenic phenomena in disorders such as the ciliopathies offers a platform to test tractability thresholds in zebrafish (Lindstrand et al., 2016); it is unclear whether coinjection

of more than two or three MOs will still yield meaningful results.

Although the semiclosed organellar basis of the ciliopathies makes them a tractable model to study epistasis, the use of zebrafish modeling is not exclusive to this class of disorder. Notably, zebrafish interaction studies were used to support the candidacy of homozygous digenic mutations in *OTUD4* and *RNF216*, encoding components of the ubiquitin system, as the genetic basis of ataxia with hypogonadotropic hypogonadism (Margolin et al., 2013). Compared to exacerbative multigene effects, protective effects are even more challenging to identify in human genetics. For example, spinal muscular atrophy (SMA) is caused by mutations in *SMN1*, but mutation-bearing unaffected individuals have been shown to overexpress plastin 3 (*PLS3*). To test the putative protective effects of *PLS3* or *CORO1C*, another F-actin binding protein, in the absence of *SMN1*, these genes were overexpressed and suppressed in zebrafish larvae and phenotyped using axon length and growth measures (Hosseinibarkooie et al., 2016; Oprea et al., 2008).

5.3 Contiguous Gene Syndromes

Frequently arising de novo, CNVs account for a significant proportion of the molecular basis of human genetic disease (Carvalho and Lupski, 2016). This class of variation can range in size from a few thousand to millions of base pairs; is not identifiable by conventional chromosomal banding; and in the absence of specific depth of coverage algorithms, can also be missed by WES (Katsanis and Katsanis, 2013). Thus, the augmented use of array comparative genomic hybridization (aCGH), and SNP arrays in recent years has uncovered a plethora of CNVs, with the progressive transition to whole genome sequencing expected to enrich the catalogs of this mutational class further. Although genotype–phenotype correlations among affected individuals with either overlapping CNVs, or clinical comparisons of individuals with deleterious point mutations in genes that are encompassed by CNVs, can assist in narrowing specific genetic drivers, this class of genomic lesion has been historically intractable to functional study (Lindsay, 2001). Until recently, the majority of reports aiming to elucidate human CNVs utilized the mouse, and rather than unbiased systematic generation of mutants corresponding to each gene within the CNV, mutants are prioritized typically because of a priori biological function that could pertain to patient phenotype (Iyer and Girirajan, 2015). Some notable examples include the *Rai1* null mutant or overexpression models that recapitulate most neurological, body mass, and craniofacial aspects of the reciprocal 17p11.2 CNV (Bi et al., 2005; Walz et al., 2003); or the *Tbx1*$^{-/-}$ mouse that has demonstrated the cardiac and craniofacial anomalies associated with 22q11.2 deletion syndrome

(Lindsay et al., 2001). Because of their superior experimental tractability in comparison to mammalian counterparts, zebrafish have emerged, recently, as a robust model to dissect both recurrent and nonrecurrent CNVs. Shown previously to model CNVs in malignant tumors (Ceol et al., 2011), one of the first reported examples to dissect a germline CNV in zebrafish was the systematic assessment of 29 genes in the recurrent reciprocal 16p11.2 duplication/deletion CNV. This locus is associated with neurocognitive defects that include intellectual disability, autism spectrum disorder, and epilepsy for either the deletion or duplication, and schizophrenia that is associated primarily with the duplication CNV (McCarthy et al., 2009; Weiss et al., 2008). Using mRNA suppression and overexpression, and focusing on the mirrored macro- and microcephaly phenotypes as directly relevant and measurable readouts for the mirrored CNVs, respectively, Golzio and coworkers showed that *KCTD13* is the major driver of head size phenotypes in zebrafish. Additionally, pairwise gene modulation of *KCTD13* and every other gene in the 16p11.2 region followed by head size measurement of embryo batches revealed that mitogen-activated protein kinase 3 (*MAPK3*) and major vault protein (*MVP*) interact genetically with *KCTD13* to worsen the phenotype (Golzio et al., 2012). In another example of CNV dissection, MO-induced knockdown of three genes orthologous to the 8q24.3 nonrecurrent deletion CNV showed that the loci encoding the planar cell polarity effector *SCRIB*, and the splicing factor, *PUF60* were the major drivers of phenotype. Both genes were implicated synergistically in the neurological and short stature phenotypes; whereas *SCRIB* appeared to be the main contributor to the renal abnormalities and coloboma; and *PUF60* ablation was linked to the cardiac phenotypes observed in the five individuals harboring overlapping microdeletions in the genomic region on 8q (Dauber et al., 2013). Finally, in vivo dissection of the 17p13.1 CNV, the underlying cause of a microdeletion syndrome involving intellectual disability, poor to absent speech, dysmorphic features, and microcephaly, showed that the combinatorial effects of at least three genes likely cause the head size defects in affected individuals. Dosage perturbation of the nine genes localized to the minimal interval the 17p13.1 locus revealed that at least three transcripts (*ACADVL*, *DVL2*, and *GABARAP*) are the major drivers of neurodevelopment phenotypes (Carvalho et al., 2014). Together, these studies demonstrate how zebrafish have provided insight into penetrance and phenotypic variability of reciprocal CNVs. The single-gene tests and genetic interaction assays have helped to classify a growing number of CNVs into recently described paradigms to explain clinical manifestation in cases. The 16p11.2 CNV exemplifies the *cis*-epistasis simplex CNV model in which one or multiple genes are necessary and sufficient to cause phenotypes but epistasis interactions modulate the expressivity and penetrance of the phenotype; or the 8q24.3 CNV typifies the *cis*-epistasis complex CNV model in which multiple primary driver genes are sufficient to cause independent or similar phenotypes (Golzio and Katsanis, 2013).

5.4 From GWAS to Biology Underlying Complex Traits

Unlike penetrant Mendelian alleles or driver genes in CNVs, GWAS are more likely to detect loci of modest effect. One consequence of this is that GWAS alone have been challenged to link risk loci with genes, while poor statistical power and scant functional data hamper the identification of potential epistatic interactions. However, recent reports have indicated promise for the utility of zebrafish to dissect genes at or near loci that confer significant risk for some complex traits. Rare alleles identified after GWAS and targeted resequencing of the associated locus are reasonably straightforward to study; the experimental paradigm is similar to that of Mendelian conditions. For example, combined in vitro analysis of enzyme stability with vascular integrity studies in the larval retina demonstrated a critical role for a rare variant in *CFI*, the gene encoding complement factor I, thus providing direct evidence supporting a loss of CFI function in age-related macular degeneration (AMD) (van de Ven et al., 2013). Similarly, in vivo complementation assays were critical to show pathogenicity for a rare missense change (p.I397V) in *BBS10* shown to be associated with type 2 diabetes (T2D) in Finnish individuals (Lim et al., 2014). Importantly, this study demonstrated a phenotypic continuum in which loss of function of a gene causing a Mendelian disorder (BBS) could also contribute to a complex trait (T2D).

Zebrafish have also been employed to test the physiological relevance of novel risk loci in the absence of underlying rare variants. For example, functional testing of loci associated with platelet count in cohorts of European ancestry identified 11 novel genes implicated in *D. rerio* blood cell formation (Gieger et al., 2011). Additionally, Liu et al. conducted a GWAS to identify risk factors for chronic kidney disease in African American populations. To assess the physiological relevance of candidate loci, they suppressed orthologous zebrafish genes systematically and analyzed glomerular filtration defects in zebrafish; these efforts yielded *KCNQ1* as a functionally relevant candidate (Liu et al., 2011). In addition, zebrafish have been instrumental in dissecting the relative contribution of the chromosome 22q12 locus, encompassing *APOL1* (apolipoprotein L1), and *MYH9* (myosin heavy chain IIA), to nephropathy risk in African Americans with sickle cell disease (SCD). Suppression or CRISPR/Cas9 genome-editing of *apol1* and *myh9* in zebrafish independently give rise to proteinuria (Anderson et al., 2015;

Muller et al., 2011), and in vivo complementation with human mRNA harboring the common *APOL1* coding G1 (encoding p.S342G and p.I384M in *cis*) or G2 (encoding p.N388del:Y389del) risk alleles indicated that both changes are pathogenic. Importantly, a genetic interaction between *APOL1* and *MYH9* loci could only be detected in zebrafish renal models in the context of anemic stress, a surrogate for SCD (Anderson et al., 2015). These exemplars provided an entry point into biology. Further work remains to dissect the combinatorial effects of multiple GWAS hits; to probe the mechanistic basis for promoting disease risk; and to develop tools to assess noncoding association loci.

6 MODELING ADULT ONSET DISEASE IN EMBRYONIC OR LARVAL STAGES

With some exceptions, the majority of the applications of zebrafish to study human genetic disorders have been focused on genes and variants identified in congenital and pediatric conditions. Nevertheless, there are multiple instances in which zebrafish have been useful in the study of adult-onset disorders through either: (1) the ability to generate a directly related phenotype in zebrafish larvae that is similar/relevant to the adult-onset disorder; (2) assessment of a surrogate (indirectly or partially related) phenotype in early zebrafish development that is relevant to the gene function of the human condition; or (3) development of a stable mutant (loss-of-function) or transgenic (gain-of-function or dominant negative) zebrafish raised to adulthood. Adult-onset muscular dystrophies represent one example; most patients with *DNAJB6* mutations had an age of onset ranging from 20 to 60 years, yet myofiber detachment was detected in zebrafish larvae at 2 days postfertilization (Sarparanta et al., 2012). AMD was another adult-onset example. Although macular degeneration is not a phenotype that can be assessed in zebrafish embryos, vascular integrity is a quantitative phenotype that can be scored in larval stages and is relevant to AMD pathology (van de Ven et al., 2013). Finally, there are certain conditions in which adult zebrafish is the optimal model, particularly for adult neurodegenerative conditions, such as schizophrenia, Huntington, Parkinson, and Alzheimer disease [reviewed extensively in (Bandmann and Burton, 2010; Best and Alderton, 2008)], and have involved stable mutant or transgenic models. In one study that modeled neurodegeneration, expression of human 4-repeat Tau showed TAU accumulation within neuronal cell bodies and axons in neurons throughout the adult brain, reminiscent of neurofibrillary tangles (Bai et al., 2007). Some human phenotypes, such as the behavioral phenotypes diagnostic of psychiatric disease, are not immediately observable through anatomic or histological methods,

making it necessary to employ more sensitive methods of analysis. For this purpose, memory and learning assays (Fernandes et al., 2016) and conditioned avoidance studies (von Trotha et al., 2014) can be employed in adult fish to detect subtle behavioral abnormalities.

7 THERAPEUTIC DISCOVERY IN ZEBRAFISH MODELS OF DISEASE

An ever-increasing repertoire of human disease models has been generated in zebrafish. Not only has this resource been useful in establishing the relevance of a candidate gene to human pathology, but it has also informed the direction of effect of mutations. A natural extension of this paradigm is to use zebrafish models to identify novel therapeutic avenues. In addition to conserved genomic content and physiology, zebrafish also has documented conservation of pharmacology and drug metabolism akin to that of human (e.g., functioning livers, blood–brain barriers, and kidneys) (Jeong et al., 2008; Li et al., 2011). Furthermore, the combined experimental tractability in which embryos will uptake small molecules when bathed in media, combined with the widespread availability of well-characterized tool compounds or FDA-approved chemical libraries make zebrafish an attractive choice for high-throughput screening. Although reviewed extensively elsewhere (MacRae and Peterson, 2015; Tan and Zon, 2011; Zon and Peterson, 2005), there are several notable examples in which treatment of zebrafish disease models with small molecules have been successful. In some instances, the known function of the human disease gene is sufficient to suggest a candidate therapeutic modulator in zebrafish; this was true for the recent identification of *NANS*, the causal gene underlying an infantile-onset severe developmental delay and skeletal dysplasia disorder. *NANS* encodes the synthase for *N*-acetylneuraminic acid (NeuNAc; sialic acid). MO-induced suppression of the zebrafish ortholog *nansa* recapitulated the abnormal skeletal development and, crucially, could be rescued with exogenous treatment with sialic acid (van Karnebeek et al., 2016). In other examples, modulation of a signaling pathway with a small molecule can restore signaling output, and thus improve the disease phenotype. Mutations in *RAP1A* have been implicated as a molecular cause of Kabuki syndrome, a congenital disorder with a characteristic facial gestalt and accompanying intellectual disability, short stature, cardiac, and renal anomalies (Bogershausen et al., 2015). Suppression or CRISPR/Cas9 mutation of the zebrafish orthologs, *rap1a* and *rap1b*, reproduced the mandibular defects observed in patients and elucidated the involvement of known Kabuki syndrome genes in MEK/ERK signaling; administration of the MEK inhibitor PD184161 was shown to

improve relevant phenotypes in zebrafish (Bogershausen et al., 2015).

In addition to candidate treatment approaches, large-scale phenotypic screens have also shown promise in either uncovering repurposing opportunities for known drugs, or discovering novel compound classes. For example, disruption of *ACVR1* activates the bone morphogenetic protein (BMP) type I receptor and causes fibrodysplasia ossificans progressiva (FOP), a congenital disorder of progressive postnatal ossification of soft tissues (Shore et al., 2006). By screening a diverse chemical library of 7500 compounds, Yu et al. (2008) identified a pyrazolopyrimidine called dorsomorphin as a BMP inhibitor that could compensate for the overactive signaling induced by *ACVR1* mutations; this compound, and its derivatives, are currently in mammalian trials for FOP (MacRae and Peterson, 2015). In sum, zebrafish phenotype screens have potential to contribute to novel therapeutic development for human genetic disorders, but are contingent upon a robust and quantifiable phenotype that can be assessed in an automated fashion. Further work is required to characterize compound exposure in zebrafish, and to understand how timing and delivery in zebrafish is relevant to that of human. Nonetheless, the increasing number of phenotype screens in zebrafish is testament to its growing niche in drug development.

8 CONCLUSIONS: THE FUTURE OF ZEBRAFISH AS A HUMAN GENETIC DISEASE MODEL

Here, we have highlighted how the zebrafish has emerged as a tractable animal model system both to inform the architecture of human genetic phenomena, and also to generate hypotheses that can be tested in human cohorts. As genomic data from human cohorts continues to amass, the community will continue to grapple with variant interpretation, as well as establishment of direction of effect as a necessary preamble to understanding pathomechanism. Zebrafish represents a premier tool by offering the benefits of high genomic and physiological conservation to that of humans, while maintaining ease of use and low cost. To keep pace with human genomics, however, further refinements are essential. These include: (1) to diversify the modulation parameters of the zebrafish genome in discrete spatiotemporal contexts; (2) to improve the resolution at which phenotypes are assessed, while still maintaining speed and throughput; and (3) to improve our ability to study noncoding regions of the genome. First, much of the utility of zebrafish has come from transient models in which MO-induced gene suppression or mRNA injection has been employed to elicit short-term, and finite effects during the first few days of development. Genome-editing tools, especially

CRISPR/Cas9, have offered a rapid new reverse genetics approach; we anticipate further refinement of this method through the use of tight spatiotemporal regulation mediated by transgenic Cas9 expression driven by tissue-specific promoters (Ablain and Zon, 2016). Further, the employment of multiplexed CRISPR/Cas9 strategies (Jao et al., 2013) and knock-in approaches using repair templates (Auer et al., 2014) will accelerate our ability to model human genetic conditions while also enabling greater precision.

Our capacity to assess measurable phenotypic differences in zebrafish is dependent upon the ability to resolve the anatomical structure of interest, and the time involved to record these data for large batches of embryos. The classic methods of RNA in situ hybridization, tissue sectioning, and histological processing are cumbersome and offer a mere snapshot of a single time point or context. New technologies have emerged to catalog either normal or diseased zebrafish phenotypes with exquisite detail down to the level of individual cells with microcomputed tomography (micro-CT) (Cheng et al., 2016); however, it will likely require augmented throughput capacity before it is embraced broadly by the community. In parallel, automated imaging technologies have been developed to overcome manual orientation challenges associated with whole-mount imaging (Pardo-Martin et al., 2010). One system, the Vertebrate Automated Screening Technology (VAST) has been used to acquire images of the larval craniofacial skeleton to model a novel tubulinopathy in humans caused by mutations in *TUBB* or *MAPRE* (Fig. 25.3), which is hallmarked by dysmorphic facial features, circumferential skin creases, and intellectual disability (Isrie et al., 2015). Development of additional transgenic reporter lines that demarcate organ systems or cell types of interest will be critical to advance further the automation of live imaging, or indeed the defined transcriptomic profiling of zebrafish in specific spatiotemporal contexts (Junker et al., 2014).

Finally, as with all laboratory model organisms, it is important to be cognizant of the limitations of the zebrafish system. Although there is substantial conservation between zebrafish and human physiology, there are some organ systems that are intractable in zebrafish (e.g., pulmonary physiology). Furthermore, there are certain processes that are either divergent from human, or have not yet been elucidated fully in zebrafish. Notably, sex determination in zebrafish remains poorly understood; *D. rerio* lack heteromorphic sex chromosomes, and genetic regions on chromosomes 4, 5, and 16 have been associated but not fine-mapped to the level of the contributory genes (Nagabhushana and Mishra, 2016; Wilson et al., 2014). Further, the majority of zebrafish models of human disease have focused on coding regions of the genome that have greater sequence conservation, rather

than regulatory regions and intergenic sequences associated with disease. Whole human genomes will continue to be generated, and further GWAS predicting noncoding loci to confer risk for complex traits will be uncovered; therefore, use of the zebrafish to study intergenic regions must expand. This work is possible in some instances, but examples are still sparse, such as the testing of multiple noncoding sequences within the regulatory domain of *IRX3*, associated with obesity in humans. This approach identified transgenic expression of a reporter gene in the zebrafish pancreas; and suppression of the *irx* transcript resulted in the physiologically relevant reduction in the number of pancreatic beta cells (Ragvin et al., 2010).

In summary, *D. rerio* is a small fish that has had a large impact on informing human genetic disease. We expect that the continued expansion of the molecular toolkit; increased phenotyping throughput capacity; and improved resolution of anatomical and molecular signatures will be necessary to achieve a saturated understanding of the morbid human genome and to eventually elucidate novel therapeutic avenues.

O U T L I N E

1 INTRODUCTION

Laboratory rodents are most widely used as models in basic biomedical research due to their high cost effectiveness, easy handling and the availability of tools for the genetic and environmental standardization of experiments to achieve valid and reproducible results. Obviously, mammalian genome sequences show species-specific differences with regard to structure and function. Therefore, additional nonrodent mammalian species including pigs are increasingly used as appropriate animal models for specific human diseases.

Pigs are members of the artiodactyls (cloven-hoofed mammals). Domestication of pigs (*Sus scrofa domestica*) from the species *Sus scrofa* (wild boar) that is classified to a number of subspecies, started about 9000 years ago. More than 500 different breeds are described worldwide, 90% of them are local breeds. Only about 60 breeds are regional or international breeds occurring in more than one country. The five most common breeds are Large White, Duroc, Landrace, Hampshire, and Pietrain, however different breeding standards are used by the respective national breeding organizations. The efforts for improving economic performance and quality of pig production resulted in hybrid breeding programs which are based on pure-bred pigs as grandparent and great-grandparent stocks. These programs use crosses between specialized sire and dam lines which have been developed through intense within-line selection of a small number of international transboundary breeds. The commercial interest in the efficient agricultural production has also driven the scientific progress in the genetic and phenotypic characterization, as well as in the artificial genetic modification of the species (http://www.animalgenome.org/cgi-bin/QTLdb/SS/index) (Food and Agriculture Organization of the United Nations, 2007; Frantz et al., 2016). Monogenic traits and diseases of pigs are collected in the "OMIA—Online Mendelian Inheritance in Animals" database (http://omia.angis.org.au).

From a female domestic Duroc pig, a high-quality draft pig genome sequence was established using bacterial artificial chromosome and whole genome shotgun sequences. The assembly (Sscrofa10.2) comprised 2.6 Gb assigned to chromosomes, and additionally more than 200 Mb in unplaced scaffolds. Predicted porcine protein sequences were compared with their human orthologues (http://www.ensembl.org) (Groenen et al., 2012). Using four 12–16-week old male and female juvenile Landrace pigs and a porcine expression array, a genome-wide transcriptome atlas of pig tissues derived from 62 tissue/cell types was generated. The transcripts were grouped according to the location and the network with coexpressed genes (Freeman et al., 2012).

For biomedical research, miniature pig breeds with substantially decreased body size and improvement in the standardization of the genetic background were produced (Köhn, 2012). Minipig outbred stocks with full pedigree can be obtained from commercial suppliers. Göttingen minipigs are approved by regulatory authorities worldwide as nonrodent models for pharmacological and toxicological studies (http://www.minipigs.dk) (Bode et al., 2010). The appropriateness of minipigs for modeling complex physiologic systems and for presenting a preclinical platform to validate efficacy and safety of therapies and devices was compiled (Schomberg et al., 2016). Minipigs inbred for many generations are also available (Mezrich et al., 2003; Wu et al., 2004; Yu et al., 2004). Whole genome sequencing of highly inbred Wuzhishan minipigs revealed a high level of homozygosity in the diploid genome combined with genomic regions with unexpectedly high rates of heterozygosity (Fang et al., 2012).

Breeding strategies (Kaneko et al., 2011), as well as genetic engineering techniques were used for the generation of pigs with even lower adult body weight for their subsequent use as genetic background for pig models in biomedical research. For instance, growth hormone receptor (*GHR*) gene knockout Bama minipigs (Li et al., 2014a), as well as transgenic Wuzhishan minipigs expressing a dominant-negative porcine GHR (Li et al., 2015a) were established.

The reproductive performance of pigs is characterized by sexual maturity at the age of 6 months, a gestation period of less than 4 months, a generation interval of less than 1 year, parturition of about 10 piglets per litter and all season breeding. Their lifespan can be 15 years and more. In pigs, a broad spectrum of techniques necessary for biomedical research are established (McAnulty et al., 2012; Swindle and Smith, 2015). Pig cell lines from kidney and other tissues are commercially available for accompanying in vitro studies (http://www.lgcstandards-atcc.org). Environmental standardization of experimental pig housing regarding microbial health monitoring was established (Rehbinder et al., 1998; Schuurman, 2009). For carrying out qualitative and quantitative analyses with porcine biomedical models, detailed protocols for the determination of sampling locations and sampling numbers, as well as recommendations on the orientation, size, and trimming of samples from about 50 different porcine organs and tissues were provided (Albl et al., 2016).

Here, we first give a short description of the techniques which are currently used for the production of genetically engineered pigs. The subsequent chapter then summarizes the genetically engineered pig models that were established for specific human diseases.

2 TECHNIQUES USED FOR THE GENERATION OF GENETICALLY ENGINEERED PIGS

Gene transfer into the porcine genome was first carried out in 1985 via DNA microinjection into the pronuclei of fertilized oocytes (Brem et al., 1985; Hammer et al., 1985). Subsequently, sperm-mediated gene transfer, lentiviral transgenesis, somatic cell nuclear transfer from genetically modified cells, as well as gene editing techniques based on designer nucleases were used for the generation of mutant pig lines. Compared to the low efficiency of the basal DNA microinjection technique, the other methods have the potential of increased efficiency thereby leading to the use of smaller numbers of animals in the production of genetically engineered animals. Functional porcine embryonic stem (ES) cells or other pluripotent stem cells are not yet available (Soto and Ross, 2016). Chronological descriptions of the milestones in the development of techniques used for the genetic modification of pigs are published (Aigner et al., 2013; Dmochewitz and Wolf, 2015).

Genetic modification of animals is done by somatic and/or germline modification of the host genome. Somatic modifications include the production of mosaics, for example, by genetic alteration of a part of the body cells by viral vectors, and of chimeras by insertion of foreign cells into an organism (Matsunari et al., 2013). Animals with germline modifications are used for the production of stable mutant lines which make the model permanently and reproducibly available during all developmental stages. Genetically engineered animals are either transgenic animals harboring experimentally transferred DNA sequences or genetically modified animals without transfer of foreign DNA into the host genome.

Genetically engineered animals are used for the analysis of gene function and gene regulation (functional genome analysis), for the generation of disease models, as well as for the production of biologically active proteins or modified animal products (gene farming). The aim of a project involving genetic engineering may be the analysis of an additional function by over- and/or ectopic expression of a transgene (gain of function) and/or the partial or complete loss of function of host genes (loss of function). This includes the inactivation of specific genomic sequences (knockout), defined genomic modifications (knockin), specific suppression of the synthesis of gene products (knockdown, gene silencing), as well as random mutagenesis of the host genome (insertional mutagenesis). The aim of the project determines the strategy and the techniques used for the genetic modification of the respective animal models. Production of valid data in such a project generally requires the generation and analysis of several independent genetically engineered lines, as genetic and/or epigenetic alterations due to the techniques used for genetic modification may occur. If these alterations are not linked to the modified locus, they can be removed by conventional breeding.

Animal welfare issues require the systematic analysis of the genetically engineered lines for the occurrence of burden caused by the induced mutation. The international nomenclature is described in the internet (http://www.informatics.jax.org).

2.1 Sequence-Specific Nuclease-Mediated Genetic Engineering

Sequence-specific nuclease-mediated gene editing in pigs may be done either in primary cells followed by somatic cell nuclear transfer (SCNT) to generate animals, or in porcine embryos (mostly zygotes). Protein-guided zinc finger nucleases (ZFN) and transcription activator-like effector nucleases (TALEN), as well as the RNA-guided CRISPR-Cas9 (clustered regularly interspaced short palindromic repeat associated protein 9) system have been successfully used for the establishment of genetically engineered pig lines (Tan et al., 2016).

All three systems induce sequence-specific double strand breaks in a targeted region of the host genome. DNA repair via the nonhomologous end joining (NHEJ) pathway often leads to insertions and/or deletions of variable length, potentially resulting in partial or complete inactivation of the target gene. Sequence analysis of the novel alleles is carried out to predict their functional effects. Simultaneously editing two host genome loci on the same chromosome can also lead to the deletion of the DNA sequence between both loci. DNA repair via nonhomologous end joining (NHEJ) in the presence of exogenous DNA, such as an expression vector, can lead to transgenic cells via nonhomologous site-specific integration. Homology-directed repair (HDR) of a DNA double strand break can either restore the previous sequence or—in the presence of a targeting vector—facilitate targeted integration of a DNA sequence via homologous recombination. This strategy can be used for multiple purposes including additive gene transfer, partial or complete inactivation, as well as defined modification of a specific gene. Possible unspecific off-target effects of the nucleases may occur in loci with DNA sequences that are highly homologous to the target locus, and have been found in pig projects using these techniques (Yang et al., 2011). Unwanted unspecific host genome alterations not linked to the specific mutation can be removed by conventional breeding. Use of the sequence-specific nuclease-mediated systems by microinjection into zygotes may give rise to a high proportion of mutant founder offspring. Monoallelic or biallelic mutant and/or mosaic (animals harboring cells with different genotypes which arise either from onset of the first cell

division in the embryo before the induction of mutations or prolonged mutation induction activity after the one-cell stage) founder animals may appear which are analyzed to detect appropriate mutations for the subsequent breeding of mutant lines.

In pigs, the use of sequence-specific nuclease-mediated techniques started with the production of a ZFN-induced knockout of the *EGFP* transgene integrated in transgenic primary porcine somatic cells and the subsequent generation of heterozygous knockout pigs with these mutant cells by SCNT (Watanabe et al., 2010; Whyte et al., 2011a). A heterozygous knockout pig was also achieved for the *PPARG* gene by using ZFN and SCNT (Yang et al., 2011) (see Section 3.10). In addition, ZFNs were used to induce a biallelic knockout of the porcine α1,3-galactosyltransferase (*GGTA1*) gene in primary porcine fibroblasts which were subsequently used for SCNT (Hauschild et al., 2011). SCNT of TALEN-modified fetal fibroblasts with various mutant genotypes resulted in Ossabaw minipigs harboring biallelic low density lipoprotein receptor (*LDLR*) gene mutations. Piglets carried biallelic *LDLR* mutations which are expected to prematurely truncate the *LDLR* open reading frame, or are implicated in familial hypercholesterolemia in humans (Carlson et al., 2012) (see Section 3.11). The CRISPR-Cas9 system was used to establish pig models for the von Willebrand disease which is caused by von Willebrand factor (*VWF*) gene deficiencies. By editing *VWF* directly in Bama minipig zygotes, monoallelic, as well as biallelic *VWF* mutant piglets were born (Hai et al., 2014) (see Section 3.13).

2.2 Somatic Cell Nuclear Transfer

Somatic cell nuclear transfer (SCNT, cloning) in pigs (Betthauser et al., 2000; Onishi et al., 2000; Polejaeva et al., 2000) is carried out to produce mutations (knockout, -in) in defined loci of the porcine genome after using the sequence-specific nuclease-mediated techniques described above or after classical gene targeting by homologous recombination of targeting vector and host genome in the nuclear donor cells. In addition, the method is also used for additive gene transfer by random transgene integration in the nuclear donor cells. In both cases, preselection of donor cells with regard to the induced genetic modification, transgene expression and/or gender is possible. The production of genetically engineered animals by SCNT includes the transfection and selection of somatic donor cells in vitro, recovery and enucleation of recipient metaphase II oocytes, transfer of genetically modified somatic cell nuclei into the cytoplasm of the enucleated oocytes, activation of the reconstructed oocytes, and embryo transfer to recipients. In the case that genetically modified donor cells are used, 100% genetically modified founder animals

without genetic mosaicism are received. As prolonged in vitro culture periods of the nuclear donor cells negatively influences the success of SCNT, use of pools of small clones of genetically modified nuclear donor cells rather than expansion of individual cell clones to high cell numbers may improve the efficiency of SCNT (Kurome et al., 2015).

The cloning efficiency is varying within relatively low values between 0.5% and 5% offspring per transferred SCNT embryos. The successful embryonic, fetal, and neonatal development of the transferred embryos derived from SCNT depends on the correct epigenetic reprogramming of the donor cell nuclei. Insufficient epigenetic reprogramming may lead to an overall low cloning efficiency, as well as to peri- and neonatal health problems of cloned mammals. Abnormal phenotypes of cloned pigs occur less frequently than in other mammals, and they normally are not transmitted to the offspring of the affected clones (Cho et al., 2007; Shi et al., 2003; Suzuki et al., 2012). Genome-wide gene expression and DNA methylation profiling of different tissues in phenotypically normal cloned pigs and conventionally bred control pigs revealed differentially expressed genes and moderate alterations in DNA methylation (Gao et al., 2011; Park et al., 2011). Proteomic analyses of hearts of adult SCNT-derived Bama minipigs compared to controls also identified differentially expressed proteins thereby demonstrating that SCNT might result in abnormal expression of important proteins in cardiac development (Shu-Shan et al., 2014). Thus, genetically engineered founders derived from SCNT may be used in experiments only with caution with regard to the validity and reproducibility of the results.

Various somatic cell types were successfully used in the cloning procedure and numerous technical variations were established to increase the efficiency of porcine SCNT (Kurome et al., 2015). Furthermore, recombinant adeno-associated virus (rAAV) vectors (Rogers et al., 2008a), as well as modified bacterial artificial chromosomes (Klymiuk et al., 2012a) were successfully used for efficient gene targeting in porcine cells. As minipigs are suitable experimental animals for biomedical research, genetically modified cloned minipigs were produced by using minipigs as nuclear donors and common large-sized domestic farm breeds as both oocyte donors and recipients. This method combines the wide availability of domestic farm breeds with the biomedical value of minipigs (Estrada et al., 2008; Kurome et al., 2008).

2.3 Embryo Microinjection

Embryo microinjection of sequence-specific nucleases with or without foreign DNA results in the generation of either transgenic animals harboring experimentally transferred DNA sequences or genetically modified

animals without transfer of transgenes into the host genome. In addition, basal microinjection of only DNA sequences as transgenes into the pronuclei of fertilized oocytes is still carried out but generally results in low efficiency of transgene integration, random integration of multiple transgene copies including rearrangement of the host genome around the integration site and/or insertional mutagenesis, high numbers of transgenic mosaic founders, and possible genome position effects on the expression of the transgene. Porcine in vivo produced embryos, as well as embryos following in vitro fertilization (IVF) of in vitro matured (IVM) oocytes derived from ovaries of slaughtered gilts are used for the procedure.

2.4 Transposon Systems

Random enzyme-mediated gene transfer is done with DNA transposon systems derived from different species, for example, Sleeping Beauty (SB) or PiggyBac (PB). The transgene is flanked on both sides by recognition sites (inverted terminal repeats, ITR) of the enzyme transposase. Usually comicroinjection of transgene and transposase is carried out. Increased efficiency of gene transfer, integration of single copies per host genome site and multiple segregating transgene integration sites may occur. Normally only small recombinations are caused in the surrounding host genome. However, efficiency of the gene transfer in vivo decreases with increasing length of the transgene (Ivics et al., 2009). In pigs, use of the Sleeping Beauty system in vitro in fibroblasts and the subsequent use of the transgenic cells in SCNT was carried out (Carlson et al., 2011; Jakobsen et al., 2011). Single transgene copies are presumably less prone to transgene silencing than concatemeric transgene insertions. Studies with the Sleeping Beauty system suggest that Sleeping Beauty rarely targets heterochromatic chromosomal regions for insertion, and that it is unlikely that certain sequence motifs in the transposon vector are recognized by mediators of silencing in the cell. In transgenic pigs, long-term observation for more than 12 months found no changes in the transgene expression suggesting that no age-related silencing of the transgene occurred (Garrels et al., 2011; Ivics et al., 2014).

2.5 Inducible Transgene Expression

Conditional transgene expression can be achieved by using regulatory elements that can be induced or inactivated by exogenous stimuli. The most widely used systems are the tetracycline-regulated Tet-On and Tet-Off systems which consist of two parts. In mice, usually two genetically engineered lines are produced and then mated to achieve double modified offspring for the induction of the transgene expression.

Due to the relatively long generation interval in pigs, the combination of all elements of this system, for example, expression of the tetracycline-dependent transactivator and the transactivator-dependent expression of the target gene, on a single construct was tested. Transgenic pigs were produced with a construct consisting of an autoregulatory bicistronic Tet-Off-based expression cassette, where the transactivator responsive promoter (PtTA) drives the cDNA for the human complement regulatory proteins CD55 (decay-accelerating factor, DAF) or CD59 (membrane inhibitor of reactive lysis, MIRL). Via a poliovirus internal ribosomal entry site (IRES), this was linked with a Tet-Off transactivator (tTA). Minimal expression of the Tet-Off transactivator promoter results in tTA expression and binding to the transactivator responsive promoter PtTA which initiates an autoregulative loop. In the presence of exogenous doxycycline, the transactivator tTA is inactivated and transgene transcription is silenced. Using the DNA microinjection technique, these constructs were used to produce transgenic pig lines expressing CD55 or CD59. Transgene expression did not affect animal health and fertility. Mosaic transgene expression restricted to muscle was observed in the transgenic lines. After crossbreeding, animals double transgenic for *CD55* and *CD59* were obtained with tissue-independent expression of CD59, but not CD55. The asymmetric expression pattern correlated with differences in methylation patterns of the integrated transgenes. Feeding transgenic animals with doxycycline for 6 days eliminated the transgene expression within 2–6 days. Doxycycline levels in porcine plasma rapidly declined after termination of the application; however, transgene reexpression did not resume earlier than 8 weeks later (Kues et al., 2006).

As only the use of the Tet-Off system has been published for pigs, we established a model for the induction of the expression of transgenes on the genetic background of the Swabian-Hall breed. The Tet-On strategy was based on a similar principle but used the modified rtTA transactivator that binds to the PtTA only in the presence of tetracycline or derivates, such as doxycycline. Binding of the doxycycline-rtTA product to PtTA causes transcriptional activation and, thus, expression of a desired gene of interest. The switch-on principle may reflect the requirements of transgene regulation in biomedical research more closely. As the Tet-On system requires the expression of two independent transcripts, and the transgene vector needs a positive selection cassette for generating transgenic pigs by SCNT, we decided to place the constitutive rtTA construct and the gene of interest on different vectors to avoid negative influences of closely adjacent transgenes on the transcription. In addition, transgenic pigs with a suitable expression level and pattern of rtTA can be used as genetic basis for any PtTA-controlled expression cassette. In a first step,

founder pigs expressing rtTA under a ubiquitous cytomegalovirus enhancer/chicken β-actin (CAG) promoter were generated and characterized for rtTA expression by RT-PCR. Primary cells were prepared from all transgenic animals and transfected with constructs carrying the genes of interest, porcine soluble receptor activator of NF-κB ligand (*RANKL*) or cytotoxic T-lymphocyte associated antigen 4-Fc domain of immunoglobulin G1 (*CTLA4-Ig*). In the absence of doxycycline, the levels of both proteins were below the detection limit. The induction upon administration of various concentrations of doxycycline was measured at protein level by ELISA for both regulated transgenes. The induction potential for RANKL and CTLA4-Ig in the cell lines grossly correlated to the transcriptional level of rtTA expression and identified several of the rtTA transgenic pigs as appropriate founder animals. Primary cells of these pigs were used to establish double transgenic animals carrying the constitutive rtTA construct, as well as the regulated gene of interest, in a second round of SCNT. For both regulated genes, *RANKL* or *CTLA4-Ig*, the potential of the Tet-On system to drive transgene expression in vivo was evaluated after oral administration of doxycycline (Klymiuk et al., 2012b).

The in vivo induction of CTLA4-Ig expression was limited to a 6-day feeding protocol with 25 mg/kg/day doxycycline to avoid impairment of the immune status. This was sufficient to yield detectable levels of CTLA4-Ig in blood serum. The serum was able to inhibit T-cell proliferation in a standard in vitro assay and confirmed the biological function of the induced transgene product. Thus, the induced expression of a transgene was successfully carried out in pigs (Klymiuk et al., 2012b). The induction of the expression of RANKL was carried out in order to produce large animal models for osteoporosis (see Section 3.19). Successful use of the Tet-On system in transgenic pigs established by SCNT was also demonstrated for inducible expression of enhanced green fluorescent protein (Jin et al., 2014) or porcine growth hormone (Ju et al., 2015).

Further refinements of the transgene technology in pigs include the *Cre/loxP* system for conditional transgenic modifications where parts of the system were analyzed in initial studies of transgenic pig lines (Li et al., 2009; Chen et al., 2010). The *Cre/loxP* system was recently used for the generation of conditional porcine cancer models (see Section 3.23).

2.6 Further Technical Improvements

In transgene projects, often multiple genes are required to be simultaneously modified in the animals to achieve the desired phenotype. This can be done by the production of transgenic lines harboring one transgene each that are subsequently used in complex breeding programs. On the other hand, expression of several proteins from a single vector has been done by using internal ribosomal entry site (IRES) placed between the coding sequences for the respective proteins. However, in vectors containing the IRES sequence, the gene placed downstream is often expressed at a much lower level than the gene located upstream. The viral 2A peptide is used as alternative. It is about 19 amino acids long and contains a conserved and functional motif. Separation of the sequences upstream and downstream of this site is done through ribosomal skipping during protein translation between the last two amino acids at its C terminus resulting in the expression of two independent proteins from a single transcription event. By SCNT, transgenic pigs were produced uniformly coexpressing four fluorescent proteins in various tissues using a single 2A peptide-based double-promoter vector. Ribosomal skipping during protein translation results in small peptides of the 2A peptide site fused to the upstream and downstream proteins. As this may interfere with intracellular localization and function of the transgene-encoded proteins, modification of the 2A sequence has been described to greatly circumvent this problem (Deng et al., 2011).

The aim of standardized expression of transgenes from defined host genome loci was addressed in projects targeting the ROSA26 locus (Kong et al., 2014; Li et al., 2014b) or the H11 locus (Ruan et al., 2015) of the pig genome.

Additional transgenic pigs with the ubiquitous or tissue-specific expression of reporter genes, such as the green fluorescent protein (GFP) were established for the use in further fine tuning the techniques for precise genetic modification of pigs, as well as tools in basic biological research (Matsunari and Nagashima, 2009).

3 GENETICALLY ENGINEERED PIGS AS MODELS FOR HUMAN DISEASES

Beneath the identification of spontaneously arosen mutations leading to interesting phenotypes (http://omia.angis.org.au), transgenic pigs initially have been predominantly established to examine traits of livestock performance (growth, reproduction, disease resistance, product quality and safety, environmental pollution) and to establish bioreactors for the production of human proteins related to biomedical applications in various body fluids or tissues (Martin and Pinkert, 2002; Pursel and Rexroad, 1993; Whyte and Prather, 2011). Recently, the development of transgenic pig models for biomedical research strongly increased (Tan et al., 2016; Rogers, 2016). The current state of the establishment and analysis of genetically engineered pigs for biomedical research is reviewed here (Table 26.1). This does not include the transgenic animals generated for the purpose

TABLE 26.1   Genetically Engineered Pigs as Disease Models

Disorder	Disease	Transgene/induced mutation	References
Neurodegenerative	Alzheimer's disease	Expression of mutant human APP^{sw} in the brain	Kragh et al. (2009)
		Ubiquitous expression of mutant human $PSEN1^{M146I}$	Jakobsen et al. (2013)
	Huntington's disease	Neuronal expression of mutant pig HTT (75Q)	Uchida et al. (2001)
		Ubiquitous expression of mutant human HTT (N208-105Q)	Yang et al. (2010)
		Expression of mutant human HTT (N548-124Q)	Baxa et al. (2013)
	Parkinson's disease	Biallelic $PARK7$ knockout	Yao et al. (2014)
		Biallelic $PARK2$ and $PINK1$ knockout	Zhou et al. (2015), Wang et al. (2016)
	Spinal muscular atrophy	Heterozygous SMN knockout and expression of human $SMN2$	Lorson et al. (2011), Prather et al. (2013)
	Amyotrophic lateral sclerosis	Ubiquitous expression of mutant human $SOD1^{G93A}$	Chieppa et al. (2014), Yang et al. (2014)
		Ubiquitous expression of mutant human $TDP43^{M337V}$ (TARDBP ^{M337V})	Wang et al. (2015a)
	Ataxia–telangiectasia	ATM knockout	Kim et al. (2014), Beraldi et al. (2015)
Retinal	Retinitis pigmentosa	Retinal expression of mutant pig RHO^{P347L} or RHO^{P347S}, or mutant human RHO^{P23H}	Petters et al. (1997), Kraft et al. (2005), Ross et al. (2012)
	Macular dystrophy	Photoreceptor-specific expression of mutant human $ELOVL4$	Sommer et al. (2011b)
	Cone dystrophy	Cone-specific expression of mutant human $GUCY2D^{E837D/R838S}$	Kostic et al. (2013)
Cardiovascular	Vascular	Endothelial overexpression of pig $NOS3$ ($eNOS$)	Hao et al. (2006)

		Homozygous disruption of the immunoglobulin κ light chain locus	Ramsoondar et al. (2011)
	Immunodeficiency	*IL2RG* knockout	Suzuki et al. (2012), Watanabe et al. (2013)
		Biallelic *RAG1* or *RAG2* knockout, *RAG1* knockout	Huang et al. (2014), Lee et al. (2014), Ito et al. (2014)
		Class I MHC knockout	Reyes et al. (2014)
		CD1D knockout	Whitworth et al. (2014)

of xenotransplantation that have been reviewed elsewhere (Cooper et al., 2016; Ekser et al., 2015; Klymiuk et al., 2010).

At least some of the genetically modified pigs established for xenotransplantation research are also used for basic biomedical research. One example is transgenic pigs ubiquitously expressing human heme oxygenase 1 (HMOX1, HO-1) which is an inducible protein capable of cytoprotection by scavenging reactive oxygen species and preventing apoptosis caused by cellular stress during inflammatory processes. The transgenic pigs exhibited lower body weights and lower subcutaneous fat tissue compared to controls. Further analyses revealed that HMOX1 overexpression reduced adipogenesis both in vivo and in vitro, which makes them an interesting model in the research of obesity and related metabolic diseases (Park et al., 2015a).

In basic research, production of valid data in a project involving genetic modification generally requires the production and analysis of several independent lines, as nontransgene-specific genetic and/or epigenetic alterations may appear in all techniques used for the generation of genetically engineered animals. In addition, different alleles of the examined gene may cause different phenotypes. For the establishment of an appropriate animal model showing specific pathophysiological characteristics of a human disease in question, selection, and analysis of one particular transgenic line exhibiting the desired phenotype stably over several generations may be practicable.

3.1 Alzheimer's Disease

Several inherited neurological diseases in humans are caused by misfolded proteins that accumulate in neuronal cells of the brain and lead to apoptosis. Transgenic mouse models of these diseases often fail to replicate apoptosis and overt neurodegeneration in the brain. Establishment of porcine models for human late-onset neurodegenerative disorders, such as Alzheimer's disease, Huntington's disease, or Parkinson's disease may solve the practical issue of ageing as a crucial pathogenic factor of these diseases. Specific disease phenotypes might eventually evolve in these pig models in 10–15 years which is theoretically possible, but practically and economically impossible for scientific research and preclinical investigation (Holm et al., 2016).

Alzheimer's disease is a multifactorial neurodegenerative disease. Aberrant processing and clearance of amyloid β-precursor protein (APP) from the brain is central to the pathogenesis of Alzheimer's disease. The onset of the disease appears after 40 years or more. In some families, *APP* mutations were identified to cause an autosomal dominant disorder where the mutant *APP* leads to the increased production of distinct protein fragments

which in turn results in neuropathy. The development of a pig model for Alzheimer's disease was attempted by producing transgenic pigs using the human dominant mutant allele *APP^sw* harboring two amino acid exchanges due to two neighboring nucleotide exchanges (K670N and M671L) which was found to cause Alzheimer's disease. The 7.5-kb transgene was the same as already used in previous transgenic mouse studies. It comprises a 1-kb platelet-derived growth factor-β (PDGFβ) promoter, intronic and exonic sequences of the β-globin gene, the cDNA encoding the mutant allele *APP^sw* and SV40 polyadenylation sequences. After stable transfection of fibroblasts of the Göttingen minipig breed, one transgenic cell clone was used for SCNT to produce seven healthy transgenic cloned pigs with normal weight gain. The transgenic pigs harbored a single full-length copy of the transgene in their genome and showed strong, promoter-specific expression of the transgene-encoded protein in brain tissues. Accumulation of the pathogenic protein and subsequent appearance of clinical consequences were estimated to develop with increasing age (Kragh et al., 2009).

As memory impairment is the most striking and consistent feature in human patients of Alzheimer's disease, the memory of the transgenic pigs was analyzed at the age of 1 and 2 years using the spontaneous object recognition test which has been established for minipigs and is based on behavioral discrimination of familiar and novel objects. High interindividual variability and no significant difference between transgenic animals and controls were revealed. Positron emission tomography (PET) scans, as well as neuropathological analysis of a 2-year old transgenic animal showed normal histology without deposition of the pathogenic protein (Sondergaard et al., 2012). In further analyses, the transgene was shown to be expressed in relevant brain regions at a fairly constant level during the 5-year examination period, but no pathological changes were revealed (Holm et al., 2016).

Further cleavage of APP is dependent on the function of the transmembrane protein presenilin 1 (PSEN1). Mutations in *PSEN1* are known to cause autosomal dominant early-onset Alzheimer's disease. Using recombinase-mediated cassette exchange (RMCE) in Göttingen minipig cells and SCNT, the same group produced transgenic animals harboring a single transgene copy consisting of the cDNA of the Alzheimer's disease-causing mutation *PSEN1^M146I* driven by a promoter allowing ubiquitous expression (Jakobsen et al., 2013). The mutant human PSEN1 protein was expressed in the porcine neurons, but no Alzheimer's disease-like pathological changes were revealed over a period of 3 years. Currently, double transgenic Göttingen minipigs exhibiting the combined expression of mutant human *APP* and *PSEN1* genes are under study (Holm et al., 2016).

3.2 Huntington's Disease

Huntington's disease is an autosomal dominant, progressive neurodegenerative disorder leading to the premature loss of specific neurons. It is associated with an expansion of a CAG trinucleotide repeat in the 5' region of the huntingtin (*HTT*) gene that results in a elongated polyglutamine (polyQ) tract of the protein. The CAG repeat number is polymorphic and ranges from 6 and 35 units in normal alleles and from 36 and 120 units in alleles associated with Huntington's disease. Several mouse models of Huntington's disease were extensively studied, but none of them showed robust neurodegeneration as observed in the brains of patients of Huntington's disease.

The 12.8-kb *HTT* transcript of Göttingen minipigs codes for a 345-kDa protein (3139 amino acids) (Matsuyama et al., 2000). A transgenic pig model was generated by DNA microinjection of an 8.2-kb transgene into minipig embryos consisting of the 4-kb rat neuron specific enolase (*Nse*) promoter, a 3.3-kb 5' minipig huntingtin cDNA which was mutated by insertion of 75 CAG repeats into the triplet region of exon 1, and a 0.9-kb SV40 polyadenylation signal. Five transgenic founder pigs were produced each harboring 1–3 different integration sites with variable copy numbers and indication of genetic mosaicism (Uchida et al., 2001). To date, no follow-up publication describing mutant phenotypes appeared.

Another transgenic pig model for Huntington's disease was established with Tibetan minipigs as genetic background. As transgenic mouse models showed that N-terminal huntingtin fragments with expanded polyglutamine tracts cause more severe neurological symptoms than full-length mutant huntingtin (3144 amino acids), two expression vectors were constructed. They included the cytomegalovirus enhancer and chicken β-actin (CAG) promoter and human N-terminal (208 amino acids) mutant *HTT* with two different expanded polyglutamine tracts (105Q or 160Q). Transfected cell clones were used for SCNT. The transfer of about 2000 reconstructed embryos for each transgene yielded the birth of five pigs transgenic for mutant *HTT* N208-105Q, but none was born that was transgenic for mutant *HTT* N208-160Q. It was concluded that the transgene with the longer polyQ repeat is more toxic and did not allow the early development of transgenic pigs. The *HTT* N208-105Q transgenic pigs were derived from different transgenic cell clones showing multicopy transgene loci with the insertion in estimated 3–4 sites. The five piglets appeared normal at birth, but three were weak and died within the first 3 days after birth. A fourth piglet died within the first month, and the fifth pig showed no obvious symptoms after 4 months after birth. Expression analysis of the transgene-derived protein and its degraded product showed that the fifth animal showed the lowest expression, and the fourth animal also showed lower expression compared to the three animals which died very early. Thus, the expression level of mutant *HTT* may negatively contribute to the life span of the transgenic pigs. For comparison purposes, two transgenic FVB mouse lines were generated with the same transgene which also expressed the transgene in the brain. Typical apoptotic neurons with nuclear DNA fragmentation were found in the brains of the four dead transgenic pigs whereas transgenic mice showed no apoptotic neurons. Compared to the transgenic mouse brains, a higher number of neurons with activated caspase-3 was found in transgenic pig brains resulting from caspase activation and reflecting early apoptotic events (Yang et al., 2010).

A further transgenic pig model for Huntington's disease was generated by using lentiviral-based transgenes carrying a human minimal *HTT* gene promoter driving either a 548-amino acid or full length (3144 amino acids) human *HTT* cDNA containing 145 repeats of a mixed CAG/CAA sequence. Transgenic founder pigs harboring one copy of the human *HTT* transgene encoding 124 glutamines due to polyglutamine contraction (N548-124Q) were born and bred for three generations. Mutant *HTT* mRNA and protein fragments were detected in brain and peripheral tissues. No aggregate formation in brain up to 16 months was seen. No developmental or gross motor deficits were observed up to 40 months of age. Compared to controls, 1-year old transgenic boars showed reduced fertility including reduced spermatozoa and oocyte penetration (Baxa et al., 2013). In addition, work is described to be underway at Exemplar Genetics (Sioux City, IA) to generate a knockin model of Huntington's disease in minipigs (Morton and Howland, 2013).

3.3 Parkinson's Disease

Parkinson's disease is a progressive neurodegenerative movement disorder that is characterized by the degeneration of dopamine neurons in the substantia nigra and the intracytoplasmic inclusion of Lewy bodies. By far the most cases are sporadic, but several causative mutations have been identified in patients of familial Parkinson's disease, including mutated *PARK7* (*DJ-1*). In Large White pig fibroblast cells, TALEN-mediated editing of *PARK7* resulted in monoallelic and biallelic mutations of *PARK7*. Use of mixed *PARK7* mutant colonies for SCNT obtained one monoallelic and two biallelic live-born *PARK7* knockout piglets. All three piglets died in the first days after birth presumably due to cloning defects. Western blot analysis confirmed the absence of PARK7 in these pigs (Yao et al., 2014).

Mutations of *PARK2*—encoding parkin, a component of the multiprotein E3 ubiquitin ligase complex—and

PINK1 (*PARK6*)—encoding PTEN induced putative kinase 1, a mitochondrial serine/threonine-protein kinase—are also known to cause autosomal recessive early-onset Parkinson's disease in humans. Using the CRISPR-Cas9 system, combined *PARK2* and *PINK1* homozygous knockout cell clones of Banna minipigs and Bama minipigs were produced by editing the first exon region following the start codon of each gene, and further used for SCNT. Viable, normally developing, combined *PARK2* and *PINK1* homozygous knockout pigs were generated harboring various types of mutations at both target loci corresponding to the respective donor cells. Expression of *PARK2* and *PINK1* in brain cortex sections was undetectable in these animals. No typical Parkinson symptoms were detected up to 7 months of age (Zhou et al., 2015).

In addition, one homozygous triple biallelic knockout piglet affecting the genes *PARK2*, *PARK7* and *PINK1* was produced using the CRISPR-Cas9 system by simultaneous coinjection of two adjacent single guide RNAs targeting one locus for each gene in Bama minipig one-cell stage embryos. A second piglet showed biallelic modifications of the genes *PARK7* and *PINK1* and a monoallelic mutation of the *PARK2* gene. Absence of PARK7 protein and highly decreased mRNA levels of *PARK2* and *PINK1* were found in the triple biallelic knockout pig. Whole-genome sequencing of the parents and the triple biallelic knockout pig was carried out to assess the degree of mutagenesis across the entire genome. No significant off-target cleavage of the CRISPR-Cas9 system was found. The two piglets remained healthy with a normal growth rate. Typical symptoms of Parkinson's disease were not observed in the study period up of 10 months p.p. (Wang et al., 2016).

3.4 Spinal Muscular Atrophy

Spinal muscular atrophy (SMA) is an autosomal recessive neurodegenerative disease that is characterized by the progressive degeneration of spinal motor neurons and muscle atrophy leading to various clinical severities. It is caused by mutations of the survival motor neuron 1 (*SMN1*) gene. The nearly identical gene *SMN2* is present only in humans and works as a disease modifier as increasing *SMN2* copy number decreases the severity of the disease. Mutations in *SMN2* have no clinical consequence if *SMN1* is functional. Several mouse models have been developed to study SMN function and SMA disease pathology, but they show limitations in testing the efficacy of therapeutics. Deletion of *Smn* in mice, as in all mammals but humans, results in embryonic lethality; however, the lethality can be rescued by transgenic expression of the human SMN2. Analogously, the prerequisite for the successful production of genetically engineered pigs with functional knockout of SMA is that

human SMA2 is functional as a transgene in porcine cells. Therefore, it was shown in vitro that splicing of human *SMN1* and *SMN2* as transgenes in porcine cells is consistent with splicing in human cells. Next, gene targeting of porcine *SMN* (Lorson et al., 2008) was carried out via homologous recombination in fetal fibroblast cells of Large White pigs leading to the deletion of essential functional domains of SMN encoded by the exons 2b, 3, and part of exon 4, and to a further disruption of the reading frame. Cells harboring the heterozygous *SMN* knockout were used for SCNT. Phenotypically normal, healthy pigs heterozygous for the *SMN* knockout were produced. No significant reduction in *SMN* RNA between heterozygous mutant and control animals was detected which is consistent with the results in humans and transgenic mice (Lorson et al., 2011). For the second step of the production of a genetically engineered pig model of SMA, heterozygous *SMN* knockout primary cells were used for transfection of a 35.5-kb fragment carrying the human *SMN2* gene and its promoter sequence. Multiple positive clones expressing SMN from *SMN2* were obtained and used for SCNT (Prather et al., 2013).

3.5 Amyotrophic Lateral Sclerosis

Amyotrophic lateral sclerosis (ALS) is a fatal neurodegenerative disease which is characterized by progressive selective degeneration of motor neurons, leading to muscle weakness and atrophy and evolving to complete paralysis. It occurs in two clinically indistinguishable forms, the sporadic and the familial form. The familial form is linked to several gene mutations, mostly heritable in a dominant manner. One of the mutant genes is the Cu/Zn superoxide dismutase 1 (*SOD1*) gene. A transgene consisting of the cDNA of the mutant human $SOD1^{G93A}$ sequence, a mutation found in human ALS patients, driven by the ubiquitous pCAGGS promoter (CMV-IE enhancer and chicken β-actin promoter) was transfected into Yucatan minipig cells, and different transgenic cell clones showing high expression were used for SCNT. Five transgenic pigs derived from various transgenic cell clones survived and developed normally reaching adulthood. Since Yucatan minipigs live up to 13–15 years, pigs with high expression of human $SOD1^{G93A}$ are expected to show ALS symptoms in 3–4 years (Chieppa et al., 2014).

