Meconium aspiration syndrome is a respiratory disorder of the term and near-term newborns. It is defined by inhalation of the meconium present in the amniotic fluid during or before delivery, secondary to anoxic gasping in utero. Meconium aspiration syndrome induces: (1) mechanical obstruction of airways, (2) chemical alveolitis and epithelial damage, (3 and 4) inhibition of surfactant pulmonary artery hypertension (Dargaville and Mills, 2005; Davey et al., 1993; Moses et al., 1991; Park et al., 1996). A variety of animal models of meconium aspiration syndrome have allowed to test various therapeutic options, such as high-frequency ventilation in mongrel puppies (Keszler et al., 1986) or piglets (Wiswell et al., 1994), pulmonary lavage with diluted surfactant in adult rabbits and newborn rhesus monkeys (Cochrane et al., 1998), piglets (Dargaville et al., 2003), newborn rabbits (Lyra et al., 2004) and lambs (Avoine et al., 2011), and liquid ventilation in lambs (Avoine et al., 2011; Foust et al., 1996; Gastiasoro-Cuesta et al., 2001) or piglets (Barrington et al., 1999; Jeng et al., 2006; Kuo et al., 1998; Onasanya et al., 2001).

2.3 Bronchopulmonary Dysplasia

Bronchopulmonary dysplasia, or chronic lung disease of infancy, occurs most frequently in the premature newborn. Bronchopulmonary dysplasia is usually defined by the need for oxygen supplementation at 28 days of life, its severity being further characterized by the level of inspiratory oxygen fraction needed at 36 weeks corrected age (Jobe and Bancalari, 2001). Despite continuing improvements in the overall perinatal care of preterm infants and, more specifically, in the treatment of neonatal respiratory distress syndrome, the increase in the number of extreme premature newborns (22–26 weeks GA) explains that the incidence and severity of bronchopulmonary dysplasia is still very high. Bronchopulmonary dysplasia is diagnosed in 30,000 infants every year in North America and increases the risk of respiratory problems in the 1st year of life, hospital admission being necessary in more than 50% of the infants (Smith et al., 2004). In addition, bronchopulmonary dysplasia has long-term consequences, the incidence of asthma and chronic obstructive pulmonary disease being increased at adult age (Hadchouel, 2016; Landry, 2016).

Numerous studies conducted in animal models have attempted to gain a better understanding of the pathogenesis as well as the prevention of this dramatic disease.

2.3.1 Pathogenesis of Bronchopulmonary Dysplasia

Bronchopulmonary dysplasia is due to both genetic factors and environmental factors. While genetic factors have been studied in humans (Lavoie, 2016), studies in animal models have contributed to give a better understanding of how the environment contributes to the disease. Environmental factors include mechanical ventilation, oxygen exposure, as well as pre- and postnatal infections. They are responsible for an important inflammatory response of the lung. The later ultimately leads to a decrease in alveolarization and pulmonary microvascular development, that is, characteristics of the bronchopulmonary dysplasia occurring in very preterm infants nowadays.

Effects of hyperoxia on the newborn lung. Though its effects are difficult to distinguish from those of mechanical ventilation, hyperoxia is undoubtedly involved in the pathogenesis of bronchopulmonary dysplasia [reviewed

in Harijith (2016)]. The transition from the intrauterine environment to ambient air at birth in itself constitutes a hyperoxic stress that is especially deleterious in the very preterm newborn. Reactive oxygen and nitrogen species released by alveolar epithelial cells and inflammatory cells promote death of the endothelial and epithelial cells. Ultimately, hyperoxia largely contributes to decreased alveolarization and microvascular pulmonary development.

Newborn mice and rats have been extensively used to study the effect of hyperoxia. Mice and rats, which are normally born at the saccular stage of lung development but with a mature lung surfactant and antioxidant system, are studied after term or near-term birth (Berger and Bhandari, 2014; O'Reilly and Thebaud, 2014). Their low price, the ability to study many newborn pups at a time, together with the availability of transgenic animals and numerous molecular biology tools, make them especially attractive. These models are, however, not adapted to the study of prolonged mechanical ventilation, and their size limits instrumentation and in vivo blood sampling.

Newborn rabbits have been used in hyperoxia research since the mid-20th century [reviewed in D'Angio and Ryan (2014)]. Like newborn mice and rats, and conversely to their adult counterparts, they can withstand exposure to 95% oxygen for several days. Like the human newborn, they are normally born at the alveolar stage of lung development. Their size permits some more instrumentation than in newborn mice and rats, and their cost is relatively low. Both term and preterm rabbit models have been used to study the effect of hyperoxia exposure, sometimes with additional neonatal infection/inflammation or postnatal malnutrition. While some studies on mechanical ventilation have been performed in newborn rabbits, their low size relative to the human preterm newborn does not offer the possibility to mimic the conditions encountered in the NICU as well as with the sheep or nonhuman primate model.

Effect of mechanical ventilation on the preterm lung. VILI has been shown to be a major factor in the pathogenesis of bronchopulmonary dysplasia, mainly via volutrauma and atelectrauma that are responsible for shear stress and stretch lesions of the lung cells [reviewed in Ramos (2016)]. These mechanical factors can very rapidly induce extensive inflammation and death of the resident lung cells and augment alveolar–capillary permeability in a few minutes. The latter leads to an influx of neutrophils and macrophages that release proinflammatory cytokines and chemokines, and amplify the inflammatory response initiated by resident lung cells. Consequences of the extensive VILI include decreased alveoralization and microvascular pulmonary development. Reduced alveolarization proceeds from alterations of the normal extracellular matrix remodeling and elastin deposition

in the developing secondary septae, which are crucially involved in alveolarization at the saccular stage. Decreased microvascular pulmonary development is caused by a decrease in vascular endothelial growth factor (VEGF) secondary to the hyperoxia associated to mechanical ventilation.

The preterm lamb and the preterm nonhuman primate newborn have been frequently used for studying the effects of mechanical ventilation. They offer several distinct advantages over the other smaller models. Lambs and nonhuman primates are normally born at term at the same early/middle alveolar stage of lung development than human newborns. While many studies have been performed on the effects of mechanical ventilation in the preterm lamb, the majority lasted only a few hours. With proper around-the-clock intensive care, however, preterm lambs and nonhuman primates born at the saccular stage of lung development and with immature surfactant, and antioxidant lung systems have a prolonged viability that allows to study them during several weeks under mechanical ventilation (Albertine, 2015). Their large size close to that of a preterm human newborn allows to mimic the conditions encountered in the NICU, with extensive instrumentation and possibility of repetitive blood sampling. They have the downside to be expensive and to necessitate special animal facilities. In addition, while the preterm nonhuman primate model is the closest to the human preterm, its price and ethical considerations severely restrict its use.

2.3.2 Prevention and Treatment of Bronchopulmonary Dysplasia

Apart from preventing premature delivery, which is the focus of many ongoing clinical studies, prevention of bronchopulmonary dysplasia begins by the prevention of respiratory distress syndrome via antenatal administration of glucocorticoids to the mother. At birth, as already summarized (see Section 1.1.3; "The quest for the optimal ventilator strategy to support lung aeration at birth in very preterm newborns"), studies are ongoing to find the optimal positive pressure ventilatory support technique to aerate the lung when needed. Thereafter, early surfactant administration, closure of the ductus arteriosus, optimization of nutritional intake, prevention of late onset sepsis, prudent use of systemic or intratracheal glucocorticoids, and the use of the less invasive form of ventilatory support are all important aspects of the care of newborns with bronchopulmonary dysplasia. While many of the studies dealing with the prevention and treatment of bronchopulmonary dysplasia have been performed in the newborn infant, animal models have greatly contributed to some important aspects, as summarized subsequently.

Antenatal glucocorticoids administration. Since the work by Liggins and Howie (1972), antenatal glucocorticoids

administration is now a standard care for the prevention of respiratory distress syndrome when preterm delivery. An elegant review of the scientific literature on the usage of glucocorticoids in pregnancy was recently performed (Kemp et al., 2016). Studies in the rhesus macaque (Bunton and Plopper, 1984), the preterm lamb (Jobe et al., 2003; Polglase et al., 2007), and in knockout mice models (Bird et al., 2015) have clearly demonstrated that antenatal corticosteroid exposure induces fetal lung maturation and largely prevents the occurrence and the severity of respiratory distress syndrome in preterm newborns. Results in these preterm models suggested that improvement in lung function was most likely mediated by surfactant production (Bolt et al., 2001; Garbrecht et al., 2006), structural lung modifications (Bird et al., 2015; Bunton and Plopper, 1984; Polglase et al., 2007), and alveolar fluid clearance (Whitsett and Matsuzaki, 2006).

Noninvasive ventilatory support. Apart from the use of noninvasive ventilatory support for ensuring lung aeration at birth, noninvasive ventilatory support has gained popularity in recent years in neonatal care, either for primary use from birth, for weaning from endotracheal ventilation, or for treating apneas of prematurity in infants with bronchopulmonary dysplasia (DiBlasi, 2011; Flanagan, 2016; Garg and Sinha, 2013; Ramanathan, 2010). The bulk of knowledge in this area comes from clinical studies. Nevertheless, some studies conducted primarily in newborn lambs have brought unique information.

The use of long-term high-frequency nasal ventilation during several weeks from birth has been shown in preterm lambs to provide adequate gas exchange at lower inspired O_2 level and respiratory pressures compared to endotracheal intermittent mandatory ventilation. Simultaneously, alveolarization was promoted (Null et al., 2014; Reyburn et al., 2008).

A series of experiments in term newborn lambs brought clinically relevant information on nasal ventilation. A major difference when using a nasal interface as opposed to an endotracheal tube for respiratory support is the interposition of the larynx between the ventilator and the lungs. Studies in newborn lambs have shown that some modes of nasal positive pressure ventilation, such as nasal pressure support, elicit an active inspiratory laryngeal closure, which impedes ventilator insufflations and limits lung ventilation in proportion to the inspiratory positive pressure (Moreau-Bussiere et al., 2007). On the contrary, neurally adjusted ventilatory assist (Hadj-Ahmed et al., 2012) and nasal high-frequency oscillatory ventilation (Hadj-Ahmed et al., 2015), did not induce active inspiratory laryngeal narrowing. The reflex inspiratory closure of the larynx in nasal pressure support ventilation was shown to originate from bronchopulmonary mechanoreceptors (Roy et al., 2008; Samson et al., 2014), and to be prevented by permitting moderate hypercapnia (Carriere et al., 2015).

Besides limiting lung ventilation, inspiratory closure of the larynx may be responsible for deviation of the insufflated gas into the digestive system, leading, in turn, to gastric distension and GERs (DiBlasi, 2011; Lagarde et al., 2010; Shepherd et al., 2013). Importance of the latter stems from their potential deleterious effects, as reviewed previously (see Section 1.2.3). Further experiments in the newborn lamb, however, have recently shown that both nasal pressure support and neurally adjusted ventilatory assist inhibit GERs at positive pressures of 15/4 cmH$_2$O (Cantin et al., 2016). An important inhibition had also been shown previously with the application of nCPAP at 6 cmH$_2$O, the mechanism being seemingly related to the decrease of the duration and depth of transient relaxation of the lower esophageal sphincter (Djeddi et al., 2014).

Stem cells and bronchopulmonary dysplasia. Stem cells are promising for preventing and treating bronchopulmonary dysplasia. The newborn mouse, rat, and sheep models of bronchopulmonary dysplasia have been used to show the beneficial effects of stem cell therapy. Stem cells, including those derived from the amnion or umbilical cord blood, were shown to induce a reduction of VILI, improved alveolarization, increased survival, and better lung function (Fung and Thebaud, 2014; Hodges et al., 2012; O'Reilly and Thebaud, 2015).

PATENT DUCTUS ARTERIOSUS

1 INTRODUCTION

The ductus arteriosus is an essential component of fetal circulation allowing for communication between the pulmonary artery and the aorta (Hermes-DeSantis and Clyman, 2006). It functions to keep blood away from lungs filled with amniotic fluid toward a descending aorta and a placenta in utero. After birth, the direction of the blood flow through the ductus arteriosus reverses as the pulmonary blood pressure drops. Then, the ductus arteriosus constricts and functionally closes spontaneously by 72 h of age in more than 95% of term infants (Lim et al., 1992). A patent ductus arteriosus (PDA) is a left-to-right shunt disease caused by the failure of the closing process. PDA is associated with several neonatal morbidities, and the severity of clinical symptoms depends on the magnitude of the left-to-right shunt and on the cardiac and pulmonary responses to the shunt (Clyman, 2013).

First, the left-to-right shunt flow causes increased pulmonary blood flow that leads to increased preload of the left ventricle. Combined with the prematurity of ventricle, namely, less distensible compared to that at term, the shunt causes high left ventricular end-diastolic pressure and increased pulmonary venous pressure. This high pulmonary venous pressure leads to pulmonary

congestion (Clyman, 2013), resulted in increased needs for respiratory support. It has been suggested this pulmonary congestion/edema contributes to develop and exacerbate bronchopulmonary dysplasia, however, there is little evidence from controlled, clinical trials to support this hypothesis (Clyman, 2013).

Second, the shunt causes the decreased blood flow to the pressure passive organs like the intestines, skin, muscle, and kidneys. This redistribution may result in several adverse outcomes including feeding intolerance, necrotizing enterocolitis (NEC), metabolic acidosis, and renal dysfunction (Dice and Bhatia, 2007; Hermes-DeSantis and Clyman, 2006).

2 NORMAL PHYSIOLOGICAL COURSE OF DUCTUS ARTERIOSUS

During fetal life, low fetal systemic PaO_2 and circulating prostaglandin keep the lumen of the ductus arteriosus open. As fetuses do not breathe but depend on the placental circulation with gas exchange in utero, the maintenance of fetal circulation is literally vital. On the other hand, failure to close the ductus arteriosus after birth leads to the morbidity described previously. The closure of the ductus arteriosus in full-term infants occurs in two steps below. First, increased arterial PaO_2 and decreased circulating prostaglandins allow the smooth muscle media of the ductus to constrict within the first few hours (functional closure). Second, the inner muscle wall of the ductus arteriosus develops profound ischemic hypoxia which leads to the anatomic remodeling that transforms the ductus into a noncontractile ligament (structural closure) (Clyman et al., 1999; Hermes-DeSantis and Clyman, 2006).

3 PATHOPHYSIOLOGY OF PATENT DUCTUS ARTERIOSUS

Contrary to full-term ductus arteriosus, premature ductus arteriosus often fails to close due to several reasons.

First, the premature ductus is less likely to constrict and is easy to reopen. The premature ductus is less sensitive to elevated PaO_2 due to immature oxygen sensitive K^+ channel (Thebaud, 2004). And it loses its ability to respond to vasoconstrictive stimulants with increasing postnatal age owing to depletion of oxygen and ATP (Levin et al., 2006). While, the premature ductus is more sensitive to the effects of prostaglandins (Clyman et al., 1985) that are produced in inflammation (Ricciotti and FitzGerald, 2011). This characteristic contributes to easy reopening of the ductus. Thus, the premature ductus is less likely to achieve the functional closure.

Second, the premature ductus is less likely to develop profound hypoxia that leads to the structural closure, because the diameter of the lumen is larger compared to that of full-term ductus (Hermes-DeSantis and Clyman, 2006), due to lack of intimal cushion formation (Gittenberger-de Groot et al., 1985; Tada et al., 1985). This anatomical characteristic makes it difficult to develop complete luminal obliteration and complete elimination of nutrient flow to its wall (Hermes-DeSantis and Clyman, 2006). As a result, the premature ductus is less likely to achieve the structural closure.

4 TREATMENT FOR PATENT DUCTUS ARTERIOSUS

Indomethacin is a cyclooxygenase inhibitor that has been used for the closure of PDA by lowering circulating prostaglandin levels since the late 1970s (Friedman et al., 1976; Heymann et al., 1976). Although the efficacy of indomethacin has been well established, paradoxically, prenatal indomethacin as a tocolytic agent increases both the incidence and clinical severity of postnatal PDA (Hammerman et al., 1998), suggesting a more complex role for prostaglandins in the developmentally regulated process of maturation and postnatal closure of ductus arteriosus. An alternative treatment strategy for PDA is a surgical ligation. It was reported that no significant difference between indomethacin treatment and surgical closure was found for in-hospital mortality, chronic lung disease, NEC, sepsis, creatinine level, or intraventricular hemorrhage (IVH) (Malviya et al., 2013).

5 ANIMAL MODELS OF PATENT DUCTUS ARTERIOSUS

Bergwerff et al. (1999) reviewed the anatomy and physiological ductal closure in various vertebrates from lungfish to mammals, and showed anatomical similarities in all mammals and differences between mammals and other vertebrates. In all mammals, including human, it is the left aortic arch that persists and only the left ductus arteriosus is maintained throughout fetal life. Most of previous studies employed mammal models, and several mammal models have been used depending on the purpose. Meanwhile, the potential utility of chicken embryo models was reported recently (Agren et al., 2007; Sutendra and Michelakis, 2007).

5.1 Large Mammal Models

Large mammals including dog, sheep, and nonhuman primates have been employed mainly in the anatomical and physiological studies.

PDA is the most common cardiac anomaly observed in dogs (Patterson, 1968). Histological features of the normal ductus arteriosus and PDA in dogs resemble those of the normal ductus arteriosus and PDA in humans, suggesting a similar pathogenesis in both species (Bökenkamp et al., 2010). Using dog models, it is reported that the aortic end of the ductus is the least advanced toward closure, and the pulmonary end the most advanced (Gittenberger-de Groot et al., 1985).

Other large mammal models, such as premature lamb or primate models have been mainly used when exploring the physiological effects of PDA including changes in ventilation and cardiac function (Pérez Fontán et al., 1987; Shimada et al., 1989). Their large body sizes allow to employ several intensive care strategies including intratracheal intubation, mechanical ventilation, and central catheterization, then enable us to reproduce the clinical setting. The premature baboon [delivered at 125 days of GA, term = 185 days] has a similar neonatal course including a spontaneous closure with premature human infants delivered between 25 and 26 weeks of GA (Clyman et al., 1999, 2012).

Although anatomically similar, there are some differences in the process of ductal closure between humans and large mammals, that is, the timing of the intimal cushion formation. Ductal closure is accompanied by intimal cushion formation as described previously, which starts during fetal life. Humans show the earliest onset of intimal thickening and, by far, the most extensive cushion formation (Bökenkamp et al., 2010; Groot and van Ertbruggen, 1980).

5.2 Small Mammal Models

In contrast to large mammal models, small mammal models including rodents have been mainly employed to explore the mechanism of ductal closure on the molecular level. Gene-targeted mouse models have been created to elucidate mechanisms by which known effectors affect ductus development, prenatal patency, and postnatal ductal closure (Bökenkamp et al., 2010). Using mouse models, it has been revealed that genetic disruption of the prostaglandin E specific receptor EP4 paradoxically results in fatal PDA (Nguyen et al., 1997; Segi et al., 1998). The deficiency in both COX-1 and COX-2 also resulted in fatal PDA (Loftin et al., 2001). Yokoyama et al. (2006) revealed the mechanism of this mystery using mouse models as well, that is, persistent prostaglandin E stimulation via EP4 plays a role of vascular remodeling of the ductus arteriosus to promote the intimal cushion formation and structural closure of the vascular lumen.

5.3 Chicken Models

Although most of current available data are derived from mammals, there is the limitation in mammal models when it comes to explore the developmental physiology of ductus in utero, since (1) the fetal/placental circulation has to be exposed to intervention only through complex surgery and (2) manipulation of the ambient oxygen levels affects both the mother and the fetus (Sutendra and Michelakis, 2007). The chicken embryo models solve these problems and represent an excellent model to investigate developmental physiology of the cardiovascular system. Birds have completely septated hearts and arterial outflows, in contrast to reptiles (except for crocodilians) and lower vertebrates (Bergwerff et al., 1999). Chicken ductus has been shown its sensitivity to a wide range of vasoactive agonists including oxygen, prostaglandin, and NO as with mammals (Agren et al., 2009). Thus, the chicken embryo appears as another good model for the study of ductus arteriosus. However, there are also limitations in these models, namely, birds maintain bilaterally developed ductus arteriosus, that is contrast to mammals but similar in anatomy and physiology to reptiles. In addition, all birds close their ductus arteriosus permanently from the time of hatching without exception (Bergwerff et al., 1999).

RETINOPATHY OF PREMATURITY

1 INTRODUCTION

Retinopathy of prematurity (ROP) is an eye disease of developing blood vessels that affects preterm babies. It was reported that the incidence of ROP was 68% among infants whose birth weights were less than 1251 g (Good et al., 2005). Although the severity decreased as the mechanism of this disease has been revealed and then the management of oxygen therapy has been refined, it becomes the leading cause of childhood blindness due to progressive increasing the number of preterm birth all over the world (Hartnett and Penn, 2012).

This disease was first described as the "retrolental fibrodysplasia" by Terry more than 70 years ago (Terry, 1942), followed by numerous studies, in which animal models including kittens, mice, and rats were mainly employed to reveal the underlying mechanism and to explore the efficient treatment strategy.

2 NORMAL VASCULARIZATION OF HUMAN RETINA

In humans, normal vascularization of the retina and vitreous body begins at approximately 16 weeks of GA (Flynn, 1992). The process starts with the most superficial (or inner) retinal layers at the optic nerve head, and radiates outward or anteriorly from this central point (Gariano and Gardner, 2004). During the early stages,

vascular supply to the eye is partially provided by the hyaloid vasculature originating from the optic nerve and traversing the primitive vitreous toward the anterior segment. The hyaloid vasculature is a transient existing network of capillaries, and is regressed and removed when ocular development proceeds (Mitchell et al., 1998). Hyaloid regression is usually completed before 34 weeks of GA in humans. By this time, development of the intraretinal vasculature is already well advanced. The nasal retina becomes fully vascularized at approximately 36 weeks of GA, and the temporal vessels reach the ora serrata at approximately 40 weeks of GA. Thus, a human term infant is born with fully developed retinal vessels and with regressed hyaloid vasculature (Stahl et al., 2010).

3 PATHOPHYSIOLOGY OF RETINOPATHY OF PREMATURITY

ROP consists of following two phases. The first phase is delayed or attenuated retinal vascular development. This occurs when the premature infant is born into a hyperoxic postnatal environment, and is worsened by supplemental oxygen therapy. The second phase is neovascularization stimulated by the oxygen-related factors, such as erythropoietin and VEGF (Hellström et al., 2013). This neovascularization potentially leads to intravitreal hemorrhages, retinal detachment, and ultimately, vision loss because these vessels are often disorganized and leaky due to a lack of the normal developmental regulatory mechanisms (Dorrell and Friedlander, 2006). The transition between first phase and second phase seems to depend on the postmenstrual age of the infant rather than the postnatal age (Hellström et al., 2013). It is reported that ROP begins at roughly 30 weeks of GA and peaked at 36–38 weeks of GA, irrespective of GA at birth (Palmer et al., 1991).

As it was reported in early 1950s that high oxygen level is strongly associated with the development of ROP (Campbell, 1951); most of the studies after that have employed oxygen-induced retinopathy models. On the other hand, the association between the ROP and the inflammatory response, which plays an important role in several diseases that affect premature infants including bronchopulmonary dysplasia and white matter injury, had not been explored for a long period. However, the evidence of association between the inflammation and the ROP has been emerged recently (Chen et al., 2011b; Dammann et al., 2009; Hong et al., 2014; Sood et al., 2010). The extreme prematurity plus multiple hits of perinatal inflammation, such as clinical chorioamnionitis and neonatal systemic inflammatory response syndrome, are associated with an increased risk of ROP (Chen et al., 2011a; Dammann et al., 2009). Of note, the three risk factors, (1) neonatal sepsis, (2) oxygen exposure, and (3) low GA, increase the risk of ROP not additively but multiplicatively (Dammann, 2010).

4 TREATMENT OF RETINOPATHY OF PREMATURITY

Cryotherapy, ablation of the peripheral nonvascularized retina in order to stop the progression of ROP by decreasing VEGF level and other angiogenic factors from the hypoxic retina, was induced in 1980s. The multicenter trial of cryotherapy revealed that this treatment had significantly reduced total retinal detachments by 19.8% at 10 years of age (Cryotherapy for Retinopathy of Prematurity Cooperative Group, 2001). This has been confirmed over time, and cryotherapy has become established as standard care for threshold ROP (Palmer et al., 2005). Laser photocoagulation has taken over the role as a standard treatment for ROP in developed countries (Cuthbertson and Newsom, 2006), owing to its advantages including easier administration, lower rates of complications, and efficacy that is at least equivalent to cryotherapy, although no randomized clinical trial that compared cryotherapy with laser photocoagulation directly has been conducted yet (Simpson et al., 2012).

5 ANIMAL MODELS OF RETINOPATHY OF PREMATURITY

Despite the severity with regards to the quality of life for affected infants, ROP is not life-threating disease. It is relatively and ethically difficult to obtain samples from human infants suffering from this disease in timely manner. Therefore, animal models have been quite important to reveal the mechanism of ROP. While, unlike humans, the retinal vascularization occurs postnatally in many mammals, which made it easy to establish animal models for exploring the underlying mechanism of ROP due to availability of administering exogenous materials, such as molecular agonists or antagonists, directly, eliminating many of the difficulties associated with studying embryonic vascular development (Dorrell and Friedlander, 2006). Meanwhile, this fact can be a potential limitation when the findings are adapted to human infants. Although no animal model is perfect, several species have been tested as appropriate animal models of ROP. An ideal animal model should reproduce the two phases of ROP. Besides, it should display revascularization of the avascular area with functional intraretinal vasculature and regression of pathologic neovascularization during the later disease stages (Stahl et al., 2010).

5.1 Kitten Models

Kitten models were historically one of the first animal models to be used to imitate the ROP (Ashton et al., 1954; Patz, 1968), as the neonatal cat retina is at a stage of development equivalent to that of the human retina at the beginning of the third trimester (Chan-Ling et al., 1990). At birth, most of the cat retina is covered by spindle cells, the inner vasculature has formed over 30%–40% of the retina, and the outer vasculature has not begun to form (Chan-Ling et al., 1990). They well mimic biphasic response of retinal vasculature to oxygen, thus, the kitten retina may provide an accurate model of the critical early and middle stages of ROP (Chan-Ling et al., 1990). However, kitten models never develop cicatricial retinal disease seen in human premature infants. In addition, major drawback to these models is high cost and poor availability of reagents (Connor et al., 2009). Thus, kitten models are no longer as popular models of ROP as they used to be.

5.2 Rat Models

Meanwhile, rat models have been proved to be alternative good models of ROP because of several reasons. First, the rat retina develops in a way similar to that of the human as follows: (1) the retina is one of the last tissues to be vascularized, (2) the retinal vasculature derives from mesenchymal precursor cells of the hyaloid artery, and (3) vascularization proceeds in a wave-like fashion, beginning at the optic disk and growing outward until the vessels reach the retinal periphery (Barnett et al., 2010). Second, the pattern of neovascularization induced by hyperoxia is quite similar to that seen in the human retina with ROP. Third, the rat models are relatively cheap compared to kitten models (Barnett et al., 2010).

Despite the utility described previously, these models were once abandoned as Ashton and Blach (1961) casted doubt on the validity of the achievements using these models before them, although Patz reported the retinal vascularization in the rat models as early as 1954 (Patz, 1954). The reason why Ashton and Blach failed to reproduce ROP in the rat models was unclear, however, it was possibly due to strain differences of susceptibility described later. The interest in these models reemerged in late 1980s. Many studies have been conducted using these models, and these models have contributed much of what is currently known regarding the growth of physiological and pathological blood vessels in the retina (Barnett et al., 2010). Rat models are useful in therapeutic drug screening or in exploring the mechanisms of angiogenesis (Lai and Lo, 2013). On the other hand, the demerits of rat models are: (1) susceptibility to hyperoxia differs among strains, and (2) the production of specific mutations, conditional mutations, and marker manipulations has been problematic (Iannaccone and Jacob, 2009).

5.3 Mouse Models

The mouse retina is quite similar with the rat retina, and therefore mouse models also have a number of reasons to be another good animal model of ROP. First, the normal development of the mouse retinal vasculature occurs within 2 weeks of birth, that allows to observe the full spectrum of vascular development. Second, the developmental stage of retinal vessels in the newborn mouse retina approximates that of premature human infants of 4–5 months of GA. Third, the retinal development of mouse is initiated by spindle-cell precursors that form a superficial layer, followed by the development of a deep retinal vascular layer, same with that of human (Smith et al., 1994). However, historically, trials to develop mouse models of oxygen-induced retinopathy had a variable success owing to its inconsistency of the neovascular response to hyperoxia and the lack of quantification of that response. This inconsistency was considered to be derived from the incomplete regression of hyaloid vessels. And in 1994, Smith and coworkers reported that the mouse retina of postnatal day 7 most closely resembled that of premature infants with optimization of maximal hyaloid vascular regression and minimal retinal vascular development. They demonstrated that exposure of postnatal day 7 mice to 5 days of 75% oxygen followed by return to room air resulted in reproducible and quantifiable retinal neovascularization without hypertrophy or dilation of the hyaloid vessels (Smith et al., 1994). Their model has become the protocol of choice (Connor et al., 2009; Scott and Fruttiger, 2010), and followed by more than 15,000 publications within only 15 years (Stahl et al., 2010).

Mouse pups also have an immature retinal vasculature and persistent hyaloid vessels at birth same with the rat models. The highly organized pruning of hyaloid vessels in the postnatal mouse eye has been a very useful tool in the study of mechanisms of physiological vessel regression (Stahl et al., 2010). Parallel to hyaloid regression, mouse retinal developmental vascularization occurs postnatally when well-defined vascular plexuses form in a highly reproducible temporal and spatial pattern (Dorrell and Friedlander, 2006; Stahl et al., 2010). Although the time course of vascularization in wildtype mice varies considerably among the strains like rat models (Stahl et al., 2010), mouse models provide a solution with regards to the difference among strains due to their availability of transgenic strains. Using the mouse models also enable access to a wide range of recombinant proteins and antibodies. Despite the merits described earlier, mouse models are not suitable for the therapeutic

drug research owing to the spontaneous regression of the neovascularization within a week (Lai and Lo, 2013).

5.4 Zebrafish Models

Zebrafish models have been emerged more recently compared to other animal models described earlier. Zebrafish and human retinal vasculatures share some common features (Alvarez et al., 2007). The genetic techniques, such as cloning, mutagenesis, transgenesis, and mapping approaches have already been established in this model (Lieschke and Currie, 2007). Besides, these models have a superiority to other animal models, namely, transparency that facilitates in vivo and in real time observation (Lieschke and Currie, 2007; Wu et al., 2015). Exposure of either embryo or adult zebrafish to hypoxia leads to neovascularization response, thus these are good models to explore the mechanism of angiogenesis (Cao et al., 2008; Wu et al., 2015). In addition, Zebrafish models cost less compared to even rodent models, and has high fecundity (Lieschke and Currie, 2007).

On the other hand, zebrafish models also have several drawbacks. First, although zebrafish and human retinal vasculatures share some common features as mentioned previously, the similarities are less compared to rodent models (Lieschke and Currie, 2007). For example, the coupled hyaloid regression and retinal angiogenesis described earlier is not observed in zebrafish (Alvarez et al., 2007). Second, skillful techniques and a large quantity of eyeballs are required in dissection and for molecular analysis due to the limited supply of tissue from a single animal (Lai and Lo, 2013).

INTRAVENTRICULAR HEMORRHAGE

1 INTRODUCTION

Intraventricular hemorrhage (IVH) is a major neurological complication of prematurity. Although it is reported that the overall percentage of infants with severe IVH decreased in past 2 decades, it is still as high as 13% in preterm infants born between 22 and 28 weeks of GA. In addition, the incidence in infants born between 22 and 25 weeks of GA demonstrated no change (Stoll et al., 2015).

A majority of these infants are asymptomatic and the diagnosis is based on screening cranial ultrasound, while some infants manifest with subtle abnormalities in the level of consciousness, movement, tone, respiration, and eye movement. Although uncommon, some demonstrate catastrophic deterioration presenting with stupor, coma, decerebrate posture, generalized tonic seizure, and quadriparesis (Ballabh, 2010).

IVH strongly correlates with neonatal morbidity and mortality. More than 60% of preterm survivors with IVH demonstrate some neurosensory impairments, including abnormal neurologic examination, cerebral palsy (CP), posthemorrhagic ventricular dilation, and seizure (Luu et al., 2009).

2 PATHOPHYSIOLOGY OF INTRAVENTRICULAR HEMORRHAGE

Pathophysiology of IVH is multifactorial, complex, and heterogeneous. IVH usually initiates in the periventricular germinal matrix and progresses to IVH upon the rupture of the underlying ependyma. Germinal matrix hemorrhage is primarily venous in origin (Ghazi-Birry et al., 1997). The inherent fragility of the germinal matrix vasculature is supposed to underlie as a basis (Ballabh, 2014), however, the trigger for the hemorrhage remains unclear although the fluctuation in the cerebral blood flow is a convincing candidate.

First, IVH mainly occurs in the germinal matrix, which consists of neuronal and glial precursor cells. The subependymal germinal matrix is highly vascular and is selectively vulnerable to hemorrhage. The thickness of the germinal matrix decreases after 24 weeks of GA, and it almost disappears by 36–37 weeks of GA (Ballabh, 2014). The vulnerability to hemorrhage derives from (1) the paucity of pericytes (Braun et al., 2007), (2) the reduced expression of fibronectin (Xu et al., 2008), and (3) the less degree of glial fibrillary acidic protein expression in astrocyte end feet (El-Khoury et al., 2006).

Second, fluctuating pattern of cerebral blood flow velocity during the 1st day of life strongly correlates with the development of IVH (Perlman et al., 1983). However, surprisingly, a correlation between the impaired autoregulation and IVH has not been demonstrated (Soul et al., 2007; Wong et al., 2008), although it is logical that cerebral autoregulation is impaired when the IVH occurs because autoregulation is the capability of the blood vessels in the brain to retain a constant blood flow in spite of fluctuation. Thus, the role of impaired autoregulation in the development of IVH needs further evaluation (Ballabh, 2014).

Other conceivable contributing factors include coagulation/clotting disorder. A number of studies have suggested the correlation between coagulopathy and IVH, although there is no significant correlation between the degree of coagulopathy and that of IVH (Lupton et al., 1988; Van de Bor et al., 1986). Therefore, Ballabh (2014) concluded that "coagulopathy does not seem to play a key role in pathogenesis of IVH, but can modify the risk and severity of IVH."

3 PREVENTION OF INTRAVENTRICULAR HEMORRHAGE

The two main strategies to prevent IVH are (1) to strengthen the germinal matrix vasculature and (2) to stabilize the cerebral blood flow (Ballabh, 2014).

First, germinal matrix is highly vascular and is selectively vulnerable to hemorrhage as described previously. The levels of VEGF and angiopoietin-2 are high in the germinal matrix than in the cerebral cortex or white matter in both humans and rabbits, and the decreased level of them resulted in the suppressed incidence of germinal matrix hemorrhage (Ballabh et al., 2007). It has been demonstrated that prenatal glucocorticoids (1) suppress VEGF expression, (2) elevate transforming growth factor-β, and (3) enhance pericyte coverage, in the germinal matrix (Vinukonda et al., 2010). Indeed, a number of studies have demonstrated that glucocorticoids reduce the incidence of IVH (Roberts and Dalziel, 2006).

Second, several trials to reduce the fluctuation of cerebral blood flow have been conducted to prevent IVH. Phenobarbital has failed to show its efficacy to reduce IVH (Smit et al., 2013). While pancuronium demonstrated a significant reduction in IVH, uncertainty remains regarding the long-term neurologic effects. Thus, the routine use of pancuronium in ventilated premature infants is not recommended at present (Cools and Offringa, 2005).

4 ANIMAL MODELS OF INTRAVENTRICULAR HEMORRHAGE

In 1980s, studies to explore the underlying mechanism of IVH were conducted using mainly rabbit and beagle models. They have played important roles in understanding the physiologic factors that predispose to IVH.

4.1 Rabbit Models

Rabbit models have been shown to be appropriate models for the study of IVH because (1) the maximal growth of the brain occurs perinatally, (2) there is an abundant germinal matrix near term, and this is substantially reduced by birth, (3) there is no *rete mirabile* that is not observed in human but observed in sheep and dog models, (4) the blood flow to the brain is via internal carotid and vertebral arteries and the proportion of brain perfused by each of these vessels is similar to that in the human, (5) the maturation of the lungs is completed just before term, (6) the rabbit pup can maintain a separate existence from the dam when delivered prematurely, and (7) although quite small, monitoring of several physiological variables can be carried out

(Lorenzo et al., 1982). In addition, IVH occurs even spontaneously in rabbit models (Lorenzo et al., 1982). Rabbit models have been used to clarify whether the physiological insult, such as intracranial hypotension, causes IVH or not (Conner et al., 1983). Although, Coulter et al. (1984) directed questions at the reproducibility of these models based on their failure to demonstrate IVH using 225 premature pups; these models are employed even nowadays and achieved long survival that enables us to observe the consequences of IVH (Chua et al., 2009).

4.2 Beagle Models

Beagle models were quite popular among researchers who explored the mechanisms of IVH in 1980s due to their reproducibility of IVH. Etiologically, IVH occurs in beagle models in a similar way with human premature infants. IVH can be produced in these animal models by several insults including hypercarbia (Goddard et al., 1980a) and hypertension (Goddard et al., 1980b). Besides, the pathologic findings in these models, namely, periventricular and intraventricular hemorrhages including hemorrhages in subependymal regions in and near the germinal matrix, in the tela choroidea, and in the choroid plexus, are similar to that in human preterm brains (Goddard-Finegold and Armstrong, 1987). Additionally, beagle models also demonstrate spontaneous IVH (Ment et al., 1982).

4.3 Other Models

There are a few more animal models to explore the posthemorrhagic ventricular dilation. Rat models (Cherian et al., 2004; Xin et al., 2010) and piglet models (Aquilina et al., 2007, 2012) have been developed to reveal the mechanisms and long-term consequences of posthemorrhagic ventricular dilation. However, in these models, IVH is not caused by some insults but is mimicked by intraventricular injection of their own blood.

CEREBRAL PALSY

The definition of CP includes five key elements: (1) it is an "umbrella term"; (2) it is permanent but not unchanging; (3) it involves a disorder of movement and/or posture and of motor function; (4) it is due to a non-progressive interference, lesion, or abnormality; (5) the interference, lesion, or abnormality arose in the developing or immature brain (Shepherd et al., 2016).

CP represents the most common physical disability in childhood. In a recent metaanalysis, including 19 studies, the global pooled prevalence was 2.11 per 1000 live births (95% confidence interval 1.98–2.25). Sadly, the

progress in reducing the numbers of individuals affected by CP has been slow; a cumulative metaanalysis demonstrated stability in the prevalence over the past 10 years (Oskoui et al., 2013). The prevalence expressed by GA was highest in children weighing 1000–1499 g at birth (59.18 per 1000 live births) and for children born before 28 weeks of gestation (111.80 per 1000 live births).

1 EPIDEMIOLOGY, ETIOLOGY, AND ANIMAL MODELS

Approximately 6% of children with CP are due to a cerebrovascular or cardiac event after the 1st month of life and before 2nd–5th year of life (Shepherd et al., 2016; Smithers-Sheedy et al., 2016). The overwhelming majority of individuals with CP (94%) will have suffered the insult antenatally or perinatally, including the first 28 days of life. Of those, ~80%–90% are due to antenatal events, rather than the labor process per se. Factors, precipitating CP include, aside of genetics, preterm birth, infection, and intrapartum acidemia (Oskoui et al., 2013). The influence of these factors is further potentiated by the chronic fetal hypoxia or inflammation, at least in part via cardiogenic insults that affect cerebral perfusion, which usually are clinically asymptomatic and thus go currently unnoticed (Frasch et al., 2011; Herry et al., 2016; Wibbens et al., 2007). Over 40% of individuals with CP are born preterm, compared with approximately 8% of the general population. Overall, however, most individuals with CP (50%–60%) are born at term (Shepherd et al., 2016; Smithers-Sheedy et al., 2016). CP and the underlying brain injury lead to life-long disabilities including motor difficulties as well as problems with hearing, sight, speech, seizures, and cognition, but with hardly diminished life expectancy for the ~90% of the individuals with CP who reach 20 years of life. The combined burden of life-long individual suffering and health-economic impact is considerable.

As evidenced by these data, the etiology of CP and the underlying brain injury are complex and so is the spread of the animal models required to mimic the causative mechanisms, which represents the first step in defining the therapeutic options. Factors to consider are the presumed timing of the insult and the key organ contributing to the insult. For example, as is the case with the impact of preterm birth, an immature brain injury manifests typically with white matter pathology due to immaturity of oligodendroglia at the time of the insult, while mature fetus will present with grey matter injury and underlying neuronal insult pattern (Dean et al., 2011; Mallard and Vexler, 2015).

The animal models mimicking various stages of CP etiology aim at understanding the molecular steps involved, biomarkers for early identification of fetuses or neonates at risk of developing CP, and early therapeutic intervention.

The selection of the animal models depends on the physiological maturity comparable to the human situation at the given GA. Consequently, mice have emerged as potent models of fetal inflammation, prematurity, and ensuing brain injury (Burd et al., 2009, 2011); guinea pigs have been used as models of intrauterine growth restriction, a condition associated with chronic fetal hypoxia, allowing studies in the offspring (Dong et al., 2011; Elias et al., 2016). Rabbits have been used to test novel promising CP treatments using nanoparticles (Kannan et al., 2012). Fetal sheep models of acute (De Haan et al., 1997; Drury et al., 2014; Frasch et al., 2016) and chronic (Keen et al., 2011) brain injury represent the most commonly used large animal model of mechanisms underlying CP and the only animal model so far that resulted in bedside translation of the research findings to mitigate CP development: the therapeutic hypothermia in neonates (Davidson et al., 2015; Gunn et al., 1997). These references represent but a snap shot of the rich experimental literature in the field.

Current methods to diagnose fetal inflammation or acidemia are inadequate as they are imprecise (indirect biomarkers measured from the mother), invasive (amniocentesis), and "noncontinuous" (sample obtained at a time point may become "out-of-date") (Fahey, 2008; Garite, 2001). They are also insensitive to subtle inflammation caused by ischemia, hypoxic acidemia, or infection. Even subtle inflammation is consequential because it "programs" myeloid cells, such as microglia in the brain to be hyperresponsive to future insults, potentially enlarging the zones of tissue damage (Cao et al., 2014; Xu et al., 2014). An urgent need exists to identify early signs of the septic or acidotic fetus and neonate at risk of adverse outcome in order to intervene therapeutically (Fahey, 2008; Garite, 2001). Early detection of incipient brain injury is urgently needed, as, currently, the diagnosis of CP is often made years after the insult.

In the subsequent sections, we focus on two select and important causes of CP, fetal inflammation and acidemia, and the animal model of fetal sheep used to mimic the condition and identify potential early biomarkers of these pathophysiological processes to reduce the disease burden. The basic experimental design of the fetal sheep model is reported in Burns et al. (2015) and many other original research articles.

2 FETAL INFLAMMATION

The main manifestation of pathologic inflammation in the fetoplacental unit, chorioamnionitis, affects 20% of term pregnancies and up to 60% of preterm pregnancies (preterm birth occurs in 8%–13% of pregnancies

in Canada). It remains often undiagnosed (Gotsch et al., 2007; Lahra and Jeffery, 2004). Even asymptomatic inflammation may inhibit placental angiogenesis, impede delivery of nutrients, and alter the fetus' hormonal/cytokine environment, leading to deranged inflammatory and metabolic responses (Dowling and Levy, 2014; Garnier et al., 2008). Both symptomatic and asymptomatic, histologically detected chorioamnionitis are associated with a ~ninefold increased risk of CP (Grether and Nelson, 1997). Similarly, chorioamnionitis is strongly associated with NEC, a frequent life-threatening complication in NICUs with 20%–40% mortality (Garzoni et al., 2013). NEC predisposes to functional impairment and confers increased risk for worse neurodevelopmental outcomes in the long term than prematurity alone (Pike et al., 2012; Rees et al., 2007; Sharma and Hudak, 2013).

Since CP is likely a result of multiple insults of various types (e.g., inflammation, hypoxia, or acidemia) intensity and duration, several labs developed multihit paradigms to mimic the human situation more closely (Cao et al., 2015; Dean et al., 2015; van den Heuij et al., 2014). Fetal sheep model provides an excellent possibility to induce and monitor fetal insult in vivo and then create primary pure brain cultures to further study molecular mechanisms involved in memory of in utero inflammatory insult, a likely contributor to the increased susceptibility to perinatal or early postnatal brain injury, especially under conditions of prematurity and during stay in a NICU (Cao et al., 2015). Fetal sheep model of lipopolysaccharide (LPS)-induced inflammatory response has further contributed to development of novel monitoring technologies to detect early fetuses at risk of brain injury due to infection, systemically, in the gut or in the brain (Durosier et al., 2015; Liu et al., 2016).

Advances have also been made using septic neonatal rat model to develop heart rate algorithms for early sepsis detection in neonates (Fairchild et al., 2011). Together, these findings in animal models point to the diagnostic potential of fetal heart rate (FHR) variability monitoring in fetuses and neonates to detect early onset of sepsis on systemic and organ-specific scales. This approach is based on the notion of the fetal cholinergic antiinflammatory pathway and the "vagus code" (Frasch et al., 2016; Herry et al., 2016; Kwan et al., 2016). Together, animal models have been instrumental in developing means to identify babies requiring neuroprotective intervention.

3 FETAL ACIDEMIA

Human clinical studies with umbilical cord blood gas and pH assessment at birth indicate an increasing risk for neonatal adverse outcome and longer-term sequelae including CP with pH values <7.00 (Liston et al., 2002a,b, 2007). Additionally, growth-restricted infants with chronic hypoxemia due to placental dysfunction are at greater risk for concerning acidemia at birth and thereby subsequent adverse neurological outcomes due to superimposed acute hypoxemia during labor (Frasch et al., 2009a, 2010, 2011; Kaneko et al., 2003). This is supported by studies in the ovine fetus showing that preexisting hypoxia alters cerebral and cardiovascular responses to labor-like umbilical cord occlusions (UCOs) (Wassink et al., 2013).

The absence of FHR decelerations along with presence of FHR variability is highly predictive for normal fetal blood gas/pH at birth (Liston et al., 2002a,b, 2007). However, clinical FHR monitoring has a low positive predictive value for concerning acidemia at birth (~50%), so there is continued need for improving existing technologies for the detection of fetal hypoxic acidemia during labor (Liston et al., 2002a,b, 2007).

Fetal sheep model of human labor allows to study patterns of electrocortical activity (ECOG) and FHR in response to repetitive UCOs insults to delineate the time-course and correlation of ECOG change with worsening acidemia (Frasch et al., 2011). Fetal ECOG responds to labor-like UCOs with amplitude suppression and frequency increase during FHR decelerations in association with pathological decreases in fetal arterial blood pressure. These changes in ECOG suggest an "adaptive brain shutdown" and occur on average 50 min prior to attaining a severe degree of acidemia with fetal arterial pH < 7.00. Translational implications are that fetal ECOG monitoring can improve the positive predictive value of FHR monitoring for worsening acidemia at birth, which should contribute to early detection of babies at risk of developing CP.

Fetal acidemia is required to produce neuroinflammation as evidenced by the findings in fetal sheep near term where chronic hypoxia does not lead to microglial activation, but acidemia does (Prout et al., 2009, 2012). Moreover, isolated systemic hypoxia without ischemia does not cause neuronal necrosis as shown in middle cerebral artery occlusion model of stroke in adult rats; however, it will exacerbate ischemic necrosis (Miyamoto and Auer, 2000). In line with these findings, pediatric patients less than 9 months old with proven hypoxic or hypotensive episodes due to perinatal asphyxia, congenital heart defects, or chronic pulmonary dysfunction were found to often show a dense infiltrate of microglial cells in the dentate gyrus making this neuroinflammation a neuropathological marker of mild hypoxic–ischemic brain injury (Del Bigio and Becker, 1994). That is, neuroinflammation, preceding brain necrosis, plays a pivotal role in mediating brain injury induced by neonatal hypoxic ischemic encephalopathy, the neuropathological

substrate of CP (Liu and McCullough, 2013). Meanwhile, suspending neuronal activity is known to result in prolonged preservation of viability in adults and neonates (Glass and Ferriero, 2007; Safar et al., 2002). It is hence plausible that fetal or perinatal neuroinflammation are mitigated by an early adaptive neuronal shutdown in response to repetitive intermittent hypoxic episodes with cumulative acidemia. These findings in rat and sheep models underscore the intricate interaction between inflammation and acidemia resulting in brain injury.

Consequently, fetal sheep studies of human labor indicate that EEG–FHR monitoring during labor, as a novel ancillary modality of intrapartum monitoring, may not only identify fetuses at risk of developing severe acidemia, but it may also provide information to the neonatologist as to which babies may be at higher risk of brain injury resulting in conditions, such as CP due to developing neuroinflammation. FHR monitoring may guide this diagnostic process by helping to distinguish chronically hypoxic fetuses prior to labor onset from the normoxic fetuses. The therapeutic implication is that neuroprotective drug treatments need to target the postnatal 24 h time window to benefit from the anti-neuroinflammatory effect the adaptive brain shutdown may have in the chronically hypoxic fetuses when they are born.

Another finding from fetal sheep model was the role of FHR sampling rate in clinical setting to enable early detection of fetal acidemia (Durosier et al., 2014). Currently, this sampling rate is inadequate explaining poor positive predictive value of FHR monitoring for detection of acidemia.

It should be noted, that animal models, such as fetal sheep model not only informed clinically testable algorithms for detection of acidemia and inflammation, but also provided a unique foundation for creation of a novel generation of "animal" models, namely *in silico* models of human labor (Wang et al., 2015). *In silico* or computer models allow, naturally, more exhaustive testing of various labor scenarios than animal models. This approach already led to new predictions for FHR-derived biomarkers of fetal acidemia (Wang et al., 2015).

NECROTIZING ENTEROCOLITIS

1 ETIOLOGY

NEC is an acute inflammatory disease that affects the intestine of neonates resulting in intestinal necrosis, systemic sepsis and multisystem organ failure (Garzoni et al., 2013). NEC is extremely frequent and affects 5%–10% of all infants born at 1500 g or less birth weight or less than 30 weeks GA (Lin and Stoll, 2006). The incidence of NEC varies from 0.3 to 2.4 infants per 1000 live births, with nearly 90% of cases occurring in infants born at less than 36 weeks of gestation. NEC affects 2%–5% of all premature infants and accounts for up to 8% of all NICU admissions. Actually, the incidence of NEC has increased despite surfactant replacement therapy because of increased survival of very premature infants (born at 800 g or less) (Lin et al., 2008). NEC is the leading cause of death and long-term disability from gastrointestinal disease in preterm infants. The overall mortality for NEC ranges from 10% to 50% but approaches 100% for infants with the most severe form of the disease, characterized by full-thickness destruction of the intestine leading to intestinal perforation, peritonitis, bacterial invasion, sepsis, and multiorgan failure.

NEC is not only one of the most serious clinical problems to affect neonates, but also one of the most challenging to treat. Since the etiology and the mechanisms leading to NEC are unknown, the treatment is symptomatic. Minor cases and early stage of NEC are managed by antibiotics and cessation of oral feeding, advanced cases, in which intestinal necrosis is present, may require surgery with intestinal resection.

Despite several decades of work into the pathogenesis of NEC (Hunter et al., 2008), the overall mortality rate remains high and our overall understanding of its causes remains low. Clearly, a more complete understanding of the causes of NEC is required to more effectively design preventive and therapeutic strategies (Bisquera et al., 2002; Ganapathy et al., 2012).

2 CHORIOAMNIONITIS: PATHOLOGICAL FETAL INFLAMMATION IS A RISK FACTOR

The events leading to NEC are complex and multifactorial, including preterm birth, complicated early neonatal trajectory, adverse intrauterine environment, and poor perinatal transition. The most important ones are preterm birth and a history of enteral feeding (Lin and Stoll, 2006). A significant number of fetuses are exposed to various degrees of inflammation, which impacts on their intestinal development.

Chorioamnionitis associated with maternal infection has been strongly implicated in fetal intracerebral hemorrhage (Andrews et al., 2006, 2008; Aziz et al., 2009). However, an increased incidence of NEC has also been reported in neonates of mothers presenting with chorioamnionitis, in several independent studies (Andrews et al., 2006; Aziz et al., 2009; Been et al., 2009) as well as a recent metaanalysis. The role of prenatal infection in the development of NEC is most significant in very preterm infants (24–26 weeks' GA) (Aziz et al., 2009), but

is also apparent in preterm births <32 weeks (Andrews et al., 2006; Been et al., 2009) and in full-term births (Martinez-Tallo et al., 1997).

3 TIGHT JUNCTIONS: INTESTINAL PERMEABILITY AND INTEGRITY

After birth, the intestinal lumen is subject to external environmental influences, including bacterial colonization of the gastrointestinal tract (Gronlund et al., 1999). Cells that cover the intestinal surface must form a barrier to protect the "*milieu intérieur*" from the external world and prevent unrestricted exchange of materials. The intestinal epithelial barrier needs to allow the passage of water and nutrients but prevent microbial contamination and the invasion of interstitial tissues by foreign antigens (Turner, 2009). Tight junctions, essential to the paracellular pathway, are the primary determinants of barrier function. Tight junctions are situated at the apical pole of epithelial cells, and comprise over 50 associated proteins. The first group includes claudins (a family of at least 24 members) and occludin. These proteins span the plasma membrane and are attached to a second group of proteins including zonula occludens (ZO)-1, -2 and -3, which link them to actin and myosin in the cytoskeleton (Turner, 2009).

The properties of tight junctions differ from one tissue to another, as evidenced by the 1000-fold variation in electrical resistance between different epithelia. Barrier properties are not fixed: they can be modulated and regulated on a short- or long-term basis. Short-term regulation is achieved by deformation of the cytoskeleton: myosin light chain phosphorylation permits interaction with actin and contraction of the actin filaments in the perijunctional ring. Contraction of the actin filaments favors the passage of macromolecules by opening the pores. Myosin light chain kinase-1 (MLCK-1) controls the phosphorylation/dephosphorylation of the myosin light chains in the villus enterocytes and surface colonocytes (Clayburgh et al., 2004). Further downstream, during alterations of the tight junction permeability, the transmembrane protein occludin is subject to endocytosis (Schwarz et al., 2007; Turner, 2009). Long-term regulation of intestinal permeability depends on the synthesis and trafficking of claudin-2, a molecule that is overexpressed in intestinal cells of animal models of colitis and in human ulcerative colitis specimens (Heller et al., 2005).

It has been suggested that abnormalities in intestinal permeability may be key to the facilitation of intestinal inflammation leading to NEC (Petrosyan et al., 2009). Intestinal barrier integrity and its appropriate regulation are essential to the prevention of antigen diffusion and bacterial contamination into the lamina propria and interstitial tissue.

4 INTESTINAL PERMEABILITY IS INFLUENCED BY PATHOGENS AND INFLAMMATION

Intestinal barrier dysfunction in newborns may be triggered by exogenous agents. Such enteric pathogens trigger local inflammatory responses through specific receptors [e.g., toll-like receptor 4 (TLR4) for LPS recognition] or by proinflammatory cytokines [e.g., tumor necrosis factor alpha (TNF-α)] (Clayburgh et al., 2005), interferon-γ (Wang et al., 2005), interleukin 1-beta (Al-Sadi et al., 2008), and high-mobility group box 1 (HMGB1) protein (Liu et al., 2006; Raman et al., 2006; Sappington et al., 2002). TNF-α-induced barrier loss is associated with increased transcription and translation of MLCK (Clayburgh et al., 2005). In vivo, intestinal epithelial MLCK is induced by TNF-α. In the rat model of sepsis, an intraperitoneal injection of LPS demonstrably resulted in a rapid rise of TNF-α in the colonic mucosa followed by an increase in myosin light chain phosphorylation and colonic permeability (Moriez et al., 2005). Interestingly, studies in the fetal rat model of NEC have also shown that prenatal bacterial LPS exposure alters the development and permeability of intestinal epithelium (Giannone et al., 2006) and increases ileal injury (Giannone et al., 2009). Similarly, in fetal sheep, preterm intraamniotic LPS exposure induces abnormal expression of ZO-1 in the ileum (Wolfs et al., 2009).

5 ENS CONTROLS EPITHELIAL BARRIER FUNCTION

The enteric nervous system (ENS) is defined as the arrangement of neurons and supporting cells throughout the gastrointestinal tract, from the esophagus to the anus (Goyal and Hirano, 1996). The ENS is organized in ganglia that contain neurons, glial cells, and interstitial cells. Each enteric ganglion contains many different neuron types (Furness, 2000). The ENS consists of some 100 million neurons, or about one tenth of the number of neurons of the spinal cord. Glial cells in the ENS have similar properties to those in the central nervous system (Gershon et al., 1993). The numbers and types of neurotransmitters expressed by enteric neurons are comparable to those found in the central nervous system. The ENS is capable of autonomy with elicitation of reflexes (complete reflex circuitry in the intestinal wall comprises intrinsic sensory neurons, interneurons, and intrinsic motor neurons) after total extrinsic denervation of the gut (Furness et al., 1995). However, the ENS is under physiological influence of the sympathetic and vagus nerves. The ENS controls intestinal motility, modulates visceral sensation, and plays a role in the regulation of the intestinal blood supply and the secretion of digestive

hormones (Boeckxstaens, 2002; Costa and Brookes, 1994; Kunze and Furness, 1999). It also plays a major role in water and electrolyte transport. As a consequence, intestinal permeability is under neural control (Keita and Soderholm, 2010). The ENS should thus be considered, along with the microflora, immune system, and fibroblasts, as a major player in the maintenance of intestinal homeostasis and integrity. The ENS has the ability to fine-tune intestinal barrier function via the release of mediators, such as acetylcholine that enhance—via muscarinic receptors—(Cameron and Perdue, 2007) and vasoactive intestinal peptide (VIP) that constrict (Neunlist et al., 2003) intestinal permeability over short-term or long-term periods (Neunlist et al., 2013). Similarly, the ENS can modulate the proliferation and differentiation of the intestinal epithelial barrier via the secretion of distinct neuromediators, such as VIP (Neunlist et al., 2013). VIP exerts antiproliferative effects, while mediators, such as acetylcholine, glucagon-like peptide 2 (GLP-2), or substance P stimulate intestinal epithelial cell proliferation (Neunlist et al., 2013).

6 NEC: IMMATURE IMMUNE RESPONSE

Local intestinal immune response is normally tightly controlled (Su et al., 2009). The premature gastrointestinal tract has increased permeability, low levels of protective mucus and secretory immunoglobuline A, higher risk of bacterial overgrowth caused by dysmotility due to ENS immaturity, and decreased regenerative capabilities (Neu, 2007). Uncontrolled intestinal inflammation may result from immaturity of the innate immune system of the developing gut (Lin and Stoll, 2006; Lin et al., 2008). Immature regulation could lead to an exaggerated inflammatory response, leading to greater injury and increased intestinal barrier damage. Alternatively, immature regulation could result in minimal immune response due to insufficient inflammatory signaling, thus contributing to bacterial overgrowth and invasion of interstitial tissue. The uncontrolled intestinal inflammation observed in NEC may also depend on dysregulation of intestinal permeability in relation to localized immune response (Turner, 2009). In most individuals and specifically in healthy full-term newborns, a localized break in the intestinal barrier induces a localized immune response that is finely tuned and controlled to avoid overinflammation and a subsequent increase of intestinal permeability. This normal immunoregulatory response is the result of a delicate balance between proinflammatory (TNF-α, IL-1β) and antiinflammatory (IL-10) processes. If even small anomalies occurred in any of the components of the system (tight junction dysregulation, immune regulatory response), the inflammatory response would be amplified and would result in

intestinal injury. Such anomalies may occur secondary to immaturity in preterm babies.

Furthermore, immunomodulatory nutrients, such as glutamine, arginine, nucleotides, omega-3 polyunsaturated fatty acids, and lactoferrin are provided with enteral nutrition and prevent diseases, such as NEC. Difficulties with enteral feeding in the 1st week of life predispose premature infants to sepsis and NEC (Neu et al., 2013).

7 DEVELOPMENT AND MONITORING OF THE AUTONOMIC NERVOUS SYSTEM ACTIVITY

The autonomic nervous system plays a predominant role in complex coordinated control of multiple vitally important physiological subsystems in the organism and is part of the neuroimmunological response to pathogens via CAP (Fairchild et al., 2011). Since autonomic nervous system development and activity are reflected in the heart rate patterns, an appropriate analysis of the fetal heart rate variability (fHRV) may provide information regarding the individual fetal development (Hoyer et al., 2013; Van Leeuwen et al., 1999). fHRV is a noninvasively obtainable marker of changes in vagal (parasympathetic) and sympathetic activity (Frank et al., 2006). Increase in fHRV is associated with fetal growth in general and with the increase in neural integration in particular (Van Leeuwen et al., 2013). Understanding of the dynamics of fHRV in human and ovine fetuses during physiologic (e.g., sleep states) and pathophysiologic (e.g., asphyxia) conditions has evolved over the past 2 decades (Frank et al., 2006; Karin et al., 1993). FHR and fHRV are regulated by a complex interplay of the parasympathetic and sympathetic nervous systems accounting for the baseline FHR as well as short-term and long-term variability and nonlinear properties (Frasch et al., 2009b; Gieraltowski et al., 2013). Nonlinear properties of fHRV in late gestation fetuses are present and a higher vagal tone is associated with more efficient regulation of homeostasis (Groome et al., 1999).

8 CAP CONTROLS IMMUNE HOMEOSTASIS

CAP has been implicated in the regulation of the inflammatory reflex in adult organisms including humans (Cailotto et al., 2012; Olofsson et al., 2012; Tracey, 2002, 2007, 2009). CAP is a neural mechanism that influences the magnitude of the innate immune response and maintains homeostasis. As part of CAP, increased vagal activity inhibits the release of proinflammatory cytokines. Vagal nerve stimulation decreases LPS-induced

systemic TNF-α release in adult rats (Borovikova et al., 2000). Suppression of proinflammatory cytokine expression via agonistic action on the α7 subunit nicotinic acetylcholine receptor (α7nAChR) was confirmed in innate immune cells, such as macrophages [reviewed in Tracey (2007)]. Systemically via CAP, this is mediated via the spleen: Adrenergic nerve fibers in the spleen activate acetylcholine-producing T-lymphocytes, thereby inhibiting systemic cytokine production (Huston et al., 2007; Olofsson et al., 2012; Rosas-Ballina et al., 2011).

Vagal nerve activity in basal conditions provides inhibitory input that dampens innate immune response (Haensel et al., 2008; Thayer and Fischer, 2009). The CAP influences the magnitude of the innate immune response and maintains homeostasis (Tracey, 2009). Depressed vagal nerve activity is associated with an exaggerated proinflammatory response and increased morbidity and mortality in various contexts, such as acute or stable coronary heart disease, metabolic syndrome or impaired glucose tolerance and kidney failure (Haensel et al., 2008; Thayer and Fischer, 2009). The inhibitory role of CAP on innate immune function can be thought of as analogous to the inhibitory role of the vagus nerve on the resting heart rate (Tracey, 2009).

Under resting conditions, the inflammatory reflex helps establish the set point for the magnitude of the innate immune response to molecules arising from infection, injury, or ischemia. Vagus nerve output maintains homeostasis by limiting proinflammatory response to the healthy, protective, and nontoxic range. However, when vagal activity is absent or diminished, the set point increases; exposure to pathogens then results in an exaggerated proinflammatory response and eventual tissue damage as demonstrated in different experiments with murine models (Ghia et al., 2006, 2007a,b, 2008).

Numerous factors can experimentally or clinically impair the CAP, each resulting in an exaggerated innate immune response. For instance, in animal models with vagotomy or deficient in α7nAChR, the magnitude of the proinflammatory cytokine response and the extent of tissue damage increase during infection, hemorrhagic shock and stroke (Ghia et al., 2008; Guarini et al., 2003; Ottani et al., 2009; Tracey, 2009; van Westerloo et al., 2005). The observation that vagal nerve activity influences circulating TNF-α amounts and the shock response to endotoxemia has widespread implications. It is a previously unrecognized, direct, and rapid endogenous mechanism that can suppress the lethal effects of biological toxins. The CAP has much shorter response times than humoral antiinflammatory pathways. Electrical stimulation of the vagus nerve or administration of α7nAChR agonists in rat model of LPS-induced sepsis reduces the magnitude of proinflammatory cytokine production by 50%–75% but does not eliminate cytokine activity (Borovikova et al., 2000; Tracey, 2009). Activation of CAP has not been observed to cause immunosuppression because maximal suppression only reduces proinflammatory cytokine levels from the toxic to the healthy range. This concept has been studied as a potential treatment for a range of inflammatory diseases, including infection [reviewed in Tracey (2009)]. The role of CAP in the perinatal inflammatory response and the priming of subsequent innate immune response require elucidation.

Studies are needed to explore the impact of CAP activity on chorioamnionitis (Shapiro et al., 2013). Such studies could lead to the development of novel prognostic markers to better identify fetuses at risk of NEC. We hypothesize that increased CAP activity would inhibit the activation of intestinal innate immune cells, such as macrophages and thus suppress the inflammatory response to bacterial infection. Effectively, pathological inflammation and intestinal permeability as a *locus minoris resistentiae* of incipient NEC would be decreased or normalized.

9 VAGAL NERVE STIMULATION AND THE GUT INFLAMMATION

As vagal nerve stimulation stimulates CAP activity without causing immunosuppression (Borovikova et al., 2000), it has been shown to improve intestinal inflammation in murine models of experimental colitis (Ghia et al., 2006, 2007a,b, 2008) and postoperative ileus (The et al., 2007; van Bree et al., 2012). The role of intestinal macrophages seems pivotal (Costantini et al., 2010a; Rosas-Ballina et al., 2011; The et al., 2007; van Bree et al., 2012). In a murine model of dextran sodium sulfate-induced colitis, Ghia et al. demonstrated an increased inflammatory response in the colonic mucosa of the vagotomy group as compared to control animals. They showed the protective effect of vagal activity in acute colitis (Ghia et al., 2006) and in acute relapses within a background of chronic inflammation (Ghia et al., 2007b).

In a murine model of postoperative ileus, the antiinflammatory effect of intracerebroventricular injection of semapimod was abolished in the presence of vagotomy (The et al., 2011). Vagal nerve stimulation also modulates intestinal permeability and integrity. In a murine model of intestinal injury caused by severe burns, vagal nerve stimulation performed before injury improved intestinal barrier integrity through an efferent signaling pathway and was associated with improved tight junction protein expression (Costantini et al., 2010b). In the same model, stimulating the vagus nerve at the time of injury promoted enteric glial cell activation. Either method could prevent intestinal barrier injury (Costantini et al., 2010a). Activation of enteric glial cells has been reported in a rat

model of burn-induced stress and gut injury (Costantini et al., 2010a).

The optimal choice of vagal nerve stimulation parameters in order to activate the CAP for therapeutic purposes remains challenging (Kwan et al., 2016). Although the literature provides a spectrum of possibilities, further studies are needed. Huston et al. (2007) demonstrated improved survival in murine polymicrobial sepsis with transcutaneous vagal nerve stimulation, suggesting that this mode might be an effective therapy for sepsis generally and NEC specifically. Pharmacologically, cholinergic neuronal circuitry can be stimulated peripherally using α7nAChR agonists to act on macrophages; or centrally using intracerebroventricular injections of semapimod (The et al., 2011), muscarinic receptor agonist McN-A-343 (Pavlov et al., 2006), or an acetylcholinesterase inhibitor (galantamine) (Pavlov et al., 2009). Importantly, enteral feeding of lipid-rich nutrition may also be used to activate the CAP pathway (Luyer et al., 2005).

10 NEAR FUTURE: EARLY DETECTION OF NEC USING FETAL AND NEONATAL HEART RATE MONITORING?

Human and animal studies using fetal sheep indicate that heart rate monitoring can signal early onset of NEC (Liu et al., 2016; Stone et al., 2013). A unique subset of fHRV measures reflecting 1.5 days ahead of time the levels of macrophage activation and increased leakiness in terminal ileum (Liu et al., 2016). Such subset of fHRV measures may reflect the brain–gut communication via the vagus nerve. This supports the notion of a common neuroregulatory mechanism via CAP and requires further studies in animal models of NEC to hack the "vagus code" (Kwan et al., 2016).

Ultimately, such animal studies should lead to a noninvasively obtained fetal CAP response signature to help identify babies at risk of developing NEC.

Together, the potential of creating organ-specific fHRV signatures of inflammation obtainable noninvasively by hacking the brain–body communication via the vagus nerve by using multidimensional HRV analysis needs to be explored and exploited in further animal studies. Some early work in human cohorts already indicates the value of such approach for early prediction of perinatal health outcomes (Frasch et al., 2014).

1 INTRODUCTION

1.1 The Concept of Fetal Programming and Overview of Animal Models

The period of intrauterine development represents a sensitive window during which disruption or modification of the environment can influence fetal development to potentially alter lifetime health trajectories (Barker and Clark, 1997; Godfrey and Barker, 2001). Depending on the time window of exposure during gestation, different physiological systems are affected by the exterior or interior milieu. Consequently, different animal models have been used to address pertinent questions about mechanisms of the programming effects and therapeutic options (Chavatte-Palmer et al., 2016; Sutton et al., 2016). Here, we focus on animal models reproducing the effects
FIGURE 32.1 **Conceptual framework illustrating the interplay between prenatal stress and altered pregnancy outcomes.** Late gestation stress alters the maternal endocrine, immune and nervous system phenotypes, and expression of epigenetic markers. Epigenetic modifications may have no influence, partial influence or extensive influences on pregnancy outcomes, altered maternal and offspring behavior, and metabolic imbalances. Some or all of these outcomes may be influenced by epigenetic modifications (Metz et al., 2015).

taking place during fetal development, rather than periconceptually (Heijmans et al., 2008) or during embryonic development. We will also consider the transgenerational effects of fetal programming as they are being modeled in a number of animal systems. This is important, as it appears established now that a combination of genetic and epigenetic mechanisms can convey memory not only across a single generation, but even persist as a multigenerational memory of acute and chronic insults endured during fetal development. The potential adaptive and maladaptive physiological phenomena resulting from such programming are considered within the concept of the developmental origins of health and disease or DOHaD (Fig. 32.1) (Gluckman et al., 2010; Metz et al., 2015).

Animal models of fetal programming contribute in three synergistic ways to understanding and treating human diseases or predispositions to diseases, which emerge from in utero insults leading to fetal programming. Firstly, animal models serve to confirm observations derived in epidemiological studies. Secondly, animal models provide insights into mechanisms and render novel putative biomarkers of various effects of fetal programming that are relevant for early identification of affected individuals, children and adults. Thirdly, animal models permit testing of therapeutic interventions before they are translated into clinical intervention studies (Care et al., 2016; Leshem and Schulkin, 2012; Zucchi et al., 2014).

DOHaD have been linked to a number of modifiable and nonmodifiable factors and factors that, arguably, are settled somewhere in between, such as socioeconomic status (Borghol et al., 2012; King et al., 2015).

The modifiable risk factors include, for example, patterns of nutrition, including both chronic fetal and early postnatal under- and overnutrition (Chavatte-Palmer et al., 2016; El Hajj et al., 2014; Morrison and Regnault, 2016), drug intake, including smoking, cannabis and alcohol (Szutorisz and Hurd, 2016; Westbrook et al., 2010), intrauterine growth restriction (Regnault et al., 2013; Zhang et al., 2015), intrauterine infection (Cao et al., 2015; Cordeiro et al., 2015). To the nonmodifiable factors belong such events as wars, famines (Symonds et al., 2001) and other inescapable stress experiences that may occur before or during pregnancy (King and Laplante, 2005; Veru et al., 2014), and, notably, can be inherited in the off-spring paternally or maternally and in a sexually dimorphic manner (Petropoulos et al., 2014; Short et al., 2016). The developmental consequences of in utero exposures to these various factors, modeled in a number of animal models including rat (Care et al., 2016), guinea pig (Iqbal et al., 2012; Pappas et al., 2014), sheep (Barry and Anthony, 2008; Burns et al., 2015) and nonhuman primate (Li et al., 2007), include metabolic syndrome, obesity and diabetes in particular; cardiovascular development including susceptibility to atherosclerosis, hypertension, and coronary heart disease, but also other forms of heart disease including cardiomyopathies (Frasch, 2008; Frasch et al., 2007; Morton et al., 2016; Thornburg, 2015) and alterations in neurodevelopment, including emotional and cognitive development which have been linked to autism spectrum disorder, attention deficit hyperactivity disorder, learning disabilities, to name a few.

Enigmatically, in the domain of stress research, in utero exposure to inescapable stress appears to exert a dramatic spectrum of effects across all of the above-mentioned physiological systems (Maccari et al., 2014). Stress exposure is also probably the most common driver of fetal programming, iatrogenic via antenatal glucocorticoids (~10% of all pregnancies), or in form of life events (~25%–50% of all pregnancies) (Roosevelt and Low, 2016; Shapiro et al., 2013; Woods et al., 2010).

The literature dealing with fetal programming has undergone rapid growth over the past decade. A PubMed search in September 2016 rendered ~150,000 hits. Hence, the authors make no attempt to provide a systematic review in this chapter. Rather, we hope to demonstrate on some select examples how exactly animal models of fetal programming due to stress exposure have continued to expand our knowledge of this fascinating phenomenon with major health-economic and social impact. We will distinguish two types of stress exposure resulting in fetal programming: iatrogenic, due to administration of synthetic glucocorticoids (sGC), where key models are guinea pig and sheep and exogenous stress, also referred to as prenatal stress (PS) where key models are rat and sheep.

2 SIGNIFICANCE

By 2007, 200 million children under 5 years of age living in developing countries were not fulfilling their developmental potential, mostly due to exposure to biological and psychosocial factors that might alter brain function (Grantham-McGregor et al., 2007; Walker et al., 2007). Maternal depression was identified as a key risk factor affecting child development that requires urgent intervention (Walker et al., 2007). Early postnatal care was shown to partially reverse the effects of PS on brain reprogramming in animal models (Barros et al., 2004, 2006b; Weaver et al., 2005).

A key challenge of the animal models of fetal programming of PS is the identification of changes of the intrauterine environment represented by reliable biomarkers of stress-related epigenetic reprogramming. This is a vital step toward diagnosis and devising early interventions such as promoting mother-infant bonding and cognitive stimulation to improve developmental outcomes in PS-exposed children. This is mainly based on education and maternal support programs which are accessible in developing countries. Testing of this hypothesis has been subject of a number of animal model-based studies, primarily in pregnant rat using enrichment paradigms (Barros et al., 2004, 2006b; Weaver et al., 2005).

Among early developmental disruptors, prenatal exposure to maternal psychosocial stress, depression, and anxiety confers lifelong risk for behavioral alterations that last beyond childhood (O'Connor et al., 2003). Concern for the infant's future underlies much of the research on transgenerational transmission of maternal stress (Leshem et al., 2016). The developmental perspective that early experience is formative of long-term behavioral and cognitive patterns is reflected in the numerous studies that have demonstrated effects of PS during the prenatal, perinatal, and postnatal periods on offspring brain development, stress reactivity, and behavior regulation (Leshem et al., 2016) and cognitive development in human infants (Beydoun and Saftlas, 2008; Mulder et al., 2002). Animal studies in rat, mouse, guinea pig, and nonhuman primate show that PS leads to vulnerability to anxiety and impaired learning, memory and locomotor dysfunction (Weinstock, 2008). Moderate to severe stressful life-events, in combination with inadequate social network, are closely associated with increased child morbidity and neurological dysfunction, such as attention-deficit hyperactivity disorder (ADHD) and sleep disturbance during infancy (Weinstock, 1997) which if persistent in adulthood might result in depression and vulnerability to psychotic disorders (Cohen et al., 1983; van Os and Selten, 1998). The intrauterine period has been implicated as the most sensitive time for the establishment of epigenetic variability, "fetal programming", which in turn affects offspring development, cell- and tissue-specific gene expression, potentially altering lifetime health trajectories and risk for a range of disorders (Barker and Clark, 1997; Tobi et al., 2009). Far less is known about how fetal programming is influenced by the PS occurring *before* pregnancy. As such, studies on PS effects during pregnancy and transgenerational transfer of PS are needed to define the mechanisms, identify the biomarkers for early detection and begin to devise early therapeutic approaches. This is especially relevant now, as nongenomic and epigenetic transmission offer a conceptualization of how experience may be transferred across generations (Caldji et al., 2011; Mulligan et al., 2012; Weaver et al., 2004). The key biological systems upon which the PS-triggered epigenetic mechanisms are thought to act are hypothalamic-pituitary-adrenal (HPA) axis and the autonomic nervous system (ANS).

The HPA axis regulates homeostatic mechanisms, including the ability to respond to stressors (Van den Hove et al., 2006) and is highly sensitive to adverse early life experiences (Meaney, 2001). Exposure to PS results in increased responsiveness of the HPA axis to stress, and reductions of glucocorticoid receptor (GR) expression in the hippocampus of adult offspring (Zuena et al., 2008). In humans, PS is associated with higher rates of preterm delivery and lower birth weight (Van den Bergh et al., 2005; Wadhwa et al., 1993), elevated cortisol (Field et al., 2004), impaired subsequent working memory performance in young women (Entringer et al., 2009) and changes in the epigenetic regulation of GR expression (Mulder et al., 1997). Increased HPA stress reactivity in the offspring of low maternal care rats is associated with higher DNA methylation at the promoter of *NR3C1* (which encodes GR) (Francis et al., 1999; Liu et al., 1997; Weaver et al., 2004). Maternal prenatal depressive symptoms predict increased *NR3C1* 1F DNA methylation in buccal cells of male infants (Braithwaite et al., 2015). Moreover, PS modified the expression of several microRNAs in the hippocampus and prefrontal cortex of prepubertal and adult offspring, microRNA-133b being altered most significantly (Monteleone et al., 2014) (Fig. 32.1). In mice, levels of both OGT [O-linked-*N*-acetylglucosamine (O-GlcNAc) transferase] and its biochemical mark, O-GlcNAcylation, were significantly lower in males and further reduced by prenatal stress (Howerton et al., 2013). In humans, differential methylation is associated with prenatal exposure to maternal depression (O'Connor et al., 2003; Teh et al., 2014), PS, and birth weight (Filiberto et al., 2011; Mulligan et al., 2012; Vidal et al., 2014). Corticosteroid administration during pregnancy has shown to affect autonomic balance in utero (Dawes et al., 1994; Derks et al., 1995; Mulder et al., 1997; Senat et al., 1998).

Early adversity may elevate corticotropin-releasing hormone (CRH) gene expression in the mother's brain and (during pregnancy) placenta, stimulating fetal cortisol and adrenocorticotropic hormone (ACTH) and signaling

premature maturation of fetal tissue (Horan et al., 2000; Moog et al., 2016). Women exposed to early adversity may be more susceptible to stress during a major life event like pregnancy. This may be due in part to HPA dysregulation along with elevated CRH and cortisol levels. Pregestational stress increased the expression of corticotropin-releasing factor type 1 (CRF1) messenger RNA in the brains of mothers and offspring, suggesting an epigenetic route of transgenerational transmission (Zaidan et al., 2013). Pregestational stress to female rats two weeks prior to mating resulted in reduced anxiety, enhanced fear learning, and improved adaptive learning for second generation offspring (Zaidan and Gaisler-Salomon, 2015). In addition, levels of the stress hormone corticosterone (CORT; an indicator of HPA functioning) was altered across the three generations in a sex-dependent manner (Zaidan and Gaisler-Salomon, 2015). Maternal stress during the third, but not the second, week of gestation in rats was associated with alterations in stress reactivity behaviors and prolonged elevations in glucocorticoid levels among adult male offspring (Koenig et al., 2005). Heightened anxiety was associated with greater CRH mRNA gene expression in the amygdala, and attenuated stress responses were associated with greater glucocorticoid mRNA expression in the hippocampus and impaired feedback to the HPA (Grundwald and Brunton, 2015). The offspring of rats exposed to either a daily injection of CORT or prenatal stress during the third week of gestation all displayed decreased GR protein levels in the medial prefrontal cortex, hippocampus, and hypothalamus, as compared to controls (Bingham et al., 2013).

Higher levels of CRH during pregnancy also increase maternal vulnerability to a suppressed HPA axis after delivery and postpartum depression, for which the CRH-R1 receptor has been implicated (Engineer et al., 2013; Meltzer-Brody et al., 2011). Changes in maternal and offspring HPA function, which can be altered via stress induced changes to CRF (or CRH) expression (Zaidan et al., 2013), are often accompanied by behavioral effects. Together, CRH can impact behavior and brain function and should continue to remain in focus of animal model-based investigations of stress-mediated fetal programming effects of neurodevelopmental trajectories.

3 PRECLINICAL STUDIES OF PRENATAL STRESS IN RODENT MODELS

3.1 Single Generation PS Exposure Effects on Programming of Postnatal Brain Development

3.1.1 PS Impairs Dopamine Metabolism Throughout Development of the Male Offspring

PS can be induced in pregnant rats by restriction of movement and subsequent crossfostering. PS increases DA D2 receptors in limbic areas, decreases DA-stimulated release in cortical areas and impairs the expression of specific transcription factors during development, as well as the expression of TH and transporters. PS alters the asymmetry in D2 type receptors in the Nucleus Accumbens, an area associated with impulsivity (Adrover et al., 2007; Berger et al., 2002; Barros et al., 2004; Carboni et al., 2010; Katunar et al., 2010; Silvagni et al., 2008). Adoption at birth reverses the receptor increase, reflecting the high vulnerability of DA system to variations both in prenatal and in postnatal environment.

3.1.2 PS Impairs the Hypothalamic-Pituitary-Gonadal Axis in Male Offspring (Fig. 32.2)

PS impairments of DA metabolism were differentially affected after puberty, suggesting that perinatal events might render the DA circuitry more vulnerable to puberty variation of the hormonal circulating hormones. PS induces long-term imbalance of male sexual hormones concentrations in serum, advanced spermatogenesis development and age-dependent misbalance in oestrogen receptor alpha expression in PFC and HPC brain areas (Pallares et al., 2013a,b).

3.1.3 PS Alters Behavioral and Morphological Parameters in Offspring

Behavioral studies have shown an anxiogenic behavior that can be reversed after early adoptions. A direct relation was found between the anxiety states and levels of benzodiazepine (BDZ) receptors. At the morphological level there is a reduced dendritic arborization and astroglial hypertrophy with synaptic loss suggesting a possible alteration of glutamate metabolism. Glutamate transporters were altered in frontal cortex and hippocampus of PS offspring (Adrover et al., 2015; Barros et al., 2006a).

3.1.4 PS Exerts Epigenetic Changes in Adult Offspring

The expression of the gene gpm6a (which encodes membrane M6A glycoprotein) is increased in the hippocampus of the PS rats' brains. The pattern of methylation in a CpG island of the first intron of the gene gpm6a was altered in rats subjected to PS (Monteleone et al., 2014).

Taken together, these results suggest that PS insults are critical in the development of biochemical responses and behavior in adults, and that maternal care is crucial in the first weeks of life. It has been postulated that several psychiatric disorders that manifest themselves in the adult human, such as schizophrenia, depression, anxiety, and drug abuse, are imbalances of dopaminergic, glutamatergic, and GABAergic systems as a consequence, among other reasons, of alterations in the early development of the corticostriatal pathway. Rat models of gestational stress will provide clues to understanding
FIGURE 32.2 **Schematic representations of the effects exerted by PS on the dopaminergic function.** The data correspond to the VTA–PFC pathway of an offspring that was prenatally stressed employing a restraint protocol. The effects described occur at different stages of development. PS exerts an inhibitory effect (indicate by [−]) on DA levels at some unknown stage of DA biosynthesis. Low levels of DA produce an up-regulation (indicate by [+]) of DA D2 receptors, which in turn activates Nurr1. High levels of this transcription factor could up- regulate TH expression, and eventually DAT and VMAT2, which will increase DA levels in an attempt to compensate for the imbalance produced by PS. PS also produces synaptic loss in the brain of adult offspring (Baier et al., 2012). DA, Dopamine; DAT, dopamine transporter; Nurr-1, nuclear receptor related 1-protein; PFC, prefrontal cortex; PS, prenatal stress; TH, tyrosine hydroxylase; VMAT2, vesicular monoamine transporter 2; VTA, ventral tegmental area.

the mechanisms by which a PS insult in early life contributes to the breakdown of the balance in neurotransmission and the formation of aberrant cortical connections, which would entail the establishment of abnormal cognitive behaviors.

3.1.4.1 EXPERIMENTAL PARADIGM FOR A SINGLE-GENERATIONAL PS RAT MODEL

Virgin female Wistar rats are individually mated with a sexually experienced male Wistar rat. The day on which the vaginal plug is found is designated as the first day of pregnancy.

Prenatal stress: Pregnant dams are randomly assigned to either the control (C) or the prenatal stress (PS) group and individually housed with *ad libitum* access to standard rat chow and water. C rats are left undisturbed in the home cage, while PS dams are subjected to a restraint stress procedure, which involves rats being transferred to an experimental room where the stressor is applied. Pregnant females are individually placed into a transparent plastic restrainer fitted closely to body size for three 45 min periods per day (09:00, 12:00, and 16:00 h) between days 14 and 21 of pregnancy. The restrainer

has ventilation holes, and dimensions appropriate for a pregnant rat of 350 g: internal diameter 64 mm, and an adjustable length of 149–208 mm. This type of stressor is chosen because it has an indirect influence on the fetuses via a direct stress on the mother. The sessions are performed in a lit environment. No other subjects should be present in the experimental room during the stress exposure.

Postnatal procedures: On the day of parturition, litter characteristics are recorded and litters are culled to 10 pups, maintaining similar number of males and females, when possible. Weaning is performed at postnatal day (PND) 21. The male and female offspring are housed in separated cages, with no more than 5 rats per cage, and in standard housing conditions. To avoid litter effects, 1–2 pups from each litter (a female and a male) should be tested for each experiment. Behavioral testing is conducted at that period using the elevated plus maze and light–dark box tests for anxiety-like behaviors and sucrose anhedonia test for depressive-like behavior. Brains are collected after decapitation at the end of behavioral tests at PND 35 or other date depending on the milestones to be assessed in the given study.
FIGURE 32.3 **Epigenetic regulation through microRNA expression.** A microRNA is a small noncoding RNA molecule containing approximately 22 nucleotides. MicroRNAs function in RNA silencing and posttranscriptional regulation of gene expression. When mRNA is translated into a protein product, a microRNA molecule can repress this process by binding to the mRNA. Each microRNA can bind to the mRNA of up to 200 gene targets. MicroRNAs can also be involved in establishing DNA methylation, and may influence chromatin structure by regulating histone modifiers (Metz et al., 2015).