Another group also generated transgenic pigs expressing mutant human $SOD1^{G93A}$ using the cytomegalovirus promoter in the genetic background of Tibetan minipigs. The transgenic pigs derived from various transgenic cell clones grew normally and did not show obvious body weight differences compared to controls. Different transgenic lines were produced from the founders. The oldest transgenic pigs were studied for about 2 years. The transgenic pigs developed movement disorders by showing hind limb motor defects, skeletal muscle atrophy and

motor neuron degeneration in a transgene expression level- and age-dependent manner. In addition, transgenic pigs showed neuronal intranuclear inclusions, which were not found in brains of corresponding transgenic ALS mouse models. The findings indicated that higher expression or rapid accumulation of mutant *SOD1* in motor neurons of the spinal cord usually induced a more severe disease phenotype (Yang et al., 2014).

The same workgroup analogously generated transgenic pigs expressing mutant human *TDP43*^{M337V}. TAR DNA binding protein 43 (TARDBP, TDP43) is a multifunctional nuclear protein that binds RNA to regulate RNA processing. Mutant TDP43^{M337V} is redistributed in the neuronal cytoplasm in human patients of both amyotrophic lateral sclerosis (ALS) and frontotemporal lobar degeneration (FTLD). In both diseases, the key pathological change is accumulation of pathogenic TDP43 in the cytoplasm and formation of cytoplasmic aggregates. In mutant human *TDP43*^{M337V} transgenic Tibetan minipigs, TDP43^{M337V} was also distributed in the cytoplasm of neuronal cells in the spinal cord and brain. Histological analysis revealed neurodegeneration in transgenic pig brains. Newborn transgenic pigs appeared normal. Compared to *SOD1*^{G93A} transgenic pigs, the transgenic pigs expressing human *TDP43*^{M337V} showed a more severe phenotype. This included reduced body weight gain from 3 months after birth, a loose and wrinkled appearance of the skin, progressive weakness, and limb movement defects associated with markedly reduced muscle fiber size, and early death starting at the age of 4–5 months. A high number of the transgenic pigs died within 1 year. Further analyses aimed at the examination of the interaction of TDP43 and further factors of RNA processing (Wang et al., 2015a).

3.6 Ataxia Telangiectasia

Ataxia telangiectasia is a recessive autosomal disorder associated with pleiotropic phenotypes, including progressive cerebellar degeneration leading to motor impairment. It is caused by mutations in the Ataxia telangiectasia mutated (*ATM*) gene (65 exons, 350-kDa protein). ATM is a ubiquitously expressed protein involved with many cell cycle checkpoints and functions as a DNA damage response protein. The *Atm* mutant mouse models did not fully reproduce the hallmark neuropathological phenotype of Purkinje cell loss. A targeting vector was used in Minnesota minipig cells to disrupt exon 59 where the kinase activity is encoded. Using SCNT, five heterozygous *ATM* knockout founders were produced. Studies of the phenotype were not described. In addition, heterozygous *ATM* mutations are suggested to predispose to breast cancer in human patients. Thus, disruption of exon 59 which is suggested to result in a truncated ATM protein, may also model this disease (Kim et al., 2014).

Another workgroup developed homozygous *ATM* knockout pigs with a targeting vector disrupting exon 57 of *ATM* which encodes a significant portion of the ATP binding region within the kinase domain, and subsequent SCNT. Homozygous *ATM* knockout Yucatan minipigs were born with the expected Mendelian inheritance ratio after mating heterozygous mutants. ATM kinase domain, kinase activity, as well as truncated proteins were not detectable in the homozygous mutants. Unlike in the mouse models, the homozygous *ATM* knockout pigs showed early cerebellar lesions including loss of Purkinje cells and altered Purkinje cell architecture, as well as growth retardation and gait/motor coordination deficits. In addition, an increased number of chromosomal breaks were found in fibroblasts derived from the homozygous mutants when compared to controls (Beraldi et al., 2015).

3.7 Retinitis Pigmentosa

Retinitis pigmentosa comprises a group of inherited retinal diseases leading to the most frequent cause of hereditary visual loss in humans. It causes night blindness early in life due to loss of rod photoreceptors. The remaining cone photoreceptors slowly degenerate leading ultimately to blindness. Over 200 mutations in 45 genes have been identified as causative in various monogenic forms of retinitis pigmentosa. Both transgenic and knockout rodent models of retinal dystrophy contributed to the analysis of disease mechanisms. Compared to humans, rodent models are limited by two disadvantages, the small number and different distribution of photoreceptors in the retina and the small eyes (Gregory-Evans and Weleber, 1997).

Mutations in the rhodopsin (*RHO*) gene are known causes for retinitis pigmentosa in humans. Transgenic pigs expressing mutant porcine rhodopsin (RHO^{P347L} or RHO^{P347S}) were produced by additive gene transfer. A 12.5-kb porcine genomic DNA containing 4-kb 5′ flanking sequences, the coding sequences for the 348 amino acid protein and 2.9-kb 3′ flanking sequences of the porcine *RHO* gene was used including the mutation CCA (Pro) to CTA (Leu) or TCA (Ser) at codon 347. DNA microinjection of the expression vectors for mutant rhodopsin resulted in the generation of transgenic lines. Retinal mRNA expression of the mutant transgene exceeded the expression of the wild-type endogenous gene. Like human patients with the same mutation, the transgenic pigs showed early and severe loss of rod photoreceptors, and the surviving cone photoreceptors slowly degenerated. The phenotypes of mutant *RHO* transgenic pigs and of patients of retinitis pigmentosa are comparable. Therefore, this pig model is intensely used for studying the pathogenesis of retinitis pigmentosa and for preclinical treatment trials (Petters et al., 1997; Kraft et al., 2005).

The stability of the mutant phenotype in the RHO^{P347L} transgenic pigs was analyzed after maintaining the model for nine generations on a heterogeneous genetic background. In each generation, hemizygous transgenic boars were mated to unrelated nontransgenic sows. The sows used were composites of the Yorkshire, Landrace, and Large White breeds to minimize inbreeding and the negative consequences thereof in the transgenic line. Assessment of the photoreceptor degeneration in transgenic animals after nine generations showed a phenotype similar to that of the first description of the transgenic animals. Thus, the RHO^{P347L} transgenic pigs exhibited a stable phenotype after multiple generations of outcrossing (Sommer et al., 2011a).

The rhodopsin mutation RHO^{P23H} underlies the most common form of human autosomal dominant retinitis pigmentosa. Therefore, in another project transgenic pigs were produced on the genetic background of NIH inbred minipigs with a 17.5-kb human genomic RHO^{P23H} sequence including 4.2 and 8.4 kb of 5′ and 3′ sequences, respectively. After SCNT, the retinal function of transgenic founders was analyzed from 3 months up to 2 years after birth. The transgenic animals showed progressive rod and cone photoreceptor dysfunction and degeneration. The animals were classified to a moderately and a severely affected group. mRNA analysis in a severely affected line found that 80% of total RHO mRNA was mutant RHO^{P23H} mRNA (Ross et al., 2012). The pathogenesis of the disease in this pig model was analyzed in detail in further prenatal and early postnatal studies using hybrid progeny of a cross of the transgenic NIH inbred minipigs and domestic pigs (Fernandez de Castro et al., 2014; Scott et al., 2014).

3.8 Macular Dystrophy

The macula is the central region of the retina and includes the fovea centralis which is essential for sharp vision in conditions of bright light. Stargardt-like macular dystrophy type 3 (STGD3) is an autosomal dominant disease leading to macular degeneration. Three different mutations in the photoreceptor-specific gene elongation of very long chain fatty acids, such as 4 ($ELOVL4$) were found to cause the disease. $ELOVL4$ encodes a 314-amino acid protein that harbors an endoplasmic reticulum retention sequence at the C terminus which is eliminated in all three STGD3 mutations. ELOVL4 belongs to the elongase family of enzymes and catalyzes the synthesis of very long chain fatty acids. The disease-associated C-terminally truncated proteins mislocalize to nonendoplasmic reticulum juxtanuclear aggregates and exert a dominant-negative effect on the wild-type protein. In addition to transgenic mice which develop rapid retinal degeneration due to the expression of human truncated $ELOVL4$ sequences, transgenic pigs were produced

as further disease models. Two transgenes were used harboring human truncated $ELOVL4$ sequences driven by the $Rho4.4$ photoreceptor-specific promoter. For DNA microinjection into zygotes (breed not stated), an $ELOVL4$ coding sequence with a 5-bp deletion, resulting in a protein lacking the last 51 amino acids, was used. For transfection of cells to be used for SCNT, an expression vector with an $ELOVL4$ 270 stop mutation and an N-terminal EYFP fusion was used. Transgenic pig lines were produced with both transgenes. Transgene expression and mislocalization in the retina, as well as abnormal retinal morphology were found for both mutations. Thus, new disease models for STGD3 were established (Sommer et al., 2011b).

3.9 Cone Dystrophy

Cone(-rod) dystrophy (CORD) is caused in some patients by dominant-negative mutations of the guanylate cyclase 2D ($GUCY2D$) gene which is involved in the regulation of calcium influx in rods and cones. Thus, a lentiviral vector was constructed with 0.7 kb of the cone-specific pig arrestin 3 ($ARR3$) promoter and the human cDNA coding for the double mutant allele $GUCY2D^{E837D/R838S}$. Using microinjection into zygotes of Large White pigs, a number of transgenic founders were produced harboring 1–6 copies of the transgene and expressing the transgene in the retina. On a gross level, transgenic founders were indistinguishable from controls both physiologically and behaviorally. Functional analysis of the retina by electrophysiological and behavioral tests, as well as histological analysis of the retina at different ages revealed a range in the severity of retinal alteration in the transgenic founders (Kostic et al., 2013).

3.10 Cardiovascular Diseases

Endothelial cell nitric oxide synthase 3 (NOS3, eNOS) regulates vascular function by releasing nitric oxide (NO) (Huang, 2009). Transgenic pigs were produced for the analysis of the cardiovascular function by eNOS. The 7.3-kb transgene consisted of the 3.6-kb Yucatan pig $eNOS$ cDNA and a V5 epitope and polyhistidine tag (V5-His tag) to discriminate between endogenous and transgenic eNOS. Endothelial cell-specific expression of the transgene was driven by 2-kb $TIE2$ promoter sequences and 1.7-kb $TIE2$ intron/enhancer elements. After additive gene transfer into Yucatan pig fetal fibroblasts, SCNT of transgene-positive cells resulted in four cloned transgenic pigs. They expressed the fusion protein which was localized to the endothelial cells of placental vasculature from the conceptuses. The same localization was shown for the endogenous eNOS. Compared to the size of endogenous eNOS (133 kDa, 1205 amino acids), the predicted size of the recombinant eNOS (1242 amino acids)

was 138 kDa. Localization of endogenous and transgenic eNOS revealed the expression in the endothelium. The transgenic pigs are further used to analyze the function of eNOS in the regulation of muscle metabolism and in the cardiorespiratory system (Hao et al., 2006). In addition, the expression of a modified porcine *eNOS* in cloned fetuses was described as a valuable tool for understanding the relationship between placental growth, vascular nutrient exchange and cloning efficiency (Whyte and Laughlin, 2010).

Endothelial hydrogen peroxide (H_2O_2) plays a key role in vasomotor control mechanisms and stimulates the upregulation of eNOS. Enzymes including catalase (CAT) tightly regulate H_2O_2 levels in vascular tissue. Therefore, transgenic pigs were produced using a 15-kb human *CAT* transgene whose expression was driven to endothelial cells by *TIE2* regulatory sequences. Earlier, transgenic mice have been produced with the same transgene. In pigs, one clone of transgenic NIH Yucatan minipig cells was used for SCNT and yielded transgenic offspring. Expression of human catalase mRNA and overall elevated catalase protein were found in isolated umbilical endothelial cells, and the endothelial localization of the protein was confirmed. In vitro tests of transgenic endothelial cells also revealed significantly reduced levels of H_2O_2 suggesting increased enzymatic activity of catalase (Whyte et al., 2011b).

The peroxisome proliferator activated receptor γ (PPARG, PPARγ) is another factor that plays an important role in cardiovascular diseases. Selective ligands of PPARG, such as thiazolidinediones (TZDs) may be analyzed for their function as insulin sensitizers for the treatment of type 2 diabetes. To establish a large animal model for these purposes, ZFN editing of the *PPARG* gene was done in fibroblast cells of Tibetan minipigs. *PPARG* mutant cell clones were isolated and genotyped, and a cell clone with a premature stop codon in exon 1 was further used for SCNT. This resulted in pigs harboring a heterozygous knockout of the *PPARG* gene. PPARG protein expression seemed to be decreased in the heterozygous knockouts. Analysis of ZFN off-target cleavage sites was done using bioinformatics tools. Sequencing of the most likely off-target sites revealed two unspecific mutation events in segregating, noncoding genomic regions of the genetically modified pigs (Yang et al., 2011).

The purposes for the generation of transgenic pig models are not strictly separated. One example is the modification of the fatty acid composition of meat products beneficial to human health by additive gene transfer of the fatty acid desaturation 2 gene for a Δ12 fatty acid desaturase from spinach (Saeki et al., 2004), by expressing a humanized *Caenorhabditis elegans* gene, Fat-1, encoding a *n*-3 fatty acid desaturase (Lai et al., 2006) or by expression of omega-3 fatty acid desaturase (s*Fat*-1) from *Caenorhabditis briggsae* (Pan et al., 2010) in transgenic pigs.

The transgenic animals may also provide large animal models for studying the role of unsaturated fatty acids in the prevention and treatment of clinical conditions, such as cardiovascular disease and immune-mediated disorders or cancer.

3.11 Atherosclerosis

Hypertriglyceridemia is an independent risk factor for cardiovascular disease, and high levels of apolipoprotein CIII (APOC3) are often correlated with hypertriglyceridemia. APOC3 acts as an inhibitor of lipoprotein lipase activity and interferes with the receptor-mediated endocytosis of lipoprotein particles. Mature APOC3 is a 79-amino acid glycoprotein which is found in chylomicrons, very low-density lipoproteins, and high-density lipoproteins. Mutant APOC3 has been found to directly affect plasma lipid profiles, whereby people with deficiencies in APOC3 generally show lower plasma triglyceride levels. *Apoc3* knockout mice have reduced levels of plasma triglyceride-containing lipoproteins, and overexpression of human APOC3 in transgenic mice leads to hypertriglyceridemia. As the lipoprotein metabolism and the functional consequences thereof in mice differ greatly from those in humans, transgenic minipigs were produced which express human APOC3. A 10-kb human genomic *APOC3* sequence including 5′ and 3′ sequences was used as transgene, and one positive cell clone was used for SCNT. Transgenic founders were born, part of them showed early postnatal death, and from the remaining five healthy grown transgenic pigs, all but one died at various ages up to 4 months p.p. The cause for this was not identified. The transgenic pigs showed expression of human APOC3 in the liver and intestine, and increased plasma triglyceride levels, but normal total cholesterol and high-density lipoprotein levels. They had delayed triglyceride absorbance and clearance. The plasma lipoprotein lipase amount was increased but the activity was significantly reduced. Thus, hypertriglyceridemic human *APOC3* transgenic minipigs were established. For comparative analyses, the same transgenic model was generated in rabbits which also showed hypertriglyceridemia (Wei et al., 2012).

High lipoprotein a levels of more than 50 mg/dL in humans are a major risk factor for the development of atherosclerosis. Apolipoprotein a [LPA, Apo(a)], the unique component of lipoprotein a, is described to be found only in Old World monkeys and humans. Analogous to human *Apo(a)* transgenic mice and rabbits, human *Apo(a)* transgenic pigs were generated using a transgene with the cDNA of human *Apo(a)* under the control of the β-actin promoter and cytomegalovirus enhancer (CAG promoter). Clawn minipig cells stably expressing and secreting human Apo(a) into the culture medium were used for SCNT. The transgenic offspring

expressed human Apo(a) in all tissues examined including blood plasma. Compared to the low plasma concentrations of lipoprotein a in *Apo(a)* transgenic mice and rabbits (<10 mg/dL), the human *Apo(a)* transgenic pig line showed high plasma levels (>400 mg/dL) of lipoprotein a without a significant change in plasma total cholesterol, low-density lipoprotein cholesterol (LDL-C), high-density lipoprotein cholesterol (HDL-C) or triglyceride levels. Studies of spontaneous or induced atherosclerosis in this novel animal model were not yet done (Ozawa et al., 2015). Using the same transgene, human *Apo(a)* transgenic pigs were also generated in the genetic background of NIBS (Nippon Institute for Biological Science) minipigs (Shimatsu et al., 2016).

In humans, loss-of-function mutations in the low-density lipoprotein receptor (*LDLR*) gene lead to familial hypercholesterolemia. The heterozygous mutant patients typically show twice the normal plasma LDL levels and a significantly increased risk for atherosclerosis. Individuals with both *LDLR* alleles defective face early-onset atherosclerosis. Pigs with spontaneous familial hypercholesterolemia have been described harboring the mutation $LDLR^{R84C}$ that reduces receptor binding (Hasler-Rapacz et al., 1998). As a model of familial hypercholesterolemia, Ossabaw minipigs harboring biallelic *LDLR* mutations were produced by SCNT of TALEN-modified fetal fibroblasts with various mutant genotypes. Piglets carried biallelic *LDLR* mutations which are expected to prematurely truncate the *LDLR* open reading frame, or are implicated in familial hypercholesterolemia (Carlson et al., 2012).

Another workgroup used gene targeting by homologous recombination to disrupt the porcine *LDLR* gene and SCNT to produce Yucatan minipigs with the mutation $LDLR^{C128X}$. Homozygous $LDLR^{C128X}$ mutants produced no functional LDLR protein. Breeding of heterozygous mutants resulted in the expected Mendelian ratio of homozygous mutant, heterozygous mutant and wild-type offspring. When fed a standard swine diet (low fat, no cholesterol), heterozygous mutant $LDLR^{C128X}$ pigs exhibited increased total and low-density lipoprotein cholesterol levels, whereas homozygous mutant $LDLR^{C128X}$ pigs showed highly elevated levels. The severe hypercholesterolemia in homozygous mutant animals resulted in atherosclerotic lesions. When fed a diet containing high fat and high cholesterol, hypercholesterolemia and atherosclerosis developed faster and more severe in the mutant pigs (Davis et al., 2014). The $LDLR^{C128X}$ mutant pig model was subsequently used to analyze the effects of statins on the hypercholesterolemia and atherosclerosis phenotype (Amuzie et al., 2016).

The same strategy (gene targeting by homologous recombination to disrupt exon 4 of the porcine *LDLR* gene and subsequent SCNT) was used in the genetic background of Landrace × Large White crossbred pigs,

and homozygous mutant *LDLR* pigs were produced by mating heterozygous mutant *LDLR* pigs. The mutant pig model was also used to analyze the effects of statins on the hypercholesterolemia and atherosclerosis phenotype (Li et al., 2016).

Atherosclerosis is a low-grade inflammatory disease of the arterial wall caused primarily by cholesterol-containing low-density lipoprotein particles in the blood. Mouse models are missing central features of human atherosclerosis. Proprotein convertase subtilisin/kexin type 9 (PCSK9) is an important regulator of low-density lipoprotein cholesterol by binding hepatic low-density lipoprotein receptors and targeting them to lysosomal degradation. The human gain-of-function mutation $PCSK9^{D374Y}$ increases affinity of this binding, which causes a severe form of autosomal dominant familial hypercholesterolemia. Using Sleeping Beauty DNA transposition and SCNT, transgenic Yucatan minipigs were created to express mutant human $PCSK9^{D374Y}$ under the control of the liver-specific human α1 antitrypsin promoter and a hepatocyte control region from the apolipoprotein E gene. Transgenic pigs with high transgene expression fed on a low-fat diet showed higher plasma low-density lipoprotein cholesterol levels compared to controls. A high-fat, high-cholesterol diet induced severe hypercholesterolemia in these animals, as well as accelerated development of atherosclerosis that has human-like lesions (Al-Mashhadi et al., 2013). Diabetes is associated with an increased risk of atherosclerotic cardiovascular disease. Mutant human $PCSK9^{D374Y}$ expressing Yucatan minipigs were fed a cholesterol-enriched, high-fat diet and injected with streptozotocin to generate a model of diabetes. Stable hyperglycemia was achieved in the diabetic minipigs, while the plasma total cholesterol, low-density lipoprotein cholesterol and creatinine levels were unaffected. Diabetes failed to increase atherosclerosis in any of the vessels examined (Al-Mashhadi et al., 2015).

Lipoprotein-associated phospholipase A2 (PLA2G7), also known as platelet-activating factor acetylhydrolase (PAFAH) circulates in human blood predominantly in association with low-density lipoprotein cholesterol and hydrolyses oxidized phospholipids into proinflammatory products. Increased circulating levels or elevated activity of PLA2G7 are associated with the risk of vascular disease. However, in the mouse circulation, it predominantly binds to high-density lipoprotein cholesterol and exhibits antiinflammatory properties. Therefore, transgenic Beijing minipigs ubiquitously overexpressing pig PLA2G7 were generated using a transgene with the pig *PLA2G7* cDNA driven by the translation elongation factor 1a promoter. Three transgenic founders derived by SCNT were examined and showed a more than fivefold *PLA2G7* RNA expression and an around twofold increased enzymatic activity in the blood compared to controls. The body weight of transgenic pigs did not differ at

birth or at 6 months of age compared to controls. The activity of PLA2G7 did not interfere with the feeding state. Inflammatory gene mRNA levels in the peripheral blood mononuclear cells of transgenic pigs were significantly elevated. Transgenic pigs did not exhibit increased total cholesterol, low-density lipoprotein cholesterol or high-density lipoprotein cholesterol levels. Triglyceride levels during the fasting state also were not different between transgenic pigs and controls. However, in the fed state, the triglyceride levels of transgenic pigs were significantly elevated compared to the fasting state which was not seen in the controls (Tang et al., 2015).

NPC1L1 (Niemann Pick C1 Like 1) is highly expressed in small intestine and plays a critical role in both dietary cholesterol absorption and biliary cholesterol reabsorption thereby influencing cardiovascular and metabolic pathways. Using the CRISPR-Cas9 system by directly editing exon 2 of *NPC1L1* in zygotes, live biallelic *NPC1L1* knockout Bama minipigs exhibiting different kinds of indels in *NPC1L1* were generated. The sequence data revealed more than two different knockout genotypes in some pigs, suggesting that cleavage had occurred multiple times and resulted in mosaicism of the modification. Analysis of the mutant phenotype was not described (Wang et al., 2015b).

3.12 Cardiomyopathy

Myocardial infarction and heart failure are severe causes for death in humans. Extracellular nucleotides (ATP and ADP) released at the site of myocardial damage induce thrombosis, apoptosis and necrosis. ENTPD1 (ectonucleoside triphosphate diphosphohydrolase 1, CD39) rapidly hydrolyzes ATP and ADP to AMP. An in vivo myocardial ischemia/reperfusion injury test in transgenic mice expressing human CD39 resulted in a decrease of the infarct size. The same transgene including the human *CD39* cDNA driven by the murine MHC class I gene H-$2K^b$ promoter was used for the generation of transgenic pigs via SCNT. Expression of human CD39 was detected on circulating blood cells and in myocardial tissue of the transgenic animals. After in vivo induction of myocardial ischemia/reperfusion injury, a reduction of the myocardial injury analogous to the results in the transgenic mice was found (Wheeler et al., 2012).

Thymosin β4 (TMSB4X, Tβ4) is the most abundant G-actin binding peptide of the cytosol and is a potent proangiogenic factor. The role of myocardin-related transcription factors (MRTF) and serum response factor (SRF) for this function was examined in experimentally induced prolonged ischemic myocardium areas of transgenic pigs ubiquitously and constitutively overexpressing Tβ4 driven by the cytomegalovirus promoter. Upon induction of a reversible loss of cardiomyocyte function which is amenable to therapeutic neovascularization,

transgenic pigs did not experience a significant loss of perfusion nor myocardial function at rest or under rapid pacing. Functional vascular regeneration by induced capillary growth and maturation was found in the transgenic pigs (Hinkel et al., 2014).

The pore-forming subunit of the cardiac sodium channel Nav1.5 encoded by *SCN5A* is a critical determinant of myocardial excitability and conduction. Loss-of-function mutations in *SCN5A* can clinically manifest as progressive cardiac conduction disorders or as arrhythmic syndromes, such as Brugada syndrome. In addition to electrophysiological dysfunction, *SCN5A* mutations are also associated with myocardial fibrosis manifesting as global cardiomyopathy. In a 10-year old child exhibiting Brugada syndrome, the mutation $SCN5A^{E555X}$ was discovered. Therefore, cardiac sodium channelopathy pig models were generated by homologous recombination in the genetic background of outbred Yucatan minipigs via SCNT exhibiting the orthologous porcine heterozygous mutation $SCN5A^{E558X}$. The heterozygous mutant animals were viable and fertile, and showed no sudden death over a 2-year monitoring period. They showed reduced SCN5A protein expression, which resulted in diminished total sodium conductance. The heterozygous mutant hearts showed slowed conduction and increased susceptibility for ventricular arrhythmias in the absence of structural defects of the myocardium or specialized conduction system. In total, a novel animal model was established for understanding the mechanisms linking sodium channel dysfunction to cardiac pathophysiology (Park et al., 2015b).

3.13 Blood Disorders

Human hemophilia A is a common X chromosome-linked genetic bleeding disorder caused by abnormalities in the coagulation factor VIII (*F8*) gene. F8 works as heterodimer of a heavy and light chain processed from the 2351-amino acid precursor (256 kDa). Hemophilia A patients suffer from bleeding diathesis. Using a targeting vector for the disruption of exon 16 of *F8*, thereby referring to the targeting vector used to generate hemophilia A mice, and two rounds of SCNT, four heterozygous *F8* knockout Large White pigs were born exhibiting severely decreased F8 levels to less than 1% compared to controls. The hemophilia A pigs showed a severe bleeding tendency upon birth leading to the early loss of the animals (Kashiwakura et al., 2012). Already some years before, transgenic pigs were established as bioreactors which produced human F8 in the milk (Paleyanda et al., 1997).

Von Willebrand factor (*VWF*) gene deficiency in human causes severe von Willebrand disease. Using the CRISPR-Cas9 system for editing exon 5 of *VWF*, which encodes the first trypsin inhibitory-like domain, directly in Bama minipig zygotes, monoallelic, as well as biallelic

VWF mutant piglets were born. Plasma VWF protein expression was largely reduced in monoallelic mutant pigs, and was nearly undetectable in biallelic mutant pigs. As in human patients, homozygous *VWF* knockout pigs showed a severe bleeding tendency and a decreased plasma level of coagulation factor VIII, but no significant differences in other parameters of the hematological analysis compared to controls (Hai et al., 2014). Already some years before, transgenic pigs were established as bioreactors which produced recombinant human von Willebrand factor in the milk (Lee et al., 2009).

3.14 Cystic Fibrosis

Alterations of the cystic fibrosis transmembrane conductance regulator (CFTR, 1480 amino acids) were identified to cause the autosomal recessive cystic fibrosis (CF) which still remains incurable. Loss of CFTR function causes pancreatic insufficiency, focal biliary cirrhosis, infertility, and chronic airway infections. In addition, up to 20% of babies with CF are born with meconium ileus. Mutant mice have been established harboring a disrupted *Cftr* gene, but they failed to develop the lung and pancreatic disease causing most of the morbidity and mortality in human patients (Cohen and Prince, 2012). Mutant pigs were produced using SCNT and fetal fibroblasts with the *CFTR* gene either disrupted or containing the most common cystic fibrosis-associated mutation (ΔF508). Therefore, recombinant adeno-associated virus (rAAV) vectors were used to target *CFTR* in male fetal fibroblasts of outbred domestic pigs. The 4.5-kb knockout gene construct disrupted exon 10 encoding a portion of nucleotide-binding domain 1 with a stop codon at position 508 (F508X) followed by a floxed neomycin resistance gene driven by the phosphoglycerate kinase (*PGK*) promoter, whereas the ΔF508 knockin gene construct harbors the 3-bp deletion in exon 10 leading to ΔF508 followed by a floxed neomycin resistance gene driven by the *PGK* promoter in the downstream intronic region. Using successfully targeted cells without viral vector sequences for SCNT, heterozygous mutant male piglets were generated with each mutation. Newborn piglets with a targeted disruption of both *CFTR* alleles exhibited similar defects as seen in newborn human patients, that is, meconium ileus, exocrine pancreatic destruction, and focal biliary cirrhosis (Rogers et al., 2008a; Rogers et al., 2008b). The analysis of the CF pigs provided detailed insights into the pathology of affected organ systems, such as the respiratory tract and the gastrointestinal organs (Cohen and Prince, 2012).

We produced an independent CF pig model on the genetic background of the Landrace breed by sequential BAC targeting of the *CFTR* locus. CH242-248P18, a BAC containing parts of the *CFTR* gene was modified by placing a STOP box adjacent to the *CFTR* start codon to suppress *CFTR* mRNA translation. Using two rounds of targeting by homologous recombination and SCNT, homozygous knockout piglets were produced. In general, the observed CF phenotype closely reflects the human situation, as well as that of the previously published CF piglets (Rogers et al., 2008b). Most prominent and in accordance to the previously published CF piglets (Rogers et al., 2008b), our homozygous knockout piglets showed 100% penetrance of a severe meconium ileus. Efforts to overcome this fatal complication by surgical or conservative treatment were not successful leading to the death or euthanasia of the animals within the first days after birth (Klymiuk et al., 2012a).

To overcome the appearance of the severe meconium ileus, *CFTR* knockout pigs were produced with the intestinal expression of wild-type *CFTR*. In analogy to experiments in rats, pig *CFTR* knockout cells were transfected with a transgene harboring 1.8 kb of the rat intestinal fatty acid binding protein (*iFABP*) promoter and the porcine *CFTR* cDNA. Using five different cell clones for SCNT, different pig lines with various intestinal expression levels of *CFTR* were produced. In three transgenic lines, intestinal *CFTR* expression improved the intestinal phenotype. In all transgenic lines, a similar degree of pancreatic destruction, microgallbladder, and focal biliary cirrhosis as previously reported in newborn *CFTR* knockout pigs was observed. They also showed reduced weight gain and lung disease (Stoltz et al., 2013).

3.15 Duchenne Muscular Dystrophy

Duchenne muscular dystrophy (DMD) is caused by loss-of-function mutations in the X-linked dystrophin (*DMD*) gene leading to progressive muscle weakness and wasting. *DMD* is among the largest genes in the mammalian genome with a length of more than 2 Mb. DMD is mostly caused by deletions in the *DMD* gene, but point mutations and duplications also appear. Pigs with the spontaneous mutation *DMD^{R1958W}* in exon 41 were identified and phenotypically characterized as a natural porcine model of DMD insufficiency (Nonneman et al., 2012).

Using SCNT, pigs with a deletion of exon 52 of the *DMD* gene which is a frequent mutation in human DMD, were produced resulting in a frame shift in the transcript. *DMD* mutant pigs exhibited absence of DMD in skeletal muscles, increased serum creatine kinase levels, progressive dystrophic changes of skeletal muscles, impaired mobility, muscle weakness, and a maximum life span of 3 months due to respiratory impairment. Unlike human DMD patients, some *DMD* knockout pigs died shortly after birth. The development of muscular dystrophy in *DMD* knockout pigs appears in an accelerated manner when compared with human patients, and was further analyzed in genome-wide transcriptome studies of muscle tissue (Klymiuk et al., 2013, 2016).

Another workgroup announced the development of a DMD minipig model harboring an in-frame exon deletion in the rod domain of DMD and their subsequent phenotypic characterization (Selsby et al., 2015). Information regarding a third porcine DMD model is available through a patent of Exemplar Genetics. The minipigs possess a deletion of exon 52 and show pathological alterations consistent with the human DMD phenotype (Selsby et al., 2015).

3.16 Diabetes Mellitus

Diabetes mellitus is a group of chronic metabolic disorders characterized by hyperglycemia resulting from defects in insulin secretion, insulin action or a combination of both. In the majority of cases diabetes mellitus is diagnosed too late, namely when considerable pathological alterations of the pancreatic β-cells are manifest. Changes in insulin secretion, glucose homeostasis, and insulin sensitivity occur many years before clinical manifestation of diabetes. Therefore biomarkers indicating early stages of β-cell dysfunction and mass reduction would allow early therapeutic intervention. For the search of biomarkers animal models resembling β-cell dysfunction in the prediabetic state are needed (reviewed in Renner et al., 2016a).

Transgenic pigs expressing a dominant-negative receptor for the incretin hormone glucose-dependent insulinotropic polypeptide (*GIPR^dn*) were established by our group (Renner et al., 2010). The incretin hormones glucose-dependent insulinotropic polypeptide (GIP) and glucagon-like peptide-1 (GLP-1) are secreted by enteroendocrine cells and are responsible for the so-called incretin effect, the phenomenon that an oral glucose load elicits a higher insulin response compared with an isoglycemic intravenous glucose infusion. Inactivation of incretins takes place via enzymatic cleavage by the enzyme dipeptidyl peptidase–4 (DPP-4). In type 2 diabetic patients the incretin effect was found to be highly diminished which is related to a reduced insulinotropic action of GIP. Nearly sustained insulinotropic action of GLP-1 in type 2 diabetic patients revealed its therapeutic potential and initiated the ongoing development of GLP-1 receptor agonists, as well as DPP-4 inhibitors. Variation in the *GIPR* gene, desensitization of the GIP/GIPR axis or downregulation of the GIPR on the β-cell have been discussed as possible reasons for the reduced insulinotropic action of GIP (reviewed in Renner et al., 2016b).

GIPR^dn transgenic pigs were generated by lentiviral gene transfer to mimic the reduced insulinotropic effect of GIP. The dominant-negative GIPR has an 8-amino acid deletion (amino acid position 319–326, nucleotide position 955–978), and two additional point mutations (amino acid position 340, nucleotide position 1018–1020) leading to an amino acid exchange from alanine to glutamic acid (Ala → Glu) in the third intracellular loop which is known to be essential for further signal transduction. The ligand GIP can bind the GIPR^dn with nearly the same binding affinity compared with the endogenous GIPR, albeit binding the GIPR^dn does not lead to any further signal transduction. As a result, competition of the GIPR^dn and endogenous GIPR for the ligand GIP leads to a reduced insulinotropic action of GIP (Herbach et al., 2005).

GIPR^dn transcription was detected in isolated islets of Langerhans. *GIPR^dn* transgenic pigs developed normally and did not show any difference in body weight gain compared to littermate controls. Young, 11-week old *GIPR^dn* transgenic pigs exhibited reduced oral glucose tolerance due to delayed insulin secretion. However, the overall insulin secretion considering the complete duration of the oral glucose tolerance test (120 min following oral glucose load), as well as the intravenous glucose tolerance was found to be unaltered compared to controls. Also, both groups showed similar β-cell mass at this age. With increasing age glucose control deteriorated so that 5-month old *GIPR^dn* transgenic pigs showed reduced oral glucose tolerance due to reduced insulin secretion. At the age of 11 months, intravenous glucose tolerance was also impaired and insulin secretion diminished. Quantitative-stereological analyses of the pancreas of 5-month old transgenic and control pigs revealed a reduction of 35% of the total β-cell volume in *GIPR^dn* transgenic pigs while an even more pronounced reduction of 58% of the total β-cell volume was detected in 1–1.4-year old *GIPR^dn* transgenic pigs compared to controls (Renner et al., 2010).

GIPR^dn transgenic pigs show progressive deterioration of glucose control and reduction of β-cell mass, but fasting normoglycemia, thus providing a unique opportunity to study metabolic changes during the prediabetic period. We used plasma samples from intravenous glucose tolerance tests of 2.5- and 5-month old *GIPR^dn* transgenic pigs for a targeted metabolomics approach. Additionally, a holistic transcriptome analysis of liver samples from 5-month old *GIPR^dn* transgenic pigs and controls was performed to evaluate if plasma metabolite alterations are accompanied by expression changes of targets within corresponding pathways (Renner et al., 2012).

GLP1R agonists represent a promising group of incretin-based therapeutics for type 2 diabetes. Liraglutide is approved for the use in adult type 2 diabetic patients and was shown to reduce body weight and improve glycemic control. Therefore, we studied the effects of liraglutide in adolescent 2-month old *GIPR^dn* transgenic pigs exhibiting a prediabetic condition including disturbed glucose tolerance, reduced insulin secretion, and progressive reduction of functional β-cell mass, by daily injections for 90 days. Although plasma liraglutide levels of adolescent transgenic pigs treated in our study were higher compared to human trials, proproliferative effects on the endocrine or exocrine pancreas were not observed (Streckel et al., 2015).

Another workgroup also generated mutant human $GIPR^{dn}$ transgenic pigs exhibiting human GIPR that is modified in the region of the third intracellular loop by a single amino acid exchange (A340E) and a deletion of eight amino acids (residues 319–326) essential for signal transduction. In the transgenic pigs established by SCNT, $GIPR^{dn}$ was expressed under the control of rat *Ins2* promoter in the pancreas. In summary, $GIPR^{dn}$ transgenic pigs exhibited impaired glucose metabolism and β-cell function (Cheng et al., 2015).

Heterozygous missense mutations in the insulin (*INS*) gene have been identified to cause permanent neonatal diabetes mellitus in humans. To establish a large animal model of permanent neonatal diabetes mellitus, we generated INS^{C94Y} transgenic pigs which correspond to the human INS^{C96Y} mutation and the $Ins2^{C96Y}$ mutation of the Akita mouse. INS^{C96Y} disrupts one of the two interchain disulfide bonds of INS. The mutant insulin leads to impaired trafficking of normal proinsulin, accumulation of misfolded insulin in the endoplasmic reticulum (ER), and ER stress which finally triggers β-cell apoptosis. The transgene harboring porcine INS^{C94Y} with its essential regulatory elements was transduced in pig cells, and SCNT was used to generate transgenic founder pigs. A line expressing high levels of INS^{C94Y} mRNA (70–86% of the wild-type *INS* transcript level) exhibited elevated blood glucose soon after birth but unaltered β-cell mass at the age of 8 days. At 4.5 months, INS^{C94Y} transgenic pigs exhibited 41% reduced body weight, 72% decreased β-cell mass, and 60% lower fasting insulin levels compared with littermate controls. β-cells of INS^{C94Y} transgenic pigs showed a marked reduction of insulin secretory granules and severe dilation of the endoplasmic reticulum. Cataract development was already visible in 8-day old INS^{C94Y} transgenic pigs and became more severe with increasing age. Diabetes-associated pathological alterations of kidney and nervous tissue were not detected during the observation period of 1 year. INS^{C94Y} transgenic pigs can be propagated by conventional breeding when treated with insulin. However, the costs for maintenance of diabetic pigs are high (Renner et al., 2013).

Effects of maternal diabetes mellitus on embryos, fetuses, and offspring are another attractive research topic which can be addressed using this model. In a preliminary study we observed that both transgenic and wild-type offspring of diabetic INS^{C94Y} transgenic sows mated to a wild-type boar exhibited reduced absolute and relative weights of most organs when compared to the offspring of matings with INS^{C94Y} transgenic boars and wild-type sows, which emphasizes potential developmental effects of maternal diabetes in this model (Wolf et al., 2014).

In addition, we previously established a mutant mouse line showing diabetes which was caused by a point mutation in the insulin 2 (*Ins2*) gene. The point mutation leads to the amino acid exchange C95S and the loss of the A6-A11 intrachain disulfide bond of the insulin. Male heterozygous $Ins2^{C95S}$ mutant mice develop progressive diabetes mellitus with strong reduction of the total pancreatic islet volume and the total β-cell volume together with severe alterations of the β-cell structure (Herbach et al., 2007). Therefore, we established a transgenic pig model expressing mutant porcine insulin analogous to the mutant mouse insulin by additive gene transfer for the subsequent study of β-cell dysfunction in diabetes mellitus. Using SCNT, transgenic founder pigs were established with normal development and unaltered fasting blood glucose levels, but disturbed intravenous glucose tolerance and reduced insulin secretion (unpublished own data).

Another transgenic porcine diabetes model was produced for type 3 of maturity-onset diabetes of the young (MODY3) which is caused by dominant mutations of the hepatocyte nuclear factor 1α (*HNF1A*) gene. The effect of the dominant-negative mutation used was previously verified in transgenic mice. The transgene consisted of the 1.2-kb chicken β-globin insulator, the 0.4-kb enhancer for the immediate-early gene of the cytomegalovirus followed by the 0.7-kb porcine insulin promoter, a 2.3-kb mutant human hepatocyte nuclear factor 1α cDNA with the most common mutation (P291fsinsC), the 0.1-kb SV40 polyadenylation signal, and the 1.2-kb chicken β-globin insulator. A transgenic cell clone with ten copies of the transgene was used for SCNT. Twenty two live transgenic cloned pigs were produced. Most of them died within 2 weeks after birth. The transgene-derived protein was detected in pancreas, heart and kidney. Persistent diabetes with nonfasting blood glucose levels over 200 mg/dL was observed in four transgenic pigs with longer living time. Histological analysis revealed abnormal pancreatic islet morphogenesis and pathological alterations of the kidneys, such as glomerular hypertrophy and sclerosis (Umeyama et al., 2009). Transgenic pigs were continuously treated with insulin to allow for normal growth to sexual maturity. Sperm quality of transgenic boars in in vitro fertilization experiments was lower compared to controls but live transgenic offspring were produced by in vitro fertilization with cryopreserved sperm (Umeyama et al., 2013).

3.17 Liver Disease

Hereditary tyrosinemia type I is a severe, autosomal recessive disease caused by a deficiency in the enzyme fumarylacetoacetate hydrolase (FAH) that catalyzes the last step of tyrosine metabolism. The absence of FAH causes accumulation of the toxic metabolite fumarylacetoacetate in hepatocytes and renal proximal tubules, the two major cell types that express FAH. This results in hepatic failure, cirrhosis, and hepatocellular carcinoma

early in childhood. For targeting porcine *FAH*, a similar approach as for the generation of *Fah* knockout mice was used. An in-frame stop codon and a neomycin resistance cassette were inserted into exon 5 of the porcine *FAH* gene, and the knockout construct was delivered to fetal pig fibroblasts with a recombinant adeno-associated virus (rAAV) vector. Heterozygous knockout cells were used for SCNT, and viable and healthy heterozygous *FAH* knockout pigs were generated. The heterozygous knockouts were phenotypically normal, showed normal tyrosine metabolism and histologically normal livers. Compared to controls, transcript, and protein expression of *FAH*, as well as the enzyme activity were reduced (Hickey et al., 2011). After mating heterozygous *FAH* knockout Large White and Landrace pigs, no homozygous *FAH* knockout piglets were born. FAH deficiency in mice does not produce an in utero lethal defect and mice are born, albeit with severe liver damage. Further analyses indicated robust FAH protein expression in wild-type pigs at day 30 of gestation and in utero lethality of the homozygous *FAH* knockouts prior to day 35 of gestation. As human patients are successfully treated with a low-tyrosine diet combined with the administration of the potent inhibitor of 4-hydroxyphenylpyruvate dioxygenase NTBC, heterozygous *FAH* knockout females were treated with NTBC prior to conception with heterozygous *FAH* knockout boars and for the duration of the pregnancy. This treatment rescued the in utero lethality of FAH deficiency as healthy homozygous *FAH* knockout piglets were born within the predicted Mendelian ratio. Animals treated with NTBC were phenotypically normal at birth, however, withdrawal of NTBC resulted in rapid clinical decline including multiple biochemical abnormalities, dysmorphic kidney morphology and death due to progressive liver injury without showing other major abnormalities (Hickey et al., 2014).

3.18 Kidney Disease

Autosomal dominant polycystic kidney disease (ADPKD) is a common human chronic genetic disease. It is characterized by the progressive formation of cysts in bilateral kidneys and numerous extrarenal manifestations including hepatic and pancreatic cysts, intracranial aneurysms, and abnormalities in cardiovascular systems. The progressive growth of cysts in kidneys eventually leads to renal failure in 50% of patients, and there is currently no effective treatment. Mutations in *PKD1* and *PKD2* are responsible for autosomal dominant polycystic kidney disease, which represent about 85% and 15% of patient cases, respectively. Polycystin 2 encoded by *PKD2* is a calcium-permeable cation channel that plays a role in many aspects of cell function. Transgenic mice or rats overexpressing cDNA or genomic sequences of PKD1 and PKD2 show typical cystic kidneys, and the severity of the disease is positively correlated with the copy number and the expression level of the transgenes. Porcine PKD1 and PKD2 are highly similar to the human orthologs. Using full-length porcine *PKD2* cDNA driven by a ubiquitous cytomegalovirus enhancer/promoter, four transgenic Chinese experimental minipigs (CEMP) were generated by SCNT. The transgenic pigs showed approximately 10 insertion events and PKD2 was more highly expressed in transgenic pigs than in wild-type controls. Blood urea nitrogen and serum creatinine levels were continuously measured up to 1 year of age to assess the pig kidney function. The transgenic pigs showed no significant alteration in kidney function, and there were no cystic manifestations by 1 year of age in this model. It is estimated that more than 2 years may be required for manifestation of renal cystogenesis in these pigs (He et al., 2013).

Subsequently, the same workgroup produced heterozygous *PKD1* knockout Chinese experimental minipigs (CEMP) by editing exon 5 of *PKD1* in porcine cells by ZFN. *PKD1* is ubiquitously expressed in various organs. Using various edited cell clones in SCNT, pigs with various monoallelic indels in *PKD1* were achieved and showed a lower *PKD1* expression at both the transcriptional and translational level. Breeding to wild-type pigs revealed the germline transmission of the mutant alleles according to the Mendelian ratio. In the heterozygous *PKD1* knockouts, no macroscopic or microscopic cysts appeared in the kidneys 48 h p.p., but renal cysts appeared as early as 3 months after birth without affecting the whole kidney in the early stage of the disease. Most renal cysts were derived from the proximal tubules and collecting ducts and grew progressively. In addition, renal fibrosis was associated with disease progression, and liver cysts were found (He et al., 2015).

The protooncogene c-Myc is overexpressed in cystic kidneys, and transgenic mouse models of autosomal dominant polycystic kidney disease overexpressing c-Myc in kidney tissue exist. Therefore, the same workgroup generated transgenic Chinese experimental minipigs (CEMP) by SCNT using the porcine *MYC-b* cDNA driven by the cytomegalovirus enhancer and the mouse cadherin 16 promoter. The transgenic founders each had multiple integrated copies of the transgene vector and exhibited overexpression of *MYC* in kidney tissues. Blood urea nitrogen and serum creatinine levels were measured up to 6 months of age, but no obvious abnormalities were detected (Ye et al., 2013).

3.19 Osteoporosis

Transgenic mice overexpressing the soluble receptor activator of NF-κB ligand (RANKL, TNFSF11) in the liver after birth showed hyperactivation of osteoclasts resulting in resorptive osteoporosis. In humans, inhibition of RANKL by monoclonal antibodies is a current approach

in osteoporosis therapy. For generating a large animal model with osteoporosis, the spatio-temporally regulated or inducible expression of RANKL is required, since mice overexpressing RANKL ubiquitously from the early developmental stage died at the late fetal stage. Therefore, the Tet-On system was used and double transgenic pigs were generated by SCNT for the inducible expression of RANKL by administration of doxycycline (Klymiuk et al., 2012b) (see Section 2.5). One living double transgenic founder pig and a double transgenic offspring on the genetic background of the Swabian-Hall breed were analyzed. In the absence of doxycycline, the RANKL protein level was below the detection limit. The oral administration of increasing concentrations of doxycycline revealed a minimal dose of 25 mg/kg/day to detect significantly increased RANKL levels after 6 days. The RANKL levels were further increased with higher doses of doxycycline, but induction with 25 mg/kg/day was sufficient not only to induce RANKL but also to increase the levels of endogenous cathepsin K, a marker for activation of osteoclasts. This confirmed the biological function of the induced transgene expression for osteoporosis. Future studies will clarify whether induced overexpression of RANKL in the pig results in osteoporosis (Klymiuk et al., 2012b).

3.20 Marfan Syndrome

Fibrillin 1 (FBN1) is the principal structural component of extracellular microfibrils in the connective-tissue matrix of the body. Heterozygous mutations resulting in the abnormal formation of the extracellular matrix cause the Marfan syndrome. Human patients experience poor quality of life caused by skeletal disorders and cardiovascular impairment. Using the ZFN system in porcine Large White/Landrace × Duroc fetal fibroblasts, a heterozygous *FBN1* mutant cell clone (Glu433AsnfsX98) was established encoding a truncated FBN1 protein caused by a new stop codon at amino acid residue 531. By SCNT, heterozygous *FBN1* mutant founder pigs were generated from one single line of nuclear donor cells but showed no homogenous phenotype, as Marfan-like skeletal symptoms occurred in only a part of the heterozygous mutant founders. Various expression of the pathological phenotype due to differences in genetic and epigenetic factors has been also observed both in human patients and heterozygous *Fbn1* mutant mouse models. Generation of heterozygous G1 mutants by mating founder animals to wild-type pigs resulted in the appearance of the similar pathological phenotype in the founder and their progeny. After mating heterozygous mutants, homozygous mutants appeared showing typical symptoms of the Marfan syndrome and a survival time up to 28 days of age. Neonatal lethality has been also described in homozygous *Fbn1* mutant mouse models (Umeyama et al., 2016).

3.21 Skin Disease

In the Sonic hedgehog signaling pathway (SHH-GLI), the soluble protein SHH activates the transmembrane protein smoothened (SMO) allowing the subsequent activation of the transcriptional regulators GLI1, GLI2, and GLI3. Normal hair follicle and sebaceous gland development is tightly regulated by SHH-GLI signaling. GLI2 has both repressor and activator functions including in the oncogenic hedgehog signaling. *Gli2* knockout mice show multiple developmental abnormalities in the skin. Basal cell carcinoma is associated with constitutive signaling of the Shh-Gli pathway. In contrast to mice, the skin of pigs is very similar to that of humans.

Transgenic pigs (breed not specified) were produced to analyze the constitutive expression of the hedgehog transcriptional activator GLI2 in porcine skin. The transgene K5-hGLI2ΔN consists of the 5.3-kb bovine keratin 5 (*K5*) promoter and a *c-Myc* tagged N-terminal truncated form of the human *GLI2* gene, which has only activator function and shows 30-fold more activity than endogenous GLI2 in vitro. After transfection of fibroblasts, four different transgenic cell clones were used for SCNT to produce transgenic animals. Nontransgenic controls were produced in the same litters by using nontransgenic fibroblasts. The transgenic animals showed the keratinocyte-specific expression of the transgene in the stratum basale and the outer follicular root sheath of the skin at different levels. SHH-GLI target genes and endogenous *c-Myc*, as well as the immature keratinocyte markers K5, K14, and K17 were upregulated. This resulted in the development of a hyperproliferative and immature epidermis. Expression of genes associated with differentiation, adhesion, and signal transduction was normal. Histological analysis showed generalized epidermal abnormalities including epidermal hyperplasia and hyperkeratosis, as well as sebaceous gland hyperplasia. The transgenic animals developed skin infections soon after birth progressing to deep alterations at exposed skin areas. The animals died or were euthanized within few weeks after birth. The transgenic animal with the lowest expression of the transgene was alive for 6 months of age. The same transgene has been used to produce transgenic mice. The mice showed epithelial alterations resembling basal cell carcinomas and advanced neoplastic development (Roessler et al., 2005). In contrast to the transgenic mice, the transgenic pigs showed no gross signs of cutaneous tumors 2 weeks after birth, but diffuse epidermal changes and susceptibility to cutaneous infections were observed. The phenotype resembled those described for some forms of human psoriasis. Association between psoriasis and activated hedgehog signaling is discussed (McCalla-Martin et al., 2010).

The development of transgenic pigs as a model for cutaneous inflammation was the aim of another project.

Integrins are transmembrane signaling receptors that are important for cell growth and differentiation, as well as inflammatory responses in the skin. Transgenic mice showing the subrasal expression of the human integrins α2 (*ITGA2*) and/or β1 (*ITGB1*) in the epidermis developed hyperproliferation and aberrant differentiation of keratinocytes and a phenotype resembling psoriasis. Using SCNT and the transposon system, transgenic Göttingen minipigs were produced with transgenes analogous to the mouse project. The subrasal expression in keratinocytes was driven by the involucrin promoter, followed by the first intron of the involucrin gene and the coding sequences of human β1 or α2 integrin. For human β1 integrin, six transgenic pigs living more than 2 weeks were produced. All of them arose from different donor cell clones, and most of them showed several transgene integration sites. The transgene-derived protein was found to be correctly processed after translation in in vitro cultured transgenic porcine keratinocytes. No apparent differences in skin morphology between the transgenic pigs and controls were visible over an examination period of 14 months. For human α2 integrin, three living transgenic pigs were produced. The transgene-derived integrin was observed in the plasma membrane of transgenic keratinocytes. In addition, lower amounts of transgenic mRNA were also detected in all other tissues analyzed. Again, no visible epidermal abnormalities or psoriasis-like phenotypes were detected. However, markers of perturbed skin homeostasis in keratinocytes and of chronic inflammatory phenotype in the skin were identified (Staunstrup et al., 2012).

Microphthalmia-associated transcription factor (MITF) is a master regulator of melanocyte development and an important oncogene in melanoma. Mutations in the human *MITF* gene have been found in patients of the Waardenburg syndrome showing hypopigmentation and deafness. Cytoplasmic injections of the CRISPR-Cas9 system into zygotes editing exon 8 of the porcine *MITF*, which encodes part of the basic helix-loop-helix leucine zipper domain and is essential for MITF DNA-binding, achieved two live-born piglets showing no pigmentation over its entire body. RFLP and sequence analysis found biallelic mutations in both piglets, and Western blot analysis of tail skin tissues showed that MITF was completely absent in the two mutant piglets (Wang et al., 2015c).

In addition, using the CRISPR-Cas9 system and SCNT, biallelic tyrosinase (*TYR*) knockout pigs in the genetic background of Banna minipigs and Bama minipigs were produced. They harbored various types of mutations in the first exon region following the start codon corresponding to the respective donor cells. The *TYR* knockouts showed typical albinism with complete absence of melanin production in skin and eyes (Zhou et al., 2015).

3.22 Circadian Rhythm Disorder

The homeostasis of circadian rhythms in both central and peripheral tissues is pivotal for numerous biological processes. Transgenic mice expressing the mutant human cryptochrome 1 (*CRY1^{C414A}*) revealed disturbance of the circadian rhythm, as well as signs of type 2 diabetes, such as hyperglycemia and polydipsia. Therefore, an analogous Bama minipig model was produced with a transgene harboring the mutant human *CRY1^{C414A}* cDNA driven by the cytomegalovirus early enhancer and chicken β-actin (CAG) promoter and SCNT. Twenty-one transgenic founder piglets originating from two different donor cell clones and expressing the transgene remained healthy and gained normal weight under controlled external factors (light, food). Core circadian clock and proinflammatory cytokine gene expression were analyzed in ex vivo derived, cultured fibroblasts, and altered expression patterns were found compared to controls (Liu et al., 2013).

3.23 Cancer

For the development of an animal model for the study of human tumors, transgenic pigs were generated with a 4.8-kb fragment containing the long terminal repeat (LTR) of mouse mammary tumor virus (MMTV) and the activated v-Ha-ras sequence. The carcinogenic effect of the transgene has been proven in transgenic mice. DNA microinjection of fertilized oocytes was carried out on the mixed genetic background of the Landrace, Large White, and Duroc breeds. One female transgenic founder was produced which gave rise to hemizygous transgenic offspring. The expression analysis detected transgene-specific RNA in various tissues of the founder. Tumor development was not found in the transgenic founder and its transgenic offspring during the observation period for 30 months and 1–8 months, respectively. Breeding of G1 transgenic pigs to nontransgenic pigs confirmed their fertility. Reasons for the absence of tumor development might be low transgene expression levels, the lack of cofactors for the tumorigenesis, and/or tumor development in older ages which were not included in this study (Yamakawa et al., 1999).

Inactivating mutations of the breast cancer 1 (*BRCA1*) gene predispose to breast cancer and are often correlated to familiar breast and/or ovarian cancer. More than 1200 BRCA1 variants have been found, often leading to functional inactivation and predisposition to cancer. The *BRCA1* gene contains 22 coding exons encoding a nuclear protein of 1863 amino acids in humans and pigs, and 1812 amino acids in mice. Compared to the human BRCA1 protein, porcine BRCA1 showed 74% identity, and mouse BRCA1 showed 58% identity. Transgenic mouse models carrying targeted disruptions of *Brca1* revealed

the crucial role of the gene in embryonic development and cell proliferation regulation. Homozygous knockout mice lacking exon 11 died during the second half of the gestation. Developing tumors in the *Brca1* transgenic mouse models showed varying degrees of similarity to their human counterparts. Heterozygous *Brca1* knockout mice are developmentally and reproductively normal. Without exogenous stress factors, they showed no predisposition to breast cancer at an advanced age whereas heterozygosity for *BRCA1* mutations in humans strongly increase the risk of developing breast cancer at an older age. Somatic loss of heterozygosity (LOH) of the remaining wild-type allele is frequently found in human breast cancer cells but not in mice.

Most of the disease-related mutations have been found in exon 11, therefore this exon was used for gene targeting via homologous recombination by using recombinant adeno-associated virus (rAAV)-mediated gene targeting. Heterozygous *BRCA1* knockout cells of Yucatan minipigs with the deletion of large parts of exon 11 were used for SCNT giving rise to the birth of eight piglets, and seven of them were identified as heterozygous *BRCA1* mutants. Compared to control animals, the heterozygous *BRCA1* mutants showed decreased *BRCA1* mRNA in isolated fibroblasts, but no significant differences were observed with respect to the BRCA1 protein levels. Unexpectedly, all heterozygous *BRCA1* knockout piglets died within 18 days after birth while the wild-type littermate was still alive after half a year. The causes for the perinatal mortality remained unclear but may be the result of the SCNT technique used. Viability problems of other transgenic or nontransgenic Yucatan minipigs cloned by SCNT were frequently observed. To examine the role of the genetic background for the phenotype, the same knockout is intended to be produced with Göttingen minipigs where both the pregnancy rate and the number of piglets referring to the number of transferred embryos are higher in SCNT. Also the creation of a conditional pig model harboring a mammary-specific *BRCA1* knockout is intended. In addition, high efficiencies in gene targeting by using recombinant adeno-associated virus (rAAV) vectors were obtained in this project. This might allow the correct design of mutant cells without selection procedures based on drug resistance in the future (Luo et al., 2011).

Familial adenomatous polyposis (FAP) is characterized by foci of dysplastic growth in the colon and rectum that develop to adenomatous polyps and adenocarcinoma. Germline mutations in the adenomatous polyposis coli (*APC*) tumor-suppressor gene are responsible for familial adenomatous polyposis, and somatic *APC* mutations are found in most sporadic colorectal tumors at the earliest stages. Using mesenchymal stem cells of Landrace/Pietrain or Landrace pigs for SCNT, gene-targeted pigs carrying translational stop signals in the

APC gene at codons 1061 and 1311, that is orthologous to common germline mutations (*APC1061* and *APC1309*) in human familial adenomatous polyposis, were generated. Mutation at human codon 1309 is associated with a particularly severe phenotype with early onset and prolific polyposis when compared to mutation at codon 1061 which causes less severe polyposis. A 1-year old heterozygous *APC1061Stop* mutant pig showed no evidence of polyposis, whereas a heterozygous *APC1311Stop* mutant pig of the same age showed aberrant crypt foci, as well as low-grade and high-grade dysplastic adenomas in the large intestine, which is similar to the precancerous lesions that develop in patients with familial adenomatous polyposis. Thus, the mutant pig exhibited the well-characterized precancer phenotypic sequence leading to adenomas in the large intestine, replicating early-stage human familial adenomatous polyposis which is not the case for *Apc* mutant mice (Flisikowska et al., 2012).

Another workgroup used TALEN-stimulated mutagenesis to generate knockout alleles of the *APC* gene by short indels in Ossabaw pig fibroblasts which were used to produce monoallelic and biallelic *APC* mutant pigs by SCNT to model colon cancer. Phenotypic data were not yet published (Tan et al., 2013).

The tumor suppressor gene *TP53* encoding p53 is the most commonly inactivated gene in sporadic human cancers. Most of the *TP53* somatic mutations occur between codons 125 and 300 including the DNA binding region. The dominant-negative mutation *TP53R175H* is the most frequent missense mutation in many sporadic human cancers. Using porcine mesenchymal stem cells of Landrace pigs, a latent oncogenic mutant porcine *TP53* gene was constructed by insertion of a floxed transcriptional termination signal (LSL cassette) in the first intron and a point mutation encoding the oncogenic activation mutation R167H (that is equivalent to human R175H) in exon 5. The allele *TP53LSL-R167H* was predicted to lack TP53 expression, whereas *Cre* recombinase-mediated removal of the LSL cassette generates the allele designated *TP53L-R167H*. Fifteen viable heterozygous mutant *TP53LSL-R167H* piglets were produced by SCNT, all of them were free of any apparent abnormality (Leuchs et al., 2012). To determine whether pigs carrying the latent *TP53LSL-R167H* mutation in heterozygous or homozygous form would spontaneously develop tumors, animals were regularly analyzed for alterations in health and well-being. Nine heterozygous knockout pigs with an age up to 32 months were examined by necropsy. There was no evidence of tumors or other abnormalities in animals up to 16 months. Of the five older animals, four had tumors, and one animal had disseminated calcifying, ossifying lesions but no identifiable primary tumor. Lesions from three pigs were determined by histology as osteoblastic osteosarcomas. Osteosarcoma is a relatively rare solid tumor but the most common primary bone cancer, and is highly malignant

with bad prognosis. In addition, two G2 generation homozygous *TP53^{LSL-R167H}* knockout pigs were examined. Both animals grew more slowly than wild-type and heterozygous mutant controls, and revealed multiple large osteosarcomas at the age of 7–8 months which indicates accelerated tumor development in the homozygous p53 mutants (Saalfrank et al., 2016).

The human mutation *TP53^{R175H}* (corresponding to R167H in pigs) is also found in the germline of Li-Fraumeni patients who are strongly predisposed to developing multiple types of cancers. Gene targeting via homologous recombination in Yucatan minipig fibroblasts and subsequent SCNT obtained heterozygous *TP53^{R167H}* mutant founders. Mating of the heterozygous mutants revealed the expected ratio of Mendelian inheritance in the offspring. No tumors were detected via in vivo imaging or necropsy in the heterozygous *TP53^{R167H}* mutant pigs over 30 months of observation. All homozygous *TP53^{R167H}* mutant pigs that reached sexual maturity developed neoplastic lesions, including lymphomas and osteogenic tumors, thereby recapitulating the tumor types observed in mice and humans expressing orthologous *TP53* mutant alleles (Sieren et al., 2014).

Activating mutations in the protooncogene KRAS initiate pancreatic adenocarcinoma and nonsmall-cell lung cancer and occur in many other human cancers with *KRAS^{G12D}* as the most common mutation. Using mesenchymal stem cells of Landrace pigs, a latent oncogenic mutant porcine *KRAS* gene was constructed by insertion of a floxed transcriptional termination signal (LSL cassette) and a point mutation encoding the oncogenic activation mutation *KRAS^{G12D}*. In the intact form, the mutant allele does not express mutant KRAS. Expression can be induced by *Cre*-mediated excision of the LSL cassette, generating the allele designated *KRAS^{L-G12D}*. By SCNT, viable gene-targeted pigs carrying a latent mutant *KRAS^{G12D}* allele were produced that can be activated by *Cre* recombination (Li et al., 2015b).

Analogously, a *Cre* recombinase inducible porcine transgene ubiquitously expressing both *KRAS^{G12D}* and *TP53^{R167H}* was constructed, and transgenic pigs were generated with Minnesota minipig fibroblasts cells and SCNT. A transgenic pig line harboring a single copy of the transgene was further analyzed. Local expression of *Cre* by adenoviral administration of *Cre* at different sites in three transgenic pigs (intramuscularly in the legs, intratesticularly, or subcutaneously in the ear, neck, or abdomen) inevitably resulted in the development of tumors at the injection sites (Schook et al., 2015).

3.24 Infectious Diseases

Multiple lines of B-cell and T-cell deficient mice have been used for the study of B-cell (humoral) and T-cell (cellular) responses for many diseases. Compared to humans, pigs are often infected by closely-related viral and bacterial pathogens. They can serve as zoonotic reservoirs for human pathogens. For major enteropathogens, mouse models do not reproduce the tropism and immunopathology of the corresponding human infections. Thus, experiments in pigs may contribute to the study of the basic immune response to a pathogenic challenge, as well as to discriminate cellular and humoral protective immunity to infectious agents.

Rodents and humans can utilize 4–6 functional joining gene segments (J_H) of the heavy chain locus, whereas pigs only possess one functional J_H locus. Targeting the single functional joining region (J_H) of the heavy chain locus in porcine fibroblasts of the Large White breed was carried out by homologous recombination with a knockout vector removing the single functional J_H sequences. SCNT using one targeted cell clone produced heterozygous knockout animals which were mated to produce homozygous knockout piglets. The homozygous knockouts appeared in the litters with the expected Mendelian ratio. mRNA analysis in spleen and mesenteric lymph nodes, as well as protein analysis by flow cytometry detected that homozygous knockout piglets did not show mature B cells and antibodies of any isotype. No circulating IgM^+ B cells were observed in the homozygous knockouts, showing that VDJ rearrangement is impaired. Functional VDJ rearrangement at the heavy chain locus has been shown to be required for B-cell development. No transcription or secretion of immunoglobulin isotypes were observed in blood and secondary lymphoid tissues. No lymph node follicles were found. The findings were consistent to published results in B-cell deficient mice and humans. Heterozygous knockouts showed IgM^+ B cells of more than half of the amount of wild-type controls. In contrast, T-cell receptor $(Tcr)_\beta$ transcription and T cells appeared largely unaffected in homozygous knockouts.

The homozygous knockout pigs were conventionally reared by allowing them to suckle until weaning 4 weeks after birth. In the suckling period they remained healthy, however, thereafter they were severely susceptible to bacterial infections leading to a wasting-like syndrome and the impossibility to conventionally maintaining them longer than a few weeks after weaning. Thus, gnotobiotic facilities have to be used for maintaining the homozygous knockouts. These antibody- and B-cell deficient pigs may be used as the first step in the generation of heavy chain knockout pigs for the subsequent complete replacement of the porcine immunoglobulin loci with the human homologous genomic sites. These genetically engineered animals in the future might also serve as a source of pathogen-specific human polyclonal antibodies thereby alleviating both the supply and specificity issues as polyclonal antibodies harvested from

human donors by plasmapheresis are of broad specificity and the supply is limited (Mendicino et al., 2011).

Therefore, the next step for this aim was carried out. The porcine κ light chain immunoglobulin locus is in the megabase range and comprises multiple families of variable (Vκ) genes, five joining (Jκ) regions and—as found for most common mammals including the mouse—a single constant (Cκ) gene. To inactivate the pig κ locus, the single Cκ gene offered the best option, as this strategy has been proven successful in the mouse. Therefore, targeted deletion of the most part of the porcine κ light chain constant (Cκ) region was carried out in pig primary fetal fibroblasts. By SCNT, heterozygous knockouts were produced with one mutant cell clone. Heterozygous knockouts were bred together to generate homozygous knockouts at a ratio close to that expected by the Mendelian inheritance. Peripheral blood mononuclear cells as circulating B cells and secondary lymphoid organs, such as mesenteric lymph nodes—which contain follicles that consist of a dense population of B cells—from homozygous knockouts were devoid of κ-containing immunoglobulins. Furthermore, there was an increase in λ light chain expression when compared to that of wild-type littermates. Tcr$_\beta$ rearranged gene transcription was not altered.

Even though there are two light chain loci (κ and λ), usage is unequal among mammals. In mice >95% of the light chain used by mature B cells are κ while >90% of immunoglobulins in ungulates, such as sheep, horses, and cattle use λ. In contrast, κ:λ usage in the pig is almost equal and corresponds to what is found in humans. The phenomenon of allelic exclusion, whereby any given mature B cell can express only one Ig heavy chain and one Ig light chain allele even though there are two alleles at each of the three Ig loci, is also true for the pig (Ramsoondar et al., 2011).

After the homozygous disruption of the J-region gene segment of the heavy chain locus (Mendicino et al., 2011) and of the porcine κ light chain (Ramsoondar et al., 2011), the targeted disruption of λ light chains was described to be underway (Mendicino et al., 2011).

Subsequently, another workgroup edited the functional JH region of the IgM heavy chain locus in porcine fibroblasts using the CRISPR-Cas9 system. Piglets with biallelic IgM heavy chain gene mutation were produced after SCNT. The piglets also showed no antibody-producing B cells which resulted in a B-cell deficient phenotype (Chen et al., 2015).

3.25 Immunodeficiency

Techniques for the production of genetically engineered animals were used to establish porcine models of severe combined immunodeficiency (SCID) primarily not to further examine analogous human SCID diseases,

but mainly to use these immune deficient pigs as tools for reconstitution experiments related to the immune system, human cancer studies, allograft and xenograft transplantation studies, regenerative medicine, and the evaluation of stem cells for clinical therapy.

X-linked interleukin-2 receptor γ chain gene (IL2RG) was disrupted in fetal fibroblasts by removing exon 6, which were used for SCNT to generate IL2RG mutant pigs on the genetic background of Landrace × Large White animals. Heterozygous IL2RG mutant females were healthy, whereas IL2RG mutant males were athymic and exhibited markedly impaired immunoglobulin and T- and NK-cell production, mirroring the situation in human SCID. Further, the model was validated by engraftment of allogeneic bone marrow transplants (Suzuki et al., 2012).

Another workgroup also generated male IL2RG knockout pigs which lacked thymus and were deficient in T and NK cells. The ZFN-mediated mutation in exon 1 consisted of both a 3-bp substitution and an 86-bp deletion spanning the major transcription start point and the start codon (ATG) of IL2RG which leads to the lack of IL2RG protein expression (Watanabe et al., 2013).

In addition, the recombination activating genes 1 (RAG1) and 2 (RAG2) were disrupted to produce immune deficient pigs. RAG1 and RAG2 are two adjacent genes, and their encoded enzymes function synergistically as a protein complex. If either of the two genes is disrupted, VDJ recombination is compromised and the B- and T-cell development is arrested in an immature status. In humans, mutations in RAG1 or RAG2 result in the complete absence of both B and T cells. TALEN were constructed to edit either RAG1 or RAG2 in Bama minipig cells. Using SCNT, live piglets with monoallelic or biallelic frameshift mutations in either RAG1 or RAG2 were generated therefore producing a nonfunctional RAG1 or RAG2 enzyme. Piglets with biallelic mutations in either RAG1 or RAG2 exhibited hypoplasia of immune organs, failed to perform VDJ rearrangement, and lacked mature B and T cells. RAG1 or RAG2 biallelic knockout pigs showed slower weight gain than controls and did not survive for more than 1 month under conventional housing conditions because of the deficient immune function. Heterozygous RAG1 or RAG2 mutants were healthy and grew normally under the same conditions (Huang et al., 2014).

Another workgroup also produced biallelic RAG2 knockout pigs. Using the TALEN system editing a functionally essential domain in exon 2 and subsequent SCNT, biallelic knockout Minnesota minipigs were established with a SCID phenotype lacking mature B and T cells but possessing NK cells and macrophages. They showed normal birth weight, but lower weight gain, and all either died or were euthanized before reaching 1 month of age under standard housing

environment. Pigs raised in a clean environment were healthier. The biallelic *RAG2* knockout pigs had no or an underdeveloped thymus, and the spleen was also smaller with a markedly hypoplastic white pulp compared to controls. Injection of human induced pluripotent stem cells (iPSC) resulted in efficient teratoma formation in biallelic *RAG2* knockout pigs. They also tolerated grafts of allogeneic porcine stem cells (Lee et al., 2014). In addition, another workgroup produced *RAG1* knockout Duroc pigs using SCNT after successfully targeting exon 2 (Ito et al., 2014). Two homozygous *RAG1* knockout neonatal piglets were established and showed phenotypical defects which are comparable to those described in the reports of Huang et al. (2014) and Lee et al. (2014).

Recently, direct injection of the CRISPR-Cas9 system into in vitro fertilization-derived Yorkshire cross breed zygotes and subsequent embryo transfer resulted in the generation of biallelic double knockout founder pigs for both *IL2RG* and *RAG2* exhibiting a SCID phenotype. Near-term founder pigs were derived via hysterectomy and maintained under germ-free condition in isolators. Various gnotobiotic double knockout founders were used for the evaluation of the infection with human norovirus (Lei et al., 2016).

The major histocompatibility complex (MHC) is pivotal to the function of the immune system in health and disease. As the function of human class I MHC in infection is already understood in great detail, the development of class I MHC deficient pigs will more aid to the species-specific response to infectious diseases in the agricultural industry, as well as allograft and xenograft rejection studies. The class I region of swine MHC contains the three classical class I swine leukocyte antigen (*SLA*) 1, 2, and 3 genes. Exon 4 has limited genetic variability in these genes and, therefore, was edited using CRISPR-Cas9 in porcine cells with known class I *SLA* alleles. After two rounds of SCNT, viable pigs were produced which were negative for class I SLA cell surface expression due to frameshifts arising from indels in the class I *SLA* genes. The SLA deficient animals showed a significant reduction in CD3$^+$/CD8$^+$ mature T lymphocytes and an increase in CD3$^+$/CD4$^+$ T cells. The class I MHC knockout pigs were observed to be healthy and grow well up to sexual maturity (Reyes et al., 2014).

CD1 molecules are a family of highly conserved antigen presenting glycoproteins. In humans, the CD1 family comprises five members encoded by *CD1A* to *CD1E*. CD1D is predominantly found on hematopoietic cell types, is considered a nonclassical major histocompatibility complex protein and is involved in presentation of lipid antigens to invariant natural killer T cells. Large White crossbred pigs deficient in this gene were produced with the CRISPR-Cas9 system. SCNT of edited

pig cells resulted in piglets containing either the biallelic or homozygous mutation of *CD1D*. In addition, embryo transfer of CRISPR-Cas9 injected in vitro-derived zygotes also led to the production of pigs with mutations in *CD1D* (Whitworth et al., 2014). *CD1D* knockout pigs failed to develop invariant natural killer T cells, whereas other leukocyte populations remained intact. In analogous mouse models, CD1d and NKT cells have been shown to be involved in shaping the composition of the commensal microbiota. However, no such effects were observed in *CD1D* knockout pigs (Yang et al., 2015).

4 CONCLUSIONS

Biomedical research requires nonrodent model organisms for the confirmation and translation of novel results for the pathogenesis and therapy of human diseases that have been found in classical rodent models. Genetically modified and/or transgenic pigs were produced and analyzed for their potential as appropriate animal models for specific human diseases. Some published projects up to now only showed the first steps in the development of the final disease model and/or only included the analysis of founder animals and/or few genetically modified animals. Apart from intrinsic problems in the use of large animals where the number of individuals and the use of aged animals in the experimental groups is practically limited, the outcome to date varies between the different projects. Some genetically modified pigs covered pathophysiological characteristics of the respective human disease which were not seen in the analogous genetically modified mouse models. In particular genetically modified pig projects, no pathologic phenotypes occurred that are similar to those seen in the respective human disease. This may be caused by project-specific parameters, as well as by species-specific differences in the respective pathway between humans and pigs. Analogous to rodent species, attempts for increasing the genetic, environmental, and experimental standardization of the studies may further increase the success in the work with genetically modified pigs.

1 INTRODUCTION

Science has advanced through observation and experimentation. So has the evolution of biotechnology. The emergence of animal models through genetic manipulation has greatly helped the development of scientific and biomedical knowledge. To speak of genetically modified animals is to focus on very important chapters in the history of the science of laboratory animals, in which the function of genes was first identified in living individuals. Based on this knowledge, new ideas for treatment of genetic diseases and other diseases have emerged; these tend to revolutionize classic medicine, bringing benefits not only to man, but to all living things. Here we give a brief history of biotechnology and the production of genetically modified animals, as well as the types of

animals that can be created, and findings derived from recombinant DNA technology, gene targeting and, more recently, gene editing.

2 SOME HISTORICAL ASPECTS

After more than 150 years of research, science has progressed from uncovering the principles of heredity to mimicking biological events in the laboratory. This information has provided significant advances in medicine over the last century, creating a new branch of industry, the billion-dollar biotechnology industry. Since the initial genetic studies of Gregor Mendel in 1865, numerous researchers have contributed to the understanding and consolidation of his idea, which until then was only promising. In the last century, important events took place, such as the discovery of the relationship of DNA with the transmission of genetic traits, the characterization of its chemical structure and of its

three-dimensional structure, methodology to produce recombinant DNA, DNA cloning, and sequencing, new animal models with random and, later, directed mutations, allowing the production of the first transgenic mice (Fig. 27.1)

3 TECHNIQUES FOR THE CREATION OF GENETICALLY MODIFIED ANIMALS

3.1 Techniques Based on Recombinant DNA

In order to create embryos in which the genome is permanently altered and the transfected DNA is permanently and irreversibly incorporated into the genetic material of the host cells, there are at least three important steps to be surmounted:

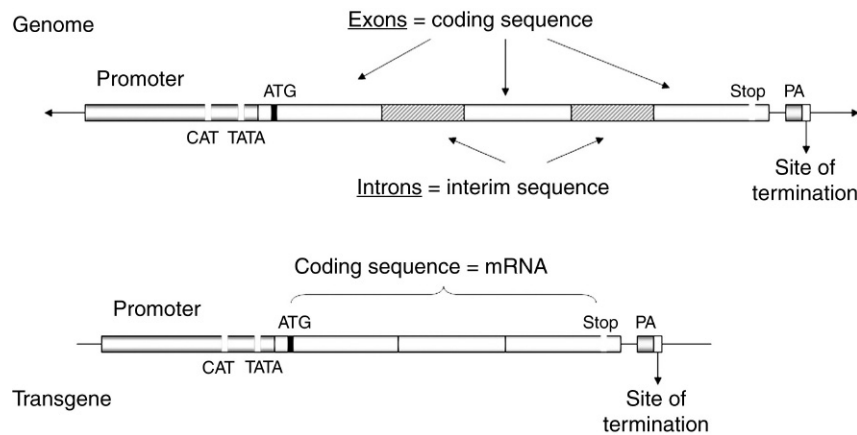
1. to produce an in vitro gene construct that is functional in accordance with the hypothesis of the proposed study.


FIGURE 27.2   **Design of basic transgenic vector carrying a single interest gene.** The interest gene has not introns to facilitate the transcription process and must have important sequences like a promoter to drive gene expression, a start and stop codon and a polyA signal called site of termination.

2. to cause the required DNA to cross the plasma membrane, the cytoplasm and reach the nucleus.
3. to make the exogenous DNA integrate into the genome of the host cell and to be transmitted to the following generations.

3.1.1 Gene Construct

A gene construct can vary in complexity according to the approach and the insertion of interest. The construct can be inserted randomly into the genome of the animal, which is called transgenesis by addition, or can be inserted into the genome at a specific targeted site, into the correct position of a determined chromosome, which is called transgenesis by homologous recombination. In both cases, the construct must be impeccable, with structures to control gene expression, such as: a promoter, a site of transcription initiation, a site of polyadenylation, a site of transcription termination, and accessories regions, for example, Intronic regions, UTR sites, tags, and polyadenylation sequence.

That means that the information that is being inserted into the receptor genome has a beginning, middle, and end, thus avoiding problems of uncontrolled expression in the host cell. In order to accomplish the objectives of the proposed genetic modification studies, a large variety of machinery is available today to control the expression of transgenes in a ubiquitous or conditional manner (Fig. 27.2).

3.1.2 Insertion of the DNA of Interest Into Cells

A variety of strategies can be used to cause exogenous DNA to penetrate the host cell.

3.1.2.1 MICROINJECTION

This is the most widely used method in transgenesis for gene addition. In this method, the DNA in solution is physically injected into the cell nucleus. This method is considered efficient to carry the DNA into the nucleus of somatic cells, but it has some disadvantages; it requires specialized equipment and highly skilled individuals, trained to perform the microinjection. This technique is widely used for insertion of gene vectors into fertilized oocytes, and it has a success rate of 4%–8% of animals born with the transgene integrated into the genome (Capecchi, 1980) (Fig. 27.3).

3.1.3 Integration

Integration of exogenic DNA into the host genome occurs with extremely low efficiency. It is believed that the integration of exogenic DNA into the genome of the host cell occurs during the mitosis, as a consequence of errors made when the DNA repair machinery of the host cell accidentally incorporates the exogenous molecule in an attempt to repair breaks in the double-stranded DNA that occasionally occur in cells (Capecchi, 1980). Due to the random nature of DNA breakage, integration of
FIGURE 27.3   **Microinjection is a process of using a glass micropipette to insert DNA into egg cell.** It is a simple mechanical process in which a needle roughly 0.5–5 µm in diameter penetrates the cell membrane. The DNA content is injected inside pronucleus and the needle is removed.

transfected DNA typically also occurs in random locations in the genome. Incorporated exogenous DNA could potentially disrupt, prevent or impede the expression of a gene of the host, although this probability is also rare.

3.2 Double-Strand Break as a Genome Editing Tool to Generate Genetically Modified Animals

Although the genome editing by DNA homologous recombination employed in embryonic stem cell has been feasible in mice, recent reports found that the double strand break (DSB), caused by endonucleases, is a powerful strategy to accomplish and boost genome engineering and generate genetically modified animals more efficiently (Carbery et al., 2010; Geurts et al., 2009; Li et al., 2014; Shen et al., 2013; Sung et al., 2013; Tesson et al., 2011; Wang et al., 2013; Yang et al., 2013). Genome editing methodologies, that target the genome in a sequence-specific site and generate DSBs, have arisen and improved in the last decade. The DSBs activate the endogenous DNA repair machinery, resulting in either nonhomologous end joining (NHEJ) characterized by recombination mediating insertions, deletions and mutations (indels), or homology directed repair (HDR) with replacement of the genomic sequence with donor DNA carrying homology arms to broken DNA sequence, that introduces or corrects mutation into genome (Fig. 27.4). The production of genetically modified mice and rats has been greatly accelerated by novel approaches using direct injection of DNA or mRNA of site-specific nucleases into the one-cell-stage embryo, generating DNA double-strand breaks (DSB) at specified sequences leading to targeted mutations (Carbery et al., 2010; Geurts et al., 2009; Li et al., 2014; Shen et al., 2013; Sung et al., 2013; Tesson et al., 2011; Wang et al., 2013).

Methodologies that combine a sequence-specific DNA binding domain with engineered FokI endonuclease in a single molecule; as zinc finger nucleases (ZFN) or as transcription activator-like effector nuclease (TALEN); were the first approaches that allowed gene editing by DSBs. Those techniques, besides showing good results in generating knockout animals, have a limited use, since the generation of the ZFN, in special, is quite expensive and with huge effort in troubleshooting during the vector design. The real propagation of gene editing occurred in 2012 in the first reporter regarding the clustered regulatory interspaced short palindromic repeats (CRISPR) associated with the nuclease Cas9 (Jinek et al., 2012) and in January of 2013 it was reported for the first time a successfully adaptation of CRISPR-Cas9 for genome editing in eukaryotic cells (Cong et al., 2013). Basically, the system designed by Jennifer Doudna and Emmanuelle Charpentier in 2012 (Jinek et al., 2012) consists in a gRNA (guide-RNA) and the tracrRNA that can be fused together to create a single, synthetic guide, which drives

the nuclease Cas9 into a specific site of action. The system will be described in details ahead.

All these techniques have shown a potential to generate knockout and knockin animals, not only mice, but also others as rats, pigs, fishes and monkey (Geurts et al., 2009; Li et al., 2014; Liu et al., 2014; Niu et al., 2014; Sung et al., 2013; Wang et al., 2013). The DSBs approaches may be launched by microinjection of the complete system (DNA, RNA, or protein) into the one cell embryo or embryonic stem cells, and generate transgenic models efficiently (Fig. 27.4).

3.3 ZFNs

Zinc finger protein (ZFP) is a common DNA binding domain found in many transcription factors. It consists of ~30 amino acids that may recognize three base pairs of DNA. Combining 3–6 ZFP in a molecule, it can recognize and bind to a specific DNA into the genome. The ZFN approach mix the features of ZFP specificity and add to this molecule a modified restriction enzyme FokI, with endonuclease feature; that is, as much the ZFP bind the specific region of DNA the FokI cleaves one strain of this DNA. To get the complete DSB is necessary two ZFNs design close to each other as exemplified in Fig. 27.4. Its use is not spread due to complex design and the high cost to develop the vectors, but is considered the best choice in gene therapy in animals and humans, since this methodology has low off-target rate.

3.4 TALENs

Similar to ZFNs, TALEN uses DNA biding motifs to get specific region of DNA to cut by FokI. The binding motifs are made with repeat domains named transcription activator-like effectors (TALEs), each domain presents 33–35 amino acids, and recognize one specific base pare. Hence it combines ~18 repeats and FokI endonuclease we may cut one strain of the specific region at the genomic DNA, addressed by the TALEs combination. TALENs also need to be applied with two designs to get DSBs. (Fig. 27.4). Genetically modified mice (Sung et al., 2013) and rats (Tesson et al., 2011) were created by this technique.

3.5 CRISPR/Cas9

Clustered regularly interspaced short palindromic repeats (CRISPR)/CRISPR-associated (Cas) adaptive immune systems are found in bacteria and other microorganisms, and their function is to protect the hosts against the invasion of viruses and plasmids. They were described by Jinek et al. (2012). Three types (I-III) of CRISPR systems with different features have been identified. The CRISPR-associated protein Cas9, that belongs
FIGURE 27.4 Genome editing techniques for generation of genetically modified animals.

to the type II CRISPR/Cas system, has attracted much attention due to its potential use in genomic engineering. This is the most recent and exciting system for genome editing to date. That is because of the easy design and specificity for DSB with only one guide. The Cas9 from *Streptococcus pyogenes* is the most widely used endonuclease used to CRISPR/Cas9 system. It consists of endonuclease Cas9 and a single guide RNA (gRNA) that is a chimera of tracrRNA; that is, *trans*-encoded RNA interacts with Cas9 protein, and crRNA; that is, RNA that specifies the region for cut. The guide RNA complexed with Cas9 targets a specific DNA sequence, and generates DSBs in the genomic DNA.

The gRNA, which drives the Cas9 to the region of cut, has around 20 nucleotides and, as a PCR primer, it must have a unique homology region. One very important characteristic during the gRNA design is the identification of the protospacer adjacent motif (PAM). The gRNA must be designed immediately upstream of this region (PAM), in the complementary strand of PAM site. This site will provide a binding site for the nuclease, for the Cas9 the PAM is the NGG sequence; it is absolutely necessary for the Cas9 activity and must not be included in the gRNA design. The DSB will occur 3 nucleotides upstream of the PAM (Garneau et al., 2010).

That is the newest technology and many improvements have been proposed to allow different features of Cas9 activity. Different Cas9 were designed to cut in just one strain as "nickase" Cas9 and dCas9 (nuclease-deficient Cas9), which is catalytically inactive. Because of dCas9 features of specific-sequence binding in genome and no cut it has been used for different propose as combining the dCas9 with some activator or repressor targeting to a promoter region in the genome then promoting gene activation or gene repression respectively (Shalem et al., 2015), or also can be associated with the FokI nuclease providing more specificity of the DSB, and decreasing the number of off-targets. Multiplex genome engineering with multiple guide RNAs has been tested to successfully target more than one region in the genome (Cong et al., 2013; Kabadi et al., 2014; Sakuma et al., 2014). Other origins of Cas9 and others groups of endonuclease has been tested and advances in this field is coming up quickly to next generation.

3.6 Knockout Mouse Lines Created by CRISPR/Cas9 Technique

Shen et al. (2013) created the first knockout animals with CRISPR/Cas9 genome editing technique. Firstly, they modified a zebrafish, and then a mouse line. Initially, the authors used the Pouf5-IRES-EGFP knockin mouse line, that carries one copy of the *EGFP* gene incorporated into the mouse genome. Twenty nanograms per microliter of NLS-flag-linker-Cas9 mRNA and 20 ng/µL preannealed EGFP-A chimeric RNA were coinjected into one-cell mouse embryos obtained from the crosses between male homozygous Pouf5-IRES-EGFP knockin mice and superovulated C57BL/6J female mice. The Pouf5-IRES-EGFP male mice were homozygous for the knockin gene, and then they were genotyped as heterozygous, as indicated by PCR amplification of a knockin fragment using genomic DNA extracted from the tails of the founders 5 days after birth. Their findings demonstrated that Cas9/RNA could site-specifically cut DNA in zebrafish and mouse embryos, "paving the way for its use in the generation of gene-disrupted animals".

Mou et al. (2015) described a series of CRISPR-generated animal models for the study of cancer and other chronic diseases (Mou et al., 2015). Among them, Xue et al. (2014) presented a CRISPR-mediated direct mutation of cancer genes in mouse liver (Xue et al., 2014).

Recently, Tu et al. (2015) proposed that CRISPR/Cas9 could be a powerful genetic engineering tool for creating animal models for neurodegenerative diseases. Among these animals, they propose that transgenic approach and CRISPR/Cas9 can be used to generate large animal models of diseases, such as nonhuman primate models.

3.7 Knockin Mouse Lines Created by CRISPR/Cas9 Technique

As the knockout animals, knockin animals can be generated using the CRISPR/Cas9 methodology. Taking advantage of DBS repair, we can drive the process of HDR to be used to generate specific nucleotide changes, changing from a single nucleotide to large insertions (e.g., addition of a fluorophore, tag, or gene replacement).

In order to drive the HDR for gene editing, a DNA repair template must be delivered at the same time of gRNA and Cas9 sequences directly into cell of interest, zygote, or ES cells. This template is called DNA donor, and can be used since single or double-stranded oligonucleotides or plasmids.

The traditional methodology of HDR was used during 20 years to produce knockout and knockin animals, however, the majority of those animal were mice models. However, the CRISPR/Cas9 approach provided a new tool, with good efficiency and low cost to create knockin in any species of interest. Yoshimi et al. (2016) showed the high efficiency to produce a rat model to KI-GFP-Rosa26 using ssODN coinjected with gRNA and Cas9 messenger RNA, the authors got 41.9% of positive animals (13 positives in 31 offspring).

4 TYPES OF GENETICALLY MODIFIED ANIMALS AND HOW THEY ARE PRODUCED

4.1 Transgenic Animals

Transgenic animals are those in which an exogenous gene was artificially inserted and stably incorporated into the genome of every cell of the organism and that can be transmitted to their descendants. The first transgenic mouse had the genome sequence of the Maloney leukemia virus inserted into its genome (Jaenisch, 1976). The best way to get all the cells that compose the organism to express the exogenous gene is to insert it into cells that give rise to other cell types, that is, the fertilized egg cell. In simple terms, the creation of transgenic animals begins with proper construction of the gene of interest and its transfection to the fertilized egg cell.

In most mammals, the exogenous DNA is inserted by pronuclear microinjection. In mice, the most commonly used model, the frequency with which the exogenous DNA is incorporated into the genome is satisfactory in the case of the egg cell, a totipotent cell with a high capacity for cell division. Certain strains possess egg cells with larger pronuclei, providing a greater ease of microinjection. An example is the use of oocytes derived from FVB animals.

The animal generated from this egg cell, known as a transgenic founder, is heterozygous for the transgene, that is, one of the chromosomes has incorporated the transgenic DNA, but not the homologous chromosome. Consequently, only half of the animals obtained from the F1 mating will also be heterozygous. Transgenic models have diverse functions in research, in which the inserted gene may have its effects evaluated in vivo during the developmental stages, as in the evolution of diseases, in studies of mutations, in the search for therapies, and other parameters that necessitate an animal model for study. Industrially, the transgenic model can be used to obtain commercial productivity characteristics, and disease resistance, and can be used as a bioreactor in the production of biopharmaceuticals.

4.2 Knockout Animals

The great contribution of these models was in the study of gene function through the phenotype presented due to the effect of allelic deletion. Until very recently, the only way to do this was to look for animals or humans suffering from hereditary diseases. In the case of animals, the incidence of such diseases could be increased by using mutagenic chemicals or irradiation, then the location of the mutation was mapped and the defective gene cloned. Unlike the transgenic model produced by the addition of random exogenous DNA, the knockout model is obtained by targeted insertion. This targeted integration is performed through the mechanism of homologous recombination and has an extremely low success rate (Gama Sosa et al., 2010).

Homologous recombination is a separate chapter in the methodology for obtaining knockout animals. This technique allows the insertion of a determined transgene into a specific locus, causing it to locate exactly in the desired portion of the chromosome. The most common way to delete exons is through the creation of a targeted construct, also called "targeted". In this case, the plasmid must contain a homologous portion of the start of the gene, known as "left arm" and a portion obtained along the gene, or even the final portion, called the "right arm" (Capecchi, 1980). Between these portions, an exon must be situated that is important for the functionality of the protein.

These homologous regions will pair with the corresponding sequences in the gene of interest. The longer the arms, the greater probability that pairing will occur. In practice, the combined length of both arms is between 6 and 10 kb (Joyner and Sedivy, 2000). As a result of this pairing and a double recombination, one in each arm, the original gene, or "wild type" is replaced by the transgene contained between the two arms of the construct. The gene sequence to be introduced may contain another gene, usually a reference sequence of a positive selection gene, thus generating substitution of expression of the original gene for NeoR.

Due to the low efficiency of the occurrence of two recombinations so close together, the strategy of performing this process in cell culture is used; but for these cells to give rise in the future to a complete organism they need to be pluripotent cells. The ideal cells are known as ES cells (embryonic stem) (Notarianni and Evans, 2006; Smithies et al., 1985). It was found that these cells called "germ lines" were perfectly suited for targeted insertion and could be identified through mechanisms of positive and negative selection. Currently, protocols for the cultivation and maintenance of these cells exist for only a few species (Grivennikov, 2008). ES cells can be transferred by micromanipulation into the interior of murine embryos at about 3–4 days of age, during the blastocyst preimplantation phase (Fig. 27.5).

4.3 Conditional Knockout Animals

Deletion of genes essential for development can result in embryonic lethality, due to lack of influence of this gene in the embryogenesis of the animal; thus mice die in the uterus, making it difficult to study events that occur after birth, and impossible to study the function of these genes in adult animals. Fortunately there are strategies, which are now becoming prevalent, to circumvent this problem, aiming to avoid problems with embryonic
FIGURE 27.5 **Microinjection of ES Cells is a process of using a glass micropipette to insert embryonic stem cells transformed by transgenic vector, theses cells are selected and cultured in vitro and microinjected inside blastocyst.** After birth the animals are called chimeras and are selected by fenotype to more analysis and verification of germline.

lethality (Gama Sosa et al., 2010). One possible strategy is the use of the conditional deletion system, which involves gene deletion under specific conditions. The main strategy is known as the Cre-Lox system.

The Cre enzyme is a 38-kDa recombinase, present in the P1 bacteriophage, which mediates recombination of DNA regions flanked by sequences, such as loxP (Hamilton and Abremski, 1984). The loxP sequence has 34 bp with a defined orientation. When the loxP flanks are in consensus, the region contained between them is excised, leaving a single loxP sequence. When the flanking sites are in opposite positions, the Cre enzyme recombines the contained region, reversing it. That is, animals with a targeted insertion in the same position as the loxP flanks are obtained by means of homologous recombination in ES cells.

This insertion gene may be the same gene present in the locus, but now flanked by the loxP sequence. The situation that will permit its normally conditional expression is expression of Cre recombinase, which may be ubiquitous or conditioned to a determined organ or cell type, and eliminates the flanked gene. This Cre recombinase gene can be inherited from another transgenic animal and will allow conditional expression of this protein. This conditional control is based on the Cre enzyme, which may have its expression controlled through the promoter related to it. The promoter that regulates the expression of the Cre gene will control the pattern of deletion of the target gene. This promoter may be specific to cell types, the physiological state of the animal or inducible by drugs.

1. Cell-specific promoter. The regulatory region of the Cre gene is important in determining the cell or group of cells that express the recombinase. Using the aP2 promoter, it is possible to delete the gene of interest only in adipocytes, the αMHC promoter for deletion in cardiomyocytes, the ALB promoter for hepatic cells, the Nestin promoter for neurons, the K5 promoter for epithelial cells of the skin, the CD19 promoter for B lymphocytes, and the Cola1 promoter for osteoblasts.
2. Temporal promoters. Regulatory sequences that promote gene expression at specific periods or physiological states. The CaMKII promoter can be used for gene deletion in neurons only after birth.
3. Inducible promoters. Regulatory sequences that are activated or deactivated by exogenous molecules. The TET system of induction, based on the TET operon system of *Escherichia coli*, is the most widely used (Sun et al., 2007). With this strategy, the Cre enzyme can be expressed, and consequently delete the gene at a specific time according to the research objective. To accomplish this, tet-Cre animals are crossed with loxP animals, and after mating of homozygous flanked animals, tetracycline or its analogue, doxycycline, is administered, excising the gene of interest and obtaining the desired knockout at the targeted systemic site, at the determined time of development of the animal.

4.4 Knockin Animals

As described, these techniques are most frequently used to introduce genes into random locations (transgenics) or to delete specific portions of genes (targeted knockout). The same techniques can be used to introduce new genetic elements into specific sites, known as knock-in (Haruyama et al., 2009). One application of this technique is to study the expression of molecules, identifying cells that express and modulate expression, using reporter molecules for this. The most commonly used reporter is the enzyme β-galactosidase, which can be detected with a variety of colored substrates, and the "green fluorescent protein", also known as GFP (Welsh and Kay, 1997).

A very interesting technical use of knock-in is the insertion of a target gene into the locus of another gene, substituting it. Some genes belong to a large family, but the members display individual characteristics, which often preclude compensation. Zheng-Fischhöfer et al. (2006), in an attempt to avoid embryonic lethality in knockout animals for the Cx43 gene, substituted the loci deleted with the Cx31 gene, producing the knock-in animal Cx43[31/31]. The authors perceived that despite the relative gene homology, the restoration of cell communication via Cx31 was not sufficient for normal development of the heart, showing selectivity of size and electrical charge between proteins Cx43 and Cx31.

Some knockin models intending the introduction of the new gene, but avoiding any problem with gene disruption, and for this proposal, the transgene must be inserted in a safe harbor locus, the most famous locus is the ROSA26 also known as ROSAβgeo26. This locus in mice genome was first found in chromosome 6 in one particular strain of mice and expresses one coding transcript and two noncoding transcripts, but only the noncoding transcripts are disrupted by the insertion. After transgene insertion that causes no apparent adverse effects on fitness, and permits stable gene expression.

ROSA26-specific TALENs or CRISPR-Cas9 system can generate a DNA DSB in ROSA26 in mouse genome, stimulating natural DNA repair mechanism. In the presence of ROSA26 ORF knockin clones, homologous recombination HR happens and integrantes DNA fragment from ORF knockin clone into the safe harbor locus.

5 GENETICALLY MODIFIED MICE AS MODELS OF HUMAN DISEASES

5.1 Genetic Disorders

Genetic disorders are changes in the communication of genes inserted into a genetic background present in the genome of living organisms that may cause disease. Diseases caused by genetic disorders are generally very common in humans and major economic partner in our community. Therefore, the development of animal models that match these diseases, or that may help unravel its mysteries and possible treatments is a major challenge to the scientific community. The use of genetic modification by insertion of foreign genetic material into the genome of an animal is a methodology widely used today to accelerate the process of mutation of animals by directed way and so favor the accumulation of scientific knowledge about living organisms and its disorders.

The disorder is hereditary or not depends largely on the type of genetic change or mutation occurred and the behavior of this information. Some disorders are caused only by changes in a particular gene, called disorder autosomal or X-linked, when this is the affected chromosome. They can be either dominant or recessive according to their power of penetration of information generated from this disorder and thus showing very typical and obvious phenotypes. Other features may be more complex, polygenic traits, where alterations can generate phenotypes depending on the genetic background of the individual. That is, there may be a phenotypic variability according to genetic susceptibility and behavior of the individual, reacting to stimuli and responses often not fully understood and clarified.

Changes in particular gene makes autosomal much simpler to interfere or manipulate through directed genetic manipulation in a living organism. Thus, soon after the advent of transgenesis methodology in the 80s, in the beginning of 90s until the early turn of the century, there was a significant increase in the development of genetically modified animal models with genetic disorders caused by the change in a single gene, as can be seen in Table 27.1.

6 MULTIFACTORIAL AND POLYGENIC (COMPLEX) DISORDERS

In general, the multifactorial disorders, as hypertension, diabetes, autoimmune diseases, heart failure, obesity among others, are more difficult to obtain genetically engineered animal models, once the phenotypes are produced by a large number of genes and so they are often not totally clear which. Therefore, it may happen the features of genetically modified animal models that are showed their phenotypes with some characteristics for complex diseases and may therefore to be utilized as this disease model, although not specific to a given disease, sometimes the models worth to better understand the disorder and much of the times it is not totally similar to human disorders. However, there are models that contribute to disorder clarifying.

Typically, because of its particular characteristics, models of complex diseases are best produced by spon-

taneous mutation, by induction by physical or chemical mutagenic agents, as well as for genome rearrangement among different inbred strains with possible genetic trait control. Some phenotype products of genetically modified models for complex diseases may be unintended consequences for the model, except those that have a well established signaling pathway, which modification of an involved gene can cause a rupture in a cascade of signaling proteins and cause disease. This is exemplified in Table 27.2 for Bardet–Biedl syndrome.

7 INFLAMMATORY DISEASES

Inflammatory diseases with genetic susceptibility are not very uncommon in humanity, as well as autoimmune diseases, rheumatoid arthritis, atherosclerosis, colitis, dermatitis, among others. They are mostly complex and multifactorial diseases that often depend on genetic susceptibility linked to individual behavior to their development. All these factors make the development of genetically modified animal models difficult to be constructed through the use of manipulation of specific genes. Even why, many diseases are not yet fully understood and known causes.

Many models are generated from spontaneous and induced mutations in addition to handling the environmental stress and diet to induce inflammations, always considering the animal's susceptible genetic backgrounds. Table 27.3 shows some models of genetically engineered animals that have been bred to develop

similar phenotypes to human inflammatory diseases, in order to allow interventions to treat these disorders and facilitate their understanding.

8 NEURODEGENERATIVE DISEASES

Neurodegenerative diseases are chronic, progressive disorders, with variable symptoms and outcomes. Clinical signs are usually related to the topography of the lesions, which usually involve neuronal degeneration and loss of function. Although the most common forms of these diseases are sporadic (with the exception of Huntington's disease), development of genetically modified animal models are mainly based on inherited, familial forms (Gama Sosa et al., 2012; Harvey et al., 2011; Van Den Bosch, 2011). Sporadic and familial forms do not share the same causes, but pathogenesis and neurodegenerative process are very similar in both forms (Gama Sosa et al., 2012; Selkoe, 2001). Therefore, animal models based on deletion or overexpression of genes linked to familial forms are important tools for the research of neurodegenerative diseases (Table 27.4).

Most used genetically modified mouse models of Alzheimer's disease (AD) (Duyckaerts et al., 2008; Gurney, 2000; Hall and Roberson, 2012; Hock and Lamb, 2001; Kokjohn and Roher, 2009; Price et al., 1998; Theuring et al., 1997; Wisniewski and Sigurdsson, 2010) Parkinson's disease (PD) (Bezard and Przedborski, 2011; Chesselet, 2008; Dawson et al., 2010; Dehay and Bezard, 2011; Gupta et al., 2008; Hall and Roberson, 2012;

Price et al., 1998; Selkoe, 2001; Theuring et al., 1997; Wisniewski and Sigurdsson, 2010), Huntington's disease (HD) (Gurney, 2000; Heng et al., 2008; Imarisio et al., 2008; Kumar et al., 2012; Price et al., 1998; Theuring et al., 1997) and amyotrophic lateral sclerosis (ALS) (Gurney, 2000; Harvey et al., 2011; Price et al., 1998; Selkoe, 2001; Theuring et al., 1997; Turner and Talbot, 2008; Van Den Bosch, 2011) are presented. The genes used in the development of the described mouse models, and the probable relevance of their encoded protein to the disease, are listed here:

1. AD:
   a. Amyloid precursor protein (APP) gene—AD1; amyloid-β (Aβ) precursor, the main constituent of amyloid plaques (Hall and Roberson, 2012; Harvey et al., 2011; Hock and Lamb, 2001).
   b. Presenilin 1 and 2 (PSEN1 and PSEN2) genes—AD3 and AD4; involved in APP processing and Aβ production (Hall and Roberson, 2012; Harvey et al., 2011; Hock and Lamb, 2001).
   c. Microtubule-associated protein tau gene—MAPT; main constituent of neurofibrillary tangles (Hall and Roberson, 2012; Harvey et al., 2011; Hock and Lamb, 2001)
2. PD:
   a. α-synuclein (α-syn) gene—PARK1 and PARK4; synaptic protein, main constituent of Lewy bodies (Blandini and Armentero, 2012; Harvey et al., 2011; Gupta et al., 2008).
   b. Parkin gene—PARK2; ubiquitin ligase activity (Hall and Roberson, 2012; Harvey et al., 2011; Hock and Lamb, 2001).
   c. DJ-1 gene—PARK7; anti oxidative-stress properties (Hall and Roberson, 2012; Harvey et al., 2011; Hock and Lamb, 2001).
   d. PTEN-induced kinase 1 (PINK1) gene—PARK6; antioxidative-stress properties, protection against mitochondrial dysfunction (Hall and Roberson, 2012; Harvey et al., 2011; Hock and Lamb, 2001).
   e. Ubiquitin carboxy-terminal hydrolase-L1 (UCH-L1) gene—PARK5; ubiquitin ligase activity (Harvey et al., 2011)
   f. Leucine-rich repeat kinase 2 (LRRK2) gene—PARK8; kinase and GTPase activity (Hall and Roberson, 2012; Harvey et al., 2011; Hock and Lamb, 2001).
3. HD:
   a. Huntingtin (htt) gene—IT15; expansions of GAC repeats lead to its aggregation in neuronal intranuclear inclusions. Mutations in htt are causative of HD (Games et al., 1995; Harvey et al., 2011; Hsiao et al., 1996).
4. ALS:
   a. Superoxide dismutase (SOD1) gene—ALS1; inactivates superoxide radicals (Harvey et al., 2011; Turner and Talbot, 2008; Van Den Bosch, 2011).

Human disease	Gene symbol	Model	Phenotype	References
Huntington's disease	IT15	B6CBA-Tg(HDexon1)62Gpb	Transgene is ubiquitously expressed. Behavioral deficits (5 weeks), choreiform-like movements, stereotypic movements, tremor, cognitive deficits (5 weeks), premature death (12-15 weeks). Decreased brain and striatal volume (12 weeks), loss of striatal neurons (12 weeks), reduced D1 and D2 receptors in striatum (8-12 weeks), Htt aggregates in c¢rtex, neostriatum and hippocampus. Widespread NIIs (12 weeks).	Slow et al. (2003)
	IT15	FVB-Tg(YAC128)53Hay	Motor abnormalities (starting from 3 months). Progressive behavioral and cognitive alterations. Striatal (9 months) and cortical atrophy (12 months) and subtle striatal neuronal loss (12 months). Httimmunoreactivity in striatal (2-3 months), cortical (3 months), hippocampal (3 months), cerebellar (3 months) neurons, spreading to many neurons (6 months). Normal striatal neurotransmitter expression.	Lin et al. (2001)
	IT5	B6.129P2-Htttm2Detl	Nuclear immunoreactivity for htt in striatum (27-29 weeks), NIIs in striatum (37 or 40 weeks; homozygotes and heterozygotes, respectively), locomotory abnormalities (70 or 100 weeks; homozygotes and heterozygotes, respectively), loss of D1 and D2 receptors in striatum (70 weeks).	Gurney et al. (1994)
Amyotrophic lateral sclerosis	ALS1	B6SJL-Tg(SOD1)2Gur	Motor neuron loss within spinal cord. Progressive hind limb weakness, leading to paralysis. Death (5-6 months).	Wong et al. (1995)
	ALS1	B6.Cg-Tg(SOD1*G37R)42Dpr	Motor neuron loss within spinal cord, Paralysis in one or more limbs.	Ripps et al. (1995)
	ALS1	FVB-Tg(Sod1*G86R)M1Jwg	Motor neuron degeneration within spinal cord, brain stem, and neocortex. Progressive decline of motor function (beginning at 3-4 months). Death (4 months)	Ripps et al. (1995)

9 CANCER

Despite the enormous numbers of studies involving cancer, it is still considered a challenging disease. One of the major challenges facing cancer research is the necessity to find suitable models to the human diseases. These needs include validating/determining the contribution of a gene to cancer, establishing systems for drug discovery and validation, and discovering factors that modify the oncogenic process.

A number of mouse strains that develop cancers spontaneously are available; in general they develop neoplastic diseases at late ages. Transplantable tumors of several types (melanomas, sarcomas, lymphomas, mammary carcinomas, and others) have been extensively used during the 20th century to answer specific questions in cancer research, including their susceptibility to antineoplastic new agents. Currently, the standard anticancer drug development pipeline uses xenograft and/or orthotopic implantation of human tumor cell lines in immunocompromised mice as the primary in vivo models for investigating drug candidate efficacy and mechanism(s) of action. Although these models provide valuable information and somewhat greater predictability than cell/tissue cultures in vitro, their prognostic usefulness for human clinical trials has been limited. Genetically engineered mouse models of cancer are becoming useful systems for understanding the molecular and cellular determinants of tumorigenesis and for refining anticancer agents targeted to various facets of carcinogenesis in vivo

There are many advantages of using genetically engineered mice in cancer research. Researchers in academia and industry, as well as clinicians are all using mice extensively in their work. What makes the mouse so special is how similar its genome is to the human genome (99% of human genes are conserved in the mouse), the availability of a unique battery of sophisticated molecular and genetic tools, and the animal's small size, all of which facilitate large scale/high throughput studies and make it a cost-efficient model providing functional information on human genes in health and disease. In fact, the potential of mouse models to make medical research, and in particular drug development, more efficient could be increased by solving a series of research, intellectual property rights (IPR), communication, training, and regulatory bottlenecks.

Although there are species (such as dogs, pigs, and nonhuman primates) that are even more closely related to us than mice, working with these large animals is extremely expensive and is fraught with ethical concerns. With their small size and short generation times, breeding, and keeping mice is comparatively simple and inexpensive. In addition, because they have been widely used in research for decades, researchers have built up a detailed understanding of mouse biology and genetics and developed large numbers of tools and techniques to study them. These powerful genetics tools are not yet available for larger mammals. Recent years have seen a rise in the use of genetically engineered mice in research and preclinical studies. Some of these models can mimic a wide range of human diseases and health problems, such as cancer and diabetes. In addition, the mouse is so far the only mammalian model in which it is technically possible to generate an organism in which a particular mouse gene has been replaced by its human counterpart. This "humanized" mouse will produce and live with the human version of the protein. "Humanized" mice can be created bearing a mutated version of a human gene known to be associated with a specific human disease. Such a mouse can be used to test the possible efficacy of a drug designed to bind to the relevant human protein.

Some strains of genetically modified mice can be used in preclinical tests in order to provide information on the carcinogenic potential of a compound, as alternative models for the conventional 2 years carcinogenicity assay. The three most extensively studied of these mice are Trp53$^{+/-}$, Tg/AC, and RasH2. Recently, a study compared their performance with the traditional 2-year rodent bioassay, and the individual transgenic models made the "correct" determinations (positive for carcinogens; negative for noncarcinogens) for 74%–81% of the chemicals, with an increase to as much as 83% using combined strategies (e.g., Trp53$^{+/-}$ for genotoxic chemicals for all chemicals). For comparison, identical analysis of chemicals in this data set that were tested in the 2-year, two-species rodent bioassay yielded correct determinations for 69% of the chemicals. RasH2 one example is the rasH2 mice.

Here we present some genetically modified mouse models for the study of human cancers (Table 27.5).

Forward and Reverse Genetics to Model Human Diseases in the Mouse

Yoichi Gondo, Shigeru Makino, Ryutaro Fukumura

RIKEN BioResource Center, Tsukuba, Ibaraki, Japan

OUTLINE

In this Chapter, we summarize development and establishment of mutant mouse strains focusing on modeling human diseases. Around the year 2000, the human disease modeling showed a striking breakthrough due to the accomplishment of the Human and Mouse Genome Projects (International Human Genome Sequencing, 2001, 2004; Mouse Genome Sequencing et al., 2002). Multidisciplinary efforts then advanced various next-generation technologies, databases, and bioinformatics. The key of modeling human diseases is the newly established mutagenesis technologies, often called "forward" and "reverse" genetics (reviewed by Gondo, 2008). Starting from the establishment of disease models for Mendelian disorders, namely, monogenic traits, modeling of quantitative and polygenic traits (classically, one of non-Mendelian traits) are also anticipated, since most of human diseases are complex traits.

1 GENETIC OR ENVIRONMENTAL

Most of human diseases are developed by a combination of genetic and environmental factors. When the genetic factor is a single exclusive element, it is easily observed the inheritance in a Mendelian fashion. A typical example is the Huntington's disease. The patients carrying the expanded CAG triplet repeats on their *Huntingtin* gene, they develop the disease in their midage irrespective of their environmental history and conditions (The Huntington's Disease Collaborative Research Group, 1993).