3.2 Effects of Multigenerational PS on Programming of Postnatal Brain Development

The lifetime risk of mental illness is greater if an individual has family history of a similar condition. Therefore, most efforts during the past decades have focused on the identification of genetic associations, but the results were often met with disappointment, as the associations with genetic variations were weak. In the postgenomic era, the focus has shifted to identify associations between epigenetic regulators that can be modified by environmental factors, such as stress. Importantly, epigenetic marks are potentially heritable. *Trans*-generational studies are uniquely suited to reveal mechanisms of *trans*-generational programming by inheritance of epigenetic, metabolomic, and phenotypic traits. The multigenerational stress resembles human populations living in chronic stress conditions, for example, several generations exposed to residential school, war, or poverty.

Compared to single-generation PS, the multigenerational stress has somewhat different consequences: it facilitates adaptation to the recurrent maternal stress across generations, thus generating stress resilience. This causes new behavioral traits and better brain activity coherence. Based on the mismatch hypothesis, the multigenerational stress leads to better adaptation because the offspring is bred for a stressful environment and the stress is indeed occurring again when the daughters get pregnant. The *trans*-generational cohort faces the mismatch problem because they are bred for a stressful environment, but there is no more experimental stress during pregnancy or any other time.

3.2.1 PS Elevates Stress Responses and the Risk of Mental Illness

PS (F1 generation) impedes developmental milestones in rats, thus desynchronizing brain development along with epigenetic signatures of human anxiety, depression,

and adverse brain development (Zucchi et al., 2014). Interestingly, PS-induced anxiety-like and depression-like behaviors become most evident at the most vulnerable periods in life, early development and old age (Erickson et al., 2014).

3.2.2 PS programs Risk of Anxiety and Depression in Future Generations (Fig. 32.3)

In a rat model of trans- and multigenerational experience, PS induces increased risk of gestational diabetes, preterm birth, and delayed brain development across generations. These manifestations are linked to microRNA (miRNA) and mRNA signatures of preterm birth (Yao et al., 2014) and mental illness, in particular anxiety and depression-like symptoms, and altered brain connectivity in adulthood (McCreary et al., 2016). Interestingly, these studies revealed striking sex differences, with stressed females displaying partial stress resilience until the F3 generation, suggesting truly epigenetic inheritance.

3.2.3 Stress-Induced Epigenetic and Metabolic Changes Propagate Across Generations

Stress alters miRNA expression patterns in the brain (Babenko et al., 2012), thus generating potentially heritable biomarkers of disease. New miRNA pathways have been identified which are involved in neurotrophin and myelin regulation, providing a mechanistic link to mental illness REF. Furthermore, altered epigenetic regulation of gene expression is also accompanied by altered metabolic footprints, which can be assessed in animals and humans using body hair, biofluids or solid tissues using NMR spectroscopy and inductively coupled plasma mass spectroscopy (Ambeskovic et al., 2013; Kiss et al., 2016). These findings suggest that PS induces stable transgenerational specific epigenetic and metabolic alterations that can also be found in human disease.

4 EXPERIMENTAL PARADIGM FOR A TRANS- AND MULTIGENERATIONAL PS RAT MODEL

The trans- and multigenerational PS rat model allows studies of the genetic and epigenetic mechanisms on DNA and miRNA levels as well as of the down-stream metabolomics signatures in organs such as brain and blood. This may identify mechanisms of transgenerational inheritance of signatures linked to mental illness and potential predictive and diagnostic biomarkers.

Multi- and trans-generational stress: Restraint is used to induce a stress response in 100–150 day old timed-pregnant dams. Assessments are performed in the parental generation (F0), their offspring (F1), grand-offspring (F2), and great-grand-offspring (F3), for both males and females in each generation. Behavioral assessments include F4 pups. The F3 and F4 generations are central to identifying germ line epigenetic influences. *Trans*-generational Stress refers to stress in only the parental generation (S in F0, SN in F1, SNN in F2, SNNN in F3; N: no stress). F3 offspring (F4) development will also be assessed. Multigenerational Stress refers to continuous experience of maternal stress through all generations (S in F0, SS in F1, SSS in F2, SSSS in F3) and Controls will consist of nonstressed, handled animals (N, NN, NNN, NNNN). To carefully standardize conditions across generations, personal breeding colony room in a dedicated facility is advised.

Postnatal Procedures: Physiological correlates of stress are determined based on body weight, food intake, post-mortem brain and adrenal weight, and blood serum markers. Litter size and sex ratios are determined prior to culling each litter to $n = 8$ to standardize litter size effects on maternal care and offspring development. Infrared surveillance systems should monitor maternal care and behavior around the clock.

Behavior: This model is amenable for continuous cage site recordings of pre-partum maternal behavior, maternal care (nest building, grooming, stereotypy, circadian rhythm, pup retrieval; and maternal defense on lactational day (LD) 5 toward a virgin intruder female approaching the nest area. A comprehensive test battery assesses offspring development (P7 infantile, P21 juvenile) in sensorimotor and physical features (skilled walking, vestibular, and proprioceptive functions, body weight, eye opening, play). Measures of maturation at P60 (adolescence) and adult behavior (P90-18 months) can include 5 classes of behavior: (1) skilled movement (reaching, ladder rung walking); (2) sensorimotor function (adhesive removal, von-Frey-hair test); (3) learning and memory (water maze, Ziggurat task, Go-No Go decision making); (4) social behavior (play fighting, hierarchy, aggressive, defensive, and submissive behavior); (5) depression- and anxiety-like behavior (light–dark test, elevated plus maze, open field, open table exploration).

Physiology: Blood samples are collected via tail vein nick on days without behavioral tests. Measurements include blood glucose to determine hyperglycemia and dehydration, stress plasma markers CRH, CORT, ACTH, and sex hormone levels of estrogen and testosterone. Puberty, estrous cycle (weekly vaginal swabs and Shorr's staining) and number of breeding sessions further determine female stress response. Multiple complementary behavioral, physical and endocrine hallmarks reflect the complex manifestations of transgenerational stress across the lifespan. HPA axis activity is closely linked to GR and MR density in the hypothalamic paraventricular nucleus and hippocampus. In all brain tissues, immunocytochemical and stereological analysis of GR, MR, CRH, and oxytocin receptor (OXTR) density and intracellular location should be performed to assess PS effects on stress axis. General morphology (cortical thickness, volume, neuron density) should be assessed for central structures involved in stress response and affective disorders, such as prefrontal cortex, hippocampus, basolateral amygdala, and paraventricular hypothalamus.

5 LARGE ANIMAL MODELS OF FETAL DEVELOPMENT TO MODEL PS: PREGNANT SHEEP

Chronically instrumented nonanesthetized fetal sheep is an appropriate and uniquely suited animal model for studying the effects of in utero insults on fetal development, because of its recognized physiological and pathophysiological similarities to human fetal developmental profile and the unique ability to chronically instrument and monitor the fetus while manipulating the intrauterine environment. Fetal sheep and guinea pig (Iqbal et al., 2012) in particular have been used extensively for studies of effects of antenatal sGC treatment on fetal brain development. Many studies showed detrimental acute and transgenerational effects on neurodevelopment and HPA axis responsiveness to stress (Anegroaie et al., 2016; Antonow-Schlorke et al., 2009; McCallum et al., 2008; Schwab et al., 2001, 2012; Iqbal et al., 2012). It is not clear whether the postnatal brain can fully compensate for these changes. Consequently, despite the acute benefits of the antenatal sGC treatment to the fetus during labour and in the early postnatal period, further studies are needed to delineate the long-term effects of repeated sGC courses on postnatal brain development. For such fetal/postnatal experimental paradigms, the guinea pig model has been most instrumental, although it is possible to do similar work in larger mammals, such as sheep or nonhuman primate. To the extent that sGCs represent a stress stimulus to

the fetus and can be injected directly intravenously to the fetus, this experimental approach also represents a possible paradigm for mimicking human fetal stress exposure to maternal stress hormones without accounting for the interindividual and interspecies differences in the placental transfer dynamics. Taken together, as an iatrogenic stressor or a model for stress-induced fetal programming, sGC-driven studies in guinea pig and sheep have shown the potential of fetal stress exposure to alter organ development, in particular that of the brain (Moisiadis and Matthews, 2014a,b).

A more "human-like", but also technically more complex experimental paradigm involves isolation of pregnant ewes based on the fact that they are flock animals and experience such isolation as stress. Such approach, as presented below, has been shown to result in acute and chronic stress-induced adaptations and represents the most comprehensive animal experimental model of human *fetal* stress exposure (Rakers et al., 2013). Rakers et al. (2013) showed that the development of HPA axis function, which matures during late gestation, is sensitive to inappropriate levels of GCs during preceding periods of fetal life. Earlier periods of gestation are particularly vulnerable. Exposure to endogenous or synthetic GCs during late gestation has similar effects, although transfer of endogenous GCs through the placental barrier is extremely limited. Finally, GCs reset the set point of the HPA axis rather than having an effect on its maturation.

6 EXPERIMENTAL PARADIGM FOR PRENATAL STRESS MODEL IN FETAL SHEEP

A detailed anesthesia and surgical protocol for creating a chronically instrumented nonanesthetized fetal sheep model has been reported recently (Burns et al., 2015). Pregnant sheep are randomly assigned to control or maternal stress groups. Stress group follows a repeated maternal stress protocol between 105 and 135 days of gestation (dGA, term = 145 dGA) according to the protocol by Rakers et al. (2013). Maternal stress is induced by isolating pregnant ewes in a well-lit box with no visual, tactile, or auditory contact with flockmates. During isolation, ewes have no access to food or water supply. Ewes are isolated 3 h for 2 days per week (Monday to Friday) with at least 2 days recovery time between the particular isolation bouts. Isolation is performed either between 07:00 and 10:00 h, 11:00 and 14:00 h, or 15:00 and 18:00 h. Day of the week and time of isolation, as well as the isolation box are to be changed randomly within the mentioned parameters to reduce habituation. Maternal blood samples are collected from the chronically installed jugular vein catheter at 105 dGA or another day of choosing, depending on the desired stress exposure observation window, before and during isolation to estimate maternal cortisol concentrations and the degree of habituation. Maternal and fetal ECG and fetal blood and amniotic pressures are recorded continuously throughout the experiment. Pregnant control ewes are held under the same conditions as the stressed ewes, but do not undergo the isolation procedures.

7 CONCLUSIONS

In summary, the protocols discussed here provides an overview and specific examples of experimental designs using animal models to assist in DOHaD-related research. Although each of the animal models comes with inherent limitations in resembling human conditions, rodents and sheep are especially suited for obtaining first primary data about human pregnancy and early development upon which to build future hypotheses.

1 INTRODUCTION

Well-developed animal models are necessary to understand disease progression, pathogenesis, and immunologic responses to viral infections in humans. Furthermore, to test vaccines and medical countermeasures, animal models are essential for preclinical studies.

Ideally, an animal model of human viral infection should mimic the host–pathogen interactions and the disease progression that is seen in the natural disease course. A good animal model of viral infection should

allow assay of many parameters of infection, including clinical signs, growth of virus, clinicopathological parameters, cellular and humoral immune responses, and virus–host interactions. Furthermore, viral replication should be accompanied by measurable clinical manifestations and pathology should resemble that of human cases such that a better understanding of the disease process in humans is attained. There is often more than one animal model that closely represents human disease for a given pathogen. Small animal models are typically used for first-line screening, and for testing the efficacy of vaccines or therapeutics. In contrast, nonhuman primate (NHP) models are often used for pivotal preclinical studies. This approach is also used for basic pathogenesis studies, with most studies in small animal models when possible, and studies in NHPs to fill in the remaining gaps in knowledge.

The advantages of using mice to develop animal models are low cost, low genetic variability in inbred strains, and abundant molecular biological and immunological reagents. Specific pathogen free (SPF), transgenic and knockout mice are also available. A major pitfall of mouse models is that the pathogenesis and protection afforded by vaccines and therapeutics cannot always be extrapolated to humans. Additionally, blood volumes for sampling are limited in small animals, and viruses often need to be adapted through serial passage in the species to induce a productive infection.

The ferret's airways are anatomically and histologically similar to that of humans, and their size enables collection of larger or more frequent blood samples, making them an ideal model for certain respiratory pathogens. Ferrets are outbred, with no standardized breeds or strains, thus greater numbers are required in studies to achieve statistical significance and overcome the resulting variable responses. Additionally, SPF and transgenic ferrets are not available, and molecular biological reagents are lacking. Other caveats making ferret models more difficult to work with are their requirement for more space than mice (rabbit-style cages), and the development of aggressive behavior with repeated procedures.

NHPs are genetically, the closest species to humans, thus disease progression and host–pathogen responses to viral infections are often the most similar to that of humans. However, ethical concerns pertaining to experimentation on NHPs along with the high cost and lack of SPF NHPs raise barriers for such studies. NHP studies should be carefully designed to ensure the fewest number of animals are used, and the studies should address the most critical questions regarding disease pathogenesis, host–pathogen responses, and protective efficacy of vaccines and therapeutics.

Well-designed experiments should carefully evaluate the choice of animal, including the strain, sex, and age.

Furthermore, depending on the pathogen, the route of exposure and the dose should mimic the route of exposure and dose of human disease. The endpoint for these studies is also an important criterion. Depending on the desired outcome, the model system should emulate the host responses in humans when infected with the same pathogen.

In summary, small animal models are helpful for the initial screening of vaccines and therapeutics, and are often beneficial in obtaining a basic understanding of the disease. NHP models should be used for a more detailed characterization of pathogenesis and for pivotal preclinical testing studies. Ultimately, an ideal animal model may not be available. In this case, a combination of different well-characterized animal models should be considered to understand the disease progression and to test medical countermeasures against the disease.

In this chapter, we will be reviewing the animal models for representative members of numerous virus families causing human diseases. We will focus on viruses for each family that are of the greatest concern for public health worldwide.

2 CALICIVIRIDAE

2.1 Norwalk Virus

Norovirus, the genus of which Norwalk is the prototypic member, is the most common cause of gastroenteritis in the United States (Hall et al., 2013). There are five distinct genogroups (GI–GV) and numerous strains of Norwalk virus, including the particularly significant human pathogens GI.1 Norwalk virus, GII.2 Snow Mountain virus, and GII.1 Hawaii virus. In developing countries, Norwalk virus, also known as "winter vomiting virus," is responsible for approximately 200,000 deaths annually (Patel et al., 2008). A typical disease course is self-limiting, but there have been incidences of necrotizing enterocolitis and seizures in infants (Chen et al., 2009; Lutgehetmann et al., 2012; Turcios-Ruiz et al., 2008). Symptoms of infection include diarrhea, vomiting, nausea, abdominal cramping, dehydration, and fever. Incubation is normally 1–3 days, with symptoms persisting for 2–3 days (Koopmans and Duizer, 2004). Viral shedding can range from 6 to 55 days in healthy individuals (Atmar et al., 2014). However, longer illness duration can be indicative of immunocompromised status, with the elderly and young having a prolonged state of shedding (Harris et al., 2008; Rockx et al., 2002). Interestingly, individuals vary greatly in susceptibility to norovirus infection depending on their fucosyl transferase 2 (FUT2) allele functionality and histoblood group antigen status, with type A and O individuals susceptible and types AB and B resistant (Hutson et al., 2005).

Transmission occurs predominately through the oral–fecal route with contaminated food and water being a major vector (Atmar and Estes, 2001; Becker et al., 2000; Koopmans and Duizer, 2004). Vomiting results in airborne dissemination of the virus with areas of 7.8 m^2 being contaminated and subsequent transmission from oral deposition of airborne particles or contact with contaminated fomites, which can remain contaminated for up to 42 days (Makison Booth, 2014; Tung-Thompson et al., 2015). Each vomiting event in a classroom setting elevates the risk of norovirus illness among elementary students with proximity correlating with attack rates (Evans et al., 2002; Marks et al., 2003). Viral titers in emesis and fecal suspensions are as high as 1.2×10^7 and 1.6×10^{11} GES (genomic equivalent copies per milliliter), respectively and the 50% infectious dose is 1320 GES (Atmar et al., 2014). Therefore, outbreaks can be extremely difficult to contain. Therapeutic intervention consists of rehydration therapy and antiemetic medication (Bucardo et al., 2008; Moe et al., 2001). No approved vaccine or therapeutic is available, and development has been challenging given that immunity is short-lived after infection, new strains rapidly evolve and the correlates of protection are not completely understood (Chen et al., 2013). However, one promising strategy utilized a virus-like particle (VLP)-based vaccine that protected or reduced infection by almost 50% in human volunteers (Aliabadi et al., 2015; Atmar et al., 2011).

Given the relatively benign disease in adults, experimental challenge has been carried out on human volunteers (Ball et al., 1999; Tacket et al., 2000). Viral titers are determined by shedding in feces and sera with histopathology changes monitored by biopsies particularly of the duodenum. The pH of emesis samples collected containing virus is consistent with viral replication in the small intestine with reflux to the stomach (Kirby et al., 2016). Additionally, Norwalk virus has been shown to bind to duodenal tissue (Chan et al., 2011). However, this type of research is technically difficult and expensive, and thus other models have been developed.

A major hindrance to basic research into this pathogen is the lack of permissive cell culture systems or animal models for Norwalk virus. NHPs including marmosets, cotton-top tamarins, and rhesus macaques infected with Norwalk virus are monitored for the extent of viral shedding; however, no clinical disease is observed in these models. Disease progression and severity is measured exclusively by assay of viral shedding (Rockx et al., 2005). Incidentally, more viruses were needed to create an infection when challenging by the oral route than by the intravenous (IV) route (Purcell et al., 2002). Chimpanzees were exposed to a clinical isolate of Norwalk virus by the IV route (Bok et al., 2011). Although none of the animals developed disease symptoms, viral shedding within the feces was observed within 2–5 days postinfection and lasted anywhere from 17 days to 6 weeks. Viremia never occurred and no histopathological changes were detected. The amount and duration of viral shedding was in-line with what is observed upon human infection. As such, chimeric chimpanzee–human anti-norovirus neutralizing antibodies have been explored as a possible therapeutic strategy (Chen et al., 2013).

A recently identified Calicivirus of rhesus origin, named Tulane virus, has been used as a surrogate model of infection. Unlike Norwalk virus, Tulane virus can be cultured in cells. Rhesus macaques exposed to Tulane virus intragastrically developed diarrhea and fever 2 days postinfection. Viral shedding was detected for 8 days. The immune system produced antibodies that dropped in concentration within 38 days postinfection, mirroring the short-lived immunity documented in humans. The intestine developed moderate blunting of the villi as seen in human disease (Sestak et al., 2012).

A murine norovirus has been identified and is closely related to human Norwalk virus (Karst et al., 2003). However, clinically the virus presents a different disease. The murine norovirus model does not include observable gastrointestinal clinical signs, possibly in part because rodents lack a vomiting reflex. Additionally, mice infected with norovirus develop a persistent infection in contrast to human disease (Hsu et al., 2006, 2007; Khan et al., 2009).

Porcine enteric caliciviruses can induce diarrheal disease in young pigs, and an asymptomatic infection in adults (Wang et al., 2006, 2007). Gnotobiotic pigs can successfully be infected with a passaged clinical norovirus isolate by the oral route. Diarrheal disease developed in 74% of the animals and virus was detected in the stool of 44% of the animals. No major histopathological changes or viral persistence was noted (Cheetham et al., 2006).

Calves are naturally infected with bovine noroviruses (Scipioni et al., 2008). Experimental challenge of calves by oral inoculation with a bovine isolate resulted in diarrheal disease 14–16 h postinfection. Recovery of virus was achieved after 53.5 and 67 h postinfection (Otto et al., 2011).

3 TOGAVIRIDAE

3.1 Eastern Equine Encephalitis Virus, Western Equine Encephalitis Virus, and Venezuelan Equine Encephalitis Virus

Eastern equine encephalitis virus (EEEV), Western equine encephalitis virus (WEEV), and Venezuelan equine encephalitis virus (VEEV) present with near synonymous symptoms. The majorities of human cases are asymptomatic, but can present as a flu-like illness progressing to central nervous system (CNS) involvement

to include seizures and paralysis. Mortality rates vary among the virus, with the highest reported for EEV at 36%–75% followed by WEEV and lastly VEEV at less than 1% (Ayers et al., 1994; Griffin, 2007; Steele and Twenhafel, 2010). There are currently no licensed vaccines or therapies but a recent Phase 1 clinical trial of a VEEV DNA vaccine resulted in VEEV-neutralizing antibody responses in 100% of the subjects (Hannaman et al., 2016).

Mouse models have been developed for numerous routes of infection including cutaneous, intranasal (IN), intracranial (IC), and aerosol. EEEV susceptibility in mouse models is correlated with age, with younger mice being more susceptible than adults. Importantly, EEEV pathogenesis is dependent on route of infection with delayed progression upon subcutaneous (subQ) exposure (Honnold et al., 2015). Newborn mice display neuronal damage with rapid disease progression, resulting in death (Murphy and Whitfield, 1970). Similarly, EEEV produces fatal encephalitis in older mice when administered via the intracerebral route, while inoculation via the subQ route causes a pantropic infection eventually resulting in encephalitis (Liu et al., 1970; Morgan, 1941). A general drawback to the usage of the mouse model is the lack of vascular involvement during the disease course (Liu et al., 1970).

After subQ inoculation with WEEV, suckling mice started to show signs of disease by 24 h and died within 48 h (Aguilar, 1970). The heart was the only organ in which pathologic changes were observed. Conversely, adult mice exhibited signs of lethargy and ruffled fur on day 4–5 postinfection. Mice were severely ill by day 8 and appeared hunched and dehydrated. Death occurred between days 7 and 14 with brain and mesodermal tissues, such as heart, lungs, liver, and kidney involvement (Aguilar, 1970; Monath et al., 1978). Intracerebral and IN routes of infection resulted in a fatal disease that was highly dependent on dose while intradermal (ID) and subQ inoculations caused only 50% fatality in mice regardless of the amount of virus (Liu et al., 1970). Comparing susceptibility of inbred and outbred strains revealed that CD-1, BALB/c, A/J, and C57BL6 mice were all highly susceptible to experimental infection via subQ inoculation when challenged prior to 10 weeks old with CNS involvement and lethality (Blakely et al., 2015). SubQ/dermal infection in the mouse model results in encephalitic disease very similar to that seen in horses and humans (MacDonald and Johnston, 2000). Virus begins to replicate in the draining lymph nodes at 4 h postinoculation. Eventually, virus enters the brain primarily via the olfactory system.

Furthermore, aerosol exposure of mice to VEEV can result in massive infection of the olfactory neuroepithelium, olfactory nerves, and olfactory bulbs and viral spread to brain, resulting in necrotizing panencephalitis (Charles et al., 1995; Steele et al., 1998). Aerosol and dermal inoculation routes cause neurological pathology in mice much faster than other routes of exposure. The clinical signs of disease in mice infected by aerosol are ruffled fur, lethargy, and hunching progressing to death (Charles et al., 1995; Steele and Twenhafel, 2010; Steele et al., 1998). IN challenge of C3H/HeN mice with high dose VEEV caused high morbidity and mortality (Julander et al., 2008b). Viral titers in brain peaked on day 4 postchallenge and remained elevated until animals succumbed on day 9–10 postchallenge. Protein cytokine array performed on brains of infected mice showed elevated IL-1a, IL-1b, IL-6, IL-12, MCP-1, IFNγ, MIP-1a, and RANTES levels. This model was used successfully to test antivirals against VEEV (Julander et al., 2008a). Additionally, a VEEV vaccine inactivated with 1,5-iodonaphthyl azide V3526 protects against both footpad and aerosol challenge with virulent VEEV in a mouse model (Gupta et al., 2016).

Guinea pigs and hamsters have also been developed as animal models for EEEV studies (Paessler et al., 2004; Roy et al., 2009). Guinea pigs developed neurological involvement with decreased activity, tremors, circling behavior, and coma. Neuronal necrosis was observed in brain lesions in the experimentally challenged animals (Roy et al., 2009). SubQ inoculation of EEEV produced lethal biphasic disease in hamsters with severe lesions of nerve cells. The early visceral phase with viremia was followed by neuroinvasion, encephalitis, and death. In addition, parenchyma necrosis were observed in the liver and lymphoid organs (Paessler et al., 2004). Harlan Sprague–Dawley hamsters develop viremia and progress to respiratory, gastrointestinal, and nervous system involvement when inoculated via subQ route. Vasculitis and encephalitis were both evident in this model, which mirrors the human disease clinical spectrum (Paessler et al., 2004).

WEEV is highly infectious to guinea pigs and has been utilized for prophylactic screening (Sidwell and Smee, 2003). Studies demonstrated that although the length of the incubation period and the disease duration varied, WEEV infection resulted in mortality in hamsters by all routes of inoculation. Progressive lack of coordination, shivering, rapid and noisy breathing, corneal opacity, and conjunctival discharge resulting in closing of the eyelids were indicative of disease in all cases (Zlotnik et al., 1972). CNS involvement was evident with intracerebral, intraperitoneal (IP), and ID inoculations (Zlotnik et al., 1972). IP inoculation of WEEV is fatal in guinea pigs regardless of amount of virus inoculum, with the animals exhibiting signs of illness on day 3–4, followed by death on day 5–9 (Nalca, unpublished results).

ID, IM, or IV inoculations of EEEV in NHPs cause disease, but does not reliably result in neurological symptoms (Dupuy and Reed, 2012). Intracerebral

infection of EEEV produces nervous system disease and fatality in monkeys (Nathanson et al., 1969). The differences in these models indicate that the initial viremia and the secondary nervous system infection do not overlap in NHPs when they are inoculated by the peripheral route (Wyckoff, 1939). IN and intralingual inoculations of EEEV also cause nervous system symptoms in monkeys, but are less drastic than intracerebral injections (Wyckoff, 1939). The aerosol route of delivery will result in uniformly lethal disease in cynomolgus macaques (Reed et al., 2007). In this model, fever was followed by elevated white blood cells and liver enzymes. Neurological signs subsequently developed and NHPs became moribund and were euthanized between 5–9 days postexposure. Meningoencephalomyelitis was the main pathology observed in the brains of these animals (Steele and Twenhafel, 2010). Similar clinical signs and pathology were observed when common marmosets were infected with EEEV by the IN route (Adams et al., 2008). Both aerosol and IN NHP models had similar disease progression and pathology as seen in human disease. Very limited studies have been performed with NHPs.

Reed et al. exposed cynomolgus macaques to low and high doses of aerosolized WEEV. The animals subsequently developed fever, increased white blood counts, and CNS involvement, demonstrating that the cynomolgus macaque model could be useful for testing of vaccines and therapeutics against WEEV (Reed et al., 2005).

VEEV infection causes a typical biphasic febrile response in NHPs. Initial fever was observed at 12–72 h after infection and lasted less than 12 h. Secondary fever generally began on day 5 and lasted 3–4 days (Gleiser et al., 1961). VEEV-infected NHPs exhibited mild symptoms, such as anorexia, irritability, diarrhea, and tremors. Leukopenia was common in animals exhibiting fever (Monath et al., 1974). Supporting the leukopenia, microscopic changes in lymphatic tissues, such as early destruction of lymphocytes in lymph nodes and spleen, a mild lymphocytic infiltrate in the hepatic triads, and focal myocardial necrosis with lymphocytic infiltration have been observed in monkeys infected with VEEV. Surprisingly, characteristic lesions of the CNS were observed histopathologically in monkeys in spite of the lack of any clinical signs of infection (Gleiser et al., 1961). The primary lesions were lymphocytic perivascular cuffing and glial proliferation and generally observed at day 6 postinfection during the secondary febrile episode. Similar to these observations, when cynomolgus macaques were exposed to aerosolized VEEV, fever, viremia, lymphopenia, and clinical signs of encephalitis were observed but the NHPs did not succumb to disease (Reed et al., 2004).

A common marmoset model was utilized for comparison studies of South America (SA) and North America (NA) strains of EEEV (Adams et al., 2008). Previous studies indicated that the SA strain is less virulent than NA strain for humans. Common marmosets were infected IN with either the NA or SA strain of EEEV. NA strain-infected animals showed signs of anorexia and neurological involvement and were euthanized 4–5 days after the challenge. Although SA strain-infected animals developed viremia, they remained asymptomatic and survived until the end of study.

3.2 Chikungunya Virus

Chikungunya virus (CHIKV) is a member of the genus *Alphaviruses*, specifically the Semliki Forest complex, and has been responsible for a multitude of epidemics centered within Africa and Southeast Asia (Griffin, 2007). The virus is transmitted by *Aedes aegypti* and *Aedes albopictus* mosquitoes. Given the widespread endemicity of *Aedes* mosquitoes, CHIKV has the potential to spread to previously unaffected areas. This is typified by the emergence of disease reported for the first time in 2005 in the islands of South-West Indian Ocean, including the French La Reunion island, and the appearance in Central Italy in 2007 (Charrel et al., 2007; Rezza et al., 2007).

The incubation period following a mosquito bite is 2–5 days, leading to a self-limiting acute phase that lasts 3–4 days. Symptoms during this period include fever, arthralgia, myalgia, and rash. Headache, weakness, nausea, vomiting, and polyarthralgia have all been reported (Powers and Logue, 2007). Individuals typically develop a stooped posture due to the pain. For approximately 12% of infected individuals, joint pain can last months after resolution of primary disease, and has the possibility to relapse. Underlying health conditions including diabetes, alcoholism, or renal disease, increase the risk of developing a severe form of disease that includes hepatitis or encephalopathy. Children between the ages of 3 and 18 years old have an increased risk of developing neurological manifestations (Arpino et al., 2009). There is currently no approved vaccine or antiviral.

Wild-type C57BL/6 adult mice are not permissive to CHIKV infection by ID inoculation. However, it was demonstrated that neonatal mice were susceptible and severity was dependent upon age at infection. Six-day-old mice developed paralysis by day 6, and all succumbed by day 12, whereas 50% of 9-day-old mice were able to recover from infection. By 12 days, mice were no longer permissive to disease. Symptomatic mice developed loss of balance, hind limb dragging, and skin lesions. Neonatal mice were also used as a model for neurological complications (Couderc et al., 2008; Ziegler et al., 2008).

An adult mouse model has been developed by injection of the ventral side of the footpad of C57BL/6J mice. Viremia lasted 4–5 days accompanied with foot swelling and noted inflammation of the musculoskeletal tissue (Gardner et al., 2010; Morrison et al., 2011). Adult

IFNα/βR knockout mice also developed mild disease with symptoms including muscle weakness and lethargy, symptoms that mirrored human infection. All adult mice died within 3 days. This model was useful in identifying the viral cellular tropism for fibroblasts (Couderc et al., 2008). ICR and CD-1 mice can also be utilized as a disease model. Neonatal mice inoculated subQ with a passaged clinical isolate of CHIKV developed lethargy, loss of balance, and difficulty walking. Mortality was low, 17 and 8% for newborn CD-1 and ICR mice, respectively. The remaining mice fully recovered within 6 weeks after infection (Ziegler et al., 2008). A drawback of both the IFNα/βR and CD-1 mice is that the disease is not a result of immunopathogenesis as occurs in human cases, given that the mice are immunocompromised (Teo et al., 2012).

A chronic infection model was developed using recombinant activating gene 1 (RAG1$^{-/-}$) knockout mice. In this study, mice inoculated via the footpad lost weight in comparison to the control group. Both footpad and subQ injected mice developed viremia 5–6 days postinfection, which was detectable up to 28 days postinfection. Inflammation was evident in the brain, liver, and lung of the subQ inoculated animals at 28–56 days postinfection. Despite minimal footpad swelling on day 2 postinfection, on day 14 there was severe muscle damage noted at necropsy, which resolved by day 28 (Seymour et al., 2015).

Golden hamsters serve as another option for small animal modeling. Although hamsters do not appear to develop overt clinical symptoms following subQ inoculation, viremia developed in the majority of animals within 1 day postinfection with clearance following from day 3 to 4. Histologically, inflammation was noted at the skeletal muscle, fascia, and tendon sheaths of numerous limbs. This study was limited in the number of animals utilized, and more work is needed to further develop the hamster model (Bosco-Lauth et al., 2015).

NHP models of disease include adult, aged, and pregnant rhesus macaques in addition to cynomolgus macaques (Broeckel et al., 2015). Differing routes of infection (subQ, IV, and IM) have been successfully administered, although there is not a clear understanding of the role that route of transmission plays in subsequent pathogenesis and clinical symptoms. Typically, viremia is observed 4–5 days postinfection with a correlation between infectious titer and time to viremia observed in cynomolgus but not rhesus (Labadie et al., 2010; Messaoudi et al., 2013). Fever began at 1–2 days postinfection and persisted for 2–7 days and 3–7 days in cynomolgus and rhesus, respectively and coincided with rash (Chen et al., 2010; Labadie et al., 2010; Messaoudi et al., 2013). Overall blood chemistries changed in conjunction with initiation of viremia, and returned to baseline 10–15 days postexposure (Chen et al., 2010). CNS involvement has been difficult to reproduce in NHP models, although it was reported that high inoculum in cynomolgus did result in meningoencephalitis (Labadie et al., 2010). The NHP models have been utilized to conduct efficacy testing on novel vaccines and therapeutics (Broeckel et al., 2015).

4 FLAVIVIRIDAE

4.1 Dengue Virus

Dengue virus (DENV) is transmitted via the mosquito vectors *A. aegypti* and *A. albopictus* (Moore and Mitchell, 1997). Given the endemicity of the vectors, it is estimated that half of the world's population is at risk for exposure to DENV. This results in approximately 50 million cases of dengue each year, with the burden of disease in the tropical and subtropical regions of Latin America, South Asia, and Southeast Asia (Gubler, 2002). It is estimated that there are 20,000 deaths each year due to dengue hemorrhagic fever (DHF) (Guzman and Kouri, 2002).

There are four distinct serotypes of DENV, numbered 1–4, which are capable of causing a wide clinical spectrum that ranges from asymptomatic to severe with the development of DHF (World Health Organization, 1997). Incubation can range from 3 to 14 days, with the average being 4–7 days. The virus targets dendritic cells and macrophages following a mosquito bite (Balsitis et al., 2009). Typical infection results in classic dengue fever (DF), which is self-limiting and has flu-like symptoms in conjunction with retroorbital pain, headache, skin rash, and bone and muscle pain. DHF can follow, with vascular leak syndrome and low platelet count, resulting in hemorrhage. In the most extreme cases, dengue shock syndrome (DSS) develops, characterized by hypotension, shock, and circulatory failure (World Health Organization, 1997). Thrombocytopenia is a hallmark clinical sign of infection, and aids in differential diagnosis (Gregory et al., 2010).

Severe disease has a higher propensity to occur upon secondary infection with a different DENV serotype (Thein et al., 1997). This is hypothesized to occur due to antibody dependent enhancement (ADE). There is no approved vaccine or drug, and hospitalized patients receive supportive care including fluid replacement. In order to further progress toward an effective drug or vaccine, small human cohort studies have taken place. However, to provide statistically relevant results, testing must progress in an animal model. In developing an animal model, it is important to note that mosquitoes typically deposit 10^4–10^6 pfu, and is considered the optimal range during experimental challenge (Chan et al., 2015).

DENV does not naturally replicate effectively in rodent cells, creating the need for mouse-adapted strains, engineered mouse lines, and a variety of inoculation routes to overcome the initial barrier. Several laboratory mouse strains including A/J, BALB/c, and C57BL/6 are permissive to dengue infection. However, the resulting disease has little resemblance to human clinical signs, and death results from paralysis (Huang et al., 2000; Paes et al., 2005; Shresta et al., 2004). A higher dose of an adapted DENV strain induced DHF symptoms in both BALB/c and C57BL/6 (Chen et al., 2007; Souza et al., 2009). This model can also yield asymptomatic infections. A mouse-adapted strain of DENV 2 introduced into AG129 mice developed vascular leak syndrome similar to the severe disease seen in humans (Shresta et al., 2006). Passive transfer of monoclonal dengue antibodies within mice leads to ADE. During the course of infection, viremia was increased and animals died due to vascular leak syndrome (Balsitis et al., 2010). Another mouse-adapted strain injected into BALB/c caused liver damage, hemorrhagic manifestations, and vascular permeability (Souza et al., 2009). IC injection of suckling mice with DENV leads to death by paralysis and encephalitis, which is rare in human infection (Lee et al., 2015; Parida et al., 2002; Zhao et al., 2014a).

Immunocompromised mice have also been used to gain an understanding of the pathogenesis of DENV. The most well-defined model is AG129 which is deficient in IFNα/β and γ receptors and can recapitulate DHF/DSS if a mouse-adapted strain is utilized (Watanabe et al., 2012; Yauch et al., 2009). SCID mice engrafted with human tumor cells develop paralysis upon infection, and thus are not useful for pathogenesis studies (Blaney et al., 2002; Lin et al., 1998). DF symptoms developed after infection in NOD/SCID/IL2RγKO mice engrafted with CD34$^+$ human progenitor cells (Mota and Rico-Hesse, 2011). RAG-hu mice developed fever, but no other symptoms upon infection with a passaged clinical isolate and lab-adapted strain of DENV 2 (Kuruvilla et al., 2007).

A passaged clinical isolate of DENV 3 was used to create a model in immunocompetent adult mice. IP injection in C57BL/6j and BALB/c caused lethality by day 6–7 postinfection in a dose dependent manner. The first indication of infection was weight loss beginning on day 4 followed by thrombocytopenia. A drop in systolic blood pressure along with noted increases in the liver enzymes, AST and ALT, were also observed. Viremia was established by day 5. This model mimicked the characteristic symptoms observed in human DHF/DSS cases (Costa et al., 2012). Vascular leakage was also observed when C57BL/6 were inoculated with DENV 2 (St John et al., 2013).

A murine model was developed that utilized infected mosquitoes as the route of transmission to hu-NSG mice. Female mosquitoes were intrathoracically inoculated with a clinical isolate of DENV 2. Infected mosquitoes then fed upon the mouse footpad to allow for transmission of the virus via the natural route. The amount of virus detected within the mouse was directly proportional to the number of mosquitoes it was exposed to, with 4–5 being optimal. Detectable viral RNA was in line with historical human infection data. Severe thrombocytopenia developed on day 14. This model is notable in that disease was enhanced with mosquito delivery of the virus in comparison to injection of the virus (Cox et al., 2012).

NHP models have used a subQ inoculation in an attempt to induce disease. Although the animals are permissive to viral replication, it is to a lower degree than that observed in human infection (Marchette et al., 1973). The immunosuppressive drug, cyclophosphamide enhances infection in rhesus macaques by allowing the virus to invade monocytes (Marchette et al., 1980). Throughout these preliminary studies, no clinical disease was detected. In order to circumvent this, a higher dose of DENV was used in an IV challenge of rhesus macaques. Hemorrhagic manifestations appeared by day 3 and resulted in petechiae, hematomas, and coagulopathy; however, no other symptoms developed (Onlamoon et al., 2010). A robust antibody response was observed in multiple studies (Marchette et al., 1973; Onlamoon et al., 2010). Marmosets also mirror human dengue infection, developing fever, leukopenia, and thrombocytopenia following subQ inoculation (Omatsu et al., 2011, 2012).

NHPs are able to produce antibodies similar to those observed during the course of human infection, making them advantageous in studying ADE. Sequential infection led to a cross-reactive antibody response which has been demonstrated in both humans and mice (Midgley et al., 2011). This phenotype can also be seen upon passive transfer of a monoclonal antibody to dengue and subsequent infection with the virus. Rhesus macaques exposed in this manner developed viremia that was 3- to 100-fold higher than previously reported, however, no clinical signs were apparent (Goncalvez et al., 2007). The lack of inducible DHF or DSS symptoms hinders further examination of pathogenesis within this model.

4.2 West Nile Virus

West Nile virus (WNV) was first isolated from the blood of a woman in the West Nile district of Uganda in 1937 (Smithburn et al., 1940). After the initial isolation of WNV, the virus was subsequently isolated from patients, birds, and mosquitoes in Egypt in the early 1950s (Melnick et al., 1951; Taylor et al., 1953) and was shown to cause encephalitis in humans and horses. WNV is recognized as the most widespread of the flaviviruses, with a geographical distribution that includes Africa, the Middle East, western Asia, Europe, and Australia

(Hayes, 1989). The virus first reached the Western Hemisphere in the summer of 1999, during an outbreak involving humans, horses, and birds in the New York City metropolitan area (Centers for Disease Control and Prevention, 1999; Lanciotti et al., 1999). Since 1999, the range of areas affected by WNV quickly extended. Older people and children are most susceptible to WNV disease. WNV generally causes asymptomatic disease or a mild undifferentiated fever (West Nile fever), which can last from 3 to 6 days (Monath and Tsai, 2002). The mortality rate following neuroinvasive disease ranges from 4% to 11% (Asnis et al., 2000; Hayes, 1989; Hubalek and Halouzka, 1999; Komar, 2000). The most severe complications are commonly seen in the elderly, with reported case fatality rates from 4% to 11%. Hepatitis, myocarditis, and pancreatitis are unusual, severe, nonneurologic manifestations of WNV infection.

Inoculation of WNV into NHPs intracerebrally resulted in the development of either encephalitis, febrile disease, or an asymptomatic infection, depending on the virus strain and dose. Viral persistence is observed in these animals regardless of the outcome of infection (i.e., asymptomatic, fever, encephalitis) (Pogodina et al., 1983). Thus, viral persistence is regarded as a typical result of NHP infection with various WNV strains. After both intracerebral and subQ inoculation, the virus localizes predominantly in the brain and may also be found in the kidneys, spleen, and lymph nodes. WNV does not result in clinical disease in NHPs although the animals show a low level of viremia (Lieberman et al., 2009; Pletnev et al., 2003). This is mirrored in New Zealand White rabbits in that they only develop fever and low levels of viremia following inoculation via footpad (Suen et al., 2015). ID inoculation of both marmosets and rhesus macaques did not yield any clinical signs of disease including fever. Viremia was detected in both NHP species, but marmosets developed a higher titer for a greater duration than rhesus (Verstrepen et al., 2014).

WNV has also been extensively studied in small animals. All classical laboratory mouse strains are susceptible to lethal infections by the intracerebral and IP routes, resulting in encephalitis and 100% mortality. ID route pathogenesis studies indicated that Langerhans dendritic cells are the initial viral replication sites in the skin (Brown et al., 2007; Johnston et al., 1996). The infected Langerhans cells then migrate to lymph nodes and the virus enters the blood through lymphatic and thoracic ducts and disseminates to peripheral tissues for secondary viral replication. Virus eventually travels to the CNS and causes pathology that is similar to human cases (Byrne et al., 2001; Cunha et al., 2000; Diamond et al., 2003; Fratkin et al., 2004). The Swiss mouse strain was inoculated IP in order to screen a variety of viral lineages to assess differences in pathogenesis (Bingham et al., 2014).

Tesh et al. developed a model for WN encephalitis using the golden hamster, *Mesocricetus auratus*. Hamsters appeared asymptomatic during the first 5 days, became lethargic at approximately day 6, and developed neurologic symptoms between days 7 and 10 (Tesh et al., 2005). Many of the severely affected animals died 7–14 days after infection. Viremia was detected in the hamsters within 24 h after infection and persisted for 5–6 days. Although there were no substantial changes in internal organs, progressive pathologic differences were seen in the brain and spinal cord of infected animals. Furthermore, similar to the previously mentioned monkey experiments by Pogodina et al. (1983), persistent WNV infection was found in the brains of hamsters.

4.3 Zika Virus

Zika virus recently came to the forefront of public health concerns with the outbreak in Brazil at the end of 2015. The clinical disease spectrum is highly variable with reports of a flu-like illness accompanied by rash, Guillan–Barre syndrome, and microcephaly in newborns (Ramos da Silva and Gao, 2016). To date, a correlation between gestational age at which exposure to the virus occurs and severity of microcephaly is not fully understood (Brasil et al., 2016). However, a recent study of pregnant women in Columbia found that infection with Zika virus during the third trimester was not associated with any obvious structural abnormalities of the fetus (Pacheco et al., 2016). Transmission of the virus occurs via the bite from an infected *A. aegypti* or *A. albopictus* (Ramos da Silva and Gao, 2016). Other reported routes of exposure include sexual transmission and blood transfusion (Cunha et al., 2016; D'Ortenzio et al., 2016; Hills et al., 2016; McCarthy, 2016). The emergence of this virus with no approved vaccine or therapy, and few diagnostic options demonstrates the utility of well-characterized animal model development.

It was first demonstrated in 1956 that experimentally infected mosquitoes could be used to transmit the virus to mice and NHPs (Boorman and Porterfield, 1956). A129 mice were susceptible to nonadapted Zika virus infection following subQ inoculation of the limbs. Mice began to lose weight 3 days postinfection and met euthanasia criteria by day 6. Microscopic lesions within the brain were noted upon necropsy. In conjunction, viral RNA was detected in the blood, brain, ovary, spleen, and liver of the infected mice. Wild-type 129Sv/Ev mice were also challenged with no observable clinical disease. However, viral RNA was detected at day 3 postinfection in the blood, ovary and spleen, and then remained at detectable levels in the ovaries and spleen on day 7 (Dowall et al., 2016). Footpad inoculation of the virus leads to a fatal disease in AG129 mice by day 7 postinoculation with significant histopathological changes in

the brain noted at necropsy (Aliota et al., 2016). AG129 mice were also observed to develop neurologic disease by day 6 postexposure (Rossi et al., 2016). Immunocompetent mice are resistant to infection via the subQ route (Rossi et al., 2016).

Recently, a mouse model was identified to verify vertical transmission of the virus. Pregnant C57 mice were injected either IP or in utero into the lateral ventricle of the fetal brain. IP inoculation induced transient viremia in the pregnant mice on day 1. Viral RNA was detected in five out of nine placentas on day 3 postinfection. The virus was able to infect the radial glia cells in the fetal brain and leads to a reduction in the cortical neural progenitors (Wu et al., 2016). Viral exposure via cerebroventricular space/lateral ventricle of the fetal brain exhibited small brain size at day 5 postexposure in addition to cortical thinning (Cugola et al., 2016; Li et al., 2016a). Ifnar1$^{-/-}$ pregnant mice exposed to the virus had nonviable fetuses. In the same study, wild-type mice were given an anti-ifnar antibody prior to and during infection resulting in detectable virus in the fetal head with mild intrauterine growth restriction (Miner et al., 2016). All of these murine studies will further study of the pathogenesis of vertical transmission and the resulting neurological disorders in conjunction with screening novel countermeasures. NHP studies are currently ongoing for animal model development.

5 CORONAVIRIDAE

Numerous viruses from the Coronavirus (CoV) family exist that infect a wide range of animals. Six species have been identified that can infect humans. Two of these are alpha coronavirues: HCoV-229E and HCoV-NL63. Four are beta coronavirueses: HCoV-OC43, HCoV-HKU1, HCoV-SARS, and MERS-CoV. HCoV-229E and HCoV-OC43 were first detected in the 1960s from the nasal passages of humans with the "common cold" (Gaunt et al., 2010). HCoV-NL63, which was first isolated in 2004, causes upper and lower respiratory infections of varying intensity and has been continuously circulating among humans (van der Hoek et al., 2006). HCoV-HKU1, first isolated in 2002, has been identified more sporadically but also causes respiratory infections (Lau et al., 2006). A significant portion of common cold infections in humans are caused by coronaviruses. In 2002 and 2012, two human coronaviruses, SARS-CoV and MERS-CoV, emerged that caused a great deal of alarm since these infections have resulted in nearly 10 and 40% fatality, respectively (Assiri et al., 2013; Peiris et al., 2004).

5.1 SARS-Coronavirus

The etiologic agent of severe acute respiratory syndrome (SARS), SARS-CoV, emerged in 2002 as it spread throughout 32 countries in a period of 6 months, with 8437 confirmed infections and 813 deaths (Roberts and Subbarao, 2006; World Health Organization, 2003). No additional cases of community acquired SARS-CoV infection have been reported since 2004. The natural reservoir of SARS-CoV is the horseshoe bat and the palm civet is an intermediate host (Lau et al., 2005). The main mechanism of transmission of SARS-CoV is through droplet spread, but it is also viable in dry form on surfaces for up to 6 days and can be detected in stool, suggesting other modes of transmission are also possible (Pearson et al., 2003; Rabenau et al., 2005; Rota et al., 2003).

SARS-CoV infection has a 10% case fatality with the majority of cases in people over the age of 15 (Peiris et al., 2003; Wang et al., 2004). After an incubation period of 2–10 days, clinical signs of SARS include general malaise, fever, chills, diarrhea, dyspnea, and cough (Drosten et al., 2003). In some SARS cases, pneumonia may develop and progress to acute respiratory distress syndrome (ARDS). Fever usually dissipates within 2 weeks and coincides with the induction of high levels of neutralizing antibodies (Tan et al., 2004).

In humans, SARS-CoV replication destroys respiratory epithelium, and a great deal of the pathogenesis is due to the subsequent immune responses (Chen and Subbarao, 2007; Perlman and Dandekar, 2005). Infiltrates persisting within the lung and diffuse alveolar damage (DAD) are common sequelae of SARS-CoV infection (Perlman and Dandekar, 2005). Virus can be isolated from secretions of the upper airways during early, but not later stages of infection as well as from other tissues (Cheng et al., 2004).

SARS-CoV can replicate in many species, including: dogs, cats, pigs, mice, rats, ferrets, foxes, and monkeys (Roper and Rehm, 2009). No model captures all aspects of human clinical disease (pyrexia and respiratory signs), mortality (~10%), viral replication, and pathology (Roberts et al., 2008). In general, the SARS-CoV disease course in the model species is much milder and of shorter duration than in humans. Viral replication in the various animal models may occur without clinical illness and/or histopathologic changes. The best-characterized models utilize mice, hamsters, ferrets, and NHPs.

Mouse models of SARS-CoV typically are inoculated by the IN route under light anesthesia (Roberts et al., 2005). Young, 6- to 8-week-old BALB/c mice exposed to SARS-CoV have viral replication detected in the lungs and nasal turbinate, with a peak on day 2 and clearance by day 5 postexposure (McAuliffe et al., 2004). There is also viral replication within the small intestines of young BALB/c mice. However, young mice have no clinical signs, aside from reduced weight gain, and have little to no inflammation within the lungs (pneumonitis) (Gillim-Ross et al., 2004). IN SARS-CoV infection of C57BL/6 (B6), also yields reduced weight gain and viral

TABLE 33.1   Coronaviridae Animal Models

Virus species	Route of exposure	Characteristics of human disease	Animal model	Route of exposure	Clinical outcome	References
SARS-CoV	Droplet	Fever, lung damage, 10% mortality	Young mouse	IN	Little to no clinical signs or lung disease	McAuliffe et al. (2004), Roberts et al. (2005)
			Old mouse	IN	Clinical signs and lung damage, mortality	Bisht et al. (2004)
			Hamster	IN	Reduced activity, lung damage, mortality	Roberts et al. (2008)
			Ferret	IT	Fever, lung damage, mortality	Skowronski et al. (2005)
			NHP	IN or IT	Little to no clinical signs, variable mild lung damage	Fouchier et al. (2003), Haagmans et al. (2004), McAuliffe et al. (2004), Rowe et al. (2004)
MERS-CoV	Droplet	Fever, lung damage, neurological symptoms, over 35% mortality (in confirmed cases)	Mice expressing hDPP4	IN	Sublethal or lethal, lung and brain involvement	Agrawal et al. (2015), Li et al. (2016b), Tao et al. (2016)
			New Zealand White Rabbits	IN and IT	Virus isolated but no clinical disease	Haagmans et al. (2015)
			Rhesus macaque	IT or combined IT, IN, oral and ocular	No lethality, mild respiratory disease, transient lung infection with pneumonia	de Wit et al. (2013), Munster et al. (2013), Yao et al. (2014)
			Common marmoset	Combined IT, IN, oral and ocular	High lethality, moderate to severe lung disease, systemic infection	Falzarano et al. (2014)

hDPP4, Human dipeptidy peptidase four; IN, intranasal; IT, intratracheal; SARS-CoV, severe acute respiratory syndrome-coronavirus.

replication in the lungs, with a peak on day 3 and clearance by day 9 (Glass et al., 2004).

In contrast, BALB/c mice 13–14 months of age show weight loss, hunched posture, dehydration, and ruffled fur on day 3–6 postexposure (Bisht et al., 2004). Interstitial pneumonitis, alveolar damage, and death also occur in old mice, resembling the age-dependent virulence observed in humans. 129S mice and B6 mice show outcomes to SARS-CoV infection similar to those observed for BALB/c mice but have lower titers and less prolonged disease. While the aged mouse model is more frequently used then young mice, it is more difficult to obtain large numbers of mice older than 1 year (Table 33.1).

A number of immunocompromised knockout mouse models of IN SARS-CoV infection have also been developed. 129SvEV mice infected with SARS-CoV by the IN route develop bronchiolitis, with peribronchiolar inflammatory infiltrates and interstitial inflammation in adjacent alveolar septae (Hogan et al., 2004). Viral replication and disease in these mice resolves by day 14 postexposure. Beige, CD1$^{-/-}$, and RAG1$^{-/-}$ mice infected with SARS-CoV have similar outcomes to infected BALB/c

mice with regard to viral replication, timing of viral clearance, and a lack of clinical signs (Glass et al., 2004). STAT1 KO mice infected IN with SARS-CoV have severe disease, with weight loss, pneumonitis, interstitial pneumonia, and some deaths (Hogan et al., 2004). The STAT1 KO mouse model is therefore useful for studies of pathogenicity, pathology, and evaluation of vaccines.

Angiotensin converting enzyme 2 (ACE2) and CD209L were identified as cellular receptors for SARS-CoV, with affinity for the spike (S) protein of the virus (Jeffers et al., 2004). The variations in the ACE2 sequence across animal species could partially explain the differences in infection severity (Li et al., 2016b; Sutton and Subbarao, 2015). Since mice in particular have a greater number of sequence differences in ACE2, transgenic mice were created that express human ACE2 (McCray et al., 2007; Netland et al., 2008; Yang et al., 2007). Unlike other murine models of SARS-CoV, mice expressing hACE2 had up to 100% mortality, with severity correlating to the level of hACE2 expression (Tseng et al., 2007). With high levels of hACE2 expression, mice developed a severe lung and brain infection. However, CNS

infection is only rarely observed in humans infected with SARS-CoV.

Syrian golden hamsters (strain LVG) are also susceptible to IN exposure of SARS-CoV. After the administration of 10^3 TCID$_{50,}$ along with a period of transient viremia, SARS-CoV replicates in nasal turbinates and lungs, resulting in pneumonitis (Roberts et al., 2005). There are no obvious signs of disease, but exercise wheels can be used to monitor decrease in nighttime activity. Limited mortality has been observed, but it was not dose dependent and could have more to do with genetic differences between animals because the strain is not inbred (Roberts et al., 2008). Damage is not observed in the liver or spleen despite detection of virus within these tissues.

Several studies have shown that intratracheal (IT) inoculation of SARS-CoV in anesthetized ferrets (*Mustela furo*) results in lethargy, fever, sneezing, and nasal discharge (Skowronski et al., 2005). Clinical disease has been observed in several studies excluding one, perhaps due to characteristics of the inoculating virus (Kobinger et al., 2007). SARS-CoV is detected in pharyngeal swabs, trachea, tracheobronchial lymph nodes, and high titers within the lungs. Mortality has been observed around day 4 postexposure as well as mild alveolar damage in 5%–10% of the lungs, occasionally accompanied by severe pathology within the lungs (Martina et al., 2003; ter Meulen et al., 2004). With fever, overt respiratory signs, lung damage, and some mortality, the ferret intratracheal model of SARS-CoV infection is perhaps most similar to human SARS, albeit with a shorter time course.

SARS-CoV infection of NHPs by intransal or IT routes generally results in a very mild infection that resolves quickly. SARS-CoV infection of old world monkeys, such as rhesus macaques, cynomolgus macaques (cynos), and African green monkeys (AGMs) have been studied with variable results, possibly due to the outbred nature of the groups studied or previous exposure to related pathogens. Clinical illness and viral loads have not been consistent; however, replication within the lungs and DAD are features of the infections for each of the primate species. Some cynos have no illness but others have rash, lethargy, and respiratory signs and pathology (Haagmans et al., 2004; Martina et al., 2003; McAuliffe et al., 2004; Rowe et al., 2004). Rhesus have little to no disease and only have mild findings upon histopathological analysis (Rowe et al., 2004). AGMs infected with SARS-CoV have no overt clinical signs but DAD and pneumonitis has been documented (McAuliffe et al., 2004). Viral replication has been detected for up to 10 days in the lungs of AGMS; however, the infection resolves, and does not progress to fatal ARDS.

Farmed Chinese masked palm civets, sold in open markets in China, were involved in the SARS-CoV outbreak. IT and IN inoculation of civets with SARS-CoV results in lethargy, decreased aggressiveness, fever, diarrhea, and conjunctivitis (Wu et al., 2005). Leucopenia, pneumonitis, and alveolar septal enlargement, with lesions similar to those observed in ferrets and NHPs, have also been observed in laboratory-infected civets. Squirrel monkeys, mustached tamarinds, and common marmosets have not been susceptible to SARS-CoV infection (Greenough et al., 2005; Roberts et al., 2008).

Vaccines have been developed for related animal CoVs in chickens, cattle, dogs, cats, and swine, and have included live-attenuated, killed, DNA and viral-vectored vaccine strategies (Cavanagh, 2003). An important issue to highlight from work on these vaccines is that CoV vaccines, such as those developed for cats, may induce a more severe disease (Perlman and Dandekar, 2005; Weiss and Scott, 1981). As such, immune mice had Th2-type immunopathology upon SARS-CoV challenge (Tseng et al., 2012). Severe hepatitis in vaccinated ferrets with antibody enhancement in liver has been reported (Weingartl et al., 2004). Additionally, rechallenge of AGMs showed limited viral replication but significant lung inflammation, including alveolitis and interstitial pneumonia, which persisted for long periods of time after viral clearance (Clay et al., 2012).

Mouse and NHP models with increased virulence may be developed by adapting the virus by repeated passage within the species of interest. Mouse-adapted SARS with uniform lethality was developed from 15 serial passages in the lungs of young BALB/c mice (McCray et al., 2007; Roberts et al., 2007; Rockx et al., 2007).

5.2 MERS-Coronavirus

Middle East respiratory syndrome (MERS-CoV) emerged in Saudi Arabia and is associated with fever, severe lower respiratory tract infection, and oftentimes renal failure (Al-Tawfiq et al., 2016; Omrani et al., 2015). MERS patients can also occasionally manifest with neurological symptoms. MERS-CoV infection has a high fatality rate. Infections in humans can also be asymptomatic. As of October 2015, there were 1589 confirmed cases and 567 deaths (Li et al., 2016b). Bats serve as the likely natural reservoir since virus with 100% nucleotide identity to the index case was isolated from Egyptian tomb bats (Memish et al., 2013). Spread to humans likely comes from infected dromedary camels (Adney et al., 2014; Azhar et al., 2014).

The host range for MERS-CoV is dependent on the binding of the viral S protein to the host receptor, which is human dipeptidyl peptidase four (hDPP4), also known as CD26 (Raj et al., 2013). The expression and distribution of DPP4 in the human respiratory tract has recently been well characterized (Meyerholz et al., 2016). Interestingly, DPP4 expression is preferentially localized to alveolar regions, perhaps explaining why MERS predominantly manifests as an infection of the lower respiratory tract.

Humans with preexisting pulmonary disease have increased DPP4 expression in alveolar epithelia.

Small animals typically used for viral disease research, such as mice, hamsters, guinea pigs, and ferrets are naturally nonpermissive to MERS-CoV infection due to a low binding efficiency of the viral S protein to the host DPP4 (Sutton and Subbarao, 2015). In contrast the rhesus macaque and common marmoset have complete homology to human DPP4, allowing productive MERS-CoV infection to occur (de Wit et al., 2013; Falzarano et al., 2014; Munster et al., 2013; Yao et al., 2014). New Zealand White Rabbits can be infected with MERS-CoV, and virus was isolated from the upper respiratory tract, but there were no clinical symptoms or significant histopathological changes (Haagmans et al., 2015).

Due to the lack of strong binding affinity of the MERS-CoV S protein to the murine DPP4 receptor, wild-type mice are not susceptible to MERS-CoV infection. As such, several approaches have been used to create susceptible murine animal models of MERS-CoV infection by inducing the expression of hDPP4. One approach utilized an adenovirus vector expressing hDPP4 to transduce mice (Zhao et al., 2014b). These mice developed pneumonia but survived MERS-CoV infection. IN MERS-CoV infection of mice with global expression of hDPP4 resulted in ID_{50} and LD_{50} values of <1 and 10 $TCID_{50}$, respectively (Tao et al., 2016). Thus, MERS-CoV infection of these transgenic mice can be either sublethal or uniformly lethal depending on the dose. Inflammatory infiltrates were found in the lungs and brain stems of mice with some focal infiltrates in the liver as well. Another strategy uses transgenic mice expressing hDPP4 under either a surfactant protein C or cytokeratin 10 promoter (Li et al., 2016b). IN MERS-CoV infection in these mice resulted in a uniformly lethal disease characterized by alveolar edema and microvascular thrombosis and mononuclear clear cell infiltration in the lungs. The brain stem was also impacted by the infection. DPP4 expression with an ubiquitously expressing promoter from cytomegalovirus also had a uniformly lethal infection with predominant lung and brain involvement, but numerous other tissues were also impacted and contained virus (Agrawal et al., 2015).

Common marmosets infected with 5.2×10^6 $TCID_{50}$ (EMC-2012) MERS-CoV by the combined IN, oral, ocular, and IT routes capitulate the severe disease in human infections (Falzarano et al., 2014). The animals manifested moderate to severe clinical disease, with interstitial infiltration of both lower lung lobes. Two of nine animals became moribund between days 4 and 6. Viral RNA was detected in nasal and throat swabs, various organs, and in the blood of some animals, indicating a systemic infection. Histologically, animals showed evidence of acute bronchial interstitial pneumonia as well as other pathological defects.

Infection of rhesus macaques with MERS-CoV results in a mild clinical disease characterized by a transient lung infection with pneumonia. Rhesus macaques were inoculated with at least 10^7 $TCID_{50}$ (EMC-2012) MERS-CoV either by the IT route or a combined IN, IT, oral, and ocular inoculation (de Wit et al., 2013). The result was a mild respiratory illness including nasal swelling and a short fever with all animals surviving. Viral RNA was recovered from nasal swab samples and replicating virus was found in lung tissue (Munster et al., 2013). Mild pathological lesions were found only in the lungs. Radiographic imaging of the lungs revealed interstitial infiltrates, which are signs of pneumonia (Yao et al., 2014).

Interestingly, MER-CoV infection is more severe in marmosets compared to rhesus macaques (Falzarano et al., 2014). This is despite the finding that both species have complete homology with humans within the DPP4 domain that interacts with the viral S protein. Other host factors influencing disease severity have not yet been identified. Transgenic mouse models expressing hDPP4 are ideal for initial development and screening of MERS-CoV countermeasures, and marmosets can be used for final selection and characterization.

6 FILOVIRIDAE

6.1 Filoviruses

Filoviridae consists of three genera, *Ebolavirus* and *Marburgvirus*, and a newly discovered group, *Cuevavirus* (Kuhn, 2008). It is thought that various species of bats are the natural host reservoir for these viruses that have lethality rates from 40% to 82% in humans. There is evidence that the Egyptian rousette bat (*Rousettus aegyptiacus*) is the natural reservoir for marburgviruses but may not be for ebolaviruses (Jones et al., 2015). Marburg virus (MARV) first emerged in 1967 in Germany when laboratory workers contracted the virus from AGMs (*Chlorocebus aerthiops*) that were shipped from Uganda. Ebolaviruses Sudan and Zaire (SUDV and EBOV) caused nearly simultaneous outbreaks in 1976 in what is now the Democratic Republic of Congo (DRC). The most recent outbreak of EBOV in West Africa was by far the largest with over 28,000 suspected, probable and confirmed cases and over 11,000 deaths. Bundibugyo virus (BDBV) first emerged in 2007 in Bundibugyo, Uganda with 56 confirmed cases (MacNeil et al., 2010). Two other ebolaviruses are known: Taï Forest (TAFV) (previously named Cote d'Ivoire) (CIEBOV) and Reston (RESTV), which have not caused major outbreaks or lethal disease in humans. Filovirus disease in humans is a characterized by aberrant innate immunity and a number of clinical symptoms: fever, nausea, vomiting,

TABLE 33.2 Filoviruses Causing Human Diseases

Genus	Species	Virus	Disease in humans
Marburgvirus	*Marburg marburgvirus*	Marburg virus (MARV)	Yes
		Ravn virus (RAVV)	Yes
Ebolavirus	*Zaire ebolavirus*	Ebola virus (EBOV)	Yes
	Sudan ebolavirus	Sudan virus (SUDV)	Yes
	Taï Forest ebolavirus	Taï Forest virus (TAFV)	Yes
	Reston ebolavirus	Reston virus (RESTV)	No
	Bundibugyo ebolavirus	Bundibugyo virus (BDBV)	Yes

arthralgia/myalgia, headaches, sore throat, diarrhea, abdominal pain, and anorexia as well as numerous others (Mehedi et al., 2011; Wauquier et al., 2010). Approximately 10% of patients develop petechia and a greater percentage, depending on the specific strain, may develop bleeding from various sites (gums, puncture sites, stools, etc.) (Table 33.2). Natural transmission in an epidemic is through direct contact or needle sticks in hospital settings. However, much of the research interest in filoviruses primarily stems from biodefense needs, particularly from aerosol biothreats. As such, IM, IP, and aerosol models have been developed in mice, hamsters, guinea pigs, and NHPs for the study of pathogenesis, correlates of immunity, and for testing countermeasures (Bradfute and Bavari, 2011; Bradfute et al., 2011). Since filoviruses have such high lethality rates in humans, scientists have looked for models that are uniformly lethal to stringently test efficacy of candidate vaccines and therapeutics. One issue to take note of in animal model development of filovirus infection is the impact of particle to plaque-forming unit (PFU) ratios on lethality, wherein it is possible that increasing the dose could actually decrease infectivity due to an immunogenic effect produced by inactive virions in the stock. Additionally, the plaque assay used to measure live virions in a stock may greatly underestimate the true quantity of infectious virions in a preparation (Alfson et al., 2015; Smither et al., 2013a).

Immunocompetent mice have not been successfully infected with wild-type filoviruses due to the control of the infection by the murine type 1 interferon response (Bray, 2001). However, wild-type inbred mice are susceptible to filovirus that has been mouse adapted (MA) by serial passage in mice (Bray et al., 1999). MARV Angola was particularly resistant to adaptation, but after 24 serial passages in SCID mice, infection caused severe disease in BALB/c and C57BL/6 mice when administered IN or IP (Qiu et al., 2014). These mice had pathology with some similarities to infection in humans including lymphopenia, thrombocytopenia, liver damage, and viremia. BALB/c mice, which are the strain of choice for

IP inoculation of MA-EBOV, are not susceptible by the aerosol route (Bray et al., 1999; Zumbrun et al., 2012a). For aerosol infection of immunocompetent mice, a panel of BXD (BALB/c x DBA) recombinant inbred strains were screened and one strain, BXD34, was particularly susceptible to airborne MA-EBOV, with 100% lethality to low or high doses (approximately 100 or 1000 pfu) (Zumbrun et al., 2012a). These mice developed weight loss of greater than 15% and succumbed to infection between days 7 and 8 postexposure. The aerosol infection model utilizes a whole-body exposure chamber to expose mice aged 6–8 weeks to MA-EBOV aerosols with a mass median aerodynamic diameter (MMAD) of approximately 1.6 μm and a geometric standard deviation (GSD) of approximately 2.0 for 10 min. Another approach uses immunodeficient mouse strains, such as SCID, STAT1 KO, IFN receptor KO, or perforin KO with a wild-type EBOV inoculum by IP or aerosol routes (Bray, 2001; Lever et al., 2012; Zumbrun et al., 2012a). Mice are typically monitored for clinical disease "scores" based on activity and appearance, weight loss, and moribund condition (survival). Coagulopathy, a hallmark of filovirus infection in humans, has been observed, with bleeding in a subset of animals and failure of blood samples to coagulate late in infection (Bray et al., 1999). Liver, kidney, spleen, and lung tissue taken from moribund mice have pathology characteristic of filovirus disease in NHPs (Zumbrun et al., 2012a). While most mouse studies have used MA-EBOV or EBOV, an IP mouse-adapted MARV model is also available (Warfield et al., 2007, 2009). MA-MARV and MA-EBOV models are particularly useful for screening novel antiviral compounds (Panchal et al., 2012).

Recently, a model was created using immunodeficient NSG [nonobese diabetic (NOD)/SCID/IL-2 receptor chain knockout] mice with transplanted human hematopoietic stem cells from umbilical cord blood. These mice were susceptible to lethal WT (nonadapted) EBOV by IP and IN exposure (Ludtke et al., 2015). The transplanted mice had all of the cellular components of a fully functional adaptive human immune system and upon EBOV

infection, had several features typical of EBOV disease. These included viremia, cellular damage, liver steatosis, and signs of hemorrhage. INFa/bR$^{-/-}$ mice infected with WT SUDV or EBOV have a partially lethal disease with weight loss and evidence of disseminated intravascular coagulation (DIC) in the liver (Brannan et al., 2015; Lever et al., 2012). Interestingly, inoculation of INFa/bR$^{-/-}$ mice with TAFV and RESTV does not result in clinical signs. Yet another strategy uses knockout mice lacking possible receptors for filovirus entry, such as Niemann-Pick C1 and C2 (NPC1 and NPC2). Npc2$^{(-/-)}$ mice were fully susceptible to infection with EBOV but Npc1$^{(-/-)}$ mice were completely resistant (Herbert et al., 2015).

Hamsters are frequently used to study cardiovascular disease, coagulation disorders, and thus serve as the basis for numerous viral hemorrhagic fever models (Gowen and Holbrook, 2008; Herbert et al., 2015). An IP MA-EBOV infection model has been developed in Syrian hamsters (Ebihara et al., 2013; Gowen and Holbrook, 2008; Herbert et al., 2015; Tsuda et al., 2011). This model, which has been used to test a vesicular stomatitis virus vectored vaccine approach, utilizes male 5- to 6-week-old Syrian hamsters which are infected with 100 LD$_{50}$ of MA-EBOV. Virus is present in tissues and blood collected on day 4 and all animals succumbed to the disease by day 6. Infected hamsters had severe coagulopathy and uncontrolled host immune responses, similar to what is observed in primates. (Ebihara et al., 2010)

Guinea pig models of filovirus infection have been developed for IP and aerosol routes using guinea pig-adapted EBOV (GP-EBOV) and MARV (GP-MARV) (Choi et al., 2012; Connolly et al., 1999; Twenhafel et al., 2015; Zumbrun et al., 2012c). Guinea pig models of filovirus infection are quite useful in that they develop fever, which can be monitored at frequent intervals by telemetry. Additionally, the animals are large enough for regular blood sampling in which measurable coagulation defects are observed as the infection progresses. A comparison of IP infection of outbred guinea pigs with guinea pig-adapted MARV Angola and MARV Ravn revealed similar pathogenesis (Cross et al., 2015). Infection with either strain resulted in features of the disease that are similar to what is seen in human and NHP infection, such as viremia, fever, coagulopathy, lymphopenia, elevated liver enzymes (ALT and AST), thrombocytopenia, and splenic, gastrointestinal and hepatic lesions. GP-MARV-Ravn had a delayed disease progression relative to GP-MARV-Ang.

Hartley guinea pigs exposed to aerosolized GP-EBOV develop lethal interstitial pneumonia. This is in contrast to subQ infection of guinea pigs, aerosol EBOV challenge of NHPs, and natural human infection (Twenhafel et al., 2015). Both subQ and aerosol exposure of guinea pigs to GP-EBOV resulted in only mild lesions in the liver and spleen. By aerosol exposure, GP-EBOV is uniformly lethal at both high and low doses (100 or 1000 pfu target doses) but lethality drops with low (less than 1000 pfu) presented doses of airborne GP-MARV and more protracted disease is seen in some animals (our unpublished observations) (Zumbrun et al., 2012c). Weight loss of between 15% and 25% is a common finding in guinea pigs exposed to GP-EBOV or GP-MARV. Fever, which becomes apparent by day 5, occurs more rapidly in GP-EBOV exposed guinea pigs than with GP-MARV exposure. Lymphocytes and neutrophils increase during the earlier part of the disease, and platelet levels steadily drop as the disease progresses. Increases in coagulation time can be seen as early as day 6 postexposure. Blood chemistries (i.e., ALT, AST, ALKP, and BUN) indicating problems with liver and kidney function are also altered late in the disease course.

Transmission of EBOV has been documented from swine to NHPs via the respiratory tract (Kobinger et al., 2011). As such, guinea pigs have been used to establish transmission models (Wong et al., 2015a,b). Nonexposed guinea pigs were placed in the cages with infected guinea pigs 1 day postexposure to GP-EBOV. Guinea pigs challenged intanasally were more likely to transmit virus to naive cagemates than those that were exposed by the IP route. NHP models of filovirus infection are the preferred models for more advanced disease characterization and testing of countermeasures because they most closely mimic the disease and immune correlates seen in humans (Dye et al., 2012). Old world primates have been primarily used for development of IP, IM, and aerosol models of filovirus infection (Twenhafel et al., 2013). Uniformly lethal filovirus models have been developed for most of the virus strains in cynomolgus macaques, rhesus macaques, and to a lesser degree, AGMs (Alves et al., 2010; Carrion et al., 2011; Davis et al., 1997; Hensley et al., 2011a; Reed et al., 2007; Zumbrun et al., 2012b).

Low-passage human isolates that have not been passaged in animals have been sought for development of NHP models to satisfy the Food and Drug Administration (FDA) Animal Rule. EBOV-Makona, the strain responsible for the recent large outbreak in West Africa, was compared to the "prototype" 1976 EBOV strain (Marzi et al., 2015). The disease in cynos was similar for both viruses, but disease progression was delayed for EBOV-Makona. This delay as well as the lower fatality rate in the 2014 epidemic compared to the 1976 outbreak suggest that EBOV-Makona is less virulent. The large number of cases in the 2014–15 EBOV outbreak brought to light previously underappreciated eye pathology and ocular viral persistence in survivors. While survivors of NHP filovirus infection are infrequent, necrotizing scleritis, conjunctivitis, and other ocular pathology has been observed in EBOV-infected animals (Alves et al., 2016).

Prominent features of the filovirus infections in NHPs are onset of fever by day 5 postexposure, viremia, lymphopenia, tachycardia, azotemia, alteration in liver function enzymes (ALT, AST, and ALKP), decrease in platelets, and increased coagulation times. Petechial rash is a common sign of filovirus disease and may be more frequently observed in cynomolgus macaques than in other NHP species (Zumbrun et al., 2012b). Immunological parameters have been evaluated and T, B, and natural killer cells are greatly diminished as the infection progresses (Fernando et al., 2015). A cytokine storm occurs with rises in IFNγ, TNF, IL-6, and CCL2 (Fernando et al., 2015). However, there is also evidence from transcriptional profiling of circulating immune cells that the early immune response is skewed toward a Th2 response (Connor et al., 2015). Strikingly, animals surviving challenge may have a delay in the production of inflammatory cytokines and chemokines (Martins et al., 2015).

Clinical disease parameters may have a slightly delayed onset in aerosol models. Dyspnea late in infection is a prominent feature of disease after aerosol exposure (Zumbrun et al., 2012b). Aerosol filovirus infection of NHPs results in early infection of respiratory lymphoid tissues, dendritic cells, alveolar macrophages, blood monocytes, and fibroblastic reticular cells followed by spread to regional lymph nodes then multiple organs (Ewers et al., 2016; Twenhafel et al., 2013). A number of pronounced pathology findings include multifocal hepatic necrosis and fibrin accumulation, particularly within the liver and the spleen. For aerosolized MARV infection of rhesus, the most significant pathology included destruction of the tracheobronchial and mediastinal lymph nodes (Ewers et al., 2016). Lymphocytolysis and lymphoid depletion are also observed (Alves et al., 2010). Multilead, surgically implanted telemetry devices are useful in continuous collection of temperature, blood pressure, heart rate, and activity levels. As such, blood pressure drops as animals become moribund and heart rate variability (standard deviation of the heart rate) is altered late in infection (Zumbrun et al., 2012b). The most recently developed telemetry devices can also aid in plethysmography to measure respiratory minute volume for accurate delivery of presented doses for aerosol exposure. Standardized filovirus-infected NHP euthanasia criteria have also been developed to enhance reproducibility for studies that evaluate therapeutic and vaccine countermeasures (Warren et al., 2014).

Filovirus infection of common marmosets (*Callithrix jacchus*) is also a viable model to study the disease course. Respiratory infection of marmosets with MARV results in a lethal infection with fever, hemorrhaging, transient rash, disseminated viral infection, increases in liver function enzymes, coagulopathy, hepatitis, and histological lesions particularly in the kidney and liver (Smither et al., 2013b). Marmosets are similarly susceptible to infection with EBOV-Kikwit (Smither et al., 2015). Thus, EBOV or MARV infection of marmosets produces features of the disease that are very similar to that of other NHPs and humans.

6.2 Hendra and Nipah Virus

Hendra and Nipah virus are unusual within the Paramyxoviridae family given that they can infect a large range of mammalian hosts. Both viruses are grouped under the genus *Henipavirus*. The natural reservoirs of the viruses are the fruit bats from the genus *Pteropus*. Hendra and Nipah have the ability to cause severe disease in humans with the potential for a high case fatality rate (Rockx et al., 2012). Outbreaks due to Nipah virus have been recognized in Malaysia, Singapore, Bangladesh, and India, while Hendra virus outbreaks have yet to be reported outside of Australia (Luby et al., 2009a,b).

Hendra was the first member of the genus identified and was initially associated with an acute respiratory disease in horses. All human cases have been linked to transmission through close contact with an infected horse. There have been no confirmed cases of direct transmission from bat to human. Nipah has the distinction of transmission among, although the exact route is unknown (Homaira et al., 2010). The virus is susceptible to pH, temperature, and desiccation, and thus close contact is hypothesized as needed for successful transmission (Fogarty et al., 2008). Both viruses have a tropism for the neurological and respiratory tracts.

The incubation period for Hendra virus is 7–17 days and is marked by a flu-like illness. Symptoms at this initial stage include myalgia, headache, lethargy, sore throat, and vomiting (Hanna et al., 2006). Disease progression can continue to pneumonitis or encephalitic manifestations, with the person succumbing to multiorgan failure (Playford et al., 2010). Nipah virus has an incubation period of 4 days to 2 weeks (Goh et al., 2000). Much like Hendra, the first signs of disease are nondescript. Severe neurological symptoms subsequently develop including encephalitis and seizures that can progress to coma within 24–48 h (Lo and Rota, 2008). Survivors of infection typically make a full recovery; however, 22% suffer permanent sequelae, including persistent convulsions (Tan and Chua, 2008). At this time, there is no approved vaccine or antiviral, and treatment is purely supportive. Animal models are being used to not only test novel vaccines and therapeutics, but also deduce the early events of disease because documentation of human cases is at terminal stages.

The best small animal model is the Syrian golden hamster due to their high susceptibility to both henipaviruses. Clinical signs upon infection recapitulate the disease course in humans including acute encephalitis

and respiratory distress. Challenged animals died within 4–17 days postinfection. The progression of disease and timeline is highly dependent on dose and route of infection. IN inoculation leads to imbalance, limb paralysis, lethargy, and breathing difficulties whereas IP resulted in tremors and paralysis within 24 h before death. Virus was detected in lung, brain, spleen, kidney, heart, spinal cords, and urine, with the brain having the highest titer. This model is used for vaccination and passive protection studies (Guillaume et al., 2009; Rockx et al., 2011; Wong et al., 2003).

The guinea pig model has not been widely used due to the lack of a respiratory disease upon challenge (Torres-Velez et al., 2008; Williamson et al., 2001). Inoculation with Hendra virus via the subQ route leads to a generalized vascular disease with 20% mortality. Clinical signs were apparent 7–16 days postinfection with death occurring within 2 days of CNS involvement. Higher inoculum has been associated with development of encephalitis and CNS lesions. ID and IN injection does not lead to disease, although the animals are able to seroconvert upon challenge. The inoculum source does not affect clinical progression. Nipah virus challenge only causes disease upon IP injection and results in weight loss and transient fever for 5–7 days. Virus was shed through urine and was present in the brain, spleen, lymph nodes, ovary, uterus, and urinary bladder (Hooper et al., 1997).

Ferrets infected with Hendra or Nipah virus display the same clinical disease as seen in the hamster model and human cases (Bossart et al., 2009; Pallister et al., 2011). Upon inoculation by the oronasal route, ferrets develop severe pulmonary and neurological disease within 6–9 days including fever, coughing, and dyspnea. Lesions do develop in the ferret's brains, but to a lesser degree than seen in humans.

Cats have also been utilized as an animal model for henipaviruses. Disease symptoms are not dependent upon the route of infection. The incubation period is 4–8 days and leads to respiratory and neurological symptoms (Mungall et al., 2007; Johnston et al., 2015; Westbury et al., 1996). This model has proven useful for vaccine efficacy studies.

Squirrel and AGMs are representative of the NHP models. For squirrel monkeys, Nipah virus is introduced by either the IN or IV route and subsequently leads to clinical signs similar to humans, although IN challenge results in milder disease. Upon challenge, only 50% of animals develop disease manifestations including anorexia, dyspnea, and acute respiratory syndrome. Neurological involvement is characterized by uncoordinated motor skills, loss of consciousness, and coma. Viral RNA can be detected in lung, brain, liver, kidney, spleen, and lymph nodes but is only found upon IV challenge (Marianneau et al., 2010). AGMs are very consistent model of both viruses. IT inoculation of the

viruses results in 100% mortality, and death within 8.5 and 9–12 days postinfection for Hendra and Nipah viruses, respectively. The animals develop severe respiratory and neurological disease with generalized vasculitis (Geisbert et al., 2010; Rockx et al., 2010).

The reservoir of the viruses, gray-headed fruit bats, has been experimentally challenged. Due to their status as the host organism for henipaviruses, the bats do not develop clinical disease. However, Hendra virus can be detected in kidneys, heart, spleen, and fetal tissue, and Nipah virus can be located in urine (Middleton et al., 2007).

Pigs develop a respiratory disease upon infection with both Nipah and Hendra viruses (Berhane et al., 2008; Li et al., 2010; Middleton et al., 2002). Oral inoculation does not produce a clinical disease, but subQ injection represents a successful route of infection. Live virus can be isolated from the oropharynx as early as 4 days postinfection. Nipah virus can also be transmitted between pigs. Nipah virus was able to induce neurological symptoms in 20% of the pigs, even though virus was present in all neurological tissues regardless of symptoms (Weingartl et al., 2005). Within the pig model, it appeared that Nipah virus had a greater tropism for the respiratory tract, while Hendra for the neurological system.

Horses are also able to develop a severe respiratory tract infection accompanied with fever and general weakness upon exposure to Nipah and Hendra viruses. Oronasal inoculation led to systemic disease with viral RNA detected in nasal swabs within 2 days (Marsh et al., 2011; Williamson et al., 1998). Animals died within 4 days postexposure and have interstitial pneumonia with necrosis of alveoli (Murray et al., 1995a,b). Virus could be detected in all major systems.

Mice, rats, rabbits, chickens, and dogs have been tested but are nonpermissive to infection (Westbury et al., 1995; Wong et al., 2003). Suckling BALB/c mice succumb to infection if the virus is inoculated intracranially (Mungall et al., 2006). IN exposure with Nipah does not induce a clinical disease; however, there is evidence of a subclinical infection in the lungs following euthanasia of the mice (Dups et al., 2014). In addition, a human lung xenograph model in NSG mice demonstrated that the human lung is highly susceptible to Nipah viral replication and damage (Valbuena et al., 2014). Embryonated chicken eggs have been inoculated with Nipah virus leading to a universally fatal disease within 4–5 days postinfection (Tanimura et al., 2006).

6.3 Respiratory Syncytial Virus

Annually, respiratory syncytial virus (RSV) is responsible for the lower respiratory tract infections of 33 million children under the age of 5, which in turn results in 3 million hospitalizations and approximately 200,000

deaths (Nair et al., 2010). Within the United States, hospital costs alone amount to over 600 million dollars per year (Paramore et al., 2004). Outbreaks are common in the winter (Yusuf et al., 2007). The virus is transmitted by large respiratory droplets that replicate initially within the nasopharynx and spreads to the lower respiratory tract. Incubation for the virus is 2–8 days. RSV is highly virulent leading to very few asymptomatic infections (Collins and Graham, 2008). Disease manifestations are highly dependent upon the age of the individual.

RSV infections in neonates produce nonspecific symptoms including overall failure to thrive, apnea, and feeding difficulties. Infants present with a mild upper respiratory tract disease that could develop into bronchiolitis and bronchopneumonia. Contracting RSV at this age results in an increased chance of developing childhood asthma (Wu et al., 2008). Young children develop recurrent wheezing while adults have exacerbation of previously existing respiratory conditions (Falsey et al., 2005). Common clinical symptoms are runny nose, sneezing, and coughing accompanied by fever.

Mortality rates from RSV in hospitalized children are 1%–3% with the greatest burden of disease seen in 3–4 month olds (Ruuskanen and Ogra, 1993). Hematopoietic stem cell transplant patients, solid organ transplant patients, and COPD patients are particularly vulnerable to RSV infection and have mortality rates between 7.3% and 13.3% upon infection (Anderson et al., 2016). Although there are almost 60 RSV vaccine candidates which are in preclinical and clinical phases, there is no licensed vaccine available and ribavirin usage is not recommended for routine treatment (American Academy of Pediatrics Subcommittee on Diagnosis and Management of Bronchiolitis, 2006; Higgins et al., 2016; Kim and Chang, 2016). Animal models of RSV were developed in the hopes of formulating an effective and safe vaccine unlike the formalin-inactivated RSV (FI-RSV) vaccine. This vaccine induced severe respiratory illness in infants whom received the vaccine and were subsequently infected with live virus (Kim et al., 1969).

Mice can be used to model RSV infection, although a very high IN inoculation is needed to achieve clinical symptoms (Jafri et al., 2004; Stark et al., 2002). Strain choice is crucial to reproducing a physiological relevant response (Stokes et al., 2011). Age does not affect primary disease manifestations (Graham et al., 1988). However, it does play a role in later sequelae showing increased airway hyperreactivity (Cormier et al., 2010). Primary RSV infection produces increased breathing with airway obstruction (Jafri et al., 2004; van Schaik et al., 1998). Virus was detected as early as day 3 and reached maximum titer at day 6 postinfection. Clinical illness is defined in the mouse by weight loss and ruffled fur as opposed to runny nose, sneezing, and coughing as seen in humans. A humanized mouse model was recently developed by

IN inoculation. The challenged mice experienced weight loss and demonstrated a humoral and cellular immune response to the infection (Sharma et al., 2016).