When the number of the genetic factors for the disease becomes more multigenic with a lower penetrance, it becomes harder to conclude the existence of genetic contributions to the disease. The key to distinguish the genetic factors is to identify the causative genes and mutations. Prominent evidences of Mendelian inheritance in a defined pedigree(s) often lead to such identification of major causative genes and responsible mutations among many genetic factors. For instance, inherited mutations of the *glucokinase* (Froguel et al., 1993; Vionnet et al., 1992) and *Apc* (Groden et al., 1991; Ichii et al., 1993; Joslyn et al., 1991; Nishisho et al., 1991) genes were independently discovered concordance with the patients of

diabetes (type 2) and colon cancers (familial adenomatous polyposis; FAP) in the pedigrees, respectively. The carriers of identified mutations mostly develop the corresponding diseases; thus, the penetrance is very high. However, many diabetic and colon cancer patients do not carry any mutations in the *glucokinase* and *Apc* genes, respectively. Other responsible genes and genetic factors have been anticipated and indeed identified affecting the diabetes (Lambrinoudaki et al., 2010; Vaxillaire and Froguel, 2008) and colon cancers (Hassen et al., 2012; Pineda et al., 2010; Plotz et al., 2012).

Most of human diseases including common diseases are caused by a combination of mutations on several major (and minor) genes with various environmental factors. It is noteworthy that the minor genetic factors, often called "modifiers," are extremely difficult to identify. The population studies, for instance, with identical twins, are also revealing that some psychiatric diseases have high heritability (reviewed by Burmeister et al., 2008). For instance, the heritability of schizophrenia, bipolar disorders, and autism is often estimated to be ~80%, indicating that the genetic influence is much higher than environmental conditions in the studied populations. Nevertheless, no major genes to cause these mental illnesses have yet been identified, although many candidate mutations and genes have been nominated. No major but many minor genes with fewer effects of environmental factors are, therefore considered to govern such psychiatric diseases that exhibit higher heritability.

2 GENOME PROJECT AND HUMAN DISEASES

The primary driving force of the Human Genome Project in 1990 was to systematically identify all the responsible genes for genetic diseases (Watson, 1990). The Huntington's disease, for instance, was identified as a dominant Mendelian monogenic disease and the responsible gene, *Huntingtin*, was mapped on chromosome 4q16.3 in human genome. The *Huntingtin* gene was then molecularly cloned, sequenced, and the causative mutation, CAG triplet expansion, was discovered (The Huntington's Disease Collaborative Research Group, 1993).

These findings gave rise to a concrete method to diagnose patients. Similar forward genetics to identify the genetic cause of various diseases and traits have been conducted. Duchenne muscular dystrophy (Monaco et al., 1985), Retinoblastoma (Friend et al., 1986), cystic fibrosis (Riordan et al., 1989), and familial adenomatous polyposis (Groden et al., 1991; Joslyn et al., 1991; Kinzler et al., 1991) were successful examples.

Considering the total cost, manpower, and time, a systematic and collaborative international effort to sequence whole human genome seemed to be much more effective (Cantor, 1990; Watson, 1990). The sequencing of the whole human genome should also contribute primarily for the detection and diagnosis and ultimately for the cure and prevention of all the human diseases and disorders.

In addition, the knowledge of the human genome should accelerate the study of basic and general biology, in particular, genetics, evolution, and developmental biology. Thus, it was recognized that the completion of the whole human genomic DNA sequence was not the ultimate goal but just the first step to conduct functional and comparative genomics to understand basic biology and to apply for the prevention and therapeutics of human diseases.

In this context, Helmholtz Zentrum München (HZM; formally, GSF) in Germany (Hrabe de Angelis and Balling, 1998; Hrabe de Angelis et al., 2000) and Medical Research Council (MRC), UK (Brown and Nolan, 1998; Nolan et al., 2000) have started the large-scale ENU mouse mutagenesis projects in 1997 to model human diseases in the mouse. The research community also proposed the necessity of the Mouse Genome Project to sequence the whole genome of the standard laboratory strain, C57BL/6J (Nadeau et al., 2001). Following to the progress of the Human Genome Project, thus, the Mouse Genome Project has been conducted and completed (Mouse Genome Sequencing et al., 2002) in parallel aiming the functional and comparative genomics between the human and mouse.

3 BASIC GENETICS TO DEVELOP AND USE MODEL MICE

In this section, basic genetics is summarized focusing on the key genetic terminology, the concept of which is useful to design and to experimentally develop new mutant mice as models for diseases. The fundamental knowledge of the genetics also promotes the better practical use of the established mutant mice as well.

3.1 Locus (pl. Loci)

The both terms of "locus" and "allele" are often collectively called as "gene." To explain the Mendelian inheritance, locus and allele are distinctively used. The gene is coded in a particular location of the genome to give rise to certain function or "trait." To define the unique location coding for the gene in the genome, the term "locus" is used. Thus, the number of loci and the sequence of each locus are predetermined specific to each species. Not only the location but also the DNA sequence of each locus is unique and distinctive from those of the other loci. The key rationale of the mutant mouse to be a model for the human disease is the high similarity of entire genome between human and mouse. Classically, the size of the genome and the number of the genes in the human and mouse genomes had been estimated to be very similar values of 3×10^9 bp and 100,000–150,000 genes (Chikaraishi et al., 1978), respectively. The completion of the Human and Mouse Genome Projects gave rise to better estimates to confirm the total size of the genome to be $\sim 3 \times 10^9$ bp but the number of the coded genes, or loci, to be 30,000 or less in both the species (International Human Genome Sequencing, 2001, 2004; Mouse Genome Sequencing et al., 2002). Not only the total number of loci, the locus order of local locations, called "synteny," but also the sequences of the corresponding loci, called "orthologs," are very similar, indicating the good conservation of the gene function between human and mouse.

3.2 Allele

Even within a species, polymorphisms exist producing various phenotypes and genetic variability in natural populations. Most of the unique sequences of a particular locus have some minor differences, giving rise to different subtypes of the locus. The subtype is called "allele." Mutations are the origin of new alleles in a particular locus (Fig. 28.1). In theory, many subtypes may exist per locus.

The Human Genome Project (International Human Genome Sequencing, 2001; International SNP Map Working Group, 2001) actually detected more than 1.4 million single nucleotide polymorphisms (SNPs) in the human population; thus, approximately 0.1% of human genomic sequences are polymorphic.

At the molecular level, the whole consensus genomic DNA sequence ultimately defines the species. The number of the alleles in one species defines the degree of the genetic variability of the species. Any subpopulations of a particular species must have the same set of the loci, namely, the same consensus DNA sequences in the genome. On the other hand, each subpopulation may have a distinct set of alleles. Thus, even in the same species, the genetic variability and diversities may be different from the other depending on each subpopulation. One extreme case is that all the loci have only one allele in a subpopulation, which is called an "inbred" subpopulation (described in details later).
FIGURE 28.1   **Molecular view of mutations to create new alleles.** In general, a gene is coded ~1000 bp or more of protein-coding sequences called open reading frame (ORF) in addition to introns and regulatory elements. Subtle mutations randomly change a small number of or a single base pair of genomic DNA sequences of the gene. The random nature of the mutation usually disrupts the normal function of the gene. Therefore, the mutant allele is usually a loss-of-function type mutation. In one wild-type locus as shown in the *upper panel*, there are many base pairs to disrupt the wild-type functional sequence. On the other hand, there is only one way to reverse a particular mutant allele to the wild type allele. It is the base of the molecular view that the mutation rate ($\sim 10^{-5}$/locus/gamete) of the gene is usually three orders of magnitude higher than the reversion rate ($\sim 10^{-8}$/locus/gamete) of any mutant allele. The reversion is a gain-of-function type event to restore the normal function of the gene. Loss-of-function type mutations are usually recessive to the wild type allele as shown in Fig. 2. Inversely, the gain-of-function type mutant allele tends to become dominant. In analogy to the reversion, the mutation rate to change the normal gene to more or additional functional gene, namely, to gain-of-function type allele, is similar to the reversion rate of $\sim 10^{-8}$/locus/gamete. Based on this molecular view, recessive mutations are usually loss-of-function types with three orders of magnitude higher mutation rate to dominant gain-of-function types mutations.

Some SNPs show no functional differences form the wild-type allele. Such functionally identical SNPs may be collectively called the wild-type alleles. Some other SNPs may be evolutionarily neutral but the function of each allele may be different from the other. For instance, in the ABO blood type locus, the three well-known alleles of A, B, and O exist. The A and B alleles produce the same enzyme, glycosyltransferase, with a subtle difference that makes distinctive glycosilation to a precursor substance, the H antigen, on the red blood cells. The O allele has no function to make such glycosilation by a single deletion of the glycosyltransferase gene (Yamamoto et al., 1990). Thus, all the three alleles of the ABO blood-type locus are functionally different but

may be evolutionarily neutral. Even in each allele, many differences of genomic sequences have been identified, indicating the practical existence of silent alleles in collectively called A, B, or O allele (Yip, 2002).

The SNPs responsible for genetic factors of human diseases have also been identified. The Haplotype Mapping (HapMap) Project (International HapMap Consortium, 2003), the Genome-Wide Association Studies (GWAS) (Wellcome Trust Case Control, 2007), and the 1000 Genomes Project (Via et al., 2010) are to primarily identify such SNPs responsible for human diseases. The scale has been expanded to the order of million based on new technologies (reviewed by Auffray et al., 2016). One of the major goals of the mouse mutagenesis is to produce mutant alleles analogous to human SNPs as a model.

4 DIPLOID AND GENOTYPE

Both human and mouse are diploid organisms, each of which has two sets of the genome. Namely, one individual has the two whole sets of loci with two alleles on each locus. When an individual carries the same and different two alleles in a locus, it is called a "homozygote" and "heterozygote," respectively, with respect to the locus. The combination of the two alleles in a particular locus is called genotype.

In the example of the ABO-blood type, three distinctive alleles exist. Accordingly, the six different genotypes, three of which are *AA*, *BB*, and *OO* homozygotes and the other three of which are *AB*, *AO*, and *BO* heterozygotes, appear in human population.

The alleles exhibiting and concealing their phenotypes in the heterozygotes are called "dominant" and "recessive," respectively. Thus, the dominant-recessive relations are defined for a set of two alleles in one locus and the effect of the relation is only observed in the heterozygotes (Fig. 28.2).

In the example of the *ABO* blood type in the previous section, the *ABO*-blood-type locus has three alleles, *A*, *B*, and *O*; thus, the dominant-recessive relations are defined for all the three possible heterozygotes, *AB*, *AO*, and *BO*. The phenotype, namely blood type, of *AO* and *BO* heterozygotes are [A] and [B], respectively. In genetics, the phenotypes are often shown in brackets like [A] in order to distinguish from the allele of *A*. *A* and *B* alleles are thus dominant to *O* allele. The *AB* heterozygotes show [AB] blood type. In this case, the relation between *A* and *B* alleles are called "codominant." As described before, the *O* allele produces no functional glycosyltransferase enzyme. Such allele, like the *O* allele, is called a "loss of function" type or a null allele. In general, the gene product of the loss-of-function allele does not hamper the functional counterpart. The functional allele, such as the
FIGURE 28.2 **Molecular and cellular view of dominant versus recessive alleles.** *Top panel*: Hypothetical locus *A* encodes mRNA that is translated to protein in the cell. Mutant allele *a* changed a part of the functional sequence of the locus so that no functional proteins translated from the *a* allele. *Bottom panel*: Due to the lack of the functional protein, *aa* mutant homozygotes, exhibit the mutant phenotype different from the *AA* wild-type homozygotes. *Middle panel*: The *Aa* heterozygotes usually exhibit indistinguishable phenotype to the *AA* wild types. It is because the one allele of *A* produces enough active proteins and the mutant allele *a* produce nothing (null) or no functional proteins (amorph) that do not hamper the normal function of the *A* protein, making the *A* allele is dominant to the *a* allele.

A and *B* alleles, is usually produces an enough amount of the active enzyme to exhibit the corresponding phenotypes. Mutations usually occur randomly by disturbing the functional sequence of the locus; thus, the mutant allele tends to become a loss-of-function type, namely, recessive. It is the basic molecular-biological-view of the Mendel's dominant versus recessive relation. It is, however, noteworthy that many exceptions have been identified. For instance, the loss-of-function mutations exhibited dominant phenotypes in *glucokinase* and *Apc* mutations in diabetes and colon cancer by haploinsufficiency and dominant negative effects, respectively.

When an allele is only observed in heterozygotes but never in homozygotes, the allele is considered to be recessive lethal. If the product of the gene function is necessary and indispensable for the organisms, the loss-of-function mutation tends to make a recessive lethal allele. Thus, the gene coded by the locus that potentially has a recessive lethal allele is considered as an essential gene.

In the previously demonstrated "inbred" subpopulations, all the loci have only the same pair of one allele, namely, all the loci are homozygous. When a female is mated to any male of an inbred subpopulation, all the offspring again have the same homozygous inbred genetic background called "isogenic." Such inbred subpopulations have hardly been found in natural population but are possible to establish in the laboratory by consecutive

mating a pair of a sister and a brother in the same litter, or sib mating, more than 20 generations. The previously mentioned C57BL/6J mouse, which is subjected to the Mouse Genome Project, is one of the many inbred laboratory strains.

5 COISOGENIC AND CONGENIC STRAINS

In mutagenesis studies, various phenotypes of the mutant mice are compared to those of the wild types to study the gene function. Since mouse is diploid, the comparison may be made between the wild-type homozygotes, heterozygotes, and mutant homozygotes. In this phenotype assessment, all the mice not only have the two alleles in the locus but also have the pairs of alleles in all the other loci in entire genome. Various allelic differences in the genetic background may disturb the phenotype assessment for the particular allelic difference of the objective locus. It is therefore ideal to make an isogenic background except for the objective locus to distinctively elucidate the function of the objective locus.

When two strains have a difference only on the objective locus but all the other loci are completely identical, they are called "coisogenic" each other. The coisogenic strains may be obtained by a spontaneously arisen mutation in an inbred strain because the mutation is a very rare event and occurs only once at most in one animal. The availability of the coisogenic strains have been, thus, very limited due to the extremely rate event of spontaneous mutations. Recently, however, the genome editing method has become available to systematically construct coisogenic strains in any loci in almost any species as described later in this Chapter.

In order to establish a coisogenic-like strain, so-called congenic strain, for any mutations in any genetic background, an objective mouse is backcrossed to an isogenic inbred strain. After six generations of backcrosses, 99% of the genome becomes the inbred isogenic background except the linked loci. The alleles in the closely linked loci may still remain the same as in the original founder mouse due to the linkage disequilibrium. The degree of the linkage disequilibrium is dependent on the probability of the recombination; thus, more backcrossing conducted, narrower down to only the objective allele from the founder. The backcrossing more than 20 generations is conventionally considered to be congenic.

Both coisogenic and congenic strains are useful to conduct the analysis of the monogenic trait of the objective locus. One of the historical landmarks using congenic strains was the discovery of the *histocompatibility-2* (*H-2*) locus in the mouse, one of the histocompatibility loci mapped by the tumor rejection and congenic technology (Snell and Higgins, 1951). The further analyses

revealed that the H-2 "locus" encompassed many loci and renamed to H-2 complex (reviewed by Klein, 1979). The discovery of the H-2 complex in the mouse led to the identification of the major histocompatibility complex (MHC) class I, II, and III that is common in the mammalian species including human, namely, HLA complex.

6 DOUBLE STRANDED DNA, LINKAGE, AND HAPLOTYPE

One chromosome consists of one double-stranded helix DNA molecule. Human and mouse has 22 and 19 pairs of autosomes, respectively, in addition to XX in female and XY in male. As mentioned earlier, the genotype is defined as a set of two alleles at a single locus. Haplotype is, on the other hand, defined a set of alleles found in a haploid gamete, namely either in a mature oocyte or sperm. The largest haplotype is, thus, the whole set of alleles in one oocyte or sperm. The haplotype is usually used, however, to describe a set of alleles in closely linked loci on one double-stranded DNA. Such alleles do not segregate independently. Rather, inherited together until a recombination disrupts the linkage on the same DNA strand. The schematic view of the haplotype with genotype is depicted in Fig. 28.3.

On five pairs of autosomal homologs, eight loci, *A, B, C, … and H* are shown. The locus names are conventionally designated as the names of the wild-type dominant alleles. The genotypes are defined on each locus, for instance, *A*, *B*, and *C* loci are all heterozygote of *Aa*, *Bb*, and *Cc*. On the other hand, from the particular three loci of A, B, and C may give rise to one of the eight different combinations of haplotypes to a given gamete, *A-B-C, A-B-c, A-b-C, A-b-b, a-B-C, a-B-c, a-b-C,* and *a-b-c*. The three loci are on independent autosomes so that the probabilities to have any one of the eight haplotypes in one gamete are all equal. On the other hand, when three loci are on a pair of autosomal homo-

logs, the set of three alleles of the three loci on the same homolog, namely, on the same double-stranded DNA, is cotransmitted to the gamete unless a recombination occurs between the three loci during the meiosis. For instance, only the two haplotypes of *C-f-g* and *c-F-G* among the eight possible ones may be transmitted to gamete without recombination in the case for Fig. 28.3. Snell and Higgins (1951) considered the *H-2* complex as a single locus at first. Later on, they identified that the *H-2* region of about 2-cM encompassed many loci; therefore the haplotypes were conventionally used to specify a particular set of alleles on one DNA strand or one homolog in the MHC complex. A particular haplotype of alleles of closely linked loci shows linkage disequilibrium in a few generations. Meantime, DNA recombinations occur in meiosis and shuffle the haplotype and gradually the linkage disequilibrium disappears. Therefore, the degree of the linkage disequilibrium of a haplotype is dependent on the genetic distances of the loci in the haplotype and the number of the generations since the haplotype was formed. It is noteworthy that the natural selection often disturbs the hypothetical situation of the established strains. For instance, twenty generations of the sib mating are theoretically enough to establish an inbred strain with more than 99% homozygosity. When detrimental alleles exist in the original mouse, however, the heterozygosity may be kept much longer generations. In the Fig. 28.3, when the *d* and *h* alleles are recessive lethal in the tightly linked loci *D* and *H*, both the haplotypes of *D-h* and *d-H* always transmitted to the next generation as *D/d, h/H* mice, because other possible mice carrying *D/D, h/h,* and *d/d, H/H* die due to the recessive lethality of *h* and *d*, respectively.

7 MUTANT MICE AS DISEASE MODELS

The spontaneous mutation rate is very low; for instance, roughly three orders of magnitude lower than that induced by the most potent mutagen, ethylnitrosourea (ENU) in the mouse (Russell et al., 1981). Thus, the development and establishment of mutant strains are often laborious and take time. Once mutant strains are established and maintained, however, any researchers may access to the strains as a research resource.

Mutations usually occur randomly in the genome. Most of the mutations are a loss-of-function type due to the disturbance or disruption of the functional DNA sequences (Figs. 28.1 and 28.2). Thereby, a biological effect(s) of most of the mutations is a detrimental to the organisms. Namely, mutations are likely to induce some disorders modeling many diseases and deficiencies in human.
FIGURE 28.3   Linkage and haplotype on the chromosome. Five pairs of autosomes with the genotypes of eight loci are schematically shown. The alleles on the different chromosomes are segregated to gamete with 50:50 chances according to the Mendel's second law. The linked alleles on the same chromosomes are cotransmitted to gamete unless a recombination occurs between the linked loci. For instance, C-f-g, c-F-G, d-H, and D-g are cotransmitted without recombination.

8 FANCY MICE

Even before the establishment of Mendelian genetics, many mutant mice in *Mus musculus*, had been isolated, established, and accumulated, called "fancy mice," by collectors, often called mouse fanciers, as pets (Rader, 2004). To make them easier to handle, smaller, gentler more fertile and less aggressive mice were usually selected in addition to some peculiar phenotypes of eye and coat colors, coat patterns, morphological anomalies, strange behaviors, and other traits. Thus, many of the mutations in fancy mice are monogenic visible mutations with high penetrance.

When the Mendel's inheritance laws were rediscovered in 1900, fancy mice immediately bacame a good resource for the experimental studies. The mutant alleles, *a*, *b*, *c*, *d*, and *e* in the *nonagouti*, *brown*, *albino*, *dilute*, and *pink-eyed dilution* loci, respectively, were established from fancy mice in this early period of the 20th century. In the classic genetics, the names of wild-type alleles, as well as the names of loci for *a*, *b*, *c*, *d*, and *e* mutant alleles were both designated to *A*, *B*, *C*, *D*, and *E*. The first linkage of any mammalian species was indeed discovered between the *C* and *E* loci by (Haldane et al., 1915). Namely, it was the first gene mapping in the mammalian species. The nomenclature of these mutant alleles is still actively used even now except for *e* of the *pink-eyed dilution* locus. At present, this classic allele of the pink-eyed dilution locus is renamed to *p*.

In the field of the mutagenesis of the mouse, Russell (1951) developed a test strain called **T** for the specific locus test (SLT) by adding two more loci to the five loci as shown in Fig. 28.4. Russell and his coworkers have extensively used the **T** strain for the various mutagenesis studies (Russell et al., 1979).

9 LABORATORY MOUSE STRAINS

Since early 20th century, various laboratory mouse strains have been developed (reviewed by Lyon et al., 1996; Rader, 2004). Updated list and information of available mutant mice and strains are also found in the Mouse Genome Informatics (MGI; http://www.informatics.jax.org/) at the Jackson Laboratory and the International Mouse Strain Resources (IMSR) (http://www.findmice.org/). The mouse and strains are directly available from a member of the Federation of International Mouse Resources (FIMRe; http://www.fimre.org/); for instance, the Jackson Laboratory (http://www.jax.org/), European Mutant Mouse Archives (EMMA; http://www.emmanet.org/) and RIKEN BioResource Center (http://www.brc.riken.jp/lab/animal/en/).
FIGURE 28.4 **Basic scheme of the Specific Locus Test (SLT).** T strain homozygously carries recessive visible mutant alleles, nonagouti *(a)*, brown *(b)*, albino *(c)*, pink-eyed dilution *(p)*, dilute *(d)*, short ear *(se)*, and piebald *(s)*, on the seven loci. In this scheme, only the five pairs of autosomes carrying the seven loci are depicted. A **T** mouse is mated with an experimental mouse that homozygously has wild-type alleles *(+)* on the seven loci with or without prior treatment by a mutagen. The produced F1 mice are subjected to the phenotype assessment for the corresponding seven visible traits. Only when a de novo mutation occurs on any of the seven visible marker loci shown by alleles with asterisks, F1 exhibits the corresponding visible phenotype of the locus. The detection is easy because the expected seven mutant phenotypes are known. The mutation rate is also quantitatively assessed by ratio of the mutant mice to the totally produced F1 mice.

10 REDUNDANCY OF GENES: OCULOCUTANEOUS ALBINISM

In human, eye and coat color anomalies have been well recognized as oculocutaneous albinisms (OCAs). The coat color mutations found in fancy mice have been contributed to identify the causative genes of human OCAs. The well-known albino locus (*c*) was mapped on chromosome 11 and 7 in human and mouse, respectively. The key enzyme in the melanin synthesis is tyrosinase that catalyzes the rate-limiting step of tyrosine to dihydroxyphenylananine (DOPA) as well as DOPA to DOPA-quinone. Shibahara et al. (1986) reported a cDNA clone, pMT4, encoding mouse tyrosinase. Later, Kwon et al. (1987) and Yamamoto et al. (1987) also reported cDNA clones for human and mouse tyrosinase, respectively, both of which were similar to pMT4. In spite of a good functional and sequence similarity to tyrosinase, the whole sequences of pMT4 were identified not of the *c* locus but of the *b* locus on mouse chromosome 4 (Jackson, 1988). This is a good lesson to note that even if a DNA clone is obtained with enough functional and sequence similarity, it might be a paralog rather than the orthologs of the objective locus. Based on these cloning and analyses, the *c* and *b* loci were revealed to encode tyrosinase and tyrosinase-related protein-1, respectively.

In human OCAs, four linkage groups have been identified; OCA1, 2, 3, and 4. OCA1 and 3 are caused by mutations of the tyrosinase (*c*) and tyrosine-related protein-1 (*b*) genes, respectively. The OCA2 (*p*) and SLC45A2 (*uw*) mutations are responsible for OCA2 and 4, respectively. The OCA2 and SLC45A2 genes are totally different from each other with respect to the sequences and their gene functions. Neither OCA2 nor SLC45A2 has any similarity to tyrosinase or tyrosinase-related protein-1. Thus, similar phenotypes may also derive from a distinct gene as well.

As shown in the cases for OCAs, the responsible genes are often redundantly coded in the genome, although mutations of each gene act as monogenic trait or Mendelian inheritance. Lyon et al. (1996) listed 81 loci in which eye and coat color mutations had been found.

It is noteworthy here that historically the locus names used to origin from the identified mutations. The locus names of brown (*b*), albino (*c*) and dilute (*d*) are typical examples. At present, HUGO Gene Nomenclature Committee and International Committee on Standardized Genetic Nomenclature for Mice currently determine the official gene names and symbols mostly based on the functionality of the gene, usually, protein product. Thus, official gene names for *b*, *c*, and *d* now are tyrosinase (*Tyr*), tyrosinase-related protein-1 (*Tyrp1*) and myosin VA (*Myo5a*), respectively.

11 BODY WEIGHT AND BRAIN FUNCTION: PLEIOTROPY OF *ob* AND *db*

Obese (*ob*) and diabetes (*db*) mutant mice spontaneously arose in laboratory stocks, both of which also exhibit very similar phenotype, the increase in body weight and infertilities in homozygotes. Zhang et al. (1994) positionally cloned and identified the mouse *ob* gene and human homolog. The *ob* gene encodes for a secretary protein, leptin.

Tartaglia et al. (1995) then cloned the leptin receptor (*db*) gene from a mouse choroid plexus cDNA library. They first found the candidate sequence mapped to the *db* locus on mouse chromosome 4; however, they could not detect causative mutations in the cDNA sequences of the *db* mice. The leptin receptor was found to be transcribed to many alternatively spliced variants. Ghilardi et al. (1996) identified a long isoform of the leptin receptor transcripts that was preferentially expressed in the hypothalamus. They further discovered a point mutation in the leptin receptor gene of the *db* mice. As a consequence, a point mutation in the leptin receptor gene of the *db* mice caused an alternative splicing only producing a short form of the leptin receptor.

Both mutant mice, *ob* and *db*, exhibit two distinct phenotypes, obesity and infertility. When one mutation affects two or more of phenotypes, it is called pleiotropic. The identification of responsive genes with causative mutations has led to the molecular and physiological understanding of the pleiotropy. The circulating adipocyte-derived endocrine hormone, leptin, is recognized by leptin receptor at the hypothalamus. The neuroendocrine system then seems to trigger the subsequent gene networks for the appetite, feeding behaviors, circadian rhythm, puberty, sexual maturation, and maintenance of the reproductive cycles. Mouse models are now revealing that the brain acts a key role in the *db* and *ob* pleiotropy (reviewed by Donato et al., 2011).

12 CONVENTIONAL POSITIONAL CLONING AND FORWARD GENETICS

In the aforementioned examples, classic mutations and de novo mutations arose in laboratory stocks have been identified by their peculiar phenotypes first. Based on the phenotype segregation in the pedigree, responsible loci have been mapped using backcross and other linkage mapping technologies. The power of the mapping is usually dependent on the recombination events. The genetic maps of human and mouse genomes are about 3000 and 1500 cM, respectively in the 3×10^9 bp genomic sequences. It implies that one gamete has ~30 and ~15 recombinations, respectively, on average. Thus, 1 cM corresponds to 1 and 2 Mbp in human and mouse genomic DNA sequences, respectively. In order to identify the responsible gene and causative mutation of the mutant, the mapping of the mutation in the genome is the first key to narrow the candidate genomic region down to about centimorgan or 1–2 Mbps. Assuming that mammalian genome encodes 30,000 genes and that 0.1% of the genome has SNPs as described earlier, the candidate region of 1–2 Mbps thus still has 10–20 genes with 1000–2000 SNPs on average. The next step to identify responsible gene is to search mutations in ORF sequences or splicing donor/acceptor dinucleotide consensus sequences. Nowadays, whole human, as well as mouse genome reference sequences with SNP information are available so that it is much simpler and quicker to nominate such candidate mutations than the time of period before the Genomic Sequencing Project. Nevertheless, The final proof from a few centimorgan to the molecular identification of the mutation and gene is not always straightforward but still laborious and times taking even now as previously shown in the case for the *db* positional cloning by Tartaglia et al. (1995).

13 UNIQUE POSITIONAL CLONING: HIGH REVERSION RATES OF d^v AND p^{un} MUTATIONS

13.1 Positional Cloning of d

Many mutant alleles have been identified exhibiting pleiotropic effect of not only the coat color reduction but also some alleles with neurological anomalies and/or lethalities. In addition to the pleiotropy, very rare event of reversion of d mutation has also been recognized. Jenkins et al., (1981, 1982) and Mercer et al., (1991) conducted the positional cloning of d depending on these unique features of the d mutation and ultimately revealed the molecular mechanism of the pleiotropic phenotypes and high reversion rate.

An endogenous ecotropic murine leukemia virus (MuLV) DNA was found in many laboratory strains with various copy numbers. One of MuLV sequences called Emv3 was 100% concordant with the d mutation in various recombinant inbred (RI) strains as described later. This particular allele was thus renamed as d^v (Jenkins et al., 1981, 1982). They also found that a spontaneously obtained revertant allele d^{+2J} had no MuLV sequence. As shown in Fig. 28.1, conventional loss-of-function type mutations hardly revert back to restore the wild-type sequence and phenotype. They interpreted the mechanism of the reversion that the MuLV had been lost by a homologous recombination between the long terminal repeats at both ends of the MuLV.

The consequent molecular identification of the interrupted gene by MuLV was myosine VA encoded by dilute (d) locus (Mercer et al., 1991). The *Myo5a* mutation interferes the formation of dendritic processes in the melanocyte, causing the melanin granules to clump around the nucleus of the melanocyte and give rise to the coat color reduction. In particular, Huang et al. (1998) found that the most of mutations with neurological anomalies existed in the C-terminal "tail" region of MyoVA, indicating some significant C-terminal function for neuron and neuron development. Their study is a good example to conduct the functional analysis of the gene by using various allelic series of mutations. Just studying with only one mutant allele, it may overlook and dismiss other significant functions of the gene.

In human, the *Myo5a* mutations have been identified for the cause of Griscelli syndrome, a rare autosomal recessive disorder characterized by hypopigmentation and either central nervous system (Griscelli syndrome type 1, or GS1) or immunologic (GS2) defects (OMIM 160777).

13.2 Positional Cloning of p

The positional cloning of another classic eye and coat color locus of pink-eyed dilution (p) was conducted in this case "without positioning/mapping" (Brilliant et al., 1991). Many de novo mutations have been identified in the p locus and one of them, pink-eyed unstable (p^{un}) had a unique feature of the highest reversion rates in mammals. Thus, some structural mutations were anticipated like retroviral integration or transposon. Brilliant et al. (1991) conducted southern hybridization analysis of p^{un} and coisogenic wild type and revertant genomic DNAs with a part of intracisternal particle A (IAP) DNA sequence as a probe. The IAP fragment had ~1,000 copies in the mouse genome; thus, if any large DNA structural change, for example, deletions and duplications, occurred, such repetitive probe may directly reveal the site of mutation without mapping or positioning (Gondo and Brilliant, 1995). In addition, IAP per se might have been the cause of mutation and high incidence of the reversion, in which case the IAP probe might have detected the mutated gene as in the case for the d^v mutation shown earlier.

The IAP probe detected 2.9-kb enhanced signal only in the p^{un} but neither in coisogenic wild type nor revertant genomic DNAs. The 2.9-kb enhanced DNA fragment was indeed mapped to the p locus (Brilliant et al., 1991). Further molecular analysis revealed that the p^{un} mutation is caused by a large direct head-to-tail duplication of an internal ~70-kb fragment of the p locus encompassing the 2.9-kb enhanced fragment (Gondo et al., 1993). All the tested revertant genomes had only one copy of the large 70-kb sequence that was indistinguishable to the wild-type genome due to an unequal homologous recombination between the duplicated fragments to revert the duplicated structure back to one single copy as in the wild-type genome (Gondo et al., 1993).

14 RECOMBINANT INBRED STRAINS FOR QUICK GENETIC MAPPING

Similar to the inbred and congenic strains described earlier, many recombinant inbred (RI) strains have also been developed as shown in Fig. 28.5 by conducting a series of sib mating of more than 20 generations starting from two established inbred strains.

The RI strains have an immediate power to map the polymorphic loci between the two inbred strains, as well as the quantitative trait locus (QTL) analyses of the complex traits. Some examples are shown in the positional cloning of dilute (d) and pink-eyed dilution (p) loci.

The d^v mutation allele described earlier was originated from DBA/2J inbred strain. Jenkins et al. (1981) vindicated the d^v cloning by the RI strain (Fig. 28.5) as follows. DBA/2J exhibited the reduced pigmentation of the coat color due to the homozygosity of d^v allele. Likewise, other established inbred strains, as well as any RI strains were easily distinguished whether they carry wild type or mutant d allele. The coat color of AKR/J
FIGURE 28.5 **Establishment of recombinant inbred strains.** The basic scheme to establish inbred strain is the continuous sister–brother (sib) mating in the same litter for more than 20 generations. The original pair of F0 mice may carry two each alleles thus a total of 4 different alleles at most on any loci. Locus *A* may have *A1/A2* in one F0 and *A3/A4* in the other F0. By chance, during the 20 consecutive sib matings, any loci may be fixed to have only one type of alleles homozygously. Once a locus is fixed to one allele, namely, A1/A1 sister and A1/A1 brother mating pair, thereafter the locus is maintained as A1/A1 homozygote forever. In theory, more than 99% of loci become homozygous. In order to establish RI strains, a pair of different inbred strains is chosen for F0 as shown in this figure. In the F1 generation, all the genome becomes heterozygous for the two strains (white and blue). Then, many pairs of F1 are intercrossed and the sib matings are conducted to establish independent RI strains as many as possible. After 20 generations of sib matings, all the loci become homozygous with mosaic components of the two original inbred strains depending on the event of recombinations.

and C57BL/5J inbred strains were indeed apparently different from that of DBA/2J and many RI strains had been established between them with the easy identification of the strain distribution pattern (SDP) of the *d* phenotypes. Thus, they used 26 and 27 RI strains of C57BL/6JXDBA2/J (BXD) and AKR/JXDBA/2J (AXD), respectively, for the mapping of the candidate DNA fragment, a part of MuLV sequence. Using the unique signals on Southern hybridization with the MuLV sequence as a probe, they found that the SDP of all the 53 phenotypes in the total of 53 RI strains were 100% concordance with the segregation of the coat the MuLV signals.

Nakatsu et al. (1992) also used the RI mapping system to indicate that the *p* locus is closely linked to the Prader-Willi chromosomal region (PWCR). First, Brilliant et al. (1991) found a 13.6-kb Southern hybridization signal with a 394-bp of genomic DNA from p^{un} duplication as a probe in DBA/2J inbred strain. On the other hand, both C57BL/6J and AKR/J inbred strains exhibited a 4.8-kb signal with the 394-bp p^{un} probe. They analyzed the SDPs of the identified Southern signals in 26 and 24 RI strains of BXD and AXD, respectively. The SDPs of the 394 bp p^{un} probe was also 100% concordant with those of the D7Nic1, the mouse homolog of the human gene in the PWCR.

RI strains have strong mapping power because neither mating nor mouse productions are needed when molecular markers in the RI genomic DNA are analyzed. Southern restriction fragment length polymorphisms (RFLPs), simple size length polymorphisms (SSLPs) and single nucleotide polymorphisms (SNPs) may be quickly assessed for the mapping. Once the SDPs are identified in a particular set of the RI strains, it is directly applicable when the same set of the RI strains are used as shown by Nakatsu et al. (1992); thus, the SDPs are cumulatively enhance the strength of the RI mapping power.

15 MUTAGENESIS FOR FORWARD GENETICS

15.1 Mutagenesis

Little and Bagg (1923) reported for the first time the possibility of X-ray induced mutations in the mouse. While taking time to prove the Mendelian inheritance of X-ray induced variation to the offspring in the mouse, the transmission of the X-ray induced phenotype was first proved in *Drosophila melanogaster* (Muller, 1927).

15.2 X-ray Induced Mutations

Since the discovery of X-ray as a strong mutagen, the risk assessment studies of radiation have been conducted in various organisms including mice (Russell et al., 1958). At the same time, obtained and established mutants contributed to accelerate the pace of genetics by providing many useful mutants compared to the very rare event of spontaneous mutations. For instance, Medical Council Research (MRC) in UK and National Oak Ledge National Laboratory (OLNR) in USA produced many mutant mice by X-ray irradiations shown by the super script numeric series of "*H*" and "*R*" alleles, respectively, in many loci (Lyon et al., 1996).

15.3 Allelic Series of *Pink-Eyed Dilution* Locus

As shown in Fig. 28.4, new *p* mutation alleles have been easily identified and established by X-ray irradiations. Among many *p* mutation alleles, variety of pleiotropic phenotypes has also been recognized in addition to the OCA2 phenotype of reduced eumelanin. For instance, neurological/behavioral anomalies (p^{6H}, p^{25H}, p^{bs}, and p^{cp}), cleft palate (p^{cp}), sterility (p^{6H}, p^{25H}, p^{bs}), lethality (p^{81H}, p^{82H}, p^{87H}) and genetic instability (p^{un}) have been reported (Lyon et al., 1992; Lyon et al., 1996). Lyon et al. (1992) analyzed X-ray induced mutant alleles by Southern hybridization and found large deletions encompassing whole or a part of the *p* locus. Based on the deletion mapping with the complementation analyses for the

pleiotropy of X-ray induced *p* allelic series, Lyon et al. (1992) implicated that the new neurological gene(s), essential gene(s), sterility-related gene(s) and cleft palate-responsible gene(s) were located closed to the *p* locus. Thus, they considered that the pleiotropy was not caused by the *p* mutations per se but a large deletion of concomitant nearby gene(s) by the X-ray. Indeed, Nakatsu et al. (1993) isolated a new neurological gene cluster of three $GABA_A$ receptor subunit genes in the p^{cp} deletion allele.

The deletion mutations, as well as previously described RI mappings are a good tool to molecularly analyze the conserved homologous region in two different species. Analysis of the *p* region on mouse chromosome 7 contributed to the molecular analysis of the syntenic region on human chromosome 15 including OCA2 and PWCR (Gardner et al., 1992; Nakatsu et al., 1992).

15.4 ENU: The Most Potent Mutagen in the Mouse

Mustard gas was first identified as a chemical mutagen in *D. melanogaster* (Auerbach and Robson, 1946) followed by many other chemicals. For instance, Russell et al. (1979) found that the ENU was the most potent mutagen in the mouse. With a fractionated dose of 100 mg/kg at weekly interval for a total of 300 and 400 mg/kg gave rise to the mutation rates of 125 and 153×10^{-5}/locus/gamete, respectively (Hitotsumachi et al., 1985). The ENU mutagenesis scheme based on their extensive studies for ENU mutagenesis in the mouse by Russell and his coworkers was adapted to the large-scale ENU mouse project started from 1997.

15.5 Forward Genetics With ENU

ENU exclusively induces base substitutions (Noveroske et al., 2000). Thus, one of the key steps of forward genetics with ENU by phenotype-driven approach is the positional cloning to identify the mutated single base pair in 3×10^9 bp of the genome that often carries many background SNPs and unrelated mutations. Around 1990, the advancement of the positional cloning technologies has made it possible to identify and isolate the causative base substitutions and responsible genes in the established mutant strains by phenotype-driven mutagenesis. In this section, two pioneering positional cloning of ENU-induced mutations are demonstrated.

15.5.1 Multiple Intestinal Neoplasia (Apc^Min)

Moser et al. (1990) conducted ENU mutagenesis to directly obtain model mice for human diseases. The basic scheme of ENU mutagenesis is shown in Fig. 28.6. Their approach is a phenotype-driven forward genetics to establish dominant mutant mouse strain. In the dominant mutation screening, larger number of G1 mice

(Fig. 28.6) gives more chance to have mutant mice. It also depends on what kind of phenotypes to focus on for the screening. An anemic G1 was found and its inheritance was confirmed in G2 (Moser et al., 1990). The anemic mice were always found in 50:50 ratios in G2 or from equivalent mating, were passed bloody feces, and had numerous adenomas in intestine with 100% penetrance. They considered that the anemic trait is secondary to the development of multiple adenomas, naming the mutant allele multiple intestinal neoplasia (*Min*).

Based on the similarity of *Min* mice to the human FAP patient, Su et al. (1992) postulated that *Min* was an allele of *Apc* locus. They conducted candidate approach to clone a mouse homolog cDNA with human APC probe just after the human *APC* cloning (Kinzler et al., 1991). Su et al. (1992) found that the isolated cDNA, as well as corresponding genomic DNA had significant homologies to human *APC* gene and identified that the *Min* mice carry a nonsense mutation of codon 850 from Leu (TTG) to Stop (TAG) in the *Apc* gene. Thus, Su et al. (1992) renamed the mutation Apc^{Min} allele.

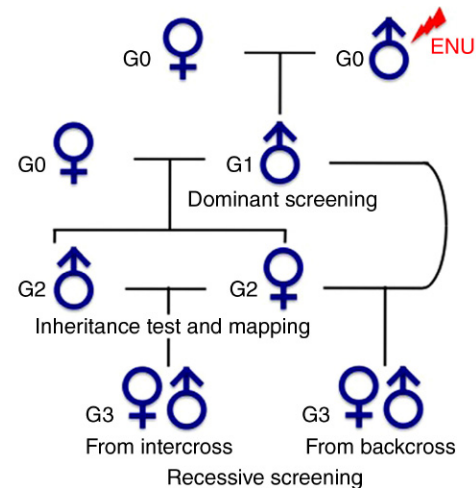
The homozygotes for the Apc^{Min} allele were never observed (Moser et al., 1995), indicating the *Apc* gene as an essential gene. As found in the human tumorigenesis with *Apc* mutations, Luongo et al. (1994) also showed


FIGURE 28.6 Typical scheme of phenotype-driven ENU mutagenesis in the mouse. ENU-treated G0 males are mated with untreated G0 females to produce G1 offspring. Each sperm in G0 males has thousands of independent ENU-induced base substitutions and each G1 mouse clonally inherits the thousands of the germline mutations in the sperm. Many G1 mice are then subjected to comprehensive phenotyping to detect dominant mutations. Each candidate G1 is then mated to a female or a male of the same inbred strain of G0 female to confirm the germline transmission in G2 population. For the recessive screening, on the other hand, the phenotype first appears in the G3 mice. Mating a G2 mouse to the parental G1 mouse may produce G3 mice. Intercrosses between G2 pairs also generate G3 mice for the recessive phenotype screening. For both dominant and recessive screening of mutant mice, all the key germline mutations exist in the G1 mice; thus, the G1 mouse preservation is the primary resource for the ENU mouse mutagenesis project.

that adenomas in Apc^{Min} mice also had loss of hetero-zygosities (LOH), indicating the effectiveness of Apc^{Min} mouse as a model for tumorigenesis due to the loss-of-function mutations of tumor suppressor genes. Further-more, Moser et al. (1992) mated the congenic B6-Min mice to several different inbred strains. They observed the effects of F1 genetic background with respect to the longevities or survival rates, number of adenomas, and development of invasive tumors, implicating the existence of modifiers and gene-to-gene interactions between *Apc* and other genetic networks.

15.5.2 Circadian Locomotor Output Cycles Kaput (Clock)

Vitaterna et al. (1994) considered that mutations for circadian-related genes might be obtained by domi-nant G1 screening, because the majority of circadian rhythm-related mutations in other species had been semidominant. Based on this assumption, they con-ducted a phenotype-driven forward genetics with ENU to establish mutant mouse models for circadian rhythm. They focused on the mutant phenotypes by using wheel-running activity in a light-dark cycle and constant dark environments. Among the tested 304 G1 mice generated from C57BL/6J G0 parents (Fig. 28.6), one G1 exhib-ited an extended clock of 24.8 h circadian rhythm in a constant dark condition. Wild-type mice usually have 23.3–23.8 h circadian rhythm. They mated this G1 mouse to C57BL/6J and obtained 23 G2 mice, of which 13 and 10 G2 had 23.3–24.0 h and 24.5–24.8 h circadian periods, respectively, indicating the Mendelian monogenic domi-nant inheritance.

Vitaterna et al. (1994) named the mutated locus and allele "*circadian locomotor output cycles kaput*" (*Clock*). The heterozygotes of *Clock*/+ were intercrossed to examine the phenotype of homozygotes of *Clock*/*Clock*. At this point they did not have any markers to distin-guish the genotypes. Nevertheless, the 1:2:1 Mendelian segregation was observed in the tested population cor-responding to short (~23.3 h) wild-type homozygotes, long (~24.4 h) heterozygotes, and very long (~27.3 h) *Clock*/*Clock* homozygotes. Therefore, the mutant allele of *Clock* had additive codominant effects. In addition, the very long circadian rhythm in *Clock*/*Clock* was only sus-tained for the beginning two weeks followed by a total loss of the rhythmicity, which had not been observe in *Clock*/ + heterozygotes and thus was a recessive trait.

Based on the monogenic inheritance of the Clock phenotype, King et al. (1997) isolated the Clock gene by positional cloning. They intensively screened cDNA libraries from suprachiasmatic nuclei (SCN) of the hypo-thalamus, because SCN had been proposed to be a cen-ter of the mammalian circadian rhythm regulation. The identified *Clock* gene encoded a novel transcription fac-tor with a basic helix-loop-helix (bHLH)-PAS domain.

The northern hybridization primarily revealed the ubiq-uitous expression of *Clock* in most tissues. In situ hybrid-ization in the mouse brain further indicated apparent expression of *Clock* mRNA in SCN and hippocampus and low-level expressions in the rest of brain. In the *Clock* mutant mice, the causative A to T transversion was found in a splice donor dinucleotide sequence caused exon skipping and deletion of 51 residues in the Clock protein. The PAS domains of the *Clock* gene as probes, the evolutionary conservation was also revealed in not only mammalian species but also in reptile, amphibian, and fish (King et al., 1997).

16 LARGE-SCALE ENU MOUSE MUTAGENESIS PROJECT

The Human Genome Project started 1990 as an inter-national collaborative effort with public funds. The next challenge foreseeing the completion of the human genome sequencing is the functional annotation to decode the sequences. As shown in previous section, mutant mice are good models to analyze the function of the gene with mutagenesis. Prior to the completion of the Genome Project, only a small part of entire gene set in the genome was known. In this context, the forward genetics was the best approach with random genome-wide mutagenesis in a large scale, in which no prior knowledge of the target genes was required at all.

ENU was chosen because it is the most potent known mutagen in the mouse as shown earlier. ENU exclu-sively induced base substitutions (Justice et al., 1999; Noveroske et al., 2000); thus, many allelic series of muta-tions were also expected for each gene with variety of effects, dominant, recessive, null, hypomorph, and so on for the fine functional analysis of the gene. The nature of base substitutions should also provide good models for the diseases due to SNPs in human populations. Finally, the success of the identification of *Apc* and *Clock* by for-ward genetics with ENU mutagenesis described in the previous section made the last push to initiate the large-scale comprehensive ENU mouse mutagenesis projects in a worldwide manner (reviewed by Gondo, 2008).

16.1 Dominant Forward Genetics With ENU

ENU randomly induces somatic base substitutions most of the tissues in the injected mouse. When muta-tions occur in germ cells, they transmitted to the next generation and may be established as mutant strains. ENU induces mutations much less effectively in oogonia than sparmatogonia; thus, only males are used as G0 for the ENU mutagenesis (Fig. 28.6). In order to avoid any genetic background effects, an isogenic inbred strain may be used for the entire ENU mutagenesis scheme except

for genetic mapping. Dominant germline mutations may be primarily detected in G1 screening by intensive and comprehensive phenotyping.

The identified dominant mutation exists only in the G1 mouse at this time point; thus, the G1 candidate is immediately mated to propagate the mutant allele. G1 males are usually much easier to propagate and preserve the induced mutations than G1 females. Males may be mated to several females consecutively or even at the same time in the same cage. On the other hand, females may produce only one litter of less than 20 pups per several months. The robust technologies are also established for the cryopreservation of mouse sperm in liquid nitrogen semipermanently and for the reviving mice from frozen sperm (Nakagata, 1993, 2000) with the in vitro fertilization and embryo transfer (Whittingham et al., 1972). No reliable ovary cryopreservation and implantation technologies, on the other hand, have been established yet.

The identified dominant-candidate character may not be due to a mutation but just a deviation by chance and/or by an environmental effect(s). With respect to this possibility, all the candidate G1 mice are also necessary to produce G2 in order to confirm the Mendelian inheritance as a dominant trait. Only one allele in G1 candidates carries the dominant mutation; therefore a 50% appearance is expected in the G2 population assuming it is a monogenic dominant trait with 100% penetrance. Any detrimental effect(s) of the dominant trait may reduce the number of the heterozygous mutation carriers in the G2 population distorting the 1:1 segregation. Considering these possibilities, we usually produced, at least, 20 G2 mice to make a decision if each G1 candidate carry a dominant mutation or not at the RINE ENU forward mouse mutagenesis. Based on this criterion, about 2%–4% in all of the produced G1 mice carried an ENU-induced dominant mutation (reviewed by Gondo, 2008; Gondo et al., 2010).

The next step is the mapping of the confirmed dominant mutations toward the positional cloning. In the aforementioned coisogenic scheme that uses a single inbred mouse strain, no genetic markers for the mapping are yet available. In this case, one heterozygous carrier is first mated to another inbred strain to use the genomewide strain polymorphisms (e.g., SNPs and SSLPs) as genetic markers. It is one option to use G0 females of another inbred strain that are different from the G0 males' strain to begin with, as in the scheme of Fig. 28.6. In this optional scheme, all the G1 have the uniform F1 genetic background between the two inbred strains, carrying the ENU-induced mutations on the paternal chromosomes. The candidate G1 is then mated to a mouse of the same inbred strain of G0 females. In this optional case, the G2 mice directly provide the materials for the genetic mapping of the candidate dominant mutation when the inheritance of the candidate domi-

nant mutation is confirmed in the same G2 population. This optional scheme significantly reduces the necessary time period from the mutagenesis to the mapping and identification of the causative mutation, although the heterogeneity of the genetic background might disturb the interpretation of experimental data.

With the dominant screening of G1 mice, RIKEN phenotype-driven mutagenesis project per se has established various human disease models; diabetes type 2 with *glucokinase* mutations (Inoue et al., 2004), amelogenesis imperfecta (AI) with *enamelin* mutations (Masuya et al., 2005), osteoarthritis with a *Gdf5* mutation (Masuya et al., 2007a), retinal degeneration with a *Rom1* mutation (Sato et al., 2010), and attention deficit hyperactivity deficit with a *Grin1* mutation (Furuse et al., 2010).

16.2 Recessive Forward Genetics With ENU

Based on the SLT, ENU induced recessive mutation at a frequency up to one in 700/locus/gamete (Moser et al., 1990; Vitaterna et al., 1994). Taking a conservative frequency of at least one in 1000/locus/gamete, any single G1 mouse may carry ~30 recessive mutations in the total of 30,000 loci. On the other hand, each G1 carried ~0.03 dominant mutations as shown in the previous section, namely 2%–4% of G1 inherited its dominant trait to G2. The ENU induced dominant mutation, thus, was at a frequency of one in million/locus/gamete. The number of recessive mutations is 1000-fold more than that of dominant mutations in the produced G1 mice (Supplementary Information in Gondo, 2008). Most of the human genetic diseases are based on the inactivation of the gene or gene network; thus, large numbers of G1 mice are a good resource for modeling such recessive human diseases.

Any recessive traits, however, cannot be recognized in G1 mice, since all the G1 mice carry the ENU-induced mutations heterozygously on only the paternal chromosome in the scheme of Fig. 28.6. The conventional mating scheme to produce homozygotes for the ENU-induced mutations is either by intercross of arbitrary chosen G2 pairs or by backcross any G2 to its G1 parent as shown in Fig. 28.6. Each G2 randomly inherits half of ~30 recessive mutations in G1. An arbitrary chosen G2 pair has 7–8 (=30 divided by 2 twice) recessive mutations in common by chance. Each of commonly inherited 7–8 recessive mutations in a G2 pair then gives rise to the 1:2:1 Mendelian segregation of wild type homozygotes:heterozygotes:recessive homozygotes in G3. In other words, any single G2 intercross pair should provide the recessive mutant homozygotes for the 7–8 loci if enough numbers of G3 are produced. The detection efficiency of ~30 and ~15 recessive mutations of G1 and G2, respectively, in the G3 population as homozygotes may be furthermore improved by the backcross scheme in Fig. 28.6.

The G1–G2 backcross pair shares all the ~15 recessive mutations in common, since the ~15 mutations are inherited from the G1 parent. The number of observable recessive phenotypes by the backcross scheme, thus, is for ~15 loci in the enough number of their G3 population, which is twofold more than that by the intercross scheme in Fig. 28.6.

In spite of the theoretical feasibility and efficacy of the recessive forward genetics with ENU described earlier, the practical identification of recessive mutant mice has been hampered with several reasons. (1) In the G3 population, 7–8 mutations from independent loci overlaid the corresponding multiple phenotypes to each G3 depending on the 3:1 ratio for each locus, exhibiting multilocus compound phenotypes. Multilocus segregation was often too complex to extract the single locus effects of each recessive mutation. In order to reduce the complexity of G3 segregation as low as possible, all the recessive forward genetics at RIKEN were conducted in the C57BL/6J background. (2) Recessive lethal mutations also segregated according to the Mendelian law but were impossible to observe other than the reduction of the litter size. The average litter size of the G3 production was indeed smaller than that of the G1 or G2 production. The litter size of G3 from the backcross scheme was also smaller than that from the intercross scheme, supporting the significant number of recessive lethal mutations or detrimental mutations in the original ~30 recessive mutations in each G1. (3) Even if a Mendelian inheritance for a recessive mutation was confirmed and the strain was established, the genetic mapping became often impossible because the identified phenotype disappeared in the F1 genetic background, which is the necessary first step of the mapping. These difficulties of the recessive forward genetics with ENU, however, strongly vindicate the value of the G1 mice as a resource for the elucidation of gene-to-gene interactions and genetic network. The further details will be discussed in Section 23.

17 MUTAGENESIS FOR REVERSE GENETICS

In 1980's, various advanced technologies for genetic and embryonic engineering were established in the mouse, which subsequently has made it possible to conduct reverse genetics in the mouse. The "giant" transgenic mouse was constructed by injecting DNA fragments encompassing the human growth hormone gene under the metallothionein promoter to fertilized oocyte (Palmiter et al., 1982), providing a new tool to introduce exogenous DNA into mouse genome and to make gain-of-function mutant mice. The embryonic stem (ES) cell technology was also established to make mice

from the pluripotent ES cells developed by Evans and Kaufman (1981). The genes and genome in the ES cells were transmitted to germline chimeric mice by injecting manipulated ES cells into blastocyst-stage embryos (Gossler et al., 1986; Robertson et al., 1986).

18 GENE TARGETING AND KNOCKOUT MOUSE

Smithies et al. (1985) and Thomas et al. (1986) independently showed the feasibility of the site-directed mutagenesis in the mouse by the somatic–homologous–recombination method, which had been a useful tool to disrupt or manipulate target genes in bacteria and lower eukaryotes. The site-directed mutagenesis in the mouse has become a practical technology in the mouse cells by using selectable marker genes (Doetschman et al., 1988; Mansour et al., 1988). These technologies were then integrated to a powerful reverse genetics tool, for the first time, in the mouse, which is gene targeting or knockout mouse (reviewed by Capecchi, 1989). It is noteworthy that in the broad sense the transgenic mouse stands for the genetically engineered mouse inheriting a modified genome by the random insertion, as well as by targeted integration using homologous recombination; however, it is often defined as the former, namely, the genome-manipulated mouse with a randomly integrated DNA fragment in a narrow sense. This manuscript uses the narrow definition in order to distinguish between the engineered mice by random and targeted integrations.

19 TRANSGENIC MICE AS DISEASE MODELS

By using transgenic mice carrying an exogenous DNA, it is possible to analyze the gain of function due to the exogenous DNA. Transgenic mice, thus, may model dominant genetic diseases in human. For instance, Mangiarini et al. (1996) constructed transgenic mice carrying an expanded CAG repeats in exon 1 of the human *Huntingtin* gene to model Huntington's disease. They found that only the small fraction of human *Huntingtin* gene with ~130 repeats of CAG was sufficient to cause various neurological anomalies that exhibited many of the characteristics of Huntington's disease. On the other hand, the homozygous and heterozygous knockout mice for the *Huntingtin* gene exhibited early embryonic lethality and no obvious phenotypes, respectively (Duyao et al., 1995; Nasir et al., 1995; Zeitlin et al., 1995). Thus, the knockout mice vindicated the essentiality of the *Huntingtin* gene but provided no models for Huntington's disease (reviewed by Menalled and Chesselet, 2002).

Another application of transgenic mice is to rescue the mutant phenotype by introducing the wild type DNA fragment to the mutant mice. It is useful for the recessive phenotypes due to loss-of-function type mutations. The transgenic rescues also provide feasibility studies toward the application for the gene therapies of recessive human genetic diseases.

20 KNOCKOUT MICE AS DISEASE MODELS

Knockout mice have been contributing for the elucidation of the biological function of target genes at the live mouse level. In particular, this new reverse genetics tool in the mouse immediately applied to the gene-driven elucidation of candidate genes for human diseases. The knockout mice for the mouse homologs of human *glucokinase* (Bali et al., 1995; Grupe et al., 1995; Postic et al., 1999; Terauchi et al., 1995 and reviewed by Osbak et al., 2009) and *Apc* genes (Fodde et al., 1994; Oshima et al., 1995) clearly vindicated the direct causality for the diabetes and colon cancer, respectively.

Another good example is p53 knockout mice. p53 was identified abundantly in various mouse tumors and originally considered to be protooncogene later hypothesized as a tumor suppressor gene (reviewed by Donehower et al., 1992). Zakut-Houri et al. (1983) identified a single p53 gene in the mouse based on the cDNA cloning. Li and Fraumeni (1969) had previously identified four human pedigrees susceptible to various types of tumors. Malkin et al. (1990) identified a strong association of p53 mutations in Li-Fraumeni tumors in human. Donehower et al. (1992) and Gondo et al. (1994) constructed p53 knockout mice and found that heterozygous p53 knockout mice were predisposed to develop thymic lymphoma and various other tumors.

Intriguingly, the homozygous p53 knockout mice were also born normally except the earlier onset for various tumors than the wild type control mice. p53 homozygous knockout mice even produced offspring normally before the tumor development. Thus, p53 was considered to simply act a gatekeeper for the cell cycle and to trigger the programmed cell death in transformed cells, consequently suppressing the tumor development (reviewed by Vousden and Lane, 2007). Norimura et al. (1996), however, found a pleiotropic function of p53. They irradiated the pregnant mice carrying p53 homozygous knockout fetuses, as well as homozygous wild type fetuses as controls with 2 Gy of X-ray on day 3.5 and 9.5 of gestation. They found no tumor development but significant increase and decrease in teratogenesis and embryonic death, respectively, in the p53 homozygous knockout fetuses.

21 CONDITIONAL TARGETING

The homozygous knockout mice for the *Huntingtin* gene were embryonic lethal, vindicating it is essential for the early development of the mouse. Such essential genes are often dispensable in adults. In order to investigate essential genes in a specific tissue and/or developmental time, conditional knockout system has been developed, for instance, by using Cre-loxP site-specific recombination in bacteriophage P1 (Sauer and Henderson, 1988). Cre enzyme efficiently recognizes and causes homologous recombination between a pair of short 34-bp sequence of loxP even in eukaryotic cells including the mouse. Placing two loxP sequences in the same and opposite orientation in a double helix DNA strand, the intervened sequence is looped out and inverted, respectively, by the site-specific recombination. Lakso et al. (1992) indeed succeeded in the conditional expression of the SV40 large tumor antigens (Tags) under the αA-crystallin (αA) promoter in the transgenic mice. The original transgene had a 1.3-kb intervening sequence flanked by a pair of loxP between the αA promoter and Tags. As a consequence, the 1.3-kb insertion hampered the expression of Tags under the control of the αA promoter. Thus, transgenic mice with the transgene was constructed and established without any tumor formation. Then, the transgenic mice were mated to the Cre-expressing transgenic mice to loop the 1.3-kb intervening sequence out from the transgenic genome, and developed lens tumors due to the expression of Tags in lens cells.

By adopting the Cre-loxP system in the targeting vector, the target gene may be conditionally knocked down based on the Cre expression under the control of tissue-specific and/or developmental time-specific promoters. Cre expression transgenic mice may be constructed independently from the conditional targeting mice. Cre transgenic mouse strains, therefore, have been a versatile tool for the conditional knockout mouse analyses. For instance, Shibata et al. (1997) constructed *Apc* conditional knockout mice based on the Cre-loxP system.

22 INTERNATIONAL KNOCKOUT MOUSE CONSORTIUM

Based on the drastic reduction of the number of encoded gene in the human genome, as well as in the mouse genome to be 30,000 or less, the mouse research communities proposed to conduct the knockout mouse project to make a full set of knockout ES cell lines for every gene in the mouse genome (Austin et al., 2004; Auwerx et al., 2004). With the core of the three public domains of KOMP, EUCOMM, and NorCOMM, the International Knockout Mouse Consortium (IKMC) was organized and the 5-year project was launched in 2007 (Editorial, 2007;

International Mouse Knockout Consortium, 2007). The accumulated technologies and knowledge of the International Gene Trap Consortium (Skarnes et al., 2004) was also integrated to the IKMC (Hansen et al., 2008). The gene trapping was originally developed as a tool for the forward genetics (Gossler et al., 1989). Then, the trapping vector has been modified to the conditional targeting vector for the reverse genetics (Hansen et al., 2008; International Mouse Knockout Consortium, 2007). Thus, the basic scheme of the IKMC was to establish "knockout first and conditional ready" ES cell lines in a C57BL/6N coisogenic background (Hansen et al., 2008; International Mouse Knockout Consortium, 2007).

The 5 years of the IKMC efforts was summarized in 2011 and availability of the developed ES cell lines and resources were reported (Skarnes et al., 2011). Many knockout alleles have been established in the C57BL/6N coisogenic background and the International Mouse Phenotyping Consortium (IMPC) has also started (Brown and Moore, 2012a,b).

23 ENU-BASED REVERSE GENETICS IN THE MOUSE

ENU may have not been considered for the reverse genetics because ENU randomly induces thousands of genomewide base substitutions. The construction of large-enough ENU mutant mouse library, however, may provide many allelic series of base substitutions in any given gene in the mouse genome. Having the large-scale ENU mutant mouse library and the high-throughput mutation discovery system, it has become possible to provide allelic series of point mutations in any target gene. (Beier, 2000; Coghill et al., 2002) suggested the feasibility of such ENU-based reverse genetics in the mouse in a small test scale.

23.1 ENU Mutant Mouse Library

During the course of the phenotype-driven forward genetics with ENU, the preservation of G1 mice were indispensable as discussed before. Thus, many ENU mouse mutagenesis projects cryopreserved the sperm of G1 males (Augustin et al., 2005; Michaud et al., 2005; Quwailid et al., 2004; Sakuraba et al., 2005). At time of their publications, the total size of the archived G1 mice in the four projects was ~40,000 G1 (reviewed by Gondo, 2008). Considering the ENU-induced mutation rate to be at least one in every megabase (Concepcion et al., 2004; Gondo et al., 2009), each G1 carries more than 3000 ENU-induced base substitution in the 3000-Mb genome. Thus, the total number of the archived ENU-induced mutations is $>1 \times 10^8$ in 40,000 G1 mice. Namely, it is possible to find one ENU-induced mutation every 25 bp in the 40,000 worldwide ENU mutant mouse library.

The best estimate of the average size of the coding sequences per gene is 1,437 bp in the mouse (MGC Project Team, 2004); therefore the average number of allelic series of ENU-induced mutations per gene in the 40,000 G1 mouse library is ~60. The worldwide ENU mutant mouse library has, therefore 60-fold coverage per protein-coding gene. When ENU-induced mutations occur in the protein coding sequences plus splicing acceptor/donor dinucleotide consensus sequence, ~70, 10, and 20% were missense, KO-equivalent and synonymous mutations, respectively (Gondo, 2008, 2010; Gondo and Fukumura, 2009).

With respect to the functional mutations, each G1 has ~30 recessive mutations that exhibit some biological changes in homozygotes as discussed before in this Chapter. The worldwide 40,000 G1 archive thus encompasses 1.2×10^6 functional mutations in ~30,000 genes or 40 functional mutations per gene, which is a consistent estimate with the expected ~60 base substitutions per gene with ~42 missense (70%) and ~6 KO-equivalent mutations (10%) as discussed in the previous paragraph.

23.2 High Throughput De Novo Mutation Discovery

The ENU mutant mouse library is an enormous resource for the reverse genetics if the mutations in target genes are effectively identified. The Sanger sequencing is a straightforward method to detect base substitutions but it is neither cost effective nor high throughput. Various PCR-based heteroduplex detection systems, therefore, have been used as a primary screening for the ENU-induced mutations on target genes. Among tested heteroduplex detection systems of denaturing high-performance liquid chromatography (Gross et al., 1999; Xiao and Oefner, 2001), temperature gradient capillary electrophoresis (Gao and Yeung, 2000; Li et al., 2002; Murphy et al., 2003), TILLING/Cel1 digestion (Oleykowski et al., 1998; Till et al., 2003), and high resolution melting (Bennett et al., 2003; Wittwer et al., 2003), we have been succeeded in identifying ENU-induced mutations effectively on target genes (Gondo and Fukumura, 2009; Gondo et al., 2009; Sakuraba et al., 2005). The RIKEN ENU mutant mouse library has been open to the research community since 2002 (reviewed by Gondo, 2008; Gondo et al., 2010; http://www.brc.riken.jp/lab/mutants/RGDMSavailability.htm).

23.3 Examples of Reverse Genetics With ENU Mutagenesis

Targeting the *disrupted in schizophrenia 1* (*Disc1*) gene in the mouse, (Clapcote et al., 2007) established two independent psychiatric disease models, schizophrenic and major depression disorder strains, from RIKEN ENU mutant mouse library. Schizophrenic mice were also established with a *serine racemase* nonsense mutation

(Labrie et al., 2009). Various behavioral mutant mice were established in the *reticulon-4* (Lazar et al., 2011), *Ncs-1* (Mun et al., 2015), and *STEP* (Kim et al., 2016) genes. Rivkin et al. (2013) discovered a novel function of the *gumby* (*Fam105b*) gene for angiogenesis with detailed molecular mechanism. Katsuragi et al. (2013) and Hirose et al. (2015) identified pleiotropic phenotypes of the S826G substitution of the *Bcl11b* gene. Shibata et al. (2015) reported abnormal hepatocyte apoptosis in the *cFLIP* mutant mice. Murata et al. (2014) found that the C429S missense mutation of the *β-catenin* gene caused sterility in both female and male in spite of their normal production of ova and sperm, respectively. Makino et al. (2015) identified that the T396 residue in the *Sufu* gene was critical for the Gli3 regulation in the Hh signaling.

The reverse genetics with ENU mutant mouse library has also been effectively identified functional noncoding mutations, since ENU induced base substitutions in noncoding sequences with equal frequencies to coding sequences in the mouse genome (Sakuraba et al., 2005). Masuya et al. (2007b) targeted ~1 kb of the MFCS1 sequence and identified six independent base substitutions in MFCS1. One strain indeed exhibited the preaxial polydactyly with an ectopic expression of sonic hedgehog gene in limb buds as expected. The MFCS1 had previously identified as a cis-regulatory noncoding sequence about 1 Mb upstream to the sonic hedgehog gene (Sagai et al., 2004).

24 FURTHER ADVANCEMENT OF GENOME TECHNOLOGIES

24.1 High-Throughput DNA Sequencing

The advancement of the next-generation sequencing (NGS) should also make the ENU mutant mouse library much more useful resource to model human diseases and for the functional genomics. The comprehensive identification of all the ENU-induced mutations in the worldwide ~40,000 G1 mouse library is very doable with comparable or even less cost and manpower compared to any large-scale Genome Projects so far conducted.

The NGS technology should also enhance the detection of causative mutations in the forward genetics. Conventional and NGS sequencing systems are summarized in Table 28.1.

Using these NGS systems, large-scale population sequencing studies in human has also been being conducted around the world (Genomes Project Consortium et al., 2010; Genomes Project Consortium et al., 2012) to primarily identify the responsible genes for Mendelian diseases (Rabbani et al., 2012; Tennessen et al., 2012) by the forward genetics.

24.2 Whole Exome Sequencing

Although the NGS has much higher throughput than ABI3730 sequencer (Table 28.1), mammalian genome including human has been too large to read entire genomic sequences. Considering only 1%–2% of human genome code proteins, various methods have been developed to focusing the sequencing on the coding regions, for example, the PCR amplification for targeted exons of interesting genes (Dahl et al., 2007; Porreca et al., 2007; Tewhey et al., 2009) and the enrichment by probe hybridization to capture targeted exons (Albert et al., 2007; Gnirke et al., 2009). In human, the methods to capture cancer or hereditary disorder-related genes have been also developed (Onoufriadis et al., 2014; Summerer et al., 2010). The whole exome sequencing (WES), by which all coding sequences were targeted, has also been developed for human, mouse, and other species (Choi et al., 2009; Hedges et al., 2009; Ng et al., 2009). The causative genes

TABLE 28.1 Example of Next-Generation Sequencing System

Sequencing system	Read length (fragment, bp)	Gigabase per run	Method
ABI 3730xl	900	0.00009	Fluorecence dye-terminator
Roche GS20	100	0.02	emPCR, pyrosequencing
Roche FLX	250	0.25	emPCR, pyrosequencing
IlluminaGAII	35	5	Bridge PCR, SBS chemistry
Illumina HiSeq2000	100	170	Bridge PCR, SBS chemistry
Illumina HiSeqX10	150	1,800	Bridge PCR, SBS chemistry
LifeTech SOLiD3	50	6	emPCR, sequence by oligo ligation
LifeTech IonProton	100	10	emPCR, hydorogen ion detection
PacBio RSII	10,000	1	Non-PCR, long single molecule sequencing

emPCR, Emulsion PCR; SBS, sequencing by synthesis.

for many Mendelian diseases and traits in human (Choi et al., 2009; Ng et al., 2009; Rabbani et al., 2012) as well as in the mouse (Andrews et al., 2012; Fairfield et al., 2011; Fairfield et al., 2015) have been identified by WES.

24.3 Whole Genome Sequencing

The further advancement of the NGS technologies have also made plausible to conduct whole genome sequencing (WGS) even in human. WGS has identified causative genes for several hereditary diseases and character of human. In addition to base substitutions and small indel, WGS has also efficiently detected structural variations, such as copy number variations, large indels, and translocations than WES (Alkan et al., 2011; Mills et al., 2011). The detection rate of the causative genes for Mendelian diseases in human by WES was ~50% (Beaulieu et al., 2014; Gilissen et al., 2012). It may have indicated that structural variations and/or noncoding mutations may, which are difficult to detect by WES, may be a significant fraction of the causative mutations. Similarly, the detection rate of Mendelian traits in the mouse was also reported to be 53% (Fairfield et al., 2015). Among such Mendelian mutant mouse strains, WGS succeeded in identifying causative mutations in four out of five strains in which WES could not identify (Fairfield et al., 2015).

PacBio RS II (Pacific Biosciences) has enabled ultralong one-molecule sequencing of more than 10-kb read path. The basecall precision of the PacBio system is somewhat lower than that of, for example, Illumina but effective in de novo assembly of microbial genomes (Eid et al., 2009; Fang et al., 2012) as well as the human genome (Chaisson et al., 2015; Pendleton et al., 2015). It may be also effective to de novo assemble and/or update reference genome sequences of any model organisms including various mouse strains.

24.4 High-Throughput Genotyping

Many SNPs have been registered in the genome of several inbred mouse strains as genetic markers for the mapping and the maintenance of strains (Petkov et al., 2004). For the genotyping of strain-specific SNPs, several high-throughput systems have also been developed by using NGS, for example, RAD-Seq and multiplexed shotgun genotyping (MSG) (Andolfatto et al., 2011; Davey et al., 2011; Etter et al., 2011) encompassing unknown SNPs or amplicon-sequencing (Campbell et al., 2015) for known SNPs. By using these methods, it is possible to genotype more than 100 markers from numbers of samples at once.

24.5 Additional NGS Applications

Not only for genotyping but also for molecular phenotyping is feasible with NGS technologies, for example,

RNA-seq, DNA methylation-seq and chromatin-immunoprecipitation (ChIP)-seq. RNA-seq determines whole transcripts comprehensively, which detects not only the expression level of the entire transcripts but also the alternative splicing products and/or chimeric transcripts (Ameur et al., 2010; Cloonan et al., 2008; Mortazavi et al., 2008). Therefore, RNA-seq provides big digital data with comprehensive coverage while the microarray gives analog data for only the known transcripts.

Whole-genome bisulfite sequencing (WGBS) is a popular method for DNA methylation sequencing using NGS (Cokus et al., 2008; Miura and Ito, 2015; Taylor et al., 2007). The bisulfite treatments in genomic DNA convert only nonmethylated cytosine residues into uracil residues while methylated cytosine intact. Therefore, cytosine residues in sequencing data from bisulfite treated DNA are a position of methylated cytosine residues in genome.

ChIP-seq uncovers the histone modifications or the binding sites of DNA-associated proteins on the genome (Barski et al., 2007; Blecher-Gonen et al., 2013; Johnson et al., 2007; Mikkelsen et al., 2007; Robertson et al., 2007). After the crosslinking DNA-binding proteins to DNA, target binding protein(s) are immunoprecipitated by the specific antibody. The recovered DNA is then subjected to NGS to reveal what kind of genomic sequences are enriched by the specific bindings.

24.6 Coming New Technologies

In addition to the PacBio one-molecule long sequencing, some other systems may become available for the forward genetics, as well as for the molecular phenotyping. Oxford Nanopore technology (Ashton et al., 2015; Sovic et al., 2016) gives rise to a median read length of more than 5,000 bp with a maximum length of over 60,000 bp. Both PacBio and Oxford Nanopore technologies exhibit a lower basecall precision of up to 85% accuracy; however, the error calls occur randomly so that 10–20 reading depth gives rise to accurate basecalls by these one-molecule long sequencing systems. Recently, another one-molecule long reading system, GemCode (10XGenomics) becomes available (Narasimhan et al., 2016; Zheng et al., 2016). This system allows constructing barcoded libraries for Illumina sequencing in a huge number of emulsion droplet each has only a few molecule of several hundred kilo base DNA fragments. As a consequence, it is possible to obtain N50 phase block length over 100 kb with the basecall precision of Illumina sequencing (Zheng et al., 2016).

25 GENOME EDITING TECHNOLOGIES

Genome-editing technologies have widely used to modify target genome sequences with high efficiency and specificity (Carroll, 2014; Kim and Kim, 2014; Maggio

and Goncalves, 2015) as a reverse genetic tool. These techniques enable us to directly introduce virtually any types of mutations, for example, small insertion/deletion (indel) mutations, base substitutions, large insertions/deletions, and chromosomal rearrangement, to any cells and whole organisms. Available genome editing systems include zinc-finger nucleases (ZFNs) (Carroll, 2011; Urnov et al., 2010) (Fig. 28.7A), transcription activator-like effector nucleases (TALENs) (Cermak et al., 2011; Joung and Sander, 2013) (Fig. 28.7B), and clustered regulatory interspaced short palindromic repeat (CRISPR)-associated Cas9 (Barrangou and Marraffini, 2014; Doudna and Charpentier, 2014; Hsu et al., 2014; Sander and Joung, 2014) (Fig. 28.7C).

All the three genome-editing vectors share the same two steps to modify the target genome sequence (Kim and Kim, 2014; Maggio and Goncalves, 2015). The first step is to deliver endonuclease to the target sequence to introduce a double-strand break (DSB) to the target site. The second step is the nonhomologous end joining (NHEJ) driven by cell autonomously. The NHEJ is error prone and often introduces a small insertion/deletion (indel) mutation to the DSB point (Jasin and Rothstein, 2013). Some "homologous" DNA may be codelivered with the

endonuclease to drive homology-directed repair (HDR) between the targeted DSB site and the homologous donor DNA at the second step (Jasin and Rothstein, 2013). By designing an insertion, deletion, point mutation, or chromosomal rearrangement in the homologous donor DNA fragment, the genome editing is also able to introduce the designed mutations to the target site. Thus, not only the knockout alleles but also any designed mutations may be created in cultured cells or animals.

25.1 Mechanism of CRISPR-Cas9 System

The CRISPR-Cas9 system is developed from a bacterial adaptive immune system against invading virus and plasmids and has been widely used since 2013 as a genome-editing tool (Barrangou and Marraffini, 2014; Doudna and Charpentier, 2014; Hsu et al., 2014; Sander and Joung, 2014). In natural type II CRISPR system, only the three components are required to introduce DSB at the target site; CRISPR RNAs (crRNAs), transactivating CRISPR RNA (tracrRNA), and Cas9 nuclease. crRNAs carry various sequences derived from invading DNA, which is known as "protospacer." crRNAs hybridizes with tracrRNA, and the hybrid generates a complex with the Cas9 nuclease.

In order to enhance the utility of CRISPR-Cas9 system as a genome-editing tool, crRNA and tracrRNA are fused to single-guide RNA (sgRNA) to simplify the components (Cong et al., 2013; Mali et al., 2013b). The expression of both sgRNA and Cas9 causes the DSB to the target genomic DNA site that is complementary to the guide sequence in the sgRNA (Fig. 28.7C).

The target sequence of the CRISPR-Cas9 system must locate immediately 5′ to a 5′-NGG-3′ sequences known as the protospacer adjacent motif (PAM), which is necessary to induce Cas9-directed DSBs (Jiang et al., 2013; Jinek et al., 2012). Cas9 specifically generates a blunt-ended DSB at 3 bp upstream to PAM through two nuclease domains, RuvC near the N-terminus and HNH at the middle part of Cas9 (Gasiunas et al., 2012; Jinek et al., 2012). HNH domain cleaves the complementary strand of the sgRNA, whereas RuvC domain cleaves the noncomplementary strand.

The CRISPR-Cas9 vector is simpler to design and conduct than the ZFN and TALEN vectors. sgRNA is produced either in vitro or in vivo. Plasmid encoding sgRNA is constructed by cloning of 20 bp guide sequences (Ran et al., 2013b). Double-stranded oligonucleotides may be used as a template to obtain sgRNA by in vitro transcription (Cho et al., 2013).

FIGURE 28.7 **A schematic representation of widely used genome editing systems.** (A) ZFNs consist of ZFPs at the N-terminal and the FokI nuclease domain at the C-terminal. Single ZFP contains typically three to six zinc fingers, each of which recognizes a 3-bp DNA sequence. Thus, DNA sequences of 18–36 bp are recognized by a pair of ZPNs. (B) TALENs contain TALEs at the N-terminal and the FokI nuclease domain at the C-terminal. Single TALE repeat consists of 33–35 amino acids and recognizes a single base pair of DNA. Individual TALEN is composed of typically up to 20 TALE repeats. Thus, a TALEN pair recognizes ~40 bp DNA sequences as a target sequence. (C) CRISPR-Cas9 system requires sgRNA and the Cas9 nuclease. The 20 bp target sequence needs to locate immediate upstream of the 5′-NGG-3′ sequences known as PAM *(blue)*. The expression of both sgRNA and Cas9 causes the DSB 3 bp upstream of PAM *(red arrow)*.

25.2 Efficiency and Specificity of CRISPR-Cas9 System

Among the three genome editing systems, the CRISPR-Cas9 has shown the high targeting rate enough to conduct multiplex simultaneous editing up to five

loci in mouse ES cells (Yang et al., 2013). In addition, the biallelic targeting rate was ~80% so that it is possible to directly obtain homozygous knockout cells without breeding (Wang et al., 2013). The high biallelic target efficiency may become a problem in some cases; for instance, live cells or animals may not be alive due to the homozygous lethality of the target gene.

Due to the efficiency and specificity of the CRISPR-Cas9 system, the genome editing may be anticipated to become a future tool for the gene therapy. Then, all the effects must be carefully examined including the off-target effects that genome sequence is modified at the sites other than desired site (Hendel et al., 2015; Peng et al., 2015). Cas9 target recognition is determined by Watson-Crick base-pairing interaction of an sgRNA, and off-target effect can be evaluated at potential Cas9 recognition sites that are similar to the guide sequence. Many studies indeed reported that substantial amount of off-target effect by CRISPR-Cas9 was observed in cultured cells (Fu et al., 2013; Hsu et al., 2013; Mali et al., 2013a; Pattanayak et al., 2013).

To minimize off-target effects, programmable Cas9 nickases that carry a mutation in one of the nuclease domains of either RuvC or HNH (Ran et al., 2013a; Shen et al., 2014) have been developed (Kim and Kim, 2014). Single strand break introduced by a Cas9 nickase is repaired through high-fidelity base excision repair pathway (Dianov and Hubscher, 2013). On the other hands, when Cas9 nickase very closely introduces a pair of nicks on the opposite strand, double strand break with 5′ or 3′ overhangs is created and is repaired by error-prone NHEJ. Double nicking strategy using two independent sgRNAs on the close position increases specificity without reducing on-target cleavage (Ran et al., 2013a; Shen et al., 2014). Thus, Cas9 nickase is expected to induce little off-target effects.

Even if the designed on-target editing is achieved, especially in the case for the design to construct knockout null alleles, any protein product from the manipulated allele may also be carefully examined, since exon skipping to produce a part of the target genes has sometimes observed (Uddin et al., 2015).

In general, the target site selection is another critical step for the successful genome editing. Designing of ZFNs, TALENs, and sgRNA requires various considerations in many criteria. The success rate and activity differ depending on the nuclease system, cell line/organism, target gene/sequence, and delivery method. Available programs to design ZFNs, TALENs, and sgRNA are summarized in review articles (Kim and Kim, 2014; Peng et al., 2015).

25.3 Additional Genome-Editing Applications

The targeting efficiency of CRISPR-Cas9 system is also applied for other uses (Hsu et al., 2014; Kim and Kim, 2014; Wang et al., 2016). For instance, nuclease deactivated Cas9 (dCas9) was fused to transcriptional repressor domain, for example, KRAB effector, and was used to inhibit transcription of the target gene, termed CRISPR interference (CRISPRi) (Gilbert et al., 2013). CRISPR activation (CRISPRa) was also reported, in which dCas9 was fused to transcriptional activator domain, such as VP16 /VP64 activation domains, and was used to activate transcription of particular endogenous genes (Gilbert et al., 2013; Mali et al., 2013a; Perez-Pinera et al., 2013). Site-specific epigenetic control by engineering of ZFNs (Keung et al., 2014; Rivenbark et al., 2012), TALENs (Konermann et al., 2013; Maeder et al., 2013; Mendenhall et al., 2013), and dCas9 (Hilton et al., 2015; Kearns et al., 2015; Thakore et al., 2015) was another example of the application.

To visualize genome organization and dynamics in live cells, programmable DNA binding modules are applied for the imaging of specific loci (Chen et al., 2016; Wang et al., 2016). Chen et al. (2013) visualized telomeres and coding genes in living human cells using EGFP tagged dCas9, showing that CRISPR imaging tool improves studies in the spatiotemporal organization and dynamics of native chromosomes. Multicolor genomic imaging was developed to determine relative distance of several loci in a living cell (Ma et al., 2015). dCas9 from three bacterial orthologs were fused to BFP, GFP, and RFP, and sgRNA cognate with each Cas9 ortholog was designed to target locus. Using three pairs of colored dCas9-sgRNA, relative distance of three loci can be determined.

26 CONCLUDING REMARKS

The knockout mouse resources and phenotyping by IKMC/IMPC now provide powerful tool to reveal the monogenic traits of most of coding sequence in the coisogenic mouse strains to C57BL/6N genetic background. The ENU mutant mouse libraries of ~40,000 G1 mice should shed light on the analyses of multigenic traits, since each G1 mouse carry thousands of base substitutions in a defined genetic background in any genomic sequences not only of coding sequences but also of noncoding sequences. Furthermore, by establishing a large-scale recombinant inbred strains between eight inbred mouse strains by Collaborative Cross (Churchill et al., 2004), the elucidation for the genetic interactions and gene networks should be systematically challenged. These three different phases of mutant mouse resources from monogenic to polygenic traits will orchestrated to the understanding of functional genomics modeling human diseases and complex traits with various environmental factors.

Experimental Febrile Seizures in Rodents

Ryuta Koyama

Graduate School of Pharmaceutical Sciences, The University of Tokyo, Tokyo, Japan

1 INTRODUCTION

The proper formation of neural circuits during early development is fundamental to brain function in adulthood. Thus, it is important to determine whether environmental factors affect neural circuit formation and characterize the mechanisms involved in this process. The results of studies on the association of febrile seizures with adult epilepsy provide insights into these underlying mechanisms. A link between complex febrile seizures and temporal lobe epilepsy has been suggested; however, the cellular and molecular mechanisms involved in this association remain unclear. The limitations of human studies on epilepsy, in which tissue samples are only available from adult patients in the advanced and drug-resistant stages of the disease, mask the underlying etiology. Thus, researchers have utilized well-established animal models of febrile seizures to examine the cellular and molecular mechanisms underlying the relationship between febrile seizures and the development of epilepsy. Here, accumulating evidence from studies that have utilized animal models to investigate the mechanisms underlying the causes and consequences of febrile seizures will be discussed. This chapter is based on a previous review article on animal models of febrile seizures from our laboratory (Koyama and Matsuki, 2010) and will include recent and more detailed information.

2 FEBRILE SEIZURES IN HUMANS AND THEIR RELATIONSHIP TO EPILEPSY

Febrile seizures associated with fevers typically greater than 38°C are the most common convulsive event in infancy and childhood. Febrile seizures usually occur between 3 months and 5 years of age, peaking at 16–18 months (Annegers et al., 1987; Hauser, 1994; Offringa et al., 1991; Vestergaard and Christensen, 2009). The worldwide incidence of febrile seizures is approximately 2%–5% of the population (Hauser, 1994; Nelson and Ellenberg, 1976, 1978; Verity et al., 1985; Verity and Golding, 1991; Vestergaard and Christensen, 2009); however, higher incidences of approximately 6%–9% in Japan (Bird, 1987; Tsuboi, 1984) and 14% in the Pacific islands (Stanhope et al., 1972) have been reported.

Febrile seizures can be classified as "simple" febrile seizures, which are generalized, isolated, brief single events that occur during febrile illness, or as "complex" febrile seizures, which are focal, multiple (more than one seizure per febrile illness), or prolonged. Approximately 60%–70% of febrile seizures are "simple," and 30%–40% are "complex" (Berg and Shinnar, 1996a; Nelson and Ellenberg, 1976). Simple febrile seizures are generalized tonic-clonic seizures without focal neurological features lasting less than 10 min (Annegers et al., 1987; Berg et al., 1997) or 15 min (Nelson and Ellenberg, 1978) without recurrence within 24 h. In most cases, simple febrile seizures are not followed by epilepsy or by the development of cognitive deficits (Annegers et al., 1987; Berg and Shinnar, 1996b; Verity et al., 1985, 1998). It was reported that only 2% of children with simple febrile seizures develop epilepsy (Annegers et al., 1987) and that these children's risk of developing epilepsy was not significantly different from that of the general population. Complex febrile seizures are prolonged, lasting longer than 10 min (Annegers et al., 1987, 1979, 1990; Berg et al., 1997) or 15 min (Berg and Shinnar, 1996a; Nelson and Ellenberg, 1976, 1978), and display focal neurological features and/or seizure recurrence within 24 h or within the same febrile illness. In a prospective cohort study of 428 children with first febrile seizures, 35% experienced complex febrile seizures (Berg and Shinnar, 1996a). Importantly, febrile status epilepticus, which is defined as the presence of febrile seizures lasting 30 min or longer, was observed in 5% of the children in the group (Berg and Shinnar, 1996a). Notably, febrile status epilepticus, which represents 5% of febrile seizures, accounts for approximately 25% of all episodes of childhood status epilepticus, and more than 60% of the status epilepticus cases occur during the second year of life (Berg and Shinnar, 1996a), as noted by Shinnar and Glauser (2002).

Whereas simple febrile seizures are typically not followed by epilepsy, it is debatable whether complex febrile seizures result in long-term sequelae (Annegers

et al., 1987; Berg and Shinnar, 1996a). Prospective epidemiological studies have generally failed to show a strong association between the occurrence of complex febrile seizures and the development of epilepsy (Berg and Shinnar, 1996b; Nelson and Ellenberg, 1976, 1978; Shinnar et al., 2001; Verity and Golding, 1991); however, according to a follow-up study that took place over more than 20 years (Annegers et al., 1987), the cumulative risk of unprovoked convulsions after complex febrile seizures increased to 49% (16%–93%). Furthermore, retrospective studies have reported an association between a history of complex febrile seizures and subsequent temporal lobe epilepsy in as many as 40% of adult patients (Cendes et al., 1993; French et al., 1993; Hamati-Haddad and Abou-Khalil, 1998; Theodore et al., 1999). In a study of 43 patients with temporal lobe epilepsy not controlled by optimal drug treatment, 15 patients (35%) had a history of complex febrile seizures (Cendes et al., 1993). In another study of 67 patients with temporal lobe epilepsy, at least 33 individuals (50%) for whom a detailed description of febrile seizure history was obtained had experienced complex febrile seizures (French et al., 1993). Importantly, patients with temporal lobe epilepsy with a history of complex febrile seizures exhibited more severe mesial temporal sclerosis than patients without a history of prolonged febrile seizures (Cendes et al., 1993). A smaller volume of the hippocampal formation was reported in patients with temporal lobe epilepsy (Cendes et al., 1993) and a history of complex febrile seizures in early childhood; a significant relationship between the volume of the hippocampus and epilepsy duration has also been shown (Theodore et al., 1999). A large-scale study of 1005 patients with epilepsy at a clinic in the United States revealed that temporal lobe epilepsy (78/310, 25%) is more likely to be preceded by febrile seizures than extratemporal epilepsy (12/216, 6%) (Hamati-Haddad and Abou-Khalil, 1998). In this study, 63 of the 78 patients with temporal lobe epilepsy had a history of complex febrile seizures. Febrile status epilepticus, in which febrile seizures last for 30 min or more, was observed in 5% of 428 children (Berg and Shinnar, 1996a).

In patients with mesial temporal lobe epilepsy, the hippocampus displays characteristic pathological changes, including dispersion of dentate granule cells (Houser, 1990; Thom et al., 2005), sprouting of hippocampal mossy fibers (Isokawa et al., 1993; Sutula et al., 1989), and hippocampal sclerosis, including selective neuronal loss and reactive gliosis in Ammon's horn (Fisher et al., 1998). Each of these features has been suggested to play a role in the initiation and propagation of epileptic activity in hippocampal neurons. The relationship between the development of these pathological changes and early life febrile seizures has been a topic of discussion. Evidence of hippocampal injury has been reported after febrile status epilepticus, particularly in

cases in which the febrile seizures lasted longer than 90 min (VanLandingham et al., 1998). More recently, a prospective multicenter study was performed by the FEBSTAT Study Team to further investigate the consequences of febrile status epilepticus (FEBSTAT study) in children between 1 month and 6 years of age (Hesdorffer et al., 2012; Lewis et al., 2014; Seinfeld et al., 2014; Shinnar et al., 2008). However, to directly dissect this relationship, cellular and molecular approaches are necessary, and these approaches cannot be adequately applied to respected and fixed human tissues.

The biological basis of febrile seizures also remains largely unclear. Although the existence of a genetic predisposition to febrile seizures has been widely suggested, both sporadic and familial cases of febrile seizures have been reported (Berg et al., 1999), indicating a considerable contribution of environmental factors to the induction of febrile seizures. Of these environmental factors, immature brain development (age specificity) and fever are indispensable contributing factors. However, the limitations of human studies have made it difficult to clarify the mechanisms involved.

To counteract these limitations, several animal models of febrile seizures have been developed through which the potential mechanisms underlying the generation and consequences of febrile seizures can be directly examined. The information obtained from these febrile seizure models has attracted the attention of clinicians and neurobiologists with a wide range of backgrounds.

3 ANIMAL MODELS OF FEBRILE SEIZURES (EXPERIMENTAL FEBRILE SEIZURES)

Several hyperthermia-induced rodent models of complex febrile seizures have been developed and used to study the mechanisms and consequences of febrile seizures (Koyama and Matsuki, 2010). These include the hair dryer model (Baram et al., 1997; Chen et al., 2001; Dube et al., 2000; Koyama et al., 2012; van Gassen et al., 2008), the heated chamber model (Holtzman et al., 1981; Schuchmann et al., 2006), the hot water model, which might also be categorized as a model for hotwater epilepsy (Jiang et al., 1999; Kim et al., 2001; Ullal et al., 1996), the microwave model (Hjeresen et al., 1983), and the lipopolysaccharide model (Heida et al., 2004).

This chapter will include a discussion of two of the most widely used models for the induction of febrile seizures in which the ambient temperature is elevated to elicit an increase in the body (rectal) temperature, the hair dryer model and the heated chamber model. Reports that refer to the hair dryer model in the methods section, as well as those that use other terms, such as "a regulated stream of moderately heated air" to describe

the heat delivery method are categorized as studies that utilized the hair dryer model and are discussed in this chapter.

3.1 Hair Dryer Model

Baram and coworkers originally developed and refined the hair dryer model (Bender et al., 2004; Dubé and Baram, 2006). We primarily use this model in our laboratory because of its relative ease of use, its low setup cost, and most importantly, the reproducibility and reliability of the behaviors observed during the process of febrile seizures induced using this method. Sprague-Dawley rats at postnatal day 10–11 (P10–11) or 129/Sv or C57BL mice at postnatal day 11–15 (P11–15) are typically used because the developmental stage of the hippocampal formation at these ages likely corresponds to that during human infancy and early childhood, when human individuals are most susceptible to febrile seizures (Avishai-Eliner et al., 2002). In addition, the threshold temperature required to evoke seizures is lowest at these ages (P10–13) in the rat (Hjeresen and Diaz, 1988) and is comparable to that observed for human complex febrile seizures (Berg et al., 1992). Considering the development of this animal model, it is also important to note that the behavioral seizures induced in rats and mice at these ages are highly reproducible (Dubé and Baram, 2006; our own observations in our laboratory). Although gender is not reported in all studies, a single sex is used in most cases. Notably, no significant gender difference in average seizure duration has been reported in this model (males, 7.86 ± 0.81 min; females, 10 ± 1.54 min) (Lemmens et al., 2005).

The description of the protocol for the hair dryer model in rats is primarily based on the procedures used in our laboratory, which have been slightly modified from the established protocol (Bender et al., 2004; Dubé and Baram, 2006). The animals are placed in individual glass jars and heated with a commercial hair dryer. A hair dryer is placed 30–50 cm above the rats, and an adjustable stream of heated air (40–45°C recorded at 2 cm above the bottom of the cylinder) is directed into the cylinder (Fig. 29.1A). The glass cylinder should be carefully selected to maintain ambient temperature. We use 20-cm-high, 10-cm-diameter glass cylinders with approximately 0.5-cm-thick walls. We also place a piece of filter paper on the bottom of the glass cylinder so that the animals are not directly heated by the glass. It is important to preheat and maintain the ambient temperature in the glass jar between 40–45°C prior to the induction of seizures. The position of the hair dryer should be adjusted depending on the height and diameter of the glass cylinder. The animal's rectal temperature is recorded digitally every 2 min starting 10 min prior to treatment and during hyperthermia treatment using a digital rectal
FIGURE 29.1   **Basic setups for the experimental induction of febrile seizures in rodents using a hair dryer.** (A) or an infrared lamp, (B). In our laboratory, a BAT12 microprobe thermometer (Physitemp Instruments, Inc., Clifton, NJ, USA) equipped with a RET4 rectal probe (Physitemp) is used to measure the rectal temperatures of neonatal rodents. To measure and maintain the temperature of the air within a glass jar, a TCAT-2DF temperature controller (Physitemp) is used. The lamp (HL-1, Physitemp) consists of a 250-W (infrared) heat lamp bulb and a reflector.

probe. Alternatively, the temperature can be recorded every 3 min if the maintenance of rectal temperature is difficult. When the core temperature reaches 39.5°C, which typically occurs after 8–12 min, the temperature and volume of the air are adjusted to maintain the animal's core temperature at 39.5–42.5°C for 30 min to induce prolonged experimental febrile seizures that typically last for approximately 24 min in total. Correlation of core temperature with brain temperature at the onset of hyperthermic seizures (core temperature, 40.7 ± 0.2°C; brain temperature 40.88 ± 0.3°C) suggests that measurements of core temperature provide an adequate approximation of brain threshold temperatures for experimental febrile seizures (Dube et al., 2005a). Urination is occasionally observed, particularly during the early stages of the hyperthermia process. Urine should be immediately wiped from the bottom of the cylinder if a piece of filter paper has not been placed on the floor of the jar. If the core temperature exceeds 42.5°C, the animal is removed from the cylinder and transferred to a cool metal surface until its core temperature decreases to 39.5–42.5°C. Immediately following the 30-min hyperthermia treatment, the animals are cooled on a cool metal surface to room temperature and subsequently returned to their mothers. In some studies, the rat pups were injected with saline to prevent dehydration during the hyperthermia procedure (Lemmens et al., 2008, 2005). We observed that the injection of saline prior to the hyperthermia process assists in the animals' recovery from hyperthermia, particularly in the case of mice (unpublished data). Oral hydration (approximately 0.1 mL water) following hyperthermia has also been reported (Dubé and Baram, 2006). If the recovery process is not properly conducted, the dams often do not take care of their pups (including a lack of lactation) and may even kill the pups.

Both normothermic controls and hyperthermic controls are included in the procedure. For the normothermic control group, rats are exposed to the same conditions as the hyperthermic group, but a stream of air is used to maintain normal core temperature (Lemmens et al., 2008).

Although it has been suggested that fever per se does not cause febrile seizures because antipyretics do not reduce the risk of febrile seizures (Bethune et al., 1993; Camfield et al., 1980), it is always important to examine the direct effects of fever on the cellular, molecular, and behavioral changes that occur after experimental febrile seizures. For this purpose, hyperthermic controls are generated via the intraperitoneal injection of a short-acting barbiturate (pentobarbital) prior to the induction of hyperthermia (Brewster et al., 2002; Dube et al., 2000, 2006) to distinguish whether the observed experimental febrile seizures are a consequence of the hyperthermia.

The onset of experimental typical febrile seizures of limbic origin typically consists of an acute sudden arrest of hyperthermia-induced hyperactivity, such as running followed by oral automatism (biting and chewing). Electroencephalographic (EEG) recordings from the basal amygdala, dorsal hippocampus, and frontoparietal cortex of freely moving rat and mouse pups suggest that the onset of hippocampal and amygdaloid EEG spike waves and trains coincides with behavioral arrest and oral automatism and precedes events recorded in the cortex (Baram et al., 1992, 1997; Brewster et al., 2002; Dube et al., 2000). Forelimb clonic movements typically follow oral automatism. Later during the seizure, tonic body flexion is frequently observed in rats, but this occurs only sometimes in mice. Strain-dependent differences in susceptibility to warm air stream-induced experimental febrile seizures have been reported in mice (van Gassen et al., 2008) but not in rats. Using a similar experimental febrile seizure induction model in mice in which a temperature-regulated laminar stream of warm air (41–48°C) is used, Jongbloets et al. (2015) reported short- and longer-term gene expression profiles after experimental febrile seizures.

In the hair dryer model, the duration of febrile seizures can be controlled. A recent study utilized this characteristic to induce febrile status epilepticus-like seizures in rat pups by increasing the duration of hyperthermia (body temperature of 39.5–41°C) to 70 min (Dube et al., 2010).

It remains unclear whether the duration of seizures is related to the development of epilepsy. Thus, a comparison of this model with the typical hair dryer model in which hyperthermia duration of 30 min is used would provide information that would contribute to our understanding of how seizure duration in febrile seizures might serve as a biomarker for the future development of epilepsy.

3.2 Heated Chamber Model

Holtzman et al. (1981) developed another reliable seizure model, the heated chamber model; a modification of this model has been used in several studies (Schuchmann et al., 2006, 2009). In the original study (Holtzman et al., 1981), Sprague-Dawley rat pups (P2–10) were placed on the paper towel-covered floor of a Lucite chamber. The body temperature of the rat pups was elevated using a 250-W infrared lamp mounted 10 cm above the chamber. In this study, the seizure threshold temperature, that is, the rectal temperature, at the onset of seizure activity was approximately 37°C at P2, 40–41°C at P5, and 43°C at P7 and P10. The age-dependent increase in rectal temperature at the seizure threshold was correlated with an increase in brain temperature. It was reported that all P2 animals immediately resumed normal nursing behavior when the temperature was reduced and that all the P5–7 animals survived and behaved normally after the procedure, whereas only half of the P10 animals survived. The onset of generalized seizure activity in P5–10 animals at a body temperature of 40–41°C was manifested by loss of upright posture, tonic extension of the trunk, and rapid synchronous clonic movements of the extremities and mouth, followed by limp and unreactive behavior for 2–3 min. It was also shown that animals older than P10 did not experience seizures until the body temperature reached 44–45°C; none of these animals survived after the procedure. Simultaneous recordings of rectal temperature and EEG have confirmed that hyperthermia induces electrocortical paroxysmal discharges in P6 and P10 rats. In our laboratory, we also used a heated chamber model with an infrared lamp placed 25–30 cm above mice (Fig. 29.1B). We found that clonic seizures can be induced in C57BL mouse pups between P10–14.

Schuchmann et al. (2006, 2008, 2009) utilized a modified heated chamber model in P8–11 Wistar rat pups. The animals were placed in a chamber at an ambient temperature of 48 ± 0.3°C (Schuchmann et al., 2006). The latency to onset of hyperthermia-induced seizures was 31.2 ± 3.7 min, and the duration of the seizures was 24.6 ± 1.7 min. Behavioral seizures began with a sudden interruption of movement, followed by oral automatism. The behavioral arrest was followed by clonic movements of the limbs and head, chewing of extremities and tonic flexion of the body, often associated with a loss of postural control.

Compared with the hair dryer model, the increase in body temperature is much slower, and the latency to the onset of hyperthermia-induced seizures is longer in the heated chamber model. However, Schuchmann et al. (2009) proposed that the rate of fever increase does not affect the likelihood of the occurrence of human febrile seizures (Berg, 1993). These authors also suggested that the possible effects of pain and inflammation are reduced in the heated chamber model, whereas in the hair dryer model, in which heat transfer is heavily dependent on convection and the increase in body temperature is rapid, activation of thermal nociceptors, as well as inflammatory responses occur, as demonstrated by examination of the ears and paws of the animals (Schuchmann et al., 2009). From our own experience with the hair dryer model, we have observed that mounting the hair dryer 50–60 cm above the animals (instead of approximately 30 cm above the animals as described in some protocols) can reduce the inflammatory responses in the ears and paws. It should be noted that the body temperature of the animals should be raised by the use of heated air in a glass cylinder but not directly by the use of heating instruments.

4 OTHER ANIMAL MODELS OF EARLY LIFE SEIZURES

Depending on their experimental purposes, researchers have also used other animal models of febrile seizure. Several examples of animal models for early life seizures will be discussed, and interested readers are encouraged to refer to the articles cited herein. The models are as follows: hypoxia-induced seizures induced using low inhaled oxygen concentrations (Jensen et al., 1991, 1992; Owens et al., 1997), recurrent generalized tonic-clonic seizures induced by flurothyl inhalation (Holmes et al., 1998; Huang et al., 1999; Sogawa et al., 2001), absent and generalized tonic-clonic seizures induced by pentylenetetrazol injection (Holmes et al., 1999; Huang et al., 2002a, b), status epilepticus induced by the injection of kainic acid (Santos et al., 2000; Sarkisian et al., 1997; Stafstrom et al., 1992) or pilocarpine (Cilio et al., 2003; Hirsch et al., 1992), and recurrent generalized tonic-clonic seizures induced by electroshock (Dwyer and Wasterlain, 1982; Jorgensen et al., 1980).

5 MECHANISMS UNDERLYING HYPERTHERMIA-INDUCED EXPERIMENTAL FEBRILE SEIZURES

5.1 Interleukin-1β (IL-1β)

Animal models of febrile seizures have revealed that several molecules are associated with fever and seizures.

Among these, the role of IL-1β, a proinflammatory cytokine, has been well documented using animal models of febrile seizures. Although it is still controversial whether IL-1β levels are increased in the brains of individuals with febrile seizures (Haspolat et al., 2002; Lahat et al., 1997), inflammation has been associated with epileptogenesis, and the involvement of inflammatory mediators in febrile seizures has also been proposed. In the hair dryer model, the threshold temperature for the generation of experimental febrile seizures was significantly higher in transgenic mice deficient in the type I receptor for IL-1β (IL-1R1$^{-/-}$ mice; 42.4 ± 0.3°C) than in wild-type 129/Sv (41.3 ± 0.2°C) and C57BL mice (39.7 ± 0.2°C) (Dube et al., 2005b). The seizure threshold of wild-type 129/Sv mice, but not that of IL-1R1$^{-/-}$ mice, decreased after intracerebroventricular (i.c.v.) infusion of IL-1β (5 ng). Furthermore, the infusion of a high dose of IL-1β (116 ng) resulted in limbic behavioral seizures that were confirmed by simultaneous hippocampal EEG recordings that showed prolonged spike trains in normothermic wild-type 129/Sv mice but not in IL-1R1$^{-/-}$ mice. These data suggest that activation of IL-1R by endogenous IL-1β underlies the fever-induced neuronal hyperexcitability that leads to the generation of experimental febrile seizures; however, it remains unclear whether seizures induce IL-1β expression and, if so, whether IL-1β contributes to the epileptogenic process that occurs after febrile seizures. The same group addressed this question using the hair dryer model with longer seizure duration (febrile status epilepticus-like seizures) (Dube et al., 2010). In that study, western blot analyses of hippocampal homogenates harvested 24, 48, and 72 h after 64-min-long febrile seizures revealed that IL-1β levels in the experimental group were significantly increased compared to the levels in control animals at 24 h and that IL-1β expression gradually returned to control levels at 48–72 h. The authors further determined that the IL-1β-secreting cells were reactive astrocytes in the hippocampus that express glial fibrillary acidic protein (GFAP). They also observed that these astrocytes were more abundant at 6 and 24 h after seizures in animals with febrile seizures than in controls. In the same study, OX-42-expressing reactive microglias were more commonly observed in the hippocampi of rats with febrile seizures compared with controls. The activation state of these microglias in rats with febrile seizures is unclear, although their morphology (they possess moderate hypertrophic processes) suggests that they are slightly more active than microglias in control rats.

5.2 Respiratory Alkalosis

Using a heated chamber model, Schuchmann et al. (2006) examined whether a hyperthermia-induced increase in the rate of breathing, which is observed in young children (O'Dempsey et al., 1993; Gadomski et al., 1994; Taylor et al., 1995), plays a role in inducing febrile seizures. These authors demonstrated that hyperthermia-induced respiratory alkalosis precipitates experimental febrile seizures. In P8–11 rats, behavioral seizures occurred approximately 30–40 min after the induction of hyperthermia, a time when breathing frequency had increased from a control level of 163 ± 14 breaths/min to an elevated level of 254 ± 44 breaths/min. The hyperthermia-induced increase in the breathing rate was also reproduced in the hair dryer model; there, the animals showed a slightly higher breathing rate at the onset of seizures than in the heated chamber model (Schuchmann et al., 2008). The thermal tachypnea observed in the heated chamber closely paralleled the observed increase in intracortical pH, which increased by a maximum of 0.27 ± 0.04 units from its control level of 7.22 ± 0.096. An increase in cortical pH of 0.29 ± 0.05 units was elicited through intraperitoneal (i.p.) injection of bicarbonate; this also caused seizures with behavioral characteristics resembling those induced by hyperthermia, suggesting that hyperthermia-induced brain alkalosis triggers experimental febrile seizures. Importantly, it has been shown that hippocampal and cortical electrographic ictal activity and the associated behavioral activity are blocked in rats exposed to 5% CO_2. Electrographic ictal activity was abolished within approximately 15–25 s without affecting the body temperature during hyperthermia. Thus, the administration of CO_2-enriched air could be a novel therapeutic strategy for the treatment of febrile seizures (Schuchmann et al., 2009).

5.3 Findings From In Vitro Analyses

In vitro studies were conducted to directly examine the effects of hyperthermia on neuronal excitability. In hippocampal slices from P2–38 rats, the effect of temperature elevation on stimulation-evoked extracellular field potentials in the CA1 region was investigated. When the temperature of the recording chamber was elevated from the control level of 35–36°C to > 38°C, an increase in the amplitude and duration of the field response was observed; this increase persisted for more than 15 min, even after the temperature was returned to the control level (Tancredi et al., 1992). In addition, the temperature elevation induced epileptiform activity such as spontaneous multiple population spikes and long-lasting ictal-like discharges in neurons. These effects were most frequently observed in slices from P13–20 rats and were not observed in slices from <P4 or >P28 rats, suggesting that age-dependent factors are responsible for the differential neuronal responses to hyperthermia observed in these rats. Age dependency of hyperthermia-induced hippocampal excitability was also observed in electrophysiological studies in vivo in which hyperthermia induced

using a heating pad resulted in a decrease of paired-pulse inhibition in CA1 that was more prominent in P15–17 rat pups than in adult rats (Liebregts et al., 2002). Applying functional multineuron calcium imaging (fMCI) techniques, Ishikawa et al. (2015) found that the epileptic activity of CA3 neurons during heating to 40.5°C was suppressed by the non-NMDA receptor antagonist CNQX in slice cultures prepared from P7 rat pups.

The involvement of $GABA_A$ receptor-governed gamma oscillations in temperature elevation-induced population spikes has been demonstrated using P17–29 rat slices (Wu et al., 2001). Hyperthermia-induced attenuation of inhibitory neurotransmission in CA1 pyramidal neurons in P11–17 rat brain slices has been reported. Specifically, both reduction of GABA release from presynaptic terminals and decreased postsynaptic function of $GABA_A$ receptors have been suggested as potential mechanisms (Qu and Leung, 2008; Qu et al., 2007). Reduced GABAergic transmission could rapidly contribute to hippocampal hyperexcitability after hyperthermia. However, it should be noted that at 2–6 h after ultrared-light-induced experimental febrile seizures in P16 rats, GABA content was significantly increased in several regions of the brain, including the hippocampus, and it returned to control levels within 24 h after the onset of the seizures (Nagaki et al., 1996).

6 NEUROANATOMICAL CHANGES AFTER EXPERIMENTAL FEBRILE SEIZURES

Conclusions concerning the causal relationship between childhood febrile seizures and subsequent hippocampal atrophy or sclerosis in temporal lobe epilepsy patients have been controversial. Several retrospective studies have reported relationships between a history of febrile seizures and increased incidence of sclerosis (Falconer, 1974; Falconer et al., 1964; Sagar and Oxbury, 1987) or reductions in hippocampal and amygdala volume (Cendes et al., 1993), whereas prospective studies, including recent magnetic resonance imaging (MRI) studies, have failed to confirm these observations (Berg and Shinnar, 1991; Shinnar, 1998; Tarkka et al., 2003). These inconsistencies may partially result from the fact that human studies inevitably involve diversity in the frequency of seizures (both febrile and afebrile), in the history of medication in retrospective studies, and in the length of the follow-up period in prospective studies.

Many of the difficulties associated with human studies can be controlled using experimental models of febrile seizures. These models have yielded reliable evidence regarding cell loss, neurogenesis, and alterations in dendritic and axonal morphogenesis that occur after experimental febrile seizures.

6.1 Cell Loss

Cell loss in the hippocampus is one of the structural hallmarks of patients with mesial temporal lobe epilepsy, but it is unclear whether febrile seizures cause the cell loss. No significant loss of pyramidal cells in the CA1 or CA3 regions, GluR2/3-immunoreactive mossy cells in the hilus, or GAD67 mRNA-positive interneurons in these regions was observed in histological studies at 3 months after induction of experimental febrile seizures in the hair dryer model, indicating that febrile seizures do not induce delayed, chronic hippocampal cell loss (Bender et al., 2003). Importantly, significant neuronal loss was not observed in adult rats that became epileptic after experimental febrile seizures induced using the hair dryer model (Dube et al., 2006), indicating that cell loss is not necessary for the development of epilepsy after febrile seizures. However, another study reported a reduced density of parvalbumin-immunopositive interneurons in the hilus at 5, 7, and 11 weeks after mercury-vapor-lamp-induced experimental febrile seizures at P11 (Kwak et al., 2008).

6.2 Neurogenesis

To examine the effects of experimental febrile seizures on granule cell neurogenesis, Bender et al. (2003) injected a single dose of the S-phase marker 5-bromo-2′-deoxyuridine (BrdU) into rat pups at 3, 7, or 28 days after experimental febrile seizures (hair dryer model, P10–11) and perfused the pups 48 h later. The number of BrdU-positive nuclei in the granule cell layer was not significantly different from that in control animals (Bender et al., 2003). However, Lemmens et al. (2005) reported that in the dentate gyrus of male (but not female) P66 animals with experimental febrile seizures (hair dryer model, P10) in which BrdU was injected twice daily from P11–16, 25% more BrdU-positive cells existed than in age-matched normothermic controls. The authors reported that gender also affected the survival of newborn cells in the dentate gyrus; the survival of BrdU-positive cells at P66 (percentage of P17) was significantly higher in female rats (control: 44% vs. experimental febrile seizures: 53%, $P < 0.05$) than in male rats (control: 20% vs. experimental febrile seizures: 23%, not significant). The factors that regulate the effects of gender on these phenomena remain unknown.

A recent study reported that experimental febrile seizures (hair dryer model, P10) decreased the percentage of cells born at P11–16 that survive and differentiate into excitatory amino acid transporter 3-positive neurons in the granule cell layer at P66 from the control level of 23%–14% ($P < 0.01$). Since the amino acid transporter eliminates glutamate from the synaptic cleft, these results suggest that experimental febrile seizures influence

the excitability of the regional network (Lemmens et al., 2008).