Cotton rats are useful given that RSV is able to replicate to high titers within the lungs and can be detected in both the upper and lower airways after IN inoculation (Boukhvalova et al., 2009; Niewiesk and Prince, 2002). Viral replication is 50- to 1000-fold greater in the cotton rat model than mouse model (Wyde et al., 1993). The cotton rats develop mild to moderate bronchiolitis or pneumonia (Grieves et al., 2015; Prince et al., 1999). Although age does not appear to factor into clinical outcome, it has been reported that older cotton rats tend to take longer to achieve viral clearance. Viral loads peak by the 5th day, dropping to below the levels of detection by day 8. The histopathology of the lungs appears similar to that of humans after infection (Piazza et al., 1993). This model has limited use in modeling the human immune response to infection as challenge with the virus induces a Th2 response in cotton rats, whereas humans tend to have a response skewed toward Th1 (Culley et al., 2002; Dakhama et al., 2005; Ripple et al., 2010). FI-RSV disease was recapitulated upon challenge with live virus after being vaccinated twice with FI-RSV.

Chinchillas have been challenged experimentally with RSV via IN inoculation. The virus was permissive within the nasopharynx and Eustachian tube. The animals displayed an acute respiratory tract infection. This model is therefore useful in studying mucosal immunity during infection (Gitiban et al., 2005). Ferrets infected by IT were found to have detectable RSV in throat swabs up to day 7 postinfection, and positive qPCR up to day 10. Immunocompromised ferrets were observed to have higher viral loads accompanied with detectable viral replication in the upper respiratory tract (Stittelaar et al., 2016).

Chimpanzees are permissive to replication and clinical symptoms of RSV including rhinorrhea, sneezing, and coughing. Adult squirrel monkeys, newborn rhesus macaques, and infant cebus monkeys were also challenged but did not exhibit any disease symptoms or high levels of viral replication (Belshe et al., 1977). Bonnet monkeys were developed an inflammatory response by day 7 with viral RNA detected in both bronchial and alveolar cells (Simoes et al., 1999). The chimpanzee model has been proven useful for vaccine studies (Hancock et al., 2000; Teng et al., 2000).

Sheep have also been challenged experimentally since they develop respiratory disease when exposed to ovine RSV (Meyerholz et al., 2004). Lambs are also susceptible to human respiratory syncytial infection (Olivier et al., 2009; Sow et al., 2011). When inoculated intratracheally, the lambs developed an upper respiratory tract infection with cough after 6 days. Some lambs went on to develop lower respiratory disease including

bronchiolitis. The pneumonia resolved itself within 14 days. RSV replication peaked at 6 days, and rapidly declined. Studying respiratory disease in sheep is beneficial given the shared structural features with humans (Plopper et al., 1983; Scheerlinck et al., 2008).

7 ORTHOMYXOVIRIDAE

7.1 Influenza Virus

The influenza viruses consist of three types: influenza A, B, and C, based on antigenic differences. Influenza A is further classified by subtypes; 16 HA and 9 NA subtypes are known. Seasonal influenza is the most common infection and usually causes a self-limited febrile illness with upper respiratory symptoms and malaise that resolves within 10 days (Taubenberger and Morens, 2008). The rate of infection is estimated at 10% in the general population and can result in billions of dollars of loss annually from medical costs and reduced work-force productivity. Approximately 40,000 people in the United States die each year from seasonal influenza (Dushoff et al., 2006). Thus, vaccines and therapeutics play a critical role in controlling infection, and development using animal models is ongoing (Braun et al., 2007b).

Influenza virus replicates in the upper and lower airways, peaking at approximately 48-h postexposure. Infection can be more severe in infants and children under the age of 22, people over the age of 65, or immunocompromised individuals where viral pneumonitis or pneumonia can develop or bacterial superinfection resulting in pneumonia or sepsis (Barnard, 2009; Glezen, 1982). Pneumonia from secondary bacterial infection, such as *Streptococcus pneumonia*, *Streptococcus pyogenes*, and *Neisseria meningitides*, and more rarely, *Staphylococcus aureus*, is more common than viral pneumonia from the influenza virus itself, accounting for ~27% of all influenza associated fatalities (Alonso et al., 2003; Ison and Lee, 2010; Speshock et al., 2007). Death, often due to ARDS can occur as early as 2 days after onset of symptoms. Lung histopathology in severe cases may include DAD, alveolar edema and damage, hemorrhage, fibrosis, and inflammation (Taubenberger and Morens, 2008).

The H5N1 avian strain of influenza, has lethality rates of around ~50% (of known cases), likely because the virus preferentially binds to the cells of the lower respiratory tract, and thus the potential for global spread is a major concern (Matrosovich et al., 2004; Wang et al., 2016). H7N9 is another avian influenza A strain that infected more than 130 people and was implicated in 37 deaths. Approximately 75% of infected people had a known exposure to birds. There is no evidence of sustained spread between humans but these viruses are of great concern for their pandemic potential (Zhang et al., 2013).

The most frequently used animal models of influenza infection include mice, ferrets, and NHPs. A very thorough guide to working with mouse, guinea pig, ferret, and cynomolgus models was published by Kroeze et al. (2012). Swine are not frequently utilized but are also a potentially useful model for influenza research since they share many similarities to human anatomy, genetics, susceptibility, and pathogenesis (Rajao and Vincent, 2015). Lethality rates can vary with virus strain used (with or without adaptation), dose, route of inoculation, age, and genetic background of the animal. The various animal models can capture differing diseases caused by influenza: benign, severe, super infection, and sepsis, severe with ARDS, and neurologic manifestations (Barnard, 2009). Also, models can utilize seasonal or avian strains and have been developed to study transmission, important for understanding the potential for more lethal strains, such as H5N1 for spreading among humans.

Mouse models of influenza infection are very predictive for antiviral activity and tissue tropism in humans, and are useful in testing and evaluating vaccines (Gilbert and McLeay, 2008; Hagenaars et al., 2008; Ortigoza et al., 2012). Inoculation is by the IN route, utilizing approximately 60 μL of inoculum in each nare of anesthetized mice. Exposure may also be to small particle aerosols containing influenza with a MMAD of <5 μL. Most inbred strains are susceptible, with particularly frequent use of BALB/c followed by C57BL/6J mice. Males and females have equivalent disease but influenza is generally more infectious in younger 2- to 4-week-old (8–10 g) mice.

Mice are of somewhat limited use in characterizing the immune response to influenza. Most inbred laboratory mice lack the MxA gene which is an important part of human innate immune response to influenza infection. The mouse homolog to MxA, Mx1 is defective in most inbred mouse strains (Staeheli and Haller, 1987). Mice with the knocked-in MX1 gene have a 1000-fold higher LD-50 for an influenza A strain (PR8) than wild-type background C57BL/6 mice (Grimm et al., 2007).

Weight loss or reduced weight gain, decreased activity, huddling, ruffled fur, and increased respiration are the most common clinical signs in influenza infected mice. For more virulent strains, mice may require euthanasia as early as 48 h postexposure, but most mortality occurs from 5 to 12 days postexposure accompanied by decreases in rectal temperature (Sidwell and Smee, 2000). Pulse oximeter readings and measurement of blood gases for oxygen saturation are also used to determine the impact of influenza infection on respiratory function (Sidwell et al., 1992). Virus can be isolated from bronchial lavage (BAL) fluids throughout the infection and from tissues after euthanasia. For influenza strains with mild to moderate pathogenicity, disease is nonlethal and virus

replication is detected within the lungs, but usually not other organs. Increases in serum alpha-1-acidglycoprotein and lung weight also frequently occur. However, mice infected with influenza do not develop fever, dyspnea, nasal exudates, sneezing, or coughing.

Mice can be experimentally infected with influenza A or B, but the virus generally requires adaptation to produce clinical signs. Mice express the receptors for influenza attachment in the respiratory tract; however, the distribution varies and SA 2,3 predominates over SA 2,6 which is why H1, H2, and H3 subtypes usually need to be adapted to mice and H5N1, H2, H6, and H7 viruses do not require adaptation (O'Donnell and Subbarao, 2011). To adapt, mice are infected intratracheally or intranasally by virus isolated from the lungs, and reinfected into mice and then the process is repeated a number of times. Once adapted, influenza strains can produce severe disease, systemic spread, and neurotropism.

H5N1 and the 1918 pandemic influenza virus can cause lethal infection in mice without adaptation (Gao et al., 1999; Taubenberger, 2006). H5N1 infection of mice results in viremia and viral replication in multiple organ systems, severe lung pathology, fulminant diffuse interstitial pneumonia, pulmonary edema, high levels of proinflammatory cytokines, and marked lymphopenia (Dybing et al., 2000; Gubareva et al., 1998; Lu et al., 1999). As in humans, the virulence of H5N1 is attributable to damage caused by an overactive host immune response. Additionally, mice infected with the 1918 H1N1 influenza virus produce severe lung pathology and oxygen saturation levels that decrease with increasing pneumonia (Barnard et al., 2007). Reassortment influenza viruses of the 2009 H1N1 virus and a low-pathogenicity avian H7N3 virus can also induce disease in mice without adaptation (Williams et al., 2016).

In superinfection models, a sublethal dose of influenza is given to mice followed 7 days later by IN inoculation of a sublethal dose of a bacterial strain, such as *S. pneumoniae* or *S. pyogenes* (Chaussee et al., 2011). Morbidity, characterized by inflammation in the lungs, but not bacteremia, begins a couple of days after superinfection and may continue for up to 2 weeks. At least one transmission model has also been developed in mice. With H2N2 influenza, transmission rates of up to 60% among cagemates can be achieved after infection by the aerosol route and cocaging after 24 h (Schulman, 1968).

Rats (F344 and SD) inoculated with rat-adapted H3N2 developed inflammatory infiltrates and cytokines in bronchoalveolar lavage fluids, but had no lethality and few histopathological changes (Daniels et al., 2003). Additionally, an influenza transmission model has been developed in guinea pigs as an alternative to ferrets (Lowen et al., 2006).

Cotton rats (*Sigmodon hispidus*) have been used to test vaccines and therapeutics in a limited number of studies (Eichelberger et al., 2004). Cotton rats have an advantage over mice in that the immune system is similar to humans (including the presence of the Mx gene) and influenza viruses do not have to be adapted (Eichelberger et al., 2006; Ottolini et al., 2005). Nasal and pulmonary tissues of cotton rats were infected with unregulated cytokines and lung viral load peaking at 24 h postexposure. Virus was cleared from the lung by day 3 and from the nares by day 66, but animals had bronchial and alveolar damage, and pneumonia for up to 3 weeks. There is also a *S. aureus* superinfection model in cotton rats (Braun et al., 2007a). Coinfection resulted in bacteremia, high bacterial load in lungs, peribronchiolitis, pneumonitis, alveolitis, hypothermia, and higher mortality.

Domestic ferrets (*Mustela putorius furo*) are frequently the animal species of choice for influenza animal studies because the susceptibility, clinical signs, peak virus shedding, kinetics of transmission, local expression of cytokine mRNAs, and pathology resemble that of humans (Lambkin et al., 2004; Maines et al., 2012; McLaren and Butchko, 1978). Like humans, ferrets exclusively express Neu5Ac, which acts as a receptor for influenza A virus, a feature likely contributing to the susceptibility of ferrets to human-adapted influenza A virus strains (Ng et al., 2014). The glycomic characterization of ferret respiratory tract tissues demonstrated some similarities and some differences to humans in terms of the potential glycan binding sites for the influenza virus (Jia et al., 2014). Ferrets also have airway morphology, respiratory cell types, and a distribution of influenza receptors (SA 2,6 and SA 2,3) within the airways similar to that of humans (van Riel et al., 2007).

Influenza was first isolated from ferrets infected IN with throat washes from humans harboring the infection and ferret models have since been used to test efficacy of vaccines and therapeutic treatments (Huber et al., 2008; Lambkin et al., 2004; Maines et al., 2012). When performing influenza studies in ferrets, animals should be serologically negative for circulating influenza viruses. Infected animals should be placed in a separate room from uninfected animals. If animals must be placed in the same room, uninfected ferrets should be handled before infected ferrets. Anesthetized ferrets are experimentally exposed to influenza by IN inoculation of 0.25–0.5 mL containing approximately 10^4–10^6 egg ID_{50} dropwise to each nostril. However, a larger inoculum volume of 1.0 mL has also been explored as being more appropriate, yielding more severe and consistent respiratory tract pathology, likely because the larger inoculum is more widely distributed in the lower respiratory tract (Moore et al., 2014). Video tracking to assign values to activity levels in ferrets can aid ferret studies, eliminating the need for collection of subjective and arbitrary clinical scores (Oh et al., 2015). Viral replication in the upper respiratory tract is typically measured by

nasal washes, but virus can also be measured in bronchoalveolar lavage fluid using a noninvasive technique (Lee et al., 2014).

Influenza types A and B naturally infect ferrets, resulting in an acute illness, which usually lasts 3–5 days for mild to moderately virulent strains (Maher and DeStefano, 2004). Ferrets are more susceptible to influenza A than influenza B strains and are also susceptible to avian influenza H5N1 strains without adaptation (Zitzow et al., 2002). However, the localized immune responses within the respiratory tract of ferrets infected with influenza A and B have been characterized and are similar (Carolan et al., 2015). Virulence and degree of pneumonitis caused by different influenza subtypes and strains vary from mild to severe and generally mirrors that seen in humans (Stark et al., 2013). Nonadapted H1N1, H2N2, and H3N2 have mild to moderate virulence in ferrets. The sequencing of the ferret genome has allowed for the characterization of the ferret host response using RNA-seq analysis (Peng et al., 2014). Distinct signatures were obtained depending on the particular influenza strain to inoculate the ferrets. Also helpful is the sequencing and characterization of the influenza ferret infectome during different stages of the infection in naïve or immune ferrets (Leon et al., 2013).

Since influenza infection is particularly devastating to the elderly population, an aged ferret model of H1N1 influenza infection was developed (Paquette et al., 2014). Features associated with increased clinical disease are weakened hemagglutinin antibody generation and attenuated Th1 responses. Pregnant and breastfeeding women and infants are also susceptible to more severe illness from influenza virus. To study this dynamic, a breastfeeding mother–infant ferret influenza infection model was created (Paquette et al., 2015). Notably, the mammary gland itself harbored virus and transcript analysis showed downregulation of milk production genes. In support of the development of therapies, the ferret influenza model for pharmacokinetic/pharmacodynamics studies of antiviral drugs as also been developed (Reddy et al., 2015). Critical to this model is ensuring pronounced clinical signs and robust viral replication upon influenza infection. Strains of low virulence have predominant replication in the nasal turbinates of ferrets. Clinical signs and other disease indicators in ferrets are similar to that of humans with mild respiratory disease, sneezing, nasal secretions containing virus, fever, weight loss, high viral titers, and inflammatory infiltrate in the airways, bronchitis, and pneumonia (Svitek et al., 2008). Replication in both the upper and lower airways is associated with more severe disease and greater mortality. Additionally, increased expression of proinflammatory mediators and reduced expression of antiinflammatory mediators in the lower respiratory tract of ferrets correlates with severe disease and lethal outcome. H5N1-infected ferrets develop severe lethargy, greater interferon response, transient lymphopenia, and replication in respiratory tract, brain, and other organs (Peng et al., 2012; Zitzow et al., 2002).

Immunocompromised humans have influenza illness of greater duration and complications. Immunocompromised ferrets infected with influenza similarly had prolonged virus shedding (van der Vries et al., 2013). Interestingly, antiviral resistance emerged in both humans and ferrets with immunocompromised status infected with influenza. Alveolar macrophage depleted of ferrets infected with 2009 pandemic H1N1 influenza also had a more severe disease with greater viral replication in the lungs and greater induction of inflammatory chemokines (Kim et al., 2013). A superinfection model resembling that of mice has been developed by IN instillation of influenza in 6- to 8-week-old ferrets followed by IN inoculation of *S. pneumonia* 5 days later (Peltola et al., 2006). This typically resulted in otitis media, sinusitis, and pneumonia.

Transmission models in ferrets have recently met with worldwide media attention and controversy with regard to the study of H5N1 (Enserink, 2013; Fouchier et al., 2012; Herfst et al., 2012; Oh et al., 2014). In general, some subtypes, such as the 2009 H1N1, can transmit easily through aerosol and respiratory droplets (Munster et al., 2009). Of concern, H7N9 isolated from humans was more pathogenic and readily transmissible between ferrets by larger respiratory droplets and smaller particle aerosols (Kreijtz et al., 2013; Richard et al., 2013; Zhang et al., 2013). H5N1 became transmissible by adopting just four mutations, spreading between ferrets in separate cages (Imai et al., 2012). Transmission occurs more readily at the height of pyrexia, but for the 2009 H1N1 in particular, can occur before fever is detected (Roberts et al., 2012). Ferret-to-ferret transmission of a mouse-adapted influenza B virus has also been demonstrated (Kim et al., 2015). Since ferrets can be expensive and cumbersome, influenza infection has been characterized and a transmission model developed in the guinea pig; however, this is a newer model with infrequent utilization thus far (Lowen et al., 2014).

Old and new world primates are susceptible to influenza infection and have an advantage over ferret and mouse models which are deficient for H5N1 vaccine studies because there is a lack of correlation with hemagglutination inhibition (Murphy et al., 1980). Of old world primates, cynomolgus macaque (*Macaca fascicularis*) is most frequently utilized for studies of vaccines and antiviral drug therapies (Stittelaar et al., 2008).

H5N1 and H1N1 1918 infection of cynos is very similar to humans (Rimmelzwaan et al., 2001). Cynos develop fever and ARDS upon IN inoculation of H5N1 with necrotizing bronchial interstitial pneumonia (Kuiken et al., 2003). NHPs are challenged by multiple routes

(ocular, nasal, and tracheal) simultaneously 1×10^6 pfu per site. Virus antigen is primarily localized to the tonsils and pulmonary tissues. Infection of cynos with H5N1 results in fever, lethargy, nasal discharge, anorexia, weight loss, nasal and tracheal washes, pathologic and histopathologic changes, and alveolar and bronchial inflammation. The 1918 H1N1 caused a very high mortality rate due to an aberrant immune response and ARDs and had more than 50% lethality (humans only had a 1%–3% lethality) (Kobasa et al., 2007).

ARDS and mortality also occur with the more pathogenic strains, but NHPs show reduced susceptibility to less virulent strains, such as H3N2 (O'Donnell and Subbarao, 2011). Influenza-infected rhesus macaques represent a mild disease model for vaccine and therapeutic efficacy studies (Baas et al., 2006). Host microarray and qRT-PCR proved useful for analysis of infected lung tissues. Other NHP models include influenza infection of pigtailed macaques as a mild disease model and infection of new world primates, such as squirrel and cebus monkeys (Baskin et al., 2009).

Domestic pig models have been developed for vaccine studies for swine flu. Pigs are susceptible in nature as natural or intermediate hosts but are not readily susceptible to H5N1 (Isoda et al., 2006; Lipatov et al., 2008). While pigs infected with influenza may have fever, anorexia, and respiratory signs, such as dyspnea and cough, mortality is rare (van der Laan et al., 2008). Size and space requirements make this animal difficult to work with, although the development of minipig models may provide an easier to use alternative.

Cat and dog influenza models have primarily been utilized to study their susceptibility to H5N1 with the thought that these animals could act as sentinels or could serve to transmit the virus to humans (Giese et al., 2008; Rimmelzwaan et al., 2006). These models are not generally used to better understand the disease in humans or for testing vaccines or antivirals.

8 BUNYAVIRIDAE

8.1 Rift Valley Fever Virus

Rift Valley fever virus (RVFV) causes epizootics and human epidemics in Africa. RVFV mainly infects livestock, such as sheep, cattle, goats, etc. After 2–4 days incubation period, animals show signs of fever, hepatitis, and abortion, which is a hallmark diagnostic sign known among farmers (Balkhy and Memish, 2003).

Mosquito vectors, unpasteurized milk, aerosols of infected animal's body fluids, or direct contact with infected animals are the important routes of transmission to humans (Abu-Elyazeed et al., 1996; Mundel and Gear, 1951). After 2- to 6-day-incubation period, RVFV causes a wide range of signs and symptoms in humans ranging from asymptomatic to severe disease with hepatitis, vision loss, encephalitis, and hemorrhagic fever (Ikegami and Makino, 2011; Laughlin et al., 1979; Peters and Linthicum, 1994). Depending on the severity of the disease when the symptoms start, 10%–20% of the hospitalized patients might die in 3–6 days or 12–17 days after the disease onset (Ikegami and Makino, 2011). Hepatic failure, renal failure or DIC, and encephalitis are demonstrated within patients during postmortem examination.

Live domestic animals especially sheep and goats were used to develop animal models of RVFV (Weingartl et al., 2014). This study indicated that goats were more resistant to the disease compared to sheep. The viremia in goats was lower and had a shorter duration with only some animals developing fever. The susceptibility is influenced by route of infection, breed of animals, the RVFV strain, and growth conditions as well as the passage history. Therefore, it might be difficult to establish an animal model with domestic ruminants.

Mice are one of the most susceptible animal species to RVFV infection. Several mouse models including BALB/c, IFNAR$^{-/-}$, MBT/PAS, 129 and C57BL/6 were exposed to RVFV via parental or aerosol routes of infection (Ross et al., 2012). SubQ or IP routes of infection cause acute hepatitis and lethal encephalitis at a late stage of the disease in mice (Mims, 1956; Smith et al., 2010). Mice start to show signs of decreased activity and ruffled fur by day 2–3 postexposure. Immediately following these signs, they become lethargic and generally die 3–6 days postexposure. Ocular disease or the hemorrhagic form of the disease has not been observed in mouse models so far (Ikegami and Makino, 2011). Increased viremia and tissue tropism were reported in mice with (Smith et al., 2010) increased liver enzymes and lymphopenia observed in sick mice. Aerosolized RVFV causes faster and more severe neuropathy in mice compared to the parental route (Dodd et al., 2014; Reed et al., 2014). The liver is a target organ following aerosol exposure and liver failure results in fatality.

Rats and gerbils are also susceptible to RVFV infection. The rat's susceptibility is dependent on the rat strain utilized for the challenge model and route of exposure. There is also noted age dependence in the susceptibility of rats. While Wistar-Furth and Brown Norway strains, and young rats are highly susceptible to RVFV infection, Fisher 344, Buffalo and Lewis strains, and old rats demonstrated resistance to infection via subQ route of infection (Findlay and Howard, 1952; Peters and Slone, 1982). Similar pathologic changes, such as liver damage and encephalopathy were observed in both rats and mice. The recent study by Bales et al. (2012) showed that aerosolized RVFV caused similar disease outcome in Wistar-Furth and ACI rats while Lewis rats developed fatal encephalitis which was much more severe than the subQ

route of infection. There was no liver involvement in the gerbil model and animals died from severe encephalitis. The mortality rate was dependent on the strain used and the dose given to gerbils (Anderson et al., 1988). Similar to the rat model, the susceptibility of gerbils was also dependent on age.

Natural history studies with Syrian hamsters indicated that the liver was the target organ with highly elevated ALT levels and viral titers (Scharton et al., 2015). Lethargy, ruffled fur, and hunched posture were observed in hamsters by day 2 post-subQ inoculation and the disease was uniformly lethal by day 2–3 postexposure. This model has been successfully used to test antivirals against RVFV (Scharton et al., 2015).

Studies thus far showed that RVFV does not cause uniform lethality in a NHP model. IP, IN, IV, and aerosol routes have been utilized to develop NHP model. Rhesus macaques, cynomolgus macaques, African monkeys, and South American monkeys were some of the NHP species used for this effort (Peters et al., 1988). Monkeys showed a variety of signs ranging from febrile disease to hemorrhagic disease and mortality. Temporal viremia, increased coagulation parameters (PT, APTT), and decreased platelets were some other signs observed in NHPs. Animals that succumbed to disease showed very similar pathogenesis to humans, such as pathological changes in the liver and hemorrhagic disease. There was no ocular involvement in this model.

Smith et al. compared IV, IN and subQ routes of infection in common marmosets and rhesus macaques (Peng et al., 2012). Marmosets were more susceptible to RVFV infection than rhesus macaques with marked viremia, acute hepatitis, and late onset of encephalitis. Increased liver enzymes were observed in both species. Necropsy results showed enlarged livers in the marmosets exposed by IV or subQ routes. Although there were no gross lesions in the brains of marmosets, histopathology showed encephalitis in the brains of IN challenged marmosets.

A recent study by Hartman et al. (2014) demonstrated that aerosolized RVFV only caused mild fever in cynomolgus macaques and rhesus macaques, while AGMs and marmosets had encephalitis and succumbed to disease between days 9 and 11 postexposure. In contrast to other lethal models, the brain was the target organ in AGMs and marmosets. Although no change was observed in AST levels, ALP levels were increased in marmosets. Little or no change was observed in hepatic enzyme levels in AGMs. Lack of information regarding human disease concerning the aerosol route of exposure makes it difficult to evaluate these animal models.

8.2 Crimean–Congo Hemorrhagic Fever Virus

Crimean–Congo hemorrhagic fever virus (CCHFV) generally circulates in nature unnoticed in an enzootic tick–vertebrate–tick cycle and similar to other zoonotic agents, appears to produce little or no disease in its natural hosts, but causes severe disease in humans.

CCHFV transmits to humans by ixodid ticks, direct contact with sick animals/humans, or body fluids of animals/humans (Ergonul and Whitehouse, 2007). Incubation, prehemorrhagic, hemorrhagic, and convalescence are the four phases of the disease seen in humans. The incubation period lasts 1–9 days. During the prehemorrhagic phase, patients show signs of nonspecific flu-like disease for approximately a week. The hemorrhagic period results in circulatory shock and DIC in some patients (Mardani and Keshtkar-Jahromi, 2007; Swanepoel et al., 1989).

Over the years, several attempts have been made to establish an animal model for CCHF in adult mice, guinea pigs, hamsters, rats, rabbits, sheep, NHPs, etc. (Fagbami et al., 1975; Nalca and Whitehouse, 2007; Shepherd et al., 1989; Smirnova, 1979). Until recently, the only animal that manifests disease is the newborn mouse. Infant mice IP infected with CCHFV resulted in fatality around day 8 postinfection (Tignor and Hanham, 1993). Pathogenesis studies showed that virus replication was first detected in the liver, with subsequent spread to the blood (serum). Virus was detected very late during the disease course in other tissues including the heart (day 6) and the brain (day 7).

The recent studies utilizing knockout adult mice were successful to develop a lethal small animal model for CCHFV infection (Bente et al., 2010; Bereczky et al., 2010). Bente et al. infected STAT1 knockout mice by the IP route. In this model, after the signs of fever, leukopenia, thrombocytopenia, viremia, elevated liver enzymes and proinflammatory cytokines, mice were moribund and succumbed to disease in 3–5 days postexposure. The second model was developed by using interferon alpha/beta (IFNα/β) receptor knockout mice (IFNAR$^{-/-}$) (Bereczky et al., 2010). Similar observations were made in this model as in the STAT1 knockout mouse model. Animals were moribund and died 2–4 days after exposure with high viremia levels in liver and spleen. Characterization studies with IFNAR$^{-/-}$ mice challenged with different routes (IP, IN, IM, and subQ) showed that CCHFV causes acute disease with high viral loads, pathology in liver and lymphoid tissues, increased proinflammatory response, severe thrombocytopenia, coagulopathy, and death, all of which are characteristics of human disease (Zivcec et al., 2013). Proinflammatory cytokines and chemokines, such as G-CSF, IFNγ, CXCL10, CCL2 increased dramatically day 3 postchallenge and GM-CSF, IL-1a, IL-1b, IL-2, IL-6, IL-12p70, IL-13, IL-17, CXCL1, CCL3, CCL5, and TNF-α concentrations were extremely elevated at the time of death/euthanasia. This model is also utilized to test therapeutics, such as ribavirin, arbidol, and T-705 (favipiravir) successfully

(Oestereich et al., 2014). Experimental vaccines developed for CCHF were evaluated in this model provided protection compare to unvaccinated mice (Buttigieg et al., 2014; Canakoglu et al., 2015, p. 725). Thus, the IFNAR$^{-/-}$ mouse model would be a good choice to test medical countermeasures against CCHFV, although they have an impaired IFN and immune response phenotype.

Other laboratory animals, including NHPs, show little or no sign of infection or disease when infected with CCHFV (Nalca and Whitehouse, 2007). Butenko et al. utilized AGMs (Cercopithecus aethiops) for experimental CCHFV infections. Except one monkey with a fever on day 4 postinfection, the animals did not show signs of disease. Antibodies to the virus were detected in three out of five monkeys, including the one with fever. Fagbami et al. (1975) infected two Patas monkeys (Erythrocebus patas) and one Guinea baboon (Papio papio) with CCHFV. Whereas all three animals had low-level viremia between days 1 and 5 after inoculation, only the baboon serum had neutralizing antibody activity on day 137 postinfection.

Similar results were obtained when horses and donkeys have been used for experimental CCHFV infections. Donkeys develop a low-level viremia (Rabinovich et al., 1972) and horses developed little or no viremia, but high levels of virus-neutralizing antibodies, which remained stable for at least 3 months. These studies suggest that horses may be useful in the laboratory to obtain serum for diagnostic and possible therapeutic purposes (Blagoveshchenskaya et al., 1975).

Shepherd et al. (1989) infected 11 species of small African wild mammals and laboratory rabbits, guinea pigs, and Syrian hamsters with CCHFV. Whereas scrub hares (Lepus saxatilis), cape ground squirrels (Xerus inauris), red veld rats (Aethomys chrysophilus), white-tailed rats (Mystromys pumilio), and guinea pigs had viremia; South African hedgehogs (Atelerix frontalis), highveld gerbils (Gerbilliscus brantsii), Namaqua gerbils (Desmodillus auricularis), two species of multimammate mouse (Mastomys natalensis and Mastomys coucha), and Syrian hamsters were negative for virus. All species regardless of viremia levels developed antibody responses against CCHFV. IV and intracranially infected animals showed onset of viremia earlier than those infected by the subQ or IP routes.

8.3 Hanta Virus

The genus Hantavirus is unique among the family Bunyaviridae in that it is not transmitted by an arthropod vector, but rather rodents (Schmaljohn and Nichol, 2007). Rodents of the family Muridae are the primary reservoir for hantaviruses. Infected host animals develop a persistent infection that is typically asymptomatic. Transmission is achieved by inhalation of infected rodent saliva, feces, and urine (Xu et al., 1985). Human infections can normally be traced to a rural setting with activities, such as farming, land development, hunting, and camping as possible sites of transmission. Rodent control is the primary route of prevention (Lednicky, 2003).

The viruses have a tropism for endothelial cells within the microvasculature of the lungs (Zaki et al., 1995). There are two distinct clinical diseases that infection can yield: hemorrhagic fever with renal syndrome (HFRS) due to infection with old world hantaviruses or hantavirus pulmonary syndrome (HPS) caused by new world hantaviruses (Nichol, 2001). HFRS is mainly seen outside of the Americas and is associated with the hantaviruses Dobrava-Belgrade (also known as Dobrava), Hantaan, Puumala, and Seoul (Lednicky, 2003). Incubation lasts 2–3 weeks and presents as flu-like in the initial stages that can further develop into hemorrhagic manifestations and ultimately renal failure. Thrombocytopenia subsequently develops which can further progress to shock in approximately 15% patients. Overall mortality rate is 7%. Infection with Dobrava and Hantaan viruses are typically linked to development of severe disease.

HPS was first diagnosed in 1993 within southwestern United States when healthy young adults became suddenly ill, progressing to severe respiratory distress and shock. The etiological agent responsible for this outbreak was identified as Sin Nombre virus (SNV) (Centers for Disease Control and Prevention, 1993). This virus is still the leading cause within North America of HPS. HPS due to other hantaviruses has been reported in Argentina, Bolivia, Brazil, Canada, Chile, French Guiana, Panama, Paraguay, and Uruguay (Padula et al., 2000; Stephen et al., 1994). The first report of HPS in Maine was recently documented (Centers for Disease Control and Prevention, 1993). Andes virus (ANDV) was first identified in outbreaks in Chile and Argentina. This hantavirus is distinct in that it can be transmitted between humans (Wells et al., 1997). The fulminant disease is more lethal than that observed of HFRS with a mortality rate of 40%.

There are four phases of disease including prodromal, pulmonary, cardiac depression, and hematologic manifestation (Peters and Khan, 2002). Incubation typically occurs 14–17 days following exposure (Young et al., 2000). Unlike HFRS, renal failure is not a major contributing factor to the disease. There is a short prodromal phase that gives way to cardiopulmonary involvement accompanied by cough and gastrointestinal symptoms. It is at this point that individuals are typically admitted to the hospital. Pulmonary function is hindered and continues to suffer within 48 h after cardiopulmonary involvement. Interstitial edema and air-space disease normally follow. In fatal cases, cardiogenic shock has been noted (Hallin et al., 1996).

Syrian golden hamsters are the most widely utilized small animal model for hantavirus infection. Hamsters

inoculated IM with a passaged Andes viral strain died within 11 days postinfection. Clinical signs did not appear until 24 h prior to death at which point the hamsters were moribund and in respiratory distress. Mortality was dose dependent, with high inoculums leading to a shorter incubation before death. During the same study, hamsters were inoculated with a passaged SNV isolate. No hamsters developed any symptoms during the course of observation. However, an antibody response to the virus that was not dose dependent was determined via ELISA. Hamsters infected with ANDV have significant histopathological changes to their lung, liver, and spleen. All had an interstitial pneumonia with intraalveolar edema. Infectious virus could be recovered from these organs. Viremia began on day 8 and lasted up to 12 days postinfection. Infection of hamsters with ANDV yielded a similar clinical disease progression as is seen in human HPS including rapid progression to death, fluid in the pleural cavity, and significant histopathological changes to the lungs and spleen. A major deviation in the hamster model is the detection of infectious virus within the liver (Hooper et al., 2001). Normally, SNV does not cause a disease in hamsters (Wahl-Jensen et al., 2007). But a recent study showed that immunosuppression with dexamethasone and cyclophosphamide in combination causes lethal disease with SNV in hamsters (Brocato et al., 2014). The disease was very similar to the disease caused by ANDV in hamsters.

Lethal disease can be induced in newborn mice, but does not recapitulate the clinical symptoms observed in human disease (Kim and McKee, 1985). The disease outcome is very much dependent on the age of the mice. Younger mice are much more susceptible to virus than the adult mice. Adult mice exposed to Hanta virus leads to a fatal disease dependent upon viral strain and route of infection. The disease progression is marked by neurological or pulmonary manifestations that do not mirror human disease (Seto et al., 2012; Wichmann et al., 2002). Knockout mice lacking IFNα/β are highly susceptible to Hanta virus infection (Muller et al., 1994). In a study of panel of laboratory strains of mice, C57BL/6 mice were most susceptible to a passaged Hanta viral strain injected IP. Animals progressed to neurological manifestation including paralyses and convulsions, and succumbed to infection within 24–36 h postinfection. Clinical disease was markedly different from that observed in human cases (Wichmann et al., 2002). In a recent study, 2-week-old ICR mice was exposed to HTNV strain AA57 via the subQ route (Seto et al., 2012). Mice started to show signs of disease by day 11 postinoculation. Piloerection, trembling, hunching, loss of body weight, labored breathing, and severe respiratory disease were observed in mice.

Studies to develop NHP models were not successful until recently. NHPs have been challenged with new world hantaviruses; however, no clinical signs were reported (Hooper et al., 2006; McElroy et al., 2002). Cynomolgus monkeys challenged with a clinical isolate of Puumala virus developed a mild disease (Klingstrom et al., 2002; Sironen et al., 2008). Challenge with ANDV to cynomolgus macaques by both IV and aerosol exposure led to no signs of disease. All animals did display a drop in total lymphocytes within 5 days postinfection. Four of six aerosol exposed monkeys and 8 of 11 IV injected monkeys developed viremia. Infectious virus could not be isolated from any of the animals. In a recent study, rhesus macaques were inoculated by the intramuscular route with SNV passaged only in deer mice (Safronetz et al., 2014). Characteristics of HPS disease including rapid onset of respiratory distress, severe pulmonary edema, thrombocytopenia, and leukocytosis were observed in this promising model. Viremia was observed 4–10 days prior to respiratory signs of the disease that were observed on days 14–16 postinoculation. With all aspects, this animal model would be very useful to test medical countermeasures against Hanta virus.

9 ARENAVIRIDAE

9.1 Lassa Fever Virus

The family Arenaviridae is composed of two serogroups: old world arenaviruses including Lassa fever virus and lymphocytic choriomeningitis virus and the new world viruses of Pichinde virus and Junin virus. All of these viruses share common clinical manifestations (McCormick and Fisher-Hoch, 2002). Lassa fever virus is endemic in parts of West Africa and outbreaks are typically seen in the dry season between January and April (Curtis, 2006). This virus is responsible for 100,000–500,000 infections per year, leading to approximately 5000 deaths (Khan et al., 2008). Outbreaks have been reported in Guinea, Sierra Leone, Liberia, Nigeria, and Central African Republic. However, cases have sprung up in Germany, Netherlands, United Kingdom, and the United States due to transmission to travelers on commercial airlines (Amorosa et al., 2010).

Transmission of this virus typically occurs via rodents, in particular the multimammate rat, *Mastomys* species complex (Curtis, 2006). Humans become infected by inhaling the aerosolized virus or eating contaminated food. There has also been noted human-to-human transmission by direct contact with infected secretions or needle-stick injuries. The majority of infections are asymptomatic; however, severe disease occurs in 20% of individuals. The incubation period is from 5 to 21 days and initial onset is characterized by flu-like illness. This is followed by diarrheal disease that can progress to hemorrhagic symptoms including encephalopathy, encephalitis, and meningitis. A third of patients develop

deafness in the early phase of disease that is permanent for a third of those affected. The overall fatality is about 1%; however, of those admitted to the hospital it is between 15% and 25%. There is no approved vaccine and besides supportive measures, ribavirin is effective only if started within 7 days (McCormick et al., 1986a,b).

The primary animal model used to study Lassa fever is the rhesus macaque (Jahrling et al., 1980). Aerosolized infection of lymphocytic choriomeningitis virus has been a useful model for Lassa fever. Both rhesus and cynomolgus monkeys exposed to the virus developed disease, but rhesus mirrored more closely the disease course and histopathology observed in human infection (Danes et al., 1963). IV or intragastric inoculation of the virus led to severe dehydration, erythematous skin, submucosal edema, necrotic foci in the buccal cavity, and respiratory distress. The liver was severely affected by the virus as depicted by measuring the liver enzymes AST and ALT (Lukashevich et al., 2003). Disease was dose dependent with IV, intramuscular, and subQ inoculation requiring the least amount of virus to induce disease. Aerosol infections and eating contaminated food could also be utilized, and mimic a more natural route of infection (Peters et al., 1987). Within this model, the NHP becomes viremic after 4–6 days. Clinical manifestations were present by day 7 and death typically occurred within 10–14 days (Lukashevich et al., 2004; Rodas et al., 2004). Intramuscular injection of Lassa virus into cynomolgus monkeys also produced a neurological disease due to lesions within the CNS (Hensley et al., 2011b). This pathogenicity is seen in select cases of human Lassa fever (Cummins et al., 1992; Gunther et al., 2001).

A marmoset model has recently been defined utilizing a subQ injection of Lassa fever virus. Virus was initially detected by day 8 and viremia achieved by day 14. Liver enzymes were elevated and an enlarged liver was noted upon autopsy. There was a gradual reduction in platelets and interstitial pneumonitis diagnosed in a minority of animals. The physiological signs were the same as seen in fatal human cases (Carrion et al., 2007).

Mice develop a fatal neurological disorder upon intracerebral inoculation with Lassa, although the outcome of infection is dependent on the MHC background, age of the animal, and inoculation route (Salvato et al., 2005). STAT1 knockout mice inoculated IP with both lethal and nonlethal Lassa virus strains develop hearing loss accompanied by damage to the inner ear hair cells and auditory nerve (Yun et al., 2015). Guinea pig inbred strain 13 was highly susceptible to Lassa virus infection. The outbred Hartley strain was less susceptible, and thus strain 13 has been the preferred model given its assured lethality. The clinical manifestations mirror those seen in humans and rhesus (Jahrling et al., 1982). Infection with Pichinde virus passaged in guinea pigs has also been used. Disease signs include fever, weight loss, vascular

collapse, and eventual death (Lucia et al., 1990; Qian et al., 1994). The guinea pig is an excellent model given that it not only results in similar disease pattern, viral distribution, histopathology, and immune response to humans (Connolly et al., 1993; Katz and Starr, 1990).

Infection of hamsters with a cotton rat isolate of Pirital virus is similar to what is characterized in humans, and the NHP and guinea pig models. The virus was injected IP resulting in lethargy and anorexia within 6–7 days. Virus was first detected at 3 days, and reached maximum titers within 5 days. Neurological symptoms began to appear at the same time, and all animals died by day 9. Pneumonitis, pulmonary hemorrhage, and edema were also present (Sbrana et al., 2006). These results were recapitulated with a nonadapted Pichinde virus (Buchmeier and Rawls, 1977; Gowen et al., 2005; Smee et al., 1993).

10 RETROVIRIDAE

10.1 Human Immunodeficiency Virus Type 1

The Lentiviruses are a subfamily of Retroviridae, which includes human immunodeficiency virus (HIV), a virus that infects 0.6% of the world's population. A greater proportion of infections and deaths occur in sub-Saharan Africa. Worldwide, there are approximately 1.8 million deaths per year with over 260,000 being children. Transmission of HIV occurs by exposure to infectious body fluids. There are two species, HIV-1 and HIV-2, with HIV-2 having lower infectivity and virulence (confined mostly to West Africa). The vast majority of cases worldwide are HIV-1 (De Cock et al., 2011).

HIV targets T-helper cells (CD4+), macrophages, dendritic cells (Fields et al., 2007). Acute infection occurs 2–4 weeks after exposure, with flu-like symptoms and viremia followed by chronic infection. Symptoms in the acute phase may include fever, body aches, nausea, vomiting, headache, lymphadenopathy, pharyngitis, rash, and sores in the mouth or esophagus. CD8+ T-cells are activated which kill HIV-infected cells, and are responsible for antibody production and seroconversion. Acquired immune deficiency syndrome (AIDS) develops when CD4+ T-cells decline to less than 200 cells/μL; thus cell-mediated immunity becomes impaired and the person is more susceptible to opportunistic infections as well as certain cancers.

HIV has a narrow host range likely because the virus is unable to antagonize and evade effector molecules of the interferon response (Thippeshappa et al., 2012). Humanized mice, created by engrafting human cells and tissues into SCID mice, have been critical for the development of mouse models for the study of HIV infection. A number of different humanized mouse models allow for the study of HIV infection in the context of an intact and

functional human innate and adaptive immune responses (Berges and Rowan, 2011). The SCIDHu HIV infection model has proven useful, particularly in screening antivirals and therapeutics (Denton et al., 2008; Melkus et al., 2006). A number of different humanized mouse models have been developed for the study of HIV, including Rag1$^{-/-}$γc$^{-/-}$, Rag2$^{-/-}$γc$^{-/-}$, NOD/SCIDγc$^{-/-}$ (hNOG), NOD/SCIDγc$^{-/-}$ (hNSG), NOD/SCID BLT, and NOD/SCIDγc$^{-/-}$ (hNSG) BLT (Karpel et al., 2015; Li et al., 2015; Shimizu et al., 2015). CD34+ human stem cells derived from umbilical cord blood or fetal liver are used for humanization (Baenziger et al., 2006; Watanabe et al., 2007). HIV-1 infection by IP injection can be successful with as little as 5% peripheral blood engraftment (Berges et al., 2006). Vaginal and rectal transmission models have been developed in BLT SCID Hu mice in which mice harbor human bone marrow, liver, and thymus tissue. HIV-1 viremia occurs within approximately 7 days postinoculation (Zhang et al., 2007). In many of these models, spleen, lymph nodes, and thymus tissues are highly positive for virus, similar to humans (Brainard et al., 2009). Importantly, depletion of human T-cells can be observed in blood and lymphoid tissues of HIV-infected humanized mice and at least some mechanisms of pathogenesis that occur in HIV-infected humans, also occur in the HIV-infected humanized mouse models (Baenziger et al., 2006; Neff et al., 2011). The advantage of these models is that these mice are susceptible to HIV infection and thus the impact of drugs on the intended viral targets can be tested. One caveat is that while mice have a "common mucosal immune system," humans do not, due to differences in the distribution of addressins (Holmgren and Czerkinsky, 2005). Thus, murine mucosal immune responses to HIV do not reflect those of humans. Another strategy uses a human CD4- and human CCR5- expressing transgenic luciferase reporter mouse to study HIV-1 pseudovirus entry (Gruell et al., 2013).

HIV-1 transgenic (Tg) rats are also used to study HIV related pathology, immunopathogenesis, and neuropathology (Lentz et al., 2014; Reid et al., 2001). The clinical signs include skin lesions, wasting, respiratory difficulty, and neurological signs. Brain volume decreases have been documented and the HIV-1 Tg rat is thus used as a model of neuropathology in particular.

There are a number of important NHP models for human HIV infection (Hessell and Haigwood, 2015). An adaptation of HIV-1 was obtained by four passages in pigtailed macaques transiently depleted of CD8(+) cells during acute infection (Hatziioannou et al., 2014). The resulting disease has several similarities to AIDS in humans, such as depletion of CD4(+) T-cells (Kimata, 2014). Simian immunodeficiency virus (SIV) infection of macaques has been widely used as a platform for modeling HIV infection of humans (Demberg and Robert-Guroff, 2015; Walker et al., 2015). Importantly, NHPs

have similar, pharmacokinetics, metabolism, mucosal T-cell homing receptors, and vascular addressins to those of humans. Thus, while the correlates of protection against HIV are still not completely known, immune responses to HIV infection and vaccination are likely comparable. These models mimic infection through use of contaminated needles (IV), sexual transmission (vaginal or rectal), and maternal transmission in utero or through breast milk (Keele et al., 2009; Miller et al., 2005; Stone et al., 2009). There are also macaque models to study the emergence and clinical implications of HIV drug resistance (Van Rompay et al., 2002).

These models most routinely utilize rhesus macaques (*Macaca mulatta*), cynomolgus macaques (*M. fasicularis*), and pigtailed macaques (*Macaca nemestrina*). All ages are used, depending on the needs of the study. For instance, use of newborn macaques may be more practical for evaluating the effect of prolonged drug therapy on disease progression; however, adult NHPs are more frequently employed. Female pigtailed macaques have been used to investigate the effect of the menstrual cycle on HIV susceptibility (Vishwanathan et al., 2015). Studies are performed in BSL-2 animal laboratories and NHPs must be Simian type-D retrovirus free and SIV seronegative. SIV infection of pigtailed macaques is a useful model for HIV peripheral nervous system pathology, wherein an axotomy is performed and regeneration of axons is studied (Ebenezer et al., 2012).

Exposure in model systems is typically through a single high-dose challenge. IV infection of rhesus macaques with 100 TCID$_{50}$ of the highly pathogenic SIV/DeltaB670 induces AIDS in most macaques within 5–17 months (mean of 11 months) (Fuller et al., 2012). Peak viremia occurs around week 4. AIDS in such models is often defined as CD4+ T-cells that have dropped to less than 50% of the baseline values. Alternatively, repeated low dose challenges are often utilized, depending on the requirements of the model (Henning et al., 2014; Moldt et al., 2012; Reynolds et al., 2012).

Since NHPs infected with HIV do not develop an infection with a clinical disease course similar to humans, SIV or SIV/HIV-1 laboratory-engineered chimeric viruses (SHIVs) are used as surrogates. NHPs infected with pathogenic SIV may develop clinical disease which progresses to AIDS, and are thus useful pathogenesis models. A disadvantage is that SIV is not identical to HIV-1 and is more closely related to HIV-2. However, the polymerase region of SIV is 60% homologous to that of HIV-1 and it is susceptible to many reverse transcriptase (RT) and protease inhibitors. SIV is generally not susceptible to nonnucleoside inhibitors, thus HIV-1 RT is usually put into SIV for such studies (Uberla et al., 1995).

SIVmac239 is similar to HIV in the polymerase region and is therefore susceptible to nucleoside, RT, or integrase inhibition (Witvrouw et al., 2004). NHPs

infected with SIVmac239 have an asymptomatic period and disease progression resembling AIDS in humans, characterized by weight loss/wasting, CD4+ T-cell depletion. Additionally, SIVmac239 utilizes the CXCR5 chemokine receptor as a coreceptor, similar to HIV, which is important for drugs that target entry (Veazey et al., 2003).

NHPs infected with SHIV strains, may not develop AIDS, but these models are useful in testing vaccine efficacy (Del Prete et al., 2014). For example, RT-SHIVs and env-SHIVs are useful for testing and evaluation of drugs that may target the envelope or RT, respectively (Uberla et al., 1995). One disadvantage of the highly virulent env-SHIV (SHIV-89.6 P), is that it uses the CXCR4 coreceptor. Of note, env-SHIVs that do use the CXCR5 coreceptor are less virulent; viremia develops then resolves without further disease progression (Humbert et al., 2008).

Simian-tropic (st) HIV-1 contains the Vif gene from SIV. Infection of pigtailed macaques with this virus results in viremia, which can be detected for 3 months, followed by clearance (Haigwood, 2009).

A number of routes are utilized for SIV or SHIV infection of NHPs, with IV inoculation the most common route. Mucosal routes include vaginal, rectal, and intracolonic. Mucosal routes require a higher one-time dose than the IV route for infection. For the vaginal route, female macaques are treated with Depo-Provera (estrogen) 1 month before infection to synchronize the menstrual cycle, thin the epithelial lining of the vagina, and increase susceptibility to infection by atraumatic vaginal instillation (Burton et al., 2011). Upon vaginal instillation of 500 $TCID_{50}$ of SHIV-162P3, peak viremia was seen around 12 days postexposure with greater than 10^7 copies/mL and dropping thereafter to a constant level of 10^4 RNA copies/mL at 60 days and beyond. In another example, in an investigation of the effect of vaccine plus vaginal microbicide on preventing infection, rhesus macaques were vaginally infected with a high dose of SIVmac251 (Barouch et al., 2012). An example of an intrarectal model utilized juvenile (2-year-old) pigtailed macaques, challenged intrarectally with 10^4 $TCID_{50s}$ of SIV_{mne027} to study the pathogenesis related to the virulence factor, Vpx (Belshan et al., 2012). Here, viremia peaked at approximately 10 days with more than 10^8 copies/mL. Viral RNA was expressed in the cells of the mesenteric lymph nodes.

The male genital tract is seen as a viral sanctuary with persistent high levels of HIV shedding even with antiretroviral therapy. To better understand the effect of HAART therapy on virus and T-cells in the male genital tract, adult (3- to 4-year-old) male cynomolgus macaques were intravenously inoculated with 50 AID50s of SIVmac251 and the male genital tract tissues were tested after euthanasia by PCR, IHC, and in situ hybridization (Moreau et al., 2012).

Pediatric models have been developed in infant rhesus macaques through the infection of SIV, allowing for the study of the impact of developmental and immunological differences on the disease course (Abel, 2009). Importantly, mother-to-infant transmission models have also been developed (Jayaraman et al., 2004). Pregnant female pigtailed macaques were infected during the second trimester with 100 MID_{50} SHIV-SF162P3 by the IV route. Four of nine infants were infected, one in utero and three either intrapartum or immediately postpartum through nursing. This model is useful for the study of factors involved in transmission as well as the underlying immunology.

NHPs infected with SIV or SHIV are routinely evaluated for weight loss, activity level, stool consistency, appetite, virus levels in blood, and T-cell populations. Cytokine and chemokine levels, antibody responses, and cytotoxic T-lymphocyte responses may also be evaluated.

The ultimate goal of an HIV vaccine is sterilizing immunity (preventing infection). However, a more realistic result may be to reduce severity of infection and permanently prevent progression. Strategies have included live attenuated, nonreplicating, and subunit vaccines. These have variable efficacy in NHPs due to the genetics of the host (MHC and TRIM alleles), differences between challenge strains, and challenge routes (Letvin et al., 2011). NHP models have led to the development of antiviral treatments that are effective at reducing viral load and indeed transmission of HIV among humans. One preferred variation on the models for testing the long-term clinical consequences of antiviral treatment is to use newborn macaques and treat from birth onward, in some cases more than a decade (Van Rompay et al., 2008). Unfortunately, however, successes in NHP studies do not always translate to success in humans, as seen with the recent STEP study which used an adenovirus-based vaccine approach (Buchbinder et al., 2008). Vaccinated humans were not protected and may have even been more susceptible to HIV, viremia was not reduced, and the infections were not attenuated as hoped. With regard to challenge route, IV exposure is more difficult to protect than mucosal exposure and is used as a "worst case scenario." However, efficacy at one mucosal route is usually comparable to other mucosal routes.

11 PAPILLOMAVIRIDAE

11.1 Papillomavirus

Human and animal papillomaviruses cause benign epithelial proliferations (warts) and malignant tumors of the various tissues that they infect (Bosch and de Sanjose, 2002). There are over 100 human

papillomaviruses, with different strains causing warts on the skin, oropharynx, nasopharynx, larynx, and anogenital tissues. Approximately one third of papillomaviruses are transmitted sexually. Of these, virulent subtypes, such as HPV-16, HPV-18, HPV-31, HPV-33, and HPV-45 place individuals at high risk for cervical and other cancers. Up to 35% of head and neck cancers are caused by HPV-16, particularly oropharyngeal cancers. Major challenges in the study of these viruses are that papillomaviruses generally do not infect any other species outside of the natural hosts and can cause a very large spectrum of severity. Thus, no wild-type animal models have been identified that are susceptible to HPV. However, a number of useful surrogate models exist which use animal papillomaviruses in their natural host or a very closely related species (Borzacchiello et al., 2009; Brandsma, 1994; Campo, 2002). These models have facilitated the recent development of useful and highly effective prophylactic HPV vaccines (Rabenau et al., 2005).

Wild-type inbred mice cannot be used to study disease caused by papillomaviruses unless they are engrafted with relevant tissue, orthotopically transplanted or transgenic, but they are often used to look at immunogenicity of vaccines (Jagu et al., 2011; Oosterhuis et al., 2011). Transgenic mice used for HPV animal modeling typically express the viral oncogenes E5, E6, E7, or the entire early region of HPV-16 from the keratin 14 promoter which is only active in the basal cells of the mouse epithelium (Chow, 2015). Cancers in these models develop upon extended estrogen exposure (Maufort et al., 2010; Ocadiz-Delgado et al., 2009; Stelzer et al., 2010; Thomas et al., 2011). Transgenic mice with constitutively active Wnt/B-catenin signaling in cervical epithelial cells expressing the HPB oncoprotein E7 develop invasive cervical squamous carcinomas (Bulut and Uren, 2015). The tumors occur within 6 months approximately 94% of the time. Another model uses C57BL/6 mice expressing the HPV16-E7 transgene which are then treated topically with 7,12-dimethylbenz(a)anthracene (DMBA) (De Azambuja et al., 2014). These mice developed benign and malignant cutaneous lesions.

Cervical cancers can also be induced in human cervical cancer xenografts transplanted onto the flanks of athymic mice and serially transplanted thereafter (Hiroshima et al., 2015; Siolas and Hannon, 2013).

A wild-type immunocompetent rodent model uses *M. coucha*, which is naturally infected with *Mastomys natalensis* papillomavirus (MnPV) (Vinzon et al., 2014). MnPV induces papillomas, keratoacanthomas, and squamous cell carcinomas and provides a means to study vaccination in an immunocompetent small animal model.

Wild cottontail rabbits (*Sylvilagus floridanus*) are the natural host for cottontail rabbit papillomavirus (CRPV), but this virus also infects domestic rabbits (*Oryctolagus cuniculus*), which is a very closely related species (Breitburd et al., 1997). In this model, papillomas can range from cutaneous squamous cell carcinomas on one end of spectrum, and spontaneous regression on the other. Lesions resulting from CRPV in domestic rabbits do not typically contain infectious virus.

Canine oral papillomavirus (COPV) causes florid warty lesions in mucosa of the oral cavity within 4–8 weeks postexposure in experimental settings (Johnston et al., 2005). The mucosatrophic nature of these viruses and the resulting oropharyngeal papillomas that are morphologically similar to human vaginal papillomas caused by HPV-6 and HPV-11 make this a useful model (Nicholls et al., 1999). These lesions typically spontaneously regress 4–8 weeks after appearing; this model is therefore useful in understanding the interplay between the host immune defense and viral pathogenesis. Male and female beagles, aged 10 weeks to 2 years, with no history of COPV, are typically used for these studies. Infection is achieved by application of a 10 μL droplet of virus extract to multiple 0.5 cm^2 scarified areas within the mucosa of the upper lip of anesthetized beagles (Nicholls et al., 2001). Some investigators have raised concerns that dogs are not a suitable model for high-risk HPV-induced oral cancer (Staff, 2015).

Bovine papillomavirus (BPV) has a wider host range than most papillomaviruses, infecting the fibroblasts cells of numerous ungulates (Campo, 2002). BPV-4 infection of cattle feeding on bracken fern, which is carcinogenic, can result in lesions of the oral and esophageal mucosa that lack detectable viral DNA. BPV infections in cattle can result in a range of diseases, such as skin warts, cancer of the upper gastrointestinal tract and urinary bladder, and papillomatosis of the penis, teats, and udder.

Finally, rhesus papillomavirus (RhPV), a sexually transmitted papillomaviruses in rhesus macaques and cynomolgus macaques is very similar to HPV-16 and is associated with the development of cervical cancer (Ostrow et al., 1990; Wood et al., 2007).

12 POXVIRIDAE

12.1 Monkeypox Virus

Monkeypox virus (MPXV) causes disease in both animals and humans. Human monkeypox, which is clinically almost identical to ordinary smallpox, occurs mostly in the rainforest of central and western Africa. The virus is maintained in nature in rodent reservoirs including

squirrels (Charatan, 2003; Khodakevich et al., 1986). MPXV was discovered during the pox-like disease outbreak among laboratory monkeys (mostly cynomolgus and rhesus macaques) in Denmark in 1958. No human cases were observed during this outbreak. The first human case was not recognized as a distinct disease until 1970 in Zaire (the present DRC) with continued occurrence of a smallpox-like illness despite eradication efforts of smallpox in this area.

During the global eradication campaign, extensive vaccination in central Africa decreased the incidence of human monkeypox, but the absence of immunity in the generation born since that time and increased dependence on bush meat have resulted in renewed emergence of the disease.

In the summer of 2003, a well-known outbreak in the Midwest was the first occurrence of monkeypox disease in the United States and Western Hemisphere. Among 72 reported cases, 37 human cases were laboratory confirmed during an outbreak (Nalca et al., 2005; Sejvar et al., 2004). It was determined that native prairie dogs (*Cynomys* sp.) housed with rodents imported from Ghana in West Africa were the primary source of outbreak.

The virus is mainly transmitted to humans while handling infected animals or by direct contact with the infected animal's body fluids, or lesions. Person-to-person spread occurs by large respiratory droplets or direct contact (Jeézek and Fenner, 1988). Most of the clinical features of human monkeypox are very similar to those of ordinary smallpox (Breman and Arita, 1980). After a 7- to 21-day-incubation period, the disease begins with fever, malaise, headache, sore throat, and cough. The main sign of the disease that distinguishes monkeypox from smallpox is swollen lymph nodes (lymphadenitis), which is observed in most of the patients before the development of rash (Di Giulio and Eckburg, 2004; Jeézek and Fenner, 1988). A typical maculopapular rash follows the prodromal period, generally lasting 1–3 days. The average size of the skin lesions are 0.5–1 cm and the progress of lesions follows the order: macules, papules, vesicles, pustules, umblication then scab, and desquamation and lasts typically 2–4 weeks. The fatality rate is 10% among the unvaccinated population and death generally occurs during the 2nd week of the disease (Jeézek and Fenner, 1988; Nalca et al., 2005).

MPXV is highly pathogenic for a variety of laboratory animals and many animal models have been developed by using different species and different routes of exposure (Table 33.3). Due to unavailability of variola virus (smallpox) to develop animal models and similar disease manifestations in humans that are similar, MPXV

TABLE 33.3 MPXV Animal Models

Animal model	Route of exposure	Clinical outcome in animals	References
Mice	IN	Weight loss, viremia, mortality	Americo et al. (2010)
	Intraperitoneal	Weight loss, viremia, mortality	Americo et al. (2010), Osorio et al. (2009)

	Intrabronchial	Fever, rash, viremia	Johnson et al. (2011)

IN, Intranasal; MPXV, monkeypox virus.

is one of the pox viruses that are utilized very heavily to develop a number of small animal models via different routes of exposure. Wild-derived inbred mouse, STAT1-deficient C57BL/6 mouse, ICR mouse, prairie dogs, African dormice, ground squirrels, and Gambian pouched rats are highly susceptible to MPXV by different exposure routes (Americo et al., 2010; Falendysz et al., 2015; Hutson et al., 2009; Osorio et al., 2009; Sbrana et al., 2007; Schultz et al., 2009; Sergeev et al., 2016; Stabenow et al., 2010; Tesh et al., 2004; Xiao et al., 2005).

CAST/EiJ mice, one of the 38 inbred mouse strains tested for susceptibility to MPXV, showed weight loss and dose dependent mortality after IN exposure to MPXV. Studies with IP route of challenge indicated a 50-fold higher susceptibility to MPXV when compared to IN route (Americo et al., 2010).

SCID-BALB/c mice were also susceptible to the IP challenge route and the disease resulted in mortality on day 9 postinfection (Osorio et al., 2009). Similarly, C57BL/6 STAT1$^{-/-}$ mice were infected IN with MPXV and the infection resulted in weight loss and mortality 10 days postexposure. Recently Sergeev et al. (2016) showed that IN challenge of ICR mice with MPXV resulted in purulent conjunctivitis, blepharitis, and ruffled fur in these mice although there was no death. The mouse models mentioned here are very promising for screening therapeutics against poxviruses but testing in additional models will be required for advanced development.

High doses of the MPXV by IP or IN routes caused 100% mortality in 6 days postexposure and 8 days postexposure, respectively, in ground squirrels (Tesh et al., 2004). The disease progressed very quickly and most of the animals were lethargic and moribund by day 5 postexposure without any pox lesions or respiratory changes. A comparison study of USA MPXV and Central African strain of MPXV strains in ground squirrels by the subQ route resulted in systemic disease and mortality in 6–11 days postexposure. The disease resembles hemorrhagic smallpox with nosebleeds, impaired coagulation parameters, and hemorrhage in the lungs of the animals. Another study by Sergeev et al. (2017) showed that IN challenge with MPXV caused fever, lymphadenitis, and skin rash in ground squirrels 7–9 days postexposure. Mortality was observed in 40% of the animals 13–22 days postexposure (Sergeev et al., 2017).

Since MPXV was transmitted by infected prairie dogs in the US outbreak, this animal model has been more thoroughly studied and utilized to test therapeutics and vaccines compared to other small animal models (Hutson et al., 2009; Keckler et al., 2011; Smith et al., 2011; Xiao et al., 2005). Studies using IN, IP, and ID routes of exposure showed that MPXV was highly infectious to prairie dogs, IP infection with the West African MPXV strain caused a more severe disease and 100% mortality than challenge by the IN route. Anorexia and lethargy were

common signs of the disease for both exposure routes. In contrast to IP route, the IN route of exposure caused severe pulmonary edema and necrosis of lungs in prairie dogs, while splenic necrosis and hepatic lesions were observed in IP-infected animals (Xiao et al., 2005). Hutson et al. (2009) utilized IN and ID infections with West African and Congo basin strains and showed that both strains and routes caused smallpox-like disease with longer incubation periods and most importantly generalized pox lesions. Therefore, this model has the utility for testing therapeutics and vaccines against pox viruses. Furthermore, MPXV challenged prairie dogs were used to perform in vivo bioluminescent imaging (BLI) studies (Falendysz et al., 2015). BLI studies showed real time spread of virus in prairie dogs as well as potential routes for shedding and transmission.

The African dormouse is susceptible to MPXV by a footpad injection or IN routes (Schultz et al., 2009). Mice had decreased activity, hunched posture, dehydration, conjunctivitis, and weight loss. Viral doses of 200 and 2000 pfu provided 100% mortality with a mean time to death of 8 days. Upper gastrointestinal hemorrhage, hepatomegaly, lymphadenopathy, and lung hemorrhage were observed during necropsy. With the hemorrhage in several organs, this model resembles hemorrhagic smallpox.

In a recent study, comparison of the disease pathogenesis was performed by using live bioluminescence imaging in the CAST/EiJ mouse and African dormouse challenged with low dose of MPXV (Earl et al., 2015). Following IN challenge, MPXV dissemination occurred through the blood or lymphatic system in dormice compared to dissemination that was through the nasal cavity and lungs in CAST/EiJ mice. The disease course was much faster in CAST/EiJ mice (Earl et al., 2015). Considering the limited availability of prairie dogs, ground squirrels and African dormice, lack of reagents specific for these species, and not having commercial sources of these species, these small animal models are as attractive for further characterization and vaccine, and countermeasure testing studies.

NHPs were exposed to MPXV by several different routes to develop animal model for MPXV (Edghill-Smith et al., 2005; Johnson et al., 2011; Nalca et al., 2010; Stittelaar et al., 2006; Zaucha et al., 2001). During our studies using an aerosol route of exposure, we observed that macaques had mild anorexia, depression, fever, and lymphadenopathy on day 6 postexposure (Nalca et al., 2010). Complete blood count and clinical chemistries showed abnormalities similar to human monkeypox cases with leukocytosis and thrombocytopenia (Huhn et al., 2005). Whole blood and throat swabs had viral loads peak around day 10, and in survivors, gradually decrease until day 28 postexposure. Since doses of 4×10^4 pfu, 1×10^5 pfu, or 1×10^6 pfu resulted in lethality for 70% of the animals,

whereas a dose of 4×10^5 pfu resulted in 85% lethality, survival was not dose dependent. The main pitfall of this model was the lack of pox lesions. With the high dose, animals succumbed to disease before developing pox lesions. With the low challenge dose, pox lesions were observed but they were few in comparison to the IV model. A recent study also evaluated the cytokine levels in aerosol challenged animals. (Tree et al., 2015). Tree et al. (2015) showed that IFNγ, IL-1rα, and IL-6 increased dramatically on day 8 postexposure the day that death was most likely to occur, and viral DNA was detected in most of the tissues. These results support the idea of a cytokine storm causing mortality in monkeypox disease.

MPXV causes dose dependent disease in NHPs when given by the IV route (Johnson et al., 2011). Studies showed that a 1×10^7 pfu IV challenge results in systemic disease with fever, lymphadenopathy, macula-papular rash, and mortality.

An IT infection model skips the upper respiratory system and deposits virus into the trachea, delivering the virus directly to the airways without regard to particle size and the physiological deposition that occurs during the process of inhalation. Fibrinonecrotic bronchopneumonia was described in animals that received 10^7 pfu of MPXV intratracheally (Stittelaar et al., 2006). Although a similar challenge dose of IT MPXV infection resulted in a similar viremia in NHPs to the aerosol route of infection, the timing of the first peak was delayed by 5 days in intratracheally exposed macaques compared to aerosol infection, and the amount of virus detected by qPCR was approximately 100-fold lower. This suggests that local replication is more prominent after aerosol delivery compared to the IT route.

An intrabronchial route of exposure resulted in pneumonia in NHPs (Johnson et al., 2011). Delayed onset of clinical signs and viremia were observed during the disease progression. In this model, similar to aerosol and IT infection models, the number of pox lesions was much less than in the IV infection model.

A major downside of the IV, IT, and intrabronchial models is that the initial infection of respiratory tissue, incubation, and prodromal phases are circumvented with the direct inoculation of virus to the blood stream or to the lung. This is an important limitation when the utility of these models is to test possible vaccines and treatments in which the efficacy may depend on protecting the respiratory mucosa and targeting the subsequent early stages of the infection, which are not represented in these challenge models. Although the aerosol model is the natural route of transmission for human VARV infections and a secondary route for human MPXV infections, the lack of pox lesions is the main drawback of this model. Therefore, when this model is used to test medical countermeasures, the endpoints and the biomarkers to initiate treatment should be chosen carefully.

13 HEPADNAVIRIDAE

13.1 Hepatitis B

Hepatitis B virus (HBV) is one of the most common infections worldwide with over 400 million people chronically infected and 316,000 cases per year of liver cancer due to infection (Lee, 1997). The virus can naturally infect both humans and chimpanzees (Guha et al., 2004). HBV is transmitted parenterally or postnatally from infected mothers. It can also be transmitted by sexual contact, IV drug use, blood transfusion, and acupuncture (Lai et al., 2003). The age at which one is infected dictates the risk of developing chronic disease (Hyams, 1995).

Acute infection during adulthood is self-limiting and results in flu-like symptoms that can progress to hepatocellular involvement as observed with the development of jaundice. The clinical symptoms of HBV infection last for a few weeks before resolving (Ganem and Prince, 2004). After this acute phase, lifetime immunity is achieved (Wright and Lau, 1993). Of those infected, less than 5% will develop the chronic form of the disease. Chronicity is the most serious outcome of the disease as it can result in cirrhosis or liver cancer. Hepatocellular carcinoma is 100 times more likely to develop in a chronically infected individual than a noncarrier (Beasley, 1988). The viral determinant for cellular transformation has yet to be determined, although studies involving the woodchuck hepatitis virus suggest that X protein may be responsible (Spandau and Lee, 1988). Many individuals are asymptomatic until complications emerge related to chronic HBV carriage.

Chimpanzees have a unique strain that circulates within the population (Hu et al., 2000; MacDonald et al., 2000). It was found that 3%–6% of all wild-caught animals from Africa are positive for HBV antigen (Lander et al., 1972). Natural and experimental challenge with the virus follows the same course as human disease; however, this is only an acute model of disease (Prince, 1972). To date, chimpanzees are the only reliable method to ensure that plasma vaccines are free from infectious particles (Prince and Brotman, 2001). This animal model has been used to study new therapeutics and vaccines. Chimpanzees are especially ideal for these studies given that their immune response to infection directly mirrors humans (Nayersina et al., 1993). Recent regulations by the National Institute of Health (NIH) and restrictions to use great apes as animal models forced researches to find alternate models for HBV infection.

Other NHPs that have been evaluated are gibbons, orangutans, and rhesus monkeys. Although these animals can be infected with HBV, none develops hepatic lesions or liver damage as noted by monitoring of liver enzymes (Pillot, 1990).

Mice are not permissible to infection, and thus numerous transgenic and humanized lines that express HBV proteins have been created to facilitate their usage as an animal model. These include both immunocompetent and immunosuppressed hosts. The caveat to all of these mouse lines is that they reproduce only the acute form of disease (Guha et al., 2004). Recently, the entire genome of HBV was transferred to an immunocompetent mouse line via adenovirus. This provides a model for persistent infection (Huang et al., 2012).

Another model that has been developed is hydrodynamic injection of HBV genomes in the liver of mice (Liu et al., 1999; Yang et al., 2002). Although this model is very stressful to mice and has liver toxicity, it is successfully used to evaluate antivirals against HBV (McCaffrey et al., 2003). Liver chimeric mouse models are an additional set of surrogate models for HBV infection (Dandri and Lutgehetmann, 2014). In these models human hepatocytes are integrated into the murine liver parenchyma (Allweiss and Dandri, 2016). This model might be used to test antivirals as well as to study the molecular biology of HBV infection.

HBV can also be studied using surrogate viruses, naturally occurring mammalian hepadna viruses (Mason et al., 1982). The woodchuck hepatitis virus induces hepatocellular carcinoma (Summers et al., 1978). Within a population, 65%–75% of all neonatal woodchucks are susceptible to chronic infection (Cote et al., 2000). A major difference between the two hepatitis isolates is the rate at which they induce cancer; almost all chronic carriers developed hepatocellular carcinoma within 3 years of the initial infection in woodchucks, whereas human carcinogenesis takes much longer (Gerin et al., 1989). The acute infection strongly resembles what occurs during the course of human disease. There is a self-limiting acute phase resulting in a transient viremia that has the potential of chronic carriage (Tennant, 2001). Challenge with virus in neonates leads to a chronic infection while adults only develop the acute phase of disease (Buendia, 1992). A closely related species to the woodchuck is the *Marmota himalayan*. This animal is also susceptible to the woodchuck hepadna virus upon IV injection. The marmot Himalayan develops an acute hepatitis with a productive infection (Lucifora et al., 2010).

Hepatitis D virus (HDV) is dependent upon HBV to undergo replication and successful infection in its human host (Gerin, 2001). There are two modes of infection possible between the viruses: coinfection where a person is simultaneously infected or superinfection in which a chronic carrier of HBV is subsequently infected with HDV (Purcell et al., 1987). Coinfection leads to a similar disease as seen with HBV alone; however, superinfection can result in chronic HDV infection and severe liver damage (Guilhot et al., 1994). Both coinfection and superinfection can be demonstrated within the chimpanzee and woodchuck by inoculation of human hepatitis D (Ponzetto et al., 1991). A recently published report demonstrated the use of a humanized chimeric uPA mouse to study interactions between the two viruses and drug testing (Lutgehetmann et al., 2012)

14 CONCLUSIONS

New models ranging from NHPs to small animals and representing the disease characteristics in humans are necessary to study viral and host factors that drive disease pathogenesis and evaluate medical countermeasures. The ideal animal model for human viral disease should closely recapitulate the spectrum of clinical symptoms and pathogenesis observed during the course of human infection. Whenever feasible, the model should use the same virus and strain that infects humans. It is also preferable that the virus is a low passage clinical isolate thus animal passage or adaptation should be avoided if model species can be identified that are susceptible. Ideally, the experimental route of infection would mirror that occurs in natural disease. In order to understand the interplay and contribution of the immune system during infection, an immunocompetent animal should be used. The aforementioned characteristics cannot always be satisfied; however, and often virus must be adapted, knockout mice must be used, and/or the disease is not perfectly mimicked in the animal model. Well-characterized animal models are critical for licensure to satisfy FDA "Animal Rule." This rule applies to situations in which vaccine and therapeutic efficacy cannot safely or ethically be tested in humans; thus licensure will come only after preclinical tests are performed in animal models. Many fields in virology are moving toward standardized models that can be used across institutions to test vaccines and therapeutics. A current example of such an effort is within the filovirus community, where animal models, euthanasia criteria, assays, and virus strains are in the process of being standardized. The hope is that these efforts will enable results of efficacy tests on medical countermeasures compared across institutions. This chapter has summarized the best models available for each of the viruses described.

Modeling Cancer Using CRISPR-Cas9 Technology

Sandra Rodriguez-Perales, Marta Martinez-Lage, Raul Torres-Ruiz

Spanish National Cancer Research Centre—CNIO, Madrid, Spain

1 INTRODUCTION

1.1 Why Use Cancer Models?

Cancer is a collection of more than 100 distinct but related diseases that involve multiple genetic and epigenetic alterations owing to dynamic changes in the genome (Hanahan and Weinberg, 2000). These alterations mainly affect genes involved in the control of cell growth and division, including oncogenes and tumor-suppressor genes (TSGs) (Futreal et al., 2004). Large-scale sequencing of numerous types of cancer has provided us with a long list of genetic alterations that are present in human tumors, for example, point mutations, chromosomal rearrangements (translocations, inversions, or deletions), and genome amplifications (Sabatello and Appelbaum, 2016). Alterations, such as passenger mutations do not affect tumorigenesis, whereas many others, such as driver mutations, promote activation of oncogenes and/or inactivation of TSGs, leading to the transformation of normal cells into cancer cells (Easton et al., 2007; Lawrence et al., 2013). The huge amount of cancer genetic alteration data recorded to date must now be processed for use in clinical practice. Hence, genetically modified cell and animal models are essential tools for studying the genes and processes involved in cancer and for investigating the factors underlying malignant transformation, invasion, and metastasis. Such models can also be used to examine the response to therapy.

1.2 Evolution of Cancer Modeling

The development of cancer models has gone through several increasingly complex phases, including human tumors-derived cell lines (Giard et al., 1973), xenograft tumors (Braakhuis et al., 1984), use of carcinogens, and genetically engineered cellular and animal models (Frese and Tuveson, 2007). The in vitro culture of human tumors made it possible to establish cell lines that retained the properties of the cancers of origin and paved the way toward a better understanding of the molecular pathogenesis of cancer. However, while a significant step, in vitro cell cultures were prone to genotypic and phenotypic drift during culture. The various disadvantages of this cancer model prevent us from studying processes,

such as angiogenesis and metastasis, thus necessitating more complex and accurate models to reproduce cancer biology.

Xenograft models enabled in vivo tumor research by the transplantation of human tumor cells into immuno-compromised mice, either under the skin or into the organ in which the tumor originated. The key advantage of xenograft models is that they address the complexity of genetic and epigenetic abnormalities in the tumor, which can be used to aid in the development of individualized molecular therapeutic approaches (Hidalgo et al., 2014; Siolas and Hannon, 2013). The limitation of xenograft models in immunocompromised mice is that they generate loss of the lymphocyte-mediated response to the tumor in the mouse host. The consequent change in tumor architecture alters the tumor microenvironment, thus preventing the study of the initial steps of carcinogenesis (Frese and Tuveson, 2007).

Environmentally induced cancer animal models develop specific tumors after exposure to a given carcinogen, such as chemicals, radiation, or even physical impact resulting in alterations and mutations that lead to uncontrolled cell growth (Kleinstreuer et al., 2013; Parsa, 2012; Rivina et al., 2014). The main limitation of these models is that they are restricted to a small number of cancer types and have incomplete penetrance.

The next complex stage in cancer modeling was the development of techniques that enabled stable modification of the genome, thus facilitating propagation through subsequent generations and the eventual creation of stable animal models. The most noteworthy techniques are transgenesis and gene targeting. Transgenesis is based on the introduction of foreign DNA into the host genome (Smith and Muller, 2013). The transgene is incorporated at a very early stage of embryogenesis so that cells of the entire organism contain the foreign DNA. There are several ways to introduce transgenes. Microinjection into the fertilized embryo is one of the most widely used and is typically applied to overexpress a gene. The main disadvantage of this technique is that it is impossible to control the insertion site and the number of copies that are inserted. In transgenesis, the transgene has to produce a dominant effect over the endogenous gene before it can manifest a phenotype. Gene targeting, on the other hand, alters the endogenous DNA sequence at a previously selected point. Originally, gene targeting was based on the use of a targeting construct containing target gene sequences to induce homologous recombination (HR) and specific modification, resulting in the introduction, inactivation, or mutation of a specific gene of interest (Thomas et al., 1986). This technique is more technically difficult than transgenesis and takes longer to perform. It is used to generate knockout (inactivation of a gene) and knockin (insertion or substitution of a DNA sequence).

1.3 Genome Engineering Technologies

Genome engineering technologies were first developed some decades ago. Using this approach, we can modify precise DNA sequences to study gene function and regulation of the genes involved in cancer through the generation of in vitro and in vivo models. As mentioned in the previous Section 1.2, traditional genome-engineered cancer models were generated using transgenes or HR in murine embryonic stem cells (mESCs) (Van Dyke and Jacks, 2002). In the early 1980s, specific genes were introduced into mESCs, which were then implanted into wild-type blastocysts, thus enabling transmission of genome modifications into the mouse germline to generate transgenic mouse models (Brinster et al., 1981; Harbers et al., 1981; Wagner et al., 1981). The first transgenic cancer models appeared in 1984, when brain tumors were reproduced by delivering the SV40 T-antigen viral oncogene into mouse eggs (Brinster et al., 1984). The second type of induced tumors were tumors resembling human breast cancer, which were created by replacing the mouse *Myc* gene promoter with a hormonally inducible mouse mammary tumor virus promoter (Stewart et al., 1984). In 1986, Capecchi and Smithies, the pioneers of gene modification, developed the technology to modify the genome of mESCs by HR (Smithies et al., 1985; Thomas and Capecchi, 1986; Thomas et al., 1986). This development paved the way for various genome-engineered mouse models (GEMMs) of cancer by inducing precise alterations, leading to gain-of-function (GOF) mutations in oncogenes, and loss-of-function (LOF) mutations in TSGs. The generation of transgenic mice by HR was limited by the need for complex targeting, low efficiency, and the time required for the generation of a mouse with the desired modification (Frese and Tuveson, 2007).

Subsequent HR technology merged with site-specific recombinases (Cre and Flp), resulting in the generation of conditional alleles of numerous cancer genes (Orban et al., 1992; Shibata et al., 1997; Smith et al., 1995). Cre recombinase recognizes two pairs of *loxP* sites, whereas Flp recognizes *FRT* sites, thus leading to reciprocal recombination of specific DNA sequences. On the other hand, numerous transgenic mouse models have been generated by overexpression of cDNA or gene knockdown by RNA interference (RNAi). RNAi technology was used widely for over a decade because it is an easy, rapid, and inexpensive approach to silencing genes (Tavernarakis et al., 2000). However, it is limited by its potential aberrant and artifactual effects, which in turn generate off-target effects (Jackson et al., 2003). Gene knockdown is usually partial and temporary.

Methods that artificially increased gene targeting were developed. These methods were based on the observation that the occurrence of a double-strand break (DSB) in the targeted region dramatically increases

gene-targeting efficiency (Jasin, 1996; Rouet et al., 1994). First, in the mid-1990s, restriction endonuclease I-SceI from *Saccharomyces cerevisiae* was used to induce breaks, thus demonstrating that the generation of controlled DSBs increases targeted HR (Choulika et al., 1995). Subsequently, tools for genome engineering based on site-specific endonucleases were developed; these included zinc-finger nucleases (ZFN) (Bibikova et al., 2003), transcriptor activator-like effector nucleases (TALENs) (Christian et al., 2010), and clustered regularly interspaced short palindromic repeats (CRISPRs) (Jinek et al., 2012). All three methods, which are described in detail later, have revolutionized the study of cancer biology, especially cancer modeling (Torres-Ruiz and Rodriguez Perales, 2015). The use of ZFN and TALEN technologies is limited owing to their problematic design and elevated cost; however, the development of CRISPR systems offers a rapid and easy method for modification of single or multiple loci that overcomes the limitations of previous genome engineering tools, thus facilitating the rapid generation of cancer models.

1.4 Site-Specific Endonuclease Techniques

Genome engineering tools make it possible to edit target genome sequences by adding, replacing, or removing DNA bases. Genome editing relies on the creation of DSBs in DNA, which cells attempt to repair via the homology-directed repair (HDR) pathway or by the error-prone nonhomologous-end joining (NHEJ) (Fig. 34.1A). The NHEJ pathway involves the alignment of one to a few (at most) complementary bases for the religation of two ends to repair the break without a homologous template. This step leads to small insertions and/or deletions (indels) at the repaired locus and therefore generates frameshift mutations that often result in gene disruption and inactivation (Honma et al., 2007). Alternatively, and less frequently, the break can be repaired through the HDR pathway, which is a more accurate mechanism that requires a homologous donor DNA template to guide repair. The HDR pathway has higher fidelity, because the DNA template assists in the repair process, which can be exploited to introduce a precise mutation into the damaged DNA when genetically modified DNA templates are used (Kim and Kim, 2014).

Gene editing methods that exploit the repair mechanism of the cell (ZNFs, TALENs, and CRISPRs) make it possible to directly manipulate the genome of many different species, including bacteria, plants, fishes, and mammals.

1.4.1 ZFNs and TALENs

ZFNs were the first genome-editing tool to use customizable endonucleases. A ZFN is a heterodimer composed of a zinc finger (ZF) domain that binds to DNA and is fused with a cleavage domain (FokI) (Wood et al., 2011). ZF domains are protein modules that recognize sequences of three nucleotides and can be manipulated modularly and designed to direct binding to a specific DNA sequence. Fusion of ZF with FokI nuclease can bind specific sequences and produce the DSB (Fig. 34.1B). Initially, this protein assembly module recognized an 18-bp sequence that was unique in the genome. This base was subsequently modified to recognize sequences measuring 24 bp and longer (Kim et al., 2009). Although ZFN technology allows scientists to make changes at a specific genomic locus, it is difficult to use, and the targeting of new genomic sites requires the creation of new ZF proteins, which is time consuming and expensive.

TALEN technology was developed 15 years after the discovery of ZFNs. TALENs are dimeric nucleases that were originally characterized in *Xanthomonas* bacteria (Richter et al., 2016). Custom sequences of TALENs can be generated to recognize unique genomic sequences and generate cohesive-ended DSBs. The principal difference between ZNFs and TALENs is that TALENs contain an array of conserved protein motifs (33 or 34 amino acids) that differ only at positions 12 and 13, the so-called repeat variable diresidues, which define the DNA-binding specificity of each TALEN module (Fig. 34.1B). Like ZFNs, modular TALEN repeats are linked together to recognize a specific DNA target sequence. The discovery of the DNA recognition code facilitated the prediction and assembly of TALEN DNA-binding domains and led this method to be more widely used by researchers than ZFN (Li et al., 2011). However, although TALENs represented a significant improvement over ZFNs, the modular nature of TALEN techniques makes working with them complicated and difficult.

The ZFN and TALEN platforms enabled us to control gene expression in a more refined way than simple knockdown (Boettcher and McManus, 2015) and have facilitated efficient modification in transformed and primary cells, as well as in animal models that were previously thought to be beyond the scope of such targeted genetic manipulation (Cui et al., 2011; Frank et al., 2013; Hisamatsu et al., 2015; Ochiai et al., 2010). However, both systems present difficulties and practical limitations, namely, laborious protein engineering and the need for selectable markers, which affect targeting efficiency. The newer CRISPR-Cas9 platform overcomes these limitations by providing a simple way to engineer target DNA breaks.

1.4.2 CRISPR-Cas9 System

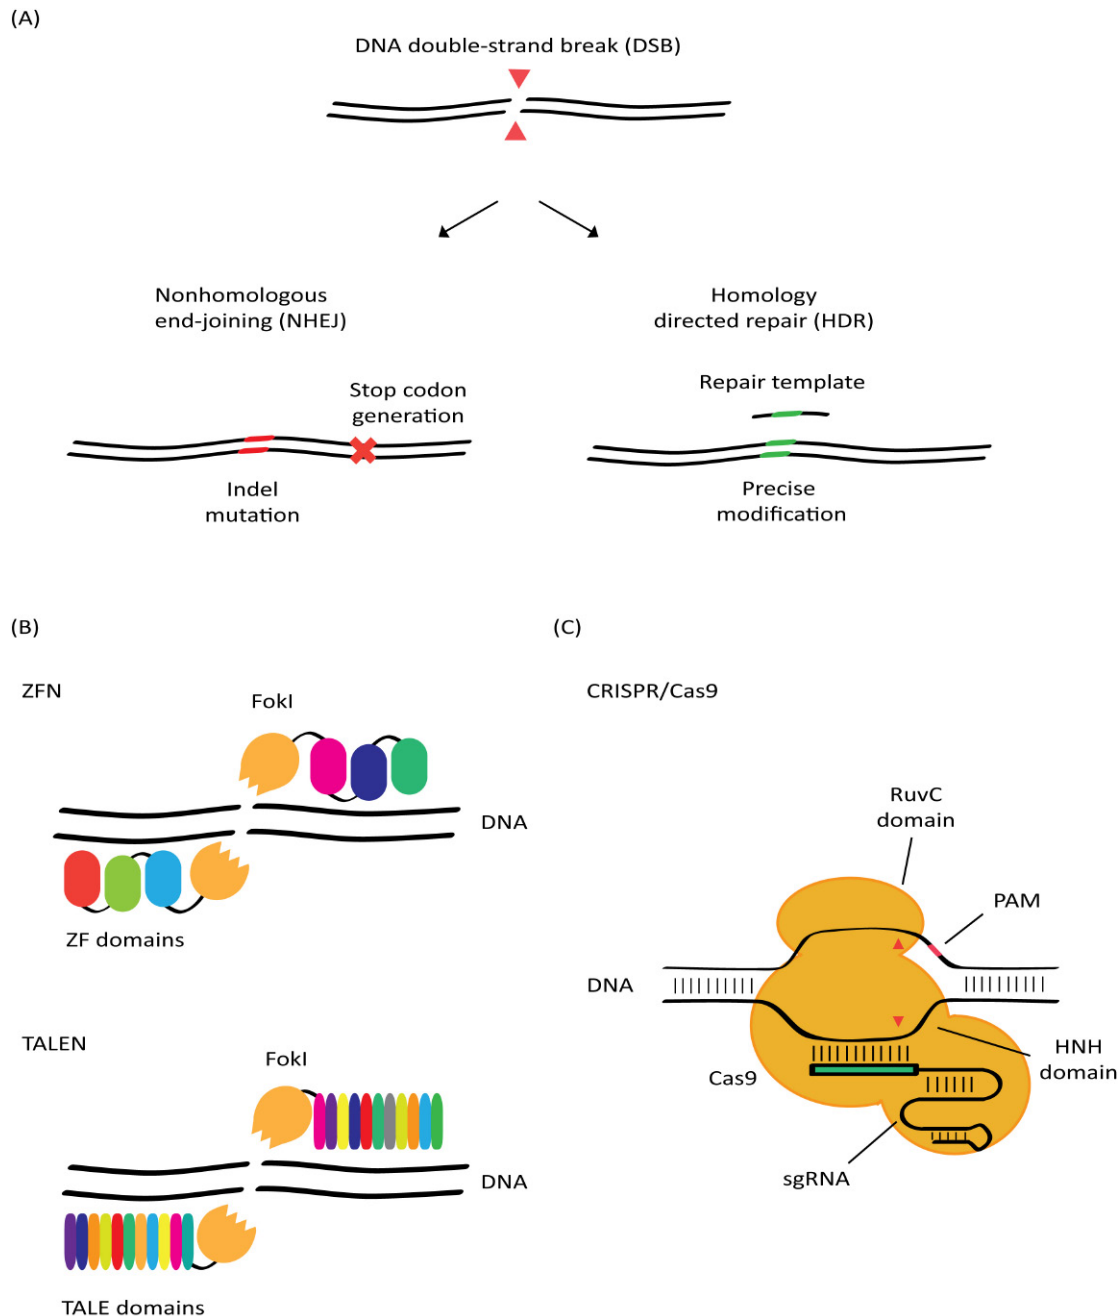
CRISPRs are short repetitions of DNA sequences present in many microorganisms, such as bacteria and Archaea. The CRISPR-Cas system is composed of CRISPR repeats and its associated Cas genes. It functions as an


FIGURE 34.1 **Double-strand break *(DSB)* repair machinery and its use by programmable nucleases.** (A) Endogenous DNA repair machinery uses two pathways to repair DSBs: nonhomologous end-joining *(NHEJ)* and homology-directed repair *(HDR)*. (B) Zinc-finger nuclease *(ZFN)* and transcription activator-like effector nuclease *(TALENs)* are DNA-binding domains (colored boxes) that can be assembled as modules to recognize specific sequences (each module recognized 3 bp in the case of ZFNs and 1 bp in the case of TALENs). (C) The CRISPR-Cas9 system is composed of a nuclease (Cas9, orange), which targets specific DNA sequences through the guidance of an sgRNA (green box and linked loops) thanks to the recognition of a PAM sequence (red box). The Cas9 nuclease has two active domains, namely, RuvC and HNH.

adaptive immune system in prokaryotes through the use of RNA-guided nucleases (Cas proteins) and recognizes and targets invasive genetic elements (Barrangou et al., 2007). Once this phase is complete, the ssRNA-Cas ribonucleoprotein complex (RNP) binds to the foreign DNA to produce a DSB that marks this DNA for degradation (Doudna and Charpentier, 2014; Sashital et al., 2012). Recently, the bacterial CRISPR-Cas system was used to create new genome engineering technology, namely, CRISPR-Cas9, which is now a widely used genome-editing tool owing to is simplicity, efficiency, and multiple applications.

The CRISPR-Cas9 system consists of two principal elements, a short synthetic single guide RNA (sgRNA) that fuses crRNA (CRISPR RNA) and tracrRNA (*trans*-activating crRNA) and the Cas9 protein. crRNA contains the named protospacer element (which gives the system the ability to target a specific genomic location) (Jinek et al., 2012), tracrRNA (which acts as a linker between the crRNA and the nuclease to fuse both elements and activate the system) (Jinek et al., 2012), and the Cas9 protein (which behaves like a nuclease producing the DSB at the DNA level) (Marraffini and Sontheimer, 2010) (Fig. 34.1C). The activated RNP complex is directed by the sgRNA to a specific genomic location of interest upstream from a protospacer adjacent motif (PAM) sequence, which consists of an NGG or NAG trinucleotide [the general PAM sequence for *Streptococcus pyogenes* although this may differ depending on the Cas9 species being used (Chylinski et al., 2013)]. By designing an sgRNA we can target a specific DNA region. Once in the cell, the sgRNA forms a complex with the Cas9 endonuclease and guides the complex to the target region. Cas9 nuclease generates blunt-ended DSB three nucleotides upstream of the PAM sequence, thus stimulating activation of the cell repair machinery (NHEJ and/or HDR pathways).

The advantage of the CRISPR-Cas9 system over ZFNs and TALENs is that CRISPR does not depend on protein engineering and requires no more than an accurately designed sgRNA that binds correctly to the target DNA directed by the Cas9 protein. New loci can be targeted by designing and synthesizing 20 new nucleotides of sgRNA that bind to the sequence of interest. Therefore, CRISPR-Cas9 is a genome-editing tool that is able to generate easy, fast, and effective cancer models (Sánchez-Rivera and Jacks, 2015; Torres-Ruiz and Rodriguez Perales, 2015).

1.4.3 CRISPR Applications

Several CRISPR-Cas9 system modifications have been adopted in genome-editing protocols. These include nickase Cas9 (Cas9D10A or Cas9H840A), dead Cas9 (dCas9), sgRNA scaffolds, RNA-targeting Cas9 (RCas9), and dead RCas9 (dRCas9), all of which are applied differently in cancer modeling (Wen et al., 2016).

1.4.3.1 DUAL NICKASE Cas9 SYSTEM

Native or wild-type Cas9 nuclease is composed of two catalytic domains, HNH and RuvC, each of which cuts a strand of the target DNA. Cong et al. (2013) developed a Cas9 mutant nickase form (Cas9D10A and Cas9H840A) that only contains one active catalytic domain. Cas9 nickases still bind DNA based on sgRNA specificity but are only able to cleave one DNA strand (to produce nicks). DNA nicks are usually repaired by the HDR pathway using an intact complementary DNA strand as a

template (either endogenous or supplied exogenously). This CRISPR variant dramatically increases target specificity and reduces off-target effects, thus making it the tool of choice for specific gene editing approaches (Liu et al., 2016).

1.4.3.2 DEAD Cas9 (DCas9)

The Cas9 variant dCas9 is generated by inactivation of both catalytic domains (D10A for HNH and H840A for RuvC in *S. pyogenes* Cas9) so that it still binds to DNA based on sgRNA specificity but is not able to cleave the DNA (Maeder et al., 2013). This variant has several applications, such as regulation of endogenous gene expression by the fusion of dCas9 with effector domains either to activate or to repress gene expression. When dCas9 is fused to a repressor domain, the approach is called CRISPRi (gene silencing), and when it is fused to an activation domain, it is called CRISPRa (gene activation) (Dominguez et al., 2016). dCas9 is also used as an epigenetic modulator through the fusion of dCas9 with epigenetic modifiers (Panda et al., 2013; Thakore et al., 2016). dCas9 can even be used for in vivo imaging when fused to a fluorescent protein and in live cells for targeting specific genomic loci (Chen et al., 2013; Deng et al., 2015). The aforementioned variants make it possible to study specific genes through their activation and repression in cancer models or even variations in architecture during tumorigenesis (Falahi et al., 2015).

1.4.3.3 sgRNA SCAFFOLD (scRNA)

sgRNA scaffolds consist of amplification of the 3′ end of the sgRNA with modular RNA domains that recruit RNA-binding proteins. The function of this variant is to physically link DNA binding and protein recruitment through scRNA. sgRNA scaffolds enable multidirectional regulation and simultaneous repression and activation of several target genes as part of the same regulatory program (Zalatan et al., 2015). Combining scRNA with dCas9 increases the efficiency of regulation, thus making it a good tool for functional investigation at genome level. It can also be applied for screening studies and has proven very useful for the study of regulation in cancer epigenetics (Konermann et al., 2015).

1.4.3.4 RCas9 AND DRCas9

CRISPR-Cas9 recognizes target DNA through sgRNA although the presence of the PAM sequence on the opposite strand is necessary. An alternative strategy that is also able to target a single strand has been generated to enable targeting of RNAs. This approach consists of an exogenous strand of nucleotides containing the PAM sequence, which acts as an opposite strand. Thus, the CRISPR-Cas9 system has been modified so that it can be used as a tool for cleavage of ssRNA (RCas9) (O'Connell et al., 2014). Similar to dCas9, the RCas9 protein has also
FIGURE 34.2   **Main applications of CRISPR-Cas9 in animal cancer models.**

been modified by inactivating its catalytic domain to obtain dRCas9, which can also be fused to effectors. This approach is useful for the study of splicing regulation and the cancer transcriptome.

The CRISPR-Cas9 system enables any desired modification when we want to model or interrogate a specific cancer system, from genome editing (using the wild-type or nickase variants) to the more complex modulation of transcription levels (dCas9 fused to KRAB or VP64 domains) or even for visualization through various cellular stages during development, malignization, or differentiation (dCas9-eGFP). This methodology is not restricted to modeling, but has also been considered in clinical scenarios (Valletta et al., 2015) (Fig. 34.2).

2 GENERATION OF CRISPR CANCER MODELS

The vast majority of cancers rely on a precise scenario that is not only dependent on a specific genomic alteration, but that also needs to take place in a particular context, that is, in a specific cell type or developmental stage or in combination with several other alterations (Hutmacher et al., 2009; Thakur et al., 2014). As explained in the previous section, many different approaches have been applied to model this complex scenario, with different success rates. During the last 4 years, the CRISPR-Cas9 system has revolutionized the field because of its high efficiency, ease of use, and fast and streamlined applicability. Therefore, it has replaced previously available tools in routine laboratory work, and its application in clinical practice is now becoming a reality (Yin et al., 2016). Consequently, it is the best choice for experts and nonspecialists alike.

2.1 In Vitro Cancer Models

All cancers share a common feature, that is, the generation of de novo genome alterations. These changes are not only restricted to specific point mutations but can also be small deletions, inversions, and duplications, and even large chromosomal rearrangements. The alterations lead to activation of oncogenes, inactivation of TSGs, and alteration of genes involved in DNA repair mechanisms (Krogan et al., 2015). In this section, we summarize the CRISPR-Cas9-based in vitro cancer models generated during the past few years.

2.1.1 Modeling Targeted Mutations In Vitro

Advances in genome sequencing technologies (Girotti et al., 2016) have enabled the discovery of a huge number of specific genetic alterations in human tumors (Vogelstein et al., 2013). To translate all this knowledge into clinical practice, functional studies must be carried out to analyze the role of the alterations in cancer biology. Several groups have edited specific genes, either in cells and animals through the multiple available applications of the versatile CRISPR-Cas9 system, which uses DNA plasmid, viral vectors, mRNA, or protein–RNA complexes to introduce the CRISPR components into the target cell (Kouranova et al., 2016; Liang et al., 2015; Lin et al., 2014; Malina et al., 2013; Nelson and Gersbach, 2016).

One of the first studies to induce targeted genome modification in somatic cells used the CRISPR-Cas9 system in combination with a classic short hairpin RNA (shRNA) approach for the study of leukemogenesis involving a deletion in the long arm of chromosome (7q) (Chen et al., 2014). Disruption in mouse hematopoietic stem cells (mHSPC) of the Mll3 gene, localized in the chromosome 7q, in a specific background (defective for ΔNf1 and Δp53) revealed that this disruption was able to induce a leukemogenic process and also that leukemic cells were heterozygous for the Mll3 gene alteration (thus indicating an unseen mechanism). The authors demonstrated that Mll3 inactivation is tolerated in leukemia cells only when present in a partial dosage, therefore the authors hypothesized that Mll3 is a haploinsufficient TSG acting as a second hit in many acute myeloid leukemia (AML) processes.

Shortly after this initial study, Antal et al. (2015) modified a previously established concept through the use of CRISPR-Cas9, demonstrating that mutations in protein kinase C (*PKC*) genes function as TSGs, thus leading to a switch in therapies from inhibition of PKC activity to restoration of PKC activity. In this case, the authors reestablished the function of the *PKC* gene in a patient-derived colon cancer cell line (DLD1) using genome engineering (via CRISPR-Cas9) in combination with single-stranded oligodeoxynucleotides (ssODNs). The effect of the correction was plausible in a xenograft model, where the tumor size was reduced after the function of the protein was restored, thus demonstrating that the *PKC* mutation confers an anchorage-independent growth advantage in this specific tumor environment and that it has a tumor-suppressive function.

One of the main characteristics of the CRISPR-Cas9 system is its multiplexing ability, which enables it to target several genes in one experiment. Consequently, primary healthy cells, patient-derived cell lines, and well-established cancer cell lines could be modified to carry several mutations. This fundamental advantage of the CRISPR system is of special interest in cancer modeling, since it enables the induction of multiple cooperating mutations, including driving and secondary events. It also facilitates analysis of several combinations of parameters, thus enriching potential results and even leading to the discovery of new variants that shed light on drug discovery screenings. One of the first studies that reported this use was from Ebert and colleagues (Heckl et al., 2014), who took advantage of the viral delivery of the CRISPR components into mHSPC to modify in a single step eight genes (*Tet2, Runx1, Dnmt3, Ezh2, Nf1, Smc3, p53*, and *Asxl1*) frequently affected in patients with AML in combination with an *Flt3* internal tandem duplication (ITD). The *Flt3*-ITD, which is found in many types of leukemia, is insufficient to drive tumorigenesis by itself. The authors demonstrated that mimicking the genetic combinations led to myeloid clonal expansion and transformation to AML, as reported for AML patients. Another major study that took advantage of the system's multiplexing ability was that of Sato and colleagues (Matano et al., 2015), who used a cellular model of human intestinal organoids to mimic colorectal cancer. The authors modeled five mutations both in oncogenes (*KRAS* and *PIK3CA*) and in TSGs (*SMAD4, TP53*, and

APC), which promote niche signal independence. They created LOF mutations in the TSGs, in combination with a knockin strategy using ssODNs to generate specific mutations in *KRAS* (G12V) and in *PIK3CA* (E545K). The desired mutant organoids were obtained using a selection procedure based on an independent growth advantage in culture media lacking specific required factors (for human normal colon cells) (Sato et al., 2011). This system enabled the authors to obtain single cell clones with a different mutational background that recapitulated the transition to adenocarcinoma.

2.1.2 Chromosomal Rearrangements Generated In Vitro

Many tumors are characterized by the presence of specific and recurrent chromosomal rearrangements (deletions, inversions, and translocations). These alterations are often the event that triggers tumorigenesis. The feature common to genome rearrangements is that is that they arise from the cooccurrence of two DSBs in the genomic DNA of a cell. As explained previously, once the DSBs are generated, the cell tries to repair the broken ends using either NHEJ or HDR repair mechanisms. However, the incorrect repair can sometimes spontaneously generate a chromosomal rearrangement (Stratton et al., 2009). Historically, the study of chromosomal rearrangements relied on the use of transgenes or cell lines from patients harboring the mutation/alteration, which, while of invaluable importance, are not the most accurate systems. Genome engineering tools in general, and the CRISPR-Cas9 system in particular, provide us with the opportunity to modify a healthy cell to generate an isogenic counterpart (Liu et al., 2005; Torrance et al., 2001) that differs only in the specific alteration generated and is not affected by possible variegation or positional effects or by the number of copies inserted (Voigt et al., 2008). Consequently, several groups rapidly adapted the system to mimic large rearrangements (including translocations, inversions, and deletions) in cellular models with the aim of recapitulating the primary oncogenic event in a more physiological environment (Torres et al., 2014; Torres-Ruiz and Rodriguez Perales, 2015).

The induction of chromosomal rearrangements requires two different sgRNAs that target both loci involved in the rearrangement to induce two DSBs, which would subsequently be repaired by the NHEJ cell pathway, thus sometimes creating the desired rearrangement. However, the efficiency of this approach varies greatly, mainly because various sgRNAs are used and these target several genomic locations with varying 3D genome structures and accessibility (Jiang et al., 2016). In their pioneering study, Torres et al. (2014) reproduced the t(11;22)(q24;q12) chromosomal translocation, which is characteristic of Ewing sarcoma and leads to the generation of the *EWSR1–FLI1* fusion gene. The authors

were able to induce the t(11;22) translocation in two different cell models, namely, human embryonic kidney cell line (HEK293) and human primary mesenchymal stem cells (hMSC). The newly generated chimeric transcription factor *EWSR1-FLI1* was able to transactivate specific genes described as downstream targets of the fusion protein in human tumors (Cidre-Aranaz and Alonso, 2015), thus confirming that the activity of the fusion protein generated by the CRISPR system was similar to that observed in the patient's cancer cells. The authors also demonstrated the universalization of the approach by recapitulating the AML characteristic t(8;21)(q22;q22)/RUNX1-ETO chromosomal translocation in HEK293 and CD34+ human hematopoietic stem progenitor cells (hHSPCs). Choi and Meyerson (2014) described the recreation of three chromosomal rearrangements in human lung cancer. The three alterations—the t(5;6)(q32;q22)/CD74/ROS1 chromosomal translocations, the inv(2)(p21;p23)/EML4/ALK paracentric inversion, and the inv(10)(p11;q11)/KIF5B/RET pericentric inversion—were generated in HEK293 and in nontransformed immortalized lung epithelial (AALE) cells. Taken together, the results of both studies demonstrated that CRISPR is a feasible tool for recreating chromosomal rearrangements; however, further refinement is necessary to facilitate appropriate recreation of the desired rearrangement. This issue is of critical importance when the cells that acquire the alteration do not possess any selective advantage with respect to their counterpart. Alternative selection approaches that could be used to enrich the target cells include the use of a specific membrane marker activated by the oncogenic protein, selection of cells based on changes in cellular morphology, and any other procedure that could lead to a specific trackable change.

Beyond chromosomal translocations and inversions, specific deletions had been carried out in noncoding regions, enhancers (Avellino et al., 2016), and promoter sequences (Chiba et al., 2015). Genome engineering is a feasible tool for recreating chromosomal rearrangements although this ability is dependent on the localization of the breakpoints, thus demonstrating that efficiency decreases as distance increases (Coppoolse et al., 2005; Schildkraut et al., 2005). Chiba et al. (2015) used two sgRNAs flanking the TERT promoter to model cancer-associated deletions in human embryonic stem cells (hESCs). The deletion induced by CRISPR leads to permanent expression of the telomerase gene, thus mimicking the levels observed in cancer cells and the length of the telomeres.

2.1.3 CRISPR-Cas9 In Vitro High-Throughput Genetic Screens

Functional genomics is an indispensable approach in the identification of gene function, especially when

genome-wide interrogation leads to changes in cellular phenotypes. One of the essential advantages of the CRISPR-Cas9 system is the option of interrogating gene function on a genome-wide scale. The simplicity of programming the CRISPR-Cas9 system suggested a new way to interrogate gene function on a genome-wide scale by the construction of large-scale oligosynthesis of sgRNA sequences. In 2014, Zhang et al. (Sanjana et al., 2014; Shalem et al., 2014) showed that lentiviral delivery of the genome-scale CRISPR knockout (GeCKO) library targeting 18,080 human genes can be used to interrogate gene function on a genome-wide scale, thus facilitating both positive and negative LOF screening in mammalian cells. Taken together with the need to validate drug targets in the drug screening process, this option made CRISPR-Cas9 a promising application in the field of cancer (Agrotis and Ketteler, 2015; Kasap et al., 2014). Through the generation of mutations that confer loss of function, Zhang et al. (Shalem et al., 2014) identified the involvement of several human genes in resistance to vemurafenib, a B-RAF enzyme inhibitor for the treatment of late-stage melanoma that promotes programmed cell death (Sala et al., 2008). The GeCKO library makes it possible to validate both previously reported genes and nonreported genes. In another study, Zhang et al. (Konermann et al., 2015) used a specific variation of the previous library. This variation consisted of GOF through synergistic activation mediators targeting all human coding genes to screen for genes that, upon activation, confer resistance to vemurafenib. As with the previous study, the authors were able to identify novel candidate genes that confer resistance to the drug.

Furthermore, this strategy has been used to interrogate genes involved in metastatic progression. Zhang and Sharp (Chen et al., 2015b) used the GeCKO library to systematically screen genes involved in metastasis in a murine nonmetastatic nonsmall-cell lung cancer cell line. The mutant cell pools were transplanted into mice and generated tumors. After deep sequencing of the metastatic tumors, a set of genes consistently represented in all of the tumors produced was found to be involved in tumor growth and metastasis.

2.2 In Vivo Cancer Models

Cancer displays a wide range of genetic and genomic modifications. Thus, research requires a variety of genomically complex animal models. Numerous GEMMs and nongermline GEMMs (nGEMMs) harboring precise mutations in TSGs and oncogenes have been generated. These models provide the scientific community with invaluable tools to study the biology of cancer and to decipher critical aspects of initiation, maintenance, and progression of the disease. They are also excellent tools for the study of drug resistance (Chen et al., 2012;

Engelman et al., 2008) and for testing new compounds and treatment approaches. Traditional approaches to generate GEMMs require complex molecular protocols, manipulation, and extensive animal husbandry. They are therefore laborious, time consuming, and expensive. nGEMMs can simplify this process because traditional approaches are not able to simultaneously introduce several genetic modifications in adult animals or mESCs (Table 34.1).

Until the advent of CRISPR-based precise genome editing, mouse models of malignancies were based on a limited number of mutations or genes (Guerra et al., 2003; Jackson et al., 2001). The CRISPR-Cas9 system enabled the systematic generation of models harboring alterations in multiple genes, thus making it possible to study collaborative effects in tumor progression or therapeutic resistance or response. The system thus facilitated the combined rapid analysis of multiple mutations in human patients and the subsequent generation of GEMMs and nGEMMs. In 2013, two studies demonstrated the ease, speed, and flexibility with which it was possible to generate multiple GOF or LOF mutations in mice using the CRISPR-Cas9 system, thus considerably increasing the speed and precision with which distinct genotypes can be generated in animals to model human cancer. Taking advantage of the potential for multiplexed genome editing of the CRISPR system, Jaenisch et al. (Wang et al., 2013) demonstrated simultaneous one-step generation of double *Tet1* and *Tet2* knockout mice with a 80% of efficiency. Cas9 mRNAs and sgRNAs were coinjected to target *Tet1* and *Tet2* in mouse zygotes, obtaining mutations in those alleles in mice. The authors also coinjected Cas9 mRNA, sgRNAs, and an ssODN into mouse zygotes to engineer double HDR-mediated edition of two endogenous genes (*Tet1* and *Tet2*) in mouse models. The same group subsequently used CRISPR components and a DNA template to generate mice carrying a tag or a fluorescent reporter construct in the *Nanog*, *Sox2*, and *Oct4* genes, as well as in *Mecp2* conditional mutant mice. The authors also used a pair of sgRNAs to generate mice carrying small Mecp2 gene deletions (Yang et al., 2013).

The CRISPR-Cas9 system can also be used to refine existing models of cancer. It enables reedition of previously established GEMMs to induce additional modifications and study the cooperative effects of several candidate target genes in vivo (Dow and Lowe, 2012). This new model better represents the genetic heterogeneity of human cancer. In the near future, it will be possible to generate in vivo models capable of reproducing the specific alterations found in an individual patient that can be used as a platform to select the most effective therapy. With CRISPR-Cas9 technology, the time necessary to generate genetically engineered mice is reduced from about a year to several weeks.

2.2.1 Manipulating Germlines to Generate Transgenic Animal Models

CRISPR-Cas9-based technologies can be used to manipulate germline for generation of transgenic animal models (Wang et al., 2013; Yang et al., 2013). Moreover, the two components of CRISPR-Cas9 (Cas9 nuclease and sgRNA) can be used separately to generate transgenic animal models. Platt et al. (2014) constructed Cre-dependent Cas9 knockin mice by targeting the Cas9 gene driven by the CAG promoter interrupted by the *loxP*-stop-*loxP* (LSL) cassette, which had been introduced at the *Rosa26* locus in mESC. Crossing this mouse line with a constitutive Cre driver or tissue-specific Cre driver strain can generate offspring with constitutive or tissue-specific Cas9 expression, respectively. Using this mouse, Jacks et al. (Sánchez-Rivera et al., 2014) were able to model lung adenocarcinoma thanks to the mutation of three different genes implicated in human pathogenesis (*Kras*, *p53*, and *Lkb1*), thus demonstrating the synergistic power of cancer mouse models based on the CRISPR-Cas9 system.

2.2.2 In Vivo Somatic Genome Engineering

Besides generating animal models through germline manipulation, the CRISPR-Cas9 system has the unprecedented ability to engineer the genome of adult animal models through somatic edition, thus enabling it to sidestep germline manipulation and animal crossbreeding. Somatic gene transfer approaches make it possible to restrict the induction of genomic alterations to tumor-forming cells, resulting in a tumor that closely resembles that of the patient. To date, several alternatives have been explored for delivery of CRISPR-Cas9 tools to a target organ. The methodological features of the delivery approaches should be taken into consideration to achieve effective cancer modeling. Some of these delivery approaches are presented in subsequent sections.

2.2.2.1 HYDRODYNAMIC GENE TRANSFER

The first cancer model based on in vivo somatic mutations was reported by Jacks (Xue et al., 2014), who used hydrodynamic gene transfer to engineer *Pten* and *Trp53* in mouse hepatocytes, thus creating LOF mutations in hepatocytes of adult wild-type mice. This in vivo gene-targeting approach uses rapid injection of controlled hydrodynamic pressure into the capillaries of a relatively large volume of DNA solution to enhance endothelial and parenchymal cell permeability. Carcinogenic CC14-induced liver tumors combined with edition of *Pten* and *Trp53* by the injection of a plasmid to express sgRNAs and Cas9 nuclease in the livers of mice made it possible to reproduce the characteristics of other models generated using classic approaches, thus indicating the feasibility of this approach. In vivo functional validation of liver cancer TSGs was achieved by

exploiting the efficacy of hydrodynamic gene transfer for the liver (Weber et al., 2015). Based on a multiplex combination of sgRNAs to target several TSGs discovered by deep sequencing of human tumors, the authors of the study used Alb-Cre/Kras$^{LSL-G12D/+}$ tumor-prone mice to analyze whether the putative TSGs play a role in the development of liver tumors. A GOF mutation in the β-catenin gene has also been obtained in the livers of adult wild-type mice. Xue et al. (2014) constructed a plasmid containing Cas9, sgRNA targeting β-catenin, and an ssODN donor bearing GOF mutations for the β-catenin gene. The plasmid was delivered into adult mice via hydrodynamic tail-vein injection, leading to accumulation of β-catenin in the nuclei of liver cells. Thus, hydrodynamic gene transfer, although potentially resulting in delivery to many organs (Liu et al., 1999), is a simple, efficient, and versatile method for delivering liver tumor cells.

2.2.2.2 VIRAL DELIVERY OF CRISPR-Cas9 COMPONENTS

The development of the CRISPR-Cas9 system as a genome engineering tool for biotechnological use was quickly followed by the development of viral vectors for delivery of CRISPR components, initially as single modification tools (Ebina et al., 2013; Malina et al., 2013) and subsequently with the aim of generating genome-wide screening (as reported in the Section 2.1.3) (Kabadi et al., 2014; Koike-Yusa et al., 2014; Shalem et al., 2014; Wang et al., 2014; Zhou et al., 2014). Although Cas9 is a large gene (4.1 kb), it can be packed efficiently into lentiviral particles (Holkers et al., 2013); however, it barely fits into recombinant adeno-associated virus (AAV) particles. While viral delivery of CRISPR components paved the way for the edition of poorly transfectable cells in vitro, a more important aspect of this approach is its ability to render somatic gene transfer accessible for in vivo edition experiments.

The applicability of delivering CRISPR components by viral vectors was first demonstrated by Zhang and Sharp (Platt et al., 2014), who developed a Cre-inducible Cas9 mouse based on a Lox-Stop-Lox (LSL)-Cas9 knockin strategy. First, the authors demonstrated that constitutive expression of the Cas9 nuclease using a ubiquitous promoter did not produce abnormalities. Platt et al. used AAVs to mediate expression of Cre recombinase together with an sgRNA targeting the *Rbfox3* gene by injection in the cortex of LSL-Cas9 mice. Three weeks later, deep sequencing of the *Rbfox3* gene revealed formation of indels in the injected region, and Western blot showed depletion of the protein. Zhang and Sharp (Platt et al., 2014) generated the first cancer disease model based on intratracheal delivery of AAVs encoding the CRISPR components to generate *Lkb1* and *Trp53* LOF mutations, specific activating mutation

in *Kras*, and Cre recombinase in LSL-Cas9 mice. Two months after inoculation, the simultaneous pulmonary delivery of AAVs carrying a multicistronic cassette led to deep penetrating lung adenocarcinoma in adult mice. Simultaneous disruption of *Lkb1* and *Trp53* and edition of *Kras* was achieved in a single step. As expected, the authors reported a high frequency of indels at the *Lkb1* and *Trp53* loci although *Kras* displayed an inefficient mutation rate.

Lentivirus delivery has also been used to show the ability of CRISPR-Cas9 to induce oncogenic chromosomal rearrangements in adult mice. Maddalo et al. (2014) and Blasco et al. (2014) reported the successful induction in vivo of Eml4-Alk inversion that is frequently found in human lung cancer. Blasco et al. used lentiviral somatic gene transfer by intrapulmonary inoculation into *Trp53*$^{+/-}$ or *Trp53*$^{-/-}$ murine lungs and generation of inversion rearrangements, thus creating the Emlk4-Alk fusion gene and forming lung tumors in all the mice. The authors demonstrated that intratracheal or intrapulmonary inoculation of lentiviruses was able to induce the *Eml4-Alk* rearrangement in lung cells in vivo.

Jacks (Sánchez-Rivera et al., 2014) used a lentivirus-based vector to express sgRNA together with Cas9 and Cre recombinase in p53$^{fl/fl}$ mice. The authors targeted *Nkx2.1* and *Pten* and found that not all of the lung tumors displayed complete loss of expression of the targeted genes.

Adenoviruses have been used to model large oncogenic chromosomal rearrangements (Maddalo et al., 2014; Shaw et al., 2013; Soda et al., 2007). In contrast to lentiviral vectors, which are integrated in the genome, adenoviruses only lead to transient expression. The use of adenoviral vectors to express CRISPR components reduces the probability of potential off-site cleavage associated with continuous expression. Maddalo et al. used adenoviral delivery of dual expression cassettes encoding both Cas9 and sgRNAs to induce *Eml4-Alk* gene fusion via intrachromosomal inversion. Eight weeks later, all the mice developed lung cancer with features similar to those of ALK+ lung cancer in human patients.

The results of these reports demonstrate the utility and illustrate the variety of currently available approaches, which range from all-in-one vector systems to single or multiple sgRNA delivery by AAVs. The examples presented previously demonstrate that CRISPR-Cas9 is an accurate and efficient platform for inducing combinational or sequential gene edition in adult mice, thus making it possible to model the complex scenario of the cancer process defined by the multistep and somatic nature of oncogenic mutations. Various aspects need to be taken into account before choosing the CRISPR delivery system, including limits in vector packaging size, distribution throughout the tissue (Kumar et al., 2001; Parr-Brownlie et al., 2015; Wu et al., 2010), and choice of serotype for promotion of preferential transduction of specific cell populations (Michelfelder and Trepel, 2009).

2.2.2.3 NONVIRAL DELIVERY OF CRISPR-Cas9 COMPONENTS

Among the nonviral techniques for gene transfer, in vivo electroporation of plasmid DNA enables the introduction of DNA with a high efficiency in specific regions of the mouse brain in utero. Genes can be focally transfected into specific regions of the brain, such as the spinal cord (Saba et al., 2003), hindbrain (Kawauchi et al., 2006), cerebellum (Kawauchi and Saito, 2008; Konishi et al., 2004), diencephalon (Shimogori and Ogawa, 2008), and retina (Matsuda and Cepko, 2004). This approach provides the opportunity to induce different types of brain tumors at specific locations. In vivo electroporation has made it possible to deliver CRISPR components to the mouse brain in utero for cancer modeling (Chen et al., 2015a; Maresch et al., 2016; Zuckermann et al., 2015). In vivo electroporation of Cas9 and an sgRNA targeting *Ptch1* in the embryonic cerebellum was able to cause medulloblastoma (Zuckermann et al., 2015). In utero electroporation of the cerebral cortex to simultaneously deliver sgRNAs targeting *Trp53*, *Nf1*, and *Pten* induced mutations of all three genes and subsequently formation of glioblastoma (Zuckermann et al., 2015). The key issues in cancer modeling based on in utero electroporation include the limited number of transfected cells and the lack of specificity of the targeted cell types. Electroporation-based CRISPR gene editing has also been applied in abdominal organs to generate pancreatic cancer using multiplexed sgRNAs combined with constitutive activation of Kras signaling (Dean et al., 2003; Liu and Huang, 2002; Maresch et al., 2016). This approach offers the advantage of targeting specific regions within an organ, which could result in several different tumor types (Swartling et al., 2012; Zhao et al., 2015).

Nonviral delivery by cationic lipid has been used to deliver Cas9-sgRNAs RNPs (Platt et al., 2014; Zuris et al., 2015). Zuris et al. reported that common cationic lipid nucleic acid transfection reagents can deliver Cas9:sgRNA nuclease complexes into cultured human cells. Delivery of unmodified Cas9:sgRNA complexes resulted in highly efficient genome modification. Interestingly, the complex Cas9:sgRNA delivery approach is substantially more specific than DNA transfection.

These studies demonstrate the potential of rapidly generating mouse models of cancer via somatic genome engineering through different approaches for delivery of CRISPR components to a target organ. Future advances in delivery methods will allow highly efficient in vivo somatic genome engineering.

3 CHALLENGES AND SOLUTIONS

CRISPR-Cas9 has proven successful for modeling cancer. However, the approach is subject to technical limitations. One of the main challenges, both in vivo and in vitro, is delivery to the target cell, tissue, or animal. Many efforts have been made to make delivery more efficient and to broaden its applicability. The various animal models generated include plasmid microinjection (Horii et al., 2014; Mashiko et al., 2013), injection of mRNA into zygotes (Hashimoto and Takemoto, 2015), or porcine oocytes (Sato et al., 2015), and Cas9 RNP (Chen et al., 2016). Recent studies indicate that the RNP approach seems to be the best alternative when no vector trace is required and when the objective is to introduce mutations or generate edition in poorly transfectable cells (Kim et al., 2014). However, this approach is not adequate for delivery to target cells in a living organism or for generating tissue-specific in vivo models, basically owing to the limited efficiency for reaching the target cells. Therefore, a plausible alternative is the use of viral vectors (Chen and Gonçalves, 2016). Currently, the most attractive gene delivery vectors are AAVs, which are nonpathogenic human viruses that enable long-term transgene expression without genomic integration (Smith, 2008). Given the nature of their DNA, they can serve as a vehicle for Cas9 and also for template DNA to repair target cells (Platt et al., 2014; Swiech et al., 2015).

Initially, the main drawback of the CRISPR-Cas9 system was the induction of off-target mutations at sites that are highly homologous to on-target sites (Cho et al., 2014; Hsu et al., 2013; Wu et al., 2014). Off-target DNA cleavage can cause unwanted genetic changes and/or chromosomal rearrangements with unpredictable consequences (Cho et al., 2014). This limitation, which is a major concern in original in vitro studies, seems less relevant in vivo and has almost no importance in the generation of mouse models (Iyer et al., 2015). Nevertheless, the alternatives that have been developed to overcome these drawbacks include the following: (1) acting on sgRNA to modify its specificity by truncating sgRNA (trugRNA) (Fu et al., 2014) or optimizing the structure to increase efficiency and reduce mutagenesis at nontarget sites (Dang et al., 2015), (2) nickases, which cleave on only one strand and must be used in pairs, can be abolished off-target without comprising on-target cleavage (Ran et al., 2013), (3) regulation of the time at which the components are delivered (Dow et al., 2015; Lin et al., 2014) in order to reduce their availability and hence their duration of action. This approach can decrease the probability of generating nondesired DSBs (a seemingly trivial aspect is, however, of critical importance), (4) the quantity of CRISPR components delivered (some of the off-target effects have been shown to be due to the high quantity used) (Hsu et al., 2013; Kuscu et al., 2014; Pattanayak et al., 2013). This issue proved critical in the efficient generation of animal models and was addressed using an appropriate optimization procedure based on appropriate quantities in specific experimental settings (Ren et al., 2014). An additional way to minimize the CRISPR drawbacks is to realize an accurate design of the sgRNA/s. Several web-tools have been developed to that aim, facilitating the design and reducing the probability of undesired off-target effects (Table 34.2).

4 CONCLUDING REMARKS

An experiment based on the CRISPR-Cas9 system can be performed using only a plasmid to express the Cas9 nuclease and an sgRNA targeting a predefined locus. The CRISPR plasmid now costs around €60 or less, can be ordered online, and requires little specialist training. CRISPR enables researchers to engineer more animals in more complex ways and in a wider range of species. Jiahao Sha and colleagues (Niu et al., 2014) demonstrated how far human disease modeling can be taken: the authors used cynomolgus monkeys as a model species for studying human diseases. Until that moment, the application of monkeys in biomedical researches has been significantly hindered by the difficulties in producing animals that have been genetically modified at the desired target sites. The authors induced simultaneous disruption of two target genes (*Ppar-γ* and *Rag1*) using coinjection of Cas9 mRNA and sgRNAs into one-cell-stage embryos.

Although the application of CRISPR-Cas9 in cancer modeling to date has focused on edition of the genome, recreation of epigenetic and transcriptome aberrations could constitute a major approach for cancer modeling in the future. Researchers are hoping to integrate the new CRISPR-Cas9 tools to precisely manipulate the genome and epigenome in animal models. This approach could make it possible to reproduce and analyze—at least partially—the complexity of human cancer. For example, "epi-modeling" of cancer could be performed using epigenetic modifiers fused to dead Cas9 or recruited by scRNA. Such tools will reach the locus of interest and subsequently change the methylation state or mediate histone modification in a site-specific manner. These new approaches will not only improve our understanding of cancer biology, but could also facilitate translational biomedical science. CRISPR could pave the way for new therapeutic approaches and drug screening assays both in vitro and in vivo (Shi et al., 2015).

The rapid advances in CRISPR-Cas9 systems toward application for treatment of human diseases have given rise to the discussion of the ethical implications of this technology (Keener, 2015). In 2015, the first study on the use of CRISPR-Cas9 in human zygotes was published. Although these zygotes were unable to develop into viable embryos because they have one oocyte nucleus and two sperm nuclei, the study raised ethical alarms and led to a worldwide moratorium on genomic engineering of human germlines by both biologists and ethicists (Hurlbut, 2015). It was proposed that, instead of imposing a moratorium on the development of such a promising technology, dynamic guidelines involving society as a whole should be developed to run in parallel with scientific advances so that they can be established progressively (Committee on Science, Technology, and Law; Policy and Global Affairs; National Academies of Sciences, Engineering, and Medicine; and Olson, 2016). Before human germlines can be genetically engineered, appropriate control models are warranted for testing efficacy and safety to minimize collateral effects. Such models would include more accurate and sensitive tools to assess off-target events and mosaicism (Chan et al., 2015).

CRISPR-Cas9 is a groundbreaking technology. It heralds an era of changes, with potential application in therapeutics, disease modeling, and genetic studies. Efforts are already under way to develop CRISPR-Cas9-based treatments for cancers of all levels of genetic complexity. The challenge facing researchers today is to develop innovative technologies and improve the safety and efficacy of the new tools. CRISPR cancer models are revealing factors with wide-ranging implications for human cancers. The combination of such approaches with next-generation sequencing data provides us with an unprecedented opportunity to create powerful and more informative cellular and animal genetic models that enhance our understanding of human cancer. We believe that many of the applications of CRISPR-based genome engineering technology will help to decipher both intrinsic and microenvironmental cellular elements that play a role in oncogenesis, cancer progression, and metastasis and may even enable a cure for some cancers.

Glossary

Chromosomal rearrangements Chromosomal abnormalities where a chromosome's structure is reorganized through deletions, inversions, translocations, or duplications. Usually is produced by a break in both helices of the DNA followed by a rejoining of the ends of the broken area, leading to new genes.

Conditional alleles Alleles that are engineered to be expressed only in the presence of a second component.

Driver and passenger mutations Mutations that differ in the fact that driver mutations give a selective advantage to the cells to grow more than the neighboring cells, increasing its survival or reproduction. In cancer cells, there are a reduced number of driver mutations, while passenger mutations appear in large number in most of tumors and do not confer selective advantage to the cells.

DSB Cleaved generated in both strands of DNA that can be repaired by HR or NHEJ pathways.

GEMMs Transgenic models of mouse used as a tool in biomedical research. They are usually engineered to mutate cancer genes.

GOF mutations Mutations that generate a new function.

HDR A mechanism in cells to repair double-strand DNA breaks (DSBs) that uses a homology sequence to the break to repair the DNA. It can be used to modify the genome of different organism by inserting a DNA with the mutation.

Indels Mutations generated by the insertion or deletion of bases in the genome of an organism.

Knockin A genetically modified organism which has replaced a normal gene by an altered gene with a specific mutation

Knockout (KO) A genetically modified organism that lacks the expression of a particular gene.

LOF Mutations that generate the lost or reduction of a function.

NHEJ pathway process of DNA reparation without the need of a homologous template. It consists in the fact that after the generation of

the DSB, a nuclease processed the ends by its junction and ligation causing generally the lost and introduction of some bases.

Oncogene A gene that had the potential to cause cancer. These genes are abnormally activated by a mutation responsible for the transformation of a normal cell into cancer cells. These genes, before mutate are involved in normal growth and division of cells

Organoid Also known as miniorgan. It is a three-dimensional culture grows in vitro to mimics organ structure and function.

PAM A sequence of three nucleotides downstream of the DNA sequence targeted by Cas9 nuclease.

sgRNA A noncoding RNA composed of a region of 20 nt complementary to the genome, and a Cas9-binding region that guides the protein to perform the cut at a specific locus. sgRNA is a condensation of the crRNA y tracrRNA

ssODNs A set of nucleotides complementary to the target site used as template for the DSB repair by HDR. It presents homology arms on either side of the cut site.

TALENs An engineered restriction enzymes that can cut specific sequences of DNA. It is composed of a transcription activator-like proteins and FokI nuclease.

Transgenesis The introduction of foreign DNA into a genome, so that it remains stable hereditary and affects all cells.

TSG A gene involved in cell growth inhibiting excessive cell proliferation. Mutation in these genes can lead to cancer. It is also known as antioncogene.

Xenograft (also referred as patient-derived xenograft, PDX) A tissue graft or organ implantation of a species into a different one. For example, implantation of human tumor cells in a mouse.

ZFNs An engineered restriction enzymes composed of a ZF DNA-binding domain and a DNA cleavage domain (FockI). The ZF domain can be designed to join a specific region of genome. It facilitates targeted editing of the genome by creating DSBs.

Modeling Breast Cancer in Animals—Considerations for Prevention and Treatment Studies

JoEllen Welsh

Cancer Research Center, University at Albany, Albany, NY, United States

1 INTRODUCTION TO ANIMAL MODELS OF BREAST CANCER

In vivo models have long been an integral component of cancer research, with a long history of use in identifying carcinogens, testing preventive agents, and screening therapeutics. This chapter specifically focuses on animal models of breast cancer with a major emphasis on rodent models. Although neither mice nor rats spontaneously develop cancer at high frequency, numerous mutations (naturally occurring, chemically induced and/or genetically engineered) increase cancer incidence in specific strains (Anisimov et al., 2005; Cheon and Orsulic, 2011). Furthermore, immunodeficient rodents can serve as hosts for human cancer cells as xenografts, a model widely used for testing tumorigenicity and evaluating new therapeutics (Clarke, 1996; Mollard et al., 2011). Additional models include virally transmitted cancers, UV or ionizing radiation induced tumors, and cancers promoted by chronic hormone treatments. Each model has advantages and disadvantages, and the specific choice will depend on the type of breast cancer being studied, as well as the specific questions being addressed by the research. Most of the models discussed have been well characterized and are widely available. In the case of heterogeneous cancers like breast, certain models more closely mimic specific subtypes or stages of the human disease. To provide a basis for understanding these diverse models, the biology and heterogeneity of human breast cancer are briefly reviewed prior to discussion of the specific experimental approaches.

2 CONCEPTS OF BREAST CANCER BIOLOGY

2.1 Incidence and Risk Factors

According to the American Cancer Society's most recent statistics (American Cancer Society, 2015), breast cancer is the most commonly diagnosed malignancy in US women, with over 230,000 cases in 2015. The majority of women are diagnosed with invasive cancers and are at high risk for development of deadly metastases. Like many of the solid tumors common in populations living in industrialized countries, the incidence and mortality of breast cancer increases with age. In fact, 80% of diagnoses and almost 90% of deaths from breast cancer are in women over the age of 50. Between 1990 and 2007, the mortality rate from breast cancer has slowly declined (approximately 2.2% per year), an effect deemed to be due to strategies aimed at prevention and treatment, as well as to earlier diagnosis due to widespread screening. Despite these improvements, breast cancer kills over 40,000 women yearly in the United States. Thus, it is clear that additional strategies for treatment and prevention of breast cancer are needed, and research progress in both of these directions often rely on animal models of breast cancer.

Risk factors and etiologic agents associated with breast cancer include those related to reproductive history (age at menarche, age at menopause, nulliparity, parity after age 30, hormone replacement therapy), family history, genetics, and radiation exposure. Tumor suppressor genes associated with breast cancer include the breast cancer susceptibility genes BRCA1 and BRCA2, p53, and ATM; however, it is estimated that only about 10% of breast cancer can be attributed to loss of function mutations in these genes. The vast majority of breast cancer cases are sporadic in nature, although as described later in the chapter several characteristic molecular changes have been linked with disease pathology and prognosis.

2.2 Subtypes and Prognosis

The term "breast cancer" collectively refers to many types of neoplastic diseases that arise in the mammary gland. Although the gland is composed of multiple cell types (epithelial cells, stromal fibroblasts, adipocytes, immune cells), the clinically relevant breast cancers typically derive from the epithelial cells and are thus termed carcinomas. The breast epithelium is a bilayer composed of luminal cells and basal (myoepithelial) cells arranged in ducts and lobules, and cancers can arise from both cell types in either location (Bombonati and Sgroi, 2011). Ductal carcinoma is the most commonly diagnosed type of human breast cancer (accounting for approximately 85% of all breast cancers). In general, the disease continuum begins with ductal hyperplasia and progresses to ductal carcinoma in situ (DCIS, a noninvasive lesion), which gives rise to invasive carcinoma if not removed (Vargo-Gogola and Rosen, 2007). A detailed evaluation of DCIS incidence and risk factors in the United States was recently compiled by the American Cancer Society (American Cancer Society, 2015). Development of invasive cancer from precursor lesions is driven by genetic and epigenetic changes within the epithelial cells and alterations in the complex communications between the epithelial cells and their microenvironment. The resulting carcinomas are highly heterogeneous, and distinct subtypes have been identified based on histopathology, putative cell of origin, genomic profiling, and clinical outcomes. Estrogen receptor-alpha-positive (ER+) and progesterone receptor-positive (PR+) breast cancers account for 60%–70% of the breast cancer cases diagnosed in humans (Anderson et al., 2002). While less common, tumors lacking ER or PR, and those with high expression of the growth factor receptor HER2, are generally more aggressive. As discussed in this chapter, distinct approaches are available to model the various histopathological subtypes of breast cancer in laboratory animals.

Despite continued research, breast cancer is associated with a 20% mortality rate within the first 5 years after diagnosis. The severity of the disease reflects many factors including metastatic potential, hormone independence, drug resistance, and histological heterogeneity. Sites of breast cancer metastasis include regional lymph nodes, lung, liver, brain, and bone. Median survival of patients with metastases is 2–3 years. Development of bone metastases is particularly common (~80% of patients with metastases have skeletal involvement) and is currently incurable. Mechanistic aspects of breast cancer cells homing to bone to induce osteolytic lesions are poorly understood. Animal models that mimic the unique sites of metastases of human breast cancer would be extremely valuable, but currently such models are limited.

Treatment of breast cancer is based on histopathological features (grade, stage, and hormone/growth factor receptor status) of newly diagnosed tumors. Early stage lesions (DCIS) are routinely treated by surgical removal (lumpectomy or mastectomy) followed by radiation therapy and in some cases antiestrogen therapies. For invasive breast cancers, surgery is followed by adjuvant systemic therapy depending on the specific stage and molecular aspects of the primary tumor. Patients with ER+ and/or PR+ tumors will receive hormone therapy; those whose tumors overexpress the growth factor receptor HER2 will receive the targeted therapy trastuzumab, usually in combination with chemotherapy. Patients whose tumors lack hormone and growth factor receptors (so called triple negative or basal-like tumors) will be treated with systemic chemotherapeutic regimens. Newly identified molecular features and the presence of distinct oncogenic pathways are continuously emerging as significant therapeutic targets as well.

Complications arising from current therapies for breast cancer include development of drug resistance, as well as side effects, such as thinking and memory problems (chemobrain), cardiac toxicity, and osteoporosis (with estrogen deprivation therapies). Animal models are increasingly being used to test strategies for prevention of drug resistance and therapeutic side effects.

2.3 Molecular Heterogeneity

Intensive genomic profiling of tumors, and resulting publically available datasets, such as The Cancer Genome Atlas (TCGA), has highlighted the heterogeneity of human breast cancer and facilitated the identification of molecular subtypes (Kreike et al., 2007; Perou et al., 2000; Sorlie et al., 2001; Strehl et al., 2011; Weigelt et al., 2008). Several major subtypes with characteristic gene expression profiles have been identified, which represent about 80% of all breast cancers. Invasive

ductal carcinomas were originally characterized into five major molecular subtypes: luminal A, luminal B, basal/triple negative, HER2 positive, and normal breast-like (Perou et al., 2000). Each subtype exhibits distinct profiles of hormone and growth factor receptors (ER, PR, HER2), cytokeratins, and proliferation markers. Most importantly, each tumor subtype has a characteristic prognostic outcome, with luminal A tumors (which are ER+, PR+, and HER2- and usually express functional p53) typically having much better prognosis than the other types. Luminal B tumors tend to be ER+, PR+, and HER2+ and are usually larger and of higher grade with more frequent p53 mutations than luminal A tumors. HER2 tumors highly express the HER2 growth factor receptor (usually due to genomic amplification), are negative for ER and PR and usually of high tumor grade. Basal/triple negative tumors are predominantly ER- PR- and HER2- but often express HER1 and/or cytokeratin 5/6 proteins and p53 mutations. Most breast cancers that develop in women with loss of function mutations in BRCA1 or BRCA2 are basal/triple negative. Molecular profiling (Lehmann et al., 2011) has confirmed heterogeneity of the basal/triple negative tumors leading to the identification of six subtypes with unique gene expression profiles and ontologies (2 basal-like, 1 mesenchymal, 1 mesenchymal stem-like, 1 immunomodulatory, and 1 luminal androgen receptor subtype). Other less common molecular subtypes have been described including normal breast-like, claudin-low type, and apocrine molecular type. As detailed further in the chapter, recent studies have focused on comparative genomic profiling of human and mouse breast tumors to ascertain whether similarities exist with respect to expression of these well-characterized human breast cancer subtype biomarkers. When possible, it is important to choose an animal model of breast cancer that best mimics the specific subtype of human breast cancer being addressed by the research.

2.4 Breast Cancer Cells of Origin

It has been suggested that the molecular heterogeneity of breast tumors might reflect distinct cells of origin (Lindeman and Visvader, 2010). Thus, the initial target for transformation could be a mammary stem cell, a committed progenitor cell, or a mature breast epithelial cell, all of which would give rise to tumors with distinct features. Another emerging related issue is the recognition that human breast cancers contain "cancer stem cells" or "tumor initiating cells" that drive tumor initiation and/or progression. Advances in techniques to identify and isolate mammary stem cells support the concept that stem cell populations exist in human breast tumors and that analogous populations can be identified in certain murine tumors and human xenografts.

3 MODELING BREAST CANCER IN RODENTS

3.1 General Approaches

Given the reality of species differences and the known diversity of human breast cancer, major challenges exist in modeling breast cancer in animals. No single model is capable of mimicking the heterogeneity characteristic of human breast carcinoma or the natural progression of the disease (particularly the metastatic process). However, molecular comparison of human breast cancers and experimental murine tumors has demonstrated that certain models are highly useful for studying specific disease subtypes. Unfortunately, models are severely limited for some of the rarer types of breast cancers (whose origin and molecular features are often poorly understood). An example is inflammatory breast cancer, which arises more often in younger women, is highly aggressive, and frequently misdiagnosed. Available models of inflammatory breast cancer are limited to a few cell lines that can be grown in immune compromised mice but fail to recapitulate the unique biology of the disease.

Because of these and other limitations, multiple in vivo breast cancer models have been developed and standardized, primarily in mice. Ideally multiple approaches should be used in a complementary fashion to fully address research questions. In addition to the study of carcinogenesis in intact animals (i.e., spontaneous, induced, or transgenic tumor models on wild-type or various knockout backgrounds), the murine mammary gland is amenable to organ culture and transplantation techniques, which have greatly facilitated our understanding of normal glandular development, mammary stem cells, and epithelial–stromal interactions. Although the anatomy and histology of the murine gland is quite distinct from that of the human gland, the epithelial structures, developmental processes, and hormonal controls are similar. The following sections will highlight the most commonly used models in terms of advantages and disadvantages for research purposes with an emphasis on comparative aspects of human versus rodent systems.

3.2 Issues to Consider When Choosing an Animal Model

There are a few key considerations that impact the choice of animal model for breast cancer studies. These include (but are not limited to) the genetic background of the mouse strain, whether an intact immune system is important, whether the research question is focused on treatment or prevention, and whether modeling of metastasis is desired. Inbred mouse strains vary widely in their sensitivity to tumorigenesis, and in some cases this is tissue-specific. In general, mice on the BALB/c, FVB,

and C3H backgrounds are highly susceptible to mammary tumorigenesis whereas those on the C57BL background are quite resistant (Medina, 2010). This has become problematic for many researchers since the C57BL background is frequently used for the generation of knockout mice. Testing carcinogen sensitivity or crossing of knockout mice on the C57Bl background with transgenic models of mammary cancer often requires initial backcrossing to the appropriate background, a laborious and costly process. Another consideration which is particularly important with xenograft studies is whether genetic defects in the immune system of host mice will adversely impact the results or their interpretation (more details on specific immunodeficient mouse strains are provided in Section 5.4). When studying breast cancer prevention, approaches are needed that focus on normal tissue or early stages of disease, whereas new therapeutic approaches are more appropriately evaluated in established tumors and/or models of metastatic disease.

4 SPONTANEOUS AND INDUCED MAMMARY TUMORIGENESIS IN RODENTS

4.1 Spontaneous Mammary Tumors

Most laboratory rodent strains spontaneously develop mammary tumors as they age, but the incidence and tumor pathology varies. In a pathological survey of spontaneous mammary tumors in various mouse strains, papillary adenocarcinomas, glandular adenocarcinomas, microacinar adenocarcinomas, type P tumors, adenomyoepitheliomas, and adenosquamous carcinomas were identified (Mikaelian et al., 2004). The papillary carcinomas that developed in BALB/cJ mice were found to be highly similar to the most common subtype of human breast cancer as they were exclusively composed of cells with a luminal phenotype. Other similarities between spontaneous mammary cancers in mice and human breast cancer are the age dependence, gender differences, hormonal influences, and circadian patterns (Anisimov et al., 2005). However, important species differences include the overall tumor spectrum, the number of genetic events thought to be required for tumor formation, the common occurrence of spontaneous regression in mouse tumors but not human tumors, and differences in dietary responses and metabolism.

4.2 Virally Induced Mammary Tumors

It has long been known that some strains of mice (C3H, GR) with high rates of spontaneous mammary tumors harbor a dominantly expressed, genetically transmitted proviral genome that encodes a highly infectious virus, the mouse mammary tumor virus or MMTV (Callahan

and Smith, 2000). Different strains of MMTV have been isolated from various mouse lines, and these vary in their infectious potency and ability to induce mammary tumors (Dudley et al., 2016). In addition to germline transmission, MMTV is shed in milk of infected females and can be transmitted to pups during lactation. Further details on the life cycle of exogenous MMTV in various murine strains, including the role of the gut microflora in viral transmission, are provided in a recent review (Dudley et al., 2016).

MMTV induces mammary tumors with relatively long latency (6–12 months). Like the majority of human breast cancers, MMTV-induced tumors are dependent on ovarian hormonal cycles. Parous females of strains carrying MMTV in their germline develop mammary tumors that arise from preneoplastic hyperplastic alveolar nodules. The incidence of tumors increases with additional pregnancy/lactation cycles. Analysis of MMTV tumors has demonstrated that they are clonal in nature and result from multiple mutations events. Mechanistically, MMTV is a retrovirus that induces tumors through insertional mutagenesis, a process whereby viral sequences integrate into the host genome and deregulate the expression of critical growth control genes. Initial analysis of viral integration sites in MMTV tumors established that the virus commonly integrates near genes involved in Wnt signaling, mechanistically linking this pathway to mammary tumorigenesis. More recently, high-throughput analysis of MMTV integration sites has been used to identify and validate additional novel mammary oncogenes including those involved in Fgf and map kinase signaling, as well as several unknown genes (Kim et al., 2011; Theodorou et al., 2007). Since it is likely that mutations induced by MMTV and genes identified at integration sites participate in signaling pathways that are relevant to human oncogenesis, the MMTV tumor model has reemerged as an important approach for identification of additional genes that contribute to breast cancer etiology and pathogenesis. In addition, recent studies have identified mammary tumor virus-like particles in samples of human milk and breast cancer suggesting the intriguing possibility that a human mammary tumor virus (HMTV) might be linked to a subset of human breast cancers (Cedro-Tanda et al., 2014; Nartey et al., 2014). If confirmed, the MMTV mouse model will become even more relevant as a research tool.

4.3 Identification of Mammary Carcinogens in Rodents

In addition to tumors that arise spontaneously or in association with MMTV infection, mammary carcinomas can be induced in rodents by various agents including chemical carcinogens, hormonal agents, and ionizing radiation. By far the most commonly used research models employ rats and mice exposed to chemical carcinogens.

Aside from research use, however, another major application of rodent models is screening of environmental, industrial, and other chemicals for carcinogenic potential. The National Toxicology Program (NTP, http://ntp.niehs.nih.gov/) has established standardized long-term carcinogenesis bioassays in rats (Harlan Sprague Dawley) and mice (B6C3F1 hybrid). These protocols employ three exposure concentrations of each test agent, plus untreated controls, in groups of 50 animals with a 2-year monitoring period. NTP maintains a publically accessible, searchable database that catalogs bioassay results. Agents that test positive in this program, which has been in place since 1978, are categorized as potential human carcinogens and further evaluated for public health relevance.

In the case of mammary tumors, the NTP protocol utilizes both male and female animals and employs various routes of administration (i.e., gavage, injection, inhalation) depending on the specific agent. Generally the route of administration is chosen that best mimics the route by which humans would be exposed. The NTP database lists 39 agents that have tested positive for site-specific induction of mammary cancer in either mice or rats (http://ntp.niehs.nih.gov/?objectid=E1D18034-123F-7908-7B2C2AE41B1F3778), including a number of endocrine disruptors. These agents should be considered *potential* carcinogens for the human breast, since it is clear that the species differences between rodents and humans limit direct extrapolation of these bioassays. Furthermore, it should be noted that the existing NTP screening protocols do not take into account important issues, such as the impact of exposure windows (e.g., in utero, puberty, pregnancy), age, or menopausal status, which are all known to be strong modifiers of breast cancer risk in humans. Although this screening program is not focused on research applications, the protocols, technical information, and results are a valuable research resource and can provide the basis for more relevant in vivo studies on environmental chemicals and breast cancer.

4.4 Standardized Protocols for Induction of Mammary Tumors by Chemical Carcinogens

Historically, the rat has been extensively used to study mechanisms of chemically induced mammary tumorigenesis (Huggins et al., 1961; Sydnor et al., 1962). Specific carcinogens that induce mammary tumors in rats include the polycyclic hydrocarbon 7,12-dimethylbenzanthracene (DMBA) and the alkylating agents methylnitrosourea (MNU) and ethylnitrosourea (ENU). The general approach involves gavage treatment of young adult virgin female Sprague Dawley rats with one or multiple doses of carcinogen (e.g., 20 mg DMBA in peanut oil) and monitoring of tumor development over periods of 2–6 months. Monitoring for tumor development is generally by weekly palpation of each mammary fat

pad with quantitation of final tumor weights at necropsy. The data outcomes for these types of studies include: time to tumor detection (latency), percentage of animals developing tumors (incidence), number of tumors per animal (multiplicity), final tumor size (volume and/or weight), and pathology. Typical mammary tumor incidence with these protocols is approximately 50% and individual animals may develop multiple tumors. The low incidence and biological variability in the induction of tumorigenicity and the rate of tumor growth in these protocols somewhat limits their suitability for prevention and therapy studies, as large cohorts of animals are required for statistical validity. However, these techniques have been used to examine the effects of dietary modifications and putative chemopreventive agents on mammary tumorigenesis.

Histologically, the mammary tumors induced in female rats by carcinogens, such as DMBA or MNU are predominantly adenocarcinomas and they generally express ER and PR. Most importantly, the incidence, multiplicity, and latency of these tumors has been shown to be modulated by age, reproductive history, and hormonal status of the rat at the time of carcinogen exposure indicating that their onset is hormone dependent (Russo and Russo, 1996). A major advantage of these rat models is that the resulting tumors are usually hormone dependent, a common feature of human breast tumors. These protocols have thus been useful for dissecting the initiation, promotion, and progression steps of mammary carcinogenesis in relation to endocrine status. A recent report characterized MNU-induced mammary tumors in male rats as a potential model for male breast cancer

(Yoshizawa et al., 2016). In contrast to human male breast cancers which are usually ER positive, however, mammary tumors induced by MNU in male rats weakly expressed ER and were negative for PR, suggesting different pathogenesis in the two species.

A major drawback of the rat chemically induced carcinogenesis model is the limited potential for these tumors to metastasize. And, although the histology and many features of these rat mammary tumors are similar to that of human breast tumors, the specific chemical agents used in these protocols are not considered relevant to the etiology of the human disease.

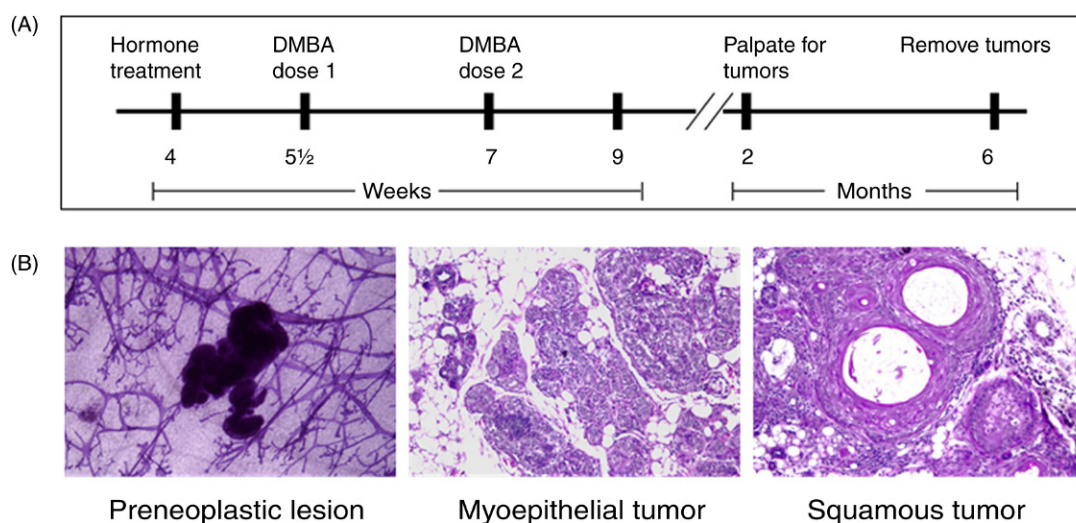
More recently, the rat protocols have been modified for use in mice in order to examine the impact of various knockout and transgenic manipulations on the sensitivity of the mammary gland to transformation (Medina, 2010). In mice, tumorigenesis is highly strain dependent (DBA2f, BALB/c, and Sencar mice are sensitive whereas C57BL mice are fairly resistant). As a rule, tumorigenesis in mice requires multiple doses of carcinogens, particularly for the less sensitive strains. As in the rat model, administration of exogenous hormones (particularly progestins) enhances tumor incidence and reduces latency of chemically induced murine tumors. A typical protocol for the induction of mammary tumors in C57Bl6 mice using DMBA as carcinogen and the synthetic progestin medroxyprogesterone acetate (MPA) as promoter is shown in Fig. 35.1. With this protocol, tumors appear within 4 months of DMBA administration and an overall incidence rate of approximately 75% is observed by 6 months. Histologically, the tumors that develop in response to DMBA are predominantly squamous or


FIGURE 35.1   **General scheme for chemically induced carcinogenesis in mice.** (A) In a typical protocol, prepubertal mice are administered medroxyprogesterone acetate *(MPA)* to stimulate proliferation of the mammary epithelium prior to administration of two doses of dimethylbenzanthracene *(DMBA)* by gavage. Tumor development is monitored by palpation of all 10 mammary glands beginning 2 months after the last dose of DMBA. (B) Whole mounts of mammary glands stained with carmine can be used to visualize preneoplastic lesions. Histological sections fixed in formalin, paraffin embedded, and stained with hematoxylin and eosin are used to examine tumor pathology. Depending on the genetic background, both myoepithelial (pilar-type) and squamous tumors can be induced with these protocols.

adenosquamous carcinomas; however, pilar tumors, scirrhous tubular, spindle cell, and papillary carcinomas are also seen. In contrast to chemically induced mammary tumors in the rat, the tumor types that develop in the murine mammary gland are not usually ER+ or hormone responsive.

One of the important applications of chemically induced mammary tumorigenesis protocols in rodents is for studying the effects of pregnancy on tumor development. In humans, a full-term pregnancy exerts long-term protective effects against breast cancer; however, the mechanisms of this protection are largely unknown (Balogh et al., 2006; Britt et al., 2007; Russo et al., 2006). Pregnancy protects against subsequent chemical carcinogen-induced breast cancer in both rats and mice. For example, the incidence of tumors in virgin rats treated with DMBA was greater than 70%, whereas age-matched animals that had completed a full-term pregnancy prior to carcinogen exposure displayed only 14% incidence. This dramatic difference in tumor development in the rodent models has been exploited in studies designed to identify the mechanisms underlying pregnancy-induced protection against breast cancer. These studies have demonstrated multiple factors that may contribute to this protection including altered hormone status, maturation of the gland, changes in stem cell populations, and altered estrogen responsiveness (Britt et al., 2007; Russo et al., 2006).

A technical problem inherent in use of the mouse model is that the commonly used carcinogens are not specific for mammary cells, and tumors at other sites (i.e., lymph, lung, stomach, and ovary) contribute to the observed morbidity and mortality. The tumor spectrum is strain and dose dependent, however, and various protocols have been developed that optimize formation of mammary tumors, somewhat alleviating this concern (Medina, 2010).

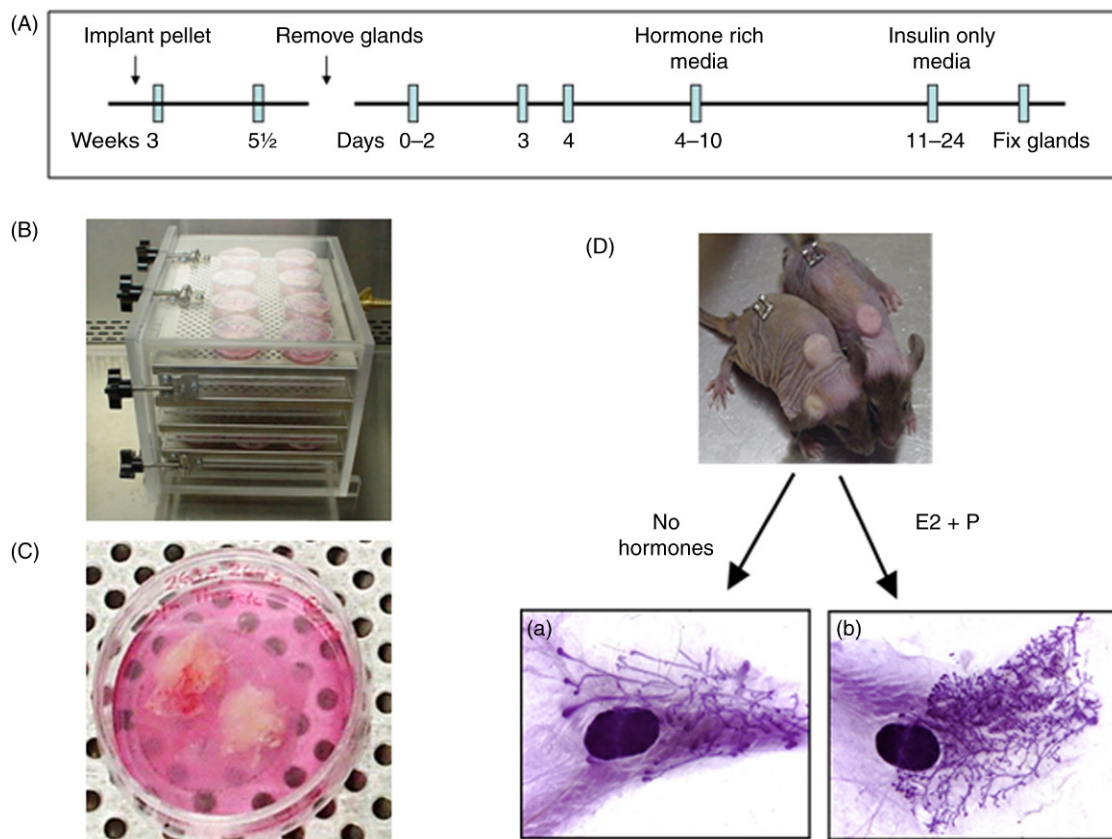
A complementary approach to the whole animal carcinogenesis protocols discussed earlier involves the use of mouse mammary gland whole organ culture (MMOC, Fig. 35.2). The MMOC technique has been extensively used for studies on mammary gland development and epithelial–stromal interactions but can also be applied to carcinogenesis studies (Mehta et al., 2008). The standard


FIGURE 35.2 **Outline of the mouse mammary organ culture procedure.** (A) Prepubertal mice are supplemented with estrogen and progesterone to stimulate glandular growth and facilitate adaptation of the whole organ to culture. Glands are dissected under sterile conditions and placed in culture with media containing specific hormone cocktails and DMBA for induction of alveolar or ductal lesions. (B) Sealed apparatus for organ culture accommodates 24 culture dishes (35 mm diameter). (C) One whole mammary gland is cultured per dish. (D) Subcutaneously implanted hormone pellets facilitate growth of glands in culture. Compared are glands removed from nonsupplemented (a) and hormone supplemented (b) mice after culture.

technique involves pretreatment of 4-week-old BALB/c female mice with 1 μg of estradiol and 1 mg of progesterone for 9 days to prime the glands for culture, followed by removal to serum-free hormone supplemented media. Under the appropriate hormonal conditions, glands undergo lobulo-alveolar development in culture and when hormones are removed these structures regress. It has been demonstrated that inclusion of carcinogens including DMBA and NMU in the culture leads to the induction of preneoplastic lesions in the MMOC system. Furthermore, the prevailing hormonal conditions in the culture modulate the type of lesion produced. Under conditions of estrogen and progesterone stimulation, mammary ductal lesions develop whereas in the absence of these hormones alveolar lesions develop. In MMOC, precancerous lesions can be triggered in response to a 24 h exposure to DMBA and can be detected within 14 days of carcinogen exposure. Suppression of the incidence and multiplicity of these lesions by a variety of natural and synthetic chemicals has been demonstrated (Mehta et al., 2008) indicating the usefulness of this technique as a screening bioassay for chemopreventive agents. Incorporation of chemopreventive agents prior to or after DMBA exposure can provide insight into stage-specific preventive mechanisms. The MMOC is also a valuable approach to rapidly test the impact of specific genes on mammary carcinogenesis using glands from transgenic or knockout mice. However, the procedure requires optimization for mice on backgrounds other than BALB/c, particularly in the length of time animals are treated with hormones prior to harvesting of the glands and the doses of carcinogens employed in cultures.

4.5 Other Mammary Tumor Inducing Agents in Rodents

Although chemical carcinogens in rodents are frequently used to study mammary tumorigenesis, they are not considered to be relevant etiologic agents for human breast cancer. In addition to genetic predisposition, major risk factors for human breast cancer include reproductive history (pregnancy, lactation, hormone use) and exposure to ionizing radiation. Of note, both chronic hormonal stimulation and exposure to radiation have been shown to induce mammary tumors in rodents. Ovarian steroids are necessary for the development of the mammary gland and as such their presence is permissive for growth and survival of the epithelial cells which are the targets for transformation. As noted earlier, estrogen and progesterone supplementation enhance the sensitivity of the mammary gland to spontaneous and chemically induced carcinogenesis. In BALB/c female mice, chronic, continuous administration of the synthetic progestin MPA induces mammary ductal carcinomas with a mean latency of 52 weeks and an incidence

of about 80% (Lanari et al., 2009). In contrast to spontaneous, chemical, or MMTV-induced tumors in mice (which are typically hormone receptor negative), more than 60% of the MPA tumors express ER, PR, and prolactin receptors. In addition, lymph node and lung metastases develop in some cases. As observed for other models, the carcinogenic effect of MPA is strain-specific, with lower incidence in C3H mice than BALB/c mice and no tumor development in C57BL/6 mice.

Several rodent models have been developed for studying the effects of ionizing radiation on mammary tumor development (Medina, 2010). In general, whole body radiation exposure (γ rays or neutrons) induces ductal hyperplasias and adenocarcinomas in female BALB/c mice at low incidence (20%–45%) and with long latency (Storer et al., 1979; Ullrich et al., 1977). The high susceptibility of Balb/c mice to radiation-induced tumors has been attributed to a polymorphism in the Pkrdc gene which codes for a DNA repair enzyme (Rivina et al., 2016). Not unexpectedly, cells derived from murine tumors induced by radiation exposure are characterized by chromosomal instability (a feature not seen in cells from chemically induced tumors). Furthermore, mammary tumors in mice exposed to radiation are hormone independent and metastasize to lung. These features suggest that the protocols used for radiation-induced mammary tumors in mice are highly appropriate for modeling radiation-induced human breast tumors.

5 GRAFTING AND TRANSPLANTATION APPROACHES

5.1 General Issues

The most commonly utilized models of breast cancer for screening therapeutics are those in which transformed cells or whole tissues are grafted into compatible host animals. There are many variations of these techniques, with different cells or tissues (animal, human), hosts (syngeneic, nonsyngeneic), and grafting sites (subcutaneous, orthotopic, systemic). These models are all based on the well-documented premise that only transformed cells are able to survive and grow into tumors in a host animal. In fact, a major use of these models is as a gold-standard test for cellular transformation (Ince et al., 2007) (Fig. 35.3).

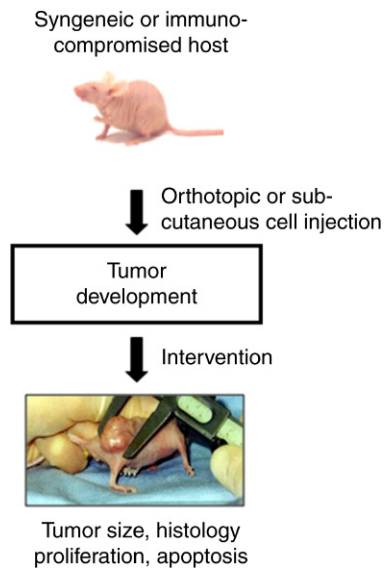
The advantages of graft models of breast cancer are that they are technically easy, fairly reproducible, relatively inexpensive, can be applied to transfected/knockout cells and can be used to study freshly isolated human cancer tissue. Furthermore, in contrast to the majority of chemically induced and transgenic models, many human breast cancer cell-line derived xenografts are ER+ and demonstrate hormone dependence in vivo. These


FIGURE 35.3 Flowchart of typical graft experiment. Similar approaches are used for syngeneic (mouse cells into host mice of same genetic background) and nonsyngeneic (human cells into immune-deficient host mice) protocols. Hosts are injected with tumor cells (often mixed with extracellular matrix preparations) at either subcutaneous or orthotopic (mammary fat pad) sites. Depending on the aggressiveness of the injected cells, palpable tumors may develop within 2 weeks. Therapeutic interventions are usually initiated once tumors reach a measurable size ($\sim$200 cm^3) as monitored by calipers. End points of these studies generally include tumor growth rate, size, and weight. Tumor cell proliferation, apoptosis, angiogenesis, and specific biomarkers of interest are usually determined histologically on tumor sections. For modeling of metastasis, cells with metastatic potential are injected directly into the circulation via tail vein, portal vein, or cardiac route and disseminated cells are monitored in lung, liver, bone, and other sites. Variations include the use of freshly obtained biopsy tissue (tumorgrafts), use of tagged cells for noninvasive imaging of tumor growth and dissemination, and intraductal cell injection for modeling of ductal carcinoma in situ.

models have been particularly useful in the identification of environmental estrogens, phytoestrogens, and synthetic ligands that act as agonists or antagonists of ER to modulate tumor growth.

There are several general limitations of graft approaches that should be noted. First, they are not appropriate for studies of primary tumor prevention since the cell lines utilized are already transformed prior to implantation. Interventions that alter tumor development (i.e., the appearance of a solid tumor after implantation of cells) do not "prevent" tumorigenesis, rather they impact on the ability of the already transformed cells to adhere, survive, and proliferate in vivo. Another limitation of graft approaches is that the critical interactions that evolve between epithelial cells and the microenvironment during tumor initiation are not recapitulated. Crosstalk between neoplastic epithelial cells and fibroblasts, immune cells, and endothelial cells is extremely important in the evolution of tumors yet in grafting models transformed cells are introduced into a normal host microenvironment. In addition, and likely related to the lack of a suitable tumor microenvironment, most human xenografts do not spontaneously metastasize in murine hosts, and those that do tend to metastasize to organ sites that are not clinically relevant for human breast cancer. Metastasis can be achieved in xenograft systems via direct injection of breast cancer cells with metastatic potential into the circulation, but these approaches mimic only part of the metastatic cascade. Another important limitation is that immune-deficient hosts must be used for human cells, precluding studies on the influence of the immune system on tumor growth or response to experimental therapies. Finally, the biggest disadvantage of graft models of cancer is that the therapeutic efficacy of drugs against xenografts is not highly predictive of clinical response. Specifically, the majority of drugs that are effective in xenograft studies fail to show similar efficacy in clinical trials. The lack of efficacy likely relates to the rapid growth rate of experimental tumors and their homogeneity compared to human breast tumors. Newer models using patient-derived material for grafting may somewhat overcome this issue (see later). Because of the great variety of models and approaches in the literature, only a few representative models and approaches will be described here. Additional information can be found in recent reviews on in vivo modeling of breast cancer (Holliday and Speirs, 2011; Jenkins et al., 2005; Khanna and Hunter, 2005; Mollard et al., 2011; Troiani et al., 2008).

5.2 Technical Issues

Site of tumor cell administration. As noted previously, during endogenous breast tumor development, complex interactions evolve between the neoplastic epithelial cells and the accessory cells (fibroblasts, adipocytes, vascular, and immune cells) in the tissue microenvironment (Hanahan and Coussens, 2012). Accessory cells secrete growth factors, hormones, and cytokines that modulate the behavior of the epithelial tumor cells, and conversely, tumor cells secrete factors that modulate cells in the microenvironment. These epithelial–stromal interactions contribute to tumor progression via promotion of cell survival, remodeling of the extracellular matrix, and chronic inflammation. Furthermore, crosstalk between tumor cells and endothelial cells is critical for driving angiogenic processes necessary for metastatic spread. Since these events can only be superficially studied in vitro (e.g., with coculture systems), in vivo systems are essential for modeling this aspect of tumor biology. Initially, breast tumor grafts were implanted or injected subcutaneously, a site that does not provide the appropriate extracellular matrix or tissue microenvironment for breast carcinogenesis. Although subcutaneous grafts are easy to establish and monitor, some breast cancer cell lines fail to form tumors when grafted this way. To address these issues, adaptations,

such as the coadministration of extracellular matrix proteins (either purified single proteins or complex biological mixtures, such as Matrigel) or viable fibroblasts with the breast cancer cells have facilitated tumor take -in some cases, however, these methods still do not closely mimic the natural microenvironment of breast tumors. Newer alternative approaches include orthotopic xenografts (injection or implantation of cells directly into the tissue of origin). For breast cancer, orthotopic injections are made into the mammary fat pad or directly into the milk ducts via the nipple (Sflomos et al., 2016; Valdez et al., 2011). As described later in more detail, orthotopic grafts are more clinically relevant and predict drug efficacy better than subcutaneous grafts.

Monitoring tumor growth rates and disease spread. Regardless of the site of grafting or cell/tissue type, procedures for monitoring tumor take and growth rates are required. Once detected by palpation, the size of subcutaneous grafts can be monitored noninvasively by caliper measurement. Inexpensive calibers with digital readout can be connected to a computer for automatic data collection (Worzalla et al., 1990). With calipers, tumor diameter is generally measured in two directions and the height of the mass is measured at its maximum. Tumor volume is calculated as an ellipsoid. For fast-growing tumors, measurements are typically collected once or twice per week over the course of the study. Since the majority of subcutaneous grafts do not infiltrate the muscle and remain in the subcutaneous space, caliper measurements are quite accurate in reflecting tumor size. However, due to considerable operator variability it is recommended that one individual perform all measurements for a particular study. When tumors are growing orthotopically, measurements are still feasible, although technically more challenging depending on the site of tumor engraftment. For these, the most accurate measurements will be at the end of the experiment when tumors are excised and directly measured by calipers and weighing. The use of specialized imaging techniques capable of whole animal fluorescence detection (for use with cells stably tagged with fluorescent markers), as well as micro computed tomography (CT) and positron emission tomography (PET) imaging is becoming more common for noninvasive monitoring of tumor growth and progression in vivo. While technically challenging and requiring specialized equipment, noninvasive monitoring has greatly facilitated the study of both primary tumors and metastatic disease (Jenkins et al., 2005; Manning et al., 2016; Mollard et al., 2011)

5.3 Syngeneic Graft Models of Breast Cancer

Syngeneic graft approaches utilize cancer cells and host mice from a common genetic background and thus avoid the need for immunocompromised host animals, allowing for study of the role of the immune system in tumor growth and metastasis. Another major advantage of syngeneic models is that the tumor cells, microenvironment (stroma, immune cells, extracellular matrix), and host are from the same species. A disadvantage of syngeneic tumor models is their limited similarity to human tumor biology as the commonly used cell lines are driven by mutations that do not mimic those found in human breast cancer. Complementary studies in human xenograft models are recommended to confirm that observations from syngeneic tumor models are relevant to human cancer.

Rodent cell lines that grow in syngeneic hosts have been isolated from spontaneous and chemically induced tumors, as well as from transgenic animal tumors. The well-characterized 4T1 series of cell lines (Aslakson and Miller, 1992) includes five isogenic tumorigenic lines (67NR, 168FARN, 4TO7, 66cl4, and 4T1) that originated from one spontaneous tumor in a BALB/cfC3H mouse. Each cell line displays unique tumorigenic and metastatic capabilities. For example, when introduced orthotopically, the 4T1 line grows rapidly at the primary site and forms metastases in lungs, liver, bone, and brain over a period of 3–6 weeks. When introduced via the tail vein or arterially, metastases are apparent in these same organs after 1–2 weeks. The rapid, efficient, and reproducible metastasis to the same organs that are affected in human breast cancer makes the 4T1 model ideal for the study of metastatic progression of breast cancer in humans. Another interesting property of this model is the availability of sublines with distinct metastatic potential. Sublines 67, 168FAR, and 4T07 are highly tumorigenic, but fail to metastasize at different steps. The nonmetastatic 67 cells fail to leave the primary graft site; 168FAR cells reach the regional lymph nodes but do not produce nodules or spread from the nodes; and the 4T07 cells are found in the circulation and colonize the lungs without advancing into visible metastases. Thus, this comprehensive set of sublines offers the potential to correlate genetic alterations with specific steps in the metastatic process, as well as to test antimetastatic therapies for their ability to interfere with known stages of the process. More recently, stable bioluminescent 4T1 cell lines expressing enhanced firefly luciferase (luc2) have been generated, which are sensitive enough for noninvasive detection of micrometastases in vivo. In addition, genomic and metabolomic profiles of 4T1 and its variant cell lines have been reported (Eckhardt et al., 2005; Lu et al., 2010).

A new syngeneic mouse model with similarities to basal and claudin-low subtypes of human breast cancer has been developed from tumors driven by the Wnt1 oncogene (Dunlap et al., 2012). In this model, two distinct cell lines isolated from Wnt1-driven mammary tumors generated in C57Bl6 mice were characterized with respect to genomic profiles and stem cell enrichment.

The mesenchymal-like M-Wnt cells were enriched for tumor-initiating cells (CD44^{high}/CD24^{low}) compared to the epithelial-like E-Wnt cells. Furthermore, M-Wnt cells demonstrated enhanced epithelial-to-mesenchymal transition (EMT) marker expression, mammosphere-forming ability, migration, invasion, and tumorigenicity relative to E-Wnt cells. Genomic clustering based on microarray profiling indicated that M-Wnt cells mimicked claudin-low breast tumors whereas E-Wnt cells clustered with basal-like tumors. When orthotopically transplanted into ovariectomized C57BL/6 mice, tumors from these two cell lines recapitulated these tumor subtypes. Thus, this model provides a unique and valuable approach to study two of the human breast cancer subtypes associated with poor prognosis in an immune-competent in vivo environment. Because these and other Wnt1-derived cells are capable of syngeneic grafting, they are amenable to study in existing transgenic and knockout mouse strains on the C57Bl6 genetic background as recently described (Zheng et al., 2012).