Altogether, the results described above suggest that experimental febrile seizures affect the survival (with gender differences) and differentiation, but not the proliferation, of newborn cells in the dentate gyrus. More specific markers for granule cells, such as prospero-related homeobox 1 (Prox1), should be used to further determine whether these "newborn" cells are indeed dentate granule cells (Koyama et al., 2012).

6.3 Ectopic Granule Cells

Both human and animal studies have indicated that febrile seizures do not result in severe loss of primary neurons in Ammon's horn or the dentate gyrus; however, it remains largely unknown whether the surviving dentate granule cells possess normal morphological, anatomical, and functional properties. Considering that the dentate gyrus prevents cortex-derived epileptiform discharges from invading the hippocampus, it is important to investigate whether the properties of the dentate gyrus are modulated by early life febrile seizures. Thus, utilizing several techniques, including time-lapse imaging of cultured neurons prepared from rats subjected to experimental febrile seizures (hair dryer model, P11), we examined whether such seizures induce hilar ectopic granule cells that persist into adulthood (Koyama et al., 2012). Ectopic granule cells of this type create abnormal neural circuits in the hippocampus that induce synchronous epileptiform bursting in other hippocampal neurons (Scharfman et al., 2007). As we have previously demonstrated, an overwhelming majority of the dentate granule cells in the adult rat brain are generated during the 2 weeks after birth and migrate toward the granule cell layer (Muramatsu et al., 2007). Therefore, we hypothesized that induction of experimental febrile seizures during this period would disturb this developmental process and result in the emergence of ectopic granule cells. This hypothesis is supported by evidence from our previous study showing that granule cells born at P0–2 become ectopic granule cells at 6 months if the animals are subjected to pilocarpine-induced status epilepticus at P14 (Muramatsu et al., 2008). We found that experimental febrile seizures induced at P11 using the hair dryer model increased the surface expression of GABA$_A$ receptors on migrating granule cells during development, resulting in increased excitatory GABAergic input to these cells (Koyama et al., 2012). The enhanced excitatory GABAergic signaling caused a reversal in the direction of newborn granule cell migration via calcium influx, resulting in an ectopic localization of these cells that persisted into adulthood. Furthermore, there was a significant correlation between the number of ectopic granule cells and the occurrence of limbic seizures in

adulthood. Importantly, these phenomena were blocked by inhibition of the Na$^+$K$^+$2Cl$^-$ cotransporter (NKCC1), which regulates the excitatory action of GABA. Furthermore, inhibition of NKCC1 by the diuretic bumetanide after febrile seizures prevented granule cell ectopia, susceptibility to limbic seizures, and the development of epilepsy. Thus, this work identifies a novel pathogenic role of excitatory GABA$_A$ receptor signaling and highlights NKCC1 as a potential therapeutic target for preventing granule cell ectopia and the development of epilepsy after febrile seizures.

6.4 Dendritic Morphogenesis

Silver staining revealed that experimental febrile seizures (hair dryer model, P10) resulted in a number of neurons with shrunken dendrites in the central nucleus of the amygdala and in the hippocampal CA1 and CA3 pyramidal cell layers within 24 h. These "injured" neurons survived for at least two weeks (Toth et al., 1998). These alterations were not followed by significant DNA fragmentation, and no significant neuronal cell loss was observed in these regions 4 weeks after seizure induction. The presence of surviving neurons with malformed dendrites could potentially disrupt the balance between excitatory and inhibitory inputs to these neurons, resulting in hyperexcitability of the focal networks. However, in another study, biocytin-mediated tracing after whole-cell recording at 1 week following experimental febrile seizures (hair dryer model, P10) did not reveal any differences in the dendritic arborization of CA1 pyramidal cells in animals subjected to experimental febrile seizures (Chen et al., 2001). Interestingly, it has been reported that the dentate granule cells born 1 day after induction of experimental febrile seizures by a regulated heated air stream at P10 had dendrites that were 66% longer than those of the corresponding cells in normothermic controls (Raijmakers et al., 2016). The authors also found an increase in the number of mushroom-type spines 8 weeks after experimental febrile seizures. These data indicate that the timing of febrile seizures with respect to neuronal differentiation affects whether febrile seizures induce changes in dendritic and spine morphologies.

6.5 Axonal Morphogenesis (Mossy Fiber Sprouting)

The contribution of experimental febrile seizures to the sprouting of hippocampal mossy fibers has also been examined. Mossy fiber sprouting is an important pathology that is frequently observed in the hippocampi of individuals with temporal lobe epilepsy, and a relationship of this sprouting to the hyperexcitability of the dentate gyrus has been suggested (Koyama

and Ikegaya, 2004). Significantly increased numbers of Timm-positive puncta, which represent the zinc-containing presynaptic terminals of mossy fibers, were observed in the granule cell and molecular layers of the hippocampus in 3-month-old rats subjected to experimental febrile seizures at P10–11 (hair dryer model) (Bender et al., 2003). Increased hippocampal activity was detected in these experimental animals, although its relationship to mossy fiber sprouting is unclear. Bundled dense sprouting in the molecular layer has also been observed at 11 weeks after mercury-vapor lamp-induced experimental febrile seizures at P11 (heated chamber model) that were later followed by spontaneous recurrent seizures (Kwak et al., 2008). Although the cellular mechanisms underlying experimental febrile seizure-induced sprouting remain unknown, brain-derived neurotrophic factor (BDNF), which is sufficient and necessary to induce sprouting in vitro (Koyama et al., 2004), is a strong candidate because BDNF mRNA has been shown to increase after hot-water-induced febrile seizures at P21 (Kim et al., 2001). BDNF has also been shown to mediate a febrile seizure (P11 and P14 mice, hair dryer model)-induced increase in the density of mossy fiber synapses in CA3 (Tao et al., 2016).

7 NEUROPHYSIOLOGICAL CHANGES AFTER EXPERIMENTAL FEBRILE SEIZURES

Long-lasting modulation of neuronal network functions after induction of experimental febrile seizures using the hair dryer model has been reported. At 1 week after the induction of experimental febrile seizures at P10, whole-cell patch clamp recordings from CA1 pyramidal cells in brain slices revealed that the amplitude of evoked inhibitory postsynaptic currents (IPSCs) was significantly increased compared with controls (Chen et al., 2001). The authors further showed that the frequency of miniature IPSCs (mIPSCs) in experimental febrile seizure-induced rats was nearly doubled and that there was no change in mIPSC amplitude or kinetics, indicating that the observed potentiation of inhibitory transmission had a presynaptic locus. Finally, it was pharmacologically shown that activation of protein kinase A (PKA) underlies the potentiation of the inhibitory responses.

Altogether, these results suggest that long-lasting potentiation of inhibitory transmission decreases susceptibility to seizures. However, increased inhibition has been associated with a persistent decrease in the seizure threshold after experimental febrile seizures (hair dryer model); one example is the observed reduction in seizure threshold in response to chemical convulsants in vivo and electrical stimulation in vitro (Dube et al., 2000).

As a mechanism underlying this paradox, the contribution of the "molecular inhibition excitation converter" has been clearly demonstrated (Chen et al., 2001). The hyperpolarization-activated depolarizing current I_h generated by hyperpolarization-activated cyclic nucleotide-gated (HCN) channels acts as a converter. In CA1 pyramidal cells in brain slices, the membrane potential for the half-maximal activation (V_{50}) of I_h was significantly shifted in the depolarizing direction by 3.3 and 5.9 mV at 1 and 9 weeks, respectively, after induction of experimental febrile seizures at P10 using the hair dryer model. A significantly larger I_h in cells from rats subjected to experimental febrile seizures compared with those from control rats has also been shown. Importantly, in pyramidal cells of rats subjected to experimental febrile seizures, a short train of inhibitory postsynaptic potentials (IPSPs; 6 IPSPs at 50 Hz) resembling those that occur spontaneously during the θ rhythm in vivo, but not single IPSPs, were shown to trigger postinhibitory rebound depolarization and firing. This phenomenon was inhibited by application of the selective HCN blocker ZD-7288. Using both whole-cell dendritic recordings and computer models of CA1 pyramidal cells, Dyhrfjeld-Johnsen et al. (2008) further confirmed the upregulation of dendritic I_h in rats with experimental febrile seizures and showed that it leads to persistent dendritic hyperexcitability as a consequence of increased I_h-induced depolarization of the resting membrane potential. Thus, it is likely that a combination of the potentiation of inhibitory input and frequency-dependent modified I_h-mediated events generates persistent hyperexcitable foci in the hippocampus following febrile seizures.

Another solution to the above paradox is suggested by the demonstration of persistent potentiation of the depolarization-induced suppression of inhibition (DSI) in CA1 pyramidal cells 1–5 weeks after the induction of experimental febrile seizures at P10 (hair dryer model) (Chen et al., 2003). In this study, depolarization of CA1 pyramidal cells resulted in a transient depression of spontaneous IPSCs (sIPSCs), or DSI; in slices from rats that had experienced experimental febrile seizures, this DSI was significantly increased both in magnitude and in duration. In both control and experimental febrile seizure slices, DSI was abolished in the presence of SR141716A, a cannabinoid type 1 (CB1) receptor antagonist, indicating the involvement of endocannabinoid signaling. Further pharmacological manipulation of the evoked IPSCs (eIPSCs) suggested the activation of presynaptic CB1 receptors by the retrograde release of endocannabinoids from pyramidal cells. Potentiation of endocannabinoid-mediated retrograde signaling after experimental febrile seizures was demonstrated using several qualitative and quantitative methods that showed an increased number of CB1 receptors in the presynaptic terminals of cholecystokinin (CCK)-positive interneurons without any

significant change in the concentration of endocannabinoids in the hippocampi of animals that had undergone experimental febrile seizures.

Thereafter, the same group succeeded in preventing both the potentiation of DSI and the increase in CB1 receptor number by i.p. injection of SR141716A 1 h prior to experimental febrile seizure induction (P10, hair dryer model) (Chen et al., 2007). By blocking CB1 receptors in vivo, the authors further prevented experimental febrile seizure-induced long-lasting hippocampal excitability in vitro and in vivo as follows: both the electrical-stimulation-induced, self-sustaining population activity of neurons in vitro (1 week after experimental febrile seizures) and the decreased seizure threshold in response to the injection of kainate in vivo (6 weeks after experimental febrile seizures) were blocked.

Notably, dentate granule cells, which do not normally show DSI in control rats, exhibited DSI via CB1 receptor activation after the induction of experimental febrile seizures (Chen et al., 2003). The dentate gyrus has been implicated as a highly resistant gate that blocks the transmission of epileptiform activity from the entorhinal cortex to the hippocampus (Heinemann et al., 1992; Hsu, 2007; Lothman et al., 1992) via the static characteristics of the dentate granule cells, including strong tonic, and phasic GABA inhibition by surrounding inhibitory interneurons (Nadler, 2003). Thus, it is possible that dentate DSI, in combination with the mossy fiber sprouting that occurs following experimental febrile seizures, induces the malfunction of this gate, leading to hyperexcitability of the hippocampus. This idea is supported by EEG recordings that show synchronized spiking and long-lasting abnormal discharges in the dentate gyrus 11 weeks after mercury vapor lamp-induced experimental febrile seizures at P11 (Kwak et al., 2008).

8 NEURONAL HYPERACTIVITY AFTER EXPERIMENTAL FEBRILE SEIZURES

Long-term hyperexcitability of the hippocampal network following the induction of experimental febrile seizures using the hair dryer model has been confirmed in both in vitro and in vivo experiments (Dube et al., 2000). In adult rats subjected to induce experimental febrile seizures, the administration of a low dose of kainate (5 mg/kg, i.p.) 10–11 weeks after the experimental febrile seizures induced hippocampal EEG seizures and associated behavioral seizures, most of which (8 of 11 rats) progressed to status epilepticus. In contrast, only 25% (2 of 8) of normothermic controls and 16.6% (1 of 6) of hyperthermic controls exhibited EEG or behavioral seizures, and none of the control animals developed status epilepticus. These in vivo data were further supported by in vitro electrophysiological experiments. In hippocampal-entorhinal cortical slices prepared 1 week after the induction of experimental febrile seizures, recurrent, spontaneous, self-sustaining field discharges of progressively increasing amplitude and frequency were recorded in the CA1 pyramidal cell layer in response to the stimulation of Schaffer collaterals. These phenomena were not observed in slices from control animals. These results indicate that induction of experimental febrile seizures in early life reduces the seizure threshold to convulsant challenge in adulthood.

In addition, chronic video monitoring of spontaneous behavioral seizures and measurement of concurrent hippocampal and cortical EEGs revealed the development of limbic epilepsy in a significant proportion of rats approximately 3 months after the occurrence of experimental febrile seizures (hair dryer model) (Dube et al., 2006).

9 BEHAVIORAL CHANGES AFTER EXPERIMENTAL FEBRILE SEIZURES

Epidemiologic studies of the outcome of febrile seizures in humans have reported no association between early life febrile seizures and global cognitive dysfunction in later life. A febrile seizure cohort in the United States demonstrated that the intelligence and school performance of 7-year-old children with febrile seizures were not different from those of their unaffected siblings (Ellenberg and Nelson, 1978). In addition, a cohort study in the United Kingdom (Verity et al., 1998) reported that 10-year-old children who experienced febrile seizures did not differ in academic progress, intellect, or behavior from children without febrile seizures.

The studies cited previously did not specifically investigate whether febrile seizures affect memory function. In another population-based study that examined the effects of febrile seizures on working memory, Chang et al. (2001) found that 87 school-aged children with febrile seizures performed significantly better than 87 age-matched control children in learning, consolidation, memory retrieval, and delayed recognition; however, children that had experienced febrile seizures prior to 1 year of age showed deficits in these skills, suggesting an age-dependent vulnerability to febrile seizures. Using a mouse model of febrile seizures (hair dryer, P11, or P14), we investigated the cellular mechanisms underlying the age-dependent effects of febrile seizures on memory (Tao et al., 2016). We found that adult mice that had been subjected to experimental febrile seizures at P14 performed better in a cognitive task that requires dentate granule cells. The enhanced memory performance of these animals correlated with an increase in the density of the large mossy fiber terminals of granule cells that was partly mediated by BDNF-TrkB signaling. In contrast, memory enhancement was

not observed in mice subjected to experimental febrile seizures at P11; these animals exhibited ectopic granule cells in addition to an increased density of large mossy fiber terminals. Importantly, the ectopic granule cells in these animals were abolished by administration of the diuretic bumetanide, which unveiled the masked memory enhancement. Our finding that experimental febrile seizures at P14 but not at P11 enhanced adult memory performance is apparently consistent with the results obtained in the human studies; the first postnatal week in rodents roughly corresponds to the first 2–3 postnatal months in humans, and the next 2 postnatal weeks in rodents correspond to postnatal years 4–5 in humans in terms of the developmental stage of the hippocampus and its role in learning and memory (Avishai-Eliner et al., 2002).

Several animal studies have investigated the molecular mechanisms underlying the relationship between early life febrile seizures and later hippocampal-dependent memory dysfunction. In an infrared-lamp-induced experimental febrile seizure model, it was shown that single experimental febrile seizures at P10, 15, or 20, but not at P5, resulted in impaired inhibitory avoidance responses at P50–60 (McCaughran et al., 1982). Seizures induced by repeated episodes of brief hyperthermia (10 min at a rectal temperature of 40–43°C) at P10–12 resulted in long-term memory deficits in both the Morris water maze (starting at P36) and an inhibitory avoidance task at P45; however, this study modeled brief, recurrent febrile seizures, not prolonged febrile seizures (Chang et al., 2003). Western blotting showed that the phosphorylation of cAMP response-element binding (CREB) protein was significantly reduced in the hippocampi of rats that had been subjected to repeated experimental febrile seizures. Moreover, the authors showed that administration of rolipram, which activates the cAMP-CREB signaling pathway, reversed long-term memory deficits via enhanced CREB phosphorylation. Repeated febrile seizures also induced long-lasting deficits in synaptic plasticity in CA1 pyramidal cells and reduced the tyrosine phosphorylation of the NMDA receptor subunit NR2A (Chang et al., 2005). Recently, abnormal firing rates of hippocampal CA1 cells and poor stability of their activity have been proposed as a basis for deficits in hippocampal-dependent memory in animals subjected to experimental febrile seizures (hair dryer model) (Dube et al., 2009).

To understand the effect of febrile seizures on later memory dysfunction, large-scale human, and animal studies targeting the age-dependent effects of febrile seizures and the cellular and molecular mechanisms underlying these effects are necessary. Moreover, the use of noninvasive methods, such as MRI (Dube et al., 2009) to detect the later effects of febrile seizures on hippocampal function is required.

10 CONCLUSIONS

Animal models of febrile seizures have provided us with extensive evidence regarding the effects of early life seizures on the formation of neural circuits and on later behavior, including the development of epilepsy, which has been difficult to assess using human tissue samples alone. Studies using these models have also identified novel therapeutic strategies, such as increased ambient CO_2 (Schuchmann et al., 2006) and the inhibition of NKCC1 (Koyama et al., 2012) that might be used to prevent the induction of febrile seizures and the later development of epilepsy, respectively. As performed in our laboratory (Koyama et al., 2012), experiments involving cultured brain slices and neurons from rat pups that experienced febrile seizures will help to further clarify the cellular and molecular mechanisms underlying febrile seizure-induced changes in neural circuit formation. It is also important to examine the role of glial cells in febrile seizures and the subsequent development of epilepsy.

Although one must be cautious when extrapolating results obtained from experimental febrile seizure models to human febrile seizures, the residual effects of a single episode of early life experimental febrile seizures have been observed in the adult brain. Future studies using these well-established experimental animal models will provide invaluable information concerning the causes and consequences of early life seizures and their relationship to epileptogenesis and will contribute both to the clarification of the mechanisms underlying neural circuit formation and to the development of therapeutic strategies to prevent epilepsy development.

1 INTRODUCTION

It is increasingly apparent that preterm birth (PTB) is a complex, multifactorial syndrome wherein both the risk of both preterm delivery and resultant perinatal outcomes for the infant are predicated on the actions of a network of intractable (e.g., genetic background, family history) and modifiable (e.g., maternal stress, environmental exposures, sterile inflammation, infection) factors (Nadeau et al., 2016; Romero et al., 2014). The classical World Health Organisation (WHO) definition of PTB is live delivery prior to 37 weeks' gestation (Blencowe et al., 2012). PTBs are further subclassified as extremely preterm (occurring before 28 weeks' gestation), very preterm (occurring between 28 and 32 weeks' gestation), and moderate to late preterm (occurring from

32 to 36 weeks' gestation) (Goldenberg et al., 2008b). Although a range of factors including a history of preterm delivery or a cervix of less than 25 mm in length at 18-week pregnancy assessment are indicators of elevated risk of preterm delivery, no definitive diagnostic test for PTB exists, and there are limited effective treatment options (Goldenberg et al., 2008a).

Highlighting comparatively recent evidence demonstrating an increased risk of perinatal death and adverse neurodevelopmental outcomes in babies delivered at 37 and 38 weeks gestation (Tita et al., 2009; Zhang and Kramer, 2009), a number of investigators have called for a reassessment of the definition of PTB, proposing a new cutoff gestation of 39 weeks (Goldenberg et al., 2012). Citing etiological similarities between spontaneous deliveries between 16 and 24 weeks' gestation, the same group has also called for the adoption of a standardized, empirically based definition of the lower limit of prematurity, including, perhaps, deliveries as early as 16 weeks' gestation (Goldenberg et al., 2012).

Currently, preterm deliveries are phenotypically classified as either: spontaneous (sPTB; 45% of preterm deliveries); preterm premature rupture of membranes (pPROM; 25% of preterm deliveries); or indicated delivery due to the identification of risk factors including fetal growth restriction or preeclampsia (30% of preterm deliveries) (Goldenberg et al., 2008b). Villar et al. (2012) have advocated for the adoption of a more granular phenotypic classification system that excludes risk factors to focus on five components of PTB: prelabor maternal conditions; prelabor fetal conditions, placental pathology, signs of the initiation of parturition, and the pathway to delivery. Given the substantial geographical variations that exist in how PTB is defined (especially with regards the lower limit of prematurity and the techniques used to estimate the date of conception), the adoption of a standardized, empirically defined definition of PTB supported by a more granular phenotypic classification system may benefit both our understanding of the PTB syndrome and allow more accurate assessment of global PTB trends.

The socioeconomic burden caused by PTB is profound. The estimates of 2010 suggest that, worldwide, 11.1% of all babies are born preterm (Harrison and Goldenberg, 2016). It is estimated that there are 15 million preterm deliveries each year; 965,000 neonatal deaths, and a further 125,000 deaths among children aged 1–5 years are attributable to PTB (Harrison and Goldenberg, 2016). Approximately 50% of chronic childhood neurological deficit is a result of preterm delivery (Harrison and Goldenberg, 2016). Preterm infants are at elevated risk of respiratory, cardiovascular, and metabolic diseases and the risk of death and developmental disability increases markedly with the degree of prematurity at birth (Harrison and Goldenberg, 2016). Data released by the

WHO reveals that, despite significant improvements in reducing total under-five deaths, there has been little or no progress in reducing the rate of early neonatal death (Lawn et al., 2005).

A 2005 report by the Institute of Medicine estimated the annual societal cost of PTB to the USA at $26 billion (Institute of Medicine Committee on Understanding Premature Books and Assuring Healthy Outcomes, 2007). A subsequent report assessing PTB-associated costs in England and Wales during 2006 reported an attributable cost of £2.946 billion, 92% of which related to in-patient hospital costs after birth (Mangham et al., 2009). The treatment-to-discharge cost for a moderately preterm infant in the United Kingdom is approximately £11,629, some 6.3 times more than the treatment-to-discharge cost of infant delivered at term (Khan et al., 2016). Treatment costs escalate markedly in proportion to the degree of prematurity; the cost of treating an extremely preterm infant has been estimated to be as high as $US 195,245 (Khan et al., 2016). The majority of PTBs occur between 32 and 36 weeks of gestation; for example, 75% of UK PTBs (6%–7% of total live births) fall in this moderate-late PTB range (Khan et al., 2016). In contrast, 2013 data from the USA show that extremely preterm (<28 weeks' gestation; 0.75% of total live births) and very preterm (28–32 weeks' gestation; 1.2% of total live births) account for a comparatively small percentage of live births (Frey and Klebanoff, 2016).

Rates of PTB demonstrate marked geographic and socioeconomic variation. Broadly speaking, the rates of PTB are lowest among Caucasian populations living in high-resource environments. The overall rate of PTB in northern Europe is around 5%; in contrast, the rate of PTB in low-resource, sub-Saharan countries is around 18%. In the USA, the overall rate of birth in 2013 was 11.4%, down from a 2006 peak of 12.8%, potentially as a consequence of fewer early inductions (Behnia et al., 2016). Interestingly, the rate of early PTB has not changed over the same period. A clear discrepancy in PTB rates exists between ethnic groups in the USA; 2013 data show, for example, that 16.3% of pregnant non-Hispanic black, 10.2% pregnant non-Hispanic white, and 11.3% of pregnant Hispanic women had a preterm delivery (Harrison and Goldenberg, 2016). Interestingly, data from migrating Chinese populations suggest that differences in PTB rates between ethnicities may be geographically modifiable (Newnham et al., 2011). A disparate range of candidate factors (e.g., stress, socioeconomic disadvantage, genetic background, lifestyle factors) make unpacking the origin of these differences in the interracial PTB rate a difficult task.

Of the factors hypothesized to induce PTB, a significant body of clinical and experimental data now exists to highlight the importance of intrauterine infection as a causal agent, especially in preterm infants who are

born at or before 32 weeks' completed gestation (Kemp et al., 2010; Menon et al., 2009; Viscardi, 2010). The development of this evidence, with specific reference to the use of animals in clarifying the role of infection and inflammation (both infectious and sterile in origin) in PTB, will constitute the focus of the present chapter.

2 INFECTION, INFLAMMATION, AND PRETERM BIRTH

Inflammation is tightly regulated process mounted by the body in response to tissue injury or microbial invasion. A properly regulated inflammatory response acts to protect the body by limiting tissue damage, preventing further dissemination of infection, and initiating tissue repair. The presence of an active inflammatory response may, depending upon the stage of inflammation and the tissue in question, be determined by clinical signs (redness, swelling, loss of function, heat), a molecular signature (elevated expression of proinflammatory cytokines and chemokines), or histological analyses (with regard to PTB, histological chorioamnionitis neutrophils, lymphocytes, and macrophages). With regard to PTB, histological chorioamnionitis [neutrophil invasion of the chorionic and amniotic membranes, with severity and additional pathology described a grading system, such as that proposed by Redline et al. (2003)], and funisitis (inflammatory involvement of the umbilical cord) are hallmarks of the presence of an intrauterine infection (Goldenberg et al., 2002; Grigsby et al., 2010; Kim et al., 2009; Lahra et al., 2007).

There is some debate, however, as to whether the infiltration of immune cells into the fetal membranes in response to infection initiates or amplifies the induction of PTB, or is merely an associated phenomenon. A recent microarray analysis of laboring and nonlaboring myometrial samples identified a pattern of molecular inflammatory signaling consistent with neutrophil activity (Sharp et al., 2016). However inflammation of uterine tissues is characteristic of uninfected pregnancies delivering at term, although the magnitude of the inflammation is considered to be lower than in cases of preterm delivery with demonstrated uterine infection (Dudley et al., 1996; Keelan et al., 2003; Liggins, 1981). Moreover, acute chorioamnionitis has also been detected in the absence of intrauterine infection (Kim et al., 2015). Perhaps even more intriguing is data generated in an elegant study by Rinaldi et al. (2014), who showed that neutrophil-depleted mice had a reduction in LPS-driven uterine and placental IL-1β expression, but no change in LPS-driven PTB. These findings were subsequently corroborated by work in a rabbit model or prematurity; again, neutrophil-depleted animals stimulated with killed *Escherichia coli* relative had negligible signs of uterine or placental neutrophil invasion relative to control, but maintained high relative expression of inflammatory cytokines (including IL-1β) and increased rates of PTB (Filipovich et al., 2015).

The strongest association between intrauterine infection and preterm delivery is in cases of early PTB (prior to 32 weeks' gestation). The long-held view of the etiology of intrauterine infection in cases of PTB was that microorganisms ascended from the genital tract, invaded the fetal membranes [either generally (Goldenberg et al., 2008b) or as proposed more recently via a discrete focal region (Kim et al., 2009)] before accessing the amniotic fluid and fetus. Recent data also suggests a role for hematogenously (Prince et al., 2014) spread oral microorganisms in PTB (Vanterpool et al., 2016) in support of earlier work by Offenbacher et al. (1996, 1998). It is tempting to speculate that the means by which a particular microorganism gains access to the gestational tissues is dependent on both host (i.e., pregnancy related) and microbial factors. For example, the *Ureaplasma* spp. are exquisitely sensitive to inactivation by complement (Kemp, 2014). Accordingly, they are unlikely to disseminate to the fetus effectively by hematogenous spread unless the mother is severely complement deficient.

The application of metagenomics technologies to the question of PTB etiology has led to the generation of data suggesting that dysbiosis of the vaginal, gastrointestinal, and perhaps even placental microbiome may play an important role or at least be predictive of PTB (Vinturache et al., 2016). Vaginal microbiome diversity has been shown to decrease and population stability to increase, as pregnancy progresses (Vinturache et al., 2016). One particularly interesting hypothesis is that dysregulation of the cervical microbiome (which appears to show some homology to the oral microbiome) is associated with microbially induced shortening of the cervix, itself a known risk factor for PTB (Vinturache et al., 2016). Complicating the interpretation of these data are observations that tissue sites once thought to be sterile, such as the placenta, do possess a native, low-biomass microbiome (Aagaard et al., 2014), and that the microbial population (most notably species diversity) of the vagina differs between ethnicities (Hyman et al., 2014), proximity to the cervix, and with gestation (Aagaard et al., 2012). Although much remains to be understood with regard to the role of the microbiome in PTB, these observations raise the question as to whether disruption of a yet-to-be defined "normal placental or intrauterine" microbiome may increase the risk of a preterm delivery.

What is apparent is data from clinical studies demonstrating that the frequency of intrauterine infection and histological chorioamnionitis correlates inversely with gestational age at birth (Bastek et al., 2011; Goldenberg et al., 2000; Romero et al., 2005, 2007). Bacterial colonization of the amniotic fluid is detected in <1% of women

not in labor at term; seminal research (now replicated by numerous investigators) demonstrated that in very low-birth weight infants (<1500 g), the extraplacental membranes had bacteria in 80% and chorioamnionitis in 60% of cases (Hillier et al., 1988). Before moving to discuss data from animal-based studies that support a role for infection and inflammation in PTB, it is useful to review some of the key microorganisms clinically associated with PTB.

2.1 Bacteria

An increasingly wide range of bacteria are identified from clinical samples in association with PTB, with some suggestion that the spread and diversity of microorganisms identified alters with gestational age at delivery (Jones et al., 2009). Both genital tract and oropharyngeal microorganisms are implicated in the etiology of PTB, and will be introduced briefly in this section.

Members of the *Ureaplasma* spp. are present in the urogenital tract of up to 40%–80% of healthy women (Viscardi, 2014). Recent work by Sweeney et al. (2016) showed that the presence of *Ureaplasma* spp. in mid-late preterm and term placental samples was associated with chorioamnionitis, elevated cord blood granulocyte colony stimulating factor [but not IL-6, IL-8, or monocyte chemoattractant protein-1 (MCP-1)], and increased postnatal oxygen use (>6 h). Interestingly, there was no difference in gestational age at delivery between the infected and noninfected groups, and the term delivery cohort (*n* = 92) had a higher total proportion of mild or severe chorioamnionitis than the mid-late preterm cohort (*n* = 443) (Sweeney et al., 2016). Chorioamnionitis and funisitis at term has also been reported due to intrauterine infection by *Fusobacterium nucleatum* (Bohrer et al., 2012). One interpretation of these data is that although chorioamnionitis and *Ureaplasma* spp. infection in mid-late pregnancy or at term is associated with modest adverse fetal outcomes (i.e., increased oxygen use), it does not correlate with an increased risk of preterm delivery, in contrast to findings at earlier gestations. This interpretation may not be true for all infecting microorganisms; however, as term still birth has been reported in association with *F. nucleatum* infection (Han et al., 2010). Further interpreting these data from a pregnancy risk perspective is difficult given the problems inherent in determining when the *Ureaplasma* spp. infection became established. That said, these data do suggest that the identification of particular factors (in this cause *Ureaplasma* spp. and chorioamnionitis) may equate with a different risk assessment at different stages of pregnancy.

In this, and numerous subsequent studies, *Ureaplasma* spp. were the microorganisms most commonly isolated in PTB, although studies by several groups have demonstrated the potential importance of polymicrobial infection of the uterus in prematurity (DiGiulio, 2012; DiGiulio et al., 2010; Jones et al., 2009). Ureaplasmas are small free-living bacteria that lack a cell wall and have been shown to activate the innate immune system via Toll-like receptors (TLRs)-1, -2, and -6 (Shimizu et al., 2008). The original 14 serovars and 2 biovars of *Ureaplasma urealyticum* have now been reclassified into two species, *Ureaplasma parvum* (serovars 1, 3, 6, and 14) and *U. urealyticum* (serovars 2, 4, 5, 7–13) (Robertson et al., 2002). This taxonomy has been inconsistently employed by investigators and *U. urealyticum* is often still used to describe all 14 serovars.

The presence of *Ureaplasma* spp. in clinical specimens can be confirmed by culture or PCR assays, with more recent assays allowing for discrimination to serovar level (Payne et al., 2014a). A substantial body of data exists to suggest an important role of *Ureaplasma* spp. in early PTB; analysis of women with preterm labor or preterm prelabor rupture of membranes at 23–34 weeks gestation demonstrated *Ureaplasma* spp. in 43.9% of cases, compared with 2.7% at this age where the indication for Cesarean section did not include preterm labor or ruptured membranes (Witt et al., 2005). In a study of umbilical cord blood at birth, positive cultures for *Ureaplasma* spp. were observed in 34.7% of spontaneous PTB at 23–32 weeks gestation, compared with 3.2% for PTB at this age where the indication for delivery was for other reasons (Goldenberg et al., 2006, 2008a). *Ureaplasma* spp. are detected in respiratory tract samples of 20%–45% of very low (<1501 g) infants (Viscardi, 2014); data from a recent US cohort study demonstrated a statistically significant association between *Ureaplasma* spp. colonization of the respiratory tract and decreased gestational age; 65% of babies born before 26 weeks' gestation tested culture or PCR positive for *Ureaplasma* spp. during the first month of life—more than double the rate of detected for preterm infants born between 26 and 33 weeks' gestation (Sung et al., 2011). *Ureaplasma* spp. are 3 times more prevalent in the chorioamnion of early PTB deliveries than in preterm deliveries at later gestational ages (Kundsin et al., 1984), with serovars 3 and 6 being the most commonly detected (Sung et al., 2011).

A multitude of studies over the past 20 years have demonstrated strong associations between *Ureaplasma* colonization of the upper genital tract (causing histological chorioamnionitis) and PTB in addition to spontaneous abortion, neonatal pneumonia, meningitis, and stillbirth (Cassell et al., 1993; Colaizy et al., 2007; Garland and Murton, 1987). Ureaplasmas are microaerophiles and demonstrate a marked affinity for epithelial surfaces (Cassell et al., 1993), and are phenotypically distinguished from Mycoplasmas by their ability to hydrolyze urea as their sole energy source, resulting in production of ammonia, an increase in proton electrochemical potential, and de novo ATP synthesis (Volgmann et al., 2005). Interestingly, despite possessing a minimal

genome, *Ureaplasma* spp. widely express an IgA protease (Paralanov et al., 2012), which may act as a virulence factor in establishing mucosal infections. More recently, mycoplasmas, which are also implicated in infection-associated PTB, have been shown to possess a two-component IgG binding and protease system (Arfi et al., 2016). Such a system may not only act as a means of circumventing host defense, it may also activate an innate immune system-drive inflammatory response; recent data have suggested that leukocyte immunoglobulin-like receptor (LILR) A2, which is expressed on human myeloid cells, has the ability to bind with variable affinity IgM, IgG1, IgG2, IgG3, IgG4 fragments produced by microbial proteases (Hirayasu et al., 2016).

There is ongoing debate regarding the role of periodontitis and oral microorganisms in the etiology of PTB. Species including *F. nucleatum* (Gardella et al., 2004), *Streptococcus agalactiae* (Feikin et al., 2001), and *Porphyromonas gingivalis* (León et al., 2007) are among the oral microorganisms most commonly identified in either chorioamnion or amniotic fluid samples from cases of PTB. The most likely means by which oral microorganisms are able to gain access to the uterine environment is predicted to be by hematogenous distribution (DiGiulio, 2012). Han et al. (2010), for example, isolated the same clonal type of *F. nucleatum* from the lung of a stillborn term infant and the mother's gingival crevice, but did not identify the same isolate in the mother's vagina, suggesting hematogenous spread. Adding weight to the argument for periodontitis having a causal role in PTB are a number of studies linking periodontitis with PTB, low-birth weight, and adverse pregnancy outcomes (Ide and Papapanou, 2013; Offenbacher et al., 2006). In addition to directly impacting pregnancy, a review of periodontitis in adverse pregnancy outcomes by Madianos et al. (2013) proposes that periodontitis may indirectly impact pregnancy well-being via cytokines/chemokines or proinflammatory bacterial products that may interfere with the immunological balance at the maternal/fetal interface. Studies performed in the pig-tailed macaque (*Macaca nemestrina)* provide further support for the importance of systemic inflammation in adverse pregnancy outcomes. Employing a chronically catheterized model, Adams Waldorf et al. (2008) established an infection of the uterus with a clinical isolate of Group B *Streptococcus* and investigated changes in fetal development and intraamniotic inflammation. Despite being unable to isolate the infecting microorganism from the amniotic fluid, maternal blood and fetal blood, the investigators demonstrated marked lung injury and significant elevation of IL-6 and IL-8 in the amniotic fluid (Waldorf et al., 2011). Increased IL-8 levels were also reported in the fetal plasma. These findings indicate that the direct induction of inflammation may not be necessary for the initiation of intrauterine inflammation or fetal injury.

Arguing against a role for periodontitis in PTB are data from two large trials, the Obstetric and Periodontal Therapy Study (Michalowicz et al., 2006) (823 women randomized to receive scaling and root planing either before 21 weeks' gestation or after delivery) and the Smile Study (1078 women with periodontitis randomized to receive periodontal treatment in midpregnancy or after delivery). Both studies noted an improvement in oral health as a result of treatment and there were no adverse side effects resulting from treatment. However, both studies also reported that periodontal treatment did not prevent PTB. Interestingly, the findings of these two studies are supported by data from a rat study of periodontitis. Observing that many previous studies used models of oral pathogen challenge, rather than periodontitis per se, Fogacci et al. (2016) showed that periodontitis in Wistar rats did not alter cytokine levels in gestational tissues and, furthermore, that there was no difference in adverse pregnancy outcomes. One difference that was identified, however, was that fertility rates were reduced in rats with periodontitis. If and how periodontitis is related to PTB remains uncertain, and several authors have concluded that differences in how periodontitis is categorized may contribute to conflicting study findings (Ide and Papapanou, 2013). With a recent appreciation that the placenta possesses its own microbiome-bearing similarities to that of the oral cavity, Aagaard et al. (2014) have assessed this apparent paradox from a microbiome perspective. They hypothesize that the apparent contradiction in the literature over the role of periodontitis in PTB may derive from the hematogenous spread of pathogenic periodontal bacteria to the placenta during early pregnancy (Aagaard et al., 2014). In such a scenario, although mid-trimester periodontal treatment may improve clinical signs of active periodontitis, it is unlikely to impact the microbial population of the placenta, or any inflammatory response potentially predisposing the pregnancy to early delivery or adverse outcome. Some support for this theory comes from work in baboons (*Papio anubis*) undertaken by Ebersole et al. (2014). Using a ligature model of periodontitis, they demonstrated significant increases in low-birth weight, spontaneous abortion, and a decrease in gestational age among animals with periodontitis, relative to control. Interestingly, the authors concluded that the animals at greatest risk of adverse pregnancy outcomes were also those that had the most severe/extensive periodontal disease in the first half of pregnancy.

2.2 Viruses

The body of literature describing the role of viral pathogens in the etiology of PTB is, relative to that describing bacterial infection, comparatively small. Accordingly, much remains to be understood about the role of

viral infection in adverse pregnancy outcomes and PTB. At an epidemiological level, maternal infection caused by a range of viruses including: influenza virus (Meijer et al., 2015; Nakai et al., 2012), human immunodeficiency virus (Montgomery-Taylor and Hemelaar, 2015; Xiao et al., 2015), dengue virus (Hanf et al., 2014), adenovirus (Tsekoura et al., 2010), hepatitis B (Sirilert et al., 2014), and hepatitis C virus (Huang et al., 2015; Money et al., 2014) are associated with variably increased rates of PTB. Using newborn screening cards, Gibson and coworkers reported that the presence of cytomegalovirus was associated with a statistically significant increase in PTB (OR 1.61, 95% CI 1.14–2.27). Of some comfort, however, are studies demonstrating that vaccination against a number of these pathogens (i.e., influenza, hepatitis) during pregnancy poses virtually no risk to the fetus (Moro et al., 2013, 2014). A number of viruses have been detected in mid-trimester amniotic fluid samples using molecular methods; two studies, by Wenstrom et al. (1998) and Baschat et al. (2003) have identified (among others) the presence of adenovirus and cytomegalovirus in amniotic fluid, but both studies concluded that there was no association between the presence of virus and pregnancy loss or adverse pregnancy outcome, respectively. In contrast, Srinivas et al. (2006) reported that the presence of histologic chorioamnionitis and any viral infection was independently associated with second trimester pregnancy loss. More recently, Gervasi et al. (2012) examined the potential association between the presence of specific viral nucleic acids (adenoviruses, herpes simplex virus, varicella zoster virus, human herpesvirus 6, human cytomegalovirus, Epstein–Barr virus, parvovirus B19, and enteroviruses) in 729 mid-trimester amniotic fluid samples and pregnancy outcomes. The authors reported identifying viral nucleic acid in 2.2% of samples, with human herpes virus 6 (seven cases), human cytomegalovirus (six cases) being the most commonly pathogens identified. Interestingly, although the study did identify an association between maternal plasma and amniotic fluid interferon-γ-inducible protein 10 and human cytomegalovirus copy number (but not human herpes virus 6 copy number), the authors concluded that their data did not support a causal association between the presence of viral nucleic acid in the amniotic fluid at mid-trimester screening and adverse pregnancy outcomes (Gervasi et al., 2012).

2.3 Fungi

Traditionally, fungi have not been considered important in the etiology of PTB. Members of the genus *Candida*, including *Candida albicans* (Romero et al., 1985), *Candida glabrata* have been identified from amniotic fluid samples, with *C. albicans* being the species most commonly isolated (DiGiulio, 2012). There is some debate surrounding the role of *Candida* spp. in the etiology of PTB. As many as 40%

of pregnant women may have vaginal colonization by *Candida* spp.—a significantly higher rate than in nonpregnant women (DiGiulio, 2012; DiGiulio et al., 2010; Jones et al., 2009). The presence of *C. albicans* has been identified in amniotic fluid samples from women with spontaneous PTB with intact membranes (Andrew Combs et al., 2014). Although congenital candidiasis is a comparatively rare finding, intraamniotic *C. albicans* infection has been linked to fetal demise and adverse pregnancy outcomes (Chaim et al., 1992; DiGiulio, 2012; DiGiulio et al., 2008, 2010). Work by DiGuilio and coworkers indicate that *C. albicans* may be present in the intrauterine environment more frequently than has been suggested by studies employing culture-based techniques.

3 INNATE IMMUNE RESPONSES

Before moving to review a selection of the studies providing evidence for the role of infection-driven inflammation in PTB, it is useful to touch briefly on the innate immune system and, more specifically, the pattern recognition receptors (PRRs) that play a key role in the recognition of microbial agonist.

Comprised of pathogen and damage-recognizing cellular [i.e., natural killer cells, macrophages, eosinophils, neutrophils (Alberts et al., 2002)] and humoral [(i.e., natural IgM, IgG3, and IgA antibodies (Cao, 2016), complement (Dunkelberger and Song, 2009), defensins (Hazlett and Wu, 2011)] elements, the innate arm of the immune system plays a pivotal role in defending the body from infection due to its ability to recognize and respond to de novo microorganisms. In addition to mounting an initial antimicrobial defense, the innate immune system also acts to recruit an adaptive immune response (Agrawal and Hirsch, 2012). Innate immune cell receptors are known as pattern recognition receptors (PRRs). PRRs are transmembrane and intracellular proteins with the ability to recognize a wide range of conserved pathogen-associated molecular patterns [PAMPs; including lipopolysaccharide, lipoproteins, peptidoglycans, and nucleic acids (i.e., unmethylated CpG motifs) (Kawai and Akira, 2011)] and danger-associated molecular patterns [DAMPs; cellular molecules generated in response to trauma, ischemia, cancer, etc., including heat shock proteins, high mobility-group box 1 (HMGB1), nucleic acids, ATP, and hyaluronic acid (Tang et al., 2012)]. Activation of PRRs leads to the induction of an intracellular signaling cascade, resulting in the production of cytokines and chemokines. Today, major classes of PRRs are known to include the TLRs (De Nardo, 2015; Kawai and Akira, 2011), C-type lectin receptors (CLRs) (Dambuza and Brown, 2015), retinoic acid-inducible gene I (RIG-I)-like receptors (RLRs) (Matsumiya and Stafforini, 2010), Nod-like receptors (NLRs) (Franchi et al., 2009), and LILRs

(Hirayasu et al., 2016; Sloane et al., 2004). In addition to acting individually, a number of investigators have suggested that PRR systems have the ability to interact; for example, Chaput et al. (2013) have suggested that the stimulation of TLRs may facilitate the internalization of muramyl dipeptide, which is necessary for the activation of NOD-2 signaling. LILRs, which demonstrate inhibitory effects on antigen presenting cell activity, may also act to downregulate TLR-driven proinflammatory signaling (Anderson and Allen, 2009).

3.1 Toll-like Receptors

TLRs were the first class of pf PRRs to be discovered. Ten TLRs in have been identified in humans (TLRs1–10) and twelve (TLRs1–9, 11, 12, 13) in mice, each recognizing a range of specific agonists (De Nardo, 2015). Plasma membrane expressed TLRs include: TLR1 (triacyl lipopeptides), TLR2 (lipopeptides, peptidoglycan, lipoteichoic acid), TLR4 (lipopolysaccharide; note TLR4 also has endosomal activity), TLR5 (flagellin), and TLR6 (diacyl lipopeptides, lipoteichoic acid). These TLRs interact with microbial wall or membrane proteins and their activation results in the upregulation of proinflammatory signaling cascades (Hess et al., 2016). TLR3 (dsRNA), TLR7 (ssRNA), TLR8 (ssRNA), and TLR9 (CpG-containing DNA) are sequestered within endosomes and mainly respond to nucleic acids, resulting in the increased expression of type-I interferons (De Nardo, 2015). TLR10 remains an orphan receptor; the activating ligand(s) and effector signaling pathways remain unresolved for this TLR. Interestingly, recent work by Jiang et al. (2016) showed TLR-10 suppression of IL-6 and tumor necrosis factor (TNF)-α expression in vitro, suggesting a potential role as a generalized negative regulator of proinflammatory TLR signaling.

TLRs have been identified in a range of human and animal fetal tissues [including lung (Petrikin et al., 2010; Sow et al., 2012), skin (Iram et al., 2012), spleen (Nalubamba et al., 2008), and CNS (Vontell et al., 2013)] from a very early gestational age. PAMP recognition by a TLR leads to the recruitment of adaptor protein(s) to the intracellular TIR domain and proinflammatory signaling via myeloid differentiation primary response 88 (MyD88)-dependent or TIR domain-containing adapter-inducing interferon-β (TRIF)-dependant pathways—TLR-4 being the only receptor to utilize both signaling pathways. Initiation of the MyD88-dependant pathway leads to early activation of NF-κβ and MAP kinases, resulting (in conjunction with TRIF signaling) in the elaboration of inflammatory cytokines including interleukin (IL)-1β, IL-6, TNF-α, and chemokines including IL-8 and MCP-1. Activation of the TRIF-dependant pathway induces TNF receptor-associated factor 3 activation of interferon regulatory factor 3 and the elaboration of type-I interferons

(Akira and Takeda, 2004; Kawai and Akira, 2011). Additionally, TRIF signaling can also promote RIP-1 kinase interaction with TRAF6, leading to NF-κB-driven proinflammatory cytokine expression (De Nardo, 2015).

3.2 C-type Lectin Receptors

Historically, CLRs have been of interest due to their involvement in host defense from fungal infection; more recently, CLRs have been shown to play a role in defense against bacterial infection (notably the mycobacteria) and tissue homeostasis (Dambuza and Brown, 2015; Sancho and Reis e Sousa, 2012). CLRs are members of a superfamily of around 1000 proteins that are subclassified into 17 groups on the basis of phylogenetic analysis and the protein domain organization. The ability to bind carbohydrate in a calcium-dependent manner is a common characteristic of CLRs, although not all CLRs possess this functionality, and many exhibit specificity for different agonists, including proteins and lipids (Dambuza and Brown, 2015; Sancho and Reis e Sousa, 2012). Dectin-1 and Dectin-2 are among the best characterized members of the CLR superfamily. Dectin-1 (alternatively named CLEC7A) is expressed by human monocytes, macrophages, dendritic cells, neutrophils, and B cells (Dambuza and Brown, 2015; Sancho and Reis e Sousa, 2012). It is activated by β-1,3 glucans from a range of fungi including *Mycobacteria* spp.—*Pneumocystis carinii, C. albicans, Aspergillus fumigatus, Penicillium marneffei, Coccidioides posadasii,* and *Histoplasma capsulatum,* which it binds with an a-typical carbohydrate-binding motif in a calcium-independent fashion (Dambuza and Brown, 2015; Sancho and Reis e Sousa, 2012). Dectin-1 signals via the recruitment and activation of Syk kinase-dependent and -independent pathways to regulate a range of cellular responses including phagocytosis, respiratory burst, enhanced production of IL-2, IL-6, IL-10, IL-23, and also the production of type-I interferons in response to stimulation by *C. albicans.* Dectin-2 (alternatively termed CLEC6A) is expressed in macrophages, monocytes, and some classes of dendritic cells (Dambuza and Brown, 2015; Sancho and Reis e Sousa, 2012). Dectin-2 is primarily activated by fungal α-mannans and in mice plays a greater role than Dectin-1 in driving dendritic cell responses to *C. albicans* (Sancho and Reis e Sousa, 2012).

3.3 RIG-I-like Receptors

RLRs are helicase proteins that respond to the presence of cytoplasmic RNA (Matsumiya and Stafforini, 2010), making them an important defense against viral infection due to their ability to induce the expression of type-I interferons (Loo and Gale, 2011; Matsumiya and Stafforini, 2010). Members of the RLR family include retinoic acid inducible gene-I (RIG-I), melanoma

differentiation-associated gene 5 (MDA5), and laboratory of genetics and physiology 2 (LGP2) (Loo and Gale, 2011; Matsumiya and Stafforini, 2010). As is the case with TLRs, RLRs each respond to a range of viruses; RIG-I has been shown to respond to viruses including Paramyxoviridae (e.g., measles and respiratory syncytial virus), Orthomyxoviridae (e.g., influenza A and B), and the Flavivirus Hepatitis C. MDA5 has a been shown to respond to a smaller range of viruses, including members of the Picornaviridae and the DNA virus vaccinia (Loo and Gale, 2011). The role of LGP2 in antiviral signaling is somewhat unclear; LGP2 differs structurally from both RIG-I and MDA5 due to the lack of two N-terminal caspase recruitment domains (CARDs), which are implicated in interacting with downstream effector molecules to drive upregulation of antiviral gene expression (Bruns et al., 2013). Studies to date have shown that LGP2 has the ability to inhibit RIG-I-driven signaling activation; conversely, LGP2 has been shown to be a critical element of MDA5-driven signaling (Zhu et al., 2014). One potential role for LGP2 may, however, lie in controlling antigen-specific CD8[+] T cell survival during population expansion in response to viral infection. Elegant work in *Dhx58* (the gene encoding LGP2)-null mice by Suthar et al. (2012) demonstrated elevated expression of death receptors in antigen-specific CD8[+] T cells. This observation led the authors to conclude that LGP2 may function as a molecular switch to control death receptor signaling during the early stages of T cell activation (Suthar et al., 2012).

3.4 NOD-Like Receptors

NLRs are a large family of cytosolic sensors primarily involved in the detection of bacteria. Human NLRs are subclassified into one of five groups based on the nature of their N-terminal effector domain homology. Of the NLRs, members of the NLRC family NOD-1 (which possesses one N-terminal CARD) and NOD-2 (two N-terminal CARDs) are among the best characterized (Moreira and Zamboni, 2012). NOD-1 is widely expressed, whereas NOD-2 expression is believed to be more restricted; NOD-2 expression has been detected in macrophages, dendritic cells, keratinocytes, epithelial cells, and osteoblasts (Franchi et al., 2009). NOD-1 and -2 expression can be induced by a range of stimuli including TNF-α, IFN-γ, and bacterial agonist (Chaput et al., 2013). NOD-1 and NOD-2 respond to products of Gram-positive and Gram-negative peptidoglycan synthesis and degradation, including *meso*-diaminopimelic acid and muramyl dipeptide, respectively. NOD-1 signaling has been shown to be induced by respiratory pathogens including *Chlamydophila pneumoniae, Legionella pneumophila, Klebsiella pneumoniae, Haemophilus influenzae*, and *Pseudomonas aeruginosa*. Similarly, NOD-2

responds to stimulation by *Streptococcus pneumoniae, Staphylococcus aureus, E. coli, C. pneumoniae*, and *Mycobacterium tuberculosis* (Chaput et al., 2013). Activation of NOD-signaling results in the NF-κB and mitogen-activated protein kinase-driven expression of numerous antimicrobial peptides, cytokines, and chemokines including human β-defensin 2, IL-6, IL-8, CCL2, and CCL5 (Chaput et al., 2013; Voss et al., 2006).

4 INFLAMMATION AND LABOR

The net upregulation of proinflammatory mediators during pregnancy has the ability to shift the uterus from a quiescent state into one primed for labor by inducing remodeling and opening the cervix (otherwise known as cervical ripening), weakening, and eventually rupturing the fetal membranes, and inducing coordinated uterine contractions.

Increased cytokine/chemokine levels in the amniotic fluid and fetal membranes elicit proparturition changes via tissue remodeling of the membranes and cervix as a result of altered matrix metalloproteinase (MMP) and tissue inhibitors of matrix metalloproteinases in conjunction with alterations in uterine contractility via alterations in prostaglandin synthesis and metabolism. MMPs comprise a group of some 20 endopeptidases whose proteolytic remodeling of the extracellular matrix plays an important role in a host of normal and pathological processes (Cockle et al., 2007). Each MMP possesses a range of substrate specificities, which results in considerable heterogeneity in their activities. A number of inducible factors including cytokines, hormones (including prostaglandins), and reactive oxygen species (especially nitric oxide) can induce MMP transcription. MMP activity is suggested to play a role in both membrane rupture and cervical ripening. Elevated levels of MMP-9, a gelatinase, which degrades basement membrane proteins, have been described in the placenta, membranes, and amniotic fluid in term and PTB studies performed in rhesus macaques (Cockle et al., 2007).

Uterine activity during pregnancy and labor can be divided into four phases (0, quiescence; 1, activation; 2, stimulation; 3, involution) during quiescent pregnancy and the eventual transformation to parturition. During phase 0, a host of endocrine mediators including corticotrophin-releasing hormone (CRH), progesterone, prostacyclin (PGI_2), relaxin, and nitric oxide act to maintain quiescence by limiting intracellular Ca^{2+} release (and thus myofilament shortening via reduced myosin light chain kinase activity) in response to elevated intracellular levels of cyclic adenosine monophosphate (cAMP) and/or cyclic guanosine monophosphate (cGMP) (Challis et al., 2000; Lye et al., 1998). In phase 1, the uterus is primed for activation (either by mechanostimulation or

uterotrophic priming) resulting in increased expression of procontractility proteins including the gap-junction protein connexion 43 and prostaglandin and oxytocin agonist receptors. The generation of prostaglandin H_2 from arachidonic acid is under the control of prostaglandin cyclooxygenase endoperoxidase synthase 1 (PTGS1) and 2 (PTGS2). PTGS1 is a constitutively expressed enzyme, whereas increases in *Ptgs*2 expression is closely associated with inflammation or injury. With regards the role of infection in PTB, of interest is work by Timmons et al. (2014) demonstrating that in mice neither the level of prostaglandins nor the expression of prostaglandin synthase enzymes are altered in term cervices; however and in contrast, LPS exposure induced significant increases in prostaglandin synthesis and tissue levels, mediated by increased activity of PTGS2. In phase 2, uterine contractility is stimulated by prostaglandins, oxytocin, and CRH. The third phase of parturition is characterized by involution of the uterus following delivery of the fetus and placenta, primarily under the control of oxytocin (Challis et al., 2000; Lye et al., 1998).

5 THE USE OF ANIMALS IN THE STUDY OF PRETERM BIRTH—JUSTIFICATION AND VALIDITY

The use of animals in the study of human PTB is, quite rightly, a contentious undertaking requiring careful consideration of pragmatic and ethical aspects. In this regard, the work of Russell and Burch (1959), a lucid, rigorous, and compassionate treatment of humane experimental technique remains a landmark text in the field of animal experimentation. It should be considered essential reading for all individuals contemplating the use of animals in scientific research (Russell and Burch, 1959).

At a pragmatic level, much of the progress made in our understanding of human PTB is, as with many areas of biomedical science, derived from the use of animal experimentation. One of the most important questions facing the investigator thus relates to the "best" animal in which to model human PTB. We, and others, have suggested that there is no "best" animal system with which to model human PTB; a particular animal model, due to the nature and regulation of fetal development, may be well suited to one area of investigation (Bastek et al., 2011; Kemp et al., 2010). Alveolar development in rats and mice, for example, occurs predominantly in the postnatal period; in contrast, alveolar development in sheep, guinea pigs, and humans is well advanced at the time of birth (Warburton et al., 2000). As such, investigating the impact of antenatal steroids, such as betamethasone phosphate or dexamethasone phosphate on antenatal alveolar development and surfactant production is likely better undertaken in the fetal sheep than in

a rodent. Similarly, demonstrating that infection of the amniotic cavity induces preterm labor is likely better undertaken in a rodent model than in a sheep, due to the sheep's resistance to preterm labor in response to florid uterine inflammation (Kemp et al., 2010). As a means of framing our subsequent discussion, we will draw briefly on mice, sheep, and nonhuman primates, three experimental models that will form the bulk of our subsequent discussion on the study of animal models of human PTB.