5.4 Nonsyngeneic (Xenograft) Models

Definition and characteristics. "Non-syngeneic" refers to the transplantation of human tumor cells or tissue fragments into hosts of another species (usually mice). Successful growth of xenografted tumors will only occur if the host animal is immune-deficient to prevent immune rejection of the foreign cells. Although these models have some advantages, they do not replicate many of the histological properties of breast cancers in human patients. Most cell lines grown as tumors consist largely of homogenous, rapidly proliferating epithelial cells with limited stromal infiltration. This is in contrast to the heterogeneity and reactive stroma that are characteristically present in human breast cancers. It is also important to recognize that xenografted tumors are a mosaic of human epithelial tumor cells growing within a murine microenvironment. Thus, all of the accessory cells that are known to infiltrate tumors (fibroblasts, immune cells, endothelial cells, adipocytes) are derived from the host mouse. In some cases, species differences in pathways and signaling (i.e., ligand-receptor complexes, gene regulation, cytokine signaling) will limit cross talk between these murine cell populations and the human breast cancer cells. A related issue is that the normal stromal compartments of the murine and human mammary glands are quite different—whereas mouse stroma primarily consists of adipocytes, human stroma is largely populated by fibroblasts.

As noted previously, recognition of the importance of the microenvironment in tumor growth has prompted investigators to compare various modes and sites of xenografting. Initial studies were conducted almost entirely with cells injected subcutaneously, which facilitates visualization and monitoring of tumor growth but does not mimic the natural environment of a developing breast tumor. To better model developing breast tumors, implantation of cells or tissue fragments into orthotopic sites is increasingly utilized. Of the 10 mammary glands in the mouse, the inguinal and thoracic glands are most commonly used. Fleming et al. (2010) demonstrated that xenografts growing in the inguinal (abdominal) mammary gland had increased tumor take rates, decreased latency, and larger final volumes compared to those growing in the thoracic gland, suggesting that the specific orthotopic site can alter tumor biology.

In a comparative study (Fleming et al., 2010), tumor incidence, latency, and volume were greater for MCF-7 cells grown in the mammary fat pad compared to those grown subcutaneously. Furthermore, estrogen sensitivity and vascularization were enhanced in orthotopic tumors compared to subcutaneous tumors. When introduced into the mammary ducts, MCF-7 cells grew slowly and exhibited desmoplasia and microcalcifications that were not present when cells were implanted in the fat pad (Sflomos et al., 2016). These studies also indicated that the intraductal microenvironment favored maintenance of the luminal gene expression profile in MCF-7 cells. Thus, it is apparent that the microenvironment, governed by the chosen implantation site, dramatically alters both genotype and phenotype of breast cancer xenografts.

Use of surgery-derived tissue for xenografting. To better mimic clinical behavior and clonal evolution of breast cancers, tumor cells or tissue fragments obtained from biopsy material (rather than established cell lines) have been utilized for xenografting (Decaudin, 2011; Ding et al., 2010; Eirew et al., 2015; Garcia-Garcia et al., 2012; Kabos et al., 2012; Kanaya et al., 2016; Marangoni et al., 2007). These so-called patient-derived xenografts (PDX) display high concordance in gene expression, chromosomal alterations, and histology when compared back to the patient's original tumor tissue. Furthermore, patient-derived ER+ luminal breast tumor models have been used to study tumor hormone and receptor action. In one model (Kabos et al., 2012) human breast tumor samples obtained at surgery and immediately transplanted into estrogen supplemented immunodeficient mice were used to select transplantable ER+ breast cancer xenografts derived from both primary and metastatic cases. Xenografts were found to morphologically resemble the tumors of origin, with similar expression of ER and PR, over multiple passages. Four of the tumor xenografts were estrogen dependent, expressed estrogen-regulated genes, and were sensitive to the antiestrogen tamoxifen, a clinically relevant drug. In a related approach, investigators introduced patient-derived cells directly into the mammary ducts to generate slow-growing ER+ tumors that metastasized to clinically relevant

sites (Sflomos et al., 2016). These studies suggest that ER+ tumorgrafts may provide a relevant model of estrogen responsive breast cancer for studies on heterogeneity, metastasis, and drug development.

An extensive panel of tumorgrafts established by Marangoni et al. (2007) includes 15 triple-negative, one ER+, and two HER2+ tumors. Interestingly, tumor take was higher in fragments from high grade, ER− tumors than low grade, ER+ tumors. The histology and genetics of these xenografts also recapitulated the tumors of origin, with common alterations in p53, Rb, and PTEN, and a few samples with amplification of HER2. Of 17 tumorgrafts, 3 demonstrated high propensity for spontaneous lung metastasis. Chemosensitivity screening indicated that 88% of tumorgrafts responded to adriamycin-cyclophosphamide, and the two HER2 amplified tumors responded to the anti-HER2 antibody trastuzumab. The IOWA-1T is another unique PDX that exhibits local spread and skin erosion with a basal molecular profile (Bogachek et al., 2015). These reports demonstrate the feasibility and promise of the tumorgraft approach for screening therapeutic efficacy. Protocols for establishing and passaging xenografts from clinically available tumor tissue have been published (de Plater et al., 2010; Kabos et al., 2012; Marangoni et al., 2007; Morton and Houghton, 2007; Sflomos et al., 2016).

Commonly used immune-deficient mouse strains. In contrast to syngeneic models, successful establishment of xenograft tumors relies on host animals with compromised immunity. Since it is well known that both innate and adaptive immune cells play a major role in cancer progression and eradication, the dependence on animal hosts with defective immunity is a major limitation of xenograft models. Human breast tumors commonly have immune cell infiltration which will not be accurately mimicked in an immune-deficient murine host. Furthermore, many therapies exploit the immune system either by bolstering antitumor immunity or neutralizing inflammation that promotes cancer progression. Screening therapeutics that potentially mediate their effects through immune mechanisms in xenograft models therefore could be misleading.

There are multiple genetic loci in mice that produce immunocompromised phenotypes, but the most commonly used models for xenograft studies are the nu (nude), scid (severe combined immunodeficient), and bg (beige) mouse strains. Although few studies have done direct comparisons, most established breast cancer cell lines appear to grow equally well in all stains. Growth of fresh tumor fragments and metastatic progression may be better in the more immune-compromised strains. Nude mice (homozygous for the nu mutation) are athymic and therefore their major defect is a lack of T cells (Pelleitier and Montplaisir, 1975). Nude mice do have B cells (albeit immature) and retain activity of natural killer (NK) cells and macrophages, which are thought to contribute to the low rates of metastasis of most human xenografts in this model (Clarke, 1996). Nude mice are also hairless, which is an advantage for visualization and measurement of subcutaneous xenografts. The scid mutation results in failure to rearrange the genes encoding antigen-specific receptors of T and B cells. Subsequently, scid mice have small lymphoid organs, lack both immature and mature B cells, and have defective T cells. Scid mice (Bosma and Carroll, 1991) retain NK cells, macrophages, and dendritic cells, all of which might influence tumorigenicity and metastasis. The beige mutation is associated with a severe deficiency of NK cells, defective bactericidal activity of granulocytes, and defective cytotoxic T-cell responses (Baca and Mowat, 1989). Studies of xenografts in both nude and scid mice crossed onto the beige background support a role for NK cells in tumor rejection (Clarke, 1996). The scid/bg mouse and other immune-deficient strains are commercially available and each has specific husbandry requirements due to their immune deficiencies, as well as other associated phenotypes. Currently, strains carrying the nude and scid single mutations remain the most commonly used mouse hosts for human breast cancer xenografts.

5.5 Detailed Characteristics of Human Breast Cancer Cell Lines Used for Xenografting

Introduction to breast cancer cell lines. Since 1958, when the first human breast cancer line BT-20 was established, upward of 50 lines have been isolated from patients with various subtypes of tumors. Most of the long-established breast cancer cell lines in current use were derived from tumor metastases, especially aspirates or pleural effusions, rather than from primary breast tumors. The majority of the patients from which these tumors were removed had completed and often failed multiple courses of therapy (radiation, chemotherapeutics, and/or antihormone). Thus, it is not surprising that most of the available breast cancer cell lines are highly proliferative, aneuploid, poorly differentiated, and drug resistant. Unfortunately, the clinical details on the donors are quite limited for most of the established breast cancer cell lines.

It is important to recognize that established cell lines undergo both genotypic and phenotypic drift when continuously cultured. For example, studies have demonstrated that MCF-7 clones obtained from different sources display differences in growth rate, estrogen responsiveness, karyotype, and clonogenicity (Osborne et al., 1987). These differences most likely represent the selection of distinct subpopulations over time under different laboratory conditions. It stands to reason that xenografts derived from different subclones would display different properties in vivo as well, although this has not been rigorously examined.

Due to their adaptation to continuous culture, most breast cancer cell lines form xenografts that exhibit rapid growth even in subcutaneous sites, precluding the development of metastases before the size of the primary tumor requires ethical sacrifice of the host. Therefore, much of the preclinical research with xenografts is biased toward tumors with high mitotic rates (which are generally rare in humans) rather than slower growing tumors at the early stage. More recently, a series of cell lines (SUM cells) have been generated by Steve Ethier's group at the University of Michigan and are commercially available from Asterand. Some of these cells were isolated from primary tumors of patients prior to initiation of any therapies. Each SUM cell line has been well characterized with respect to known oncogenes, gene expression data, and biomolecular markers, such as ER and HER2. Orthotopic xenografts grown from these cell lines display a range of histologies more reminiscent of the original tumors from which they were derived (with more stromal involvement) than earlier cell lines (Kao et al., 2009).

Recently there has been an interest in determining how well the existing established breast cancer cell lines reflect the known heterogeneity of human breast tumors. Molecular and cellular analysis of a large panel of human breast cancer cell lines has been performed to determine how well their genomic profiles and protein expression patterns mimic primary human breast tumors (Kao et al., 2009; Keller et al., 2010; Neve et al., 2006). As summarized in Table 35.1, the available cell lines can be categorized on the basis of protein biomarkers, genomic analysis, cell surface markers, and breast cancer-associated mutations into groups that model all subtypes of human breast cancer. This list was compiled from recent literature (Herschkowitz et al., 2007; Hollestelle et al., 2010; Kao et al., 2009; Keller et al., 2010; Neve et al., 2006; Riaz et al., 2009) where original data and more specific details are available. Here we will briefly discuss the most commonly used cell lines for modeling each subtype of the human disease, with the caveat that not all cell lines discussed have been thoroughly characterized as xenografts. Additional resources related to human breast cancer cell lines suitable for xenografting include ATCC (http://www.atcc.org/), Asterand (http://www.asterand.com/Asterand/), and the Lawrence Berkeley laboratory breast cancer cell database (http://icbp.lbl.gov/ccc/celllines.php). A comprehensive comparison of morphology, growth, and biomarker expression of 16 human breast cancer cell lines and their xenografts has been published (Keller et al., 2010).

Models for early stage disease. The MCF-7 cell line, which was established from a pleural effusion at the Michigan Cancer Foundation in 1973, is by far the most commonly used xenograft model of breast cancer. Despite its origin from the metastases of an advanced tumor, the cell line is noninvasive and represents a model of early stage disease due to the presence of functional ER and estrogen dependence for growth both in vitro and in vivo. In microarray profiles, the MCF-7 geneset clusters with the luminal subtype of breast cancer (Kao et al., 2009). MCF-7 xenografts express wild-type p53 and remain localized when implanted subcutaneously or into the mammary fat pad but metastasize to bone, lung, brain, and other sites when introduced into the milk duct (Sflomos et al., 2016). This model has been particularly valuable in preclinical testing of antiestrogen therapies (such as tamoxifen and aromatase inhibitors) and identification of mechanisms of resistance to such drugs. Another commonly used ER+ cell line of the luminal subtype is T47D, which was also isolated from a pleural effusion of a patient with invasive ductal carcinoma. Due to their high expression of PR, T47D cells are commonly used to study progesterone signaling in breast cancer and therapeutic efficacy of antiprogestins. Unlike MCF-7 cells, T47D cells express a mutated, nonfunctional form of the tumor suppressor p53. From the SUM series of cell lines, SUM44PE cells (isolated from a pleural effusion) are the best model of the luminal subtype as they express ER. However, they lack PR and have mutated p53 and there is limited information on the biology of xenografts of this cell line. Other luminal breast cancer cell lines that can be used to study early stage disease are listed in Table 35.1.

Models for invasive disease. The MDA-MB-231 cell line (isolated at M D Anderson from a pleural effusion of a patient with invasive ductal carcinoma) is commonly used to model late stage breast cancer. This cell line is ER, PR, and E-cadherin negative and expresses mutated p53. In microarray profiling, the MDA-MB-231 cell genome clusters with the basal subtype of breast cancer. Since the cells also lack the growth factor receptor HER2, they represent a model of triple-negative breast cancer. MDA-MB-231 cells are invasive in vitro and when implanted orthotopically produce xenografts that spontaneously metastasize to lymph nodes. Variants of MDA-MB-231 cells with unique metastatic properties have been selected from the parental cell line (Kang et al., 2003). Bone-seeking (MDA-231BO) and brain-seeking (MDA-231BR) clones were selected by repeated passaging in nude mice and in vitro culture of metastatic cells obtained from bone and brain metastases (Yoneda et al., 2001). When tested in experimental metastasis models, these variants showed preferential homing to bone and brain following intracardiac injection. Stable incorporation of luciferase tags in specific MDA-MB-231 subclones has enabled noninvasive in vivo imaging of experimental metastasis (Jenkins et al., 2005).

Triple-negative breast cancers (TNBC) have been further divided into three major subtypes based on gene expression profiling (Lehmann et al., 2011), and established cell lines have been identified to model each

TABLE 35.1   Appropriate Models for Study of Breast Cancer Stages and Subtypes

Application	Model	Appropriate approaches	Comments
Normal development and carcinogenesis	Mouse mammary gland organ culture	Whole gland ± hormones, DMBA	• Strain dependent (BALB/c preferred) • Suitable for screening preventive agents • Can be performed with tissue from transgenics and knockouts
DCIS	Orthotopic xenografts	MCF10DCIS.COM, SUM-225	• Intraductal cell injection via nipple
Luminal subtype	Orthotopic xenografts	*Wild-type p53*: MCF-7, CAMA1, ZR75-1 *Mutant (m) or negative (−) p53*: T47D(m), BT483(−), SUM44PE(−), HCC202(−), HCC1428(−)	• All except HCC202 are ER+ • MCF7, T47D, HCC1428, CAMA1, ZR75-1, SUM44PE are PR+ • All show little-no invasive activity in Boyden chamber assays
	Transgenic	MMTV-Neu, MMTV-PyVMT, TgWAP-Myc	• Tumors in transgenic mice show weak luminal phenotype and lack ER
	Induced	Chronic MPA treatment-mice NMU—rats	• Both protocols induce ER+ tumors
HER2+	Orthotopic xenografts	*Luminal*: BT474, MDA-MB-361, SK-BR-3, SK-BR-5, UACC812, ZR75-30 *Basal A*: HCC1569, HCC1954, HCC202, SUM190PT	• MDA361, ZR75-30 are ER+ • BT474, SK-BR-3, SK-BR-5, UACC812, HCC1569, HCC1954, HCC202, SUM190PT are ER-
	Transgenic	MMTV-Neu	• Useful for testing anti-Her2 therapies • Genomic profiles show limited conservation between MMTV-Neu tumors and human Her2+ breast cancers
Basal B/triple negative	Orthotopic xenografts	*Wild-type p53*: BT20, HBL100, SUM149PT *Mutant (m) or negative (−) p53*: MDA-MB-231 (m), MDA-MB-435 (m), BT549 (m), SUM159PT (−)	• All except BT20 are invasive in Boyden chamber assays
	Transgenic	Conditional BRCA1 and BRCA2 deletion on p53$^{+/-}$ background, MMTV-Wnt1	• MMTV-Wnt1 tumors show mixed luminal and basal phenotype
	Chemically induced	MPA-DMBA model	• Phenotype strongly influenced by genetic background; genomic clustering based on FVB tumors
Hereditary syndromes	Orthotopic xenografts	MX-1(BRCA1,BRCA2), HCC1937 (BRCA1), HBCx-17(BRCA2)	• Not well-characterized in vivo
	Knockout	Conditional BRCA1 and BRCA2 deletion/ mutation on p53$^{+/-}$ background	• Tumors are triple negative
Metastatic disease	Orthotopic grafts	MDA-MB-231, MDA-MB-453 [4T1] series	• Some luminescent clones are available • [4T1] is syngeneic in BALB/c mice
Inflammatory breast cancer	Orthotopic xenografts	SUM149PT, SUM190PT MARY-X (transplantable)	• Not well-characterized in vivo

TNBC subtype. These cell lines include HCC1806 and MDA-MB-468 (basal-like); CAL-51 and SUM159PT (mesenchymal-like); and SUM185PE and CAL-148 (luminal-androgen receptor). Xenograft studies with these six cell lines indicated subtype-specific drug sensitivity in vivo that matched predictions based on specific genomic alterations.

Models of familial breast cancer. Loss of function mutations in the breast cancer susceptibility genes BRCA1 and BRCA2 are strongly linked to hereditary breast cancer. Although many cell lines exhibit mutations in these tumor suppressor genes, the majority are sporadic mutations that developed either during tumor progression or during cell line establishment. The exception is the few cell lines that have been isolated from tumors of individuals with known BRCA germline mutations. Only one such breast cancer cell line is readily available: HCC1937 cells, which were initiated from a Stage IIB primary ductal carcinoma of a 23-year-old Caucasian female from a family with a known deleterious BRCA1 mutation. HCC1937 cells are homozygous for the BRCA1 5382C mutation, whereas lymphoblastoid cells derived from the same patient are heterozygous for this mutation, indicating loss of heterozygosity in the tumor

cells. This mutation encodes a truncated BRCA1 protein lacking the C-terminus BRCT domain required for repair of DNA damage and regulation of the cell cycle. The tumor-derived cells are ER- and PR-, express mutated p53, and exhibit homozygous deletion of the PTEN gene. HCC1937 cells are highly transformed with a modal chromosome number of 100 (Tomlinson et al., 1998). These cells have been utilized in xenograft models to examine the role of BRCA1 in sensitivity to DNA damaging agents, such as cisplatin in vivo (Tassone et al., 2009). Three additional cell lines with BRCA1 mutations were identified (Elstrodt et al., 2006) in a screen of 41 established breast cancer cell lines: MDA-MB-436 (adenocarcinoma/age 39), SUM149PT (inflammatory breast cancer/age 35), and SUM1315MO2 (invasive ductal carcinoma/age of onset unknown). Another line, HCC3153, which is homozygous for the BRCA1 943ns10 mutation that causes a frameshift leading to a stop at codon 289 in exon 11, was identified during molecular profiling of 52 breast cancer cell lines (Kao et al., 2009). Since mutation analysis was not conducted at the time of isolation of these three BRCA1 mutant cell lines, it is unclear whether the BRCA1 mutations represent germline events (although at least two donors had early onset breast cancer and thus could be bona fide BRCA1 carriers). Furthermore, there is little to no information on the pathology or biology of xenografts derived from these cells. Despite these caveats, these cell lines are suitable for studying BRCA1 functions in the context of breast cancer. In contrast to BRCA1, no established cell lines have been derived from breast tumors of known BRCA2 mutation carriers.

Two xenograft models of BRCA-associated breast cancer (MX-1 and HBCx-17) have been reported to date. The MX-1 breast xenograft which carries mutations in both BRCA1 and BRCA2 has been used to test the antitumor efficacy of PARP inhibitors (Donawho et al., 2007), a class of drugs that targets cells with defects in homologous recombination. Other than its use to screen therapeutics for activity against tumors with mutations in the BRCA genes, the molecular and pathological features of MX-1 xenografts have not been well characterized. The HBCx-17 xenograft model was generated from an infiltrating ductal carcinoma of a woman carrying a germline c.6033_6034delTT BRCA2 mutation (de Plater et al., 2010). Within 1 month after fresh tumor fragments were grafted into the interscapular fat pad of a female nude mouse, a basal-like triple-negative xenograft developed which accurately reflected both the genotype (BRCA mutation, chromosomal changes) and the phenotype (especially with respect to drug sensitivity and resistance) of the primary tumor from which it was derived. These studies demonstrate the feasibility of this approach and support the concept that tumor grafts represent a valuable and relevant complementary approach to traditional cell-line based xenografts for studying molecular aspects of human breast cancer, as well as for testing therapies.

Models of inflammatory breast cancer. Although inflammatory breast cancer accounts for a small (1–5) percentage of all breast cancers, it is a very aggressive disease with high mortality. Inflammatory breast cancers represent a unique subtype of invasive ductal carcinomas that form and grow as emboli which accumulate in and block lymphatic ducts in the dermis. Inflammatory breast cancers are usually diagnosed at an advanced stage and progress rapidly, accounting for their high mortality. Two established cell lines are known to be derived from inflammatory breast cancer patients: SUM149 and SUM190. SUM149 cells were isolated from a pleural effusion, are triple negative, and cluster with the basal subtype of breast cancers. SUM190 cells were isolated from a primary tumor, are ER-, PR-, and HER2+ and cluster with the luminal subtype of breast cancers. When xenografted into immunocompromised mice, both cell lines grow as solid tumors, thus it is unclear how well they model the unique growth characteristics of inflammatory breast cancers in patients (Wang et al., 2009).

Another model of inflammatory breast cancer (MARY-X) has been developed by the Barsky lab (Alpaugh et al., 1999). The MARY-X xenograft is a stable, serial transplantable tumor that was established directly from a 45-year-old patient with inflammatory carcinoma and dermal lymphatic invasion. In scid/nude mice, MARY-X tumor cells grow exclusively within the lymphatics and blood vessels, providing a model highly reminiscent of the human disease. MARY-X tumors are triple negative, lack functional p53, and overexpress E-cadherin and MUC1 similar to cases of human inflammatory breast cancer. There are technical challenges in continuously passaging the MARY-X tumor cells, which must be separated from the associated murine cells, and the model is not widely available. At this point, the paucity of relevant animal models that mimic the unique characteristics of inflammatory breast cancers severely limits progress into this devastating form of breast cancer.

Models of DCIS. Ductal carcinoma in situ (DCIS) is the most common type (80%) of noninvasive breast lesion and is considered a precursor of invasive ductal carcinoma (Bombonati and Sgroi, 2011; Muggerud et al., 2010). While the vast majority of women will not recur after removal of DCIS, there are no validated biomarkers to stratify the subset of patients who will, from those who will not. Thus, in most cases, DCIS is treated conservatively (with surgery, radiation, and/or hormonal therapies) to reduce the risk of recurrence. Further insight into the evolution and progression of DCIS would benefit greatly from relevant animal models, which could be used to develop biomarkers and screen for agents that prevent progression of the disease. Experimental models of noninvasive breast tumors are limited, and the existing

in vivo models do not mimic the known heterogeneity of human DCIS. Within the last few years, a new model of DCIS based on human cell lines and biopsy tissue xenografted into immunocompromised mice has been developed (Behbod et al., 2009; Valdez et al., 2011). This unique approach involves injection of human DCIS cell lines (MCF10DCIS.COM, SUM225) or cells derived from human DCIS biopsies directly into the murine mammary ducts via the nipple. With this method, MCF10D-CIS.COM cells developed into a basal-like DCIS model, whereas SUM225 cells represented a model for HER2+ DCIS. The xenografted tissues initially grew within the mammary ducts, forming single and multilayered epithelium after 8 weeks with stromal invasion in some cases. The grafts recapitulated the patient's original DCIS with respect to heterogeneity and expression of biomarkers, such as human cytokeratins, ER, and HER2. These studies demonstrate that DCIS xenografts can retain the unique pathology and heterogeneity of the human lesions and provide a new tool for probing the cellular and molecular events associated with DCIS progression.

6 GENETICALLY ENGINEERED MOUSE MODELS OF BREAST CANCER

6.1 General Overview

In the early 1980s technology for generating mouse lines carrying cloned genes was developed and at about the same time viral and cellular oncogenes were identified in animal and human cancers. Merging of these two advances in the mid-1980s led to the development of the first transgenic mice carrying activated oncogenes. Some of these mice were found to display heritable predisposition to tumor development. In 1988, the "oncomouse"—a line expressing the c-Myc oncogene specifically in mammary epithelial tissue was developed and patented (Hanahan et al., 2007). This transgenic line spontaneously developed mammary carcinomas in a delayed and asynchronous fashion. As specific genetic events associated with human breast cancers were identified, mice carrying genetic alterations that mimic mutations found in patients were generated. Many of the transgenic models were created with selective oncogene expression in mammary tissue through the use of promoters that are highly active in breast cells. The most commonly used of these promoters are the MMTV-derived long terminal repeat (MMTV-LTR), the whey acidic protein (WAP), and the β-lactoglobin (BLG), which are all active in the luminal epithelial cells of the mouse mammary gland. Activity of these promoters is hormone dependent to some degree, but generally they are highly efficient at driving mammary specific expression beginning at puberty (MMTV) or pregnancy (WAP, BLG). Less frequently used is the keratin 14 (K14) promoter which is expressed in basal and myoepithelial cells but not in luminal cells, allowing for targeting of oncogenes to a different cell of breast cancer origin in the gland. Although selective for mammary tissue, none of these promoters are completely specific, and transgene expression is often detected at low levels in lungs, kidney, prostate, seminal vesicles, salivary glands, and other tissues. Extramammary transgene expression can create problems in interpretation of tumor phenotypes if it results in systemic changes that secondarily affect mammary gland development.

To complement the oncogenic models, mice in which tumor suppressor genes are ablated were generated and many of these lines display increased susceptibility to spontaneous or induced mammary carcinoma (Deng, 2014). To date, thousands of murine models of breast cancer have been generated, using more advanced technologies including inducible promoters, such as the tetracycline regulators and conditional ablation techniques, such as the cre/lox system (Borowsky, 2011; Menezes et al., 2014). Furthermore, many of these mouse lines have been crossed to investigate synergy, or bred onto different background to explore genetic susceptibility. Thus, there are a myriad of models to choose from for studying breast cancer in genetically engineered mice (GEM). It should be remembered that the specific initiating oncogene, the cell of origin that is targeted by the chosen promoter and the developmental timing of oncogene expression will all impact the tumor phenotype of these GEM models. In depth discussion of these approaches and technologies is outside the scope of this chapter, but many reviews are available on the strategies and applications (Borowsky, 2011; Cheon and Orsulic, 2011). A few of the more commonly used models will be briefly described here, including a short comparison of the resulting tumors from some of these mice, and how well they model the pathology and molecular heterogeneity characteristic of human breast tumors.

6.2 Examples of GEM Mammary Tumor Models With Activation of Oncogenes

By definition, an oncogene is a gene whose gain of function (whether by amplification, mutation, or overexpression) increases the risk of carcinogenic transformation for the cell in which it is active. In GEM models of mammary cancer, oncogene activation is mimicked by transgenic overexpression of a normal or mutated version of the gene of interest usually driven by mammary-specific promoters. The most commonly used models are those in which strong oncogenes (Myc, Ras, Wnt, TGFα, and ErbB2) are selectively driven in mammary luminal epithelial cells by the MMTV or WAP promoters. However, new models are routinely being developed and characterized (Borowsky, 2011; Greenow and Smalley, 2015).

The first transgenic model of breast cancer was the MMTV-Myc mouse strain, which developed spontaneous mammary adenocarcinomas by 4–8 months of age (Stewart et al., 1984). When Myc is expressed under the transcriptional control of the WAP promoter, 80% of female transgenics developed multiple tumors affecting single or multiple glands after two pregnancies as early as 2 months of age. The heterogeneity of MMTV-Myc induced mammary tumors was recently evaluated in mice expressing either wild-type Myc or the constitutively active mutant T85A (Andrechek et al., 2009). While the majority of tumors in MMTV-Myc mice were microacinar (composed of cuboidal cells arranged in acini with basal myoepithelial cells), those in mice expressing T85A Myc were predominantly papillary (composed of fibrovascular stalks lined by columnar cells that form gland like spaces). Other tumor types included squamous carcinomas, adenocarcinomas, and those defined as epithelial-mesenchymal transition (EMT)—type tumors. Genomic analysis indicated that these histological subtypes reflected different signaling pathways including β-catenin and Stat3 activities. In addition, activating mutations in the Ras oncogene were particularly prevalent in the EMT-type tumors (Leung et al., 2012). Collectively, these mouse models demonstrated that Myc is a mammary oncogene, but the focal nature of the lesions, the asynchrony and heterogeneity of tumor development, and the prolonged time course indicated that additional molecular events cooperate with Myc to drive carcinogenesis (Hutchinson and Muller, 2000).

Using a similar approach, MMTV-Ras mice were created and characterized by the Leder group (Sinn et al., 1987). In contrast to MMTV-Myc mice, in which only females develop mammary adenocarcinomas, both male and female MMTV-Ras mice exhibited mammary and salivary gland neoplasms within 5 weeks of age. The tumors that developed in MMTV-Ras mice were primarily papillary adenocarcinomas. When MMTV-Myc and MMTV-Ras mice were crossed, the kinetics with which tumors developed was considerably accelerated (Sinn et al., 1987). Comparative aspects of the myc, ras, and bigenic mammary tumors, which are all ER-, have been described (Pattengale et al., 1989).

The MMTV-Neu models (Andrechek et al., 2000; Muller et al., 1996, 1988) were designed to mimic the 20%–30% of human breast cancers that overexpress the growth factor receptor HER2. Human HER2 positive breast cancers are characterized by amplification of the region on chromosome 17 (17q21-q22) which encodes the ERBB2 gene, causing marked upregulation of the HER2 growth factor receptor in tumors. The presence of HER2 amplification in human tumors is associated with aggressive disease that has a high rate of recurrence and poor prognosis. In MMTV-Neu mice, the wild-type form of the rat gene Neu (the homolog of the ErbB2 gene) is expressed from the MMTV promoter. In this model, both virgin and nonvirgin female mice exhibited mammary hyperplasia with a 50% incidence of focal adenocarcinomas by 205 days of age. Lung metastases were detected in 72% of tumor-bearing mice that lived 8 months or longer. Transgenic expression of a constitutively active form of Neu (containing a point mutation that facilitates receptor oligomerization and ligand-independent activation) in the mammary gland markedly accelerated the onset of tumors (Muller et al., 1988; Pattengale et al., 1989). Tumors that developed in MMTV-neu mice were solid nodular adenocarcinomas with some evidence of lumen formation and weak to no detectable expression of ER.

Related to the MMTV-Neu model is the MMTV-PyVMT model, which expresses the polyoma virus middle T antigen under the control of MMTV (Guy et al., 1992). The PyVMT encodes a membrane spanning protein that potently activates pathways downstream of growth factors including ERBB2, including SRC and phosphatidylinositol 3-kinase (PI3K) (Dilworth, 2002). Female MMTV-PyVMT mice developed highly aggressive multifocal ER negative mammary tumors involving the entire fat pad with 100% incidence and an average latency of 35 days. Tumors developed in both virgin and parous females, as well as in males. Tumor-bearing mice developed spontaneous lung metastases within ~90 days (85% penetrance).

Other models in which growth factor pathways are deregulated in association with mammary tumor formation include mice expressing the EGFR ligand TGFα (Lee and Muller, 2010; Pattengale et al., 1989). In three different models, overexpression of TGFα in the mammary epithelium was associated with hyperplasia of alveoli and terminal ducts in virgin female and pregnant transgenic mice. A range of morphologic abnormalities including lobular hyperplasia, cystic hyperplasia, adenoma, and adenocarcinoma were seen in the mammary tissue of transgenic females. With multiple pregnancies and increasing age, up to 40% of multiparous animals developed tumors by 16 months of age (Halter et al., 1992; Matsui et al., 1990). Bigenic mice carrying both WAP-TGFα and WAP-Myc displayed a dramatic acceleration of tumor development, with 100% of bigenic mice developing synchronous mammary tumors at a mean age of 66 days. Of note, when TGFα was driven by the Neu-related lipocalin (NRL) promoter, the hyperplasias, cystic and solid tumors that developed all expressed ER (Rose-Hellekant et al., 2007). These tumors were also hormone dependent as ovariectomy decreased tumor incidence. Thus, this model represents a good choice for studying the formation of ER+ mammary tumors.

6.3 Examples of GEM Mammary Tumor Models With Inactivation of Tumor Suppressor Genes

By definition, tumor suppressor genes are those whose loss of function increases the risk of cancer. Since in general, both alleles of a tumor suppressor gene must be inactivated for cancer to develop, most GEM models of breast cancer have utilized homozygous knockout mice. There are some examples where engineered loss of function or dominant negative mutations have been constructed. Since many tumor suppressor genes have critical roles in development, conditional deletion/mutation is often necessary to avoid embryonic or perinatal lethality or associated disturbances in tissues other than the mammary gland.

The best-characterized tumor suppressor gene is p53, a transcription factor with essential roles in cell cycle and apoptosis control, DNA damage signaling, and metabolism. p53 is commonly mutated in sporadic breast tumors and its germline loss of function increases the risk for development of breast cancer in individuals with Li–Fraumeni syndrome. Not surprisingly, mice lacking p53 develop tumors in multiple tissues (primarily sarcomas and lymphomas) and early mortality from these malignancies precludes the development of mammary tumors (Donehower et al., 1992; Jacks et al., 1994). Thus, other approaches, such as transplantation of p53 null tissue into syngeneic mice (Medina, 2010), use of p53 heterozygous (+/−) mice (Kuperwasser et al., 2000), expression of dominant negative alleles (Wijnhoven et al., 2005), or conditional p53 deletion with cre/lox technology (Lin et al., 2004) have been necessary for studying the role of p53 in mammary tumorigenesis in vivo. Notably, tumor spectrum is altered in p53 deficient mice on the BALB/c genetic background, with preferential development of mammary tumors in p53$^{+/-}$ mice. Median survival was 15 weeks for BALB/c-p53$^{-/-}$ mice compared to 54 weeks for BALB/c-p53$^{+/-}$ mice. Although sarcomas and lymphomas were the most frequent tumor types in BALB/c-p53$^{-/-}$ mice, 55% of the female BALB/c-p53$^{+/-}$ mice developed mammary carcinomas. The mammary tumors in p53$^{+/-}$ mice were highly aneuploidy with frequent loss of the remaining wild-type p53 allele. Transplantation of p53$^{-/-}$ epithelium into syngeneic hosts resulted in 75% tumor formation indicating that complete loss of p53$^{-/-}$ also favors mammary carcinogenesis (Kuperwasser et al., 2000). Using the Cre/loxP system, p53 inactivation with a constitutively active WAP-Cre, but not with MMTV-Cre, led to the development of ER+ mammary tumors (Lin et al., 2004) with genetic alterations, such as Myc amplification and Her2 activation and a high rate of metastasis. Thus, there are multiple p53-deficient GEM models to choose from that recapitulate many aspects of human breast cancer.

The best-characterized mammary-specific tumor suppressor genes in humans are BRCA1 and BRCA2. Germline deletion of either BRCA1 or BRCA2 is embryonic lethal, and mice heterozygous for BRCA1 or BRCA2 do not have increased spontaneous tumor development (Borowsky, 2011). Conditional alleles of both BRCA genes have been created with various promoters (MMTV, WAP, BLG, K14) and in most of these, females indeed developed mammary tumors of diverse types, albeit with long (greater than 1 year) latency (Evers and Jonkers, 2006; Ludwig et al., 2001; Xu et al., 1999). When conditional BRCA models have been crossed with p53$^{+/-}$ mice, synergistic acceleration of spontaneous mammary tumor development was observed. Tumors from MMTV-Cre;Brca1$^{Co/Co}$;p53$^{+/-}$ mice were triple negative, basal-like, and displayed gross genomic instability (Brodie et al., 2001). In K14-Cre;Brca1$^{F5-13/F5-13}$;p53$^{F2-10/F2-10}$ mice, tumors were also highly aneuploid solid carcinomas with basal-like characteristics, including high-proliferation index, poor differentiation, and lack of ER expression (Liu et al., 2007). Tumors from BRCA2 conditional mice displayed aneuploidy and chromosomal aberrations, were usually ER- and HER2-negative with high cyclin D1 expression. Combined tissue-specific inactivation of both Brca2 and p53 resulted in highly efficient mammary tumor formation in K14-Cre;Brca2$^{F11/F11}$;p53$^{F2-10/F2-10}$ female mice (Jonkers et al., 2001). Although there was some heterogeneity in tumor types, most did not express ER, PR, or ErbB2 and were positive for basal cell cytokeratins. Thus, these tumors resembled the human BRCA1-associated cancers, which are triple negative, but not the BRCA2-associated human cancers which are typically ER positive.

Additional GEM models of mammary tumorigenesis involving tumor suppressor genes include Stat1 (mimics human ER positive luminal breast cancers and synergizes with MMTV-Neu driven tumorigenesis) and E-cadherin (mimics human lobular carcinoma in association with p53 deletion) (Derksen et al., 2011). Additional details on mouse models and their relevance to human breast cancer are available in several reviews (Borowsky, 2011; Lee and Muller, 2010; Manning et al., 2016; Menezes et al., 2014; Mohibi et al., 2011; Vargo-Gogola and Rosen, 2007).

7 COMPARATIVE PATHOLOGY AND GENOMICS: MOUSE MAMMARY TUMORS VERSUS HUMAN BREAST CANCER

A consensus report on the comparative pathology of 39 breast cancer GEM models and human breast cancer was generated in 1999 (Cardiff et al., 2000). The conclusion from that analysis was that the overall histology of the available GEM tumors did not resemble the common types of human breast cancer. However, GEM tumors were deemed valuable since genes known

to be associated with human breast cancer did cause cancers in mice and the more heterogeneous tumors did contain regions reminiscent of human breast cancer histology. Notable differences in most mouse tumors compared to human tumors included the lack of fibrosis and inflammation, the limited metastasis, and the hormone independence. Other than xenografts, the rat chemically induced mammary tumorigenesis model was noted as the best model for studying hormone independence. As described in this chapter and recent reviews (Borowsky, 2011; Lee and Muller, 2010; Mohibi et al., 2011) there are considerably more GEM models now, with unique phenotypes including ER positive luminal-type tumors. Furthermore, many of these models have yet to be characterized with respect to sensitivity to induced carcinogenesis (i.e., chemical, hormone, or radiation paradigms). Still lacking, too, are models of the less-frequent tumor types (such as mucinous, tubular, medullary, and inflammatory breast cancers) and those that truly mimic the metastatic patterns characteristic of human breast cancers.

Genomic profiling has provided another approach to assess how well murine tumors model human breast cancers. Profiles of 10 distinct mouse mammary tumor models were conducted to characterize their diversity with an emphasis on the similarities to human breast tumors (Herschkowitz et al., 2007). This analysis indicated that while some mouse models (including WAP-Myc, MMTV-Neu, MMTV-PyVMT) developed tumors with consistent, model-specific patterns of gene expression, others (DMBA-induced models, BRCA/p53$^{+/-}$) displayed much more diversity. In addition, murine tumors clustered into 10 groups which could be subdivided into four main categories (normal, mesenchymal, basal/myoepithelial, and luminal). Based on these genomic profiles, four of the GEM models (WAP-Myc, MMTV-Neu, MMTV-PyVMT, and Wap-Int3) developed luminal-like tumors with the important caveat that the murine tumors lacked ER and thus did not express core ER regulated genes found in the human luminal cluster. Several models, including the Brca1-deficient and DMBA-initiated tumors, showed genomic profiles consistent with human basal-like tumors. Another study applied comparative genomics of p53 null tumors in mouse and basal breast cancers in humans to identify common aberrations (Pfefferle et al., 2016). This study reported five potential drug target genes that were amplified in both murine and human basal-like tumors: *Cul4a*, *Lamp1*, *Met*, *Pnpla6*, and *Tubgcp3*. Collectively, these studies and other publically available comparative genomic analyses provide exceptional resources for choosing the most appropriate mouse model for study of distinct breast cancer subtypes (Usary et al., 2016).

8 STUDYING METASTASIS IN MICE WITH AN EMPHASIS ON NEW MODELS

In general, the patterns of breast cancer dissemination in the available animal models do not recapitulate those observed in human breast cancer. Although several of the GEM models progress to distant metastases, the incidence is relatively low and disease spread to clinically relevant sites, such as brain and bone, is rare. Despite this caveat, both xenograft and GEM approaches have been utilized to study specific aspects of breast cancer metastasis, yielding insights into mechanisms, as well as providing evidence of circulating tumors cells and metastasis suppressor genes in these models (Bohl et al., 2014; Kabeer et al., 2016; Simmons et al., 2015).

Better models of bone metastasis are of particular interest due to the frequency and clinical impact of skeletal spread in patients. Typically, studies of bone metastasis have relied on direct injection of tumor cells (ideally expressing luciferase or other traceable tag) into the tail vein, the left cardiac ventricle, or the bone (tibia, femur, calvaria) of immunocompromised mice. The most frequently used syngeneic model utilizes the 4T1 series of cell lines derived from the BALB/c strain, which when transplanted directly into the bone invade and generate osteolytic lesions with morphologic and genomic similarities to that observed in the human bone–tumor interface (Futakuchi and Singh, 2013). With respect to use of human breast cancer cells in xenograft models, several lines have been identified with propensity for growth in bone, including MDA-MB-435 and certain sublines of MDA-MB-231 cells (Jenkins et al., 2005). However, these also require direct inoculation into the circulation or ectopic implantation into bone for reliable metastases. Advantages, limitations, and specific details are available in recent reviews (Hibberd et al., 2013; Horas et al., 2015; Simmons et al., 2015).

Other approaches involve implantation of neonatal mouse vertebrae or fragments of fetal human bone into the host mice to provide a substrate for cancer cell spread. Rosenblatt (2012) created an "all human" model of breast cancer metastasis to adult bone. In this approach, ER/PR negative, HER2 positive SUM1315 cells injected into the mammary fat pad of immunodeficient mice migrated to previously implanted adult human bone fragments obtained at biopsy (Moreau et al., 2007). The team also created 3D bone-like scaffolds seeded with mesenchymal stromal cells and demonstrated that SUM1315 cells metastasized from the fat pad to both the tissue-engineered scaffolds and native human bone implants. The use of engineered scaffolds as homing sites for breast cancer metastasis from an orthotopic site may provide new opportunities to manipulate the bone microenvironment for mechanistic studies.

9 EMERGING NONRODENT MODELS OF BREAST CANCER

In recent years, efforts have been made to identify nontraditional models of breast cancer through characterization of spontaneous tumors in cats and dogs, induced cancers in primates, and modeling of metastasis in zebrafish. These emerging models are briefly discussed here with an eye to the future. Spontaneous mammary cancers develop in both dogs and cats and are often highly malignant. Dogs develop invasive mammary carcinomas with epidemiological and biological similarities to human breast cancers including a high prevalence of the triple-negative subtype (Rasotto et al., 2014). Interestingly, overexpression of the insulin-like growth factor Type 1 receptor (IGFR1) is common in canine invasive mammary carcinoma (as in human breast cancer) and is associated with aggressive features including lymphovascular invasion, high grade and the triple negative phenotype. IGFR1 overexpression in canine triple-negative tumors is associated with shorter overall and specific survival and shorter disease free index (Jaillardon et al., 2015). Thus spontaneous canine mammary cancer offers a relevant model for preclinical studies on new therapies targeting IGF1R and related pathways in triple-negative breast cancer. Guidelines for characterizing immunohistochemical biomarkers (ER, PR, HER2) and pathology (epithelial vs. myoepithelial, invasion, and micrometastases) of canine mammary tumors have been published to ensure reproducibility and comparison of various studies (Pena et al., 2014).

Feline mammary adenocarcinomas are also highly aggressive with strong similarities in clinical behavior to human basal-like breast cancers (Wiese et al., 2013). Molecular classification of feline mammary carcinomas indicated that the luminal B/HER2-negative subtype was the most common (30%), followed by luminal B/HER2-positive subtype (20%), triple negative basal-like (17%), luminal A (15%), triple negative normal-like (13%), and finally, HER2-positive subtype (7%). Highest survival was observed in cats with the Luminal A subtype while lowest survival was in animals with triple negative basal-like subtypes (Hassan et al., 2016; Soares et al., 2016). Lung was the most frequent site of metastasis. Interestingly, cats with multiple primary tumors showed different molecular subtypes in each carcinoma indicating considerable heterogeneity in etiology. Studies on feline mammary cancer are facilitated by the availability of cell lines (Borges et al., 2016; Hassan et al., 2016), some of which have been characterized for growth and metastasis in nude mice. When inoculated subcutaneously, feline carcinoma cells did not metastasize, but lung, brain, liver, kidney, eye, and bone metastases were confirmed following intratibial and intracardiac injection. Genomic analysis identified upregulation of genes encoding growth factors in the PDGF, EGF, and VEGF families in metastatic lesions. Collectively, these reports provide evidence that both spontaneous and experimental feline mammary carcinomas represent additional models for human breast cancer.

Zebrafish represent a powerful genetic model that is amenable to engraftment approaches and is highly suitable for studies of angiogenesis and metastasis (Moore and Langenau, 2016; Tulotta et al., 2016). Cancer cells can be transplanted into embryonic zebrafish prior to development of a functional immune system or into adult zebrafish with genetic or induced ablation of the immune system. Breast cancer cells of diverse malignant potential exhibit invasive and metastatic properties within embryonic zebrafish that correlate with their tumorigenicity in mouse models (Drabsch et al., 2013). Furthermore, blocking known mediators of metastasis (TGF-β, Smad4, matrixmetalloproteinases) reduces invasion and metastasis in the zebrafish xenograft model and closely mimics results from mouse metastasis models (Drabsch et al., 2013). Combined with sensitive imaging techniques, this model allows for cost-effective and rapid screening of potential inhibitors of angiogenesis and metastasis.

A unique model of breast cancer has been developed in tree shrews, a small primate that is easy to manipulate, maintain, and propagate. While breast cancer can be induced in tree shrews with chemical carcinogens, the incidence is low (50%) and the latency is long (7 months). In a novel approach, mammary tumors were induced within 3 weeks after injection of a lentivirus driving expression of the polyoma middle T oncogene into the mammary ducts (Ge et al., 2016). All injected animals developed tumors and one case showed metastasis to lymph node and lung. Tumor growth was significantly inhibited by established chemotherapeutics (cisplatin and epidoxorubicin). Once fully characterized, this primate model could represent a clinically relevant model suitable for screening of breast cancer therapeutics due to its high efficiency and short latency.

10 CONCLUSIONS

Advances in prevention and treatment for breast cancer rely heavily on the use of animal models. As described in this chapter, rodent models provide good surrogates for human breast tumors and are particularly useful for identification and testing of therapeutics. More efficient use of published data may benefit from sharing of archived resources between labs, a goal of the new web-based tool SEARCHBreast (https://searchbreast.org/), a searchable database, and online collaborative network of breast cancer researchers with experience with in vivo, in vitro, and in silico models of breast cancer. The

aim of this web-based resource is to reduce duplicative research by sharing data and archived materials, thereby accelerating discoveries (Blyth et al., 2016). As emerging models in other species become better characterized and shared, appropriate models for addressing clinical and molecular research questions relevant to human breast cancer can easily be identified.

Animal Models of Systemic Sclerosis

Toshiyuki Yamamoto

Fukushima Medical University, Fukushima, Japan

1 INTRODUCTION

Systemic sclerosis (SSc) is a connective tissue disease which shows fibrogenesis and vasculogenesis. Although the pathogenesis of SSc has not been fully elucidated yet, it is characterized by the excessive accumulation of extracellular matrix (ECM) proteins in the skin and various internal organs, vascular injury, and immunological abnormalities (Yamamoto, 2009). In early stages of SSc, activated fibroblasts in the affected areas produce high amounts of collagen. Histological analysis of the initial stage of scleroderma reveals perivascular infiltrates of mononuclear cells in the dermis, which is associated with increased collagen synthesis in the surrounding fibroblasts. A number of studies have demonstrated the crucial role of several fibrogenic cytokines released from immunocytes in initiating the sequence of events leading to fibrosis.

Animal models are useful in providing clues for the study of various human diseases and for the exploration of new treatments. Although animal models which exhibit all the aspects of SSc are not currently available, several experimental animal models, such as tight skin (Tsk) mice, Tsk2 mice, bleomycin-induced murine scleroderma, sclerodermatous graft-versus-host disease (Scl-GvHD) mice, exogenous injections of transforming growth factor-β (TGF-β)/connective tissue growth factor (CTGF)-induced murine fibrosis model, Friend leukemia integration-1 (Fli1)-deficient mice, and UCD-200 chicken, etc., as well as several transgenic or knockout mice, have been examined so far (Yamamoto, 2010). In this review, recent insights into the pathogenesis and therapeutic interventions gained from use of animal models of SSc are discussed.

2 BLEOMYCIN-INDUCED MURINE SCLERODERMA

Bleomycin was originally isolated from the fungus *Streptomyces verticillus*, and is frequently used as an antitumor agent for the treatment of various kinds of malignancy. In addition, bleomycin is used by dermatologists as a treatment for recalcitrant warts, hypertrophic scars, and keloid (Yamamoto, 2006a). Bleomycin hydrolase inactivates bleomycin by hydrolyzing the amide bond in the β-aminoalanineamide moiety. Due to the deficiency of the enzyme in the lungs and the skin, bleomycin-induced toxicity occurs predominantly in these organs. Pulmonary fibrosis is a well-known adverse effect of bleomycin, and bleomycin-induced lung injury in rodents is an established model for human pulmonary fibrosis. Mountz et al. (1983) reported that rats injected repeatedly with sublethal doses of bleomycin over a 58-week period developed severe dermal fibrosis similar to those found in human scleroderma with structural abnormalities of collagen fibers; however, histological features were not shown in their paper. On the other hand, we established bleomycin-induced murine scleroderma model by repeated local injections of bleomycin into the shaved back skins, and published in a series of studies (Yamamoto et al., 1999a,b; Yamamoto and Nishioka, 2001; Yamamoto and Nishioka, 2002a; Yamamoto and Nishioka, 2004a; Yamamoto et al., 2000a). Thereafter, this model has been admitted worldwide as a representative scleroderma model, and making use of this model, a number of studies have been performed. Further, modified models have also been reported (Ishikawa et al., 2009; Shibusawa et al., 2008).

Mice at the age of 4–6 weeks are usually chosen. Although dermal sclerosis can be induced by bleomycin in various mice strains, C3H/He, A/J, DBA2, B10.D2, and B10.A, and Balb/c mice develop intense dermal sclerosis, characterized by deposition of homogenous materials and thickened collagen bundles in the dermis. Both males and females can be used, and there are no differences of the degrees in induced fibrosis. Although dermal sclerosis was not very strongly induced in C57BL/6J strain, a frequently used strain as a control wild type in studies using gene-deficient mice, C57BL/6J strain can be used in those experiments. 100 μl of bleomycin at a concentration (higher than 100 μg/mL) is repeatedly injected in the shaved back skin intradermally or subcutaneously. Bleomycin administration is recommended to the superficial areas in the skin to avoid diffusion. Mice are getting thin with weight loss, and easily die if high concentration of bleomycin is given. Bleomycin at a concentration less than 1 mg/mL is usually used.

Histopathological examination revealed definite dermal sclerosis characterized by thickened collagen bundles and deposition of homogenous materials in the thickened dermis with cellular infiltrates, which mimicked human scleroderma. Dermal thickness gradually increased with the onset of the sclerosis. Cellular infiltrates were composed of T cells, monocytes/macrophages, and mast cells, which are supposed to play an important role in the induction of dermal sclerosis. By contrast, dermal sclerosis can be compulsorily induced by bleomycin treatment, even in nude mice, severe combined immunodeficiency (SCID) mice and mast cell-deficient mice (Yamamoto et al., 1999b; Yamamoto and Nishioka, 2001; Yamamoto and Nishioka, 2004a). A study shows that transfer of CD4+ T cells from bleomycin-treated mice induced the same pathological changes and antibody production in untreated Balb/c nude mice (Ishikawa et al., 2009). Mast cells increased in number in tandem with the induction of dermal sclerosis. Also, a marked degranulation was found in particular in the early phase, with elevated plasma histamine levels (Yamamoto et al., 1999a). In some strains, epidermal thickness was also induced as well (Yamamoto et al., 1999b). Further, lung fibrosis showing thickened alveolar walls with cellular infiltrates was also induced early on. Cutaneous changes were generally localized to the area surrounding the injected site, and sclerotic changes were not induced in the remote regions, such as fingers or abdominal skin. After the stoppage of bleomycin injections, sclerotic changes remained at least 6 weeks, suggesting that the induction of dermal sclerosis is not transient but persistent. Thickness of vascular wall in the deep dermis was also observed (Yamamoto and Katayama, 2011). There was some variation among strains in the intensity of the symptoms and the period required to induce dermal sclerosis, and C3H/He, DBA/2, B10.D2, and B10.A strains demonstrated intense dermal sclerosis by bleomycin treatment, suggestive of bleomycin-"susceptible" (Oi et al., 2004; Yamamoto et al., 2000a). Hydroxyproline contents in the bleomycin-treated skin were significantly increased in comparison with those of the PBS-treated skin. Increased production as well as upregulation of mRNA levels of type I collagen was found in the sclerotic skin (Yamamoto et al., 1999a; Yamamoto et al., 2000a). In the bleomycin-induced scleroderma, α-SMA-positive myofibroblasts were observed in the dermis, and gradually increased in tandem with the induction of dermal sclerosis (Yamamoto and Nishioka, 2002a). Interestingly, autoantibodies were detected in the serum after bleomycin treatment (Yamamoto et al., 1999a). Bleomycin hydrolase inactivates bleomycin by hydrolyzing the amide bond in the β-aminoalanineamide moiety. Due to the lack or shortage of this enzyme in the lungs and the skin, bleomycin-induced fibrosis and sclerosis occurs predominantly in these organs. A recent report shows that a one-time injection of bleomycin-poly(L-lactic acid) microspheres can induce dermal sclerosis in mice (Shibusawa et al., 2008); however, this technique is

difficult and can be available in limited institutes. The induction of dermal sclerosis is considered to be, in part, mediated by inflammatory and fibrogenic cytokines, as well as by the direct effect of bleomycin on ECM synthesis in fibroblasts.

Bleomycin exerts various effects on skin-constituted cells, such as fibroblasts, keratinocytes and endothelial cells, as well as immunocytes (Yamamoto, 2006a). In vitro, bleomycin upregulates collagen and TGF-β1 mRNA expression in cultured rat lung (Clark et al., 1980) and human skin fibroblasts (Yamamoto et al., 2000b). Also, bleomycin enhances gene expression of ECM proteins as well as fibrogenic cytokines (Yamamoto et al., 2000b), which may contribute to the induction of fibrosis. Increased TGF-β mRNA transcription is followed by TGF-β mRNA accumulation and TGF-β protein, which causes upregulation of procollagen gene transcription (Breen et al., 1992). It was shown that TGF-β is a mediator of the fibrotic effect of bleomycin at the transcriptional level and that the TGF-β response element is required for bleomycin stimulation of the proα1(I) collagen promoter (King et al., 1994). Endothelial cells have been reported to play an important role in the inflammatory as well as fibrotic process. In vitro studies showed a dose-dependent stimulation of endothelial cell secretion of collagen synthesis by bleomycin (Phan et al., 1991). This stimulatory activity was inhibited by the anti-TGF-β antibody (Phan et al., 1991). TGF-β increases the synthesis of ECM, such as collagen type I and type III, or fibronectin by fibroblasts, modulates cell–matrix adhesion protein receptors, and regulates the production of proteins that can modify the ECM by proteolytic action, such as plasminogen activator, an inhibitor of plasminogen, or procollagenase. In addition, TGF-β is capable of stimulating its own synthesis by fibroblasts through autoinduction. Thus, maintenance of increased TGF-β production may lead to the progressive deposition of ECM, resulting in fibrosis. Actually, TGF-β mRNA is elevated in the lesional skin of SSc, and also shown to colocalize with type I collagen in scleroderma skin (Kulozik et al., 1990). In the bleomycin model, immunohistological analysis showed that TGF-β was detected on the infiltrating cells, which were predominantly composed of macrophages, as well as fibroblasts at sclerotic stages. TGF-β1 and -β2 mRNA expression was also detected in the lesional skin at early phases. Additionally, expression and synthesis of TGF-β1 were increased in bleomycin-"susceptible" mice strains (Oi et al., 2004). CTGF (CCN2) is selectively induced in fibroblasts after activation by active TGF-β, and also regulated by TGF-β accessory receptors (Holmes et al., 2011). CTGF may functionally coordinate the mode of action of TGF-β, such as fibroblast proliferation and ECM production in fibroblasts. High level of CTGF is shown in the lesional skin of bleomycin-induced scleroderma (Liu et al., 2010). Plasminogen activator inhibitor-1 (PAI-1)

is induced by TGF-β, and its promoter contains Smad binding elements. PAI-1 expression was upregulated in the bleomycin-treated skin; however, dermal sclerosis was similarly induced by bleomycin in even PAI-1-deficient mice (Matsushita et al., 2005). PAI-1 plays an important role, but may not be the prerequisite factor, in the development of bleomycin-induced scleroderma. Signaling by TGF-β elicits profibrotic responses in fibroblasts. Upon binding of TGF-β to the type II receptor, the type I receptor becomes activated, and signaling to the nucleus occurs predominantly by phosphorylation of cytoplasmic mediators belonging to the Smad family. Three families of Smads have been identified; receptor-regulated Smad2 and -3 (R-Smads), common partner Smad4 (Co-Smad), and inhibitory Smad6 and -7 (I-Smads). Smad7 has been shown to act as an intracellular antagonist of TGF-β signaling, and an inhibitor of TGF-β-induced transcriptional responses. In scleroderma skin and cultured scleroderma fibroblasts, basal level and TGF-β-inducible expression of Smad7 are selectively decreased, whereas Smad3 expression is increased (Dong et al., 2002). On the other hand, Smad7 expression levels in scleroderma fibroblasts are unclear and disputed (Asano et al., 2004a; Mori et al., 2003). In the bleomycin-treated skin, fibroblasts showed predominantly nuclear localization of Smad3 and intense staining for phospho-Smad2/3 (Takagawa et al., 2003). On the other hand, expression of Smad7 was downregulated, which may account for sustained activation of TGF-β/Smad signaling in the lesional skin. Targeted disruption of Smad3 ameliorated bleomycin-induced scleroderma, unassociated with inflammation (Lakos et al., 2004). Recently, other signaling pathways besides the Smad proteins have also been shown to mediate TGF-β signaling in scleroderma fibroblasts, such as the p38 mitogen-activated protein kinase (MAPK) (Ihn et al., 2005), phosphatidylinositol 3-kinase (PI3K) (Asano et al., 2004b), and Egr-1 (Bhattacharyya et al., 2008) pathways. Other signaling pathways, such as c-abl, Src kinase, and Rac1 are also involved in the induction of scleroderma by bleomycin (Liu et al., 2008; Skhirtladze et al., 2008). Type 2 cytokines, that is, IL-4 and IL-13, have also been suggested to be important in scleroderma. IL-4 is produced by activated memory T cells and mast cells, and promotes fibroblast proliferation, gene expression, and synthesis of ECM proteins, such as collagen and tenascin (Makhluf et al., 1996; Postlethwaite et al., 1992). IL-4 upregulates TGF-β production in eosinophils (Elovic et al., 1998) and T cells (Seder et al., 1998). Increased IL-4 production is detected in the sera or by activated peripheral blood mononuclear cells of patients with SSc (Needlemann et al., 1985). Scleroderma fibroblasts express more IL-4 receptor α and produce more collagen after IL-4 stimulation (Serpier et al., 1997). In the bleomycin model, IL-4 levels in the serum (Yamamoto et al., 1999c) as well as in the

lesional skin (Matsushita et al., 2004) were significantly elevated following bleomycin treatment. Transcription factor T-bet is a master regulator of type 1 immunity, and mice lacking T-bet showed increased sensitivity to bleomycin and exhibited significantly enhanced dermal sclerosis (Aliprantis et al., 2007; Lakos et al., 2006). IL-13 is a potent stimulator of fibroblast proliferation and collagen production (Doucet et al., 1998a; Jinnin et al., 2004; Oriente et al., 2000). The profibrotic effect of IL-13 is postulated to involve irreversible fibroblast activation, triggered either directly (Doucet et al., 1998b) or indirectly through TGF-β (Lee et al., 2001; Oriente et al., 2000). IL-13 transgenic mice show increased lung fibrosis, as well as increased levels of TGF-β1 (Belperio et al., 2002). In the bleomycin model, IL-13 mRNA levels and protein synthesis in the lesional skin were increased, and IL-13 receptor (IL-13R)-α2 expression in the lesional skin was augmented mainly in the infiltrating mononuclear cells and macrophages after bleomycin exposure (Matsushita et al., 2004). Another study showed that IL-13-deficient mice failed to develop an increase in skin sclerosis after bleomycin treatment (Aliprantis et al., 2007). IL-13 may promote the progression of cutaneous fibrosis/sclerosis in the development of bleomycin-induced scleroderma.

Chemokines and chemokine receptors have also been implicated in the pathogenesis of SSc (Yamamoto, 2006b). CCL2/monocyte chemoattractant protein-1 (MCP-1) is a most important chemokine for SSc (Yamamoto, 2008). In vitro studies show that CCL2 upregulates type I collagen mRNA expression in rat fibroblasts, which is indirectly mediated by endogenous upregulation of TGF-β gene expression (Gharaee-Kermani et al., 1996). CCL2 enhances expression of matrix metalloproteinase-1 (MMP-1), MMP-2, as well as TIMP-1 in cultured skin fibroblasts (Yamamoto et al., 2000c). Current studies have demonstrated increased expression of CCL2 in patients with SSc (Distler et al., 2001; Galindo et al., 2001a; Hasegawa et al., 1999; Yamamoto et al., 2001a,b). Scleroderma fibroblasts express increased levels of CCL2 mRNA and protein (Galindo et al., 2001a; Yamamoto et al., 2001a), and stimulation with platelet-derived growth factor (PDGF) resulted in a significant increase in CCL2 mRNA and protein (Distler et al., 2001). Furthermore, the autoinduction of CCL2 was observed in scleroderma fibroblasts, but not in normal fibroblasts (Yamamoto et al., 2001a). CCL2 acts indirectly via IL-1α (Yamamoto et al., 2000c). IL-1α as well as IL-1 receptor levels, in turn, were shown to be significantly increased in scleroderma (Kawaguchi et al., 1999). In addition, IL-1α as well as tumor necrosis factor (TNF)-α are potent inducers of CCL2. Thus, in addition to a direct autocrine stimulatory loop, a mutual induction between IL-1α and CCL2 might lead to a self-perpetuating activation of scleroderma fibroblasts. CCL2 levels may also be increased by IL-13 because IL-13 is a potent stimulator of CCL2 (Zhu et al., 2002). In the

bleomycin model, expression of CCL2 in the infiltrating mononuclear cells was enhanced following bleomycin treatment, and expression of CCL2 in fibroblasts was detected at later stages in the sclerotic skin (Yamamoto and Nishioka, 2003). Expression of CCR-2, a major receptor for CCL2, was also upregulated in the lesional skin at both protein and mRNA levels following bleomycin treatment. Administration of anti-CCL2 neutralizing antibody together with local bleomycin treatment reduced dermal sclerosis, along with collagen content in the skin as well as mRNA expression of type I collagen. These data suggest that CCL2 and CCR-2 signaling plays an important role in the pathogenesis of bleomycin-induced scleroderma. In the CCL2-deficient mice, skin fibrosis was diminished even by the bleomycin treatment (Ferreira et al., 2006). CCL2 may contribute to the induction of dermal sclerosis directly, via its upregulation of mRNA expression of ECM on fibroblasts, as well as indirectly through the mediation of a number of cytokines released from immunocytes recruited into the lesional skin. On the other hand, oxidative stress transiently induces CCL2 mRNA and protein expression in cultured skin fibroblasts (Galindo et al., 2001b), suggesting that ROS may play a regulatory role in inflammation by modulating monocyte chemotactic activity.

Expression of TNF is detectable during the early stages of scleroderma (Hebbar et al., 1996). The serologic level of TNF increases with the clinical severity and biologic activity of the disease (Alecu et al., 1998), or in association with pulmonary fibrosis (Hasegawa et al., 1997). TNF-α targeting therapies are suggested to be effective for reduction of skin fibrosis (Distler et al., 2008). Bleomycin activates human alveolar macrophages to produce TNF-α, and in vivo studies show increased levels of TNF-α protein and mRNA in lungs following bleomycin treatment in mice (Phan and Kunkel, 1992; Piguet et al., 1989). The development of lung fibrosis by bleomycin was prevented by inhibition of TNF signaling through administration of antibodies against TNF-α (Piguet et al., 1989), or in TNF receptor (TNFR)-deficient mice (Ortiz et al., 1999). By contrast, TNFRp55-deficient mice developed severe sclerotic changes of the dermis following bleomycin exposure at extremely earlier time points, as compared with wild-type mice (Murota et al., 2003). Induction of MMP-1 expression was significantly inhibited in the bleomycin-treated skin of TNFRp55-null mice. The authors suggest that signaling mediated by TNFRp55 plays an essential role in MMP-1 expression and a key role in the collagen degradation process in the bleomycin model. The controversial results between skin and lung are also observed in PAI-1 knockout mice (Matsushita et al., 2005). Involvement of the apoptotic process in the pathogenesis of SSc has been investigated. Recent studies have shown that apoptosis of endothelial cells induces resistance to apoptosis in

fibroblasts largely through PI3K-dependent mechanisms (Laplante et al., 2005). Furthermore, fibroblasts exposed to medium conditioned by apoptotic endothelial cells presented myofibroblast changes (Laplante et al., 2005). By contrast, cultured scleroderma fibroblasts were resistant to Fas-induced apoptosis (Jelaska and Korn, 2000; Santiago et al., 2001). Although the effect of TGF-β on apoptosis differs according to cell type, stage of maturation, and other factors, TGF-β1 may play a role in inducing apoptosis-resistant fibroblast populations in SSc (Santiago et al., 2001). In scleroderma fibroblasts, Bcl-2 level was significantly higher, whereas the Bax level significantly decreased (Santiago et al., 2001). On the contrary, alterations in endothelial apoptosis induction were not involved in the development of the disease in either Tsk1/+ or Tsk2/+ mice (Sgonc et al., 1999). In the bleomycin model, TUNEL positivity was prominently detected on keratinocytes and infiltrating mononuclear cells, but not endothelial cells and fibroblasts (Yamamoto and Nishioka, 2004b). DNA fragmentation revealed laddering of the bleomycin-treated skin, and increased expression of Fas and FasL was detected in the lesional skin. mRNA expression as well as activity of caspase-3 was also enhanced after bleomycin treatment. Administration of neutralizing anti-FasL antibody together with local bleomycin treatment reduced the development of dermal sclerosis, in association with the reduction of TUNEL-positive mononuclear cells and with the blockade of apoptosis. Caspase-3 activity was also significantly reduced after anti-FasL treatment. Excessive apoptosis, which cannot be treated by macrophages, may induce proinflammatory cytokines, such as TNF-α or interferons (IFNs), and play a triggering role in the pathogenesis of bleomycin-induced scleroderma. T cells, macrophages, and mast cells are present in increased numbers or in an activated state in the lesional skin of SSc patients, and are thought to play an active role in the pathogenesis of the disease. Additionally, activated peripheral B cells are found in abnormally large numbers in patients with SSc (Sato et al., 2001). B cells contribute not only to antibody production, but also to T cell activation and differentiation and the production of various cytokines. In CD19-deficient mice, induction of dermal and lung fibrosis, cytokine expression and autoantibody production were inhibited (Yoshizaki et al., 2008). They speculate that hyaluronan activates B cells via toll-like receptor (TLR)-4 in this model. Also, expression of TLR-3 is increased in the dermis in this model, which may result in the increase of production of IL-6 and of differentiation into myofibroblasts (Agarwal et al., 2011). Role of innate immunity in SSc has recently been suggested, and TLR stimulation of fibroblasts may trigger cytokine cascades in fibrosis, via activating innate immune system (Fullard and O'Reilly, 2015). In particular, TLR-2, -3, and -4 may play an important role (Fang et al., 2016; Fullard and O'Reilly, 2015; Takahashi et al., 2015). TLR-3 expression was upregulated in SSc, and IFN-α2 induced an upregulation of TLR-3 in human dermal fibroblasts (Agarwal et al., 2011), suggesting an important role of TLRs activation via type I IFNs in fibrosis. Activation of nod-like receptors (NLRs) leads to the activation of inflammasome, and then caspase-1 activation, resulting in the processing and secretion of IL-1β and IL-18. Mice with a deletion of NLR protein 3 were resistant to bleomycin-induced skin fibrosis (Artlett et al., 2011). IL-18 acts as a fibrogenic cytokine, and expression of IL-18 is elevated in SSc (Scala et al., 2004). By contrast, IL-18 downregulated collagen production via the ERK pathway in human dermal fibroblasts (Kim et al., 2010). Thus, role of IL-18 in the development of fibrosis needs further analysis. MicroRNAs (miRNAs) are noncoding small RNAs, and dysregulation of miRNAs is recently shown. miRNA-29a is spontaneously downregulated in scleroderma fibroblasts, and fibrogenic cytokines, such as TGF-β, PDGF-B, and IL-4 reduced the level of miRNA-29a in normal fibroblasts (Maurer et al., 2010). Also, expression of miRNA-29a was reduced in the mouse model of bleomycin-induced scleroderma, suggesting a key regulator of collagen expression in SSc (Maurer et al., 2010). Alternatively, miR-155 was upregulated in scleroderma skin, and miR-155 deficient mice were resistant to bleomycin treatment (Yan et al., 2016). In vitro silencing of miR-155 in fibroblasts inhibited collagen synthesis and signaling pathways of Wnt/β-catenin and Akt. Bleomycin treatment reduced adipose tissues (Ohgo et al., 2013). Myofibroblasts within the fibrotic dermis were derived from intradermal adipocytic cells that had undergone phenotypic transformation, and proposed the term of adipocyte–myofibroblast transition (Marangoni et al., 2015). Cytokines derived from adipose tissues, such as adiponectin and leptin regulate fibroblast proliferation, differentiation, and function, via peroxisome proliferator-activated receptors (PPAR-γ). Leptin is suggested to play a profibrotic by augmentation of TGF-β by reducing PPAR-γ.

Numerous therapeutic approaches have been investigated so far in bleomycin-induced scleroderma model. Systemic administration of anti-TGF-β neutralizing antibody in combination with local bleomycin treatment, suppressed the development of scleroderma (Yamamoto et al., 1999c). This effect was accompanied by the reduction of the number of myofibroblasts, mast cells, and eosinophils. Topical application of a peptide inhibitor of TGF-β has been shown to ameliorate skin fibrosis in bleomycin-induced scleroderma (Santiago et al., 2005). Latency-associated peptide (LAP) is released from latent TGF-β. Local LAP administration along with bleomycin treatment suppressed the induction of dermal sclerosis, as well as collagen and CTGF gene expression, in an ongoing experiment (Wakatsuki-Nakamura

et al., 2012). IFN-γ causes potent inhibition of collagen production in cultured skin fibroblasts. IFN-γ decreased TGF-β-induced α-SMA expression in palatal fibroblasts, as well as changes in morphology (Yokozeki et al., 1999). Moreover, IFN-γ inhibits the TGF-β-induced phosphorylation of Smad3 and the accumulation of Smad3 in the nucleus, whereas induces the expression of Smad7 (Ulloa et al., 1999). In the bleomycin model, systemic administration of IFN-γ together with bleomycin reduced dermal sclerosis, even after the onset of scleroderma (Yamamoto et al., 2000d). Administration of inhibitor of TGF-β/Smad signaling by the activation of nuclear translocation of Y-box binding protein 1 suppressed skin fibrosis in this model (Hasegawa et al., 2009). A small molecule antagonist of CCL2 prevented skin sclerosis induced by bleomycin (Kimura et al., 2007). Bleomycin produces free radicals and induces apoptosis. A reduction of free radical formation may contribute to the decrease of collagen content by inhibition of proline hydroxylation, which leads to the improvement of scleroderma. Lecithinized superoxide dismutase (SOD) with high tissue accumulation and a long half-life in the blood showed an inhibitory effect on bleomycin-induced scleroderma, suggesting that antioxidant therapy may lead to an antifibrotic effect; however, postonset administration of SOD could not attenuate the dermal sclerosis (Yamamoto et al., 1999d). Also, a free radical scavenger, edaravone, inhibited dermal sclerosis (Yoshizaki et al., 2011). Halofuginone has an inhibitory effect on collagen synthesis, and shows antifibrotic effects in a few animal models of scleroderma. By contrast, bleomycin-induced scleroderma was not attenuated by treatment with halofuginone (Yamamoto and Nishioka, 2002b). Halofuginone may not ameliorate dermal sclerosis along with strong inflammation caused by repeated application of bleomycin. Hepatocyte growth factor (HGF) prevented the progression of organ fibrosis. The promoter region of the HGF gene contains a TGF-β inhibitory element. HGF induces proteases which degradate ECM proteins, such as MMPs, membrane type 1-MMP (MT1-MMP), and urokinase-type plasminogen activator (uPA), and also decreases TIMPs (Matsumoto and Nakamura, 2001). Gene transfer of HGF not only prevented the ongoing dermal sclerosis induced by simultaneous local injections of bleomycin, but also ameliorated the previously induced dermal sclerosis (Wu et al., 2004). This effect was mediated by suppressing TGF-β levels. Adenosine is a nucleoside that is generated in response to cellular stresses, such as chronic inflammation and hypoxic conditions. Adenosine A2A receptor-deficient and A2A receptor antagonist-treated mice were protected from developing bleomycin-induced dermal sclerosis (Chan et al., 2006). PPARs are ligand-activated transcription factors that regulate cell proliferation, differentiation, and immune/

inflammation response. PPAR-γ inhibits TGF-β signaling and collagen synthesis (Burgess et al., 2005; Ghosh et al., 2004). Insulin-sensitizing drugs, such as rosiglitazone and pioglitazone, activate PPAR-γ, inhibit TGF-β-induced fibrotic responses. Treatment with PPAR-γ ligand rosiglitazone prevented dermal sclerosis with downregulation of collagen gene expression and myofibroblast accumulation in the lesional skin (Wu et al., 2009). Imatinib mesylate (Gleevec) targets specifically the TGF-β and PDGF signaling pathways by inhibiting the tyrosine kinase activity of c-abl and PDGF receptors. Imatinib reduced dermal thickness, the number of myofibroblasts, and synthesis of ECM proteins in the bleomycin-induced dermal sclerosis (Distler et al., 2007). Further, imatinib induced regression of preexisting ECM accumulation in the skin and decreased dermal thickness (Akhmetshina et al., 2009). Dasatinib and nilotinib, both are dual inhibitor of c-abl and PDGF receptor, potently reduced dermal thickness, the number of myofibroblasts, and collagen content of the skin in the bleomycin model (Akhmetshina et al., 2008). An interaction between CD40 and its ligand CD40L has been suggested as a pathway for immune and inflammatory responses. Cultured scleroderma fibroblasts express CD40 (Fukasawa et al., 2003). In the lesional skin of bleomycin-induced scleroderma, dermal fibroblasts expressed CD40, and mast cells and CD4+ T cells expressed CD40L (Kawai et al., 2008). Anti-CD40L antibody inhibited the induction of skin sclerosis by suppressing fibroblast proliferation and downregulation of CCL2 expression in this model (Kawai et al., 2008). α-Melanocyte-stimulating hormone (α-MSH) has many effects, such as immunomodulation, regulation of exocrine activity and apoptosis, and antifibrotic effect. α-MSH suppresses TGF-β-induced collagen synthesis in vitro. Treatment with α-MSH suppressed bleomycin-induced collagen accumulation in the skin (Kokot et al., 2009). Intravenous immunoglobulin (IVIG) treatment significantly inhibited dermal sclerosis and collagen accumulation, by downregulating TGF-β and CCL2 (Kajii et al., 2011). Lysophosphatidic acid (LPA) is recently implicated to play an important role in fibrosis. LPA receptor inhibitor, a selective LPA1 and LPA3 antagonist, exerted an antifibrotic effect on the bleomycin-induced scleroderma (Ohashi and Yamamoto, 2015). Moreover, a number of new candidates for future treatment have been reported (Avouac et al., 2012; Balistreri et al., 2011; Desallais et al., 2014; Kitaba et al., 2012; Pamuk et al., 2015; Toyama et al., 2016; Ursini et al., 2016).

This model has several advantages, such as easy technique to induce dermal fibrosis, easy handling, short duration until the induction of dermal fibrosis, and high reproducibility independent of mice strains. One of the most useful advantages of this model is that this system can permit to investigate the induction of fibrosis from

prior to, during, and after the development, through the fibrotic process continuously. This great advantage means that the initial event of skin fibrosis can be analyzed. By contrast, skin fibrosis is not diffusely induced, but restricted to the bleomycin-injected sites. Also, many factors, including nonspecific or unessential factors in fibrosis, may be affected by bleomycin treatment.

3 HOCL-INDUCED MURINE SCLERODERMA

Recently, local injections of agents generating various types of ROS induced skin sclerosis in mice. Daily intradermal injections of hypochlorous acid (HOCl) induce skin and lung fibrosis, kidney damages, and serum Topo-I antibody production in Balb/c mice (Servettaz et al., 2009). On the other hand, local injections of agents generating peroxynitrite anions ($ONOO^-$) induced limited skin, but not lung, fibrosis and anti-CENP-B antibody production. As well as bleomycin, those agents capable to produce ROS, which induces phenotypic differentiation into myofibroblasts and enhances production of type I collagen, possibly via the phosphorylation of ERK1/2 and activation of the Ras pathway. In the HOCl-induced fibrosis model, the overproduction of ROS activates ADAM 17, a protease involved in NOTCH cleavage, suggesting that NOTCH pathway is activated (Kavian et al., 2010). In this model system, skin fibrosis is ameliorated by sunitinib (Kavian et al., 2012a) and arsenic trioxide (Kavian et al., 2012b). Some of the agents which induce DNA injury and ROS production exert various effects on endothelial cells and fibroblasts, as well as cause immune imbalance and mediator secretion, leading to dermal sclerosis. As is the same with bleomycin-induced scleroderma, many therapeutic approaches have been reported (Bagnato et al., 2013a,b; Kavian et al., 2015; Marut et al., 2013a,b).

4 TIGHT SKIN MOUSE

4.1 Tsk1 Mouse

Tsk mice are heterozygous for a mutation in the fibrillin-1 gene (Tsk1/+). Fibrillin is a large ECM structural protein and the major component of microfibrils. The most striking feature is the presence of thickened fibrotic skin that is firmly bound to the subcutaneous and deep muscular tissue; however, dermal sclerosis is lacking, and the fibrosis is much deeper in comparison with human SSc. In spite of those differences, there are numerous biochemical and molecular abnormalities that closely resemble those present in patients with SSc. Tsk1/+ mice also display certain visceral changes in the

lungs and hearts; however, vascular involvement has not been reported. The lung abnormalities are present at birth and histologically resemble human emphysema with little fibrosis. Additionally, aged Tsk1/+ mice produce autoantibodies, such as topoisomerase-1 (Topo-1) (Kasturi et al., 1994). mRNA levels of TGF-β, type I, III, and VI collagen in the skin were under temporal and spatial regulation during postnatal growth and development in the Tsk1/+ mice (Pablos et al., 1995). Collagen α1(I) and α1(III) gene-expressing fibroblasts were increased in Tsk1/+ fibrotic lesions. Transient transfections of a series of human α1(I) procollagen promoter constructs into Tsk1/+ fibroblast cultures showed increased transcription rates caused by the lack of the strong inhibitory influence of the regulatory sequence contained in the promoter between -675 and -804 bp (Philips et al., 1995). Additionally, Tsk1/+ nuclear extracts displayed decreased binding to a consensus AP-1 sequence. Transcriptional activation of collagen genes was demonstrated in Tsk1/+ mice in vivo employing reporter transgenes harboring upstream fragments of the 5' flanking region of the mouse α2(I) collagen genes. Wnt signaling stimulated matrix assembly of microfibrillar proteins including fibrillin-1, and increased expression of Wnt2 and SFRP2 in Tsk1/+ mouse skin (Bayle et al., 2008).

In Tsk1/+ mice, mast cells are abundant in the dermis and exhibit prominent degranulation. Mast cell density was dramatically increased in control littermates skin grafted onto Tsk mice, associated with the increase in mRNA levels of TGF-β, stem cell factor, and IL-15 (Wang et al., 2005). In Tsk mice, mast cells are abundant in the thickened dermis and exhibit prominent degranulation (Walker et al., 1987). Mast cells are a rich source of various cytokines, including IL-4 and TGF-β. IL-4 has been shown to induce significant levels of CCL2 production in stromal cells (Kikuchi et al., 1993; Lee et al., 2003). On the other hand, CCL2 upregulates IL-4 mRNA expression and protein production (Lukacs et al., 1997). These observations have led to the hypothesis of the mutual induction of CCL2 and IL-4. IL-4 and TGF-β possibly play important roles in the pathogenesis of fibrosis in Tsk mice. TGF-β was expressed during the rapid postnatal growth of the skin in parallel with high expression of α1(I), α1(III), and α2(VI) collagen genes (Pablos et al., 1995). By contrast, another study did not detect upregulation of TGF-β signaling pathway in Tsk1/+ mice skin (Baxter et al., 2005). Fibroblasts from Tsk1/+ mice are hyperresponsive to IL-4 and TGF-β, displaying increased synthesis of α1(I) collagen mRNA, collagen protein, and activity of a luciferase reporter construct containing α2(I) collagen promoter (MacGaha et al., 2001). After IL-4 stimulation, JAK-1 and JAK-2 were phosphorylated to a greater degree in Tsk1/+ fibroblasts than in C57BL/6 fibroblasts (MacGaha et al., 2003). Targeted mutations in

either the signaling chain of the IL-4 receptor or STAT6 prevents cutaneous hyperplasia in Tsk mice, suggesting the importance of IL-4 (Ong et al., 1999). Smad2 and Smad3 are considered to be the primary signaling molecules involved in the TGF-β signaling transduction pathway. Tsk fibroblasts have elevated Smad3 transcriptional activity compared with normal fibroblasts (MacGaha et al., 2002). This may explain why Tsk fibroblasts are more responsive to TGF-β stimulation. Recent studies have shown that CCL7 is highly overexpressed by neonatal Tsk fibroblasts (Ong et al., 2003). Increased CCL7 protein secretion by Tsk fibroblasts is observed, and CCL7 is abundantly expressed in the dermis of Tsk mice at 10 days and 3 weeks old.

CD4+ T cells have been shown to be required for the excessive accumulation of dermal collagen in Tsk1/+ mice (Wallace et al., 1994). By contrast, the Tsk phenotype fully develops in SCID mice. B cell functional defects caused by the loss of CD19 significantly decreased skin fibrosis in Tsk1/+ mice, suggesting that B cells play an important role (Saito et al., 2002). In Tsk1/+ mice overexpressing CD19, anti-Topo-I antibody levels were significantly increased, although skin thickness was not enhanced (Saito et al., 2002). B cell antigen receptor cross-linking augmented activation of extracellular signal-regulated kinase in Tsk1/+ B cells (Saito et al., 2002). Further, B cell depletion by anti-CD20 antibody significantly suppressed skin fibrosis and autoantibody production in newborn Tsk1/+ mice (Hasegawa et al., 2006). Thus, disrupted B cell signaling may contribute to immunologic abnormalities in Tsk1/+ mice. Endothelial dysfunction has been shown in Tsk1/+ mice (Marie and Beny, 2002). Expression of endothelial nitric oxide synthase (eNOS) protein and gene was significantly reduced in Tsk1/+ skin, and NOS activity was also decreased (Dooley et al., 2008). There is abnormal nitric oxide metabolism in the Tsk1/+ skin, and expression and activity of protective antioxidant enzyme HO-1 was reduced.

Previous studies showed that administration of anti-IL-4 antibody to neonatal Tsk1/+ mice prevented skin fibrosis and dermal collagen content (Ong et al., 1998). Also, shift of a Th2-based immune imbalance in Tsk1/+ mice by treatment with synthetic oligodeoxynucleotides (ODN) containing immunomodulatory CpG motifs prevented the skin fibrosis and thickening (Shen et al., 2005). IVIG therapy decreased splenocyte secretion of IL-4 and TGF-β, resulting in abrogation of fibrogenesis (Blank et al., 2002). A decrease in fibrosis was previously reported by inhibition of mast cell degranulation (Walker et al., 1987), and a recent report showed that intraperitoneal injection of mast cell chymase inhibitor significantly reduced skin fibrosis and the thickness of the subcutaneous fibrous layer (Shiota et al., 2005). Halofuginone has an inhibitory effect on collagen synthesis, and

shows antifibrotic effects in a few animal models of scleroderma. Halofuginone attenuates collagen synthesis as well as collagen gene expression in avian and murine skin fibroblasts (Granot et al., 1993). Halofuginone specifically inhibits α1(I) collagen gene expression without affecting the synthesis of other types of collagen, such as types II and III (Choi et al., 1995; Levi-Schaffer et al., 1996). Halofuginone inhibited TGF-β-induced upregulation of collagen protein and α2(I) promoter activity, as well as phosphorylation and subsequent activation of Smad3 after TGF-β stimulation (McGaha et al., 2002). Dermal application of halofuginone on Tsk1/+ mice for 60 days reduced dermal fibrosis as well as collagen α1(I) gene expression (Pines et al., 2001). Intraperitoneally administered halofuginone also prevented the thickening of the dermis and eliminated the increase of skin collagen in Tsk1/+ model (Choi et al., 1995). Dermal application of halofuginone on Tsk1/+ mice for 60 days reduced dermal fibrosis as well as collagen α1(I) gene expression (Pines et al., 2001). Intraperitoneal administration of anti-CD40L attenuated skin fibrosis and anti-Topo-I antibody production (Komura et al., 2008). HGF gene transfection in Tsk1/+ mice resulted in a marked reduction of hypodermal thickness (Iwasaki et al., 2006). Treatment with imatinib reduced dermal and hypodermal thickening in Tsk1/+ mice (Akhmetshina et al., 2009). Other therapies targeting TGF-β/Smad signaling pathway or SOD are also effective for suppression of skin fibrosis in Tsk mice (Hasegawa et al., 2009; Yoshizaki et al., 2011). A number of new therapies have been tried for cutaneous fibrosis using Tsk mice (Badea et al., 2012; Stenström et al., 2016).

4.2 Tsk2 Mouse

The second murine Tsk mutation was a result of administration of the mutagenic agent, ethylnitrosourea (ENU) (Christner et al., 1995). This mutation has been localized to mouse chromosome 1, is inherited as an autosomal dominant trait, and only heterozygous (Tsk2/+) animals survive. Tsk2/+ mice develop a Tsk phenotype that becomes apparent at 3–4 weeks of age. Histologic examination of the skin revealed marked accumulation of collagen similar to that observed in Tsk1/+ mice. By contrast, a prominent mononuclear cell infiltration is present in the dermis and adipose tissues of Tsk2/+, in contrast to Tsk1/+ mice. Lungs were normal. Biochemical analysis showed that Tsk2/+ skin had 50% more collagen contents than the normal mouse skin, and collagen synthesis in Tsk2/+ cultured dermal fibroblasts was 100% higher compared with normal fibroblasts. Transient transfection experiments with α1(I) collagen promoter constructs demonstrated increased transcriptional activity of the gene, and Sp1 and NF-1 transcriptional factors were involved in the upregulated transcriptional activity of α1(I) collagen promoter in Tsk2/+ fibroblasts

(Christner et al., 1998). Sequences from −96 to +16 bp of the α1(III) collagen promoter play an important role in the upregulated expression in Tsk2/+ fibroblasts (Christner et al., 2003). A recent study has demonstrated that the Tsk2 point mutation is due to a gain-of-function mutation associated with α1(III) (Long et al., 2015). Analysis using a collagen promoter GFP reporter transgene also showed an increase in transgene activity of α1(I) collagen (Barisic-Dujmovic et al., 2008). The presence of antinuclear antibody in the plasma was 92% of the Tsk2/+ mice, and other autoantibodies were also developed (Gentiletti et al., 2005), suggesting the aspects of autoimmunity in this model.

5 SCLERODERMATOUS GRAFT-VERSUS-HOST DISEASE MODEL

Scl-GvHD was produced by transplanting B10.D2 bone marrow and spleen cells into BALB/c mice after lethal gamma irradiation of recipients (Mccormick et al., 1999). Scl-GvHD mice exhibited skin thickening and pulmonary fibrosis by 21 days after bone marrow transplantation. A significant increase of type I collagen mRNA expression and protein synthesis was induced in the dermis. A number of CD11b + 2F8+ monocytes/macrophages and CD3+ T cells of donor origin were seen in the lesional skin. TGF-β1 mRNA levels were upregulated in the lesional skin of Scl-GvHD mice at early phases. Expression of CCL2, CCL3, and CCL5 was increased in the lesional skin prior to skin thickening and infiltration of CD45+ cells (Zhang et al., 2002). Also, allograft inflammatory factor-1 (AIF-1) and IL-6 were significantly expressed in the infiltrating mononuclear cells and fibroblasts in the thickened skin (Yamamoto et al., 2011). Otherwise, DNA microarray analysis showed a number of upregulated genes for CCL2, CCL5, CCL17, IFN-γ-inducible chemokines, PDGF, CTGF, fibroblast growth factor (FGF), epidermal growth factor (EGF), nerve growth factor (NGF), vascular endothelial growth factor (VEGF), and also adhesion molecules in the skin (Zhou et al., 2007). Additionally, Scl-GvHD can be produced by transplanting allogeneic (C57BL/6J) bone marrow and spleen cells into lethally irradiated recipients (LP/J). Onset of GvHD starts at 7 days after transplantation, with epidermal injury and round cells infiltrating in the dermis and subcutis with mononuclear cell exocytosis. By day 14 after bone marrow transplantation, the dermis and subcutis of GvHD mice become sclerotic with compressed and atrophic pilosebaceous units. Extracutaneous involvement includes periportal mononuclear cell infiltrating liver and interstitial round cell influx to lungs and kidneys. Further, a modified model of GvH-induced SSc has been developed (Ruzek et al., 2004). Injection of spleen cells from B10.D2 mice into RAG-

2 knockout mice on the BALB/c background induced dermal thickening, progressive fibrosis of internal organs, and autoantibody generation; however, lung fibrosis was absent.

Neutralization of TGF-β prevented fibrosis in the skin as well as in the lung in this model (Mccormick et al., 1999). LAP treatment prevented skin fibrosis as well as skin thickening in this model (Zhang et al., 2003). Upregulation of mRNA levels of TGF-β and CTGF were also abrogated, while showed no suppressive effects on immune cell activation or recruitment into the skin, which may suggest a more specific target for TGF-β. Intraperitoneally administered halofuginone prevented the thickening of the dermis and eliminated the increase of skin collagen in GvHD model (Choi et al., 1995). Recently, erlotinib prevented dermal fibrosis and organ involvements, as well as reduction of CD4+ T cells infiltration (Morin et al., 2015).

6 SKIN FIBROSIS BY EXOGENOUS INJECTION OF GROWTH FACTORS

TGF-β induces rapid fibrosis and angiogenesis when injected subcutaneously into newborn mice; however, this change was transient. TGF-β-induced subcutaneous fibrosis and subsequent CTGF or basic FGF application caused persistent fibrosis (Mori et al., 1999; Shinozaki et al., 1997). TGF-β caused skin fibrosis after three consecutive days of injection, and serial application of CTGF led to long-term and ECM-rich fibrosis. They suggest that TGF-β play an important role in inducing granulation and fibrotic tissue formation, and CTGF and bFGF are important in maintaining fibrosis, by sustaining α2(I) collagen promoter activation and increasing the number of activated fibroblasts (Takehara, 2003). bFGF induces collagen production by stimulating fibroblasts and CTGF cooperates with bFGF. The mast cell count was significantly but transiently increased in the early phase, while the number of macrophages continued to rise (Chujo et al., 2005). In the lesional skin, serial injections of CTGF after TGF-β increased CCL2 mRNA expression up to 8 times in comparison with only a single injection of TGF-β or CTGF (Chujo et al., 2005). Anti-CTGF reduced skin fibrosis and collagen content (Ikawa et al., 2008). Simultaneous treatment with bFGF and CTGF increased skin fibrosis (Chujo et al., 2009). By contrast, these treatments in CCL2-deficient mice resulted in decreased collagen levels in the skin (Chujo et al., 2009), suggesting an important role of CCL2 for the recruitment of inflammatory cells. In their fibrosis model induced by exogenous injection of growth factors, application of any single growth factor is not sufficient to induce persistent fibrosis, and interaction of CTGF with other growth factors is necessary.

7 UCD-200 CHICKEN

UCD-200 chickens spontaneously develop vascular damage, mononuclear cell infiltrates, fibrosis of the skin and internal organs, and polyarthritis (Van De Water and Gershwin, 1986; Gruschwitz et al., 1991). Additionally, positive AECAs, antinuclear antibodies, anticardiolipin antibodies, and rheumatoid factors are detected in the serum. The disease starts 1–2 weeks after hatching with erythema and swelling of the comb, which subsequently proceeds to a chronic stage characterized by fibrosis with excessive accumulation of collagen. In the inflammatory phase, T cell receptor (TCR)γ/δ+/CD3+/MHC class II$-$T cells prevail in the stratum papillae, while TCR α/β+/CD3+/CD4+/MHC class II+ T cells predominate in the deeper dermis. AECAs can induce apoptosis of endothelial cells through antibody-dependent cell-mediated cytotoxicity via Fas (Sgonc et al., 2000); transfer of AECA-positive sera into healthy chickens induced endothelial cell apoptosis, although this was not followed by skin sclerosis (Worda et al., 2003). These studies demonstrated the in vivo apoptosis-inducing effects of AECAs.

8 TRANSGENIC MOUSE MODELS

8.1 TGF-β Receptor I Transgenic Mouse

Fibroblast-specific TGF-β transgene activation model is an elegant method. Conditional constitutively active TGF-β receptor I transgenic mice offsprings show collagen accumulation in dermis and small pulmonary vessels, epidermal thinning, loss of adipose tissues in subcutis (Denton et al., 2003). By contrast, autoimmune as well as inflammatory aspects are absent in this model.

8.2 Kinase-Deficient Type II TGF-β Receptor Transgenic Mouse

Denton et al. (2005) generated transgenic mice expressing a kinase-deficient type II TGF-β receptor selectively on fibroblasts. These mice develop dermal and pulmonary fibrosis. Transgenic fibroblasts proliferate more rapidly, produced more ECM, and show increased expression of PAI-1, CTGF, Smad3, Smad4, and Smad7. Additionally, transgenic fibroblasts show myofibroblast differentiation.

8.3 Fra-2 Transgenic Mouse

Fos-related antigen-2 (Fra-2) is one of the subfamily of activation protein 1 (AP-1) transcriptional factors. Fra-2 transgenic mice developed severe, proliferative vasculopathy of the lungs resembling pulmonary arterial hypertension (Maurer et al., 2012), suggesting a probable model of SSc-associated pulmonary arterial hypertension. By contrast, a severe loss of small blood vessels is seen in the skin, in parallel with progression of skin fibrosis (Maurer et al., 2009). The reduction in capillary density was preceded by a significant increase in apoptosis in endothelial cells. The most characteristic feature in this model is that Fra-2 transgenic mice exhibit both vasculopathy with capillary loss in the skin and proliferative vasculopathy with arterial hypertension in the lung.

9 KNOCKOUT MOUSE MODELS

9.1 Relaxin Knockout Mouse

Relaxin is a small peptide hormone with antifibrotic and vasodilatory properties. A recent report shows that relaxin-deficient mice present dermal fibrosis characterized by thickening of the skin and increase in collagen content (Samuel et al., 2005). Fibroblasts derived from the skin of the null mice produce higher levels of collagen.

9.2 Fli1 Knockout Mouse

Fli1, a member of Ets transcription factor family, is a potent suppressor of the type I collagen gene, and persistently downregulated in scleroderma fibroblasts (Kubo et al., 2003), in association with increased CTGF and decreased MMP-1 levels (Nakerakanti et al., 2006). Fli1-deficient mice show significant upregulation of collagen (Kubo et al., 2003). Also, expression of Fli1 is greatly reduced in endothelial cells in SSc skin, and endothelial Fli1 deficiency impairs vascular homeostasis, and reduction of pericytes (Asano et al., 2010). Thus, aberrant expression of Fli1 contributes to skin fibrosis and vasculopathy in SSc. c-Abl is an upstream regulator of the PKCδ/phosphor-Fli1 pathway (Bujor et al., 2011). Fli1$^{+/-}$mice developed densely packed collagen bundles, whereas the thickness of the dermis is comparable as wild-type mice. Mice with homozygous targeted deletion of Fli1 carboxyl terminal activation domain partially recapitulate dermal fibrosis, but without dermal thickness. Also, endothelial Fli1 deficiency impairs vascular homeostasis (Asano et al., 2010). Thus, aberrant expression of Fli1 contributes to skin fibrosis and vasculopathy in SSc.

Krüppel-like factor 5 (KLF5) is a member of Sp1/KLF transcription factor family, involved in cardiac and renal fibrosis. Double heterozygous mice for FLI1 and Klf5 spontaneously developed remarkable dermal fibrosis, increased dermal thickness, collagen contents in the skin, and mRNA levels of collagen (Noda et al., 2014). An excellent review regarding a series of Fli1-related scleroderma mice model should be referred (Asano, 2016).
FIGURE 36.1 Histological features of bleomycin-induced scleroderma in C3H/ HeJ strain.

9.3 Caveolin 1 Knockout Mouse

Caveolin 1 regulates TGF-β signaling through internalization of TGF-β receptors. Caveolin 1-deficient mice induced develop skin and lung fibrosis showing increased collagen deposition, and also vascular changes with altered vessel tone and permeability (Castello-Cros et al., 2011).

10 CONCLUSIONS

Complex networks involve cell–cell and cell–matrix interactions via mediators in the induction of cutaneous sclerosis. Activated fibroblasts are a part of the immune system, and modulate immune cell behavior by conditioning the local cellular and cytokine microenvironment. The major characteristic of the bleomycin-induced experimental murine model of scleroderma is the histological mimicry to human scleroderma, which is shown in Fig. 36.1. Since each model has its own advantages, and also disadvantages, researchers are recommended to choose depending on the purpose of studies, that is, to study pathogenesis (fibrogenesis or vasculogenesis), to explore the antifibrotic effect of new drugs, and so on. Transgenic and knockout mice are elegant tools, but not available to anyone, needs special techniques and long periods to be made. It must be mentioned that the animal model is a simplification of the more complex human scleroderma. Nonetheless, the pathogenic mechanism discovered in the animal model may provide novel information, and assist in helping us the better understand the mechanisms underlying human scleroderma. Animal models of scleroderma may also serve as promising tools for the development of new therapies specifically targeting individual cytokines, cytokine antagonists (i.e., antibodies, soluble receptors), cytokine mutants, or of drugs that specifically interfere with the signal transduction pathways involved in the fibrotic process.

Bleomycin-induced murine model has already established a standard model for scleroderma over 15 years, and a number of therapeutic approaches have been tried. However, very few effective drugs are available in the clinical settings. It is greatly and urgently required that new effective antifibrotic therapies will be available for human SSc.

Many studies using knockout mice have demonstrated resistance for skin fibrosis by bleomycin treatment (Akashi et al., 2016; Saigusa et al., 2015; Yang et al., 2012), suggesting several candidate targets of inhibiting cutaneous fibrosis.

1 THE COMPLEX BIOLOGY OF MULTIPLE SCLEROSIS

The development of animal models of human diseases has, in general, two main functions. The first function is to generate a greater level of understanding of the basic biology of the disease and the second is to use the models to guide the development of new therapeutic approaches for treatment of the disease. Research into multiple sclerosis (MS) and other demyelinating diseases of the central nervous system (CNS) has followed this path closely over the last 60 years since the first description of an animal model of MS (Rivers et al., 1933). Unfortunate-ly, like many other disease conditions our understanding of the underlying biology of MS has remained quite limited and as a consequence the design of accurate animal models has been challenging and the most frequently utilized models have provided limited insights and effective therapeutics (Furlan et al., 2009).

MS was first described in the 1800s as a malaise that resulted in increasing functional disability. With the advent of histological techniques it became clear that MS was a disease of the CNS that affected regions of the brain and spinal cord. Until quite recently MS was conceived as a white matter disease, largely as a result of the detection of multiple focal areas of demyelination

known as plaques in CNS white matter tracks. This concept is changing with an increasing realization that there are also frequent areas of damage in gray matter suggesting that MS is not simply a disease of white matter (Grothe et al., 2016). The pathology of MS plaques or lesions is characterized by areas of demyelination that often contain a blood vessel at their core and show damage to the myelin sheaths that insulate CNS axons, as well as the formation of an astrocytic response or gliosis contributing to scar formation (Fawcett and Asher, 1999).

The vertebrate CNS contains three major classes of neural cells, Neurons the cells that are electrically active and transmit information throughout the brain and spinal cord extremely rapidly and with a high level of fidelity (Fig. 37.1). Different subpopulations of neurons arise

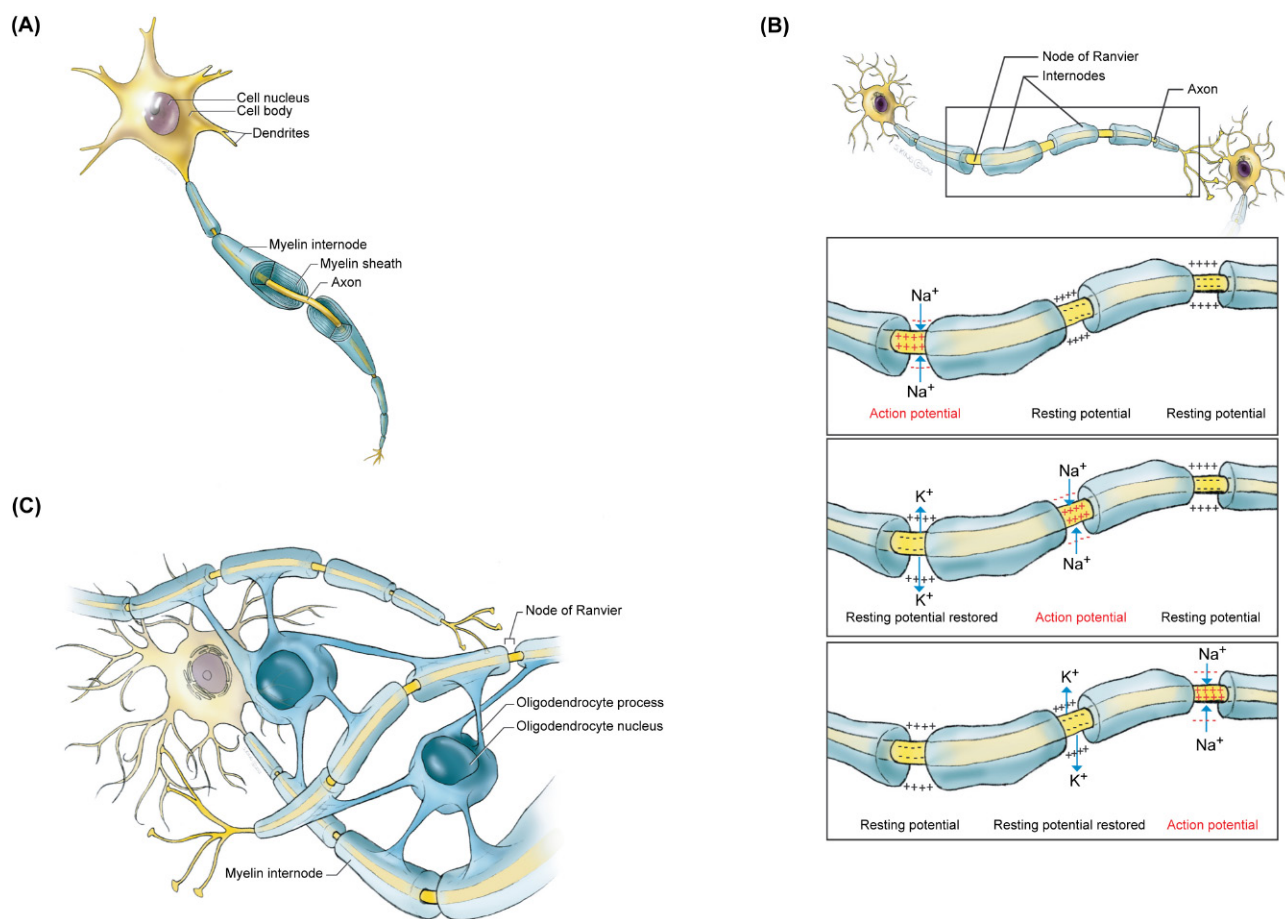
from distinct regions of the CNS and their characteristics such as neurotransmitter phenotype, morphology and connectivity reflect the interplay of both intrinsic factors and the environment in which the cells develop (Eriksson et al., 1998; Nornes and Das, 1974). The second major class of neural cells is astrocytes (Eng, 1985; Hirano and Goldman, 1988; Miller and Raff, 1984; Montgomery, 1994). These cells, which constitute a heterogenous population of cells, are probably as numerous in the CNS as neurons and perform multiple functions that support both the development and maintenance of the brain and spinal cord (Eng, 1985; Hirano and Goldman, 1988; Miller and Raff, 1984; Montgomery, 1994; Eng and Ghirnikar, 1994). For example, during development radially oriented astrocytes or their precursors


FIGURE 37.1 **Organization of the myelinated axons in the vertebrate CNS.** Myelination, the fatty insulation surrounding axons in the central and peripheral nervous system, facilitates rapid conduction of electrical signals. (A) Neurons are polarized cells that as a general rule receive information onto their dendrites that is processed through the cell body and transmitted to their target along their axons. While most neurons have multiple dendrites they have only a single axon, which is wrapped in myelin. The myelin sheath is composed of spiral wraps of plasma membrane organized into internodes separated by Nodes of Ranvier where the axonal surface is exposed. (B) During the transmission of an action potential along an axon the presence of myelin enhances the velocity of transmission since the signal "jumps" from node to node (see top to bottom). The threshold activity required to fire an action potential is also reduced because the extent of the exposed axon membrane is reduced and the ion channels are more concentrated. During the firing of the action potential sodium flows into the axons resulting in depolarization and the resting potential is subsequently restored through outward transport of potassium channels. (C) Myelin in the CNS is synthesized by oligodendrocytes. One oligodendrocyte can myelinate multiple internodes on multiple different axons. As a result, loss of a relatively small number of oligodendrocytes can have a significant effect on the functioning of multiple axons.

are important as guides for the migration of neuronal cell bodies from their germinal zones to their final destination (Rakic, 1971, 1972). Likewise, astrocytes act as identifiable substrates for the growth of axons toward their appropriate targets (Smith et al., 1986). In the adult CNS, astrocytes play multiple supportive roles including removal of excess neurotransmitters, maintenance of the ionic environment of the CNS and stabilization of the blood–brain barrier (Eng and Ghirnikar, 1994) and potentially promoting regeneration (Miller, 2006). One relatively poorly understood function of astrocytes is the generation of a glial scar in response to CNS injuries (Fitch et al., 1999; Fitch and Silver, 2008; Silver and Miller, 2004). For example, penetrating insults to the brain and spinal cord result in breakdown of the blood brain barrier and provoke hypertrophy and proliferation of astrocytes in the vicinity of the insult (Fitch et al., 1999; Fitch and Silver, 2008; Silver and Miller, 2004). This results in a dense glial scar or gliosis comprised of astrocyte processes and extracellular matrix that is thought to inhibit axonal regeneration (Fitch et al., 1999; Fitch and Silver, 2008; Silver and Miller, 2004). A similar robust glial scar is formed around chronic demyelinating lesions in the absence of a penetrating insult and by analogy has been suggested to block myelin repair (Fuller et al., 2007). The third major class of neural cells in the adult CNS is oligodendrocytes (Miller, 2002) (Fig. 37.1). These cells are derived from progenitors that arise in distinct regions of the CNS and subsequently disperse throughout the CNS (Miller, 2002; Ono et al., 1997; Pringle and Richardson, 1993; Rowitch, 2004). Oligodendrocytes are the primary source of myelin in the adult CNS

(Bunge et al., 1962; Bunge, 1968; Miller, 2002; Raine, 1977). Myelin is a specialized plasma membrane that wraps axons and forms a fatty insulation that promotes the rapid conduction of electrical impulses (Raine, 1977). One primary function of myelin is to provide insulation and protection to axons within the CNS (Morell et al., 1990) and it is composed of multiple layers of modified plasma membrane that acts to increase the conduction velocity of action potential along the axon as well as reduce the threshold for firing axonal action potentials. The bases of this improved conductivity are the nature of the myelin sheath (Fig. 37.1). Myelin sheaths are discontinuous, and the space between adjacent myelin segments is known as the Node of Ranvier. The Node of Ranvier is a highly specialized region comprised of a wide range of unique proteins in both the oligodendrocytes and the axonal membrane including high concentrations of ion channels that are essential for conduction of electrical impulses. This structure is particularly sensitive to damage and disruption of the node results in perturbation of axonal conduction (Fig. 37.2). The composition of the intermodal myelin has been extensively studies. The development of biochemical isolation procedures (Larocca and Norton, 2007; Norton and Poduslo, 1973) identified a number of myelin specific proteins including myelin basic protein that constitutes more than 50% of the myelin sheath, proteolipid protein (PLP) a second major component of CNS myelin and other smaller components such as myelin—associated glycoprotein (MAG), myelin oligodendrocyte protein (MOG), myelin-associated oligodendrocyte basic protein (MOBP) and 2'3' cyclic nucleotide 3'phosphdiesterase (CNP) (Campagnoni, 1988).
FIGURE 37.2 **Demyelination results in a loss of functional conduction and may result in axonal damage and synapse loss.** Under normal conditions the axon is myelinated along the majority of its length and information flows from one neuronal cell body to the other through action potentials and synapses between the myelinated axon and its target dendrites. As a result of demyelination the myelin covering is destroyed, conduction along the axon is compromised and synaptic connections are lost.

The precise roles for each of these myelin components is unclear although animals with mutations in MBP, such as *shiverer* fail to form compact myelin in the CNS and are not viable (Nave, 1995) while animals lacking PLP appear to develop normally but acquire an axonal pathology later in life (Griffiths et al., 1998; Rosenbluth et al., 2006).

Pathological studies provide strong support for the involvement of neuronal damage in disease progression in MS. For example, considerable axonal loss is observed in areas of demyelination (Trapp et al., 1998) and in some chronic MS patients there is clear brain atrophy as a result of large-scale loss of neuronal cell bodies and axons (Ge et al., 2000; Moore, 1998; Waxman, 1998). The evidence for the role of astrocytes in the pathogenesis of MS is less clear. In regions of demyelination astrocytes undergo a reactive responses that results in an increase in the expression of glial fibrillary acidic protein (GFAP) containing intermediate filaments (Fuller et al., 2007). Whether this represents a protective or pathogenic event is currently unclear (Sofroniew, 2005). The blood brain barrier appears to be a critical entity in the formation of demyelinating lesion in MS and astrocytes have been proposed to play an important role in the maintenance of the blood brain barrier in the adult CNS (Janzer and Raff, 1987).

While there is no conclusive evidence to demonstrate that compromising the integrity of the blood brain barrier leads directly to localized demyelination, a disease variant of MS that preferentially targets the optic nerve known as neuromyelitis opticus (NMO) is thought to result from immune mediated attack on astrocytes and opening of the blood–brain barrier. The evidence for the engagement of oligodendrocytes in the development of MS is strong. First, MS is characterized primarily as a demyelinating disease and since oligodendrocytes are the predominant myelinating cells of the CNS they have long been considered to be the potential target of the disease process (Kerlero et al., 1993; Waxman, 1982).

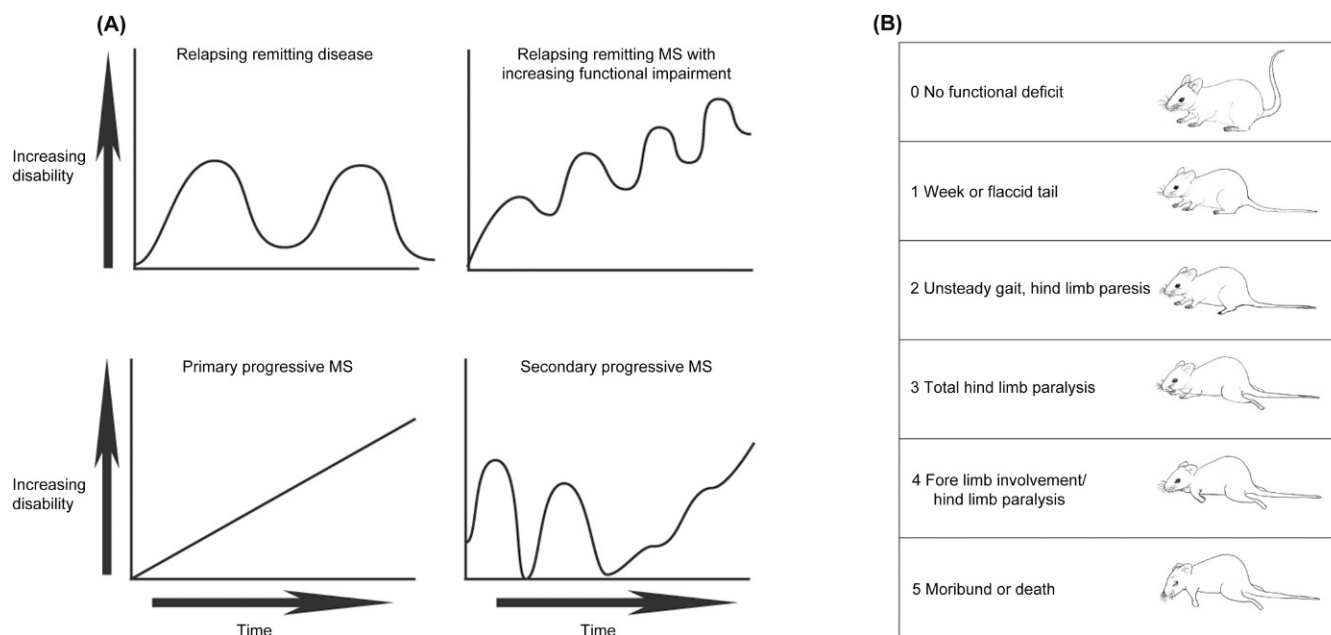
Currently, it is clear that MS is a complex disease (Moore, 1998; Joy, 2001; Lassmann et al., 2001; Lublin and Reingold, 1996; Lucchinetti et al., 2000; Poser et al., 1983) and MS may in fact reflect a number of distinct but relate diseases all of which share some common characteristics. This diversity of disease is evident in both the presentation of the disease and its pathogenesis (Joy, 2001; Lublin and Reingold, 1996; Lucchinetti et al., 2000; Moore, 1998; Poser et al., 1983). In many cases, MS initially presents as a relapsing remitting disease that frequently progresses over time to a more chronic secondary progressive disease (Fig. 37.3). In a distinct subset of patient the disease


FIGURE 37.3 **Comparison of the progression of disease in the different types of Multiple Sclerosis (MS) and the different models of EAE.** Multiple sclerosis (MS) manifests as several different patterns of functional deficits. Relapsing remitting disease is the most common and often develops into secondary progressive MS. Different stages of MS are functionally mimicked by the animal model EAE. (A) There are general patterns of progression of functional deficits in MS. Early in the disease it manifests as a relapsing-remitting disease in which intervals of functional deficit (relapses) are interspersed with recovery (remission). As disease progresses there is frequently a cumulative functional impairment with each relapse. In a subset of MS patients primary progressive MS results in increasing functional deficit without intervals of remission. Finally, after an extended period of relapsing remitting disease, with or without increasing functional impairment the disease progresses to a secondary progressive pattern. (B) Variations of the EAE model mimic some aspects of disease progression in MS. For example, PLP immunization of SJL mice results in a relapsing remitting disease. The level of functional impairment in EAE animals is scored on the 1–5 scale outlined.

presents as progressive functional impairment from its initial identification known as primary progressive MS (Fig. 37.3), while in other cases the rounds of relapsing–remitting disease slowly accumulate increasing functional impairment (Fig. 37.3).

The diagnosis of MS is relatively complicated (Poser et al., 1983). Currently there is no definitive biomarker that is specific to MS and as a result a diagnosis is dependent on a number of factors rather than a single diagnostic test. Pathological studies demonstrate that regardless of the specifics of presentation virtually all types of MS show white matter regions of demyelination, axonal loss, and gliosis. In the clinic MS is diagnosed through a combination of approaches that includes medical history and clinical examination, as well as imaging and biochemical assessments including both MRI and CSF oligoclonal analyses [reviewed in (Joy, 2001)]. Because the disease is frequently intermittent and has a variable presentation unambiguous diagnosis is often complex. In general, a diagnosis of MS requires clinical evidence of at least two white matter lesions on at least two independent occasions (Lublin and Reingold, 1996; Poser et al., 1983). Such a definition does not include progressive MS, however, the inclusion of MRI analyses is an important aid in the diagnosis. Evidence of neuropathological changes can be detected by MRI in the majority of MS patients although the precise nature of the pathological changes and the specificity for MS is poorly defined since other neuropathological conditions, such as myelopathy can also generate MRI images similar to that seen in with MS. Since demyelination will lead to a slowing or blockade of axonal conduction (Waxman, 1982) some clinical studies have used measurement of axonal conduction through analysis of evoked potentials to assess the level of CNS demyelination although their use has declined in recent years.

Despite intense research efforts the initial stimuli for the onset of MS remains unclear. One hypothesis that has received significant attention is that the trigger for MS is a response to a prior infection or other environmental signal (Correale and Gaitan, 2015). This notion is supported by the findings that MS patients have elevated immunological responses to a variety of pathogens, and may account for some aspects of the epidemiology of MS (Kastrukoff, 1998). The chronic nature of MS and the likelihood that the disease has been ongoing for an extended interval prior to becoming symptomatic makes it extremely difficult to isolate the initial pathogenic signal. A wide range of pathogens have, however, been linked to the onset of MS and these include such diverse entities as spirochetes, Chlamydia and a range of viruses (Joy, 2001). While it may be that multiple pathogens can initiate the disease, or some specific variant of the disease, or that the identification of putative pathogens is non causative it seems likely that the role of the pathogenic insult may

be to enhance susceptibility rather than overtly induce disease. The evidence for a viral link in MS is perhaps the strongest for any pathogen (Das Sarma, 2010; Kakalacheva et al., 2011) and a number of different viruses have been implicated including Epstein–Barr, human herpes virus 6 and human endogenous retroviruses (Das Sarma, 2010; Kakalacheva et al., 2011; Tselis, 2011). Precisely how the viral infection triggers the onset of MS has not been clarified, but it may reflect the initial stimulation of immune responses to viral antigens or the induction of cell death in oligodendrocytes as a result of viral infection.

One aspect of MS that has received extensive interrogation is its genetic linkage (Oksenberg et al., 1996). Several general themes have emerged from these studies. First it is clear that MS is not caused by a gain or loss of function of an individual gene. Rather it appears to be linked to a wide range of genetic associations (Lazzarini, 2004). Several genome wide association studies (GWAS) have identified genes in the major histocompatability locus (MHC) as being associated with MS. In particular it has been proposed that MHC class 11 molecules, such as HLA-DR and HLA-DQ alleles represent risk factors for the disease. Several excellent reviews have been recently written on the genetic linkage of MS and the details will not be discussed further in this review (Baranzini and Nickles, 2012; Gourraud et al., 2012; McElroy and Oksenberg, 2011). It is perhaps not surprising that there would be a detectable linkage to genes that modulate the immune system in MS given the immunological nature of the disease. What is less clear from these studies is the mechanisms by which these genetic changes enhance MS susceptibility. One possibility is that changes in MHC molecules enhance the susceptibility of individuals to mount an autoimmune response following a subacute challenge from an unrelated antigen.

The heterogeneity of MS represents a significant challenge in developing effective animal models that accurately mimic the disease and this has led to the generation of a number of different models each of which share some specific characteristics with a component of the disease (Didonna, 2016). The most long-standing and best-studied models of MS are those that utilize selective stimulation of the peripheral immune system as the major driver of CNS pathogenesis.

2 IMMUNOLOGICAL MODELS FOR CNS DEMYELINATION

One of the characteristics of MS discussed above is the engagement of the immune system. Much of the experimental evidence for a role for the immune system in the pathogenesis comes from animal models that are collectively known as experimental allergic encephalitis (EAE)

(Gold et al., 2006; Mix et al., 2010; Teixeira et al., 2005). In general EAE is an inflammation/demyelinating disease that is induced in host animals through the injection or immunization of the animal with CNS tissue (Krishnamoorthy and Wekerle, 2009). Like MS the presentation of EAE is characterized by functional deficits that are correlated with immune cell infiltration into the brain and spinal cord. The extent of functional deficits is classified on a scale of 1–5 in which 1 represents a flaccid tail, 2 represents hind limb weakness, 3 represents serious hindlimb weakness, 4 represents forelimb engagement and hind limb paralysis and 5 represents death (Fig. 37.3). In most studies the degree of severity is adjusted to between 2.5 and 3.5 that allows for clear determination of increased functional severity or functional recovery.

The utilization of EAE in the study of MS has a long history. The early studies followed the observation that inoculation of rabies infected rabbit CNS tissue into rabies patients induced functional deficits and subsequently involved the injection of spinal cord homogenates derived from human or sheep into rabbits (Stuart, 1928). These treatments resulted in hind limb paralysis and other functional deficits. The initial demonstration of EAE in the primate resulted from immunization of monkeys with spinal cord homogenate derived from rabbit CNS (Rivers et al., 1933). These studies were among the earliest to reveal that the functional deficits were correlated with the pathological accumulation of cells around blood vessels of the brain and spinal cord. Such observations prompted the adoption of the term acute disseminated encephalomyelitis. The term experimental allergic encephalomyelitis was subsequently adopted for multiple variants of this experimental approach. Early studies were somewhat limited since the severity of the disease and even the adoption of pathological conditions was highly variable following injection of spinal cord homogenates. The recognition that EAE had an underlying immunological basis provoked modifications in the experimental protocol to more effectively stimulate the immune system. This was accomplished both by the use of an immune stimulant such as complete Freund's adjuvant (CFA) ultimately combined with pertussis toxin (Munoz et al., 1984). Remarkably, this protocol has changed very little and the majority of modern day EAE experiments still use a combination of CNS derived material delivered in combination with CFA and followed by pertussis toxin.

Although early studies identified important components of the biology of EAE they continued to be challenging due to variability between animals and individual studies. Much early work utilized either guinea pig (Freund et al., 1947) or monkey (Kabat et al., 1947) as the host animal and in efforts to generate more reproducible results investigators explored two avenues. In one case they reproduced the early studies in rats and subsequently mice (Lipton and Freund, 1952; Olitsky and Yager, 1949) in which the individual host variations could be minimized. Second, the relevant immunogenic peptides in the spinal cord and brain homogenates were identified. Perhaps not surprisingly given the demyelinating nature of the model the initial antigenic proteins were predominantly myelin-associated proteins including myelin basic protein (MBP), myelin-oligodendrocyte glycoprotein (MOG) and proteolipid protein (PLP) (Mix et al., 2010). Minor myelin components were also found to be capable of inducing disease when injected into naïve animals suggesting that there was not a tightly restricted repertoire of antigenic proteins that may stimulate an immune attack on the CNS, but rather that most myelin components could act as effective priming antigens. Further refinement of the model resulted from the identification of specific peptides of myelin proteins that provoked a reproducible and consistent disease profile following immunization into genetically defined host populations. As a consequence, several major models of EAE have gained prevalence in the last two decades (Gold et al., 2006; Mix et al., 2010; Teixeira et al., 2005). Among these are the inductions of EAE in the *SJL* mouse genotype following immunization with the PLP $_{139-151}$ peptide. This model generates a relapsing remitting disease that mimics some of the characteristics of relapsing remitting MS. A second commonly used model is that induced in C57/Bl6 mice following immunization with the MOG peptide $_{35-55}$. This model generates a more chronic and progressive disease course that is often used to model later stages of MS. Other models such as the induction of EAE in PL/J mice following immunization with MBP or MOBP (Kaye et al., 2000) and immunization of Biozzi ABH mice with MOG protein (Amor et al., 2005) model selective aspects of MS.

The mechanisms of disease development in the murine models of EAE have been extensively studied and while like MS they are complex, some general concepts have emerged. One central feature is that in many of the models there is a primary role for T cells in the development of the disease. The most compelling demonstration of the pathogenic properties of T cells in CNS demyelination was obtained using an adoptive transfer approach (Ben-Nun et al., 1981; Kojima et al., 1994, 1997). Using rats these investigators showed that T cells specific for an MBP antigen grown in vitro from immunized donor animals were capable of transferring disease to naïve hosts. These studies revealed that while transferred T cells alone were sufficient to induce CNS damage, they did not generate a persistent ongoing disease. Rather the functional deficits were transient, resolving within 1–2 weeks after immunization and more importantly, the pathology generated was not characterized by extensive demyelination. These results suggest the pathology seen

in other models of EAE and in MS itself reflect multiple pathogenic processes in addition to T cell cytotoxicity. One likely candidate to contribute to the pathology of EAE and MS are B cells (Bielekova and Becker, 2010; Cross et al., 2001; Franciotta et al., 2008; Kerlero et al., 1993; Meier et al., 2012). B cells may play multiple roles in the formation of immune mediated pathology in the CNS (Cross et al., 2001). First, they may act as antigen presenting cells, facilitating the activation and expansion of T cell populations within the CNS, as well as enhancing the recruitment of other immune cells into the CNS (Franciotta et al., 2008; Hohlfeld et al., 2008). Perhaps more importantly, B cells act as a source of antibodies directed against myelin antigens. It has been suggested that some subsets of MS lesions are characterized by the expression of antimyelin antibodies and experimental studies implicate MOG as a potential target (Haase et al., 2001). The importance of understanding the roles of B cells in the development of pathology and functional deficits in EAE and MS has increased recently with the demonstration that the therapy Rituximab, which inhibits B cells (Bielekova and Becker, 2010; Hauser et al., 2008) appears to be highly effective in some MS patient populations. One area that has not received extensive attention until relatively recently is the role of the innate immune system in the development of demyelinating pathologies. The activation of microglial cells and their role in myelin clearance has been proposed, and whether they also play a role in antigen presentation along with dendritic cells is currently not well established. It may be that depending on the stage of the disease the prevalent pathological mechanisms are different. For example, while relapsing remitting disease may be largely driven by influx from the peripheral adaptive immune system, progressive disease may be largely a consequence of the innate immune system (Weiner, 2009).

The array of antigens capable of inducing CNS immune responses is extensive and not limited to myelin components. Given that the disease is characterized by demyelination this is somewhat of a surprise. Antigens associated with axons such as the neurofilament triplet and node of Ranvier components such as Contactin/TAG-1and the more ubiquitous S100 are also associated with EAE and MS (Charles et al., 2002). Whether these represent primary targets of the disease such that targeted attack on neurofilaments results in axonal damage, or whether they represent the result of damage to adjacent cells that is secondary to myelin sheath insults is currently unclear. What seems likely, however, is that once the disease has been initiated the destruction of neural tissue that occurs results in a broadening of the pathological basis of the disease and more widespread damage and functional deficits.

The EAE models have a number of characteristics that are extremely useful for understanding the biology of MS and have been the subject of detailed and informative reviews (Gold et al., 2006; Mix et al., 2010). Among the major strengths include the variety of the models and fact that they utilize well-defined antigens in numerous well-developed transgenic animal systems. The engagement of the immune system (Lassmann et al., 1988), the diversity of genetic influences and the distinct pathologies have facilitated the identification of well-defined cytokine/chemokine networks involved in T cell activation and trafficking as well clarification of the role of T cell subsets in regulating disease progression. These models have allowed major contributions to our understanding of the pathobiology of MS and currently serve as the primary tools with which to validate and identify new therapeutic approaches for the treatment of MS.

3 LOCAL INDUCTION OF DEMYELINATION FOLLOWING INJECTION OF MYELIN PEPTIDES

One limitation of the systemic EAE models discussed aforementioned is that like MS, the location and timing of lesions in the CNS is unpredictable. This makes these models difficult to use for directly correlating histologically the loss of myelin with the subsequent functional deficits in any particular axon tract. To address this issue and to facilitate the development of new therapeutic approaches for demyelinating disease investigators have targeted demyelinating lesions to selected CNS regions (Merkler et al., 2006). To achieve targeted immune mediated demyelination, one approach has been to sensitize host animals with subthreshold levels of encephalogenic peptides and subsequently deliver a local injection of a proinflammatory cytokine to stimulate local demyelination. For example, subcutaneous injection of recombinant $_{1-125}$ MOG peptide into the Lewis Rat in combination with incomplete Freund's adjuvant results in a robust anti-MOG immune response that does not generate overt clinical symptoms (Kerschensteiner et al., 2004). After a period of approximately 20 days-localized injection of recombinant rat tumor necrosis factor alpha (TNFα) or interferon-gamma (INF-γ) resulted in localized infiltration of immune cells that was associated with intense local demyelination and axonal damage. The extent of demyelination and the reaction to the injection of proinflammatory cytokines was directly proportional to the level of initial immunization with the immunogenic peptide suggesting that the level of sensitization is a major contributing factor to subsequent myelin loss. Due to the localized nature of the demyelinating lesion, more refined functional studies could be undertaken. Such studies revealed a rapid functional deficit that presumably reflects the damage caused by the intense local immune response. This initial functional deficit was followed by

some degree of functional recovery, even though some structural damage to the targeted axon tract remained.

There are several attractive elements to the model of targeted immune mediated demyelination. These include the ability to assess the long term consequences of a localized immune response on functional outcome and the capability to develop novel therapies that may alleviate not only the initial immunological insult but also promote long-term functional recovery. Such a model, however, also has several weaknesses. This includes the very localized nature of the insult without the engagement of surrounding tissue, such as may occur in MS. A more significant concern is the method of induction of the inflammatory stimuli. The local injection of cytokines results in damage to the blood–brain barrier and the stimulation of a robust astroglial response. The complication of the injection paradigm makes mechanistic interpretation of the outcome of these studies difficult.

Regardless of the exact details of the EAE models there are however a number of important differences between MS and the animal model EAE. Perhaps the most obvious is that MS is a spontaneous occurring disease within human populations while EAE is an induced pathology. By contrast, there are no known spontaneous occurring animal models of MS or EAE and the added complexity of provoking a strong immune response with unrelated antigens may have a significant effect on the ultimate mechanism of the disease and its natural history. As a consequence, therapies developed using the EAE models have not always proven as effective against ongoing MS as predicted.

4 DEVELOPMENT OF MS THERAPIES BASED ON MODELS OF IMMUNE MEDIATED DEMYELINATING DISEASES

The extensive history of research using EAE as a model for MS has resulted in the development of a range potential therapies' for MS and other demyelinating diseases. Given the immunological basis of the model it is not surprising that the majority of these therapies have been oriented toward modulation of the immune response and specifically T cell mediated infiltration and activation in the CNS. While several of these therapies have been quite effective in modulating disease progression in EAE and in controlling MS relapses they have been less effective in promoting long term recovery in MS. Examples of therapies that have been tested in animal models of EAE include Fingolimod otherwise known as FTY720 that is directed against the spingosine-1-phosphate receptor and regulates T and B responses but also appears to directly stimulate remyelination in the CNS (Balatoni et al., 2007; Miron et al., 2010; Miron et al., 2008) and natalizumab that is directed toward adhesion molecules on lymphocytes and blocks the entrance of those cells in the parenchyma of the CNS (Rice et al., 2005; Rose et al., 2008). Such therapies, while modulating relapse activity, have generated unexpected side effects in the setting of clinical applications that have limited their utilization. The development of new therapeutic approaches that likely combine dampening of the immune response with stimulating endogenous myelin repair are likely to be more effective in promoting long-term functional recovery. The development of such combinatorial therapies will be leveraged through the utilization of other animal models of disease.

5 VIRAL MEDIATED MODELS OF DEMYELINATION

Viral infections have been implicated in enhancing susceptibility to MS in a number of studies (Correale and Gaitan, 2015) and a number of effective viral models of demyelination have been developed in order to better understand the pathobiology of MS. Among the most commonly used for the induction of neurological diseases are mouse hepatitis virus (MHV) and Theiler's murine encephalomyelitis virus (TMEV). There are a number of strengths to the viral demyelination models. These include the genetic linkages, the involvement of B cells as well as T cells, the ability to modulate the virus, and alter host responses. Compared to the immunological models of MS, such as EAE the extent of demyelination is substantially greater and the functional deficits longer lasting providing a better opportunity to study the cellular and molecular mechanisms mediating myelin repair. The progression of TMEV induced disease is well established depending on the strain of the virus and the genetics of the host. In some combinations the disease is biphasic in which an early acute phase is followed by more chronic demyelinating disease that usually develops a month or so after infection (Dal Canto and Rabinowitz, 1982). The functional deficits are correlated with extensive demyelination in both the brain and spinal cord. The mechanisms underlying viral induced demyelination have been attributed to two primary pathways. In one case virally infected cells are lysed as a result of the infection and the lysis of oligodendrocytes leads to subsequent demyelination. In the second case the loss of oligodendrocytes and demyelination is a reflection of immune responses to virally infected cells. Several lines of evidence are consistent with a role for the immune system in viral demyelination. These include the finding that passive transfer of anti-TMEV antibody can enhance demyelination in the setting of EAE and demyelination can be stimulated by macrophages infected with TMEV (Tsunoda et al., 1996) and inhibited by macrophage depletion (Rossi et al., 1997). Similar general pathology

and underlying mechanisms have been suggested to mediate disease resulting from MHV infections (Wang et al., 1990). When immune compromised animals are infected with MHV little or no demyelination is seen, however if effective T and B cell functions are restored through transfer of immunocompetent cells then demyelination is seen (Wu et al., 2000). One additional complexity is that the mechanism and extent of demyelination is dependent on both the strain of the virus and the genetics of the host animal since even in some MHV strains, demyelination does not appear to be independent of stimulation of the immune system. To begin to clearly delineate the relative effects of immune stimulation and oligodendrocyte death in the development of demyelinating diseases requires additional animal models that separate these two phenomena.

6 OLIGODENDROCYTE INDUCED CELL DEATH MODELS OF DEMYELINATION

While EAE has provided important insights into the potential role of the immune system in the onset and progression of demyelination in the vertebrate CNS, recent studies suggest that in some conditions the onset of T-cell-mediated inflammation reflects a response to primary CNS damage rather than an initiation of the original insult. Demyelination ultimately reflects damage to oligodendrocytes, the cell responsible for CNS myelin formation. Whether in the complex setting of disease damage to oligodendrocytes is direct (Locatelli et al., 2012) or indirect likely depends on the immediate pathological conditions. An alternative cellular target that may trigger oligodendrocyte damage and demyelination are the axons that are enwrapped in myelin. Indeed, axonal damage is evident in many MS lesions even at early stages of the disease (Trapp et al., 1998), as well as in many of the animal models of immune mediated demyelination (Moreno et al., 2011; Soulika et al., 2009; Traka et al., 2010). Given the complexity of MS and its immune-based animal models, it remains unclear whether axonal degeneration follows myelin loss or whether demyelination is a consequence of axonal damage and degeneration. To distinguish between these possibilities, a new general approach involving the induction of primary oligodendrocyte death is being developed. In these models oligodendrocytes are being targeted by various means to assess whether the loss of oligodendrocytes results in demyelination, how effectively and rapidly remyelination occurs, and whether localized demyelination results in axonal damage. These studies, which compared to the immunological models discussed earlier, are in their infancy, have begun to provide interesting insights and potential model systems for the diversity of pathologies seen in MS. Here we focus on three distinct

methodological approaches for selectively inducing cell death in oligodendrocytes in the adult vertebrate CNS.

6.1 Induction of Oligodendrocyte Cell Death Through the Cell Type Specific Expression of Diphtheria Toxin a (DT-α)

One approach to drive selective death of neural cells that has proven to be effective in the adult CNS involves the selective expression of a toxic molecule targeted to specific cell types (Pohl et al., 2011; Traka et al., 2010). For example, extensive loss of oligodendrocytes has been achieved through the targeted expression of the alpha subunit of the diphtheria toxin (DT-α). Diphtheria toxin (DT) in its natural state is composed of two subunits that have specific functions. While the beta subunit is essential for the entry of the toxin into the cell through interaction with its appropriate receptors the alpha subunit is the cytotoxic component that acts intracellularly.

The cytotoxicity of DT-α is conferred through the inhibition of elongation factor 2 and the subsequent halting of protein translation that in turn results in cell death (Fig. 37.4). In the absence of its "β subunit DT is unable to penetrate cells, limiting the nonspecific induction of cell death in neighboring cells. Targeting the expression of the DT to oligodendrocytes is achieved using Cre/LoxP technology (Fig. 37.4). In this system on one allele, the sequence corresponding to DT-α is knocked-in to the ROSA26 locus while upstream the sequences for
FIGURE 37.4 Schematic showing the overall design for the generation of the DTA mouse. (A) Diagram of the mating scheme used to generate a Tamoxifin responsive DTA mouse. (B) Schematic representation of the functionality of the DTA mouse resulting leading to cell death.

GFP, a Neo cassette, and a strong transcriptional STOP sequence are inserted. On another allele, a cell type specific promoter such as for the proteolipid protein (PLP), a major CNS myelin protein promoter that has repeatedly been shown to target expression to oligodendrocytes and their precursors, drives the expression of a Tamoxifen-inducible CreER^T transgene. In such animals, treatment with Tamoxifen results in experimentally controlled Cre-mediated recombination only in oligodendrocytes (targeted by PLP), excision of the STOP sequence, and selective cell-type expression of cytotoxic DT-α that results in death of the cells in which it is expressed. This approach has a number of major advantages. If CRE recombines efficiently, then a comparatively high number of oligodendrocytes in a given mouse line could potentially express the transgenes and be susceptible to Tamoxifen-mediated cell death. Under such conditions the induction of oligodendrocyte cell death occurs in the absence of any direct insult to the brain or spinal cord and allows accurate assessment of the subsequent CNS responses. Control studies indicate that at low doses Tamoxifen is not selectively toxic to neural cells.

Although only a limited series of studies using the DT-α model of induced oligodendrocyte death have been published there are clearly common themes emerging from this model. For example, independent studies corroborate the observation that severe pathology occurs as a result of the expression of genetically recombined DT-α in oligodendrocytes (Pohl et al., 2011; Traka et al., 2010). One somewhat unexpected outcome of these studies is that following Tamoxifen treatment, while there appeared to be a relatively rapid loss of oligodendrocyte cell bodies as anticipated, there was an apparent retention of myelin and minimal initial functional deficits. After a posttreatment delay of approximately 3 weeks the mice displayed progressive motor deficits associated with significant myelin degradation and vacuolization. The extent of the demyelination was directly correlated with the animals' clinical symptoms suggesting that the functional deficits were a primary consequence of myelin loss. A second somewhat unexpected outcome of these studies was that the widespread loss of oligodendrocytes in this model did not trigger a rapid robust immune response and the clearance of myelin was slow and primarily accomplished by local microglial cells without a significant influx of cells of the peripheral immune system. These studies suggest that oligodendrocyte death alone does not provoke a rapid large-scale immune response. While remyelination was robust in this model, and the animals appeared to recover completely, with longer survival times recovery was compromised. In animals allowed to recover for approximately 30 weeks from the initial demyelination a secondary pathology consisting of demyelination and axonal loss was detected (Traka et al., 2016). This second

phase of demyelination was accompanied by T cell infiltration to the CNS and adoptive transplantation of the T cells into naïve hosts was sufficient to transfer disease. These important findings imply that as a consequence of the priming of the immune system with the first insult the animals develop a long-term autoimmune condition that ultimately leads to CNS demyelination occurring

Not all of the independent studies provide identical results. One important difference between the different analyses is in the area of functional recovery. While clinical recovery was essentially complete in one study, it was completely absent in a parallel report using identical mice, such that the treated mice died only 6 weeks after treatment. Reports of axon health are also conflicting, with clear signs of pathology in one study and no axonal effect in another. Nevertheless, both studies report alterations in evoked potentials in two different sensory modalities suggesting that regardless of the underlying histological abnormalities, the functional outputs of neural networks are similarly perturbed.

As with any animal model of disease, it is important to consider the extent to which specific aspects of human disease are successfully captured by the animal model. In the case of DT-α induced oligodendrocyte cell death, and MS, there are important similarities. A disruption in visual evoked potentials coupled with significant myelin loss, for instance, is reminiscent of the initial symptom in many MS patients. Similarly, newly forming MS lesions, often in normal-appearing white matter, are characterized by the presence of activated microglia but not extensive infiltration of peripheral immune cells (van der Valk and Amor, 2009; van Horssen et al., 2012). A similar cellular profile is observed following oligodendrocyte-targeted expression of DT-α.

The DT-α model also differs from MS in a number of key ways. As discussed previously, MS is not induced but rather is a spontaneous disease with focal lesions separated in time and space. Multiple Sclerosis is also not thought to be toxin-induced although the role of pathogens in its initiation is unclear. In this cell death model there are likely broad, if subtle, effects owing to a toxin that halts cellular protein translation including the de novo production of proteins required for a nonimmunogenic cell suicide and the subsequent recruitment of phagocytic cells. Further, in MS it is thought that the clearance of myelin is relatively rapid following oligodendrocyte death and this accomplished by both CNS-resident and peripheral immune cells. By contrast, the delayed myelin clearance in the DT-α model would suggest either an inhibited or nonexistent rapid stimulation of immune clearance mechanisms. There are concerns with this model surrounding the complete nature of oligodendrocyte loss. If all oligodendrocytes throughout the neuroaxis are lost following Tamoxifen treatment, this differs greatly from the focal loss of oligodendro-

cytes in MS. If, on the other hand, only a portion of cells undergo effective recombination then it is difficult to define the threshold of oligodendrocyte loss that is required for the development of myelin pathology.

6.2 Induction of Oligodendrocyte Cell Death Through Cell Type Specific Expression of the Diphtheria Toxin Receptor

A variation of the model discussed above has also been recently developed (Oluich et al., 2012). In this case specificity of the toxic insult is targeted through the transgenic expression of the appropriate receptor on animals that have a receptor null background. For example, the transgenic expression of the DT receptor (DTR) under the control of an oligodendrocyte specific promoter results in cell type sensitivity to systemically delivered diphtheria toxin. This model has the advantage over the DT-α model in that is somewhat simpler, since it eliminates the need for the Cre/LoxP technology. An example of this approach is the expression of a transgenic DTR under transcriptional control of the promoter for myelin basic protein (MBP), a major oligodendrocyte-specific protein (Oluich et al., 2012) (Fig. 37.5). Intraperitoneal injection of DT then allows selective uptake by transgenic oligodendrocytes expressing the receptor, resulting in the induction of cell death by a mechanism similar to that evoked by DT-α, namely by inhibiting protein synthesis (Fig. 37.5).
FIGURE 37.5 **Schematic showing the overall design for the generation of the DT-R mouse.** (A) Diagram of the construct used to selectively express DT-R in oligodendrocytes on a background strain that is DT resistant. (B) Schematic representation of the functionality of the DT-R mouse resulting in cell death.

The clinical phenotype following the systemic injection of DT into DTR transgenic mice is similar to that seen in the DT-α mice except that it occurs on a faster time scale and does not show the same delay between initiation of cell death and onset of functional deficits. Neurological symptoms including ataxia, limb paralysis, and tail spasticity appear around 10 days postinjection and progressively develop until euthanasia is required (Oluich et al., 2012). Perturbations in somatosensory evoked potentials together with histological markers of neurodegeneration and abnormal Nodes of Ranvier indicate dysfunctional neural networks. A clear intrathecal immune response is provoked in this model which is reflected in elevated numbers of activated microglia, as well as a wide spread gliotic response characterized by elevated levels GFAP expression in astrocytes (Oluich et al., 2012).

Given the similarities in the targeting and mechanism of cell death, it might be anticipated that the histology and pathology of the DT-α and DTR models would be identical. Somewhat surprisingly this is not the case and while the DT-α mice display severe demyelination, the DTR mice show few if any myelin disturbances. The explanation for such differences is currently unclear. It may be that in the DTR model there is a more extensive engagement of axonal damage that leads to rapid mortality, prior to the development of significantly detectable myelin perturbations. Even if this hypothesis were correct it remains unclear why there would be differential axonal susceptibility in the two models. Possibly, the mode of cell penetration (receptor mediated vs. nonreceptor mediated) regulates the detailed cell death pathways activated in oligodendrocytes. As these models become more established the basis of such differences will likely become resolved.

A potential strength of the DTR model is that it may provide a model system to examine the mechanisms and develop targeted therapies against axonal damage in demyelinating diseases. It is well established that axonopathy is a pathological finding in MS (Trapp et al., 1998), even at early stages of the disease and this axon damage is generally accepted as the biological basis of permanent disability for patients with either primary or secondary progressive MS. Therefore, animal models such as DTR that recapitulate aspects of this pathological feature represent important tools for understanding and manipulating the CNS response to axonopathies. At the current time the DTR model does not appear to provide an accurate representation of the lesions that develop in MS. Indeed, the conspicuous absence of demyelination, a hallmark pathological feature of MS, calls into question its utility as a useful general model of human disease. It may be, however, that on different background strain the degree of demyelination may be greater or the survival of the animals longer. For now, the short sur-

vival time of the oligodendrocyte-DTR mice represents another significant limitation in its ability to model human disease, as MS is not generally associated with a substantially shortened lifespan.

6.3 Induction of Oligodendrocyte Cell Death Through Targeted Activation of the Apoptotic Pathway

Two general pathways mediate cell death. During necrosis, a pathological form of cell death resulting from overwhelming cellular injury, cells swell, membrane integrity is perturbed, and noxious intracellular molecules are released into the extracellular space (Steller, 1995). Apoptosis, on the other hand, is a genetically encoded, noninflammatory means of cellular suicide in which a dying cell fragments into membrane-bound bodies that can be digested by macrophages or neighboring cells. Activated by many different signals that may originate either from within or outside a cell, the controlled dismantling of unwanted cells requires a group of protein degradation enzymes called caspases (Thompson, 1995). An early step in the activation of one arm of the apoptotic cascade is the dimerization of caspase 9 mediated by the molecule APAF1 (Pop et al., 2006; Srinivasula et al., 1998). A model of selective cell ablation has been developed in which a modified, experimentally inducible caspase 9 (iCP9) is introduced into targeted cells using cell type specific promoters. Originally developed to eliminate distinct classes of lymphocytes (Straathof et al., 2005), the iCP9 gene was engineered so that the APAF-1 binding site was replaced with a FK506-like binding site for dimerization by a FK506 analog. Chemically induced dimerization (CID) by the FK506 analog is sufficient to initiate the apoptotic cascade in cells expressing iCP9. An initial study targeted iCP9 to mature oligodendrocytes using the MBP promoter and a lentiviral delivery system. Subsequent injection of the chemical inducer of dimerization (CID) results in the rapid and specific induction of oligodendrocyte death.

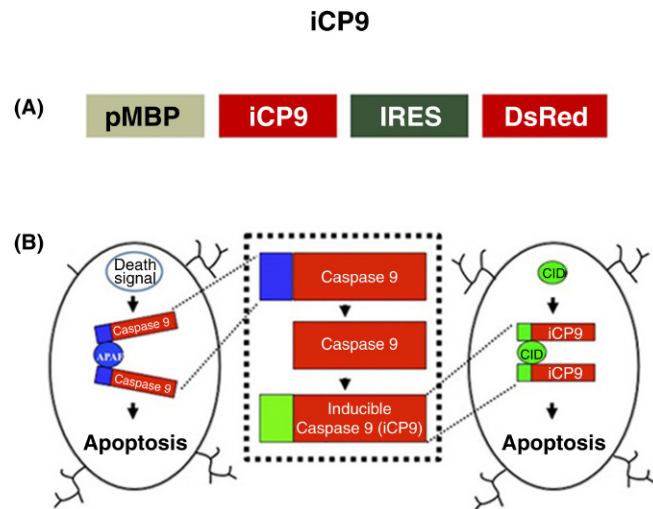
In this model, a lentivirus containing iCP9 under transcriptional control of the oligodendrocyte-specific MBP promoter, as well as a reporter expressed from a constitutive, viral promoter was injected into the corpus callosum of adults rats and the animals were allowed to survive for 7–14 days (Fig. 37.6). This resulted in local viral infection of all neural cell types as detected by reporter expression. Intrathecal injection of the CID at a remote site 7–14 days after viral injection resulted in the selective activation of the apoptotic cascade and cell death of oligodendrocytes. Unlike other oligodendrocyte cell death models of demyelination, the iCP9 model resulted in extremely rapid (within 24 h) demyelination, intense localized microglial activation, myelin clearance and localized OPC proliferation in the absence of an initial infiltration of peripheral immune cells including T cells (Caprariello et al., 2012).


FIGURE 37.6   **Schematic of the overall design and function of the MBP-iCP construct.** (A) Diagram of the construct used to selectively express the modified caspase 9 in oligodendrocytes. (B) Schematic of the mechanisms of inducible oligodendrocytes apoptosis.

Curiously, these effects are not associated with a behavioral phenotype and the histological abnormalities may recover over time. More recently this model has been extended to eliminate the confound of viral delivery. Transgenic animals expressing the iCP9 construct off the MBP promoter have been generated. Local delivery of CID targets oligodendrocyte death specifically. During development delivery of CID to a region of the spinal cord in the first postnatal week, blocks local myelination (Caprariello et al., 2015). Myelination recovers over a subsequent 2-week period and appears to have relatively normal histology. When the treated region of the spinal cord is challenged with a second mechanistically unrelated demyelinating insult in the adult, myelin repair is compromised. While the cellular and molecular bases of these phenomenas are currently poorly defined these studies raise the possibility that insults to the developing CNS compromise the potential for subsequent repair in the adult (Caprariello et al., 2015).

The significance of the iCP9 model to understanding the pathology of MS is still unclear. There are however several aspects of this model that may provide important insights into the development of early MS lesions and perhaps continuing development of the disease in a subset of MS patients. For example, apoptotic oligodendrocytes have been reported in neuropathological specimens from the earliest known lesions (Lucchinetti et al., 2000; Barnett and Prineas, 2004) suggesting this may represent an early event in the generation of an MS plaque. The immunological cell profile of the iCP9 model also mirrored the human condition in certain situations, in which activated microglia but not peripheral immune cells were recruited to the lesion site. Importantly, this pathological profile was reported from

a subset of MS patients (Lucchinetti et al., 2000) but given the heterogeneity of MS is unlikely to accurately represent all patients. It is surprising that rapid histological abnormalities would not generate behavioral abnormalities, however, it is possible that the iCP9 mice display subtle sensory and/or cognitive deficits that have yet to be identified. Additional studies in which oligodendrocyte apoptosis is targeted to critical motor tracts, such as in the spinal cord may reveal such functional deficits. Many rodent models of demyelination are typically associated with complete repair and further studies are needed to assess whether the rapid demyelination seen in the iCP9 model results in a chronic impairment of myelination or undergoes complete repair.

The emergence of new models that selectively target oligodendrocyte death are likely to provide critical new insights into the diversity of demyelinating lesions and the heterogeneity seen in the MS patient population. These models are still in their infancy and whether they will provide a useful platform for the development of therapies for distinct subsets of MS awaits further refinement and analysis.

7 TOXIN MODELS OF DEMYELINATION

The third general approach used to model the biology of demyelination and remyelination in the vertebrate CNS are those utilizing the introduction of a demyelinating toxin.

The use of toxins to induce demyelination is extremely useful for addressing specific questions regarding the biology of the remyelination process given the ability to regulate the generation of the lesions in both time and space. These models are not intended to recapitulate the complex etiology and pathogenesis of MS but instead enable investigators to gain insight into the precise cellular and molecular mechanisms that characterize remyelination in the central nervous system. A major strength of the toxin models is that the location and timing of demyelination and remyelination are distinct. Unlike in the immune mediated demyelinating models where demyelination and remyelination are concurrent, in many of the toxin models the epoch of demyelination is temporally distinct from the epoch of remyelination and this allows for the clear characterization of molecular cues regulating each aspect of lesion generation and repair.

7.1 Focal Toxins

Focal areas of demyelination can be induced by directly injecting chemicals that selectively ablate oligodendrocytes and their myelin. Many different demyelinating agents have been used over the last several

decades including antibodies to oligodendrocyte-related molecules, 6-aminonicotinamide, and diphtheria toxin (see aforementioned), however, those most commonly used include lysolecithin, ethidium bromide, and antibodies against the major sphingolipid component of myelin, galactocerebroside.

7.1.1 Lysolecithin

Lysolecithin (L-α-Lysophosphatidylcholine or LPC) is a potent membrane-dissolving chemical that is typically injected into the white matter as a 1% solution in saline in order to induce focal demyelination (Gregson, 1989). In 1972, Hall was the first to demonstrate the use of LPC to create demyelinating lesions in the white matter of the adult mouse spinal cord (Hall, 1972). Since then, LPC has been used in several additional species including rat (Harrison, 1985), rabbit (Waxman et al., 1979), cat (Blakemore et al., 1977; Gledhill and McDonald, 1977), and monkey (Dousset et al., 1995). The most common locations for the generation of LPC induced lesions include the dorsal or ventral funiculi of the spinal cord typically at the thoracic level, the corpus callosum, the optic nerve, and the caudal cerebellar peduncle. LPC injection results in a rapid loss of myelin and the majority of oligodendrocytes in a focal area. Compared to other models, the loss of oligodendrocytes is somewhat less specific and there is a reduction in astrocytes and some loss of axons although this tends to be limited to the area close to the injection site. One of the remarkable features of the LPC lesions is their ability to recover (Blakemore and Franklin, 2008). In general demyelination occurs rapidly and the lesion area is largely devoid of myelin with 2–3 days after LPC injection (Fig. 37.7). The lesions rapidly become repopulated with oligodendrocyte precursors and after a period of proliferation these cells differentiate into oligodendrocytes and initiate remyelination. In rats and mice, remyelination begins between 7 and 14 days post lesion depending on the location of the lesion and the age of the animal and by 30 days post lesion, remyelination is essentially complete (Fig. 37.9). This reproducible pattern of myelin repair has facilitated the identification of molecular mechanisms that either enhance or inhibit the repair process including the Notch pathway (Zhang et al., 2009), the WNT pathway (Fancy et al., 2009), retinoid X receptor gamma signaling (Huang et al., 2011), growth factors, such as hepatocyte growth factor (Bai et al., 2012), and neuregulin (Penderis et al., 2003a), hormones, such as progesterone (Garay et al., 2011), cell cycle proteins, such as cyclin-dependent kinase (Cdk2) (Caillava et al., 2011), chemokine receptors, such as CXCR2 (Kerstetter et al., 2009), the NOGO receptor LINGO-1 (Mi et al., 2005; Mi et al., 2009), and death receptor 6 (DR6) signaling (Mi et al., 2011), as well as several others. Not all the oligodendrocytes are lost in an LPC lesion. In white matter tracts where there are many large-caliber axons, the myelin generated by the

LFB of LPC lesions overtime
FIGURE 37.7 **Local delivery of the gliotoxin lysolethicin into the corpus callosum of the adult mouse generates a demyelinating lesion that repairs over time.** Two days after stereotactic injection of LPC, coronal sections through the level of the corpus callosum show an area of demyelination following staining with luxol fast blue. The lesion repairs spontaneously beginning at around 7 days post injection and is almost completely repaired by 28 days post lesion as shown by a recovery of luxol fast blue staining in the area.

spared oligodendrocytes can be easily distinguished from newly generated oligodendrocytes by the thickness of the myelin sheaths that they generate. Remyelinated axons are covered by myelin sheaths that are much thinner and have shorter internodes than those generated during development (Figs. 37.8 and 37.9). Remyelination occurs spontaneously in both rats and mice, is quite rapid, and is accomplished mainly by newly generated oligodendrocytes derived from local precursors and not Schwann cells in this model.
FIGURE 37.8 **Demyelination changes the structure and cellular composition of the lesion area.** In regions of the CNS that are undergoing demyelination as shown by: (A) the reduced staining with the myelin probe Luxol fast blue, there is (B) an increase in the number of activated microglial cells compared to surrounding tissue. This is shown by the upregulation in the density of IBA-1+ microglia following labeling frozen sections with antibodies to IBA-1. (C) The density of Oli2+ oligodendrocyte precursors, the cells that will differentiate into oligodendrocytes is substantially reduced in the lesion area. (D) Demyelination also alters the organization of astrocytes in the lesion area as shown by labeling with antibodies to GFAP. In the middle of the lesion there is a reduction in the number of GFAP+ cells while at the perimeter of the lesion there is an increase in the expression of GFAP as a result of reactive astrocytes that are undergoing gliosis.
FIGURE 37.9 **Remyelination is characterized by thinly myelinated axons.** Fourteen days after the induction of a local demyelinating lesion by the injection of LPC remyelination is ongoing in the dorsal spinal cord of the 8-week old mouse. Toluidine blue stained 1mm sections clearly show remyelinated axons in the initial lesion when viewed at high power. (A) Low power micrograph with the lesion border clearly delineated (dotted line). (B) Higher power micrograph from the box outlined on a showing thinly remyelinated axons demonstrating myelin repair in the adult spinal cord.

7.1.2 Ethidium Bromide

The toxic effects of ethidium bromide are due to its DNA intercalating properties, therefore all nucleated cells are affected by this agent. The very first experiments that made use of this toxin demonstrated that a direct infusion of ethidium bromide into the cisterna magna resulted in a reproducible acute demyelinating lesion of the rat brain stem (Reynolds and Wilkin, 1993; Yajima and Suzuki, 1979a, 1979b). Over time, the mode of injection has changed, and ethidium bromide is now typically injected directly into white matter tracts as a saline solution that varies from 0.01% or 0.05% to 0.1% depending on the injection site. The lesions following ethidium bromide injections in the dorsal spinal cord tend to be quite large compared to LPC-induced lesions and can involve almost the entire dorsal funiculus, extending up to 8mm longitudinally. The caudal cerebellar peduncles of rats have also been targeted with this approach in order to address critical questions regarding the effects of age, sex, growth factors, and the role of microglia/macrophage activation on remyelination (Penderis et al., 2003a; Li et al., 2005; Li et al., 2006; Zhang et al., 2012; Ibanez et al., 2004; Adamo et al., 2006; Penderis et al., 2003b; Sim et al., 2002).

Although ethidium bromide injections are typically made in either rats or mice, injection into the spinal cords of cats has also been shown to result in large demyelinating lesions (Blakemore, 1982). The early response to ethidium bromide injection involves the destruction of astrocytes, oligodendrocytes, and OPCs while axons are typically spared. Soon after, the initial genera-

tion of the lesions' large numbers of macrophages are found in and around the lesioned area and astrogliosis occurs only around the perimeter of the lesion leaving the center of the lesions essentially devoid of astrocytes (Blakemore, 1982). Following the clearance of myelin debris, remyelination is relatively rapid, although it occurs more slowly than after LPC-induced demyelination. In a comparative study where either LPC or ethidium bromide-induced demyelinating lesions were examined in the caudal cerebellar peduncle of adult rats, extensive oligodendrocyte remyelination was already seen throughout LPC-induced lesions at 6 weeks post injection whereas, a significant proportion of axons remained demyelinated in ethidium bromide-induced lesions. By 3.5 months postinjection, however, almost all axons had remyelinated in ethidium bromide lesions (Woodruff and Franklin, 1999). Interestingly, in contrast to LPC or anti-GalC-induced lesions where most remyelination is mediated by oligodendrocytes a significant amount of remyelination in ethidium bromide-induced lesions are undertaken by Schwann cells (Woodruff and Franklin, 1999; Blakemore, 2005). Remyelinating Schwann cells are typically found in astrocyte-depleted areas of the demyelinated spinal cord and it was initially assumed that they were derived from Schwann cells associated with peripheral nerves or spinal nerve roots in the vicinity (Franklin and Blakemore, 1993). A recent study, however, used in vivo fate mapping to demonstrate that after demyelinating injury, CNS-derived OPCs are able to generate Schwann cells, a surprising finding given that Schwann cells normally develop from the embryonic

neural crest and are restricted to the peripheral nervous system (Zawadzka et al., 2010). One likely hypothesis is that in the absence of astrocyte signaling, cells specified for the oligodendrocyte lineage are diverted to become Schwann cells suggesting the commitment to a myelinating fate over rides the commitment to a specific cell type. The molecular mechanisms responsible for this regulation of cell fate are currently unclear. In MS, when remyelination occurs, it is largely mediated by oligodendrocytes and not Schwann cells thus the significance of the ethidium bromide model for therapeutic development is somewhat limited.

7.1.3 Anti-GalC Antibodies

One approach for selective cell type elimination that has been used in multiple systems is the targeting of the complement cascade though binding to cell type specific, cell surface antibodies (Piddlesden et al., 1993; Raff et al., 1978). In this model the antibody binds to specific cell surface epitopes and addition of complement results in selective cell lysis. This model has been used effectively in vivo using antibodies to galactocerebroside (GalC) the major myelin sphingolipid that marks mature oligodendrocytes as the targeting vector (Raff et al., 1978). Initial studies demonstrated that a single intraspinal injection of complement proteins plus antibodies to GalC resulted in demyelination (Keirstead and Blakemore, 1997). In this model of demyelination in the adult rat spinal cord, some oligodendrocytes survived demyelination enabling the authors to demonstrate that the oligodendrocytes that survive within demyelinated lesions are not induced to divide in the presence of naked axons demonstrating that fully-differentiated oligodendrocytes are postmitotic and do not contribute significantly to remyelination in the adult CNS. Demyelination has also been induced in the rat cerebellar peduncle using this model where axons tend to be spared and remyelination is typically accomplished by oligodendrocytes, not Schwann cells (Woodruff and Franklin, 1999).

7.1.4 Advantages of Focal Toxins

All of these agents produce large areas of demyelination with minimal axonal damage. Focal toxins induce synchronized demyelination in a defined region allowing the investigation of remyelination in the absence of concurrent demyelination. This offers a clear advantage when analyzing molecular changes specific to remyelination since the processes of demyelination and remyelination have temporal separation and spontaneous remyelination follows a highly reproducible time course in rodents. The timing of remyelination has been shown to differ between the three most commonly used focal toxins although all models eventually undergo extensive spontaneous remyelination. After LPC-injection into the cerebellar peduncle of adult rats, remyelination was

evident by 14 days and extensive by 6 weeks whereas, ethidium bromide or anti-GalC induced lesions showed very little remyelination after 14 days although they did show extensive remyelination after 3 months (Woodruff and Franklin, 1999). Finally, unlike immune or viral-mediated models of demyelination, focal toxin-induced lesions have the advantage that they can be induced at any age, in either the brain or the spinal cord, and in any strain or species. The disadvantage of these models is that, particularly in the case of LPC and ethidium bromide the mechanisms of induction of cell death is nonphysiological and if the development of the lesion and the potential repair process is in part dependent on the mechanisms of cell death then it is unclear whether these models will be useful in defining pathogenic processes in MS. Where these models have proven extremely useful is in the development of therapeutics targeted towards remyelination rather than immune regulation. One of the best examples of such therapeutic development is the identification and characterization of anti-LINGO-1 antibodies as a therapy promoting remyelination. A major role of the leucine-rich repeat and Ig domain containing NOGO receptor (LINGO-1) is to inhibit the differentiation of oligodendrocyte progenitor cells (Mi et al., 2005, 2009). LINGO-1 knockout mice show precocious myelination, which suggested that LINGO-1 antagonists might be useful to accelerate myelin repair after demyelination. Using both the LPC and cuprizone models of demyelination, anti-LINGO-1 antibody treatments have been shown to significantly increase the speed of remyelination, a finding that may result in a new therapeutic option for MS patients (Mi et al., 2005, 2009). The anti-LINGO-1 Li81 antibody is the first MS therapy that directly targets myelin repair and is currently being evaluated in clinical trials for MS (Pepinsky et al., 2011). Finally, the use of complement binding antibodies to target oligodendrocyte death may have immediate relevance to MS. It has been suggested that in some MS lesions complement mediated cell lysis contributes to the generation of the pathology and thus this model may directly reflect the generation of lesions in a subset of MS patients.

7.2 Systemic Toxins

One disadvantage of the local toxin models is that they require the injection of the toxin in the parenchyma of the CNS. While this allows for precise localization of the subsequent lesion, it introduces the complexity that any pathology that develops is a consequence of both the injection and the presence of the toxin. An alternative strategy is to utilize a systemic toxin that preferentially targets oligodendrocytes in specific regions of the CNS. The most commonly utilized systemic toxin is Cuprizone.

7.2.1 Cuprizone

Ingestion of the copper chelator cuprizone (biscyclohexanone oxaldihydrazone) results in the reproducible demyelination of specific brain regions in either C57BL/6 or SJL/SVJ mice. The exact mechanism underlying cuprizone-induced demyelination remains unknown but the toxicity is thought to result from a combination of mitochondrial stress and an innate immune response (Linares et al., 2006; Liu et al., 2010; Pasquini et al., 2007). Cuprizone-induced demyelination appears to result from the degeneration of oligodendrocytes rather than a primary attack on the myelin sheaths (Carlton, 1966, 1967; Tansey et al., 1996). Experiments conducted in the late 1960's demonstrated that high doses (0.5%) of cuprizone mixed with basic rodent chow and given to mice early in development resulted in high mortality but that lower doses resulted in demyelinated lesions accompanied by astrogliosis (Carlton, 1967). This model has been refined to the point where mice aged 6–9 weeks are now typically given 0.2%–0.3% cuprizone treatment of for 5–6 weeks which results in acute demyelination of the corpus callosum (Matsushima and Morell, 2001; Stidworthy et al., 2003), as well as the hippocampus (Hoffmann et al., 2008; Koutsoudaki et al., 2009) external capsule (Pott et al., 2009), cerebellar peduncles (Blakemore, 1973; Ludwin, 1978; Torkildsen et al., 2008), cerebellum (Skripuletz et al., 2010; Groebe et al., 2009) cerebral cortex (Skripuletz et al., 2010; Gudi et al., 2009), and striatum (Pott et al., 2009). Far less demyelination is seen in spinal cord suggesting either a differential susceptibility of oligodendrocytes to the toxin or non-uniform penetration of the toxins to the CNS. Distinct gray matter regions have also been shown to be affected in the cortex and hippocampus (Gudi et al., 2009; Norkute et al., 2009), which may reflect death of oligodendrocytes in those regions or a toxic effect of curpizone on other neural cell types. Mice exposed to cuprizone exhibit extensive reactive gliosis, activation of microglia, and significant oligodendrocyte apoptosis. Similar to what is noted with the focal models of demyelination discussed above, acute demyelination is followed by spontaneous remyelination that occurs during the weeks following treatment removal while the mice are fed regular chow. When cuprizone treatment is prolonged to 12 weeks or longer however, remyelination is very sparse resulting in a model of chronic demyelination (Ludwin, 1980).

7.2.2 Advantages of Systemic Toxins

While it is debatable whether the cuprizone model reflects human MS pathology, this reversible demyelination model is useful for studying the biological processes related to both demyelination and remyelination in the CNS. Two major pathological features characteristic of the cuprizone model, however, include primary oligodendrocyte death along with the activation of microglia and these two features are known to occur in a subset of human MS lesions (Barnett and Prineas, 2004). The cuprizone model has been extensively used to examine the potential of various compounds to stimulate myelin repair (Koutsoudaki et al., 2010; Moharregh-Khiabani et al., 2010). A significant advantage of this model is that demyelination can be induced in a reproducible manner in both space and time and mechanisms specific to both demyelination and remyelination, which are not specific to primary inflammatory events, can be investigated. Because the time-course of cuprizone treatment is so long, demyelination is progressive in this model and remyelination begins while demyelination is still taking place. The reappearance of myelin protein expression and partial remyelination has been shown to occur during the late stages of acute demyelination (after 3 weeks) while the mice are still undergoing cuprizone treatment (Jurevics et al., 2001; Lindner et al., 2008; Norkute et al., 2009). This temporal overlap presents a challenge when trying to understand the mechanisms specific to either demyelination or remyelination, however, it does model the human condition more closely since demyelination and remyelination occur concurrently in patients with MS. Recent studies have shown that when Cuprizone treatment is combined with rapamycin treatment which blocks mTor signaling, the spontaneous remyelination is dramatically reduced thereby allowing better quantification of repair processes. A significant advantage of the cuprizone model over other approaches is the relative simplicity of the experimental paradigm. Cuprizone is simply added to regular mouse chow that is fed to the animals each day in contrast to the focal toxin models, which call for potentially technically challenging surgeries involving the use of a stereotactic apparatus to direct the focal lesions to specific areas. Despite the apparent simplicity of this model there are a number of confounding features. First the use of cuprizone is generally limited to mice (although recent studies have reported its use in rat (Adamo et al., 2006; Silvestroff et al., 2012) and there is a clear genetic linkage to the susceptibility for cuprizone toxicity. The basis for such strain difference is unknown. Likewise there are significant differences in susceptibility between gender and age that are poorly understood (Kipp et al., 2009). This lack of clarity is likely a reflection of the lack of understanding about the mechanism mediating Cuprizone toxicity, however proof of principle studies have indicated that signals known from in vitro studies to stimulate oligodendrocyte differentiation such as thyroid hormone (T3) promote remyelination in the cuprizone model (Franco et al., 2008).

8 CONCLUSIONS AND COMMENTS

The heterogeneity of the demyelinating disease MS is well established and this is readily reflected in the wide range of models that mimic a wide range of different attributes of the disease. While some of the models, such as EAE have been established for many years and have formed the basis of a range of current therapies used to treat the disease, other models, such as those that target oligodendrocyte cell death to particular regions of the CNS are recent additions to the arsenal of understanding the pathology of the disease. Each of the model systems discussed in this review has particular merit for developing our understanding of some specific aspect of the disease. For example while EAE models have been very effective at furthering our insights of the immunological basis of the CNS demyelination and particularly the role of T cells in MS, the use of gliotoxins, such as LPC or ethidium bromide have been particularly useful in developing our understanding of the cellular and molecular mechanisms of remyelination.

1 INTRODUCTION

Mood disorders are a severe mental health condition with a high incidence and comorbid medical problems. According to the Diagnostic and Statistical Manual of Mental Disorders Fifth Edition (DSM-5), the two major mood disorders are major depression (MD) and bipolar disorder (BD). Mood disorders are characterized by extreme and inappropriate mood alteration with significant social, cognitive, and functional impairment. MD is characterized by persistent sadness, fatigue, eating disturbances, sleep disturbances, suicidal thoughts, guilt, and social withdrawal. BD is characterized by episodes of mania and depression with euthymic or normal mood states between the episodes. Manic episodes can consist of hyperactivity, elevated mood or

agitation, racing thoughts, reckless behavior, little need for sleep, and, sometimes, psychosis. Several pharmacological compounds are validated as effective for mood disorders. The most common medications used to treat BD are lithium, anticonvulsants (valproate, carbamazepine, and lamotrigine), and atypical (e.g., clozapine, olanzapine, and risperidone) and typical (haloperidol and chlorpromazine) antipsychotics. MD is generally treated with antidepressants, including tricyclics (e.g., desipramine and imipramine), selective serotonin reuptake inhibitors (SSRIs; fluoxetine and paroxetine), and monoamine oxidase inhibitors (MAOIs; phenelzine and tranylcypromine).

Despite receiving adequate treatment, most patients continue to have recurrent mood episodes, residual symptoms, functional impairment, psychosocial

disability, and significant medical and psychiatric comorbidities. In addition, many patients do not adequately respond to the available medications and cannot tolerate the side effects of these drugs. Research for developing new drugs for mood disorders has focused on specific targets, which could offer more effective and safe treatments. However, a better understanding of the pathophysiologic mechanisms of these disorders is important for designing new drugs and implementing them in clinical practice. The advances in genetic, neurobiological, and pharmacological methodologies have helped in the development of animal models, and these models have been an important tool for investigating new intracellular systems that may be involved in the specific pathophysiology of psychiatric disorders.

However, it is important to emphasize that no animal model developed to date can fully mimic its "corresponding" human psychiatric disorder. Given that BD is a complex mood disorder with recurrent mood swings, including manic, depressive, and mixed episodes, the development of an adequate animal model for this disorder is a challenge. Ellenbroek and Cools (1990) have proposed that valid animal models in psychiatric disorders should demonstrate the following three major criteria: face validity, construct validity, and predictive validity. Face validity indicates how similarly the model can mimic the symptoms of a given illness. Construct validity is related to the ability of the model to reproduce some pathophysiological aspects of the illness. Finally, predictive validity evaluates whether the therapeutic agents used in treating this illness can reverse the symptoms in the animal model.

This chapter seeks to provide a comprehensive overview of traditional and recent animal models for mania and depression, recapitulating their different features, and the possible pathophysiology of mood disorders emulated by those models.

2 ANIMAL MODELS OF MAJOR DEPRESSION

2.1 Environmental Models of Major Depression

The relationship between environmental stress and the incidence of MD in humans is widely described in the scientific literature. Different stress stimuli at different life stages can affect neurodevelopment, decreasing stress resilience in the long run, which increases the odds of developing MD. These stressful situations include intrauterine adversities, child abuse, drugs, life pressure, material and emotional losses, and hardships of modern life.

Based on these clinical observations, the main animal models of depression involve exposing the animals to different stressor stimuli at specific developmental stages, mimicking the human triggers to developing MD. Chronic mild stress (CMS) and maternal deprivation are well-established environmental models of MD that meet the criteria for the aforementioned three validities. These models are able to induce depressive-like behavior, as well as monoaminergic and neuroendocrine alterations in adult animals, and these alterations can be reversed by treatment with classical antidepressants. Further, we will discuss these and other environmental models of MD.

2.1.1 Animal Model of Depression Induced by Maternal Deprivation

It is widely described in the literature that early life adversities, including childhood maltreatment and trauma, can lead to a depressive condition in adult life, and this relationship can occur via several pathways, such as monoaminergic alterations, immune-inflammatory system changes, and neuroplasticity impairment. Among these childhood adversities, we can cite physical violence, sexual abuse, neglect, and loss of the primary caregiver.