Rats (commonly derived from the brown or Norwegian rat, *Rattus norvegicus*) and mice (*Mus musculus*) are commonly employed as models of infection-derived PTB. Their use confers numerous advantages due to their small size, ease of housing, and that they may be cheaply and easily obtained from defined, commercial breeding lines. Rats and mice have a brief gestation (21–23 days for rats and 19–21 days for mice), produce large litters (6–12 pups for rats and 4–15 pups for mice), and rapidly reach sexual maturity (puberty occurs at 50–60 days for rats and 6–7 weeks of age in mice) meaning that colonies can rapidly be expanded to meet experimental needs and precise age/gender matching is generally achievable (Wolfenson and Lloyd, 2003). Mice in particular are especially amenable to genetic modification and both rats and mice have well-characterized genomes. Studies involving rats and mice also benefit from the wide range of array platforms, multiplex protein assays, and siRNA probes that are commercially available (Kemp et al., 2010).

There are also a number of potential drawbacks to the use of rodents to model human PTB that need to be considered in experimental design. Rats and mice have a greatly shortened gestation when compared with humans and large litters, which limits the usefulness of this model when studying chronic infections/standardized fetal drug exposures or performing longitudinal analyses. There are significant variations in responsiveness to inflammatory compounds (e.g., LPS) exhibited between strains of mice, which necessitates caution in designing and comparing experiments. Additionally, their small anatomical size and elevated litter size makes maternal and fetal instrumentation, surgical interventions, perinatal ventilation, and amniotic fluid sampling difficult.

Primates are the closest animal model to humans in terms of pregnancy and labor, and marmosets and macaques are among the most commonly used primates in research (Wolfenson and Lloyd, 2003). Primate genomes are well studied and a host of molecular tools and commercially available antibody/probe/array tools exist to support analytical work. Despite possessing a host of attractive attributes, their use in PTB research remains comparatively limited. Primates possess elevated sentience, resulting in their use in experimental studies constituting an ethically difficult question. They are expensive, require substantial environmental enrichment,

are at times aggressive and are also a potential source of zoonotic disease, all of which necessitate specialized housing and care and dedicated, experienced technical staff (Wolfenson and Lloyd, 2003). Although amenable to chronic instrumentation and surgical interventions, they require significant suppression of labor postoperatively and extended postoperative recovery times which may introduce a potential source of experimental confounding in addition to posing additional cost to the investigators (Gravett et al., 2007).

Sheep have traditionally proved a valuable model in which to study fetal physiology, respiratory development and the development of neonatal ventilation techniques. More recently, sheep have been employed in the study of the infectious and inflammatory origins of PTB and in the development of antibiotic therapies for PTB. Sheep can be selectively bred for single pregnancies by adaptation of the ewe's nutritional plane and have a gestational length of 144–150 days (the average is 147 days) (Wolfenson and Lloyd, 2003) which enables longitudinal sampling and the analysis of the effects of chronic fetal exposure to pharmaceutical compounds and infectious agents. Both the ewe and fetus are well suited to a range of surgical interventions, ultrasound-guided injections, and studies requiring long-term catheterization (Meschia et al., 1969; Newnham et al., 1989). Sheep are easy to handle once an appreciation of flock behavior is gained and show a remarkable resilience to surgical interventions. The disadvantages of using sheep as an experimental model relate primarily to their size and their historical status as a production rather than laboratory animal. Sheep require large landholdings to breed, specialized housing facilities and are, relative to rodent models, expensive to purchase and slow to reach sexual maturity (ewes may be mated at 6 months of age assuming 70% of adult body weight has been achieved) (Wolfenson and Lloyd, 2003) and breed. From a postoperative care perspective, sheep are adept at disguising pain, making assessment of pain difficult. Sheep are well characterized from a physiological and parturition perspective but their immunology and genome is much less well understood. The pronounced lack of commercially available molecular and protein-based tools available to perform analyses on sheep tissues constitutes an additional drawback.

6 ANIMAL MODELS OF INFECTION-ASSOCIATED INFLAMMATION

As will be discussed, animal studies addressing the form and origins of PTB-associated inflammation have utilized nonviable microbial agonist (i.e., *E. coli* lipopolysaccharides or synthetic TLR3 agonist poly I:C), viable microorganisms (i.e., *Ureaplasma* spp., *C. albicans*,

F. nucleatum, Group B streptococci), or inflammatory cytokines and chemokines (i.e., IL-1, IL-8, TNF-α) to directly and indirectly induce inflammatory changes in gestational tissues (the fetus, uterus, and placenta) with a view to investigating fetal injury responses, patterns of uterine activation and perinatal outcomes. The use of purified bacterial or synthetic TLR agonist allows for assessment of the inflammatory response derived from the activation of a discrete set of PRRs (such as TLR-4 activation by *E. coli* LPS or TLR-3 activation by poly I:C) but is artificial in the sense that in utero inflammation is likely caused by more than one microbial agonist. The use of intact heat-killed bacteria (including *E. coli* and Group B Streptococci) may, on the basis that many PRRs act synergistically, provide a more translatable response and controls for growth-related variation in bacterial stimulation; however, the presence of multiple potential agonists may complicate investigations into pathway-specific signaling in the induction of subsequent inflammation.

The use of viable microorganisms including *F. nucleatum, U. parvum,* or *C. albicans* may provide the most translatable model of fetomaternal inflammation, and is certainly appropriate when antimicrobial and antiinflammatory interventions are being tested. However, there are a number of potential complications to be controlled for in the study design, as host-dependent variations in microbial growth and tissue colonization in utero may greatly increase the variability of experimental data. As with the choice of a particular animal model with which to assess inflammation, we suggest that the choice of agonist employed needs to be selected with reference to the specific objectives of the experimental model. Purified agonist is likely of most use when investigating specific inflammatory responses to identify potential signaling control points for therapeutic intervention, and live microorganism is an appropriate choice when seeking to assess the therapeutic efficacy of a combined antibiotic and antiinflammatory intervention.

6.1 Cytokine and Chemokine-Based Models of Intrauterine Inflammation

The elevated expression of proinflammatory mediators in gestational tissues, amniotic fluid, and cord blood is associated with both preterm labor and adverse perinatal outcomes (Gomez et al., 1998; Gotsch et al., 2007). Accordingly, a number of investigators have focused on specific cytokines and chemokines as the basis of in vivo experiments to investigate the role played by individual proteins in the induction of these two processes. Of these, IL-1 (Kallapur et al., 2009, 2013; Leitner et al., 2014; Romero and Tartakovsky, 1992; Romero et al., 1991; Sadowsky et al., 2006; Wang et al., 2006), IL-6 (Robertson et al., 2010; Sadowsky et al., 2006; Wakabayashi et al., 2013), IL-8

(Cheah et al., 2009; Sadowsky et al., 2006), and TNF-α (Ikegami et al., 2003; Sadowsky et al., 2006) have received particular attention.

There is good evidence to suggest an important role for IL-1 in PTB. Expression of precursor IL-1β is induced following PRR signaling induction. Precursor IL-1β then undergoes caspase-1-mediated proteolytic cleavage before being secreted as mature IL-1β. In human cord blood monocytes, overexpression of IL-1β is controlled by inhibition of precursor IL-1β production and the downregulation of TLR-mediated NLRP3 expression, of which caspase-1 is a component (Sharma et al., 2015). The mature forms of both IL-1α and IL-1β bind to the widely expressed IL-1 receptor 1 (IL-1R1). IL-1R2, which has a more restricted pattern of expression (neutrophils, monocytes, and B cells), acts as a signal transduction-deficient decoy due to the absence of a cytoplasmic tail (Nadeau-Vallée et al., 2016). Binding of ligand to IL-1R1 induces accessory protein recruitment leading to the translocation of signaling pathway intermediates including MyD88, TRAF6, and IL-1 receptor-associated kinase 4, resulting in MAPK and or NF-κB activation (Sims and Smith, 2010).

Unlike IL-1β, IL-1α is primarily an intracellular mediator and is seldom released to the extracellular environment unless cell damage occurs (Werman et al., 2004). IL-1α is constitutively expressed in a wide variety of cell types and functions as an early responder to an inflammatory stimulus, acting before IL-1β to initiate an immune response (Idan et al., 2015). IL-1α also differs from IL-1β in that it is biologically active in its precursor form. Work by Werman et al. (2004) demonstrated that TLR stimulation induces translocation of precursor IL-1α to the nucleus where it has the ability to activate NF-κB and AP-1. Subsequent studies have demonstrated that IL-1α is an important early responder to DNA damage, hypoxia, or heat shock (Idan et al., 2015).

Increases in amniotic fluid IL-1β concentrations have been identified in women in labor at term and in infection-associated PTB (Nadeau-Vallée et al., 2016; Romero et al., 1989). Studies in several population groups have concluded that IL-1, IL-1R1, IL-1R2 polymorphisms modify the risk for PTB (Cui et al., 2015; Kayar et al., 2015; Langmia et al., 2015; Pandey and Awasthi, 2016; Schmid et al., 2012). Accordingly, IL-1 is of interest in terms of both PTB etiology and as a potential therapeutic intervention point. However, whether IL-1 plays a role in all PTB phenotypes, or only those induced by infection, remains unclear. Wei et al. (2010), for example, performed a metaanalysis of the association between common inflammatory cytokines and spontaneous PTB as an outcome in asymptomatic women. Their findings demonstrated an association between IL-6 and C-reactive protein (CRP), but did not identify a PTB association for a number of common inflammatory mediators including IL-1, IL-2, IL-8, IL-10, and TNF-α. It

is important to note, however, that this conclusion may be due to the small number of studies involving these mediators that were included in the metaanalysis (Wei et al., 2010). In contrast, cervical concentrations of IL-1β were shown to be elevated in a cohort of symptomatic women (22–33 weeks' gestation) with intact membranes who delivered preterm (Edwards et al., 2006). A metaanalysis of IL-1β gene variants in four ethnicities (Caucasian, African American, Hispanic, Asian) from the USA, China, and Chile revealed an association between IL-1 genotype pattern and moderate to severe periodontitis (itself associated with an increased risk of PTB) with an odds ratio of 1.95 ($P < 0.001$) (Wu et al., 2015). Additional work in a Turkish population has reported a potential association between IL-1 receptor antagonist (IL-1ra) allele 2, periodontal disease, and previous PTB, or low-birth weight delivery (Kayar et al., 2015).

In addition to investigations based on human clinical samples, animal studies have made a substantial contribution to our understanding of the role of individual cytokines and chemokines in PTB and fetal injury. Work by Romero et al. (1991) describing the systemic administration of IL-1 to pregnant, C3H/HeJ LPS resistant mice revealed that IL-1 induces preterm delivery in pregnant mice via interaction with the IL-1 receptor (Romero and Tartakovsky, 1992). Interestingly, studies undertaken by Hirsch et al. (2002) demonstrated that IL-1β is not an essential regulator of preterm labor induction in the mouse; mice lacking a functional IL-1 receptor were as equally susceptible to LPS-induced preterm labor as their wild-type counterparts (Hirsch et al., 2002). Genetically modified mouse models allow detailed studies of the molecular pathways underlying inflammation and PTB. An excellent example of this is work by Hirsch et al. (2002, 2006), who utilized a double knockout (Il1r1/Tnfrsf1a) mouse model to demonstrate marked reductions in the rate of PTB even at high (1.4×10^8) doses of intraamniotic heat-killed *E. coli*. This study is of particular interest as it serves both to highlight the importance of multisystem signaling in infection-derived inflammation and PTB and also suggests that cytokine signaling (in this case IL-1 and TNF-α) constitutes an appropriate therapeutic target for pharmacological intervention. Interestingly, at the highest dose delivered (7×10^8–1.4×10^9 heat-killed *E. coli*) there was no difference in the rate of preterm delivery between wild-type and double-knockout groups. Although this may be attributable to confounding following the exclusion of most of the double knockout group on the basis of maternal shock, it may also suggest that targeting cytokine pathways may only be efficacious up until a certain infectious or inflammatory load has been reached.

Reznikov et al. (1999) employed a IL-1β knockout mouse model to study the mechanistic role of IL-1β signaling in the induction of preterm labor. Intracervical

E. coli or LPS was administered to C57BL/6J wild-type and IL-1β knockout mice at 70% of term gestation. PTB was initiated within 36 h of inoculation in 90%–100% of both groups of animals studied. Control animals treated with saline did not exhibit preterm delivery of pups. Interestingly, although analysis of infected IL-1β knockout mice demonstrated lower levels of cytokine expression, pregnancy loss rates were not reduced (Reznikov et al., 1999). These data suggest that an intervention for infection-derived preterm labor may require the control of IL-1 family signaling (in addition to the control of other proinflammatory cytokines/chemokines) as opposed to controlling the expression of an individual cytokine.

In a study of chronically instrumented rhesus monkeys (*Macaca mulatta*), Sadowsky et al. (2006) demonstrated that infusions of IL-1β resulted in significant increases in amniotic fluid concentrations of IL-6, IL-8, TNF-α, prostaglandins, MMP9, histologic chorioamnionitis, coordinated uterine contractions, and preterm delivery. TNF-α infusions generated a similar response pattern, but with smaller increases in amniotic fluid prostaglandin concentrations and preterm delivery in only two of five animals. Interestingly, although both IL-6 and IL-8 were upregulated in response to IL-1β and TNF-α, infusion of these mediators alone (albeit in only two animals per group) was insufficient to provoke the induction of preterm labor, but did induce histologic chorioamnionitis (Sadowsky et al., 2006). In earlier work employing in a sheep model of pregnancy, Ikegami et al. (2003) demonstrated that preterm fetal sheep exhibit only a minor inflammatory response to TNF-α, but a comparatively pronounced response to IL-1α. Subsequent work, again in the sheep, demonstrated that IL-1α signaling was involved in intestinal injury and caused disruption to the maturation of the fetal gut (Nikiforou et al., 2016). More recent work by Kallapur et al. (2013) demonstrated a similarly strong proinflammatory response in rhesus monkeys given intraamniotic injections of IL-1β. The investigators reported substantial increases in histologic chorioamnionitis, neutrophil infiltration of the fetal airways, and increased pulmonary surfactant and cytokine mRNA expression. Of interest in this study was the observation that IL-1β administration was associated with a perturbation of the frequency of CD4⁺FOXP3⁺ cells in the CD4⁺CD3⁺ cell population (predicted to be T-regulatory cells) in the mediastinal and mesenteric lymph nodes and the spleen at 24 h post-IL-1β administration. A transient increase in the frequency of IL-17⁺ T cells was also identified (Kallapur et al., 2013). These data are in keeping with clinical observations demonstrating that CD4⁺ T cells collected from extremely preterm infants have a strong IL-17 bias (Black et al., 2012). The importance of these findings relates to an appreciation for the importance of CD4⁺ T cell polarization during pregnancy.

An increasing body of data exists to suggest that the balance of Th1 (CD4⁺ T cells polarized by IL-12 and characterized by prodigious interferon-γ production), Th2 (CD4⁺ T cells polarized by IL-4 and characterized by the expression of several cytokines including IL-4, -5, and -6 and IL-13), T-regulatory (CD4⁺CD25⁺FOXP3⁺ T cells) and Th17 (CD4⁺ T cells polarized under the control of transforming growth factor β, IL-6, IL-21, and IL-23 that express IL-17a and IL-17f) is critical to the maintenance of pregnancy (Polese et al., 2014). For example, a decrease in T-regulatory cells has been linked with abortion in human pregnancy and that Th17 cells may promote inflammation at the fetomaternal interface in PTB (Polese et al., 2014). For a comprehensive review of T cell regulation in pregnancy see Polese et al. (2014).

In a sheep model of pregnancy, use of recombinant IL-1ra in combination with LPS-driven TLR-4 stimulation showed the importance of IL-1 signaling chorioamnionitis and lung maturation; the use of IL-1ra significantly inhibited, but did not entirely resolve fetal lung and systemic inflammation (Kallapur et al., 2009). Arguing for a central role for IL-1 in the induction of infection-associated PTB, Nadeau-Vallée et al. (2016) have developed a noncompetitive peptide termed rytvela which functions to selectively inhibit IL-1β signaling in an NF-κB-independent fashion. Data from a number of elegant in vitro and murine studies suggested that rytvela acts by inhibiting the p38, JNK, c-jun, and the Rho/ROCK pathways (Nadeau-Vallée et al., 2015). Rytvela has shown promise for prolonging labor and reducing the magnitude of intrauterine inflammation. When administered to mice in combination with bacterial agonists TLR2 and TLR4 or recombinant IL-1β it has exhibited strong inhibitory effects; however, as with other inhibitors tested to date, it does not entirely resolve inflammatory activation or completely prevent preterm labor.

Wakabayashi et al. (2013) reported a similar pattern of findings in murine experiments with the anti-IL-6 receptor antibody MR16-1; administration of this inhibitor prior to LPS treatment lowered, but did not inhibit preterm delivery. Studies undertaken in C57BL/6 *IL6* knockout mice by Robertson et al. (2010) demonstrated that IL-6 is likely an important, but nonessential factor in the induction of labor either at term or preterm. These experiments demonstrated a significant delay in term labor in *IL6⁻/⁻* mice of around 24 h, a reduction in the ability of LPS to induce preterm labor, and a reduction in the number pups that died in response to LPS exposure (Robertson et al., 2010). Given changes in genes involved in uterine activation (e.g., oxytocin receptor) relative to wild-type animals, combined with an absence of change in serum progesterone levels in *IL6⁻/⁻* mice, the authors concluded that IL-6 acts within the uterus to regulate genes important to uterine activation (Robertson et al., 2010). In addition to suggesting the importance of

specific inflammatory mediators, such as IL-1β and IL-6 in the induction of preterm labor, these data from animal studies also suggest that any potential intervention will likely have to account for the action of multiple cytokines and redundancy in cytokine signaling to prevent fetal injury and PTB.

6.2 Microbial Agonist

A number of animal models based around the intravenous, intraamniotic, intraperitoneal, or intracervical administration of LPS from *E. coli* or *P. gingivalis* have been employed to explore the causal relationship between infection, inflammation, and PTB. Each model is useful for unpacking slightly different elements of the PTB-infection paradigm. Intraamniotic models allow the analysis of direct exposure of agonist to the gestational tissues and fetus; cervical models are useful in studying inflammatory signaling arising from vaginal dysbiosis or ascending infection; intravenous and intraperitoneal studies allow the assessment of the impact of systemic maternal inflammation and, in the cause of intravenous systems, hematogenous spread on pregnancy well-being.

Studies undertaken in the early 1990s by Collins et al. (1994a,b) demonstrated that the intravenous administration of LPS isolated from *E. coli* or *P. gingivalis* caused a dose-dependent inflammatory response and negatively affected fetal well-being in hamster models of pregnancy. In a series of elegant experiments performed by Hirsch et al., high doses of attenuated *E. coli* were injected into a ligated uterine horn of pregnant mice, resulting in localized induction of IL-1α, IL-1β, and IL-6 expression. The unligated horn, which did not receive *E. coli*, was subsequently induced to labor (Hirsch et al., 2002).

Studies in mice revealed that repeated, low doses of LPS [which does not readily cross cell–cell barriers (Romero et al., 1987)] administered via intraperitoneal injection resulted in preterm delivery and uterine inflammation in a cohort of 60 C3H/HeN × B6D2F1 mice. Together, these studies suggest that labor may be induced by systemic mediators, and even when the primary site of infection is at a distance from the gestational tissues. The scenario of "remote inflammatory activation" is supported by work undertaken in rhesus monkeys by Adams Waldorf et al. (2008). With the use of chronically catheterized animals, a Group B streptococci infection of the uterus was initiated, with subsequent analyses focusing on alterations to fetal development and the presence of intraamniotic inflammation (Waldorf et al., 2011). Of additional interest with regards the potentially infection-specific nature of PTB is subsequent work demonstrating, again in mice, that different isolates of *E. coli* LPS exert markedly different effects on inflammatory signaling, and fetal well-being (Migale et al., 2015).

The impact of direct exposure of the fetomaternal tissues has also received a significant amount of attention from investigators. Work undertaken in the 1990s by several groups demonstrated the induction of uterine inflammation and preterm delivery in a rabbit model following intrauterine administration of *E. coli* to does at 21 days (70% of term) gestation (Dombroski et al., 1990; Heddleston et al., 1993; McDuffie et al. 1991). Compounding the complexity introduced by apparent species-derived differences in LPS response is a recent appreciation of the differences in inflammatory response conveyed by alterations in the structure of LPS itself. Chang et al. (2010) employed a macaque explant model to investigate changes in cytokine, chemokine, prostaglandin, and TLR expression in response to LPS structural variants. First demonstrating consistency in TLR expression, they demonstrated the macaque amniochorion could distinguish between LPS variants—suggesting that some strains of a particular microorganism may be more adept at inducing an inflammatory response, fetal injury, and PTB than others (Chang et al., 2010).

Identifying the tissues responsible for driving intrauterine inflammation is an important step in efforts to develop interventions for PTB and fetal injury. Applying the observation that MyD88 is a critical mediator in TLR signaling; Filipovich et al. (2009) demonstrated an absence of preterm labor in MyD88 knockout mice following LPS challenge, whereas wild-type and TRIF knockout animals remained susceptible to LPS-induced preterm labor. Using rhesus macaques, the pretreatment of pregnant animals with a TLR-4 antagonist reduced proinflammatory cytokine expression and uterine contractility following LPS administration, relative to animals that received LPS alone (Adams Waldorf et al., 2008).

In sheep, selective exposure of *E. coli* LPS to the lung, gut, or oropharyngeal cavity has been demonstrated to induce a systemic fetal immune response characterized by changes in liver enzymes associated with injury, changes in LPS-isolated tissues, and alterations in cord blood immunocyte populations (Kemp et al., 2013; Maneenil et al., 2015a; Nikiforou et al., 2016; Wolfs et al., 2014). More recently, Kemp et al. (2016) demonstrated that in a sheep model of early pregnancy, acute systemic fetal inflammation is rapidly initiated by *E. coli* LPS stimulating amniotic fluid-exposed tissues (most notably the fetal lung), and that this acute response is not derived from cells in the fetal blood. A rabbit model has also been used to study the temporal relationship between histological inflammation and intraamniotic infection, illustrating that inflammation was present in the placenta and uterus 8 h after infection, and inflammation in the fetal lung 30 h after infection.

A similar pattern has been identified in a sheep model of pregnancy; intraamniotic injection of *E. coli* LPS

resulted in immunocyte infiltration of the chorioamnion by within 5 h, and increases in chorioamnion cytokine/chemokine mRNA by 15 h. Cytokine mRNA was increased in the fetal lung at 2 days postexposure, and evidence of lung maturation was apparent after 7 days (Kallapur et al., 2001). These studies suggest that inflammation and fetal injury is an evolving process rather than a "single strike" phenomenon. This observation may be of importance as it suggests that timely diagnosis of infection and treatment may allow for the prevention of preterm delivery and fetal injury. This phenomenon has been assessed in rhesus macaques by Grigsby et al. (2010), who concluded that choriodecidual inflammation occurs before premature ripening of the cervix, fetal membranes rupture, and eventual preterm labor.

One of the most interesting contemporary areas of study involving animal models involves assessment of the impact of subclinical intrauterine inflammation, partly in response to the identification of an association between intrauterine inflammation and an increased risk of developing cerebral palsy or other neurodevelopmental disorders in infancy. Burd et al. used RU486 (a progesterone antagonist) and LPS in a PTB mouse model to investigate the effect of PTB per se on the fetal brain. When administered individually at embryonic day 15, both agents induced PTB, however, only the LPS-induced animals demonstrated increases in neuronal damage and cytokine expression (Burd et al., 2010).

The impact of subclinical inflammation in term and preterm fetuses was then elegantly demonstrated by employing a low dose LPS (50 μg) model of intraamniotic inflammation in CD-1 mice. In this study, 30% of animals exposed to LPS at embryonic day 15 delivered preterm, compared with no preterm deliveries in animals exposed to LPS at embryonic day 18. At both gestational ages, 50 μg LPS exposure elicited an increase in IL-1β and TNF-α expression in the fetal brain, but no increase in IL-6. White matter injury was induced at both time points although the expression of glial fibrillary acid protein (GFAP, a 432 residue type III intermediate filament protein expressed in astrocytes and used as a marker of astrocytosis) was unchanged (Elovitz et al., 2011). A further study in term CD-1 mouse fetuses demonstrated aberrations in in vitro dendrite arborization and growth following in utero exposure to LPS (Burd et al., 2011). These studies suggest that although PTB may not occur, exposing the fetus to even relatively low levels of uterine inflammation early in gestation and, perhaps most surprisingly, close to term can lead to alterations in fetal neurological development and neurological injury. As such these recent findings highlight the need to control both the preterm induction of labor and uterine inflammation in an attempt to improve pregnancy outcomes.

Data from several studies suggest a potential role for virus-driven TLR3 signaling (agonized by ds-RNA) in PTB. Ilievski et al. (2007) used intraamniotic injections of the synthetic TLR3 agonist, polyinosinic:cytidylic acid (poly[I:C]) to demonstrate increased expression of interferon-β and PTB in one-third of mice treated intraamniotically at 75% gestation. Similar findings were reported by Koga et al. in a series of experiments involving wild-type (C57B/6) and TLR-3 knockout mice (Koga et al., 2009); maternal administration (intraperitoneal) of poly[I:C] had no effect in knockout animals, but induced preterm delivery in wild-type mice in a dose-dependent fashion (Koga et al., 2009). Interestingly, more recent work involving TLR-3 has suggested the existence of a synergistic, "double hit" mechanism wherein the simultaneous administration of peptidoglycan (a TLR-2 agonist) and poly[I:C] resulted in enhanced expression of proinflammatory mediators (IL-1β, TNF-α, CCL5) relative to the response elicited by either agonist in isolation (Ilievski and Hirsch, 2010).

Two subsequent papers by Racicot et al. have provided additional and important insights into the potential role of viruses in PTB. First, using a mouse model, maternal infection with murine γ-herpesvirus 68 (MHV-68) was shown to downregulate cervical TLR expression and cytokine/chemokine expression, relative to uninfected control. Interestingly, this observation correlated with both reduced cytokine/chemokine expression and increased ascending (intrauterine) infection when MHV-68-infected animals were challenged with *E. coli* or *U. urealyticum*. The authors concluded by proposing a role for viral infections in making the female reproductive tract more permissible for the transcervical passage of PTB-associated bacteria (Racicot et al., 2013). Second, the authors demonstrated that inhibition of the interferon-β signaling pathway results in impaired control of LPS-driven proinflammatory changes. In trophoblast cells, MHV-68 downregulated two transcription factors, STAT3 and Twist1—changes consistent with increased expression of inflammatory mediators when combined with TLR-4 activation by LPS (Racicot et al., 2016). Based on these data, a viral infection may play multiple roles in predisposing a pregnancy to preterm labor; by making the cervix more permissible to the passage of invading bacteria, and by increasing the subsequent proinflammatory response at the maternal–fetal interface.

6.3 Viable Infection

As discussed, the use of viable, PTB-associated microorganisms to study fetal injury and inflammatory activation of the uterus presents a number of challenges. It also affords the opportunity to investigate the role

of infection in PTB and the efficacy of potential anti-microbial and antiinflammatory interventions. Model systems describing the use of viable *Ureaplasma* spp., oral microbes, and *Candida* spp. will be covered in the present section.

Some of the earliest studies into the effects *Ureaplasma* spp. on pregnancy well-being were undertaken in early gestation sheep by Ball et al. (1985). *Ureaplasma* spp. infection and intraamniotic inflammation has also been demonstrated in a baboon model (Yoder et al., 2003). We have developed a sheep model of intraamniotic *Ureaplasma* spp. infection wherein chronic (70 day) and acute (1, 3, and 7) day exposures can be initiated and then sequentially sampled using ultrasound-guided injections. Using this model, we have demonstrated that intraamniotic injection of *Ureaplasma* spp. in early pregnancy induced statistically significant increases in fetal lung IL-1β mRNA expression 6 and 10 weeks after administration (Moss et al., 2005). We have also demonstrated that *Ureaplasma* spp. elicits a robust inflammatory response in the fetal skin characterized by increases in TNF-α and MCP-1 expression, but no changes in IL-1β or IL-8 expression as recorded in response to LPS exposure (Kemp et al., 2011). These data indicate that *Ureaplasma* spp. induces a far more variable and subtle inflammatory response than purified LPS, an observation in agreement with data obtained from studies of PTB in humans. Lending weight to the association of *Ureaplasma* spp. with PTB, work Novy et al. (2009) in a macaque model demonstrated increases in cytokine, MMP, and prostaglandin expression along with enhanced uterine activity in response to intraamniotic administration of *U. parvum*.

As noted previously, *Ureaplasma* spp. are the microorganisms most commonly isolated from cases of PTB. Novy et al. (2009) employed a macaque model to investigate the fetomaternal responses to intrauterine infection with *U. parvum* and *Mycoplasma hominum* infection. They demonstrated a correlation between amniotic infection and elevated MMP-9 activity, increased amniotic fluid cytokines, prostaglandins (E2 and F2a), and chorioamnionitis (Novy et al., 2009). We have previously demonstrated similar findings including lung inflammation, chorioamnionitis, and inflammation of the fetal skin in response to intrauterine *U. parvum* infection in sheep (Kemp et al., 2011; Moss et al., 2005, 2008). These data are in agreement with clinical findings and support the hypothesis that *Ureaplasma* spp. and *Mycoplasma* spp. are key microorganisms in PTB.

Maternal treatment with the macrolide antibiotic erythromycin is a standard clinical intervention for *Ureaplasma* spp. infection. Attempts to prevent PTB with maternally administered antibiotics during the third trimester of pregnancy have proven largely ineffective.

Inappropriate antibiotic use, antibiotic resistance, and a lack of maternal–fetal transfer, and continued inflammatory activation by nonviable microbial agonist are all potential reasons for these disappointing results to date. The ORACLE II trial, for example, compared perinatal outcomes in 6295 women (in spontaneous preterm labor with intact membranes and no evidence of clinical infection) randomly assigned to maternal amoxicillin clavulanate (coamoxiclav) or erythromycin, or both, or placebo, 4 times daily, orally for up to 10 days. Approximately 90% of participants were enrolled in the third trimester of pregnancy. No improvement in primary outcome measure (a composite of neonatal death, chronic lung disease, or major cerebral abnormality) was associated with antibiotic use compared to placebo (Kenyon et al., 2001). In contrast, recent metaanalyses demonstrated a statistically significant reduction in the risk of early PTB and increased average gestational age at delivery when macrolide antibiotics were administered to women with bacterial vaginosis before 22 weeks' completed gestation (Lamont et al., 2011).

We hypothesized that the inability of maternally administered antibiotics to resolve PTB may be derived from a lack of placental transfer, rather than microbial resistance to the antimicrobial agents used. Using a chronically catheterized sheep model, we generated data in third trimester sheep pregnancies to demonstrate that maternally administered erythromycin failed to reach therapeutic levels in utero due to poor placental transfer. Maternal administration of erythromycin achieved therapeutic maternal plasma macrolide concentrations (<0.5 μg/mL) with low concentrations in amniotic fluid equivalent to less than 7% transfer; fetal plasma levels were even lower (<1.5% transfer). In contrast, maternal administration of azithromycin during the second trimester of pregnancy has been demonstrated to result in significant fetal tissue accumulation and plasma levels in the sheep model (Kemp et al., 2014). These data are in keeping with additional studies demonstrating the efficacy of macrolide antibiotics azithromycin and solithromycin in eradicating amniotic fluid *U. parvum* infection in a sheep model of pregnancy (Kemp et al., 2014). Grigsby et al. employed a chronically catheterized macaque model to similarly address the question of placental transfer of maternally administered azithromycin and the clearance of *U. parvum* serovar 1 from the amniotic sphere. *U. parvum* serovar 1-infected macaques received maternal intravenous azithromycin (12.5 mg/kg) twice daily for 10 days. Repeated dosing yielded amniotic fluid azithromycin levels similar to that of maternal plasma and effective clearance of *U. parvum* serovar 1 from the amniotic environment (Grigsby et al., 2009).

A number of investigators have used a mouse model of pregnancy to study the impact of *F. nucleatum* on

pregnancy outcomes (Han et al., 2004; Liu et al., 2007; Stockham et al., 2015). Han et al. used a CF-1 mouse model of pregnancy to induce a transient bacteremia by intravenously administering *F. nucleatum*, resulting in PTB, and fetal demise. The authors demonstrated that *F. nucleatum* preferentially colonized the uterus by invading blood vessel endothelial cells in the placenta, proliferating in the surrounding tissues, and subsequently gaining access to the amniotic cavity (Han et al., 2004). Subsequent work in TLR4$^{-/-}$ knockout mice suggested that TLR-4 plays a primary role in *F. nucleatum*-driven inflammation signaling, and that inflammation, rather than the microbe itself was likely the primary cause of fetal demise (Liu et al., 2007). *P. gingivalis* is also implicated as a PTB-associated pathogen of oral origin. Miyoshi et al. used a mouse model to generate a chronic (6 weeks) odontogenic *P. gingivalis* infection, and then mated the animals to assess the impact of infection on inflammation, contractile apparatus, and pregnancy outcomes. Having previously demonstrated an association between shortened gestation and *P. gingivalis* infection relative to control (18.3 ± 0.9 days vs. 20.5 ± 0.5 days, respectively) (Ao et al., 2015), *P. gingivalis* colonies were identified in villus cells and amniotic epithelial cells in association with two- to threefold increases in serum IL-1β and TNF-α, and significant increases in myometrial oxytocin receptor and connexion 43 mRNA (Miyoshi et al., 2016) at 18 days gestational age.

A small number of studies have also investigated the impact of intrauterine *C. albicans* infection on fetal well-being in a sheep model of pregnancy (Maneenil et al., 2015b; Ophelders et al., 2016; Payne et al., 2014b; Stock et al., 2016). In these studies, infection with *C. albicans* was accompanied by marked fetal inflammatory responses, increased amniotic fluid cytokines, fetal cardiac dysfunction, but a lack of chorioamnionitis in both mid-late and early gestation pregnancies, highlighting the highly nuanced and organism-specific nature of responses to intrauterine infection.

Studies in macaques have demonstrated the potential for using combined immunomodulating and antibacterial agents to simultaneously prevent preterm labor and downregulate in utero inflammation. Gravett and Sadowsky demonstrated that an intraamniotic infusion of the nonsteroidal antiinflammatory drug (NSAID) indomethancin suppressed uterine contractility (ostensibly via reduced prostaglandin expression in utero) in chronically catheterized macaques exposed to intraamniotic IL-1β. Interestingly, indomethacin did not resolve the amniotic fluid leukocytosis or levels of proinflammatory cytokines IL-1β, IL-8, or TNF-α (Sadowsky et al., 2000). Similar findings were derived from a subsequent study employing dexamethasone and IL-10 to control uterine contractility following IL-1β infusion in chronically

catheterized macaques (Sadowsky et al., 2003). More recently, the same investigators used ampicillin in conjunction with dexamethasone and indomethacin to successfully resolve Group B *Streptococcus* infection and limit the expression of IL-1β, TNF-α, prostaglandin E2 and F2α (Gravett et al., 2007). Despite this, chorioamnionitis was unresolved and the expression of MM-9 (a key agent in cervical remodeling and fetal membrane degradation) remained elevated.

7 SUMMARY

Animal models, including rodents, nonhuman primates, and sheep have played a key role over the past 2 decades in allowing the advancement our understanding of the pathophysiological mechanisms underlying PTB. These studies have: (1) demonstrated the proinflammatory role of microorganisms in human preterm labor, (2) provided clarification on the route(s) by which uterine infection may occur, (3) identified the innate immune signaling pathways involved in the induction of preterm labor via modulation of prostaglandin metabolism and structural alteration of the fetal membranes and the cervix, (4) demonstrated the importance of controlling fetomaternal inflammation, not just as a means of preventing PTB but also to protect the fetus, and (5) offered insight into how antibiotics and antiinflammatory agents may be used in combination to develop interventions for PTB.

8 PRACTICAL STUDY—FETAL SURGERY IN THE SHEEP

The sheep is a uniquely versatile model organism; its size, resistance to labor following surgery and inflammatory agonist exposure allows for the surgical isolation of maternal and fetal tissues and the chronic catheterization of maternal and fetal circulations and the amniotic cavity. The remainder of this chapter will focus on providing an introduction to a number of the key issues relating to performing aseptic, recovery surgery in pregnant sheep. This section will begin with a discussion of the perioperative management of sheep, and provide an introduction to the anesthetic and analgesic management of animals. An important point to note at this juncture is that rigorous perioperative management of pregnant sheep is as *absolutely critical* to the success of a surgical study as is the conduct of the surgery itself. In this regard, we cannot overemphasize the importance of gaining an appreciation for sheep behavior (both in flock and pen environments) to accurately assess animal welfare and analgesic requirements in the postoperative phase of a study.

8.1 Anesthesia of Pregnant Sheep

8.1.1 Planning

Preparation of pregnant sheep for general anesthesia and surgery begins well before the day of surgery: transport from the farm of origin and acclimatization to the research facility must be carefully planned to minimize the stress associated with a change in feed, climate, company, and daylight hours. Transport from the farm of origin or the field should be no later than 100 days gestation and pregnant sheep should not be starved prior to transport. The veterinary inspection prior to transport must include assessment of body condition score as underweight pregnant sheep are more prone to pregnancy toxemia.

8.1.1.1 INTRODUCTION TO THE ANIMAL FACILITY

The institutional procedures for introduction of sheep to the facility should be adhered to with particular emphasis on low stress handling of pregnant sheep. Communal pens will maintain the dynamics of the sheep group so they should be housed as such until the day prior to surgery. This acclimatization period should be at least 7 days. On the day prior to surgery the ewes should be introduced to single pens, which are large enough for them to turn around in. They should always have at least one other ewe adjacent to them. A sudden change of available feed may decrease caloric intake and this may be detrimental to the pregnant ewe and the fetus. Introducing the feed that will be available in the research facility at the farm of origin may help familiarize the sheep with the different substrate. The ration should be carefully calculated to ensure it meets the requirements of pregnancy and decreases the risk of metabolic disorders.

8.1.1.2 PREGNANCY TOXEMIA

Pregnancy toxemia is a potentially fatal metabolic disorder of glucose and fat metabolism in sheep, which usually occurs spontaneously in the last 3 weeks before parturition (Schlumbohm and Harmeyer, 2008). While ewes with multiple fetuses are more commonly affected, the disease can occur in singleton pregnancies as well. The clinical signs of the disease may take a few days to develop and include weakness, drowsiness, sluggish behavior, and apparent blindness. These signs may deteriorate to recumbency, tremors, spasms, and death. A combination of low plasma glucose concentration and increased plasma concentration of ketone bodies characterize the disease (Van Saun, 2000) and occur as a result of inadequate energy intake in the face of growing energy demands of the developing fetus(es). The pathophysiology, however, is complex and several preventative measures must be taken to reduce the risk of this disease. Preventative measures include: avoid interruptions to feed intake (e.g., transport-associated stress), ensure a suitable body condition score prior to transport, utilize singleton ewes where possible, and monitor food intake during the acclimatization period. Treatment is more likely to be successful if a timely diagnosis is made and an energy source is administered to sick animals (Brozos et al., 2011). Oral or injectable glucose solutions can be administered in the short term but veterinary advice should be sought urgently.

8.1.1.3 HYPOCALCEMIA

An increase in calcium demand by a fetus may overwhelm the ewe's calcium homeostasis mechanisms and cause a drop in plasma calcium concentration (Larsen et al., 1986). Late pregnant ewes are particularly susceptible to this metabolic disorder and prompt and aggressive treatment may be required. The clinical signs of hypocalcemia usually develop relatively rapidly and include tremors, a stilted gait and generalized weakness. Death may ensue within hours. Preventative measures should always be considered when working with pregnant sheep: avoid interruptions to feed intake (e.g., transport-associated stress) and supplement calcium, especially if the diet is low in calcium. Oral administration of a calcium solution, such as Unimix (The Mackinnon Project, Werribee, Victoria, Australia) prior to transport or as part of the introduction to the facility has been incorporated into the standard operating procedures of the authors' institution to decrease the risk of hypocalcemia. The pathophysiology of this metabolic disorder is complex and treatment should be administered promptly and in accordance with veterinary advice. Hypocalcemia is potentially fatal and as it often occurs as a result of nutritional stress, it is commonly associated with pregnancy toxemia. Preventative measures taken for one disease, invariably apply to both.

8.1.1.4 LAMINITIS

As sheep transition from a farm environment to a research facility their diet changes from a cellulose-based diet to a more readily digestible starch-based diet. If this change is abrupt ruminal acidosis may develop. Ruminal acidosis may manifest as laminitis, which is a painful condition of the hooves. Laminitis refers to inflammation of the laminae of the hoof wall and presents with reluctance to stand or move. The hooves may feel warm and the animal may overreact to pressure applied to this area. The condition is painful so, while the underlying cause should be addressed, the administration of analgesia is essential. Treatment of

the underlying cause is focused on modification of the diet to increase the intake of lucerne hay and chaff (at least matchstick length) and limit the intake of grain or pelleted feed. Oral sodium bicarbonate may be administered under veterinary direction to alter the pH of the rumen. For analgesia buprenorphine is suitable and a single dose of a nonsteroidal antiinflammatory may be appropriate. Analgesia should be administered under veterinary direction.

8.1.2 Anesthetic Considerations for Pregnant Sheep

General anesthesia causes a range of major physiological alterations and in combination with pregnancy there are a number of specific considerations, which require attention when planning anesthesia for pregnant animals. These considerations relate to the global increase in oxygen consumption and decreased functional residual capacity of the lung during pregnancy. Furthermore, during pregnancy, the mean arterial blood pressure (ABP) is lower and the heart rate and cardiac output are higher than during the nonpregnant state. Pregnant animals also have an increased blood volume and a dilutional anemia. These changes contribute to an increased risk of hypotension, hypercapnia, and hypoxemia during general anesthesia. It is important that these physiological parameters are monitored and managed for the well-being of both the ewe and the fetus.

8.1.3 Preanesthetic Preparation, Assessment, and Premedication

Preanesthetic fasting is routine for ruminants but during pregnancy it is preferable to maintain caloric intake prior to anesthesia and allow access to food and water up until the administration of preanesthetic medication. This approach will minimize the risk of perioperative pregnancy toxemia and hypocalcemia, and will contribute to an uneventful recovery from anesthesia and surgery. However, the anesthetic complications associated with a full rumen include: regurgitation of rumen contents and the risk of aspiration; rumen bloat; a decrease in functional residual capacity as a result of the weight of the rumen on the diaphragm, especially in dorsal recumbency; hypoventilation; and decreased cardiac output due to decreased venous return. These potential complications can be managed by ensuring placement of an appropriately sized cuffed endotracheal tube promptly after induction of anesthesia, monitoring, and management of rumen bloat, intermittent positive pressure ventilation during anesthesia and appropriate cardiovascular support during anesthesia (e.g., intravenous fluid therapy).

On the morning of anesthesia and surgery, the ewe should be examined. This preanesthetic assessment should include observation of the ewe from a distance to subjectively assess demeanor, comfort, and gait. Objective measurements of rectal body temperature, heart rate, respiratory rate, and character should also be made. If the preanesthetic assessment is satisfactory a tranquilizing combination of drugs should be administered as a "premed." This preanesthetic medication provides anxiolysis, mild tranquilization, and preemptive analgesia and will facilitate a smoother induction of and recovery from anesthesia. Premedication should also make physical restraint for placement of an intravenous catheter less stressful for both the ewe and personnel. The premedication combination of drugs should be administered by intramuscular (IM) injection 30–40 min prior to induction of anesthesia unless α_2 adrenoreceptor agonist drugs are being used. In this case the premed can be given just 10–15 min prior to induction of anesthesia. It is best to leave the ewe in the same room as other ewes until the latest possible moment. Isolating her will cause significant stress. The induction of anesthesia should occur a short distance from the housing area to minimize the stress of being alone. Table 30.1 includes drugs that can be used for premedication. The dose of drugs should be calculated according to lean body mass. If the sheep have significant wool growth then this should be considered when estimating their actual weight from the weight given by reliable scales.

8.1.4 Induction of Anesthesia

Following premedication, the ewe should be tranquilized or sedated, and can be transported to the anesthetic induction area. The ewe should be restrained in the "shearing position" (Fig. 30.1A). The wool over the cephalic vein should be clipped and the site prepared for aseptic placement of an intravenous catheter. The person restraining the ewe will occlude the vein by placing pressure over it as it traverses the radius and ulna, close to the elbow joint (Fig. 30.1B). This occlusion will "raise" the vein to facilitate identification and catheterization. An 18 gauge catheter can be placed in most pregnant ewes (Fig. 30.1C). The catheter should be secured in place with adhesive tape and flushed with 3–5 mL of heparinized saline (5 IU/mL heparin in 0.9% NaCl).

Once the catheter is placed, secured and flushed intravenous anesthetic induction drugs can be administered. Drugs that can be used for induction of anesthesia are listed in Table 30.2. Immediately after induction of anesthesia, an oral endotracheal tube is placed. The positioning of the ewe is important to ensure that saliva or regurgitated rumen contents are not aspirated. The neck should be extended and the tongue must be withdrawn (Fig. 30.2A). A laryngoscope is used to facilitate placement of the endotracheal tube by optimizing the view of the larynx. A long straight laryngoscope blade is used

TABLE 30.1 Premedicant Drugs for Use in Pregnant Sheep Prior to General Anesthesia

Drugs	Dose	Comments
Acetylpromazine (phenothiazine tranquilizer)	0.01–0.04 mg/kg SC or IM	Mild tranquilizer when used alone, moderate tranquilizer when used in combination with an opioid
		Causes a dose-dependent decrease in arterial blood pressure due to vasodilation
		Long duration of action (~6 h)
Buprenorphine (partial μ agonist opioid)	0.01–0.02 mg/kg IM	Moderate tranquilization occurs when combined with acepromazine
		Provides preemptive analgesia
		Long duration of action (~6–8 h)
Morphine (pure μ agonist opioid)	0.1–0.3 mg/kg IM	Moderate tranquilization occurs when combined with acepromazine
		Provides preemptive analgesia
		Moderate duration of action (~2–4 h).
Xylazine (α₂ adrenoreceptor agonist)	0.1–0.3 mg/kg IM	Heavy sedation, especially when combined with an opioid
		Provides some analgesia.
		May cause pulmonary edema in sheep
		Short duration of action (~1 h).
		Side effects include hyperglycemia, hypotension, hypoxemia, and cardiac arrhythmias
		Can be reversed with yohimbine or atipamezole
Medetomidine (α₂ adrenoreceptor agonist)	10–30 μg/kg IM	Heavy sedation, especially when combined with an opioid
		Provides some analgesia
		May cause pulmonary edema in sheep
		Short duration of action (~1 h).
		Side effects include hyperglycemia, hypotension, hypoxemia, and cardiac arrhythmias
		Can be reversed with yohimbine or atipamezole

IM, Intramuscular; SC, subcutaneous.

and the tip of the blade is positioned to depress the base of the tongue and allow a good view of the arytenoid cartilages. The endotracheal tube must have an inflatable cuff to create a seal within the lumen of the trachea. An 8–8.5 mm cuffed endotracheal tube is appropriate for a 50–60 kg ewe.

To confirm correct placement of the endotracheal tube in the trachea, there are a few tests which should be performed: visualize the passage of the endotracheal tube over the epiglottis and between the arytenoid cartilages, attach a capnograph to ensure carbon dioxide is detected during expiration, observe condensation on the inside of the tube, observe the displacement of wool fibers held at the end of the tube during inspiration and expiration. Once correct placement is confirmed, secure the tube in place with a gauze tie and inflate the cuff. Do not move the animal until the tube is secured and the cuff has been inflated.

To optimize conditions for successful tracheal intubation, the animal must be adequately anesthetized. Trauma to the larynx, laryngospasm, and laryngeal edema are all more likely if the patient is inadequately anesthetized. Consider giving more of the intravenous induction agent or, in the instance of using midazolam or diazepam and ketamine, wait another 15–30 s to allow the drugs to have their full effect. A long straight blade laryngoscope with a light is also essential in this species. The position of the neck has been discussed but subtle changes can alter the view of the larynx considerably so instruct the person restraining the animal accordingly. Suction may also be helpful as saliva can accumulate around the larynx if there is a delay to intubation. Regurgitated rumen material can also present a risk of aspiration, but the potential for active regurgitation is less if the depth of anesthesia is adequate.

8.1.5 Maintenance of Anesthesia

The best option for maintenance of anesthesia in pregnant sheep is delivery of an inhalational anesthetic agent, such as isoflurane or sevoflurane in 100% oxygen. An anesthetic machine with a circle breathing system and a mechanical ventilator is required and this should be assembled and leak tested prior to induction of anesthesia.
FIGURE 30.1   (A) Restraint in the "shearing position." (B) An assistant occludes the cephalic vein to facilitate identification of the vessel and placement of the intravenous catheter. (C) An intravenous catheter placed in a cephalic vein for administration of anesthetic induction drugs and intraoperative fluid therapy.

The breathing system is connected to the endotracheal tube and an initial fresh gas flow of 2 L/min and an appropriate vaporizer setting should be set. The vaporizer setting should then be adjusted according to clinical assessment of anesthetic depth with an understanding of the physicochemical properties of the agent being used (Table 30.3). Maintenance of anesthesia at 1.5 x MAC is standard.

The use of nitrous oxide as part of the carrier gas for sheep is controversial. Nitrous oxide has a very low blood:gas partition coefficient so rapidly moves from the blood to gas filled cavities in the body, including the

TABLE 30.2   Anesthetic Induction Drugs for Use in Pregnant Sheep. The Authors' Preference is Midazolam or Diazepam and Ketamine

Drugs	Dose	Comments
Propofol (phenol)	4–6 mg/kg IV	No analgesia
		Rapid onset and short duration of action
		Postinduction apnea may occur for 3–5 min
		May cause a decrease in blood pressure due to vasodilation
Alfaxalone (steroid anaesthetic)	1–2 mg/kg IV	No analgesia
		Rapid onset and short duration of action
		Postinduction apnea may occur for 3–5 min
		May cause a decrease in blood pressure due to vasodilation.
Midazolam or diazepam and ketamine (benzodiazepine and a dissociative anaesthetic)	0.25 and 5 mg/kg IV	Delayed onset of action (~30–60 s)
		Ketamine has analgesic properties
		Maintenance of heart rate and blood pressure
Thiopentone (barbiturate)	6–10 mg/kg IV	No analgesia
		Rapid onset of action
		May cause a decrease in blood pressure due to vasodilation
FIGURE 30.2   (A) Placement of an endotracheal tube after induction of anesthesia. The neck is extended and the tongue is withdrawn. A long straight bladed laryngoscope is used to help visualize the larynx. (B) Positioning of the head and neck during general anesthesia is essential to facilitate drainage of saliva and regurgitated material away from the larynx. A bucket is used to collect this fluid, which may be a significant volume after 2 h of anesthesia. (C) Profuse salivation is normal for sheep.

rumen. Given this property of nitrous oxide there is a theoretical concern, at least, that the inclusion of nitrous oxide in the carrier gas will exacerbate rumen bloat and compromise both venous return to the heart and therefore cardiac output, and decrease the functional residual capacity of the lungs. The argument for using nitrous oxide is that through the second gas effect it will increase the speed of uptake of other inhalant anesthetic drugs, such as isoflurane, and it may have analgesic properties. If nitrous oxide is included in the carrier gas, it should be no more than 70% and no less than 50% of the fresh gas flow. Hypoxemia is a common complication of general anesthesia in pregnant sheep so 100% oxygen as the carrier gas is often required, precluding the use of nitrous oxide.

8.1.5.1 MECHANICAL VENTILATION

Intermittent positive pressure ventilation during general anesthesia of pregnant sheep will achieve a stable plane of anesthesia, adequate oxygenation, and ventilation and

TABLE 30.3   Physical and Chemical Properties of Isoflurane and Sevoflurane in Pregnant Sheep

Physicochemical property	Isoflurane	Sevoflurane
MAC (%) in pregnant sheep (Okutomi et al., 2009)	1.02 ± 0.19	1.52 ± 0.15
Blood:Gas partition coefficient	1.46	0.68
Boiling point (°C)	49	59
Saturated vapor pressure at 20°C (mmHg)	240	160

may help prevent lung collapse associated with positioning (Dugdale, 2007). It is routine to use a mechanical ventilator throughout anesthesia to achieve normocapnia and prevent hypoxemia. Ventilator settings will vary between models but delivering a tidal volume between 10 and 15 mL/kg to a peak inspiratory pressure no greater than 20–25 cmH$_2$O at a rate to achieve normocapnia (end-tidal CO$_2$ of 35–45 or ~4.6–5.8 kPa) should be appropriate for the majority of animals (Davis and Musk, 2014). Monitoring the adequacy of ventilation is covered in Section 9.13.

Efficient mechanical ventilation will only be possible if the animal is adequately anesthetized. If resistance to breaths is observed (bucking the ventilator), the depth of anesthesia should be assessed carefully and adjusted accordingly. Neuromuscular blockade may be required, but in this species it is not usually necessary. Atracurium and pancuronium are nondepolarizing neuromuscular blocking agents that could be used for this purpose. These drugs should only be administered by personnel familiar with their clinical effects, when adequate monitoring of the depth of anesthesia can be performed, and when intermittent positive pressure ventilation can be provided.

8.1.5.2 INTRAVENOUS FLUID THERAPY

Fluids are administered during general anesthesia to expand the blood volume and offset drug-mediated vasodilation, replace losses associated with surgery or exposure of body cavities, and provide maintenance needs. A balanced electrolyte crystalloid solution is usually sufficient (e.g., Hartmann's or lactated Ringer's solution) when delivered at 10 mL/kg/h during anesthesia. If the animal is hypotensive or there is significant hemorrhage

associated with the surgical procedure, a higher infusion rate of the crystalloid should be administered and a colloid solution may be indicated. Colloids are starch, gelatin, or dextrans in origin and have the advantage of more prolonged plasma volume expansion when compared to crystalloids. The infusion rate of a colloid is lower than that of a crystalloid (2–5 mL/kg/h). Crystalloids and colloids can be given concurrently but if large volumes are required a second intravenous catheter may be useful. Consider catheterizing the other cephalic vein or the jugular vein. Blood pressure should be monitored throughout anesthesia and the infusion rate of fluids adjusted accordingly.

8.1.5.3 POSITIONING

The surgical procedure will usually dictate the position in which the animal is placed for the majority of the anesthetic. Invariably dorsal recumbency is required but this position predisposes the animal to hypotension and a decrease in the functional residual capacity of the lungs. Monitoring and managing blood pressure and ventilation is important during anesthesia, but especially during positioning in dorsal recumbency. Given the propensity for ruminants to salivate it is important to position the animal to prevent saliva entering the larynx by lowering the head or creating an uphill gradient to the pharynx to prevent accumulation of fluids around the cuff of the endotracheal tube (Fig. 30.2B). Creating a passage for drainage of these secretions and any regurgitated material is essential (Fig. 30.2C). It is also important to avoid hyperextension of the hips and shoulders during positioning on the surgery table.

8.1.5.4 MONITORING ANESTHESIA

The ultimate aims during anesthesia are to ensure an adequate depth of anesthesia, the provision of appropriate analgesia and maintenance of oxygen delivery to ensure cells and tissues can continue functioning normally. This approach can be considered as monitoring the central nervous system, the cardiovascular system (delivering blood to the tissues) and the respiratory system (adding oxygen and removing carbon dioxide from the circulation). Analgesia will be discussed in the next section.

8.1.5.5 ASSESSMENT OF DEPTH OF ANESTHESIA

Monitoring central nervous system depression is essential during anesthesia. Electroencephalography (EEG) may be one of the most extensively utilized methods for objective evaluation of the state of responsiveness of the central nervous system and is considered the most direct indicator of central nervous system depression (Serfontein, 2010). There is, however, considerable variation between species and the EEG changes associated with different drugs may also complicate interpretation. Recent work suggests that the EEG can be relied upon in sheep to determine depth of anesthesia (Otto et al., 2012) but in the majority of environments assessing the depth of anesthesia will be a subjective exercise.

There are a number of observations to make when undertaking subjective assessment of anesthetic depth in sheep: palpebral (blink) reflex, muscle tone, eye position, and tongue withdrawal. At an adequate depth of anesthesia, there should be a sluggish palpebral reflex when the medial commissure of the eyelids is gently stimulated. The muscles should be relaxed without any resistance to manipulation. During a laparotomy an anesthetist has access to the head so testing jaw tone is helpful to determine the muscle tone of the masseter muscles. The position of the eye will change during anesthesia and although it can be difficult to interpret when an animal is in dorsal recumbency the basic pattern is that the eye is in a central position initially and rotates ventrally during anesthesia. It will return to the central position if the depth of anesthesia is too deep or if the animal is waking up. Lastly, tongue withdrawal can easily be checked regularly. The tongue should be relaxed at an adequate depth of anesthesia. When assessing depth of anesthesia by these subjective techniques, it is essential to evaluate more than one parameter before deciding whether the depth of anesthesia is adequate.