Parental care is a strongly established behavior in rodents that is essential for the healthy development of offspring. The animal model of depression induced by maternal deprivation is based on this behavior and induces depressive-like behavior in adult animals after an early life stressor stimulus, mimetizing the incidence of MD following this trigger. In fact, this animal model is very effective and fulfills all three validities, and it has been one of the most frequently described models for MD.

Several studies have consistently demonstrated that adult animals exposed to maternal deprivation in early life show a wide range of depressive-like behaviors, such as increasing immobile time on the tail suspension and a forced swimming test, more dramatically decreased sweet food consumption and anxious-like behaviors. In addition to face validity, maternal deprivation can reproduce several biochemical alterations that are implicated in the pathophysiology of depression, such as impairment in mitochondrial metabolism via the tricarboxylic acid cycle and mitochondrial chain complex activity; increased oxidative stress; decreased dopaminergic, serotoninergic, and GABAergic systems; immune system dysregulation and decreased neurotrophic factor levels. The face validity of this model is well established. Several studies have demonstrated that treatment with a classical antidepressant, imipramine, as well as ketamine and tianeptine can reverse these behavioral and biochemical alterations induced by maternal deprivation, supporting its predictive validity.

This animal model was first described by Levine (1967) in which the animals were maternally deprived for a period of 24 h. This protocol has undergone some adaptations in the deprivation period, which is more commonly 3–4 h of separation per day between the 1st and 20th postnatal day (the duration of the protocol ranges from the authors). This separation consists of removing the mother from the cage for 3–4 h, leaving the progeny alone with only wood shavings and the mother's smell. After the deprivation period, which may vary, the animals go through normal care and are weaned at a regular age. At the adult stage, these animals present with depressive-like behavior. This model can also be used to study the neurobiology of depression and the effects of classical or new candidate therapeutic agents. For this, the animals must undergo a treatment protocol—which can be acute, repeated, or chronic administrations—when the animals reach adulthood, which is at approximately 60 days of age. After the end of the treatment protocol, the depressive-like behavior can be measured with the behavior tests that are described at the end of this section.

The main limitation of the animal model for depression induced by maternal deprivation is its methodological complexity. The entire process must to be carefully monitored because the matrices copulate until the end of the deprivation protocol. Because one litter, in most cases, does not generate sufficient offspring for a complete study, a schedule must be arranged to work with different litters with different dates in the same project.

2.1.2 Animal Model of Depression Induced by Chronic Mild Stress

The modern life style involves several stress events, such as long working journeys, excess responsibilities, noise and visual pollution, violence, insecurity, and others. There is a clinical relationship between stress and the development of MD; patients suffering intense acute stressful situations or chronic stress have a greater vulnerability to developing this disorder. Recently, several studies have demonstrated that stress can interact with DNA expression by a mechanism called epigenetics. These social stress-induced alterations are most evident in specific genes that are related to the neurobiology of MD, including glucocorticoid receptors, neurotrophic factors, and serotonin transporters, strengthening the role of stress in the etiology of depression.

The animal model of depression induced by CMS uses this premise to induce depressive-like behaviors in rodents. Long-term exposure to environmentally stressful situations can cause several behavioral alterations, such as increased immobility on the tail suspension and forced swimming tests, decreased body

licking on the splash test, and decreased consumption of sweet food, supporting the face validity of this model. Classic depressive neurobiological alterations are also observed in rats that are treated with this protocol; these include increasing oxidative stress, mitochondrial alterations, increasing corticosterone levels, decreasing neurotrophins levels, and immune-system alterations. All behavioral and biochemical changes induced by CMS respond positively to treatment with antidepressants, such as imipramine, tianeptine, and ketamine. This finding shows that exposure to stressful situations during adulthood can induce depressive-like behavior and pathophysiological alterations in rodents that are similar to the effects of maternal deprivation. Treatment with classical antidepressants can reverse these alterations, demonstrating the three validities for this model.

Katz (1981) was the first author to describe a protocol based on chronic stress stimuli in rodents that induce anhedonic-like behavior in rats. However, this protocol consisted of a very invasive stimulus, such as cold water swimming and electric shocks, to induce increased corticosterone levels and reduce sucrose consumption. This protocol was adapted to a minor invasive version by Willner et al. (1987) using different and more realistic stimuli that induce depressive-like behavior, and it has been used up through the present. In this protocol, the adult animals are exposed to different stressful situations daily over 40 days. These situations include food deprivation, water deprivation, space containment, space containment at 4°C, exposure to strobe light, social isolation, cage tilting (30 degrees), and damp bedding. The situations are randomly applied during the 40 days and at different periods to avoid predictability. Each stressor has a specific duration, as shown in the table below.

Stressor type	Duration
Food deprivation	24 h
Water deprivation	24 h
Space containment	1–3 h
Space containment at 4°C	1.5–2 h
Strobe light	120–210 min
Social isolation	3 days
Cage tilting	4 h
Damp bedding	4 h

Twenty-four hours after the final stressor, the depressive-like behavior can be measured by the behavioral tests described in this section. As well as the animal model induced by maternal deprivation, this model can be a tool for studying the neurobiological mechanisms of MD and can offer an important approach for investigating novel and classic therapeutic agent targets. For this, acute, repeated, or chronic treatment with

antidepressants or candidate drugs may be started after the last day of the chronic stress protocol.

2.2 Surgical Model of Depression

Surgical animal models are based on anatomic alterations or deletions of specific brain structures, resulting in behavior and biochemical alterations that are similar to the clinical manifestations. The rat sense of smell is a highly evolved, important sense for a series of social behaviors. Pheromones, chemical signals, carry information about the animal's behavior and physiological status, and pheromone detection by other rats modulates several processes, such as reproduction, gender recognition, social dominance, and aggressive and avoidance behaviors. The brain structure responsible for recognizing these pheromones is the olfactory bulb.

Considering the importance of this brain region in the social behaviors of rodents, Jancsar and Leonard (1981) first reported that bilateral olfactory bulbectomy induced irritability in rats, and this behavior was reversed by amitriptyline treatment. Afterward, several other studies demonstrated that this procedure can induce anhedonic and other depressive-like behaviors, such as anorexic manifestations, decreased sexual activity, impairment of social interaction, and reduced sweet food consumption. In addition, the animal model of depression induced by bilateral olfactory bulbectomy caused spatial learning damage in rats. The olfactory bulb has connections with other brain structures that are responsible for mood modulation, such as the amygdala, nucleus accumbens, caudate putamen, and hypothalamus. Disruption of these connections triggers depressive-like biochemical alterations, decreased noradrenergic and serotoninergic activities, increased acetylcholine levels, decreased BDNF levels, and increased TNF-α and IL-1β levels in rat brains. Chronic treatment with clinically effective antidepressants agents—imipramine, sertraline, amitriptyline, fluoxetine, and others—after bilateral olfactory bulbectomy can reverse, partially or completely, these alterations, supporting their predictive validity.

The olfactory bulbectomy surgery was standardized by Kelly et al. (1997) and it consists of a midline frontal incision in the skin on the skull of an animal that was previously anaesthetized with ketamine and xylazine. After skull exposure, 2 burrs are drilled at points 7 mm anterior to the bregma and 2 mm lateral to the bregma. Both olfactory bulbs are aspirated, paying attention to avoid damaging the frontal cortex, and the dead space is filled with a hemostatic sponge to prevent blood loss. The skin above the lesion is closed with suture material and the antibacterial agent is applied. After the surgical procedure, the animals must recover for 14 days; then, depressive-like behavior can be measured or antidepressant treatment can be initiated.

2.3 Genetic Models of Depression

MD has a multifactorial etiology, and genetic and environmental factors interact with each other to determine the pathophysiology and pathogenesis of this disorder. The growing body of genetic study data provides substantial knowledge of specific genes that are related to MD, and these can help with the development of potential animal models for studying this condition. The genetic model of depression consists of inducing rodent DNA alterations in genes that correspond to the human genes in MD.

This class of models is relatively recent, but it has helped provide significant, powerful information on the neurobiology and therapeutic approaches for MD. In this section, we will discuss the main candidate genes for developing animal models of depression.

2.3.1 Tph2 Gene

Monoaminergic dysfunction is one of the first and most described theories of depression pathophysiology. The role of serotoninergic signalization impairment in this disorder is widely evaluated in the clinical literature, and its modulation is a target of several antidepressant agents. Based on the serotoninergic hypothesis, a genetic modified mouse strain was created, showing reduced expression of tryptophan hydroxylase 2 (Tph2), an enzyme that participates in serotonin synthesis. This genetic modification triggers to a decrease in the brain serotonin levels, which is similar to the alterations observed in humans. In addition, animals with this genetic alteration had increased immobility time in the forced swimming test, reinforcing its face validity (Beaulieu et al., 2008). This animal model has great potential to mimic all aspects of depression; however, the data in the literature are scarce, making it necessary to perform more studies with face, construct, and predictive validity.

2.3.2 CB1 Gene

Endocannabinoids play an important role in mood regulation, and several preclinical and clinical studies have demonstrated that alterations in the cannabinoid system can be involved in the pathophysiology of several mental diseases, such as schizophrenia, anxiety, BD, and MD. This role is so evident that endocannabinoid modulation is a new target for pharmacological approaches. Therefore, genetic alteration of cannabinoid receptor 1 (CB1) expression has been proposed for use in an animal model of depression. In fact, CB1 knockout mice demonstrate anxious and depressive-like behavior beyond increased corticosterone in the serum and decreased BDNF levels in the hippocampus. Other notable alterations include

altered serotoninergic alteration, suggesting there is a relationship between these two systems.

2.3.3 BDNF and TrkB Genes

Beyond the neurotransmitter systems, a growing body of evidence has indicated a strong relationship between neurotrophins and mood disorders, especially BDNF. Several animal models of depression can induce a reduction in the brain BDNF levels. In humans, a polymorphism of the BDNF gene denoted Val66met and epigenetic alterations on this DNA region seem to be related to MD. In addition, BDNF upregulation is one of the mechanisms of action for several antidepressant drugs, highlighting the involvement of this protein in depression neurobiology. Because of this role, genetic modifications in BDNF expression in rats have been considered in an animal model of depression.

However, beyond mood modulation, BDNF plays a pivotal role in neurodevelopment, and knockout mice have serious neural damage and perinatal lethality. Conversely, Chan et al. (2006) produced a heterozygote conditional knockout mouse, which only presents with adulthood reductions in BDNF levels. These animals showed depressive-like behavior on the tail-suspension test with an antidepressant phenotype in the forced swimming test. In another study, Saarelainen et al. (2003) showed that a strain of mice expressing nonfunctional versions of TrkB, the main BDNF receptor, was resistant to the effect of antidepressants, indicating the importance of this receptor for depressive-like behavior and the response to treatment.

These results suggest that genes related to BDNF pathway signaling are important for the development of genetic animal models of depression; however, as a protein with different functions in the nervous system, its modulation needs to be enhanced.

2.4 How Can Depressive-Like Behavior be Evaluated in Laboratory Animals?

Mood disorders have a highly complex clinical manifestation. By not having a specific biomarker, these disorders are exclusively diagnosed by behavioral symptoms. MD has a wide range of symptoms because changes in the physiological alteration, such as anorexic behavior, lead to decreased self-esteem.

Mimic symptoms are part of the triad to animal model validations; however, a depressive episode in humans involves such a complex core of behaviors that cannot be evaluated in rodents, including decreased self-esteem, suicidal thinking, low mood, and feelings of guilt. Nevertheless, a selective class of behavioral manifestations can be measured in animals, reflecting human symptoms. One such set of behaviors is called anhedonia, which consists of a loss of interest in pleasurable activities. Other classes of behavior that can be observed in animals include hopelessness, which is a classical manifestation in depressive humans.

As the animals do not present with all behavior criteria for a depressive state, it is not possible to claim that the animal is depressed; as a result, the animal models of depression intend to induce some depressive-like behavior in these animals. There are some tests to evaluate these depressive-like behaviors in rodents, and the primary tests will be described later in the chapter.

2.4.1 Forced Swimming Test

This behavior test aims to evaluate a hopelessness state in rodents by forcing the animal to swim in a water cylinder without a method of escape. After an initial period of motor agitation, the animals naturally tend to adopt a motionless posture, performing movements only to keep their heads out of water, indicating the animal had learned that escape is impossible. This behavior can be anthropomorphically interpreted as if the animals had lost hope in this stressful situation.

In fact, animals submitted to models of depression adopt this immobile posture earlier and longer than control groups. Another interesting fact is that classical antidepressant drug administration per se can reduce the immobile time in healthy control animals, and this test is an important tool for investigating antidepressant effects of new drugs without subjecting the animals to depressive behavior induction protocols.

The forced swimming test is one of the most commonly used approaches for evaluating depressive behavior in animals, and it was first described by Porsolt et al. (1977). It consists of a very simple test without a very sophisticated apparatus and has two versions, one for rats and another for mice. In this section, we will present both protocols.

For rats, the test is divided into two sessions, denoted the training and test sessions, which are separated by 24 h. In the training session, the rat is forced to swim for 15 min in a narrow cylinder that is full of water at $25 \pm 2°C$ and sufficiently deep that the rat cannot touch the bottom and keep its head above water at the same time. No behavior is evaluated in this session, which is only aimed to habituate the animal to the apparatus so that it can learn that there is no way to escape. At the test session, the animal is forced to swim in the same apparatus for 5 min, and the following behavior parameters can be measured (Fig. 38.1):

Swimming: Time that the animal moves around in the water. This behavior tends to reduce over time until the end of the test.

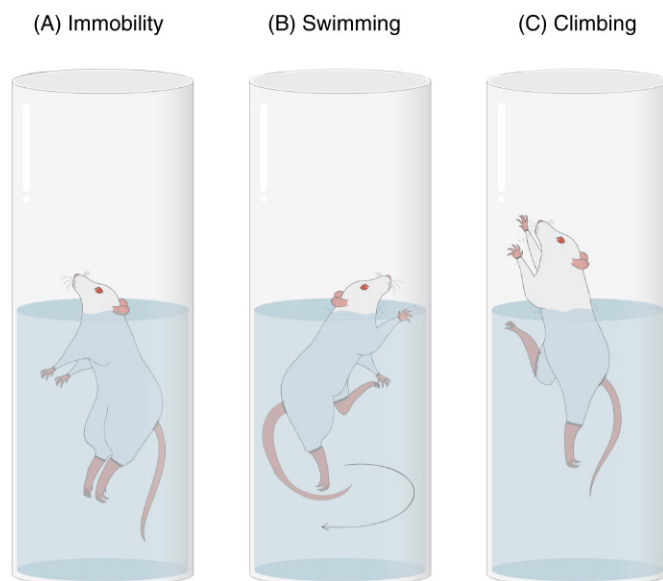
Climbing: Time that the animal tries to climb to the cylinder wall to escape the water. This behavior is decreased in animals that are submitted to models of depression. The walls must be high enough to prevent animal escape.


FIGURE 38.1 **Forced swimming test.** Representation of (A) immobility, (B) swimming, and (C) climbing parameters.

Immobility: Time the animal spends with no movements, or moves to keep its head out of water while not intending to move around the apparatus.

It is important to note that the training and test sessions must be as similar as possible, with the same applicator and location in the room, and the apparatus must be identical in the two sessions.

The forced swimming test for mice is even simpler than for rats. The apparatus is the same, which is proportional to the different sizes of the two species; the only difference is that mice do not need two separate sessions for the training and test. Mice demonstrate a significant, stable level of immobility after a single exposure session; then, this test lasts for 6 min. The first 2 min are used for the training time and the last 4 min are spent on immobility, climbing, and swimming evaluations.

2.4.2 Tail Suspension

Tail suspension is an alternative method that was designed by Steru et al. (1985) to be a "dry forced swimming test." This test is also based on hopelessness behavior; however, the immobility is induced by suspending the animal upside down by the tail. As in the forced swimming test in mice, this test has a single 6-min session and, in the first minutes, mice will try to escape from this stressful situation by performing vigorous movements (Fig. 38.2). Afterward, they become immobile. Antidepressant drugs also act on this behavior, decreasing the immobility time.

This test has several advantages compared to the forced swimming test for both the applicator and animal. Tail suspension is a more comfortable position than forced swimming for the animal; in addition, this test does not present the risk of hypothermia at completion.

This test can be performed in a simple box and the animal can be suspended while tied to a hook or taped to the ceiling of the apparatus, not requiring a very large space or handling of substantial equipment.

2.4.3 Sweet Food Consumption

This behavioral test evaluates anhedonic behavior in rats, which is based on the intake of palatable sweet food after repeated training sessions. This protocol, which was originally described by Gamaro et al. (2003) and adapted by some other authors (such as, Lucca et al., 2009), is performed in an open-field apparatus with a sweet cereal pellet in each quadrant of the open-field floor. The animals are submitted to five training sessions during which the animals are placed, once daily for 3 min, in an open-field arena with sweet cereals for the animal to habituate to the food and apparatus. After the training sessions, the animals are submitted to two test sessions of 3 min each, once daily, wherein the number of ingested pellets is counted. Some studies standardize the protocol so that when the animal eats part of the pellet (1/4, 1/3, or 1/2), the fraction is also considered (Fig. 38.3).

It is important to note that animals must be deprived of food for 22 h before all five training sessions and the first test sessions. This deprivation aims to stimulate the animals to consume the sweet pellets, and they are easily habituated to this food. For the last test session, the animals must have ad libitum access to food in the prior 24 h; as a result, the consumption will not be as a food necessity but a search for a pleasurable activity.

The ability of this test to detect depressive-like behavior is well established in the literature, and it is a powerful tool to validate animal models for testing the antidepressant effects of specific drugs. However, by including an extensive protocol and involving a period of stressful situations, such as food deprivation, which can interfere with some protocols, this test is not widely used.

2.4.4 Splash Test

The splash test protocol discussed in this section was described by Ducottet and Belzung (2004) and simultaneously evaluated depressive-like behavior based on two different motivations, anhedonia as sucrose consumption and self-care. This simple test does not require a special apparatus and can be performed in the murine home cage. The splash test consists of spraying a 10% sucrose solution twice on the back of the animal. Because of the solution viscosity, the sucrose dirties the murine fur, inducing a body-licking behavior, called grooming. The sucrose solution acts as a releaser and palatability, permitting persistent grooming. The frequency and total time of grooming within 5 min after sucrose solution application are recorded. Several preclinical studies have demonstrated the sensitivity of the splash test for evaluating depressive-like behavior in different animal

FIGURE 38.2   **Tail suspension test.** Representation of (A) immobility and (B) mobility parameters.
FIGURE 38.3   **Sweet food consumption test.** Representation of apparatus with sweet cereal.

models of depression, as well as the effect of antidepressant treatment in these models. However, this test should be evaluated with other, well-described models, including the forced swimming or tail suspension test.

3 ANIMAL MODELS OF MANIA

As described previously, BD presents a complex, alternating clinical course, with recurrent mood swings including manic and depressive episodes, making the development of an adequate animal model a challenge.

At this time, there is no animal model mimicking both manic and depressive episodes in the same animal. However, the clinical hallmark in diagnosing BD is the presence of manic symptoms, thus an adequate animal model of BD should resemble some features of a manic episode, such as euphoria, irritability, aggressiveness, hyperactivity, insomnia, hypersexuality (an increase in mounting behavior), risk-taking behavior, and/or increased stereotypy (sniffing and grooming) (face validity). Some pharmacological and environmental rodent models of bipolar mania are described later in the chapter.

3.1 Animal Model of Mania Induced by Amphetamine

A number of animal models of mania have used hyperlocomotion induced by psychostimulants. In fact, the most useful model to study BD is the animal model of mania induced by amphetamine (AMPH). Intraperitoneal injection of AMPH in rats induces manic-like behaviors, including hyperactivity, risk-taking behavior, aggressive behavior, and hypersexuality (face validity). Therefore, the manic-like behavior induced by repeated AMPH administration (14 days) in rats is considered a good animal model of mania (Frey et al., 2006). In medical clinic, to be characterized as a manic episode, the subject must demonstrate at least 1 week or more of manic symptoms. In addition, repeated intermittent exposure to stimulants, such as AMPH progressively increases the drug's effect—this phenomenon is called sensitization. Several studies have strongly indicated the presence of behavioral sensitization in patients with BD as an explanation for the progressive behavioral dysfunction observed in this mood disorder.

AMPHs are central nervous system stimulants and act by increasing dopamine (DA) efflux, inhibit the

uptake of DA and inhibit monoamine oxidase. These sympathomimetic substances are chemically related to betaphenylethylamines (the core structure for catecolamines), such as dextroamphetamine (d-AMPH) and methamphetamine (m-AMPH). It is interesting that dopaminergic drugs, such as AMPH, are able to induce manic symptoms in both normal human volunteers and BD subjects (Strakowski and Sax, 1998). It was demonstrated that emergence of manic symptoms is associated with higher urinary DA levels (Joyce et al., 1995). In addition, studies have demonstrated DA receptor changes in BD patients (Pantazopoulos et al., 2004; Vogel et al., 2004; Zhao et al., 2015). Therefore, the construct validity of the animal model of AMPH-induced mania is based on the fact that this drug alters the dopaminergic system, mimicking the pathophysiology of BD.

Mood stabilizing drugs, particularly lithium and valproate, are considered first line agents for both acute mania and maintenance treatment. Therefore, considering the construct validity of the model, lithium and valproate are able to reverse the manic-like behaviors induced by AMPH in rats, such as hyperactivity and risk-taking behavior. Several studies have suggested that the neuroprotective effects of lithium and valproate may be responsible for their therapeutic effects. Indeed, some studies have demonstrated that lithium and valproate are able to protect the brain of rats against AMPH-induced oxidative stress and mitochondrial alterations (Valvassori et al., 2010), which are also observed in brain and blood of BD patients (Andreazza and Young, 2014; Gama et al., 2013). Several biochemical targets of lithium and valproate have been identified, such as the neurotrophin signaling pathway, glycogen synthase kinase-3 (GSK-3), and protein kinase C (PKC). It is interesting that alterations in these molecules elicited by AMPH in rats can be reverted by lithium and tamoxifen (Cechinel-Recco et al., 2012). The animal model of mania induced by AMPH has been important in investigating new intracellular systems that may be involved in BD, while also being a good tool for testing new drugs.

3.2 Animal Model of Mania Induced by Ouabain

The animal model of mania induced by intracerebroventricular (ICV) administration of ouabain was described firstly by Li et al. (1997). However, in the last years, other groups have better characterized the model. The ICV injection of ouabain acutely induces hyperactivity in rats (face validity), which is normalized by the treatment with lithium, carbamazepine, and haloperidol (predictive validity). Interestingly, Ruktanonchai et al. (1998) observed a persistent hyperactivity response 9 days following a single ICV injection of ouabain in rats. In fact, bipolar illness is a recurrent and chronic condition, thus a model of mania which mimics some of these

aspects is a useful tool to investigate the underlying pathophysiological mechanism of BD.

Ouabain is a digitalis-like compound (DLC) that inhibits the sodium- and potassium-activated adenosine triphosphatase (Na + K + ATPase) activity. It is known that inhibition of the Na + K + -ATPase induces depolarization and subsequent neuronal excitation that leads to increased intracellular Ca^{2+} levels and neurotransmitter release, which are related to increases in locomotor activity in rats and manic episodes in bipolar patients. It is interesting that DLC-like compound levels in the parietal cortex from bipolar patients were significantly higher than in normal individuals and depressed patients (Goldstein et al., 2006). These endogenous DCL-like compounds in the brain regulate Na + K + -ATPase activity of the neuron. Additionally, the Na + K + -ATPase activity is reduced in manic and depressed bipolar patients (Looney and El-Mallakh, 1997), pointing the constructs validity of this animal of mania induced by ouabain.

Studies with this animal model have shown that the manic-like hyperactivity induced by ouabain is accompanied by severe brain damage due to an increased formation of lipid and protein oxidation products (Jornada et al., 2011) and a decrease of neurotrophins (Jornada et al., 2010) levels—also observed in BD patients. It was demonstrated that mood stabilizers, lithium and valproate, are able to reverse this brain damage. An increase in oxidative stress has been associated with decreases in the activity of the Na + K + -ATPase in bipolar patients. A recent study has demonstrated that BD patients have impaired Na + K + -ATPase activity and increased lipid peroxidation in serum. In addition, the authors demonstrated that Li induced improvement in the enzyme activity, which was associated with a significant reduction in lipid peroxidation (Banerjee et al., 2012). It is interesting that a recent study from Valvassori group showed that BDNF ICV administration was unable to reverse the ouabain-induced hyperactivity and risk-taking behavior. Nevertheless, BDNF treatment increased BDNF levels, modulated the antioxidant enzymes, and protected the ouabain-induced oxidative damage in the brain of rats. These results suggest that BDNF alteration observed in BD patients may be associated with oxidative damage, both seen in this disorder. Together, these studies suggest that the present model fulfills adequate face, construct, and predictive validity as an animal model of mania; therefore, an important tool to investigating new intracellular systems that may be involved in BD.

3.3 Animal Model of Mania Induced by Sleep Deprivation

The paradoxal sleep deprivation (PSD) protocol is performed in a cage (38 × 31 × 17 cm). The mice are placed 5 per cage, each cage containing 12 platforms (3.5 cm

diameter). In the same box is placed a volume of water 1 in. deep, obligating the animals to stay on platforms. It is important that mice can freely move from one platform to another (Armani et al., 2012; Tufik et al., 2009). Thus, when animals entered the paradoxical phase of sleep, due to muscle atonia, they were awoken by falling into the water. Food and water should be available ad libitum. The period of 36 h of PSD induces the manic-like behaviors in mice (Armani et al., 2012). The mice in the control group should be exposed to the same conditions, except there was no water in the bottom of the box.

PSD in mice has been considered a good animal model of mania because it induces some aspects of a manic episode, such as hyperactivity, hypersexuality, and aggressive behavior (face validity). Indeed, PSD can induce mania in healthy subjects and exacerbates manic attacks or leads to a switch from depression to mania in bipolar patients. Interestingly, PSD has been considered as a rapid-acting antidepressant strategy, improving severe depressive symptoms in major depressive patients. In addition, circadian rhythms and the genes that make up the molecular clock have long been implicated in BD.

Regarding predictive validity, rats treated with lithium and haloperidol demonstrated a decreased latency to fall asleep relative to vehicle-treated animals, which is interpreted as a reduction in manic-like insomnia induced by SD. In addition, the hyperactivity induced by SD is also reversed by lithium and haloperidol. Thus, differently of the pharmacological models of mania, SD induces a range of behavioral alteration beyond simple hyperactivity and this model is responsive to mood-stabilizing drugs treatment, making it perhaps more effective in mimicking the human bipolar mania.

Some studies have suggested that manic states and sleep deprivation could contribute to the pathophysiology of BD through protein kinase C (PKC) signaling abnormalities. Indeed, rodents submitted to the sleep deprivation showed an increase of phosphorylation of MARCKS, a marker for PKC activity in vivo, in the frontal cortex (Szabo et al., 2009). A clinical study demonstrated an increase of PKC activity in platelets from bipolar patients during a manic episode, while lithium and valproate treatments attenuated the activity of this enzyme (Hahn et al., 2005). It is well described in the literature that lithium and valproate directly inhibited PKC, while promanic psychostimulants activate this enzyme, suggesting that PKC modulation plays a critical role in the treatment of mania. PKC plays an important role in regulating neuronal excitability, neurotransmitter release, gene expression, and plasticity, which are systems that modulate mood. Indeed, PKC overactivity has been associated with hyperactivity, risk-taking behavior, and excessive hedonic drive, all of which are symptoms of mania. Together, these studies indicate that animal model of mania induced by SD may have construct validity in the neurobiological alterations that may induce manic-like behaviors.

3.4 How Can Manic-Like Behaviors be Evaluated in Laboratory Animals?

3.4.1 Open-Field Test

The open-field test is used to provide a qualitative and quantitative measurement of exploratory and locomotor activity in rodents. The apparatus consists of an arena surrounded by high walls, to prevent escape, and the floor of the open field is divided into squares. In the test session, the number of square crossings, rearing, and time spent moving are used to assess the activity of the rodent. Automatic open-field apparatuses, which have software-linked infrared beams or video cameras to make the process easier and more accurate, are currently available. Manic-like behaviors, such as hyperactivity, risk-taking behavior, and/or increased stereotypy is easily measured in rats or mice using the open-field test (Fig. 38.4).

Hyperactivity is evaluated in the open-field apparatus through crossings and rearings behaviors. Crossings refer to the total number of square crossings during the test period, used to provide measurement of locomotor activity of the animals. Rearings are the total number of erect postures, adopted by the rodent with the intention of exploring, during the test period. Risk-taking behavior is evaluated through the measurement of total number of visits to the center of open-field. Increased exploration in the center of the open-field by the rodents is
FIGURE 38.4 **Open-field test.** Representation of (A) crossing, (B) risk behavior, (C) rearing, (D) grooming, and (E) sniffing parameters.

interpreted as a tendency for novelty-seeking and risk-taking behavior. Increased novelty seeking/risk taking has been associated with predisposition to rewarding and addictive behaviors

Stereotypy refers to repetitive behaviors in animals, which occur mainly in animals with brain alterations. It can be evaluated by grooming and sniffing behaviors. Grooming refers to the measurement of the total time of grooming behavior during the test period and sniffing is the total time of sniffing behavior during the test period. The stereotypy is a behavioral pattern in which various motor activities are characterized by their repetitiveness and intensity, generally decreasing the locomotion. In other words, the overlap of the two behaviors may lead to false negative results. For example, low dose of AMPH induces increased number of crossings and rearing in rats, while higher doses of this drug induce stereotypy. Therefore, it would be important to assess hyperactivity and stereotypy in the animal models of mania.

3.4.2 Aggressive Behavior

In BD some symptoms, such as violent aggression, anger, and irritability contribute considerably to the diagnostic of this disorder. The aggressive behavior in rodents is evaluated by the resident-intruder test. In this paradigm, the rodents were placed individually in an observation cage for 30 min to habituation. The test is conducted by introducing a male intruder, weighing at least 10 g less than the resident, in this cage. During the test, the latency and duration of social interaction (nose–nose interactions) is measured, as well as the latency to attack, the number of attacks, and the duration of crawl over behavior. Each intruder male should be used only once and then returned to its cage, and the resident should make part of the experimental groups.

3.4.3 Sexual Behavior

It is well described in the literature that the sexual behavior increased in adults with BD during hypomanic or manic episodes. In laboratory rodents it can be evaluated because these animals belong to the internally fertilizing species that require sexual behavior for reproduction. The evaluation protocol of sexual behavior in rodents is given as follows:

Before sexual behavior test, the rats acquired sexual experience through training. The training is important because sexually inexperienced male rats can display low performance. In the test period, a male rat is introduced into the arena 5 min before a female rat. Sexual receptivity in the female rats is established by subcutaneous administration of estradiol benzoate and progesterone before testing sexual behavior. During test of sexual behavior, the following variables are recorded: time to first mount; intromission and ejaculation latencies; total numbers of mounts (i.e., mounts with pelvic thrusting); intromissions (mounts with pelvic thrusting and penile insertion); and ejaculations.

In rodents, sexual behavior can be evaluated indirectly by penile erection and ejaculation. Penile erection can be counted when the rat stood on its hind limbs, bent its body forward, bent its head down to reach the genital area, held and licked its penis in full erection, and displayed hip movements. The erect penis is always visible. In this paradigm ejaculation is scored by the number of ejaculatory plugs. The frequency of penile erection and ejaculation (total number of genital reflexes divided by the number of rats) and latency (time elapsed between the injection to the first genital reflex) is assessed for 60 min.

4 CONCLUSIONS

This chapter has described multiple animal models of MD and BD, and how these models can help our understanding about the pathophysiology of these psychiatric disorders. It is a fact that no animal model developed to date can fully mimic the "corresponding" human psychiatric disorder. However, the available animal models of BD and MD are able to reproduce a large number of symptoms which resemble the human disorder. Despite all limitations, animal models are an important tool for investigation of the neurobiological mechanisms underlying psychiatric disorders, and for preclinical screening of mood-stabilizing and antidepressant drugs.

Pigs as Model Species to Investigate Effects of Early Life Events on Later Behavioral and Neurological Functions

Rebecca E. Nordquist, Ellen Meijer,
Franz J. van der Staay, Saskia S. Arndt

Utrecht University, Utrecht, The Netherlands

1 INTRODUCTION

Animal models are used to study causes of disease, search for and test potential treatments, and to study fundamental processes. They are often used to study human disease, but animal models can also be used in veterinary or animal sciences, in which an animal can serve as a model for another species, or indeed for its own species. The use of large animal models is discussed in depth in Chapter 3 of this volume.

The importance of early (or even prenatal) life on later functioning in an organism has long been recognized. In humans, early life experience is often seen as influencing predisposition to develop a vast array of physical and mental diseases (Roseboom et al., 2006), including diabetes (Beyerlein et al., 2016), cardiovascular diseases (Barker and Martyn, 1992; Elford et al., 1992), schizophrenia (Matheson et al., 2013), and cognitive deficits (Rooij et al., 2010). Clearly, human studies are based on correlations, not on studies in which early life is manipulated experimentally (which would be unethical). This is an area of research where animal models can play an important role in aiding understanding of underlying mechanisms of effects of conditions during early life, and potential treatment of diseases and disorders resulting from maladaptive early life experiences.

It is increasingly recognized that pigs bear strong resemblance to humans perinatally and during early life, with respect to brain development, physiology, diet, and gastrointestinal function (Gieling et al., 2011a,b,c). This is in strong contrast to rodents, which constitute the most common animal model species at present, but which are vastly different from young humans in terms of development around birth (Gieling et al., 2011c). This implies that young pigs could be useful as models for young humans, and indeed, there are piglet animal models in use for neonatal processes including traumatic injury, neonatal nutrition, and effects of low birth weight (Gieling et al., 2011c).

In farming, management practices in early life can affect the ability of an animal to adapt to its circumstances later in life, and thus its welfare state (Ohl and van der Staay, 2012). Pigs are kept on farms, in some cases for years, as is the case for breeding sows and boars. Fattening pigs are kept until slaughter weight, usually at around 8–12 months of age. This is well past puberty, and in that sense these animals are young adults. Examining effects of management practices during early life on pig development, can give us information about the welfare of these animals and potential compromises to their welfare. In this case, the experimental pig can serve as a model for its own species on farms.

A number of tests have been developed to study the behavior and neurological state of pigs. In this chapter, these tests will be discussed, particularly with respect to their suitability for testing young animals. The potential implications of testing for pig welfare, and particularly the practical aspects herein, are reflected upon in the final section of this chapter.

2 OPERANT TASKS FOR TESTING COGNITIVE FUNCTIONING

In operant tasks, a subject is required to provide a response to elicit a specific outcome. Operant tasks can be very simple, as widely used in feeding stations in group housed pigs; in this type of housing, pigs learn to stand in front of a feeder, which reads a chip in its ear and then provides the pig's daily ration of food. Complex tasks are also possible, which can measure various forms of memory, behavioral flexibility, or internal state of an animal. Several operant tasks which have been developed and used in pigs are described further in the chapter.

2.1 The Holeboard Task

Spatial learning and memory tasks can be highly useful and suitable for testing pigs at both young and older ages. In these types of tasks, animals must learn to search for rewards within either an alley, with fixed starting positions and a single correct route to find all rewards, or within a "free choice" maze (Crannell, 1942; Lachman and Brown, 1957; van der Staay and Bouger, 2005). In the latter, animals are allowed to explore arenas in which rewards can be found in various places. Animals are free to determine in which order they search for rewards, and whether to return to a previously visited location or not. The most efficient strategy is to only visit locations containing rewards, and to visit the rewarded locations only once. The fact that pigs are mobile essentially from birth facilitates the use of spatial learning tasks in piglets, though it is important that the animals have the maturity to be able to learn the task at the age tested. For the full Pig Holeboard, this appears (in our hands) to be from about 6 weeks of age (Antonides et al., 2015b and informal observations).

In spatial memory tasks, an animal must remember where it has already been in order to avoid unrewarded revisits. This list of locations already visited is temporarily held in working memory (Olton and Samuelson, 1976). The information held in working memory is relevant only within a specific trial, as it reflects where an animal has been and already either consumed the rewards, or realized that a location is not baited. Reference memory (Olton and Samuelson, 1976) holds trial-independent information about, for example, the locations where the food reward can be found. One advantage of free choice mazes is that working memory and reference memory can be assessed simultaneously within the same test.

In the pig holeboard test, modeled after the rodent holeboard task, a fixed number of locations within a larger field is baited, for instance 4 locations of a possible 16 (so 1 in 4). For rodents, this test apparatus usually consists of literally a board with holes, some of which contain bait, and some of which do not. For pigs, various constructions suited to the pigs' size and strength have been used, including buckets affixed to the floor (Arts et al., 2009; Bolhuis et al., 2013; Clouard et al., 2016; Haagensen et al., 2013). In our lab, we use a setup in which plastic dog dishes are affixed to a slatted floor, covered by plastic balls. These plastic balls can be nosed
FIGURE 39.1   Holeboard apparatus to assess spatial discrimination learning in pigs (A), and an apparatus for assessing judgment bias and decision-making behavior in pigs (B). (A) In the holeboard task, rewards are hidden underneath hard plastic balls that the animal can raise using its snout. (B) In the gambling task and decision-making apparatus for pigs, the experimental animal enters the testing arena via an antechamber. Each goal-box contains a large hard-plastic ball which can be raised as operant response. Reward (usually M&M's) can be found in a central food trough. The accessibility of the bait in the trough is controlled by the experimenter operating a lid that covers the food trough. *Source: Modified from Antonides et al. (2015a), according to Open Access terms and used with permission from Murphy, E., Kraak, L., van den Broek, J, Nordquist, R.E., van der Staay, F.J., 2015. Decision-making under risk and ambiguity in low-birth-weight pigs. Anim. Cogn. 18(2), 561–572.*

aside to uncover the dishes, which may contain rewards. In our setup, scoring is automated using magnets and sensors installed in the balls and food dishes (Figs. 39.1 and 39.2), which are connected to a computer via an interface. We had specialized software compiled to register time stamps of visits to each bowl, and to calculate various measures, including, among others, working memory, reference memory, latency time to first visits, and order of visits.

The pig holeboard has been shown to produce highly reproducible results when comparing between studies. Independent experiments have used the pig holeboard to compare holeboard performance of low birth weight and normal birth weight animals (Antonides et al., 2015a; Gieling et al., 2012b), animals from large or small litters (Fijn et al., 2016), effects of pharmacological intervention with the M1R blocker biperidin (Gieling et al., 2013), effects of enriched housing (Bolhuis et al., 2013; Grimberg-Henrici et al., 2016), effects of overnight social isolation (van der Staay et al., 2016), and effects of iron deficiency during early life (Antonides et al., 2015b) show highly similar performance between control groups, indicating replicability of the test between studies. The test also shows sensitivity for deficits in performance (Antonides et al., 2015b; Gieling et al., 2013), as well as enhanced performance (Antonides et al., 2015a; Grimberg-Henrici et al., 2016), although the latter will reach ceiling-level

FIGURE 39.2   **Details of the "holes" used in both the pig holeboard setup and the active choice setup used in judgement bias and decision making.** Plastic balls are fitted with magnets and hung from a stainless steel wire in between four stainless steel rods. The balls lay in plastic dishes which contain sensors that can detect movement of the magnet. When the animal displaces the ball, either to gain access to a reward or as an operant response, the sensor detects movement of the magnet, and sends a pulse through the interface to a computer running registration software. *Source: Modified from Antonides et al. (2015a), according to Open Access terms.*

performance relatively quickly as normal animals reach near-perfect performance, particularly on working memory.

Behavioral tests can give valuable information, provided that the tests used are valid and reliable. Validity can be defined as the degree to which a test measures what it is supposed to measure. Reliability on the other hand is defined as the repeatability of scores, obtained from unchanged patients (humans or animals), under diverse scoring conditions (Mokkink et al., 2009). Four different types of reliability are defined: tests-retest, internal consistency, interrater and intrarater reliability. In simpler terms, a test that is valid, gives "right" results while one that is reliable, gives "good" results (Martin and Bateson, 2007). Behavioral tests for pigs are not frequently tested for reliability, which is a major hindrance to the development of the pig as a model species for cognition testing.

We have tested intrarater and interrater reliability in the pig holeboard test, calculating intrarater reliability by comparing data obtained from live video scoring against data obtained from scoring the video recordings of the same trials. We also tested interrater reliability by comparing the results of working and reference memory of the computer program used to register hole visits, the results of working and reference memory as visually scored by the observer. Results from this study showed high interrater reliability when comparing manual scoring to scoring by the specialized software, which points to high reliability of the test setup. The study also showed, however, that for manual observation, experience may play an important role in interrater reliability; interrater reliability was low, possibly due to a learning curve in the observer (Meléndez Suárez, 2014). See Box 39.1 for a detailed description of the methods and results of this reliability study.

BOX 39.1

METHODS AND RESULTS OF A VALIDATION STUDY OF THE PIG HOLEBOARD TASK

Originally reported in Meléndez Suárez (2014).

Procedure: Twenty average weight piglets [(Terra × Finnish landrace) × Duroc], 10 males, and 10 females, from the farm at Utrecht University were selected at 3 weeks of age from 10 different litters. Males and females were housed separately in enriched pens with straw and a ball. The holeboard training started when the piglets were 41 days old. The animals were habituated to the experimenters for a period of 2 weeks, during which they were fed M&M's to get them used to the bait. Each pig was assigned randomly to one of the four configurations, with different locations of the baited bowls. Males and females were divided into two subgroups, with a total of four groups consisting of five pigs each. The four groups were tested randomly using the ABBA and BAAB testing orders on alternate days, where letter A represented the female group and letter B the males. The pigs within the subgroups were tested in a random order as they presented themselves to the door. Each pig was tested twice during a day, one trial right after the other (massed trials).

Intrarater Reliability: On day 18 of training, a veterinarian, with no previous experience at scoring animal behavior, live scored the visits to the bowls for 20 pigs, two trials each. Live scoring was done using a monitor that was connected to a camera located above the Holeboard. Trials were recorded for a second evaluation. The visits to the bowls were scored using a computer with JWatcher Version 1.0 installed. One week after the live scoring, the same

observer scored the video recording, in order to compare both files and obtain the intrarater reliability. JWatcher Version 1.0 was used to calculate the percent of agreement and the kappa coefficient.

Interrater Reliability: Based on the results obtained from the intrarater reliability the working and reference memory of the 40 trials were calculated using the formulas:

$$\text{WM}: \frac{\textit{Number of rewarded visits}}{\textit{Number of visits and revisits to the rewarded set of holes}}$$

$$\text{RM}: \frac{\textit{Number of visits and revisits to the rewarded set of holes}}{\textit{Number of visits and revisits to all holes}}$$

The results obtained for working and reference memory from the computer were compared to those obtained by the observer.

Statistical Analysis: For the intrarater reliability kappa statistics were used to obtain the percentage of agreement and the kappa coefficient.

For the interrater reliability a Wilcoxon *t*-test and a Pearson correlation test were used to see the association between the results from the computer program against the observer, for reference and working memory of the two scoring procedures (automatic vs. observer). All statistical analyses were carried out using a SPSS for Windows (version 16.0) computer program (SPSS Inc., IL, USA).

Results: The kappa coefficient values obtained from the 40 trials are shown in Table 39.1. The highest kappa coefficient score has a value of 1 and represents that the two scoring procedures that are compared have the same sequence of key codes. In this table, we can see that there are several scores with a value of 1, but there are also many low values. The average kappa coefficient for the 40 trials is 0.8.

Table 39.2 contains Pearson correlations from the two data sets and the *P*-values of the correlations. The data sets are highly correlated.

TABLE 39.1   Intrarater Reliability Results (Kappa Coefficient)

Pig	A	B	C	D	E	F	G	H	I	J	K	L	M	N	O	P	Q	R	S	T
RT1	0.73	0.84	1	1	0.49	1	1	1	1	0.25	1	0.32	1	1	1	0.47	1	0.64	0.75	0.75
RT2	0.08	1	1	1	0.26	0.68	1	1	1	1	1	1	1	1	1	1	1	1	1	0.18

The animals were identified with letters from A to T. The reliability of trail 1 and trail 2 were calculated (RT).

2.2 Judgement Bias

Judgement bias tests (JBTs) measure behavioral responses to ambiguous stimuli after animals have been trained to discriminate between a stimulus (or set of stimuli) predicting a positive consequence (S⁺; reward) and another stimulus (or set of stimuli) predicting a negative consequence (S⁻; punishment or lower-value reward). The "quality" of the ambiguous stimulus lies somewhere between S⁺ and S⁻ (Fig. 39.3). Go/Go and Go/No-go tasks form the two different classes of JBTs in which Go/No-go entails the suppression of the response at S⁻, whereas Go/Go entails that the animal responds to both stimuli types with an active response (Murphy et al., 2013a). JBTs provide a cognitive measure of optimism and/or pessimism since a negative emotional state is expected to cause a negative (pessimistic) judgement of an ambiguous stimulus, whereas a positive emotional state is expected to cause a positive (optimistic) judgement of the same ambiguous stimulus (Boleij et al., 2012; Roelofs et al., 2016).

The pig is one of the species in which JBTs became a frequently used tool to assess emotional states (Brajon et al., 2015; Roelofs et al., in press; Roelofs et al., 2016). Fig. 39.4 shows the JBT used, for example, by Murphy et al. (2013b) for pigs. Since it is known that early life experiences (e.g., stress) can have consequences for later emotional functioning (Pechtel and Pizzagalli, 2011), JBTs might be a useful tool to investigate, especially, the effects of early life experiences. Murphy et al. (2015) succeeded in showing that effects of low birth weight in piglets can be detected in a JBT. Table 39.3 summarizes points to consider when testing pigs in a JBT.

2.3 The Pig Gambling Task—A Variant of the Iowa Gambling Task

Strategies in animal decision-making may relate to differences in early life experiences as suggested by Potenza (2009) for environmental factors in general, by Andrews et al. (2015) for rodents and birds, or by Murphy et al. (2015) for birth weight in pigs. Negative (early life) experiences can induce negative mood states later in life (Mendl et al., 2010), which can consequently affect decision-making when outcomes are uncertain (Mendl et al., 2009). Studying decision-making strategies might thus allow drawing conclusions on emotional states. Decisions have to be made when conditions are uncertain (Kacelnik and Bateson, 1997) and might involve a risk (with a known probability of each outcome) or ambiguity (with an unknown outcome) (Bechara, 2005; Krain et al., 2006).

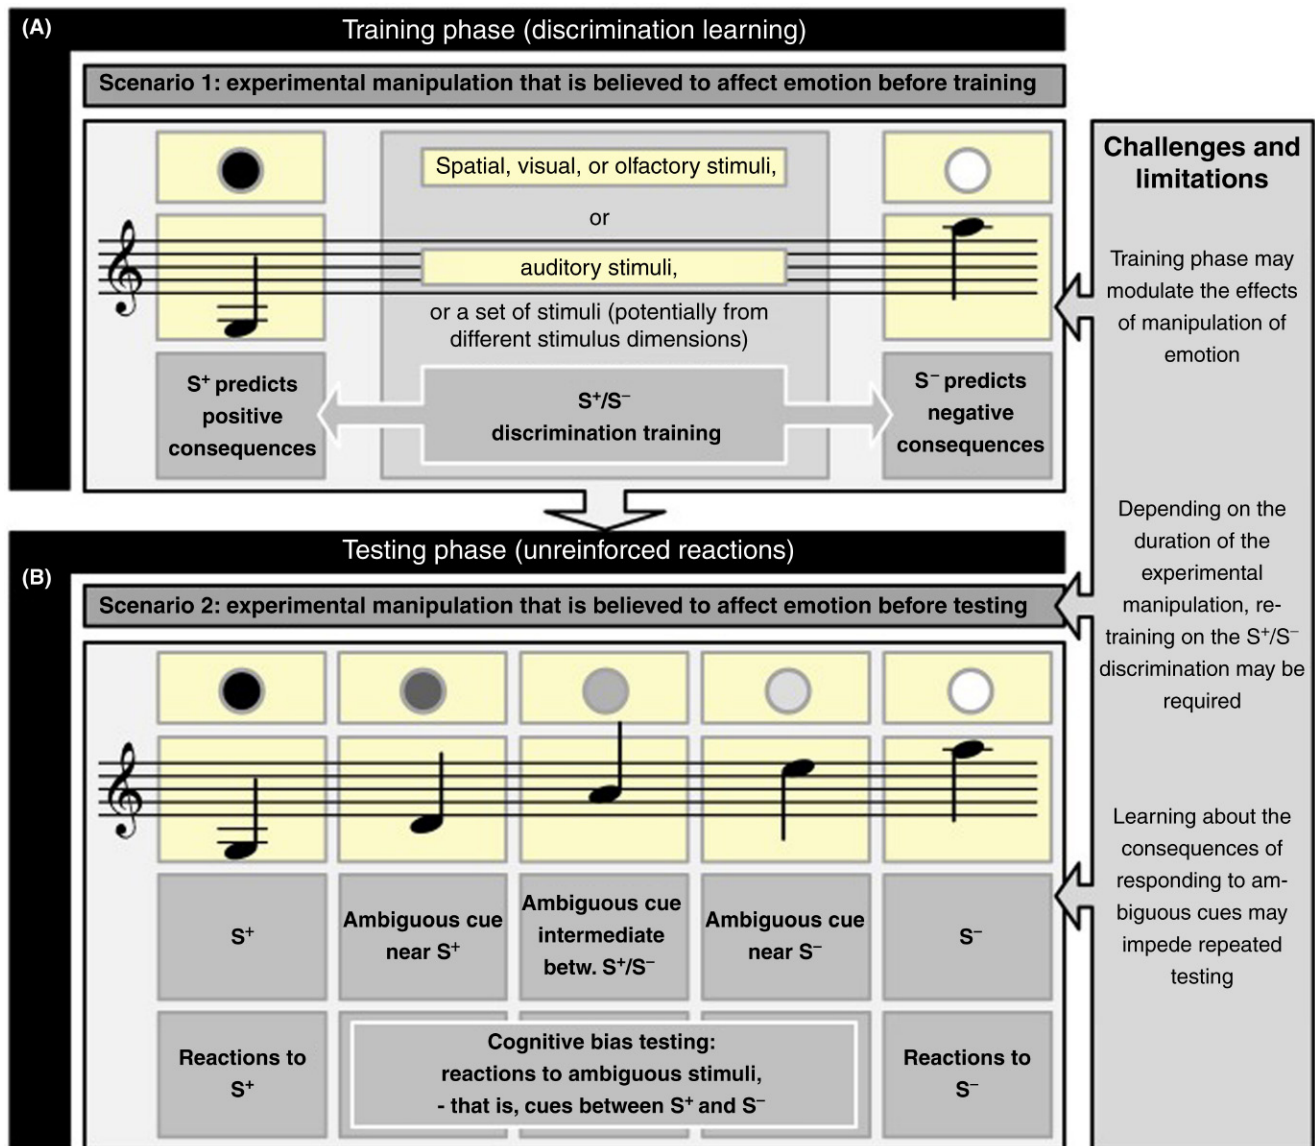
A common test to study decision making is the Iowa Gambling Task (IGT; Bechara et al., 1994). Animals have


FIGURE 39.3   **Schematic representation of judgment bias training and testing using visual, olfactory, spatial, or auditory cues, or a combination of cues from different stimulus dimensions.** The experimental manipulation that is believed to affect emotion precedes the training phase (A; Scenario 1) or the testing phase (B; Scenario 2). Refreshment of the discrimination acquired during the training phase may be necessary, if the experimental manipulation preceding phase (B) lasts for a longer time period. An example of scenario 1 is studying the effects of growing up in different housing systems, whereas scenario 2 may be applied in a study assessing the effects of shorter lasting experimental manipulations, such as confinement, on emotion. Phase (B) may be repeated multiple times (Douglas et al., 2012) to test the effects of different experimental manipulations in the same animal. Specific challenges and limitations may be connected to the different phases. See Fig. 39.3 for an example of the specific contingencies connected with responding to S⁺, S⁻, and ambiguous cues. *Source: Reprinted from Roelofs, S., Boleij, H., Nordquist, R.E., van der Staay, F.J., 2016. Making decisions under ambiguity: judgment bias tasks for assessing emotional state in animals. Front. Behav. Neurosci. 10, 119, according to Open Access terms.*

to choose between two options: a "safe" or "risky" one. Risk is manipulated by varying the amount of reward, the probability of reward occurrence, or time delay until rewards are delivered (Murphy et al., 2015). Risk-prone individuals have been found to prefer risky options, while risk-averse individuals prefer safe options (Mazur, 1988). Anxiety led to increased risk-prone behavior in humans, as well as in rodents (Miu et al., 2008; de

Visser et al., 2011). Positive mood on the other hand, led to earlier choices for safe options (de Vries et al., 2008).

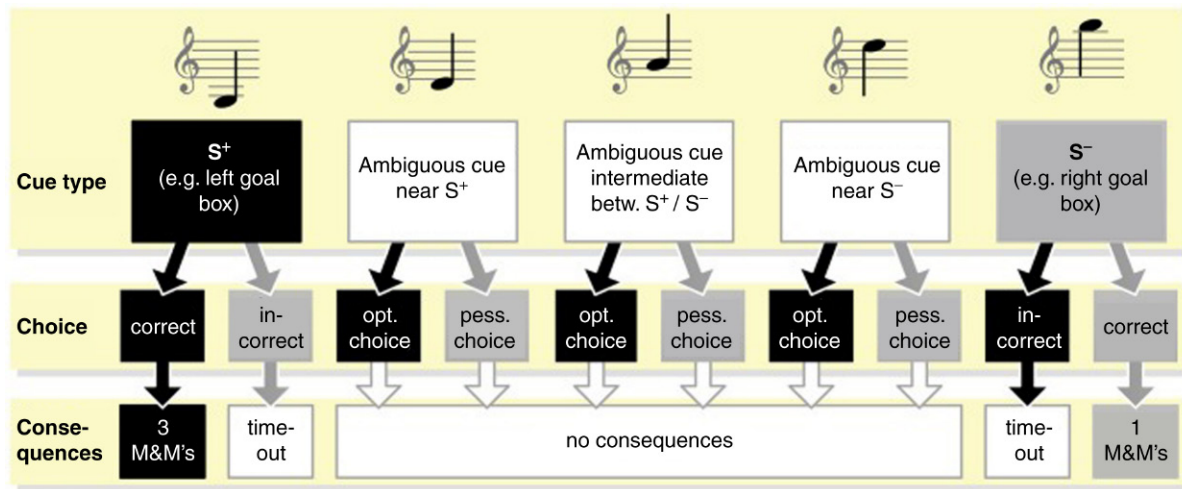
Murphy et al. (2015) developed the Pig Gambling Task (PGT; see Figs. 39.1 and 39.5), inspired by the IGT. This two-choice probabilistic decision-making task allows studying decision-making under risk, in which the safe, or advantageous option yields greater overall gain. In the setup used by Murphy and coworkers an


FIGURE 39.4 **Example of the exact contingencies connected with responding to the different cues presented during the testing phase (Fig. 39.1B) in a judgment bias tasks (JBT; programmed consequences of choices as used in Murphy et al. (2013b).** *Source: Reprinted from Roelofs, S., Boleij, H., Nordquist, R.E., van der Staay, F.J., 2016. Making decisions under ambiguity: judgment bias tasks for assessing emotional state in animals. TABLE 39.3 Points to Take Into Consideration When Testing Pigs in a Judgement Bias Task (JBT)

Effects of training/testing on emotional state	Procedural pitfalls
• Training within JBTs might be seen as cognitive enrichment, *improving the welfare* of the study subjects and affecting its emotional state (Carlstead and Sheperdson, 2000; Guldimann et al., 2015; Pomerantz and Terkel, 2009; Puppe et al., 2007; Zebunke et al., 2011).	• Pigs need *extensive habituation* before training and testing of individual animals can take place (Murphy et al., 2013b, 2015). • Initially ambiguous stimuli might *lose their ambiguity* within repeated testing (Roelofs et al., 2016). • Animals might *fail in reaching a required criterion* during training (Brajon et al., 2015).

FIGURE 39.5 **When tested for decision-making strategies, for example, in the PGT, pigs can decide on an advantageous or disadvantageous side.** Rewards used here were chocolate M&M's (Mars Nederland b.v., Veghel, The Netherlands). To illustrate, 8 rewarded trials per series of 10 trials (each yielding 2 M&M's as reward) (advantageous choice) are presented against 3 rewarded trials per series of 10 trials (each yielding 4 M&M's as reward) (disadvantageous choice). The number of rewards used might be varied. Advantageous choices yield, in the long run the largest number of rewards (here 16). *Source: Reprinted from van der Staay, F.J., Schoonderwoerd, A.J., Stadhouders, B., Nordquist, R.E., 2015. Overnight social isolation in pigs decreases salivary cortisol but does not impair spatial learning and memory or performance in a decision-making task. Front. Vet. Sci. 2, 81, according to Open Access terms.*

advantageous option was characterized by small but frequent rewards, whereas a disadvantageous option was characterized by large but infrequent rewards. The advantageous option thus led to greater overall gain in the long run (see also Fig. 39.5). Table 39.4 summarizes some of the considerations when testing pigs in the PGT

2.4 Discrimination Learning

Discrimination learning can be used as a part of training for more difficult tasks, including the judgement bias tasks and Iowa gambling task described earlier in the chapter. It can, however, also be used as a task in and of itself, to determine the ability of animals to discriminate between two stimuli and the capacity of animals to learn and perform tasks based on discrimination in different modalities.

TABLE 39.4 Points to Take Into Consideration When Testing Pigs in a Pig Gambling Task (PGT)

Effects or training/testing on emotional state	Procedural pitfalls
• Training within JBTs might be seen as cognitive enrichment, *improving the welfare* of the study subjects and affecting its emotional state (Carlstead and Sheperdson, 2000; Guldimann et al., 2015; Pomerantz and Terkel, 2009; Puppe et al., 2007; Zebunke et al., 2011)	• Pigs need extensive habituation before training and testing of individual animals can take place (Murphy et al., 2013b, 2015). • Means by which risks are manipulated can influence preferences (Kacelnik and Bateson, 1997). • It is unknown whether pigs can assess maximum number of rewards or minimum number of punishment. They might decide on the option that provides reward in the majority of trials (van der Staay et al., 2016) . • It is unknown how many trials are needed to train pigs to consistently make advantageous choices (van der Staay et al., 2016).

Visual discrimination is frequently used in discrimination learning in various species. This can entail the use of lights, including discrimination between light color, intensity, or frequency of flashing lights. Visual stimuli can also include the use of pictures or patterns. Pigs have visual acuity which is inferior to humans, sheep, and cattle (Entsu et al., 1992; Tanaka et al., 1995; Zonderland et al., 2008) but which should, in theory, be quite sufficient for learning visual discriminations. In practice, however, discrimination based on visual stimuli in pigs has proven quite difficult, requiring lengthy training to show operant responses to distinct 2D shapes (Gieling et al., 2012a; Graf, 1976; Haagensen et al., 2013). Discrimination of conspecifics based on photographs, which has been demonstrated in domestic sheep (Ferreira et al., 2004) and cows (Coulon et al., 2009) did not seem to be possible in pigs (Gieling et al., 2012a).

Discrimination tasks based on auditory stimuli have been more successful, with pigs showing distinct operant responses to auditory stimuli of different frequencies (Murphy et al., 2013a). Other modalities, such as odor cues or tactile cues, have yet to be tested in pigs. Given their strong olfactory and tactile abilities (the snout is particularly sensitive), this may be an interesting avenue to explore to improve discrimination learning.

2.5 Practical Aspects of Training in Operant Tasks

Operant tasks, such as the pig holeboard, judgement bias, or gambling task, are work-intensive in terms of extensive time needed to habituate the animals to being alone in the setup, and because the animals need to be moved from the home pen to a test setup each time testing occurs. The latter can be partly offset by providing a waiting area where animals can stay for up to several hours between trials (thus with at the very least access to water). Training, while relatively fast in terms of learning tasks, still takes several weeks of daily training. On the other hand, the pig holeboard provides a number of measures of spatial memory and motivation within a single test, which can save time relative to conducting multiple sequential behavioral tests.

Training of very young animals in an operant conditioning task needs to be carried out keeping their cognitive, emotional, and physical abilities in mind. One manuscript reporting an attempt to train very young piglets (starting at 17 days of age) in a visual discrimination task reports that attempts at visual discrimination were suspended, as the first response of inserting the snout into a hole to be rewarded with milk was already quite difficult for unimpaired piglets (Andersen et al., 2016). In our hands, we found that piglets before the age of 4–6 weeks had difficulty habituating to being alone in the holeboard setup, and had difficulty learning

the operant response of lifting a ball to gain a reward. This may reflect too high demands of the emotional and cognitive maturity of the animal before these ages to successfully perform an operant response.

For any task in pigs that involves intensive training, there will be a number of practical considerations having to do with the size of the animals. One of these is habituation of the animals to allow movement of the animals from a home pen to a test setup, and testing with as little interference from stress as possible. Even juvenile pigs are quite strong, and within a few weeks after birth it is very difficult to fixate or restrain piglets. If the animals can be fixated, this certainly will lead to stress in the piglets, with all of the welfare implications and potential for confounding the experimental result that this entails. To avoid this, extensive habituation to human contact, handling, and the test setup are highly desired before embarking on cognitive training. For holeboard testing, this entails daily habituation for 2–4 weeks (Fijn et al., 2016; Gieling et al., 2014a). The time involved in habituation of animals will, of necessity, increase the age at which animals can be tested. This may be a hindrance to the use of the holeboard test for testing very young animals. For testing of very young (preweaning) animals, one might consider the use of test setups that can be used either in the presence of or very near the sow and/or siblings. The 8-arm radial maze and the T-maze have been successfully used in very young animals (Dilger and Johnson, 2010; Elmore et al., 2012; Naim et al., 2010). If space allows these apparatus could be placed in the same room as the sow and littermates, allowing auditory and olfactory contact, which may reduce habituation time needed.

For any operant task, the type of reinforcer used will need consideration. Given that the animals need to be repeatedly trained and that the size of the animals requires that they voluntarily enter a test setup, it is advisable to work with a reward rather than an aversive stimulus. We have successfully used M&M's chocolate candies, which are easy to dose and highly palatable to pigs. For very young animals, M&M's have proven to be difficult to chew. In that case, we used small marshmallows. Other groups have used chocolate-covered raisins (Arts et al., 2009; Bolhuis et al., 2013), fruit, and for preweaning animals, milk replacers (Dilger and Johnson, 2010; Elmore et al., 2012) or applesauce (Bertholle et al., 2016; Meijer et al., 2014a).

Automation is also an important consideration in measuring any animal behavior. There are a few obvious advantages to at least some level of automation. First, automatic detection of responses can lead to much more detailed and fine-grained data, particularly regarding time (latency times, total time on task, etc.). This can be nearly impossible to score by hand for fast or repeated behaviors, or when more than one behavior is being scored, but can be relatively easily built into

software. Second, automation can vastly reduce the effects of the experimenter, allowing multiple experimenters to work on a single test and produce similar results. As the experimenter will always have contact with the animals, even if just to move them from the home pen to the experimental setup, there will always be some effects of the experimenter. Different experimenters will be more or less gentle or patient with the animals, and some combinations of personalities of animals and experimenters may provide for either positive or negative interactions, that may differ for a single experimenter with individual animals. Moreover, automatic registration of behavior will reduce the observer bias (Bello et al., 2014).

There are some challenges to automation. For pigs specifically, experimental setups need to be built extremely robustly. Automation involves sensors and wires, which certainly can be built to withstand pigs, but this is (1) specialized work that is frequently not included in standard setups built for automation of behavioral measures, (2) can become quite costly, and (3) needs to be extremely well thought through if flexibility in the setup is required, that is, for disassembling and reassembling a setup if a space is to be used for multiple purposes. Stable builders who are experienced in building pig dwellings can be instrumental in building robust, automated setups.

An important aspect for implementing automation, is that one must know exactly what one wishes to measure in order to operationalize the measures in sensors and software. This can be an issue in pigs, where there is much less data on behavioral responses in tasks or to stimuli than, for instance, the vast amount of data available for rodents. It is highly advisable when introducing a new task, to first observe the animals closely in the task to determine which behaviors and which parameters should be scored. Once the automated setup has been built, the data should be validated (usually by comparing with hand-scored data, see Box 39.1 on validation of the pig holeboard). Raw data should be carefully examined after each experiment, to ensure that no malfunctions are taking place (i.e., dirty or old sensors, loose wires, software bugs, and so on) that can influence results. Some behaviors or parameters will not be easy or possible to detect automatically,as discussed further in the section gait scoring, for example, determining which foot produced a certain footfall. Advances in automation techniques, particularly in sensor development, make automation of more and more parameters possible.

3 NONOPERANT BEHAVIORAL TESTS

Behavior can also be tested in tasks which do not require extensive training, as operant tasks generally do. This may provide an advantage when one wishes to test very young animals; clearly one cannot test a 2-week-old piglet in a task that requires 4 weeks of training. Operant tasks can often give detailed information on cognitive functioning, but for specific questions on cognition or neurological function, nonoperant behavioral tests may provide more useful data. A number of tasks have been developed and used in pigs.

3.1 Measuring Motivation

Motivation is the process within the brain controlling which behaviors and physiological changes occur and when (Fraser et al., 1990). It is a reflection of the inner state of an animal. The inputs for this process may arise both from internal and external sources. For example, the decision to start foraging for food may be based on both internal cues, such as blood glucose level or gut distension and external cues, such as the presence of predators. Changes in motivational state can give rise to changes in appetitive behavior (i.e., searching for stimuli) or consummatory behavior.

Measuring the motivation of an animal to perform a certain behavior may provide information on the relative importance of that behavior for the animal. Captive animals, such as farm animals, may be restricted from performing some behavior. For example, nest-building in prepartum sows is impossible in many of the barren farrowing pens that are used in modern pig farming. Knowledge on the strength of motivation to perform behavior may help to understand the welfare implications of husbandry systems that restrict that behavior.

The motivation of pigs can be assessed in several ways. Perhaps the simplest method is to assess how often or how long an animal performs a behavior. For example, pigs that are food-restricted spend more time performing foraging behavior than nonrestricted animals (Day et al., 1995). Runways or obstacle courses have been used to assess the effect of feed composition on feeding motivation (Souza da Silva et al., 2012) and the difference between low-birthweight and normal-birthweight pigs on feeding motivation (van Eck et al., 2016). In the latter experiment, novel objects were added as obstacles to the runway in order to increase the difficulty of the task.

In operant conditioning, the animal is taught to perform a certain task in order to obtain access to a resource that allows them to perform a particular behavior. The "cost" of the resource can be manipulated by increasing the difficulty of the task (e.g., by increasing the amount of weight an animal needs to displace) or by increasing the number of times an animal needs to perform the task in order to get rewarded (e.g., increasing the number of times a lever needs to be pressed). Operant conditioning tasks have been used in pigs to assess motivation for, for example, food (Lawrence and Illius, 1989; Souza

da Silva et al., 2012; van Eck et al., 2016), illumination (Baldwin and Start, 1985), straw (Pedersen et al., 2002), and heat (Baldwin and Ingram, 1967) and to get away from ammonia or draught (Baldwin and Ingram, 1967; Jones et al., 1998). Operant responses in a food-motivation task using nosewheel turning showed large interindividual variation (Souza da Silva et al., 2012), therefore within-subject designs should be considered when designing experiments using this task. Another parameter that may influence the performance in this test is social context: demand curves for food differ between pigs that are tested alone or together with another pig (Pedersen et al., 2002).

Other tasks may be used to assess motivation as well. The spatial holeboard task (see earlier for more information) includes parameters, such as trial duration and intervisit-interval (reflecting the speed of searching for bait) that can be used as measures for food motivation (Antonides et al., 2015b).

3.2 Mirror Use

The ability to use a mirror to guide movement or decision making has long been considered an indicator of complex cognitive ability. Instrumental use of mirrors (as opposed to the use of mirrors to show self-awareness) has been indicated in some types of primates (Anderson and Gallup, 2011; Heschl and Burkart, 2006; Menzel et al., 1985), dolphins, birds (Medina et al., 2011; Pepperberg et al., 1995), and elephants (Povinelli, 1989).

A paper by Broom et al. (2009) described a study in which pigs appeared to use a mirror to navigate an obstacle to gain access to food, indicating use of high cognitive functioning to solve a spatial problem. This would be an important finding, influencing our perception of pigs and their cognitive abilities. A later study failed to replicate the finding by Broom and coworkers (Gieling et al., 2014b). This indicates that mirror use is not universal in pigs, and may be at the periphery of their cognitive ability.

3.3 Open Field Test

The open field test, originally developed as a test for emotionality in rodents, has been used in pigs since the 1960s (Beilharz and Cox, 1967). It is generally performed in an unfamiliar square, rectangular, or circular arena. The pig is placed in the arena for a certain amount of time, usually between 4 and 10 min, and the behavior of the pig is recorded. Several categories of behaviors can be scored, such as locomotion and exploration (Andersen et al., 2000; Beattie et al., 1995; Donald et al., 2011; Fijn et al., 2016; Fraser, 1974; Gieling et al., 2014a; Meijer et al., 2015; van der Staay et al., 2009), location within

the open field (Andersen et al., 2000; Donald et al., 2011; Fijn et al., 2016), vocalizations (Beattie et al., 1995; Donald et al., 2011; Fijn et al., 2016; Fraser, 1974; Gieling et al., 2014a), elimination (Andersen et al., 2000; Fijn et al., 2016; Fraser, 1974; Gieling et al., 2014a), and escape attempts (Fijn et al., 2016; Meijer et al., 2015).

The open field test is often used as a test for anxiety, exploration, and locomotion. Since it is known from several animal studies, as well as from human studies that stressful experiences in early life can modulate adult behavior (Taylor, 2010), the open field test may be useful to study these early life effects on anxiety later in life. Moreover, in a recent study in pigs, open field test locomotor activity was used as part of behavioral profiling in order to explain differences in learning abilities (Brajon et al., 2016) and it may therefore be a helpful tool when designing experiments.

Although the open field test is often used as a test for anxiety, there are some considerations that need to be taken into account. In general, the open field test may cause anxiety to animals due to social isolation and due to fear of novel environments and open spaces. Social isolation has been linked to indicators for stress by several studies (Kanitz et al., 2009; Poletto et al., 2006; Ruis et al., 2001). However, unlike rodents which show a tendency to remain close to the walls in unfamiliar surroundings, no evidence for this "wall-hugging behavior" in pigs has been found. Treatment with anxiolytics, such as diazepam (Andersen et al., 2000) and azaperone (Donald et al., 2011; Prut and Belzung, 2003), did not result in an increased time spent in the center of the open field. Location within the open field may therefore not be an ethologically valid indicator of anxiety in pigs (Fijn et al., 2016; Murphy et al., 2014).

When designing experiments using open field tests, the behavioral responses that are scored and their interpretation should be carefully considered (Forkman et al., 2007; Murphy et al., 2014). Scoring of the behavioral parameters can either be performed directly while observing the pigs, or from video recordings, or using video-tracking devices (van der Staay et al., 2009). The advantage of using video recordings is that the arena can be divided into several areas without physically having to place lines on the floor of the pen, which may influence the locomotor behavior of the pig. In a study looking at several behavioral parameters scored by two observers and both directly or from video, interrater reliability was ≥0.73 and intrarater reliability was ≥0.78 (Fijn et al., 2016). Open field behavior is generally repeatable over time (Fraser, 1974; Jensen et al., 1995), although repeated exposure within a short period of time will decrease the novelty of the open field and may influence activity and vocalizations (Donald et al., 2011).

3.4 Clinical Examination of Central Nervous System Function

The clinical examination of the central nervous system in pigs has been extensively described in the setting of veterinary medicine, and is still the cornerstone in diagnosing neurologic disease in pigs (Radostits et al., 2007). In research settings, the clinical examination can also provide valuable insight into the functioning of the central nervous system. Some neurological conditions, presenting with one or several well-described symptoms, may be assessed by clinical examination alone. In other cases, the clinical examination may help to narrow down the possible localizations of the problem and may therefore help to limit the necessary ancillary techniques (such as imaging), saving both time and resources and limiting invasive and stressful procedures for the animal. The development of the central nervous system in young animals may be followed by using functional tests (Fox, 1964a,b; Muir, 2000), and may therefore be useful to study the effect of early life influences on development and functioning of the central nervous system later in life.

The clinical examination can be performed by any veterinarian, and with some training biomedical researchers, lab technicians, or students will be able to perform the clinical examination reliably as well. No specialized equipment is needed, and it is therefore an inexpensive technique. An additional advantage is that it is minimally invasive, and therefore may have minimal impact on the welfare of the experimental animals.

There are, however, also some drawbacks to using the results from the clinical examination as outcome parameters in experiments. Adult pigs are large and may be aggressive. This may limit the possibilities to perform some parts of the clinical examination, for example, tests that require the animal to lie down. Another drawback is that the clinical examination only provides functional information but no information on the underlying structural characteristics of the dysfunction.

3.5 Components of the Clinical Neurologic Examination

The components that are described further are for a large part derived from veterinary diagnostic protocols (Hajer et al., 2000). Not every component may be needed for each experiment, and some experiments may benefit from modified or additional tests. Table 39.5 provides an overview of common components of the neurologic examination, how to perform the test, and the expected response from the animal. It is important to perform the tests in an order that causes the least stress to the animal. Tests that require little or no fixation should be performed before more invasive tests and tests that require fixation.

3.6 Proprioception

Proprioception, the awareness of deep pressure and the position and movement of limbs, is mediated through receptors in muscles, tendons, and joints. They relay information to the spinal cord and brain via large Aα and Aβ myelinated fibers. Proprioceptive information is used to adapt body position and gait, and defects in the proprioceptive system may lead to ataxia. The lack of position sense in a limb may be demonstrated by placing the limb in an abnormal position. Unimpaired animals will correct this abnormal position directly. Commonly used tests are dorsal placement of the feet (Fig. 39.6A, Table 39.5) and crossing of limbs (Fig. 39.6B, Table 39.5).

3.7 Cranial Nerve Function

Many cranial nerve deficits can be identified by careful inspection of the head and neck. An abnormal position of the eye may be indicative of lesions to either the oculomotor nerve (divergent strabismus, often accompanied by a drooping eyelid and dilated pupil), trochlear nerve (rotated eyeball), or abducens nerve (converging strabismus). Abnormalities in the motor component of the trigeminal nerve may lead to a drooping lower jaw, facial nerve paralysis may present as a drooping ear, lip, and nose and an inability to close the eye. Atrophy of the neck muscles may be caused by accessory nerve dysfunction, and a paralysed tongue hanging from the mouth may be due to hypoglossus nerve dysfunction.

Several tests specific for certain cranial nerves are possible to perform in pigs (Fig. 39.6C, Table 39.5), although they require a relaxed animal. They may be difficult to perform in very young animals, either because the response is difficult to see (pupillary light reflex) or because animals only develop the adult-like response over time (menace response) (Enzerink, 1998).

3.8 Motor Function

Muscle tone and muscle strength as indicators of motor function may be assessed by observing the gait of the animal. Passive movement of the extremities, when the size of the animal permits, may give a more accurate impression of muscle tone.

3.9 Spinal Reflexes

A spinal reflex requires an intact reflex arc (muscle receptors, sensory axons within a peripheral nerve and dorsal root, lower motor neuron and its axon, muscle). No central input is required for a spinal reflex. However, sensory information may also be relayed to the brain and may result in additional behaviors. An example is the withdrawal reflex (Fig. 39.6D), in which stimulation
FIGURE 39.6   **Neurologic tests in pigs.** (A) Dorsal placement of foot, (B) crossing of limb, (C) Palpebral blink reflex, (D) withdrawal reflex.

TABLE 39.5   Common Components of the Clinical Examination of the Nervous System

Test	Action	Expected response
Dorsal placement of feet (Fig. 39.6A)	Placing dorsal side of foot in ground surface	Animal corrects abnormal position
Crossing of limbs (Fig. 39.6B)	Crossing the legs of the animal and let the animal put weight on it	Animal corrects abnormal position
Menace response	Moving an object fast in the direction of the eyes	Animal closes eyes
Pupillary light reflex	Shining into the eye with a flashlight	Pupil constricts
Palpebral blink reflex (Fig. 39.6C)	Tactile stimulation of the skin between the eyes	Animal blinks
Patellar reflex	Tapping the patella tendon with a reflex hammer	Flexion of the knee
Withdrawal reflex (Fig. 39.6D)	Pinching the skin between the claws	Flexion of the limb

This overview describes how the test is performed and the expected response from the animal.

of the skin between the claws results in flexing of the limb. Usually light stimulation of the skin is sufficient for the reflex to occur, but when stronger stimuli are needed, pain may be relayed to the brain and may result in guarding behavior or aggression.

In normal animals, central modulation of some reflexes is possible. In some conditions, such as complete transections of the spinal cord, this central modulation is not possible anymore, resulting in so-called "pathological responses." An example is the crossed extensor reflex. When performing the withdrawal reflex, the limb opposite the one being examined is extended. Another example is the occurrence of a massive response or repeated responses after performing the patellar reflex.

3.10 Gait Analysis

The ability to move from one place to another is an important ability for many species, including pigs. Locomotion is achieved through gait, "a complex and strictly coordinated, rhythmic and automatic movement of the limbs and the entire body of the animal, which results in the production of progressive movements" (Back and Clayton, 2013a). In order to produce gait, the integrated efforts of nervous tissue, muscles, bones, joints, tendons, and specialized skin are required. Many parts of the nervous system are involved in healthy gait.

3.11 Why Measure Gait in Neurological Research in Pigs?

Since the nervous system is so heavily involved in locomotion, problems in this system may produce a variety of gait disorders. Therefore, the analysis of gait may yield important information on the functioning of the nervous system. Several aspects of gait may be affected.

Strength may be affected when lower motor neuron function is impaired, resulting in weakness, paresis, or paralysis. Conditions affecting lower motor neurons may be limited to one muscle group, one limb, or may affect several or all limbs (e.g., in polyneuropathic conditions). Muscle tone is usually decreased, and weight bearing or propulsion may be affected, resulting in gait deficits.

Automated rhythmic movement is produced in the so-called spinal pattern generators. Although the presence of spinal pattern generators for limb movement has not been conclusively demonstrated in pigs, it has been shown in several other species, such as cats (Duysens and Van de Crommert, 1998). Due to the presence of these spinal pattern generators, even animals with complete transections of the spinal cord are able to produce rhythmic stepping movements. However, adaptation to the environment is only possible with additional input.

Coordination and adaptation are achieved through the integration of information from the visual, proprio-

ceptive, and vestibular system. Integration and coordination take place in the brainstem, cerebellum, frontal cortex, and spinal cord (Nielsen, 2003; Sahyoun et al., 2004). Lesions in these systems may lead to ataxia, inability to correct for variations in the walking surface, deviations to one side, and hypermetric gait.

3.12 What Aspects of Gait are Important?

In the previous section some gait abnormalities resulting from neurologic impairment have been described. In order to determine the presence and severity of neurologic impairment, several aspects of gait may therefore be assessed.

Kinetic parameters assess the forces that affect motion. Examples of kinetic parameters are the amount of weight that is put on a limb, or the propulsive force that is used to produce forward motion. Kinetic parameters are therefore mainly indicative of the strength of a limb. Additionally, large step-to-step variations in the forces on a limb may be indicative of ataxia. There are of course other factors that may influence the forces involved in locomotion, such as mechanic impairments or pain resulting in voluntary modification of weight bearing.

Temporospatial parameters describe gait in terms of time and space. The timing of footfalls relative to each other, the distance that is bridged in one step or the deviations in the center of gravity are examples of temporospatial parameters. Rhythmicity may be assessed by looking at the consistency of timing parameters (Vrinten and Hamers, 2003). Ataxia may result in large variability in both temporal and spatial parameters and adaptations to neurological impairments, such as decreased balance that may result in wide-based gait (Givon et al., 2009; Gordon-Evans et al., 2009; Ishihara et al., 2009; Stolze et al., 2001).

3.13 How Can we Measure These Aspects of Gait?

There are several methods to measure the aspects of gait that we mentioned earlier in pigs. The most important ones, along with their advantages and drawbacks are described in short further in the chapter (Table 39.6).

3.14 Visual Assessment

Traditionally, visual assessment of gait is the technique that is used most often in research using pigs. Protocols specifically aimed at gait analysis in pigs do exist (Grégoire et al., 2013; Main et al., 2000; Mustonen et al., 2011; Van Steenbergen, 1989), but usually these protocols are geared toward recognizing orthopedic problems rather than neurologic dysfunction. Visual gait

TABLE 39.6 Advantages and Disadvantages of the Use of Pressure Mat Analysis of Pig Gait

Advantages	Drawbacks
Measurements can be performed fast and are minimally invasive	Expensive compared to visual scoring protocols
Several aspects of gait (both kinetic and temporospatial) are collected in one run	Assigning footfalls to the correct claw manually is time-consuming
Objective and repeatable, in contrast to visual scoring protocols	
Several footfalls can be recorded in one run, in contrast to force plate analysis	

assessment does not require costly or elaborate setups and is therefore fast and cheap. There are, however, several drawbacks to visual assessment of gait. It has only moderate interobserver agreement (D'Eath, 2012; Keegan, 2007; Main et al., 2000; Petersen et al., 2004), although the use of experienced observers increases the repeatability of results (Main et al., 2000), and it is inherently subjective (Arkell et al., 2006). Furthermore, since pigs are prey animals they tend to hide signs of disease, complicating the detection of abnormalities (Weary et al., 2008).

3.15 Kinematics

Kinematic analysis is performed by tracking body segments, either by following markers that are placed on anatomical landmarks, or by "markerless" tracking using dedicated software. The temporal and spatial characteristics of gait, along with angles between body segments can be analyzed. Kinematics in pigs have mainly been used to quantify gait abnormalities associated with orthopedic problems (Conte et al., 2014; Stavrakakis et al., 2015a; Thorup et al., 2007). Kinematic setups are usually elaborate and expensive, although efforts to develop simpler and more cost-efficient methods for use in pigs are underway (Stavrakakis et al., 2015b). Another drawback is the possibility of skin movement artifacts. Markers are placed on the skin over bony anatomical landmarks, but during movement skin slides over bones and markers may be displaced so they do not correctly represent the landmarks anymore.

3.16 Force Plates

Force plates are platforms that translate the magnitude and direction of forces exerted onto them (ground reaction forces) into electrical signals using either piezoelectrical transducers or strain gauges. They have been used since the late 1960s and are still considered the "gold standard" for kinetic gait analysis. A large body

of knowledge on the use of force plates in quadrupeds exists, and they have been used, for example, in experiments on the effect of flooring on gait of healthy pigs (Thorup et al., 2008; Von Wachenfelt et al., 2009a,b, 2010) and to assess static weight distribution in standing sows (Karriker et al., 2013; Pluym et al., 2013; Sun et al., 2011). Force plates are able to measure forces in three dimensions and may therefore not only be suitable to assess weight distribution, but also the strength of propulsion which may in turn be an indication for overall strength.

An important drawback of force plates is that they cannot distinguish between feet that are placed simultaneously on the plate. Measurements in which two feet are on the plate simultaneously have to be discarded. This means that the optimal size of the plate is different for animals of different sizes, and that many trials may be needed in order to collect sufficient valid measurements. This may be a drawback in studies that follow growing animals over a longer period of time, for example, in studies investigating the effect of influences early in life on motor function in older animals. Also, there may be large variations between measurements, especially since velocity has a large influence on the ground reaction forces. In species, such as dogs and horses, which can be easily led by a collar or halter, this problem may be solved by setting strict limits for velocity and guiding the animal over the force plate at the required pace. In pigs, this is much more difficult since they resist to being led by a collar. A solution might be to use either an instrumented treadmill or several force plates in a row (Back and Clayton, 2013b), however, this setup has not been used in pigs to this date.

3.17 Pressure Mats

Pressure mats (also called pressure plates or pressure-sensing walkways) contain a dense array of sensors, each of them individually measuring the magnitude and the duration of the force exerted on them. When measurements of all sensors under one claw are combined, a pressure profile for each limb, but also for specific regions, such as the inner or outer claw can be constructed. Unlike force plates, pressure mats only measure vertical forces under the claw.

There are multiple pressure mat systems available, some of which are large enough to capture several footfalls in one measurement. In contrast to force plates, pressure mats allow to distinguish between individual footfalls. This opens up the possibility to eliminate influencing between-run factors, such as velocity, and to collect additional temporospatial parameters, such as step length, stance time, and base of support. These temporospatial parameters may be particularly interesting in the assessment of neurological causes of gait deficits.

In pigs, pressure mats have been used to assess pressure distribution under the claws of healthy sows

(Carvalho et al., 2009), to quantify experimentally induced lameness (Karriker et al., 2013), to assess the effect of pain medication on lameness (Meijer et al., 2015; Pairis-Garcia et al., 2015), to follow the development of normal gait in growing piglets (Meijer et al., 2014a), and to identify lameness due to several orthopedic conditions (Bertholle et al., 2016; Meijer et al., 2014b).

3.18 Pressure Mat Analysis in Pigs

Since pressure mats are able to collect both kinetic and temporospatial information and are fairly straightforward to use in pigs, their potential as a research tool to detect and quantify neurological gait abnormalities will be discussed in more detail.

When a pig steps on the pressure mat, several pressure sensors will be triggered. The frequency with which the sensors measure the force exerted on them can be set manually and usually varies between 63 and 126 Hz. On each timepoint, a certain force will be recorded under the sensor. All forces of the sensors belonging to one footfall are grouped, creating an outline of each footfall with corresponding force-time curves (Fig. 39.7). From these force-time curves several parameters can be derived (Figs 39.7 and 39.8), the most common of which are:

Peak vertical force: the highest peak in the time-force curve.
FIGURE 39.7 **Schematic representation of footfall outlines with associated force-time curves.** Outlines and their associated force-time curves have the same color. The temporal parameters Step Duration and Stance Duration in association with the force-time curves are shown in the upper part of the figure. The spatial parameter Step Length in association with the footfall pattern is shown in the lower part of the figure. *LF*, Left front; *LH*, left hind; *RF*, right front; *RH*, right hind.
FIGURE 39.8 **Force-time curve of one footfall with associated kinetic parameters.** Peak vertical force *(PVF)*: The highest peak in the force-time curve. Load rate *(LR)*: The slope of the imaginary straight line from the start of the stance phase to the peak of the force-time curve. Vertical impulse *(VI)*: The area under the force-time curve.

Load rate: The slope of the imaginary straight line from the start of the stance phase to the peak of the time-force curve.

Vertical impulse: The area under the time-force curve.

Peak vertical pressure: The highest peak in the time-pressure curve, in which pressure is defined as the force at a timepoint divided by the contact area at that timepoint.

Stance duration: The time the limb is in contact with the ground surface.

Step length: Travelled distance between left and right limb.

Step duration: Time needed for one Step Length to be completed.

Stance percentage: Ratio between the time a limb is in contact with the ground and the duration of the swing phase of that limb.

Additionally, pressures can be visualized by color-coding pressure under each sensor, together creating an outline of each claw. Additional spatial parameters, such as Step Length can be derived from these footprints.