8.1.5.6 CARDIOVASCULAR PERFORMANCE

The overall aim of monitoring and managing the cardiovascular and respiratory systems during anesthesia is to ensure that the oxygen supply to the tissues exceeds the oxygen demand of the tissues. If oxygen delivery (DO_2) is a product of the cardiac output (CO) and the oxygen content of arterial blood (CaO_2) then maintaining these two parameters is essential. Measuring the cardiac output is not routinely performed during anesthesia as it is a technically challenging technique that is relatively invasive and expensive. As a surrogate for cardiac output, ABP is measured. If CO = heart rate × stroke volume and ABP = CO × total peripheral resistance, we can see that measuring the heart rate and ABP during anesthesia can indirectly indicate the adequacy of cardiac output. During anesthesia pregnant ewes may be anemic so CaO_2 may be lower than normal (Musk and Kemp, 2016). Low CaO_2 will compromise DO_2 so it is especially important that CO is monitored and managed.

The heart rate can be measured with an electrocardiograph (ECG) and the pulse rate can be measured with a pulse oximeter. The ECG displays the electrical activity of the heart and is used to assess heart rate and rhythm. The pulse oximeter measures oxyhemoglobin saturation and pulse rate. The normal heart rate of a pregnant sheep during anesthesia will vary according to anesthetic and

TABLE 30.4 Factors Affecting the Heart Rate During Anesthesia

Change in heart rate	Cause	Management
Increase	Inadequate depth of anesthesia: "too light"	Assess depth of anesthesia and deliver more anesthetic agent (intravenous or inhalant drugs) if appropriate. Check endotracheal tube position and cuff
	Inadequate analgesia	Assess depth of anesthesia and if adequately anesthetized, administer more analgesia
	Hypotension	Isotonic crystalloids: initiate intravenous fluid therapy (10 mL/kg/h) or deliver a bolus of (40–80 mL/kg/h) for 10–15 min
		Colloids: deliver 2–10 mL/kg/h of gel or starch-based colloid
	Hypovolemia	Isotonic crystalloids: initiate intravenous fluid therapy (10 mL/kg/h) or deliver a bolus of (40–80 mL/kg/h) for 10–15 min
		Colloids: deliver 2–10 mL/kg/h of gel or starch-based colloid
	Hypercapnia	Initiate mechanical ventilation or adjust ventilation parameters to achieve normocapnia
	Hypoxemia (early)	Mechanical ventilation with 100% oxygen and positive end-expiratory pressure (PEEP)
	Drugs	Ketamine may cause a transient tachycardia after induction of anesthesia
Decrease	Excessive depth of anesthesia: "too deep"	Assess depth of anesthesia and adjust delivery of anaesthetic drugs accordingly
	Overdose of analgesic drugs (especially opioids)	Administer atropine (0.02 mg/kg) or glycopyrrolate (0.01 mg/kg) IV
	Hypertension	Stop IV fluids
	Hypervolemia	Stop IV fluids
	Hypoxemia (advanced)	Mechanical ventilation with 100% oxygen and PEEP
	Hypothermia	Check core body temperature and provide insulation, circulating warm air blankets, hot water bottles, heat pads, heat lamps, warm IV fluids
	Overdose of alpha 2 adrenoreceptor agonist drugs (e.g., xylazine)	Administer atipamezole (5 µg/kg) IM

analgesic protocol employed but should be between 70 and 100 beats/min. Alterations in the heart rate can be caused by a number of different factors (Table 30.4).

ABP can be measured noninvasively with either an oscillometric technique or a Doppler technique. The former measures systolic, mean, and diastolic ABP while the latter measures systolic ABP only. The aim is to maintain mean ABP over 60 mmHg or the systolic ABP over 90 mmHg. It is important to familiarize yourself with your equipment to ensure accurate measurements are made and appropriate therapy is instituted. The gold standard of ABP measurement is an invasive technique where a catheter is placed in a peripheral artery, connected by a fluid filled tube to a transducer, and converted to an electrical signal. Invasive ABP measurement is the most accurate method for the measurement of ABP and should be considered if the duration of anesthesia is likely to be greater than 1 h.

The most common alteration to ABP is hypotension and in turn, the most common cause of hypotension is vasodilation induced by inhalant anesthetics (especially isoflurane). Decreasing inhalant anesthetic requirements can be achieved with premedication, as discussed previously and appropriate analgesia. The management of hypotension is usually most successful with IV fluid therapy. Isotonic crystalloids should be delivered at 10 mL/kg/h during anesthesia but the rate of administration can be increased up to 80 mL/kg/h for a brief period if required. Colloid infusions can be given concurrently (2–5 mL/kg/h). The most common causes of hypotension are presented in Table 30.5.

8.1.6 Respiratory Performance

The adequacy of ventilation is best assessed by measuring the partial pressure of CO_2 in arterial blood ($PaCO_2$). Alternatively, end-tidal CO_2 can be measured as a noninvasive estimate of $PaCO_2$. In the absence of significant lung collapse or compromise to pulmonary perfusion, the measurement of end-tidal CO_2 by capnography gives a good indication of the adequacy of

TABLE 30.5   Factors Affecting Blood Pressure During Anesthesia

Change in blood pressure	Cause	Management
Increase	Inadequate depth of anesthesia: "too light"	Assess depth of anesthesia and deliver more anesthetic agent (intravenous or inhalant drugs) if appropriate. Check endotracheal tube position and cuff
	Inadequate analgesia	Assess depth of anesthesia and if adequately anesthetized, administer more analgesia
	Hypervolemia	Stop IV fluid therapy
	Hypercapnia	Initiate mechanical ventilation or adjust ventilation parameters to achieve normocapnia
Decrease	Excessive depth of anesthesia: "too deep"	Assess depth of anesthesia and adjust delivery of anesthetic drugs accordingly
	Bradycardia	Check heart rate and/or pulse rate and administer atropine (0.02 mg/kg) IV or glycopyrrolate (0.01 mg/kg) IV if the heart rate is below 50 beats/min
	Overdose of alpha 2 adrenoreceptor agonist drugs (e.g., xylazine)	Administer atipamezole (5 μg/kg) IM
	Hypovolemia	Isotonic crystalloids: initiate intravenous fluid therapy (10 mL/kg/h) or deliver a bolus of (40–80 mL/kg/h) for 10–15 min
		Colloids: deliver 2–5 mL/kg/h of gel- or starch-based colloid

ventilation (Bilbrough, 2006). End-tidal CO_2 should be between 35 and 45 mmHg (~4.6–5.8 kPa). If the $PaCO_2$ increases ventilation is inadequate and if it decreases ventilation is excessive (Table 30.6).

Oxygenation should also be monitored during anesthesia. Pulse oximetry is a noninvasive method for assessing oxyhemoglobin saturation (Quinn et al., 2013) and is useful as an indicator of peripheral perfusion and oxygenation. The normal oxyhemoglobin saturation (SpO_2) is above 95% and if it decreases it is essential to determine if the reading is accurate. To obtain a reliable reading, the pulse oximeter must be positioned on a nonpigmented and hairless tissue. The tongue is an ideal site. Factors that interfere with the accuracy of the reading include: vasoconstriction, pigment, theatre lights, movement, and hypotension. If the carrier gas for inhalant anesthesia is 100% oxygen, a decrease in SpO_2 will be a late indicator of respiratory compromise. Pulse oximetry is, in fact, best used to monitor peripheral perfusion.

Arterial blood gas analyses are the best method for assessing the physiological status of the ewe. These analyses provide information about the acid base status of the ewe and the blood gases carbon dioxide and oxygen. This information is invaluable for guiding the management of ventilation and fluid therapy during anesthesia. These data will also help in determinations about fetal health

TABLE 30.6   Alterations in Ventilation May Occur During General Anesthesia and Should be Managed Appropriately

Change in end-tidal CO_2	Cause	Management
Increase due to hypoventilation (decreased minute volume)	Excessive depth of anesthesia: "too deep"	Assess anesthetic depth and decrease anesthetic drug delivery if possible
	Dorsal recumbency	Mechanical ventilation. Minimize the duration of time in this position
	Pressure of the gravid uterus on the diaphragm	Mechanical ventilation. Tilt the table to decrease pressure on the diaphragm.
Decrease due to hyperventilation (increased minute volume)	Inadequate depth of anesthesia: "too light"	Assess anesthetic depth and administer more anesthetic drugs
	Inadequate analgesia	If depth of anesthesia is appropriate, more analgesia may be required
	Hypoxemia	Mechanical ventilation with 100% oxygen and PEEP

(Musk and Kemp, 2016). Arterial blood samples can be collected from the radial artery of the ewe through a pre-placed catheter or from a single needle-stick sample.

8.1.6.1 RECOVERY FROM ANESTHESIA

Ruminants present a number of challenges during the recovery phase of anesthesia. Their propensity for regurgitation and salivation becomes particularly problematic when the endotracheal tube is removed and the airway is no longer protected. The primary challenge during this time is to prevent aspiration of such fluids. Returning the animal to a more physiologically normal position is important to facilitate eructation and the expulsion of gas from the rumen. Positioning in "sternal recumbency" will also support spontaneous ventilation. The endotracheal tube should be removed when the animal is observed to swallow. The return of this reflex indicates the animal is able to protect the airway and aspiration is less likely. It is worth having equipment on hand to reintubate a sheep if they develop an upper respiratory tract obstruction following extubation. This equipment should be kept in the area where sheep are recovered from anesthesia and surgery, and be readily available in the event of a crisis. Anesthetic drugs for induction of anesthesia, heparinized saline, a laryngoscope, and endotracheal tube are the basic necessities. An ambu bag will enable ventilation on room air if required. A syringe to inflate the cuff of the endotracheal tube and a gauze tie to secure it in place will also be useful. Food and water should be offered as soon as possible and in the author's experience sheep that have received appropriate analgesia will eat within 30 min of recovery from anesthesia.

8.1.7 Analgesia

Sheep have evolved to hide signs of pain. Pain assessment is difficult in any species, but this instinctive behavior to conceal pain makes the provision of analgesia particularly challenging. Nevertheless, analgesia must be provided if an animal has undergone a surgical procedure. There are important ethical and moral obligations, which ensure the administration of analgesic drugs and techniques that are appropriate to the species, the procedure that has been performed and the circumstances in which it has been performed (Australian Government, 2013). This remit is difficult to achieve in sheep as there is not an extensive scientific database from which to draw sound conclusion. Furthermore, there are no validated pain scoring systems, which reliably indicate the severity of pain a sheep may be experiencing. With these limitations in mind a multi-modal analgesic approach is prudent. In the perioperative period, analgesia can be provided by administering drugs from the following drug classes: opioids; NSAIDs; local or regional anesthetic drugs; alpha 2 adrenoreceptor agonist

drugs; and other miscellaneous drugs, such as ketamine and tramadol. The efficacy of opioids in sheep is controversial and while there is little convincing data to support or refute their use for acute surgical pain, the author includes these drugs in perioperative analgesic protocols as part of the premed and for postoperative analgesia (Musk et al., 2014). Transdermal fentanyl delivery in pregnant sheep has been described and is part of the author's multimodal analgesia regime for pregnant sheep undergoing anesthesia and surgery (Heikkinen et al., 2015; Musk et al., 2014). There is a significant body of evidence regarding the danger of NSAID use in a range of species, during pregnancy, as theoretically these drugs may cause premature closure of the ductus arteriosus (Baragatti et al., 2003; Van Overmeire and Chemtob, 2005). This side effect may be fatal for the fetus and the author therefore excludes this class of drug from perioperative analgesia protocols for pregnant sheep. Local anesthetic drugs are commonly used in sheep for regional anesthesia and analgesia (Harris, 1991; Hodgkinson and Dawson, 2007) and should always be considered as part of a multimodal analgesic regime. Local anesthetic drugs should be administered preemptively to optimize their effects. Alpha 2 adrenoreceptor agonists are commonly used in sheep (Grant and Upton, 2001, 2004; Grant et al., 2001; Kastner et al., 2003; Murdoch et al., 2013). They are perhaps the most extensively studied class of analgesic drugs in sheep but have significant side effects, which must be understood. These side effects are dose dependent and include peripheral vasoconstriction, bradycardia, hypoxemia, and uterine muscle contraction. Ketamine is a drug with analgesic properties that may be used as part of the anesthetic induction protocol and/or infused during surgery for both analgesia and anesthetic sparing effects. The cardiovascular and respiratory side effects of ketamine are unlikely to have detrimental effects on uterine blood flow (Strumper et al., 2004). Finally, tramadol has also been used in sheep for its opioid analgesic effects and could be considered an option for chronic pain management.

Combining analgesic drugs from different classes (multimodal analgesia) will decrease the dose of each individual drug, thus enhance the effects, and decrease the potential for adverse side effects of the drugs. Furthermore, multimodal analgesia targets the pain pathway at multiple sites and mitigates pain more effectively than using an analgesic drug from a single class. As more research is conducted in sheep, valuable data about pain assessment and efficacy of analgesic drugs data will enable more evidence-based decision-making in this species. Until then the pharmacokinetic and pharmacodynamic data of a drug should form the basis of analgesia regimes. Table 30.7 includes some analgesic drugs for consideration in pregnant sheep.

Pain assessment must form part of any analgesic protocol. Ideally, pain should be assessed before and after the administration of analgesic drugs to determine the

TABLE 30.7   Analgesic Drugs for Use in Pregnant Sheep

Drug	Dose and route of administration	Side effects
Buprenorphine (partial μ agonist opioid)	0.01–0.02 mg/kg IM	Moderate tranquilization occurs when combined with acepromazine
	Long duration of action (~6–8 h)	Bradycardia at high doses
Morphine (pure μ agonist opioid)	0.1–0.3 mg/kg IM	Moderate tranquilization occurs when combined with acepromazine
	Moderate duration of action (~2–4 h)	Bradycardia at high doses
Fentanyl (pure μ agonist opioid)	0.1–0.3 μg/kg/min IV	Bradycardia and respiratory depression
	1–2 μg/kg/h transdermal (allow 12–24 h to achieve therapeutic plasma concentrations)	
Lidocaine (local anesthetic)	Up to 5 mg/kg infiltration at the surgical site	Rare unless given IV
	Short duration of action (~1 h)	Hypotension, tachycardia, cardiac arrhythmias, seizures
Bupivacaine (local anaesthetic)	Up to 2 mg/kg infiltration at the surgical site	Rare unless given IV
	Long duration of action (~6 h)	Cardiac arrhythmias, seizures, death.
Xylazine (alpha 2 adrenoreceptor agonist)	0.1 mg/kg then 0.04 mg/kg/h IV (Grant et al., 2001)	Dose-dependent sedation, hyperglycemia, hypotension, hypoxemia, cardiac arrhythmias
		Can be reversed with yohimbine or atipamezole
Medetomidine (α_2 adrenoreceptor agonist)	1–3 μg/kg/h IV	Dose-dependent sedation, hyperglycemia, hypotension, hypoxemia, cardiac arrhythmias
		Can be reversed with yohimbine or atipamezole
Ketamine (N-methyl-D-aspartate antagonist)	2–5 μg/kg/min IV	Tachycardia and hypertension

analgesic requirements and response to therapy. Objective assessments of pain include changes in physiology (e.g., alterations in the heart rate and circulating plasma cortisol) and nociceptive threshold testing (Musk et al., 2014) while subjective assessments rely upon observations of behavior. Understanding the normal behavior of sheep (in a specific environment) is essential for the identification and interpretation of abnormal behaviors. A composite pain score assessing a combination of physiological and behavioral parameters should be developed for the environment in which the sheep will be kept. An intervention score should also be set to ensure that optimal analgesia is achieved. Pain assessment tools for sheep require further development and investigation to determine the most accurate method.

8.2 Preoperative Preparation for Aseptic Surgery

Surgical preparation of the skin may commence once anesthesia has been induced and stabilized. The ewe should be placed in dorsal recumbency, allowing exposure of the abdomen (Fig. 30.3A). The wool should be wetted with 70% ethanol in H_2O and clipped to the skin between the groin and the sternum (Fig. 30.3B) to create a surgical field. Special care should be taken not to abrade or cut the skin during clipping (especially around the groin flaps)—placing tension on the skin will assist in ensuring a clean, trauma-free clip. Once the abdomen has been carefully shorn, use a damp sponge and chlorhexidine (4%) surgical skin disinfectant to thoroughly remove all feces and lanolin from the clipped area. Wetting down the wool at the periphery of clipped surface helps to prevent loose strands of wool falling back onto the surgical field during cleaning and subsequent draping.

Once all obvious contaminants have been removed from the surgical field, the skin may be disinfected with a chlorhexidine surgical scrub (4%) as follows: take a clean, fist-sized wad of cotton wool, and soak liberally in chlorhexidine surgical scrub. Starting on the abdominal midline, scrub a 15 cm × 5 cm (length × width) zone moving in a straight line up and down the abdomen. Then scrub the skin in a circular pattern, moving outward from the abdominal midline until you reach the periphery of the surgical field. Clean the surgical site with 70% ethanol. Then discard the used wad of cotton wool for a new one, soak in chlorhexidine surgical scrub,
FIGURE 30.3 (A) Ewe abdomen clipped for presurgical preparation. (B) Ewe abdomen following preoperative scrub. (C) Ewe abdomen prepared for surgical draping. Inset demonstrates subcutaneous administration of local anesthetic to the incision site.

and repeat the previous process 3 times. This process should take no less than 5 min to complete, leaving the abdomen resembling the image shown in Fig. 30.3C.

Once preparation of the skin is complete, the ewe should be transferred to the operating theatre and positioned for surgery on a surgical table. Care should be taken not to contaminate the surgical field during the transfer. Furthermore, care should be taken not to hyperextend the ewe's hips or shoulders during positioning. Prior to draping the animal, the surgical team should select an incision site (approximately 8 cm in length) just large enough to allow exteriorization of the fetal head and neck. A number of large, superficial veins populate the abdomen in a pregnant ewe and the incision site should be selected to avoid cutting these. Using a 21-gauge needle, introduce 10 mL of 1% ropivacaine hydrochloride (or similarly long-acting local anesthetic) subcutaneously along the incision site (Fig. 30.3C Inset).

Once the animal has been covered with a fenestrated surgical drape and an anesthetist has confirmed that the ewe is adequately anesthetized, the surgical team (at least two skilled surgeons) can proceed to scrub and gown prior to commencing surgery. We cannot overemphasize that rigorous aseptic technique from the initiation of scrubbing through to the closure of the abdominal incision is *absolutely critical* to the success of surgical studies of this nature. All surgical equipment should be sterilized by high temperature autoclave and all sterile consumables opened by a surgical assistant proficient in theater technique.

8.3 Surgical Protocol—Isolation of the Fetal Lung and Gut

The following protocol provides a guide to surgically isolating the fetal lung and gut from the amniotic environment. We have performed this protocol on fetuses at 118–122 days gestation. Following exteriorization of the fetal head, the fetal esophagus and trachea are sequentially exposed and ligated. In addition, a tracheal catheter attached to a fluid collection bag (1.5 L total volume) is installed, with the collection bag sited in the amniotic cavity. This apparatus allows for collection of fetal lung fluid preventing overdistension and injury to the fetal lung. This basic protocol may be readily adapted to allow for the selective exposure of the fetal lung or gut to an agent of interest by inserting a fine catheter attached to a subcutaneously sited osmotic pump. Additionally, the fetal skin and membranes can be selectively isolated and exposed to intervention compounds by the installation of an additional surgical seal around the fetal snout. Interventions may be administered for between 24 h and 6 days following surgery. Suggested surgical consumables and equipment are detailed in Table 30.8 and 30.9, respectively.

8.3.1 Surgery Phase 1—Abdominal Incision (Laparotomy) to Exteriorization of the Fetal Head via Hysterotomy

Surgery should only commence once an anesthetist has confirmed that anesthesia is stable. The following protocol assumes a good level of surgical proficiency and as such does not detail fundamental techniques, such as those necessary for maintaining hemostasis, suturing tissue, and general instrument handling. This protocol also assumes that a veterinary anesthetist (or similarly experienced person) is continually monitoring the animal throughout surgery to ensure the maintenance of an adequate plane of anesthesia.

1. Using a disposable size 20 scalpel blade, make a superficial, 8 cm long incision along the incision site

TABLE 30.8 Sterile Surgical Consumables

Number	Item
1	0–0 Sofsilk (Medtronic, Australia)
1	1–0 Polysorb braided suture with 26 mm taper needle (Medtronic, Australia)
1	1–0 Maxon monofilament suture with 65 mm taper needle (Medtronic, Australia)
1	Bag of large laparotomy sponges
1	Catheter bag and circuit for lung fluid collection
1	Transdermal fentanyl patch

TABLE 30.9 Sterile Surgical Equipment

Number	Item
1	Size (20) scalpel blade (maternal)
1	Size (10) scalpel blade (fetal)
1	Size (4) scalpel handle (maternal)
1	Size (3) scalpel handle (fetal)
1	Metzenbaum (14 cm) curved tissue scissors (maternal)
1	Vessel scissors (fetal)
1	Suture scissors
2	Curved needles—curved triangular cutting size 10
2	Straight needles—straight triangular cutting size 6
4	Atraumatic (Babcock) clamps
4	Medium traumatic (Kelly) clamps
4	Small (14 cm) hemostat (curved nose)
4	Medium (16 cm) hemostat (curved nose)
1	Small (14 cm) needle driver
1	Large (18 cm) needle driver
1	Medium Steinhauser forceps
1	Medium Allis clamps

where local anesthetic has been injected, taking care to stay lateral to the superficial mammary vein. The surgical pack should contain a number of precut lengths of size 0 Sofsilk that can be rapidly deployed to control any bleeding.

2. Using 2–3 surgical swabs in each hand, a-traumatically dissect the subcutaneous tissue to expose the *linea alba*.
3. Using a size 20 scalpel blade, make a superficial 1 cm long incision in the *linea alba*.
4. Using an index finger rotating in a circular motion about the incision site, ensure that *linea alba* is separated from the tissue below.

5. Elevating/tensioning the *linea alba* with the index and forefinger, use pair of 14 cm curved Metzenbaum tissue scissors to enlarge the *linea alba* incision to a final length of 8 cm.
6. Retract the omentum and palpate the uterus to identify the fetal head. Careful pressure may be used to reorient the fetal head within the uterus, allowing for exteriorization of the head.
7. Using both hands, gently exteriorize the fetal head within the uterus and stabilize with laterally placed laparotomy sponges (Fig. 30.4A).
8. The surgical assistant now places the uterine wall under tension. Taking care to avoid uterine vasculature, use a disposable size 10 scalpel blade to make a 5 cm long incision in the uterine wall and fetal membranes (Fig. 30.4B).
9. Use 4×20 cm atraumatic Babcock tissue clamps to secure the incision site and exteriorize the fetal snout by gently pushing down on the fetal skull while simultaneously squeezing the snout forward and up through the uterine incision. It is important to minimize the loss of amniotic fluid and to exteriorize as little of the fetus as possible (Fig. 30.4C).
10. The fetal head and neck are extended and rested on a sterile laparotomy sponge. Each Babcock clamp used in (9) should be relocated to clamp the uterine wall to the fetal neck, creating a seal, and preventing the loss of amniotic fluid during the subsequent fetal surgery (Fig. 30.5A).

8.3.2 Surgery Phase 2—Installation of Fetal Esophageal and Tracheal Ligations

1. Palpate the cricoid cartilage on the fetal neck to identify the trachea. Use forceps to raise the skin above the cricoid cartilage and make a small lateral incision with the fetal vessel scissors. Keeping tension on the skin flap, use the Metzenbaum tissue scissors to make a 3 cm long incision, parallel to the trachea.
2. Blunt dissect the connective tissue from around the trachea using a small hemostat. Introduce two lengths of size 0 Sofsilk around the trachea, laterally relocate and clamp in place (Fig. 30.5B).
3. Blunt dissect the connective tissue from around the esophagus using a small hemostat. Introduce two lengths of size 0 Sofsilk around the esophagus and ligate.
4. Using a size 10 scalpel blade, make a transverse incision around one of the cartilage rings in the fetal trachea, taking care not to cut completely through the trachea.
5. Using traumatic forceps to hold the tracheal incision open, insert the tracheal catheter into the incision site to a depth of 2 cm.
FIGURE 30.4 (A) Exposure of the fetal head within the uterus. (B) Lateral incision of the uterine wall and fetal membranes. (C) Atraumatic Babcock clamps are used to secure the fetal membranes and uterine wall in preparation for exteriorization of the fetal head.
FIGURE 30.5 (A) The fetal head is secured in place, exposing the trachea. (B) Surgical silk is introduced underneath the trachea (following blunt dissection) to assist in manipulation and to allow occlusion superior to the tracheal cannula. (C) The fetal head with surgical implants installed, prior to reintroduction to the uterus.

6. Introduce two additional lengths of size 0 Sofsilk around the tracheal catheter site and ligate firmly in place. Pull gently on the ligated catheter to confirm sound installation.
7. Use the two lengths of Sofsilk introduced around the esophagus in (3) to ligate the esophagus superior to the tracheal catheter insertion site and to tether the extension of the catheter line.
8. Holding the catheter line flat to the fetal neck, use an additional length of size 0 Sofsilk to close the incision site made in the fetal skin (Fig. 30.5C).

8.3.3 Surgery Phase 3—Closure of Uterine and Abdominal Incisions

1. Elevate the fetal head and release the Babcock clamps from the fetal neck. Reattach Babcock clamps to the uterine wall and elevate to prevent the loss of amniotic fluid and to make room to return the fetal head to the uterus.

2. Gently slide the connection bag attached to the tracheal catheter along the fetal spine and into the uterus. Administer an appropriate dose of prophylactic antibiotic to the fetus via subcutaneous injection.
3. Keeping the uterine incision elevated by tensioning the attached Babcock clamps, tilt the fetal snout forward and down. Using gentle downward pressure, reintroduce the fetal head into the uterus, taking care to return the head and neck to the same preoperative orientation.
4. Use size 2.0 Polysorb in a purse-string oversuture pattern to close the uterine incision. Take particular care to suture the fetal membranes to the internal aspect of the uterus during closure of the first layer (Fig. 30.6A–B).
5. Use size 1.0 Maxon in a running suture pattern to close the *linea alba* incision. Take particular care the suture through the fascia on the internal aspect of the *linea alba* incision (Fig. 30.6C).
6. Pause briefly to ensure that incision hemostasis has been achieved. Use size 2.0 Polysorb to close the

FIGURE 30.6　(A) Closure of the uterine wall (first suture layer). (B) Closure of the uterine wall (overlapping suture layer). (C) Closure of the *linea alba.*

superficial incision made in (1). Spray the incision site with Opsite (or similar spray dressing)

7. If the provision of postoperative analgesia is from a transdermal fentanyl patch, clean and dry the skin in the groin and apply the patch to this site. Judicious use of surgical adhesive may assist in keeping the patch in place.

8.4 Euthanasia

The most common method of euthanasia is intravenous injection of pentobarbitone (Leary et al., 2013). In an adult sheep, intravenous access is possible at a number of sites. If a catheter has been placed for use during surgery then ensure the catheter is kept patent with continuous delivery of IV fluids or intermittent flushing with heparinized saline. The cephalic or jugular veins are usually easily accessible. If euthanasia of the fetus is required during surgery an intravenous injection can be given into the umbilical vein. Death must be confirmed before tissues are harvested or the carcass is disposed of. Three checks must be made: ensure absence of a heart beat by auscultating the chest, ensure absence of spontaneous ventilation by observing the chest wall, and ensure absence of a corneal reflex by stimulating the cornea with light digital pressure.

NEONATAL RESPIRATION

A thorough review of the literature on the animal models used to study neonatal breathing is clearly beyond the scope of this short review. A biased choice of a few items in this area is proposed in the following paragraphs. We have attempted to illustrate the variety of animal models that have been used to unravel the normal establishment of successful breathing at birth and its maintenance in the early postnatal period, as well as a number of abnormal conditions that can interfere with those processes.

1 ESTABLISHMENT OF AIR BREATHING AT BIRTH

At birth, an immediate adaptation to air breathing is a vital requirement for the newborn. This adaptation includes lung aeration as well as maintenance of regular and efficient respiratory efforts.

1.1 Transition From a Liquid-Filled Lung to Air Breathing at Birth

1.1.1 Normal Lung Aeration at Birth

Rapid aeration of liquid-filled lungs at birth is mandatory for a successful transition from the fetal to the newborn state. Forceful inspiratory efforts create a pressure gradient within the airways, which moves air into the lungs. This in turn opens the distal airways and moves the liquid across the epithelial alveoli into the parenchyma. At the same time, lung inflation decreases the pulmonary vascular resistance and increases pulmonary blood flow, creating an optimal situation for gas exchange. Air stacking in the lungs initially depends not only on inspiratory efforts, but also on active expiratory laryngeal closure to keep a sufficient amount of air into the lung at the end of expiration, namely the functional residual capacity. The presence of surfactant is crucial in this process; by decreasing the surface tension of the distal airways, the surfactant decreases the elastic recoil of the lung, hence decreasing expiratory emptying of the lung.

Studies in spontaneously breathing newborn rabbits have shown that lung aeration is predominantly achieved by inspiratory efforts, while expiratory efforts are involved in maintaining functional residual capacity (Siew et al., 2009). Further studies in newborn rabbits have shown that lung aeration is not homogeneous at birth (Hooper et al., 2007), and that monitoring of expired CO_2 in lambs and rabbits is a useful indicator of the degree of lung aeration (Hooper et al., 2013).

1.1.2 Influence of Premature Birth and Resuscitative Maneuvers to Aerate the Lung at Birth

While the transition to air breathing occurs smoothly at birth in the vast majority of full-term newborns, a number of premature neonates, especially the very low birth weight, are not capable to successfully transition to air breathing at birth. Inadequate command from the respiratory centers to initiate breathing, weak inspiratory muscles, absence of functional surfactant, extremely pliable rib cage, persistence of a high pulmonary vascular resistance are among the factors that negatively impact respiration onset at birth.

Most very preterm infants at birth hence require the use of some form of positive pressure respiratory support, such as positive end-expiratory pressure, sustained lung inflation, or mechanical ventilation at fixed tidal volumes. This can, however, have highly deleterious effects on the immature lungs. For instance, studies in preterm lambs have shown that the use of large tidal volumes (35 mL/kg) for only six breaths to aerate the lungs at birth is sufficient to induce lung inflammation, initiate ventilator-induced lung injury (VILI), setting the stage for chronic lung disease, namely bronchopulmonary dysplasia (Bjorklund et al., 1997). In addition, very high pressures (40 cmH_2O) are needed in the preterm lamb to open the airways filled of liquid and assure a tidal volume of 6–8 mL/kg at 5 min of life (Wada et al., 1997). Convincing evidence on the proinflammatory effect of positive pressure ventilation at the onset of breathing

at birth has now been collected in a number of preclinical studies, using the preterm lamb model (Hillman et al., 2011a,b; Hillman et al., 2012b; Tingay et al., 2015a). Long-lasting consequences of this lung inflammation will be further reviewed in the section on bronchopulmonary dysplasia (see Section 2.3).

1.1.3 The Quest for the Optimal Ventilator Strategy to Support Lung Aeration at Birth in Very Preterm Newborns

Given the deleterious effect of positive pressure ventilation at birth in preterm lungs, a number of studies have been conducted in animal models, mainly in preterm lambs, with the aim to find out which ventilator strategy could minimize lung injury and reduce the development of bronchopulmonary dysplasia. Unfortunately, as reviewed later, the results do not allow to draw a clear picture of the optimal ventilator strategy to use to aerate the lung at birth (Jobe, 2015).

Endotracheal respiratory support. Lung inflammation induced at birth by endotracheal positive pressure mechanical ventilation was not prevented by using a low tidal volume (8 mL/kg) and a PEEP in lambs (Polglase et al., 2008). Moreover, other studies found that the inflammatory response and lung injury were lessened with surfactant treatment prior to ventilation (Hillman et al., 2011a; Wada et al., 1997), with antenatal corticosteroid treatment (Hillman et al., 2009) or with the use of PEEP (Hillman et al., 2011a; Ingimarsson et al., 2004). The latter was especially shown in lambs supported with higher levels of PEEP during high-frequency jet ventilation (Pillow et al., 2011).

On the other hand, variable ventilation improves ventilation efficiency and in vivo lung compliance (Pillow et al., 2011). While the use of a sustained inflation with a fixed duration was reported not to prevent lung inflammation (Hillman et al., 2013; Polglase et al., 2014), a further study suggested that a sustained inflation with an individualized duration is a better approach (Tingay et al., 2015a). However, this team also demonstrated that an incremental tidal volume strategy resulted in worse oxygenation and gravity-dependent heterogeneity of aeration in 131 days preterm lambs resuscitated at birth (Tingay et al., 2015b).

Noninvasive respiratory support. Given the deleterious effects of aerating the lungs at birth using endotracheal mechanical ventilation, noninvasive respiratory support from birth is an attracting modality. Studies using preterm experimental animal models (mainly lambs, but also piglets or mice) have revealed that the early use of noninvasive respiratory support is associated with better respiratory outcomes (Dargaville et al., 2015; Null et al., 2014; Reyburn et al., 2008; Thomson et al., 2004, 2006; Yoder et al., 2016). However, the optimal noninvasive support modality for preventing lung injury remains unclear. An animal model of nasal CPAP applied from birth has been designed, using short binasal prongs in newborn preterm lambs at 136 days of gestation (Rahmel et al., 2012). Also, nonintubated preterm lambs were effectively transitioned from nasal intermittent positive pressure ventilation + respiratory stimulants to nasal CPAP soon after birth (Dargaville et al., 2015). However, premature lambs with significant respiratory distress showed a progressive deterioration of respiratory gas exchanges after 3–4 h, while supported with bubble CPAP through nasal prongs or a nasopharyngeal tube (Reyburn et al., 2008).

1.2 Establishment and Maintenance of Regular Breathing Movements in the Newborn

Besides successful lung aeration at birth, regular breathing movements are vital for the newborn. Animal studies have allowed to show that breathing movements are present in the fetus before birth, and have helped to understand the normal perinatal control of breathing and its alterations in disease states.

1.2.1 Fetal Breathing Movements

Fetal breathing movements have been observed in utero either by chronic instrumentation or via ultrasound in a number of mammal species, including the horse, goat, rat, guinea pig, dog, rabbit, and baboon [reviewed in Jansen and Chernick (1983), Teppema and Dahan (2010)]. The vast majority of our knowledge on fetal breathing movements comes, however, from studies in the chronically instrumented lamb in utero initiated by Barcroft's team in the 1930s in Cambridge. Numerous experiments since then have shown the presence of fetal breathing movements, which can be observed as early as 40 days in the fetal lamb (versus 110 days in the human fetus). While continuous in early gestation, they follow the differentiation of electrocorticogram between states so that they are linked to low voltage electrocorticogram (REM sleep-like state) in the third trimester. This modulatory role of sleep states is demonstrated by the observation in the fetal lamb of almost continuous fetal breathing movements following brainstem transection at the upper pontine level [close to the principal trigeminal nuclei; reviewed in Teppema and Dahan (2010)]. Beyond being evidence of the early maturation of respiratory control, fetal breathing movements are crucial for prenatal lung growth [reviewed in Jansen and Chernick (1983), Teppema and Dahan (2010)]. During fetal breathing movements, diaphragmatic contractions are already well coordinated with contraction of the upper airway muscles, so that laryngeal constrictor muscles are tonically active when phasic diaphragm activity is absent, but silent when the diaphragm contracts (Kianicka et al., 1998a). Together with continuous lung liquid secretion, this tonic closure of the larynx allows to build

up positive pressure in the lung, in turn promoting lung growth. Fetal breathing movements have been shown to be the major stimulus for lung growth and maturation via mechanical stretch of the lung (Kitterman, 1996) and, at least partly, via stimulation of the epidermal growth factor receptor (Huang et al., 2012). Mechanical stretch of the lung occurs both with fetal breathing movements, which change the shape of the thorax, and during the prolonged phases without FBM, when active tonic closure of the larynx prevents the egress of lung liquid into the amniotic cavity, in turn distending the lungs.

1.2.2 Control of Breathing in the Perinatal Period

Establishment of respiratory efforts at birth. The process underlying the dramatic change from intermittent breathing in the fetus to continuous breathing in the newborn is far from being completely understood. Most of the information comes from studies in the fetal and newborn lamb. A number of stimuli are likely involved in the process, including the increased arterial pressure in CO_2 (Kuipers et al., 1992; Praud et al., 1997) and decreased arterial pressure in O_2 (not if severe hypoxia is present), the surge in catecholamines, the state of wakefulness, body cooling, and sensorial stimulations (Hillman et al., 2012a). In addition, controversial results have been reported on the crucial importance of a breathing inhibitory factor from placental origin, which would be prostaglandin E_2, and whose effect is suddenly stopped at birth with section of the umbilical cord (Alvaro et al., 1993; Kuipers et al., 1992).

Maturation of the hypoxic ventilatory response in the newborn. The importance and frequency of hypoxic conditions in the newborn has led to numerous experiments conducted in various animal species, including newborn lambs, kittens, piglets, monkeys, guinea pigs, rats, and mice, to study the hypoxic ventilatory response in the neonatal period [see reviews by Darnall (2013), Teppema and Dahan (2010)]. Prenatally, results have shown that hypoxia in the fetal lamb as well as in rhesus monkeys and rats is responsible for a decrease in ventilation. This inhibitory effect of hypoxia on fetal breathing movements' response is likely due to stimulation of the upper pons, as shown by the conversion to a stimulatory effect after lesions in the region of the upper pons, in the region of the parabrachial, and Kolliker-Fuse nuclei [reviewed in Teppema and Dahan (2010)]. Postnatally, the hypoxic ventilatory response is biphasic in the newborn mammals studied to date. Following a rapid increase in minute ventilation for 1–2 min due to carotid body stimulation, various central mechanisms, such as adenosine, GABA and endogenous opioids, as well as decreased metabolism are responsible for a roll-off of the hypoxic ventilatory response (Darnall, 2013; Teppema and Dahan, 2010). In newborn rats and mice, as well as in the preterm human, minute ventilation in the second phase of

the hypoxic response can even decrease below baseline level, with a significant decrease in body temperature (Gallego and Matrot, 2010). In the preterm lamb, the decreased hypoxic ventilatory response is related to the absence of the normal increase in tidal volume (as well as in heart rate) seen in full-term lambs (Pladys et al., 2008).

Postnatal maturation of the carotid body response to hypoxia has also been the subject of numerous studies in animals (Canet et al., 1996). Overall, these studies have established that following birth, carotid body sensitivity to O_2 is reset in a few days, from 3 days in lambs to 2–3 weeks in rodents and 4 weeks in the kitten [reviewed in Carroll and Kim (2013)]. Carotid body resetting is related to the increase in PaO_2 occurring with the transition to air breathing at birth (PaO_2 rapidly increases from 25 to 80 mmHg), as demonstrated by the fact that rising PaO_2 in the fetal lamb in utero by mechanical ventilation during 27 h is responsible for increased carotid body sensitivity at birth (=carotid body resetting had occurred prenatally) (Blanco et al., 1987).

Ventilatory response to CO_2 in the newborn. The ventilatory response to CO_2 in the newborn is very different from the hypoxic ventilatory response. Hypercapnia was shown to stimulate fetal breathing movement in lambs (Jansen and Chernick, 1983). Several studies have been conducted in animals (piglets, puppies, newborn rats, and mice) on the postnatal maturation of the ventilatory response to CO_2 [reviewed by Putnam et al. (2005)]. Depending on the species and the experimental conditions, the response at birth appeared as vigorous or sometimes less than the adult response. In all species, the CO_2 response was low between the 1st and 2nd postnatal week and then increased toward the adult level. The relative importance of breathing frequency or tidal volume in the response to CO_2 during maturation was variable among studies. Intriguingly, a prolongation of expiration was shown during the response to CO_2 in piglets, suggesting that postinspiratory laryngeal braking of the expiratory flow served to reduce the large variations in functional residual capacity, in turn optimizing gas exchange (Dreshaj et al., 2001).

Importance of vagal afferences for neonatal breathing. By constantly monitoring the mechanical status of the lungs throughout the breathing cycle, continuous vagal afferent information from bronchopulmonary receptors has a major influence on respiratory center output. Among other roles, slowly adapting receptors are responsible for the Hering–Breuer reflex that tightly controls tidal volume in newborn mammals, rapidly adapting receptors induce augmented breaths (=sighs), and C fibers participate with slowly adapting receptors in dynamically maintaining a high end-expiratory lung volume (Diaz et al., 1999). The vital importance of such information in the immediate postnatal period has been demonstrated in vagotomized newborn lambs, which die

from respiratory failure in a few hours, likely from at-electasis and hypoxia secondary to the loss of both the active maintenance of a high end-expiratory lung volume and the augmented breaths (Lalani et al., 2001). Though not so crucial a few days after birth, vagal afferent information is still of major importance for normal breathing in the 1st month of life. Indeed, the role of the Hering–Breuer reflex in exerting a tight control at this period is well established in newborn mammals (Trippenbach, 1994), underlying the important role of slowly adapting bronchopulmonary receptors. Experiments in lambs have shown that preterm birth does not alter maturation of the Hering–Breuer reflex. In addition, reflexes originating from C fibers are also present at birth in preterm lambs, though less potent than after full-term birth (Arsenault et al., 2003).

1.2.3 Apnea of Prematurity

Apnea of prematurity continues to be a daily, very important problem in neonatology. It is clearly related to the overall neural immaturity of the preterm newborn, so that the incidence is proportional to the degree of prematurity. Given that virtually all preterm infants born before 28 weeks of gestation suffer from clinically significant apnea of prematurity, and that the number of extreme preterm newborns (22–26 weeks) has been on the rise in neonatal intensive care units (NICUs) within the last years, the incidence of severe apnea of prematurity has similarly increased.

Apnea of prematurity is defined by the occurrence of repetitive, acute, and symptomatic cardiorespiratory events manifesting in a preterm infant as apneas longer than 20 s or shorter if accompanied with bradycardias and/or desaturations. Various mechanisms can be responsible for apnea of prematurity. For instance, the event can be primarily due to immaturity of the brainstem centers responsible for the basal respiratory rhythm, manifesting either as periodic breathing with intermittent hypoxia or as an isolated prolonged apnea + bradycardia + desaturation. In addition, other events can represent a reflex response, for example, originating from laryngeal or esophageal receptor stimulation during a gastric reflux.

A number of studies on apnea of prematurity have been conducted directly in preterm human infants. Animal models, however, have been also frequently used, when there was a need either for invasive instrumentation (e.g., in studies on upper airway muscle activity) or for experimental conditions unacceptable in human infants (e.g., repeated stimulation of the laryngeal mucosa, use of drugs). The following paragraphs summarize a few studies performed in that area. It begins by highlighting the preterm lamb model, which constitutes a unique and real asset for studying apnea of prematurity.

Preterm animal models to study apnea of prematurity. Apart from human newborn infants, most of the studies on spontaneous breathing reported in unanesthetized preterm animals have been performed in lambs, rabbits, monkeys, and in the very immature newborn opossum (Davey et al., 1996; Farber, 1972; Guthrie et al., 1980; Hedner et al., 1984; Marchal et al., 1982). To our knowledge, however, the only reports of *prolonged* recordings during sleep of cardiorespiratory variables in nonsedated, spontaneously breathing preterm mammals are in lambs. The preterm lamb constitutes a unique model of neonatal spontaneous respiratory instability, in which extensive chronic instrumentation and prolonged polysomnographic recordings are possible.

Personal experience (JPP) in prolonged recordings of spontaneously breathing, nonsedated preterm lambs dates from about 20 years. Our preterm lamb model has a postconceptional age of 131 ± 2 days (normal gestation 147 days). Over the years, many improvements have been made in order to increase survival rate and health outcomes of the animals. Following several protocols comparing cesarean section versus vaginal delivery, different methods to induce delivery, more or less postnatal intensive care (Arsenault et al., 2003; Reix et al., 2003, 2004; Renolleau et al., 1999; St-Hilaire et al., 2007), we are now using the following protocol, which ensures a mean survival of ~75% after 5–7 days of life, when we can perform surgical instrumentation followed by polysomnographic recordings. Premature labor is induced by mifepristone in ewes with dated gestation, after antenatal lung maturation by two betamethasone injections. Vaginal delivery occurs under continuous surveillance, in order to intervene in case of dystocia. At birth, lambs are cared by their mother, under strict and continuous supervision by an observer present for 48 h. Vital signs, including body temperature, heart and respiratory rate, oxygen saturation, blood glucose level, and weight are regularly monitored. Lambs need to be bottle-fed (preferably with mother's milk) in the first 24–48 h until they are strong enough to feed by themselves from the ewe. Apart from severe dystocia, the problems often encountered in the first 24–48 h include hypoglycemia, slight hypoxemia and hypothermia, which are immediately corrected. No exogenous surfactant is administered and no endotracheal support is given (Boudaa et al., 2013). The most recent addition is the successful use of high-frequency nasal cannula as a primary respiratory support in lambs with mild to moderate respiratory distress syndrome, which parallels recent results from randomized controlled trials in preterm infants with a gestational age (GA) greater than 28 weeks (Lavizzari et al., 2016). About 20% of the preterm lambs must be euthanized within the first 24 h due to severe respiratory distress syndrome. General anesthesia for chronic surgical instrumentation can be given

without problem after 5 days; local anesthesia is preferable when the research protocol necessitates earlier surgical instrumentation.

Availability of both the preterm and full-term lamb model constitute a truly unique asset to assess the effect of preterm birth both during physiological studies and in experiments mimicking pathological conditions encountered in the NICU and beyond. We have taken advantage of this comparison especially to perform studies on the control of breathing and apneas of prematurity, as reported in the following sections.

Active glottal closure during neonatal central apneas. Current knowledge ascribes an essential role to the larynx in perinatal respiration. Accordingly, the larynx helps the newborn in its transition from intrauterine to extra uterine environment by promotion of fetal lung growth, establishment of functional residual capacity, reabsorption of lung water (Praud et al., 1995), and maintenance of a high functional residual capacity in the early postnatal life (Harding, 1984). Moreover, several studies suggest an important role of the larynx in neonatal central apneas. In 1980, Milner speculated that glottal closure was frequently present during central apneas in preterm newborns (Milner et al., 1980). Since then, several observations in the newborn lamb have supported Milner's speculation [reviewed in Dorion and Praud (2003)]. In a first series of experiments on artificially induced central apneas, continuous electrical activity (EMG) of the thyroarytenoid muscle (TA, a glottal constrictor muscle) was observed throughout central apneas, irrespective of arterial oxygenation (from hypoxemia to hyperoxemia) and arterial pressure in CO_2 (from hypocapnia to hypercapnia) (Kianicka et al., 1998b; Praud et al., 1992, 1996). Moreover, direct endoscopic observation showed complete glottal closure, associated with positive subglottal and translaryngeal pressure and with a high apneic lung volume well above the end-expiratory volume during these central apneas (Fortier et al., 2003; Lemaire et al., 1999). Overall, results showed that central apneas in the lambs were alike inspiratory breath holdings due to active glottal closure. The latter was also shown to be present between the gasps observed during anoxic gasping in lambs. This was interpreted as allowing the lamb to keep more air within its lungs to promote more efficient oxygenation between the low-frequency gasps (Thuot et al., 2001).

However, all of the aforementioned results were obtained during artificially induced apneas, as very few spontaneous apneas are actually observed in full-term lambs. Thus, laryngeal dynamics were also studied and characterized during spontaneously occurring apneas in preterm lambs (Renolleau et al., 1999). Results from preterm lambs born between 129 and 132 days of gestation showed that continuous TA EMG was observed throughout 88% of all apneas, including periodic

breathing epochs and regardless of the sleep state (Diaz et al., 1999). This glottal constrictor activity was also associated with positive subglottal pressure and maintenance of a high apneic lung volume well over the passive functional residual capacity, consequently limiting the decrease in hemoglobin desaturation secondary to the central apnea (Reix et al., 2003).

Apneas triggered by the stimulation of laryngeal chemoreceptors. Laryngeal chemoreflexes (LCR) are a set of reflexes triggered by the contact between a liquid, especially acid or liquid with low chloride content, and the laryngeal mucosa. LCR trigger highly protective lung reflexes in the mature organism, consisting primarily of swallowing, coughing and arousal, aimed at limiting contact duration with the laryngeal mucosa and at preventing subglottal aspiration (Thach, 2001). However, in immature organisms, LCR are rather characterized by a vagal efferent component that includes laryngospasms, central or mixed/obstructive apneas, oxygen desaturation and bradycardia, and can be life-threatening; LCR also comprehend a sympathetic efferent component, which includes systemic hypertension and redistribution of blood flow to vital organs (Thach, 2001). Clinical relevance of LCR stems from common observations that LCR can be triggered by laryngopharyngeal refluxes or during oral feeding, or intake of medications (e.g., vitamins or iron) and even by upper airway secretions in preterm neonates (Thach, 2001). In addition, LCR can be responsible in a few infants, even when born after full-term gestation, for apparent life-threatening events and probably some cases of sudden infant death syndrome (Page and Jeffery, 2000; Thach, 2001).

Since the first observation by Johnson et al. (1972) in the anesthetized lamb, several studies have assessed LCR in response to various liquids in newborn mammals (Marchal et al., 1982, 1986; Page et al., 1995; St-Hilaire et al., 2005, 2007) or in human infants (Davies et al., 1988; Page and Jeffery, 1998; Pickens et al., 1988). In full-term lambs, LCR induced during non-REM sleep are mainly characterized by lower airway protective responses, such as swallowing, cough and arousal, with mild cardiorespiratory responses (St-Hilaire et al., 2005); results similar to those obtained in nonsedated piglets (Page et al., 1995). Identical observations have been made in healthy human neonates in whom the onset of apnea-bradycardia is rare after a term birth, apart from the unexpected apparent life-threatening events described in ~1% of infants in their 1st weeks of life (Thach, 2010). Conversely to full-term lambs, studies in the preterm lamb strongly suggest that prematurity is responsible for fetal-type LCR, with prominent apnea, bradycardia and hemoglobin desaturation, which can at times be life-threatening (St-Hilaire et al., 2007). A similar enhancing effect of prematurity on reflex apnea from laryngeal origin had been previously reported in the monkey (Sutton

et al., 1978). This enhanced LCR-related cardiorespiratory inhibition in preterm lambs largely decreases with postnatal maturation (St-Hilaire et al., 2007). In addition, while application of nasal continuous positive airway pressure was consistently found to blunt the LCR-related cardiorespiratory inhibition in preterm lambs, the overall effect of caffeine was nonsignificant, which is in accordance to the well-reported observation in preterm human infants that some apneic–bradycardic events, especially those related to oral intake, are not prevented by caffeine (Boudaa et al., 2013).

Apart from preterm birth, other neonatal conditions have been reported to enhance the cardiorespiratory inhibition during LCR. These conditions include reflux laryngitis artificially induced in rabbits (Ludemann et al., 1998) or full-term lambs (Carreau et al., 2011), respiratory syncytial virus infection in newborn lambs (Lindgren et al., 1992), hyperthermia in piglets, (Xia et al., 2008), sedation in piglets (Donnelly and Haddad, 1986), hypoxia in newborn lambs (Sladek et al., 1993) or piglets (Lanier et al., 1983), and acidosis in piglets (Heman-Ackah et al., 2009).

Apneas triggered by the stimulation of esophageal receptors. The involvement of gastroesophageal refluxes (GERs) in apnea–bradycardia of prematurity remains controversial (Abu Jawdeh and Martin, 2013). While a few physiological studies have shown that the stimulation of esophageal receptors leads to cardiorespiratory reflexes (Jadcherla et al., 2005; Lang et al., 2008; Ramet et al., 1990), the later remain largely unknown in the neonatal period, especially after premature birth. Recent results in nonsedated preterm lambs revealed that, compared to full-term lambs, esophageal stimulations (balloon distension and/or HCl injection) can induce forceful, clinically relevant apneas and bradycardias, especially when mimicking a proximal GER (unpublished results).

Neonatal apneas and sepsis. Late-onset sepsis in the preterm newborn is a life-threatening condition, occurring in about 35% of preterms born before 28 weeks of gestation in the NICU. Mortality is as high as 15% (Dong and Speer, 2015). The first sign of sepsis is often repetitive, severe bouts of apneas and/or bradycardias (Fairchild, 2013). Studies in newborn rats have shown that apneas are related to systemic inflammation via the inhibiting action of prostaglandin E_2 on the respiratory centers; during sepsis, interleukin 1-beta binds to receptors on the vascular endothelial cells of the blood brain barrier, which in turn induces microsomal prostaglandin E synthase-1 (mPGES-1) activity and the secretion of prostaglandin E_2 (Hofstetter et al., 2007). Though this hypothesis has received some confirmation in preterm humans, the severe bradycardias that are often prominent in late onset sepsis do not seem to be fully explained by the action of PGE_2 (Siljehav et al., 2015).

2 NEONATAL LUNG DISEASES

2.1 Congenital Diaphragmatic Hernia

Congenital diaphragmatic hernia is an anatomical defect of the diaphragm, most often located on the left side posteriorly. Its prevalence is between 1000 and 4000 live births. It is secondary to various genetic mutations as well as poorly known environmental factors. It is a life-threatening condition, resulting from the lung hypoplasia directly related to the volume of the abdominal viscera herniating through the diaphragmatic hole into the thorax. Congenital diaphragmatic hernia can be diagnosed prenatally by ultrasound; the latter can measure the extent of lung hypoplasia, which is directly related to postnatal clinical outcomes. When isolated, congenital diaphragmatic hernia is lethal in about 30% of the cases (Deprest et al., 2014). Randomized control trials have shown that surgical repair of the hernia in utero does not increase survival. Following in utero transfer in a specialized tertiary center as soon as the diagnosis is made by prenatal ultrasound, current management at birth consists in "gentle" ventilation with permissive hypercapnia and minimal sedation to prevent VILI, the surgical closure of the diaphragmatic defect being delayed until clinical stabilization. In addition, nitric oxide inhalation, high-frequency ventilation and extracorporeal oxygenation are used as needed. However, despite in utero transfer and optimized postnatal care, about 30% of newborns with congenital diaphragmatic hernia still do not survive the neonatal period in tertiary centers. The problem is that postnatal care cannot be sufficient in the most severe cases with major lung hypoplasia and persistent pulmonary hypertension of the newborn, so that treatment of lung hypoplasia must be addressed prenatally.

Animal models of congenital diaphragmatic hernia have greatly contributed to the understanding of the pathogenesis and to the design of treatment options, especially in the fetal period. The two main animal models are the nitrofen-induced congenital diaphragmatic hernia in the rat and the surgically induced congenital diaphragmatic hernia in the fetal lamb or rabbit (van Loenhout et al., 2009). These models are well established and reproduce not only the diaphragmatic defect, but also the accompanying bilateral pulmonary hypoplasia. The fetal lamb model has been the most useful for preclinical studies on in utero surgical procedures to alleviate prenatal lung hypoplasia, due to its size similar to a human fetus. Conversely, the nitrofen rat model can be used to understand the pathogenesis of congenital diaphragmatic hernia. More recently, transgenic models have also been designed by ablation of the retinoic acid receptor signaling (Mendelsohn et al., 1994).

Numerous preclinical studies have focused on the prenatal treatment of congenital diaphragmatic hernia, with the aim to reverse lung hypoplasia. Fetal endoscopic tracheal occlusion consists in the placement of a balloon in the trachea to prevent the efflux of lung fluid, increase the pressure into the lung and promote lung growth via pulmonary stretch (Deprest et al., 2014). Preclinical studies in lambs, rats, rabbits, and mice have indeed shown that tracheal obstruction at the late canalicular–early saccular stage efficiently stimulates lung growth and maturation [reviewed in Khan et al. (2007)]. Consequent lung hyperplasia was shown to be associated to decreased pulmonary hypertension resulting from decreased muscularization of the distal pulmonary vessels. More recently, a further translational model of percutaneous fetoscopic tracheal occlusion has been reported in baboons, in order to obtain the closest possible model to humans (Mari et al., 2014). Translation of those preclinical studies is currently culminating in the still ongoing international TOTAL trial (Tracheal Occlusion To Accelerate Lung growth trial) (Deprest et al., 2014). Previous studies with historical controls suggest that this randomized control trial will confirm a decrease in mortality with percutaneous fetal endoscopic tracheal occlusion in congenital diaphragmatic hernia patients with moderate to severe lung hypoplasia. However, given that survival should reach 50% at best in the most severe cases after fetal tracheal occlusion, studies on complementary medical treatments given prenatally have been also conducted in animal models of congenital diaphragmatic hernia.

Medical treatment, consisting mainly of vitamins (A, C, or E) and corticoids (betamethasone, dexamethasone, or prednisolone), was given either to the mother (rats, rabbits, or lambs) or directly into the amniotic cavity (rats, rabbits, or lambs) or the trachea (lambs) [reviewed in Eastwood et al. (2015)]. While some positive effect was shown, the overall conclusion is that at the moment no medical treatment can be considered effective for use in humans.

2.2 Meconium Aspiration Syndrome