Pressure mat parameters may be influenced by several variables. Velocity has an important effect on most pressure mat parameters. In a study in growing pigs aged 5–15 weeks, velocity influenced Peak Vertical Force, Load Rate, and Peak Vertical Pressure, but not Vertical Impulse (Meijer et al., 2014a). Although no information is available on the influence of velocity on temporospatial parameters in pigs, it is known from horses (McLaughin et al., 1996; Khumsap et al., 2002) that velocity does in fact have a substantial influence on these parameters. Most quadruped species, including pigs, carry about 60% of their weight on their front limbs and the remaining 40% on the hindlimbs (Fernihough et al., 2004; Meijer et al., 2014a; Oosterlinck et al., 2011; Weishaupt, 2008).

It is therefore difficult to directly compare front- and hindlimb-kinetic parameters to each other. Depending on the experimental setup, there may be additional influences on pressure mat parameters, for example, measurement session and variations in body composition between animals or over time (Meijer et al., 2014a; Mölsä et al., 2010; Nordquist et al., 2011).

In order to deal with these influences, asymmetry indices (ASIs) may be used. Symmetry is considered as an important feature of normal locomotion. When one or more limbs of an animal are affected by neurological conditions, the symmetry of the gait may be affected. In kinetic, as well as kinematic gait analysis, this asymmetry may be quantified by comparing parameters of healthy and affected limbs to each other using ASIs. ASIs can be calculated in several ways (Budsberg et al., 1993), but they are most useful when limbs from an animal within one run are compared to each other. This minimizes the effect of interrun variations that may be caused by, for example, velocity differences. In pigs from 5 to 15 weeks old, time did not influence ASIs, which makes them particularly suitable for experiments that follow animals over time (Meijer et al., 2014a).

Perfect symmetry theoretically indicates that an animal is sound. The assumption that a sound animal moves perfectly symmetrically, however, has to be used with caution. In humans, symmetry indices of up to 7.6 (with 0 indicating perfect symmetry and 100 indicating complete lack of weight-bearing on one limb) for PVF were found in clinically healthy subjects (Herzog et al., 1989). Limb dominance and functional differentiation between limbs has been proposed as a reason for the frequently observed gait asymmetry in healthy humans (Sadeghi et al., 2000). Limb dominance has been shown in dogs (Colborne et al., 2011, 2008) and horses (Oosterlinck et al., 2011) and may also be present in pigs. In neurological conditions that affect all four limbs, ASIs may not be useful and other outcomes, such as coefficients of variation, may be more suitable (Hausdorff et al., 1998).

3.19 Obtaining Valid Runs Efficiently

As discussed previously, in order to obtain meaningful results, pigs need to ambulate in a straight line, at a constant velocity, and looking straight ahead. Data collection can be greatly facilitated by using a suitable setup, by habituating the piglets to the test apparatus and by training the animals to perform the desired behavior.

In order to facilitate that the pigs walk in a straight line over the pressure mat, borders on each side of the pressure mat should be placed to guide the pigs over the mat. Older, heavy pigs have a tendency to lean into walls when walking, influencing pressure distribution between limbs. This can be prevented by making the sides of the runway slightly inclined away from the pig.

Furthermore, there should be enough space before and after the actual mat for the pigs to accelerate and decelerate, so that they cross the pressure mat at a constant velocity. The pressure mat should be level with the rest of the runway, and the pigs should not be able to see the borders of the mat. This can easily be achieved by placing a rubber mat over the entire runway including the pressure mat, but the mat should be recalibrated after the rubber mat has been placed. Manufacturers are usually able to provide advice on optimal properties for the rubber mat. Since pigs are curious animals and will chew on anything they find interesting, distractions in the runway (such as cables, screws, changes in color of the floor or borders), as well as in the environment should be removed. An example of an experimental setup is shown in Fig. 39.9. The effect of sudden noises can be minimalized by having a radio playing during the measurements, as long as the pigs are used to the sound of the radio.

Gradually habituating pigs to the test apparatus, social isolation, and the presence of humans increases the efficiency of data collection and decreases the amount of stress an animal experiences. Pigs are social animals and isolation of an animal is known to cause stress (Herskin and Jensen, 2000; Kanitz et al., 2009), which in turn may negatively affect cognitive functioning and thus make training of the animals more difficult (Mendl, 1999; Schwabe and Wolf, 2010). Fear of the experimenter may cause hesitation while crossing the runway and will disrupt the normal gait pattern.

Pigs are easily trainable and they can be taught to cross the runway at a predetermined gait (walk, trot, or canter). We have good experiences with operant conditioning using a secondary reinforcer (clicker training) and with food rewards, such as M&M chocolates (Mars, Incorporated), as the primary reinforcer. Although training is time-consuming, it greatly facilitates data collection. This is particularly important when animals are used that have painful or debilitating conditions, as prolonged testing that may be required in untrained animals to obtain reliable runs may seriously impair their welfare. Also, experimental setups where animals are followed over time and measurements are performed more often may benefit from properly trained animals.

3.20 Conclusions

Gait analysis in pigs may be interesting as an outcome measure for neurological impairment. Several techniques are available. Pressure mat analysis is a promising tool that allows collection of several gait characteristics and multiple footfalls in one run. Some advantages and drawbacks of the technique are summed up in Table 39.6. A suitable setup of the testing apparatus and training of pigs greatly facilitates data collection and may improve the quality of the recorded data.
FIGURE 39.9 **Example of an experimental setup for collecting pressure mat data in pigs up to 60 kg of weight.** Walls of the runway are inclined to prevent pigs from leaning into them. Holding pens are situated at both ends of the runway. The pressure mat is built in level with the runway and the entire runway is then covered with a rubber mat (not shown).

4 WELFARE ASPECTS IN THE USE OF PIGS AS MODEL SPECIES

Minimizing unnecessary suffering and increasing the welfare of animals in general is imperative from a legal and ethical point of view. Regardless of the species of interest it is widely accepted that better welfare is inherent to better science. Poole (1997) was one of the first to state that "physiological and behavioral responses to avoidable suffering can act as experimental confounds…."

However, before elaborating on welfare aspects regarding the pig as model animal species we have to clarify some general questions.

4.1 Animal Welfare

The concept of animal welfare is poorly defined and, especially regarding farm animals like the pig, often based on the principle of the "five freedoms", which demand freedom from: (1) thirst, hunger, malnutrition; (2) suffering; (3) pain, injury, disease; (4) the freedom to express normal behavior; and (5) freedom from fear and distress (Newman, 1994) in order to safeguard welfare. The five freedoms, however, do not translate immediately into "measures" for animal welfare (Barnard, 2007; Cuthill, 2007; Ng, 1995; Terranova and Laviola, 2004; Weed and Raber, 2005) and have been criticized, for example, by Korte et al. (2007). Welfare of animals in their view is not at stake as long as the animal has the ability to meet environmental challenges. Other concepts of animal welfare, such as the concept of evolutionary salient welfare (Barnard and Hurst, 1996) are based on the idea that welfare is not at stake as long as the animal is able to fulfill its adaptive needs and is able to make its own decision. Ohl and van der Staay (2012) suggest a dynamic concept of animal welfare, taking the animal's ability

to cope with environmental challenges, the relevance of positive emotions, and the importance of so-called "negative" emotions into consideration. They state that "An individual is in a positive welfare state when it has the freedom adequately to react to hunger, thirst or incorrect food; thermal and physical discomfort; injuries or diseases; fear and chronic stress, and thus, the freedom to display normal behavioral patterns that allow the animal to adapt to the demands of the prevailing environmental circumstances and enable it to reach a state that it perceives as positive." (Ohl and van der Staay, 2012). This appears to represent one of the most appropriate concepts.

Irrespective of which welfare concept is favored, welfare criteria based on scientific evidence are needed, for example, in order to estimate animal suffering. However, identification and validation of welfare-related measures, the prerequisite to improve animal welfare, remains a major challenge and is subject to several studies (Boissy et al., 2007; Duncan, 2005; Yeates and Main, 2008).

4.1.1 Assessment of Welfare

The question remains how to assess welfare of animals. The animals' perception of its inner, thus emotional state is central to present concepts of "animal welfare" (Fraser and Duncan, 1998; Nordenfelt, 2011; Ohl and Putman, 2014; Ohl and van der Staay, 2012; Taylor and Mills, 2007; Webster, 2011). This perception can be inferred indirectly using behavioral and physiological measures. Those measures form the (biological) basis of animal welfare, since they allow to define target values (for welfare states), based on the demands (needs) and behavior of the animal [note that the fact, that those target values are influenced by moral concepts will not be discussed here. For an elaboration see, Ohl and van der Staay (2012)].

4.1.2 Pig Welfare

Chapter 3 elaborates on the relevance of large animal models and large animal model species, such as pigs, for research related to productivity, animal health, and for translational biomedical research. One should, however, not forget another important role of pigs: they are well suited to serve as models in pig-welfare related studies (Renggaman et al., 2015), since using the same species as model offers the highest amount of the external validity (generalizability) (van der Staay et al., 2009).

It is inherent to experimental work that welfare of the study subjects might be impaired. Thus, welfare needs to be taken into consideration at any stage of a study and any attempt must be made to avoid unnecessary impairment of welfare. Since the conceptual and assessment related assertions above are species-transcending, they are applicable to pigs as well. Concerns regarding the welfare of pigs have been raised. However, attention is mainly paid to pigs in (industrial) farming. Many of these concerns are also applicable to pigs used in research. However, the latter are frequently exposed to additional situations or procedures potentially affecting their welfare even more.

Better welfare of pigs and better science with pigs "go hand in hand" (Hawkins et al., 2014). Next to investigating factors that might lead to an impairment of welfare it is of outmost importance to gain more knowledge regarding indicators of positive pig welfare states.

Especially young animals are prone to the effects of environmental factors and handling (Hargreaves and Hutson, 1990) but experiences, like exposure to testing and training have potential consequences for emotional responses and thus the welfare of adult animals as well (Boissy et al., 2007). It is important to realize that stimulation and experiences have a high potential to modulate emotional responses.

4.2 Assessment and Improvement of Pig Welfare

4.2.1 Health of Pigs

As stated earlier, good health is essential for animal welfare. Clinical evaluation needs to be the first step when attempting to assess welfare of pigs. Clinical signs of injury or disease provide a first indication that welfare might be affected. Body condition scoring tools [MAFF (Ministry of Agriculture, Fisheries and Food (1998)], cardiovascular responses, and stress-related hormone measurements might especially be helpful in gaining such first indications of affected welfare. It is obvious that impaired health is inherent to certain experimental manipulations performed on pigs, however, unintended health impairments need to be detected and solved to forestall welfare impairments.

4.2.2 Needs of Pigs—General Remarks

In order to allow pigs to fulfil their needs and/or to provide them with the necessary resources, we need to gain knowledge about their needs. Broom and Johnson (1993) defined needs as "a requirement, which is a consequence of the biology of the animal, to obtain a particular resource or respond to a particular environment or bodily stimulus." Needs furthermore (very likely) vary with factors, such as age, sex, and genetic background and previous experiences. However, the needs of recently created genetically manipulated pigs (Søndergaard and Herskin, 2012) are almost unknown. Comprehensive knowledge about the actual needs of pigs is urgently needed.

The animal's perception of its emotional (welfare) state might be derived by the use of behavioral and physiologicalmeasures. This chapter describes a series of behavioral tests, allowing to gain information on pigs emotional perception and thus, being also useful for

gaining information about the effects of early life events on later emotional functioning.

We suggest that the assessment of welfare, regardless for which purpose an animal is used, should focus on the question whether an animal has the freedom and the capacity to adapt to environmental challenges, including those intrinsically tied to the experimental procedures applied in biomedical experiments.

4.2.3 Behavior in General

A prerequisite for conclusions on the adaptive capacity of an animal is knowledge of the normal/natural behavioral repertoire of the animal species in question (ethograms). Detailed information about the normal behavioral repertoire and the behavioral needs of farm animals is urgently needed. As early as 1978, Kilgour (1978) pointed to the exigency to obtain this basic information: "The ethogram of farm animals should have a high priority for current animal science goals and the farming system must be designed to fit the animal" (Kilgour, 1978, p. 1481).

For pigs, comprehensive ethograms are missing (although at least some ethograms for specific behavioral domains are available). To fall back on ethograms for the wild ancestor, the wild boar (*Sus scrofa*), is only an option under the assumption that domestication and selection on performance characteristics did not alter behavior. However, one needs to realize that the behavior of domesticated pigs is rooted in the wild pig (Baxter et al., 2011; D'Eath and Turner, 2009). Thus, certain behaviors seen in wild pigs might be important for the welfare of domesticated pigs as well.

4.2.4 Aggressive Behavior

Since 2013 sows on farms in the European Union must be housed in groups due to European legislation (DIRECTIVE 2008/120/EC) with the intention to improve welfare. Pigs are indeed socially living animals (Estevez et al., 2007) and individual housing of pigs is thus, generally speaking, a potential risk for welfare (see also Chapter 3). However, as discussed, for example, by Mendl et al. (1992) and Nicholson et al. (1993), aggression, as seen in group housed pigs, might result in an impairment of welfare since stress and injuries are very common consequences. Thus, several studies focus on measures of aggression [like, e.g., skin injuries (Meyer-Hamme et al., 2016)] in order to judge the effects on welfare. However, one has to realize that aggression is adaptive in nature and necessary for resource competition, offspring protection, defense and hierarchy-establishment (Koolhaas and Bohus, 1992). Thus, aggression might form a risk to welfare when its adaptive value is exceeded and consequences like stress and injuries (in receivers of aggression) are excessively present.

Several attempts have been made to reduce aggression among pigs to a minimum. Fredriksen et al. (2008) and Rydhmer et al. (2013), for example, recommend to socialize pigs early and to keep them in (sibling) groups. According to Day et al. (2002) the provision of rooting material (to distract the animals from penmates) successfully reduces aggression.

Dedicated mixing pens are recommended by Verdon et al. (2015). The authors, however, point out that the effects of housing in such mixing pens, on aggression (and stress), have not been investigated yet. Importantly, they point out that a secure development of a hierarchy may lead to less aggression when animals are mixed later in life with unfamiliar females and that such a secure development of a hierarchy might be realized by socialization of juvenile gilts (i.e., young female pig not yet mated, or not yet farrowed) to sows. In general, mixing sows that have been housed together earlier might help to reduce aggression as well (Verdon et al., 2015). The same authors furthermore mention hunger as a possible reason for aggressive behavior and recommend full-body length feeding stalls to reduce aggression (and stress). It is important to note that hunger as a transient state does not negatively affect welfare, because it represents a motivational state that triggers foraging and eating (Phillips et al., 2016). Thus, hunger is essential for the animal to protect its own welfare.

4.2.5 Affiliative Behavior

Pigs have been found to maintain preferential relationships (friendships) with other pigs (Stolba and Wood-Gush, 1984). Affiliative behavior may thus be essential for pig welfare. It is, however, important to identify valid measures of affiliation. Boissy et al. (2007) mention the risk of using proximity between individuals as a measure of affiliation. Proximity might simply be a result of limited space. Allogrooming belongs to the class of affiliative interactions and is believed to be part of pigs natural behavioral repertoire (Meynhardt, 1990), inducing relaxation in groomed pigs (Hansen and Von Borell, 1998). Nevertheless, pigs might experience disturbance due to being (excessively) groomed. Also here, more research is needed to verify the relevance for welfare.

4.2.6 Stereotypic Behavior

Stereotypic behavior has been investigated in pigs (Meunier-Salaün et al., 2001). However, whether the display of behavior reflects an impairment of welfare might be questioned, since, for example, Koolhaas et al. (1999) suggested that stereotypic behavior rather reflects a coping style.

4.2.7 Nest-Building Behavior

Damm et al. (2003) and Thodberg et al. (1999) found nest-building behavior to be essential for sows (at least approximately 1½ day before farrowing). Thus the provision of nesting material is essential for those sows (see also Baxter et al., 2011).

4.2.8 Anticipatory Behavior

Positive anticipation has been suggested to be useful in assessing positive emotional states (welfare) in animals (Boissy et al., 2007). Pigs indeed show increased locomotor activity and frequent behavioral transitions when anticipating food rewards (Dudink et al., 2006). The usefulness of anticipatory behavior in an attempt to draw conclusions on welfare must, however, be judged with care. If pigs do not show such reactions they might simply be fully satisfied or anhedonic (Boissy et al., 2007) or might not be able to learn to anticipate the delivery of feed at fixed time points of a day.

4.2.9 Emotions in General

The emotions discussed in the following can be inherent to certain experimental procedures, as discussed earlier in this chapter, and can thus affect the further life of the animal in question. Especially young pigs experiencing these emotions (unintended; excessively and thus adaptability-exceeding) might perform aberrant in experiments performed later in life (their welfare might have been affected, leading to long-term adverse consequences).

4.2.10 Fear and Anxiety

Fear and anxiety, investigated commonly in pigs (Forkman et al., 2007; Donald et al., 2011), are not negative by nature but trigger important adaptive responses (Ohl et al., 2008), and are not per se indicators of negatively affected welfare. Factors causing undesired, inappropriate, or prolonged anxiety (pathological anxiety; Ohl et al., 2008) need to be identified in order to remove or at least reduce them.

4.2.11 Pain

Like the emotions mentioned earlier, pain is an adaptive response, important for welfare (Ohl and van der Staay, 2012) and survival since it elicits protective vegetative and motor reactions, resulting in learned avoidance. The assessment of pain in animals is still a major challenge. There are some attempts to measure pain in pigs by investigating behavior (Meijer et al., 2015; Sutherland et al., 2012) and/or physiology [clinical and neuroendocrine approaches; Lonardi et al. (2015)]. However, pain is an individual sensation and thus, difficult to measure and compare among animals (Sneddon and Gentle, 2000).

Behavioral changes in general have been suggested to allow for the assessment of overall pain and discomfort by Hay et al. (2003), Moya et al. (2008), and Sutherland et al. (2012). Meijer et al. (2015) suggested locomotion asymmetry and spontaneous locomotor activity as potential indicators of pain associated with lameness in pigs. Classical physiological parameters used, probably indicative of pain, are clinical indicators, such as respiratory rate, blood pressure, rectal temperature, and heart rate in restrained awake piglets (White et al., 1995). A promising tool in assessing pain in pigs are changes in eye temperature due to sympatic and parasympathic systems variations (Lonardi et al., 2015).

All mentioned parameters potentially indicative for pain in pigs need, however, further validation. It is essential to take additional potentially confounding factors into consideration. Prunier et al. (2005), for example, made the important annotation that handling may interfere with physiological and behavioral responses of pigs.

Until valid measures of pain in pigs are available, one should, in particular, rely on the assumption that everything that causes pain in humans potentially causes pain in animals as well (Barnard and Hurst, 1996).

4.2.12 Stress

Stress is not negative by nature but an adaptive response. As outlined earlier, animals need to be able to adapt in order to safeguard welfare. In case the animal's adaptive capacity is reduced, the animal will experience chronic stress when adaptation to the environment is needed (Weiss, 1971) and welfare might be at stake (Korte et al., 2005; McEwen, 1998).

Unfortunately, valid measures for detecting when adaptive stress turns into distress (Holden, 2000) do not yet exist. Lack of control has been suggested to result in chronic stress (Heldt et al., 2002) and controllability has been suggested as being essential for animal welfare (Boissy et al., 2007). Thus, a controllable, or predictable environment is of high importance.

Fredriksen et al. (2008) suggested to socialize pigs early and to keep them in groups in order to reduce stress (Rydhmer et al., 2013). Furthermore, environmental enrichment might be helpful in preventing stress. Next to the fact that enrichment always needs to be decided on, taking the animals' biological needs into consideration, van der Staay et al. (see Chapter 3) made the important annotation that pigs need to be given the opportunity to learn to use enrichment. They furthermore elaborated on stressful situations for pigs on intensive farms. The majority of the discussed situations are applicable to pigs used as model animals in research: changes in housing systems, equipment, types of feed, introduction into groups of unfamiliar pigs, and the role of the human handlers. Thus, pigs in research need to be subjected to housing and experimental conditions with care, keeping possible consequences for welfare in mind.

4.2.13 Housing/Management Procedures

Welfare of pigs might be affected by several housing-related factors, such as space allowance, nutrition, group size, static and dynamic groups, mixing pens (Verdon et al., 2015).

Animals are highly motivated to perform behaviors that lead to the experience of positive emotional states. Housing or management procedures that allow the animals to perform those behaviors promote positive emotional states/welfare.

Pigs are highly motivated to play (Zupan et al., 2016). The degree of expression of this behavior has been considered to be indicative of good welfare (Lawrence and Appleby, 1996; Muller-Schwarze et al., 1982; Newberry et al., 1988; Siviy and Panksepp, 1985; Spinka et al., 2001). Furthermore, play seems to be essential for the development of social and cognitive abilities of many animal species (Fagen et al., 1981; Smith, 1982; Spinka et al., 2001) and of high importance especially during the neonatal period (Spinka et al., 2001). As summarized nicely by Martin et al. (2015) pigs show the whole spectrum of play behavior—including object-, social-, and locomotor play—and point out that play in pigs appears to be sex and age dependent and might form a training for the future.

Play behavior (in pigs) might thus be used as an indicator of welfare and should be stimulated whenever possible. The, probably, most important factor in promoting play is the environment since it can either stimulate or restrict (Martin et al., 2015).

If we intend to stimulate a certain behavior, such as play, we need to familiarize ourselves with the characteristics of the different categories of play (which holds true for all ethological readout parameters). The literature provides several ethograms for play in pigs (Martin et al., 2015; Zupan et al., 2016). As soon as we know what we are looking for we can test play-stimulating procedures/conditions.

Giving pigs the opportunity to play during neonatal development is essential, especially when exposed to behavioral testing later in life. Martin et al. (2015) observed that piglets kept in enriched, thus play-stimulating, environments develop greater sociocognitive abilities.

4.2.14 Space Allowance

Space is essential to pigs since they need to be able to move, assess resources, and to interact with each other and to explore (Verdon et al., 2015).

This factor becomes highly important within farrowing crates in which the execution of the behaviors listed earlier is severely restricted (Chidgey et al., 2016).

4.2.15 Enrichment

Enrichment is believed to improve animal welfare (van der Staay et al., 2009) allows, as stated (Ferguson, 2014) for pigs, the animal to fulfill its needs and to adapt to its environment. Based on these considerations, chains and bite sticks (Scott et al., 2006) and/or rooting material (Studnitz et al., 2007) are frequently given to pigs.

In order to decide on certain forms of enrichment, it is essential to take the animal's biological (behavioral) needs into consideration. The enrichment should be useful for the animal, as inappropriate enrichment can even lead to fear, anxiety, or stress. Pigs may lose interest in biologically nonrelevant enrichment quickly (Newberry, 1995; Van de Perre et al., 2011).

As pointed out by van der Staay et al. (Chapter 3) (cognitive) enrichment might be provided unintended: when testing animals, prior training is often required. This training and testing itself might act as (cognitively) enriching. Thus, while "unintended" enrichment might improve welfare on one side, at the same time it might mask the effects of experimental manipulations (Grimberg-Henrici et al., 2016; Westlund, 2014) In an attempt to make use of the (at least potentially) welfare increasing nature of such cognitive enrichment, the potentially experimental result-confounding characteristics need to be identified first.

4.2.16 Lighting Conditions

Operant preference tests in pigs revealed that they have a preference for lower light intensities (Roelofs et al., in press). This finding might be implemented in housing of pigs in general but also in experimental setups. Carrying out experiments under low light intensities does very likely correspond to the animal's needs and might thus improve welfare during testing.

4.2.17 Handling

Early life experiences, such as handling are quite influential as described earlier in this chapter and pigs have been found to be less fearful later in life when (positive) handling started early in life (Hemsworth et al., 1989).

4.2.18 Testing

Welfare might be at stake at different stages in a pig's life. This is especially important to realize when pigs are intended to be used as animal model species. Early welfare-impairing life experiences have a great potential to affect experimental results (e.g., during cognitive testing). But, when pigs are exposed to experimental studies their welfare might be at stake as well. Thus, within the test- and model evaluation process, the possible consequences of testing on the animals need to be investigated. Otherwise, the validity of the gained test results might be at stake (van der Staay et al., 2009).

Van der Staay and coworkers (see Chapter 3) raised another welfare-related concern within experimental animal work, applicable of course to pigs as well: widely accepted and implemented actions are taken in order to reduce the number of animals being used. This entails sometimes excessive reuse of animals. What does that mean for the welfare of those animals? It is of course desirable to reduce the number of experimental animals

(while still guaranteeing the validity and thus quality of research). However, we urgently need to investigate the possible welfare consequences of reusing pigs in subsequent, additional tests or additional studies.

4.2.19 The 3Rs

Russell et al. (1959) introduced the principle of the 3Rs (refinement, reduction, replacement) to the research community. It is inherent to "replacement" that welfare is not at stake since living animals are not used anymore. "Reduction" might entail welfare consequences if animals are excessively reused. "Refinement" appears to be the most important "R" when it comes to animal welfare since it represents the attempt to reduce negative effects on the animal's welfare by refining husbandry and experimental procedures (Nuffield Council on Bioethics, 2005). Adherence to the principles of the 3Rs is legally required in many countries. Research on the potentially welfare-improving qualities of certain refinement procedures can benefit pigs being used as model species but at the same time pigs used on farms. This becomes even clearer when one realizes that research with pigs is for the largest part carried out on farms and that thus experimental and farm animals are for a major part exposed to the same (e.g., housing and handling) procedures.

4.2.20 Humane Endpoints

A humane endpoint represents the very moment in an experiment at which pain and/or distress, experienced by the animal itself is alleviated or ended by means of discontinuing a procedure or humane killing of the animal in question (see e.g., "Humane endpoints in laboratory animal experimentation"; https://www.humane-endpoints.info/en).

There is ample literature dealing with humane endpoints in general, but almost no literature on humane endpoints for pigs exists. However, Ellegaard et al. (2010) elaborated on possible humane endpoints for the minipig based on the consideration that pain, distress, and discomfort are fundamental for the development and implementation of humane endpoints. The authors list the following signs as a potential basis for determining humane endpoints:

- decrease in bodyweight,
- locomotor or obvious signs of discomfort,
- not wagging the tail or the tail is held between the legs (look for tail bites),
- the animal crouches in a corner (and does not react to people entering),
- ears and head are hanging,
- lacks normal curiosity, and
- change in the normal vocalization pattern upon touch.

—*Ellegaard et al. (2010, p. 174)*

Next to the potential indicators of pain, stress, and discomfort described in this chapter these signs might be useful in determining humane endpoints for pigs.

5 CONCLUSIONS

Recent years have seen an increase in the use of pigs, particularly young pigs, in experimental animal models. While it seems clear that pigs have strong potential as models for young humans, and that examining effects of early life management practices on later life will give us insight into farm pig welfare, the utility of pig-based models can only be tested and validated with the use of reliable and valid tests. The reliability and validity of the tests described in the current chapter have to some extent been determined, but concerted efforts from groups involved in pig research should be undertaken to further develop tools for testing effects of early life events on behavior and welfare in pigs.

1 INTRODUCTION

Alzheimer's disease is the most common form of human neurodegenerative disease. Worldwide, around 36 million people are known to suffer from dementia and the majority of these have Alzheimer's disease (World Alzheimer Report 2010: The Global Impact of Dementia, 2010). Total worldwide costs of dementia exceeded US $600 billion in 2010 equaling about 1% of world GDP and these costs are projected to rise as the average age of the world's population increases (World Alzheimer Report 2010: The Global Impact of Dementia, 2010). The ability to delay the average age of onset of Alzheimer's disease by even relative short periods could result in large budgetary savings for national health systems (Barnes and Yaffe, 2011; Ltd., 2004). Therefore, research into understanding the pathogenesis of Alzheimer's disease is well motivated.

Alzheimer's disease is broadly classified into two forms. A rare, familial early-onset form (FAD) accounts

for less than 1% of Alzheimer's disease cases (Cruchaga et al., 2012). It is defined as occurring before 65 years of age and is commonly caused by dominant mutations in one of three genes, the *PRESENILIN1* (*PSEN1*), *PRESENILIN2* (*PSEN2*), and *AMYLOID BETA A4 PRECURSOR PROTEIN* (*APP*) genes. The common, late-onset form of Alzheimer's disease occurs from 65 years of age and is frequently regarded as "sporadic" (SAD) without obvious familial inheritance. Nevertheless, it is now evident that mutations in the three genes mentioned earlier can increase the risk of late-onset Alzheimer's disease (Cruchaga et al., 2012). Polymorphisms at a number of other genetic loci have been identified as contributing to the risk of late-onset Alzheimer's disease. The most prominent locus is the gene *APOLIPOPROTEIN E* [*APOE*, (Saunders et al., 1993)] but genome-wide association studies (GWAS) have suggested roles in Alzheimer's disease pathogenesis for numerous other loci [reviewed in Moraes et al. (2012)].

Clinically, Alzheimer's disease is characterized by progressive deterioration of memory and thinking ability and changes in behavior, such as increased mood swings and aggression before eventual withdrawal from communication and interpersonal relationships ultimately leading to death (Neugroschl and Wang, 2011). Confirmation of Alzheimer's disease diagnosis requires postmortem histopathological examination of the brain to demonstrate the characteristic presence of extracellular deposits (plaques) of amyloidβ peptide (a proteolytic product of APP) and intracellular aggregations of the tau protein [derived from the gene *MICROTUBULE-ASSOCIATED PROTEIN TAU* (*MAPT*) (Goedert et al., 1988)] in the hippocampus and neocortex. Alzheimer's disease histopathology also commonly includes reactive gliosis (Serrano-Pozo et al., 2011) and the inappropriate reentry of neurons into a cell cycle that they cannot complete [cell-cycle events (Busser et al., 1998)]. Oxidative stress is also an early marker of Alzheimer's disease pathology and it is now widely understood that the pathological process leading to Alzheimer's disease begins decades before overt symptoms become evident (Nunomura et al., 2001).

Alzheimer's disease was first defined as a distinctive form of dementia by Alois Alzheimer over 100 years ago (Cipriani et al., 2011). By mid-2016 the scientific literature had accumulated over 117,000 papers addressing the disease but there is still no consensus regarding its cause(s) or the molecular mechanisms that underlie the disease process. Tens of hypotheses for the pathological mechanisms underlying Alzheimer's disease have been proposed. Some of the main hypotheses are summarized in Table 40.1.

It is important to remember this diversity of hypotheses when attempting to model Alzheimer's disease in whole organisms since assumptions regarding the disease process will always influence experimental design and the interpretation of experimental results. The widespread dissatisfaction with transgenic mouse models of Alzheimer's disease (Hargis and Blalock, 2016; Robakis, 2011; Zahs and Ashe, 2010 and described later in this review) and the failure in humans of numerous drugs that appeared potent in animal trials (Smith, 2010) are graphic illustrations of this.

It is also important to remember that the early-onset familial forms of Alzheimer's disease and sporadic Alzheimer's disease may have quite distinct pathological mechanisms. Importantly, the GWAS studies of late-onset sporadic Alzheimer's disease did not reveal associations with polymorphisms at *PSEN1*, *PSEN2*, or *APP* [Table 40.1 (Moraes et al., 2012)].

In broad terms, there are two ways to use animal models to investigate human disease. The normal function of genes/proteins involved in the disease can be investigated, mainly through investigating loss-of-function phenotypes, for example, in gene knockout models. Alternatively, when disease-causing mutations are dominant, the motivation is to engineer the human mutations into the animal's genome in an attempt to create a pathological state resembling the human disease. Since mutations causing early-onset Alzheimer's disease are gain-of-function/dominant the majority of animal modeling of Alzheimer's disease has focused on attempts to generate Alzheimer's disease-like neurodegeneration in the highly manipulable, mammalian mouse. However, as we will discuss later, it now appears that genes involved in early-onset Alzheimer's disease are evolving particularly rapidly in the mouse (and rat) relative to most other mammals including other rodents, such as the guinea pig (Sharman et al., 2013). This may explain the overall failure of mouse models to enlighten us greatly regarding Alzheimer's disease pathogenesis. This also highlights the necessity of investigating alternative in vivo models for Alzheimer's disease.

2 INVERTEBRATE MODELS OF ALZHEIMER'S DISEASE

2.1 Invertebrate Models and Their Advantages and Disadvantages for Disease Modeling

Over the last 2 decades, invertebrates have become increasingly popular as models for human neurodegenerative (Alexander et al., 2014; Fernandez-Funez et al., 2015; Jaiswal et al., 2012; Li and Le, 2013; Wentzell and Kretzschmar, 2010). Favored models have been *Drosophila melanogaster* and *Caenorhabditis elegans*, which are well-established model systems that have long been used to address fundamental biological questions. In addition, these models are inexpensive and easy to maintain, produce large numbers of progeny, and have a relatively short life span which allows to study age-dependent degenerative

TABLE 40.1 An Incomplete List of Hypotheses of the Mechanism(s) Underlying Alzheimer's Disease Pathogenesis

Hypothesis	Brief description	References
Amyloid cascade	Accumulation of Aβ peptide by overproduction from APP or by failure of clearance leads to formation of oligomers that have numerous toxic effects	Fjell and Walhovd (2012), Karran et al. (2011)
APP	Changes in other aspects of APP function (e.g., signaling by the intracellular domain or release of the extracellular domain) are important	Ghosal et al. (2009), Israel et al. (2012), Pimplikar et al. (2010)
Axonal transport dysfunction	Changes in active transport in axons lead to neuronal dysfunction	Muresan and Muresan (2011)
Calcium	Changes in calcium are correlated with neurodegeneration	Fedrizzi and Carafoli (2011), Tu et al. (2006)
Cholinergic	AD is due to reduced acetylcholine production	Craig et al. (2011), Francis et al. (1999)
Cholinergic vasculature	Cholinergic deficit decreases cholinergic innervation of cortical neurons and blood vessels causing cerebral hypoperfusion, which contributes to neurodegeneration	Claassen and Jansen (2006)
Hypoxia	Hypoxia initiates AD pathology, for example, by increasing Aβ synthesis	Moussavi Nik et al. (2012), Oresic et al. (2011)
Inflammation	AD is due to long-term inflammatory responses in the brain. This may relate to Aβ accumulation or an autoimmune response	Zotova et al. (2010)
Metal ions	Dysregulation of metal ion transport/accumulation underlies AD pathology	Duce and Bush (2010)
Mitochondria	Pathological changes in mitochondrial function cause AD, for example, by affecting axonal transport	Selfridge et al. (2013)
Mitochondria-associated ER membranes (MAM)	AD is a disorder of ER–mitochondrial communication via MAM dysfunction	Schon and Area-Gomez (2013)
Notch and Aβ	Changes in Notch signaling and Aβ production affect blood vessel density/development	Ethell (2010)
Oxidative stress	Oxidative stress initiates pathological changes that eventually lead to AD pathology	Nunomura et al. (2001)
Pathogens	Herpes simplex virus type-1 and other pathogens initiate AD	Miklossy (2011)
Presenilin (autophagy)	The Presenilins' role in autophagy is central to AD (e.g., through failure to clear aggregated Aβ)	Lee et al. (2010), Yang et al. (2011)
Presenilin (holoprotein)	Presenilin mutations generate mutant Presenilin holoproteins that multimerize with wild-type holoprotein and dominantly interfere with AD-critical functions	Jayne et al. (2016)
Presenilin (γ-secretase)	Changes in γ-secretase activity other than changes in Aβ peptide production contribute to AD	Shen and Kelleher (2007)
Prion-like	Prion-like pathological forms of Aβ and/or tau move between neurons to spread AD pathology in the brain	Guo and Lee (2011), Jucker and Walker (2011)
Synapse	Changes in synapse function are critical, possibly caused by oligomeric Aβ	Pozueta et al. (2013)
Tauopathy spectrum	AD is part of a spectrum of neurodegenerative disorders founded in tau pathology	Dermaut et al. (2005)

(Continued)

TABLE 40.1   An Incomplete List of Hypotheses of the Mechanism(s) Underlying Alzheimer's Disease Pathogenesis (*cont.*)

Hypothesis	Brief description	References
"Two-hit"	Brains showing increased oxidative stress combined with inappropriate cell cycle entry by neurons (cell-cycle events) develop AD pathology	Zhu et al. (2007)
"Two-hit vascular"	Pathological changes in brain vasculature (hit one) induce early neuronal injury and increase brain Aβ (hit two), which amplifies neuronal injury and accelerates neurodegeneration	Zlokovic (2011)
Vascular	AD is due to pathological changes in cerebral vasculature	Marchesi (2011), Stone (2008)

Most hypotheses have numerous variants. Relationships can be seen between many of these ideas. Many of the hypotheses probably encompass elements of the truth. References are given as examples and coverage is certainly incomplete. Refer to "current hypotheses" for more information.

processes after a couple of weeks instead of month. Furthermore, a plethora of molecular methods and techniques are available in these systems and their development and anatomy is well described. Most importantly, these models allow unbiased large-scale genetic screens, making them potent tools for investigating the genetic mechanisms and pathways underlying neurodegenerative diseases like Alzheimer's disease and for identifying possible risk factors.

The nematode *C. elegans* has a generation time of approximately 3 days and a life span of about 3 weeks (Brenner, 1974). Its nervous system consists of 302 neurons in hermaphrodites, and the position and synaptic connections of each neuron have been mapped and are reproducible from animal to animal (White et al., 1986). Due to its transparent body, cells and proteins can be easily visualized using fluorescently tagged proteins; a feature that greatly facilitates the analyses of protein trafficking and cellular degeneration in living animals. Transgenic lines can be created by fusing a *C. elegans* promoter to a cDNA of interest and injecting it into the gonad or by introducing bacterial artificial chromosomes (BACs) (Gama et al., 2002; Teschendorf and Link, 2009). A major advantage of this model for genetic screens is that RNAi-based knockdowns can be performed by simply feeding animals with bacteria expressing double-stranded RNA libraries (Kamath et al., 2001). In addition, worms can be used for a fairly high throughput drug screen (Lublin and Link, 2013). However, *C. elegans* has a very simple nervous system with a nerve ring in the head region but not a compartmentalized brain. In addition, assays to address cognitive decline in this model are quite limited.

By comparison, *Drosophila* has quite a complex nervous system with approximately 200,000 neurons (Zars et al., 2000). In addition, their brain is organized into distinct regions that control specific functions equivalent to vertebrate brain nuclei, like the antennal lobes that receive olfactory input and that are comparable to the olfactory bulb in mammals. Also similar to the mammalian brain, the fly brain contains several types of morphologically distinguishable glial cells, including some that form a "blood–brain barrier" (Hartenstein, 2011; Parker and Auld, 2006) or astrocyte-like glial cells (Freeman, 2015). Although flies do not have a vascular system like mammals, they also have to supply their brain with oxygen and other gases which is achieved by an air filled tubular network, the tracheal system (Metzger and Krasnow, 1999). At room temperature, the development of *Drosophila* takes about 10 days and adult flies have a live span of 60–80 days (Greenspan, 2004). Although a variety of unique tools have been developed for *Drosophila*, one of the most important technical advantage is based on the use of P-elements, transposable elements that allow stable integration into the genome (Rubin and Spradling, 1982). Initially, this system was used to insert genomic DNA or promoter-gene fusion constructs

into the fly genome but it has also been used to disrupt genes or to insert marker genes into promoter regions to identify expression patterns (Ryder and Russell, 2003). Subsequently, a binary expression system was developed (Brand and Perrimon, 1993), in which individual fly promoters were fused to the yeast transcription factor GAL4, whereas genes of interest were cloned downstream of the UAS sequence (the yeast GAL4-binding region). This method allows a particular responder sequence to be combined with a variety of promoter constructs by a simple genetic cross, resulting, for example, in the expression of a gene of interest in specific cell populations or the labeling of specific cell populations by inducing fluorescent responders like UAS-GFP. In addition, hormone- or heat shock-inducible GAL4s can be used to achieve temporal control of expression, whereas UAS-RNAi lines (which are available at various *Drosophila* stock centers) can be used to knockdown genes in a spatial or temporal fashion. The P-element-based FLP/FRT site-specific recombination system allows the creation of genetic mosaics and site-specific mutagenesis (Bischof and Basler, 2008), and more recently the CRISPR (clustered regularly interspaced short palindromic repeats)/CAS9 system has been added as a powerful tool to manipulate the fly genome (Bassett et al., 2013; Gratz et al., 2013; Yu et al., 2013). Furthermore, several genetic tools are available to study neuronal circuits and functions, including "sensors" to measure PKA activity or Ca^{2+} levels, the light-inducible channelrhodopsin, and genetically engineered neuronal channels (Riemensperger et al., 2012; Stortkuhl and Fiala, 2011; Wachowiak and Knopfel, 2009). Finally, additional binary expression systems have been developed, the Q and LexA system (Lai and Lee, 2006; Potter et al., 2010) that now allow to manipulate several genes independently. Although *Drosophila* provides an excellent model for studying neurodegenerative diseases due to this wealth of available tools, the high level of gene conservation (Wangler and Yamamoto, 2015), and the availability of learning and memory assays, this system has its limitations. Compared to the human brain, the fly brain is less complex and their behavioral repertoire is comparatively small. As mentioned before, flies do not have a blood-carrying vascular system which prevents studying vascular effects of Alzheimer's disease and while *Drosophila* has a conserved innate immune systems, flies lack conventional adaptive immune responses (Hoffmann, 2003).

2.2 Aβ-Based Models and Their Neurotoxic Effects

The amyloid cascade hypothesis, formulated by Hardy and Higgins (1992), has been one of the favored models to explain the pathogenic mechanisms leading to Alzheimer's disease. It is based on the fact that Aβ accumulation

is a key factor in Alzheimer's disease (Glenner and Wong, 1984; Wong et al., 1985) and it gained considerable support with the discovery that mutations associated with familial Alzheimer's disease lead to increased Aβ production (Chartier-Harlin et al., 1991; Goate et al., 1991; Levy-Lahad et al., 1995; Sherrington et al., 1996).

To address whether Aβ peptides are indeed sufficient to induce an Alzheimer's disease-like pathology, several transgenic fly and worm models have been developed that express different forms of human Aβ (Crowther et al., 2005; Finelli et al., 2004; Iijima et al., 2004; Link, 1995; Link et al., 2003). In the first *C. elegans* model the 42 amino acid residue form of Aβ, $Aβ_{42}$ was constitutively expressed in muscles, which caused a progressive paralysis and the accumulation of intracellular amyloid deposits (Link, 1995). This finding was confirmed in an inducible model, which, due to higher expression levels, showed a more severe and rapid paralysis (Link et al., 2003). Later models focused on the expression of $Aβ_{42}$ in neurons and this resulted in deficits in odor preference learning (Dosanjh et al., 2010) and neuronal degeneration (Treusch et al., 2011). Using this model, several modifiers of the neurodegenerative phenotype could be identified that were associated with cytoskeletal genes. When using the locomotion deficits as a screening phenotype, genes involved in protein folding, degradation, and insulin signaling were shown to ameliorate or aggravate this phenotype (Cohen et al., 2006; Fonte et al., 2002, 2008; Hassan et al., 2009). Another study identified a protective effect of mitochondrial thioredoxin in $Aβ_{42}$-expressing transgenic worms (Cacho-Valadez et al., 2012), connecting mitochondrial functions to Alzheimer's disease.

In *Drosophila*, transgenic animals have been created that express full-length APP_{695}, $Aβ_{40}$, $Aβ_{42}$, or mutant forms of APP_{695} and Aβ associated with familial forms of Alzheimer's disease, using the GAL4/UAS system (Cao et al., 2008; Crowther et al., 2005; Fossgreen et al., 1998; Gunawardena and Goldstein, 2001; Iijima et al., 2004). Several studies in mammals have suggested that an increase in $Aβ_{42}$ levels (or an increase in the ratio of $Aβ_{42}$ to $Aβ_{40}$) is an important factor in Alzheimer's disease (Findeis, 2007), although both Aβ peptides are known to accumulate in amyloid plaques in Alzheimer's disease patients. The increased toxicity of $Aβ_{42}$ was confirmed in *Drosophila* because only the induction of $Aβ_{42}$ caused progressive degeneration and plaque formation in *Drosophila*, whereas $Aβ_{40}$ did not (Crowther et al., 2005; Finelli et al., 2004; Iijima et al., 2004). Unexpectedly, however, expression of either peptide resulted in age-dependent decline in olfactory learning, with no significant difference in progression or severity detected between flies expressing $Aβ_{40}$ versus $Aβ_{42}$ (Iijima et al., 2004). That plaque formation is not prerequisite for behavioral deficits was also shown in a climbing assay, which revealed a decline in performance before the appearance of overt Aβ deposits although in this case only

$Aβ_{42}$ was tested (Crowther et al., 2005). Interestingly, this study also showed that the decrease in climbing ability correlated with the accumulation of intracellular Aβ, and a following study showed that the toxicity correlated with the levels of soluble $Aβ_{42}$ oligomers (Speretta et al., 2012). The importance of oligomer formation in pathogenicity was further underscored by generating mutant Aβ constructs that were predicted to affect aggregation. Analyzing 14 mutant $Aβ_{42}$ constructs expressed in flies, Crowther and coworkers found a strong correlation between the propensity to form protofibrils and toxicity (Luheshi et al., 2007). Furthermore, a mutation in $Aβ_{40}$ (E3R) that increased its ability to form soluble aggregates became neurotoxic while a mutation in $Aβ_{42}^{Arctic}$ (I31E) that reduced its propensity to form prefibrillary aggregates decreased its toxic effects (Brorsson et al., 2010). In addition, a mutation that decreased the oligomerization of $Aβ_{42}$ (in this case L17P) reduced its deleterious effects on life span and locomotion (Iijima et al., 2008). Surprisingly, however, the propensity of the different peptides to form oligomers did not correlate with their effects on short-term memory because the L17P mutation caused an even earlier onset of the memory deficits than the more efficiently aggregating Arctic mutation. Intriguingly, pan-neuronal expression of the different Aβ isoforms also induced distinct region-specific neurodegenerative effects, with the Arctic mutation mostly affecting cell bodies and the L17P mutation mostly affecting neurites (Iijima et al., 2008). These findings strongly support evidence obtained from mammalian models that intracellular oligomers of Aβ constitute the toxic species, rather than extracellular plaques (Finder and Glockshuber, 2007; Lublin and Gandy, 2010). Furthermore, these results suggest that oligomer formation and neurotoxicity do not correlate with behavioral deficits and that the formation of Aβ oligomers in specific subcellular compartments induces different pathological phenotypes.

In addition to degeneration and behavioral deficits, $Aβ_{42}$ expression induced several other phenotypes in flies. This includes synaptic deficits, supporting results in mammals that Aβ impairs neuronal transmission and synaptic plasticity (Jang and Chung, 2016; Tampellini, 2015; Zhang et al., 2016). This was first demonstrated at the larval neuromuscular junction where $Aβ_{42}$ induction reduced neurotransmitter release (Chiang et al., 2009). This was later confirmed in the adult nervous system by expression of $Aβ_{42}$ in the giant fiber system, and the projection neurons of the olfactory system which resulted in reduced synaptic activity (Lin et al., 2014b; Zhao et al., 2010). In addition, Huang et al. (2013) described a reduced number of synaptic vesicles, calcium channels, and active zones in these flies which is probably the underlying cause for the defects in synaptic transmission. Recently, it was described that $Aβ_{42}$ expression can also lead to neuronal hyperactivity by degrading K_v4 channels and that, this may be part of the

pathogenicity, was suggested by the finding that over-expression of K_v4 ameliorated the locomotion deficits in expressing $A\beta_{42}$ flies (Ping et al., 2015). Iijima et al. found a change in the localization of mitochondria in $A\beta_{42}$-expressing flies, with fewer mitochondria in axons and dendrites and an accumulation in neuronal somata (Iijima-Ando et al., 2009). Furthermore, interfering with mitochondrial transport by genetic means enhanced the locomotion deficits of $A\beta_{42}$-expressing flies, and even caused age-dependent defects in locomotion in the absence of $A\beta_{42}$, suggesting that changes in mitochondrial distribution are due to transport defects. The resulting depletion of mitochondria at synaptic terminals (Iijima-Ando et al., 2009; Zhao et al., 2010) may further contribute to the observed synaptic dysfunctions. Although the expression of $A\beta$ in these models certainly does not completely recapitulate Alzheimer's disease pathology, these studies nevertheless clearly demonstrate that $A\beta$ peptides alone can have neurotoxic and behavioral effects, providing support for the amyloid cascade hypothesis.

Based on the foregoing evidence that $A\beta$ peptides induce various disease-related phenotypes ranging from synaptic deficits to disrupted behaviors, this model has subsequently been used to identify factors that ameliorate $A\beta$ toxicity by genetic interaction tests. For the purpose of this overview, we will focus on a few of these interacting factors although many more have been described. The suppression of $A\beta_{42}$-induced neuronal degeneration by inhibition of c-Jun amino-terminal kinase (JNK) reveals a role of the JNK pathway in $A\beta_{42}$-induced cell death (Tare et al., 2011) while reducing PI3k-Akt signaling suppressed the memory deficits (Chiang et al., 2010). Another pathway that has been identified to affect $A\beta$ toxicity in flies is ER stress and Ca^{2+} dysregulation because Casas-Tinto et al. (2011) identified X-box-binding protein 1 (XBP1), a protein involved in ER stress responses as neuroprotective in the fly $A\beta_{42}$ model. They also showed that this protein prevented Ca^{2+} release from intracellular stores, supporting data linking calcium homeostasis with Alzheimer's disease (Fedrizzi and Carafoli, 2011). Consistent with the proposed involvement of copper and iron in Alzheimer's disease (Prakash et al., 2016), overexpression of the iron-binding protein ferritin or the MTF-1 transcription factor, which is involved in metal detoxification (Hua et al., 2011; Rival et al., 2009), suppressed deleterious phenotypes caused by $A\beta_{42}$. In contrast, a mutation in the copper transporter Atox1 enhanced $A\beta$ toxicity (Sanokawa-Akakura et al., 2010). The *Drosophila* $A\beta$ model has also been used to investigate the role of the innate immune system in Alzheimer's disease. Immune factors in the Toll pathway were upregulated in $A\beta_{42}$-expressing flies and mutations in Toll and its downstream targets decreased the retinal degeneration observed after $A\beta_{42}$ expression (Tan et al., 2008), suggesting a deleterious effect of immune responses. However, another group using

an $A\beta_{42}{}^{Arctic}$ fly model and microarray-based analyses did not observe an upregulation of genes in the Toll pathway (Favrin et al., 2013).

Lastly, this model has been used to test pharmacological interventions and these studies have identified several protective natural products, like curcumin or traditional Chinese extracts (Caesar et al., 2012; Hou et al., 2014; Ng et al., 2013; Park et al., 2013; Wang et al., 2015), as well as synthetic compounds and peptides (Luheshi et al., 2010; Nerelius et al., 2009; Pratim Bose et al., 2009; Wacker et al., 2014). The relative simplicity with which pharmacological compounds can be tested in *Drosophila* (and in *C. elegans*) will hopefully eventually lead to the discovery of therapeutic strategies that can ameliorate the toxic effects of $A\beta$.

2.3 APP-Based Models and Disruptions of APP Functions

In addition to $A\beta$-based models, transgenic flies have been generated that express wild-type full-length APP_{695} or APP_{695} carrying the Swedish or London mutation associated with familial forms of Alzheimer's disease (Fossgreen et al., 1998; Gunawardena and Goldstein, 2001; Singh and Mahoney, 2011). Inducing these constructs in the larval nervous system induced apoptotic cell death that was more severe when using the FAD mutations (Gunawardena and Goldstein, 2001). Expressing APP_{695} in the eye also caused neuronal degeneration (Fig. 40.1) that was accompanied by amyloid deposit formation and both were enhanced when promoting amyloidogenic cleavage by coexpressing BACE1 or PSN (Greeve
FIGURE 40.1 **Degeneration in the retina after APP_{695} expression in the *Drosophila* eye.** (A) A 30-day-old control fly shows an intact retina *(re)* and lamina *(la)*. (B) In contrast, numerous vacuoles (some indicated by *arrowheads*) have developed in a 30-day-old fly expressing APP_{695} in the eye using GMR-GAL4.

et al., 2004). In addition, APP expression caused axonal transport defects and synaptic alterations, as well as locomotion and learning deficits (Mhatre et al., 2014; Peng et al., 2015; Rodin et al., 2015; Sarantseva et al., 2009). These phenotypes are similar to what has been described after expression of Aβ and together with the finding that an Aβ fragment can be cleaved from APP$_{695}$ by the endogenous *Drosophila* secretases (Greeve et al., 2004); it is possible that these effects are due to the generation of Aβ. Therefore, this model can possibly be used to study the toxicity of the Aβ peptide and to identify factors that affect its generation. Consequently, APP$_{695}$-expressing flies have been used for testing of β- and γ-secretase inhibitors (Chakraborty et al., 2011; Greeve et al., 2004; Groth et al., 2010; Wang et al., 2009). Similarly, this model has been employed to identify genetic factors that impact secretase activity, for example, proteins involved in phospholipid synthesis and membrane composition that have been demonstrated to interfere with γ-secretase activity (Michaki et al., 2012; Nesic et al., 2012).

Although a large body of evidence supports a central role for Aβ in Alzheimer's disease pathology (including the studies in invertebrates described previously), it is still an open question whether disruptions of physiological functions of APP contribute to Alzheimer's disease. In contrast to mammals, which have three APP family members (APP, APPL1, and APPL2), worms and flies have only one APP protein, facilitating loss-of-function studies. Like their mammalian orthologs, the invertebrate APP proteins are membrane-spanning proteins with a large N-terminal extracellular domain and small C-terminal intracellular domain (Luo et al., 1990). Several studies in cell culture have linked the extracellular fragments released by secretase cleavage of APP with functions as cell proliferation, survival, and adhesion (Turner et al., 2003). In contrast, the small intracellular domain (AICD), which is released by γ-secretase cleavage, has been proposed to function as a transcriptional regulator (Beckett et al., 2012). Interestingly, the AICD has the highest degree of sequence conservation when comparing APP proteins from invertebrates and mammals.

Like the mammalian protein, the *C. elegans* APP protein (APL-1) is expressed in a variety of cells, including neurons, muscles, and hypodermal cells (Hornsten et al., 2007). Loss of APL-1 results in lethality during development, which can be rescued by expression of the soluble N-terminal fragment alone, suggesting that the N-terminus is sufficient for the vital function of APL-1 (Hornsten et al., 2007). In contrast, expression of the *Drosophila* APP protein (APPL) appears restricted to neurons, and flies lacking APPL are viable (Luo et al., 1990) although they have a shorter life span and a weak degenerative phenotype when aged (Wentzell et al., 2012). In addition, they show defects in neurite outgrowth (Leyssen et al., 2005; Li et al., 2004; Soldano et al., 2013), axonal transport (Gunawardena and Goldstein, 2001),

and synaptic morphology (Torroja et al., 1999), which are accompanied by changes in neuronal excitability (Ashley et al., 2005; Li et al., 2004). Furthermore, loss of APPL results in memory defects (Bourdet et al., 2015; Goguel et al., 2011). This indicates that disruption of the normal physiological functions of APP may also play a role in the synaptic changes and memory impairment described in Alzheimer's disease (Wang et al., 2012). Like human APP, APPL has been shown to be cleaved by α-, β-, and γ-secretase activity (Carmine-Simmen et al., 2009; Stempfle et al., 2010) and interestingly this also creates a toxic Aβ-like peptide (Carmine-Simmen et al., 2009). Using several fly mutants that develop neurodegenerative phenotypes, Wentzell et al. (2012) showed that expression of the full-length APPL as well as the α-cleaved N-terminal fragment could ameliorate their degenerative phenotype, whereas β-cleavage aggravated the neurodegeneration. Therefore, disease-associated changes in the processing pattern of APP could result in a decrease of the protective α-cleaved N-terminus and an increase of the deleterious β-cleaved form, thereby contributing to the pathology of Alzheimer's disease. Lastly, induction of the AICD fragment of APPL induces changes in the sleep/activity pattern in flies (Blake et al., 2015), indicating that changes in the function of the AICD that occur in Alzheimer's disease could be responsible for the disruptions of the sleep pattern and other daily rhythms that are very common in Alzheimer's disease patients (Guarnieri and Sorbi, 2015; Hastings and Goedert, 2013; Kondratova and Kondratov, 2012; Reddy and O'Neill, 2010; Van Someren and Riemersma-Van Der Lek, 2007).

2.4 Tau and the Role of Phosphorylation

Another hallmark of Alzheimer's disease is the formation of neurofibrillary tangles (NFTs) and in fact NFT accumulation correlates better with the severity of the disease than plaque formation (Arriagada et al., 1992). A major component of NFTs is hyperphosphorylated tau, a protein which like other microtubule-associated proteins binds and stabilizes microtubules (Lee et al., 2001). NFTs not only occur in Alzheimer's disease but in a variety of diseases together called tauopathies that include frontotemporal dementia (FTD) with Parkinsonism linked to chromosome 17 (FTDP-17), Pick's disease, corticobasal degeneration, and progressive supranuclear palsy (Iqbal et al., 2010). Although no mutations have been found in tau that cause Alzheimer's disease, there are mutations that lead to FTDP-17 (Hutton et al., 1998; Spillantini et al., 1998). Some of these mutations have been shown to increase tau phosphorylation (Gendron and Petrucelli, 2009; Iqbal et al., 2009) which in turn has been shown to increases its propensity to form NFTs (Alonso et al., 2008).

Surprisingly both, the expression of wild-type human tau or mutant tau, containing the FTDP-17-associated tau mutations P301L or V337M, in *C. elegans* neurons

induced insoluble aggregate formation, axonal degeneration, and uncoordinated movement (Kraemer et al., 2003). However, the lines expressing mutant tau showed a more rapid accumulation of aggregates and more severe locomotion defects. Analyzing their phosphorylation pattern revealed that not only the mutant forms were hyperphosphorylated but also the wild-type form, which probably accounts for its toxicity. Using the uncoordinated phenotype of these models as a screenable assay, Kraemer et al. (2006) performed a genome-wide RNAi-based interaction screen and in support of the role of hyperphosphorylation in tau neurotoxicity, the RNAi-based knockdown of the PP2A phosphatase enhanced the phenotype. Surprisingly, however, the knockdown of several kinases involved in tau phosphorylation, including glycogen synthase-3 (GSK-3β), also enhanced the locomotion defects. These conflicting findings show that genetic interaction studies in vivo can sometimes be difficult to interpret and one complicating factor could be compensatory mechanisms involving other interacting genes and proteins. Alternatively, the enhancing effect of the kinase knockdowns could be due to increased aggregate formation because experiments in vitro have shown that tau phosphorylation can in some contexts actually inhibit tau aggregation and NFT formation (Schneider et al., 1999). Nevertheless, the value of this interaction test was confirmed by the isolation of other candidate genes, including several chaperones and proteins involved in ubiquitination that, when knocked down, enhanced tau toxicity, presumably by increasing the stability or aggregation of tau (Kraemer et al., 2006).

The first transgenic fly models for tau were published in 2001 by Feany and coworkers (Wittmann et al., 2001) and since then over 30 different tau *Drosophila* models have been established. Similar to what has been described in the *C. elegans* model, expression of wild-type or mutant human tau (R406W and V337M) pan-neuronally in *Drosophila* generated abnormally phosphorylated tau and caused progressive degeneration, whereby the mutant forms had more severe effects (Wittmann et al., 2001). In contrast to *C. elegans*, however, no aggregates could be detected when either the wild-type or the mutant tau variants were expressed in the nervous system, suggesting that the formation of NFTs is not necessary for tau toxicity. Interestingly, NFT-like aggregates were detected when tau was coexpressed with GSK-3β (Jackson et al., 2002), supporting the role of phosphorylation in tau pathology. The link between phosphorylation and neurotoxicity was further investigated by creating mutations in several of the more than 80 predicted phosphorylation sites of tau (Sergeant et al., 2008). Confirming that phosphorylation of tau is a crucial step in acquiring toxic function, mutating 14 known proline-phosphorylation sites did indeed abolish its deleterious effects, whereas single or double mutations had no effect (Steinhilb et al., 2007a,b). In contrast, transgenic flies expressing a tau construct that was pseudophosphorylated at these 14 sites showed enhanced degeneration, compared to flies expressing the wild-type form (Khurana et al., 2006). Surprisingly, the loss of 11 of these sites in a different tau isoform (2N4R) did not have an effect on toxicity (Chatterjee et al., 2009), which indicates that either the critical residues were not mutated in this construct or there is an isoform-specific effect. The latter is supported by the finding that S262 and S356 were shown to be required for subsequent phosphorylation by GSK-3β in one tau isoform (Kosmidis et al., 2010; Nishimura et al., 2004) but when mutated in another tau isoform this had no effect on GSK-3β-mediated phosphorylation (Chatterjee et al., 2009). Tau can be phosphorylated by several kinases besides GSK-3β, including microtubule-affinity regulating kinase (MARK), cdk5, and protein kinase A (Lee et al., 2001). To determine the role of specific kinases in tau toxicity, several groups have performed genetic interaction tests with tau transgenic flies overexpressing specific kinases. Coexpression of either cdk5 or Shaggy (SGG; the *Drosophila* ortholog of GSK-3β) with wild-type human tau increased its phosphorylation and enhanced the degenerative phenotype (Chau et al., 2006; Jackson et al., 2002). Furthermore, these flies now also exhibited detectable tau aggregates, suggesting that phosphorylation by these kinases is an important factor in tau neurotoxicity. However, although phosphorylation by SGG can aggravate tau toxicity, it appears not to be required because as mentioned previously the tau variant with 11 SGG phosphorylation sites mutated was not phosphorylated by SGG but it still caused degeneration (Chatterjee et al., 2009). In contrast, phosphorylation of tau by PAR-1, the fly MARK, seems to be required for tau toxicity because mutating the PAR-1 sites abolished toxicity, whereas overexpressing PAR-1 aggravated the toxicity (Chatterjee et al., 2009; Nishimura et al., 2004). Phosphorylation by PAR-1 could also regulate phosphorylation by other kinases, although this model is still controversial; whereas Nishimura et al. described that phosphorylation by PAR-1 is a prerequisite for phosphorylation by cdk5 and SGG, Jackson et al. detected phosphorylation at the SGG sites even when the PAR-1 sites were mutated (Chatterjee et al., 2009). Further complicating matters, which sites within tau are actually phosphorylated in vivo (and in which sequence) may ultimately depend on the cell type: when tau was expressed in photoreceptors, there was little or no phosphorylation at the SGG sites, whereas these sites were phosphorylated when tau was expressed in CNS neurons (Grammenoudi et al., 2006). The same group also showed that some patterns of tau phosphorylation caused neuronal degeneration, whereas phosphorylation events at other sites were associated with neuronal dysfunction but not degeneration (Kosmidis et al., 2010). Such cell-specific phosphorylation patterns and effects could explain why some neurons are more susceptible to the toxic effects of tau than others, an issue that can be addressed in the

fly model by using neuronal subtype-specific promoter constructs. Lastly, genetic interaction screens have also identified several kinases and phosphatases as modifiers of the tau-induced retinal degeneration (Ambegaokar and Jackson, 2010; Karsten et al., 2006; Shulman and Feany, 2003). Surprisingly, in one of these interaction screens PAR-1 overexpression suppressed the degenerative phenotype in the eye (Shulman and Feany, 2003), in contrast to the PAR-1 overexpression studies described previously which resulted in an enhancing effect. This may indicate that under certain circumstances phosphorylation of tau can actually reduce its toxicity whereas in other contexts it is deleterious. Such a scenario is also supported by the findings that GSK-3β-mediated phosphorylation can be protective, as described previously in the *C. elegans* model (Kraemer et al., 2006) and by Povellato et al. (2014) in *Drosophila*. However, what factors determine when tau phosphorylation has a protective effect versus an enhancing effect still needs to be determined. Nevertheless, these results suggest that phosphorylation of tau is an important aspect for its toxic function, whereby the combined action of several kinases might be more critical than the phosphorylation by one specific kinase or phosphorylation at a single site. In addition, determining the effects of phosphorylation on tau toxicity is further complicated by the finding that the phosphorylation at specific sites and in a specific order affects different tau-associated phenotypes differently (Papanikolopoulou and Skoulakis, 2015). Lastly, it should be noted that tau undergoes many other posttranslational modifications, including glycation, deamination, and acetylation, and only a few studies have addressed their effects on pathogenicity. One recent study using the fly model to address other modifications has reported increased toxicity by pseudoacetylation of tau (Gorsky et al., 2016).

2.5 Effects of Tau Manipulations on Cellular Functions

Genetic interaction tests using flies expressing human tau have also identified proteins involved in many other cellular processes as modifiers of tau toxicity, including cytoskeletal proteins and proteins involved in cell cycling (Ambegaokar and Jackson, 2010; Blard et al., 2006; Butzlaff et al., 2015; Shulman and Feany, 2003). Feany and coworkers showed that expression of Cyclin A, Cyclin B, or Cyclin D enhanced the degenerative phenotype caused by tau, whereas blocking cell-cycle progression by expressing Retinoblastoma factor 1 or the cdk2 inhibitor Dacapo decreased it (Khurana et al., 2006). In addition, this group showed an abnormal activation of the cell cycle in tau-expressing flies and a recent publication demonstrated that microtubule-bound tau inhibits cell mitosis (Bouge and Parmentier, 2016). Maybe not surprisingly, several studies connected cellular defense

pathways with tau toxicity; tau activated the ER stress factor XBP1 and the loss of XBP1 enhanced tau-induced phenotypes (Loewen and Feany, 2010). Similarly, promoting antioxidative pathways suppressed tau toxicity whereas inducing oxidative stress enhanced it (Dias-Santagata et al., 2007). Tau was also shown to affect the cytoskeleton, especially filamentous (F)-actin; tau^{R406W} expression resulted in an accumulation of F-actin and actin-rich rods that resemble the Hirano bodies found in patients with Alzheimer's disease or Pick's disease (Fulga et al., 2007). By interfering with actin dynamics, it also caused a mislocalization of the mitochondrial fission factor DRP1, resulting in mitochondrial abnormalities (DuBoff et al., 2012). Interestingly, changes in mitochondrial distribution and trafficking were also observed in a *C. elegans* model expressing tau^{A152T}, although no insoluble tau aggregates were found (Pir et al., 2016). Nevertheless, these worms showed uncoordinated behavior and a reduced life span, supporting findings in flies that tau toxicity does not depend on aggregate formation. More recently, the Feany group also showed effects of tau^{R406W} on chromatin structure, with a loss of heterochromatin and increased gene expression (Frost et al., 2014), and on lamin and the nucleoskeleton, which plays a role in anchoring heterochromatin (Frost et al., 2016). These studies in the invertebrate model suggest that tau is involved in many more cellular processes than previously anticipated but whether and to what degree a loss of these functions plays a role in Alzheimer's disease or tauopathy pathology still needs to be determined.

The well-known function of tau in binding and stabilizing microtubule has been suggested to play a role in Alzheimer's disease (Trojanowski and Lee, 2005). Phosphorylation releases tau from microtubules, and it has therefore been hypothesized that the toxicity of hyperphosphorylated tau could be due to a loss of its microtubule-interacting function and consequent changes in the cytoskeleton and axonal transport (Yang et al., 2005). This model has gained further support by the discovery that mutations in tau linked with FTDP-17 reduce the ability of tau to bind and promote microtubule stability (Dayanandan et al., 1999; Hasegawa et al., 1998; Hong et al., 1998). When human tau is expressed in *Drosophila*, most of it becomes hyperphosphorylated and localizes to the cytosol, while its microtubule-binding capacity is reduced (Cowan et al., 2010a,b; Feuillette et al., 2010). However, whereas Mudher and coworkers reported that the human tau sequestered endogenous *Drosophila* tau away from microtubules, thereby supporting a loss-of-function mechanism (Cowan et al., 2010a), Lecourtois and coworkers did not observe such an effect (Feuillette et al., 2010). A role of a loss of tau function in neurodegeneration is also supported by the recent findings that a knockdown or a partial deletion of *Drosophila* tau resulted in retinal degeneration and modest degeneration in

the CNS (Bolkan and Kretzschmar, 2014). Furthermore, as mentioned previously, the disruptions of other physiological functions may play a role in Alzheimer's disease. Although future experiments might provide more insights into how disease-related tau modifications affect its physiological functions, tau toxicity might not be due strictly to a gain- or loss-of-function mechanism, but rather to a combination of both.

2.6 Interactions Between tau and Aβ

Several studies have suggested that an interaction between Aβ and tau plays a role in Alzheimer's disease pathogenesis, whereby this might be due to Aβ acting upstream of tau, increasing its phosphorylation, or by synergistic effects of tau and Aβ (Han and Shi, 2016; Small and Duff, 2008). An interaction has also been demonstrated in the *Drosophila* model because coexpression of $Aβ_{42}$ with tau in the eye enhanced the degenerative phenotype (Fulga et al., 2007) and it also exacerbated the axonal transport defects caused by expression of either of these proteins (Folwell et al., 2010). Consequently, several studies have addressed the hypothesis that this interaction is mediated by the effects of APP/Aβ on tau phosphorylation. Iijima and coworkers showed that $Aβ_{42}$ increased the phosphorylation of coexpressed tau, which correlated with enhanced degeneration and increased microtubule-unbound tau but not NFT formation (Ando et al., 2016; Iijima et al., 2010). The changes in phosphorylation appeared to be mediated by the DNA damage-activated Checkpoint kinase 2, suggesting a connection to DNA repair pathways. Coexpression of $Aβ_{42}$ and tau in motorneurons also enhanced tau phosphorylation, in this case probably phosphorylation by GSK-3β (Folwell et al., 2010). Similarly expression of full-length APP increased the phosphorylation of both tau and PAR-1, a process that depended on the LKB-1 kinase (Wang et al., 2007). Interestingly, loss of endogenous tau suppressed the toxicity of Aβ^Arctic expression and although Aβ^Arctic did increase GSK-3β activity, it did not seem to alter tau phosphorylation (Sofola et al., 2010). This supports findings in other models that Aβ can indeed promote tau phosphorylation but also that Tau and Aβ may have other synergistic effects.

Together these studies show that invertebrate models provide a valuable in vivo model to study the physiological and pathogenic functions of APP/Aβ and tau. Although significant advances have been made using these and other models, we are still far away from understanding the pathogenic mechanism leading to Alzheimer's disease. Due to the experimental advantages of these models, together with the low costs, invertebrates provide a system in which complex interactions can be studied, unbiased interaction screens can be performed, and they can be used as a medium-throughput and economical system for drug screening (Table 40.2).

3 NONMAMMALIAN VERTEBRATE MODELS OF ALZHEIMER'S DISEASE

Historically, some nonmammalian vertebrate species have been popular for analysis of the mechanisms controlling embryo development. Typically, the embryos of these species are more accessible and manipulable than those of mammalians. However, being vertebrates, their anatomy and development resemble those of humans more closely than invertebrate embryos.

The three main nonmammalian vertebrate models are the chicken (*Gallus gallus*), the African clawed frog (*Xenopus laevis*), and the zebrafish (*Danio rerio*). Chick embryos develop on the surface of a relatively huge yolk cell and their nearly flat early structure is advantageous for tissue transplantation studies. They have also proven useful for the examination of neuronal differentiation and development, particularly through examination of defined neuronal groups, such as the trigeminal ganglion (Gaik and Farbman, 1973a,b). However, the chicken's long generation time slows genetic analysis and manipulation [but does not make it infeasible (Han, 2009)].

The amphibian *Xenopus* has smaller embryos than the chick and the dividing cells of early cleavage embryos incorporate yolk. *X. laevis* are pseudotetraploid which complicates analysis of gene function due to widespread genetic redundancy (Chain and Evans, 2006). Therefore, a related diploid frog, *Xenopus tropicalis*, has become popular for such studies (Hellsten et al., 2010). Unfertilized *Xenopus* eggs have only low levels of ion channels and other transporter proteins and so forced high-level expression of such proteins in these eggs (e.g., by mRNA injection) has been used to identify and analyze their functions (Sobczak et al., 2010).

The zebrafish has gained considerable popularity in recent years due to its genetic manipulability, the experimentally amenable characteristics of its embryos, and its low cost of maintenance compared to mammals. The use of zebrafish as an experimental model dates back over half a century (Hisaoka, 1958a,b) but in the 1980s it became the first vertebrate model to be used in large-scale mutagenesis screens to detect genes controlling embryo development (see *Development* volume 123 of December 1996). The development of morpholino antisense oligonucleotides made reliable blockage of gene expression feasible in 2000 (Nasevicius and Ekker, 2000). The TILLING (targeting induced local lesions in genomes) methodology allows discovery of point mutations in desired genes (Wienholds et al., 2002). Efficient transposon-based transgenic vectors (Davidson et al., 2003; Kawakami, 2004) and the application of split transgenesis systems, such as Gal4/UAS (Scheer and Campos-Ortega, 1999) have permitted enhancer- and gene-trap screening (Abe et al., 2011). The very rapid development and optical transparency of zebrafish embryos has

facilitated labeling of cells with vital dyes and fluorescent proteins for real-time monitoring of experimental effects (Ko et al., 2011). Zebrafish embryos are also very well suited to the application of optogenetics techniques where light is used to modulate and monitor neuronal activity (Del Bene and Wyart, 2012). A previous disadvantage of the zebrafish model relative to mammalian models was the absence of technology available to generate targeted mutations. In recent times, however, zinc finger nucleases (ZFNs), transcription activator-like effector nucleases (TALENS), and the type II prokaryotic CRISPR/Cas systems have been developed for targeted mutagenesis of gene sequences in the zebrafish genome (Ekker, 2008; Hoshijima et al., 2016; Hwang et al., 2013; Sander et al., 2011; Schmid and Haass, 2013).

3.1 Chicken and Frog

Compared to invertebrate or mammalian models relatively little investigation of Alzheimer's disease mechanisms has been performed with nonmammalian vertebrates. The chick embryo expresses the Alzheimer's disease-relevant genes, *APP*, *BACE1*, *BACE2*, *PSEN1*, *PSEN2*, *NCT*, *Neprilysin*, and *ADAM17*. Of particular relevance is that the chick *APP* gene has 96% similarity and the Aβ sequence has 100% similarity to the human sequence (Mileusnic and Rose, 2010). Therefore, the chick is a highly relevant model for the analysis of APP and Aβ peptides. At the biochemical level, the lysozyme that is readily available from chick eggs has been used to analyze the general formation of amyloid protein aggregates (Krebs et al., 2000). A number of studies investigating the properties of Aβ peptides exploiting explanted chick neurons and injection of peptides into chick brains. Membrane-bound and soluble fragments of APP can increase neurite outgrowth (Milward et al., 1992). Small and coworkers have cultured chick sympathetic neurons that are cholinoceptive neurons and so are similar to neurons receiving reduced stimulation in Alzheimer's disease. The neurons are derived from the paravertebral sympathetic ganglia of 11- to 12-day-old chicks. These researchers used cultured chick sympathetic neurons to observe the relationship between APP's stimulation of neurite outgrowth and lipoprotein receptor-related protein (LRP) (Postuma et al., 1998). They also observed how different forms of exogenous human Aβ affect the secretion of the extracellular domain of APP (sAPP) and of endogenous Aβ peptides. Some forms of exogenous Aβ decreased the secretion of sAPP and endogenous Aβ while a calcium ionophore increased sAPP secretion (Mok et al., 2000).

The young chick has been proposed to be suitable model for the analysis of memory consolidation. Together with Gibbs, Small and others have used intracranial injection of Aβ of various sizes and aggregation states into 1-day-old hatchlings to observe how this affected memory. They showed that the ability of Aβ to block consolidation of memory into long-term storage was dependent on its aggregation state. Interestingly, aggregated Aβ only blocked memory consolidation into long-term storage and not short-term/intermediate memory so the action of Aβ on memory in the chick may model the anterograde amnesia seen in Alzheimer's disease (Gibbs et al., 2010). Gibbs et al. have also injected various alternative metabolic substrates into trained and Aβ-injected chicks. This allowed them to show that Aβ's involvement in inhibiting memory consolidation appears to be via a blockage of oxidative metabolism of glucose specifically in astrocytes (Gibbs et al., 2009). Subsequently, a study using cultured chick retinal neurons demonstrated that exogenous soluble $A\beta_{42}$ peptides interfere with the distribution of the glucose transporter, GLUT4 (Oliveira et al., 2015). GLUT4 is the major insulin-responsive glucose transporter and this study provides further support that the $A\beta_{42}$ peptide may interfere with glucose regulation. Primary chicken cell culture models have been employed to examine the contribution of brain cell types to the generation of varying Aβ peptides. Aβ-ELISA followed by subsequent immunoblot analysis revealed that astrocytes and microglia but not neurons preferentially secrete N-terminally truncated Aβ peptides (Oberstein et al., 2015).

Oligomers of Aβ are thought to be toxic possibly via formation of pores in lipid bilayers (Strodel et al., 2010). Alternatively, the oligomers may dysregulate existing signal receptors or membrane channels/transporters, such as the acetylcholine receptors (AChRs) that show reduced activity in Alzheimer's disease. *Xenopus* oocytes have been exploited to investigate these possible activities. Lamb et al. (2005) used expression of various forms of AChR in oocytes and treatment with $A\beta_{42}$ to show that Aβ blocks various subtypes of neuronal nicotinic AChRs but not the α7 subtype. In contrast, Demuro et al. (2011) applied oligomeric $A\beta_{42}$ externally to *Xenopus* oocytes and used patch clamping to show that this treatment creates pores allowing transmembrane Ca^{2+} ion movement. In a follow-up study, quantification of fluorescent time-series data from thousands of individual pores from the *Xenopus* oocytes demonstrated an increased Ca^{2+} flux through the Aβ pores. This disruption to a cell's Ca^{2+} homeostasis would have detrimental implications for cell survival (Ullah et al., 2015).

The *N*-methyl-D-aspartate (NMDA) receptors for glutamate that gate high levels of Ca^{2+} flow are thought to play an important role in synaptic plasticity and memory formation (Bordji et al., 2011). Since NMDA receptor antagonists can, apparently, prevent cell death caused by Aβ oligomers, Texido et al. (2011) expressed NMDA receptors in *Xenopus* oocytes to show that Aβ can activate these receptors and that this effect is suppressed by the

antagonists. One-day-old chicks were used to test the effects of the NMDA receptor antagonist memantine on intact memory function. Through passive avoidance learning tests, Samartgis et al. (2012) was able to demonstrate that memantine (an approved drug for the treatment of cognitive problems in Alzheimer's disease) is capable of facilitating memory consolidation and reconsolidation in 1-day-old chicks.

Xenopus oocytes have also been used to investigate the channel forming/regulating properties of other proteins involved in Alzheimer's disease, such as the Presenilins. Frank LaFerla and coworkers (Leissring et al., 1999b) injected mRNAs encoding normal and mutant forms of PSEN1 to show that the M146V mutation increases the ability of PSEN1 to potentiate the Ca^{2+}-activated Cl^- currents evoked by inositol 1,4,5-trisphosphate (IP3). Similar effects were also observed for PSEN2 (Leissring et al., 1999a). The same laboratory also used *Xenopus* oocytes to investigate the relationship between PSEN1 protein and the calcium transporter sarco-/endoplasmic reticulum Ca^{2+}-ATPase (SERCA) and to show that changes in SERCA activity could affect Aβ production (Green et al., 2008). *Xenopus* oocytes have also been used to explore the function of the APP protein. Suh et al. (1996) showed the injection of a 105 amino acid residue (aa) C-terminal fragment of APP directly into oocytes was, apparently, able to form ion channels.

Reductionist approaches to examining the pathological mechanisms behind Alzheimer's disease (such as those mentioned previously) can reveal a great deal but more holistic approaches will also be necessary for complete understanding. Fascinating work by the laboratory of Ricardo Miledi has shown that cell membranes can be extracted from postmortem Alzheimer's disease brains and then injected into *Xenopus* oocytes (Miledi et al., 2004). These membranes incorporate into the plasma membranes of the oocytes and are then available for measurement of ion channel activities, etc. Brains that have been frozen for many years can, nevertheless, act as a source material for membrane analysis. Miledi and coworkers used this technique to find reduced activity of glutamate receptors in Alzheimer's brains and they were able to show that this was due to relatively decreased expression of glutamate receptors in the diseased brains (Bernareggi et al., 2007).

In large cells, such as the eggs of *Xenopus* or zebrafish (or invertebrates, such as *Drosophila*), the relative volume of cytoplasm is so great that the nucleus is unable to control the cell's biology. Therefore, after fertilization transcription of nuclear genes is not initiated until "midblastoderm transition" when the cytoplasm:nucleus volume ratio is sufficiently small. Before this time, cell division and embryo development are under the control of the RNA and protein products of the maternal genome.

The rapid, successive cleavages that the early embryo undergoes are only possible because large quantities of these products have been deposited in the egg by the mother's ovary. For this reason, *Xenopus* eggs can be used to examine the structural and regulatory molecular machinery involved in the cell cycle. A number of studies have shown aneuploidy in neurons in Alzheimer's disease brains, especially aneuploidy of chromosome 21 on which the APP gene resides (Iourov et al., 2009; Zekanowski and Wojda, 2009). Huntington Potter and coworkers (Borysov et al., 2011) have exploited extracts of *Xenopus* oocytes that can form large numbers of mitotic spindles to examine the effects of Aβ42 on spindle formation and maintenance. They showed that Aβ appears to interfere specifically with interactions between mitotic kinesins and microtubules, and this would likely also lead to aneuploidy in mitotic cells.

The pseudotetraploidy of *X. laevis* illustrates the viability of animals with completely duplicated sets of chromosomes. Whole genome duplication provides the genetic raw material upon which the forces of evolution can act to generate organismal diversity and complexity. There is now considerable evidence that vertebrates underwent two rounds of whole genome duplication early in their evolution such that humans now possess four paralogs of many genes only present as singletons in invertebrate genomes (Furlong and Holland, 2002). One of the advantages of investigating gene function in invertebrate species can be the absence of functional redundancy provided by paralogous genes allowing less ambiguous definition of mutant phenotypes and gene functions.

3.2 Zebrafish

Sequencing of the entire zebrafish genome began in 2001 and has now been through many rounds of assembly (The Danio rerio sequencing project). The genome is extensively annotated and regions of conserved chromosomal synteny between humans and zebrafish have been defined (Catchen et al., 2011). Since the human (tetrapod) and zebrafish (teleost–bony fish) evolutionary lineages separated approximately 450 million years ago (Kumar and Hedges, 1998), it appears that the teleosts probably underwent an additional round of whole genome duplication followed by considerable loss of gene duplicates (Catchen et al., 2011). Thus zebrafish have seven *hox* gene complexes where humans have four and most invertebrates have one (Amores et al., 1998). This can complicate the analysis of human disease genes in zebrafish. In many cases zebrafish genes are identifiable that are clear orthologs of human genes. For example, the Alzheimer's disease-relevant genes *PSEN1* and *PSEN2* have clear zebrafish orthologs *psen1* (Leimer et al., 1999) and *psen2*

(Groth et al., 2002), respectively. However, there are many Alzheimer's disease-relevant genes that have "duplicate orthologs." (Strictly speaking such genes must be described as paralogs since they evolved by duplication within an organism rather than by a speciation event.) Thus, zebrafish possesses the genes *appa* and *appb* that evolved from an ancestral gene that was orthologous to human *APP* (Musa et al., 2001). Similarly, *apoea* and *apoeb* are related to human *APOE* (Babin et al., 1997; Woods et al., 2005) and *mapta* and *maptb* are related to human *MAPT* (tau) (Chen et al., 2009).

The existence of "duplicate orthologs" of human disease genes in zebrafish can present both problems and advantages. Overlapping functions of the duplicates (redundancy) can mean that loss-of-function phenotypes are obscured unless the function of both duplicates is blocked simultaneously. However, if the duplicates have evolved partially nonoverlapping expression patterns then manipulation of the function of only one of the duplicates can result in phenotypes restricted to particular cells or tissues. In some circumstances this may facilitate functional analysis (Blader and Strahle, 1998).

Morpholino antisense oligonucleotides (morpholinos) can rapidly and inexpensively provide information on the function of genes during zebrafish embryogenesis. They are most commonly used to block translation of specific mRNAs (Nasevicius and Ekker, 2000). The morpholinos are injected into recently fertilized eggs before the 4-cell stage at which time they can spread into all cells though cytoplasmic bridges. (Earlier injection is preferable since some translation begins immediately upon fertilization.) Morpholinos can generally be assumed to act potently for the first 48 h of development before hatching and the effect of a morpholino may last longer than 48 h but this must be confirmed for each particular oligonucleotide. However, the effectiveness and specificity of a morpholino should always be thoroughly assessed if this information has not previously been published. (The Zebrafish Model Organism Database, ZFIN, www.zfin.org collates successful morpholino sequences from published articles.) Important controls for work with morpholinos can include examining phenotypes from two or more nonoverlapping morpholinos that target the same mRNA, "rescuing" the morpholino-generated phenotype by injection of an mRNA engineered to lack morpholino complementarity and western blotting to demonstrate loss of translation of the endogenous mRNA (Eisen and Smith, 2008). Recently, technology has been developed for the activation and inactivation of morpholinos by light (Deiters et al., 2010).

The recent availability and feasibility of using genome editing technologies presents an exciting opportunity to develop zebrafish genetic models of neurodegenerative diseases, such as Alzheimer's disease.

ZFNs, TALENs, and CRISP/Rs have been validated for use in the zebrafish and it is inevitable that FAD mutations will be introduced into zebrafish FAD gene orthologs (Hoshijima et al., 2016; Hwang et al., 2013; Schmid and Haass, 2013).

An interesting consequence of the widespread use of morpholinos to investigate gene function in zebrafish was the observation of noncorrespondence between phenotypes produced by morpholino-based interference in gene expression versus endogenous gene mutations. Many genes that show distinct phenotypes when their activity is reduced using morpholinos, (and for which the specificity of the phenotype is validated by rescue experiments in which artificially synthesized mRNA for the gene is injected into embryos), nevertheless, fail to show these phenotypes when supposedly null mutations are introduced into the endogenous gene (Kok et al., 2015). A fascinating paper by Rossi et al. (2015) explained this phenomenon by demonstrating that mutations in endogenous genes—but not morpholino inhibition of gene expression—cause upregulation of related genes that compensate for the loss of expression of the mutated genes. The basis of this difference in response to morpholino- versus mutation-based alterations in gene expression is currently unknown. However, this phenomenon provides the opportunity to identify nonmutated genes that can be upregulated to compensate for particular disease-causing mutations and so may possibly be exploited to alleviate disease in humans (e.g., by identifying drugs that force expression of those nonmutated genes).

3.2.1 Presenilins, γ-Secretase and Manipulation of Gene Splicing

Over the last 20 years there has been extensive research into the normal functions of the genes involved in Alzheimer's disease but our understanding is still quite limited. The majority of genes involved in human disease play roles during embryogenesis so analysis of their loss-of-function phenotypes in zebrafish can be informative. Mutations in the human *PSEN* genes cause the majority of early-onset Alzheimer's disease (mentioned previously). In zebrafish embryos, the *psen1* and *psen2* genes are ubiquitously expressed (Groth et al., 2002; Leimer et al., 1999) as shown by whole mount in situ transcript hybridization (WISH) although higher-level expression of *psen2* was observed in melanocytes (Groth et al., 2002). Lardelli and coworkers have used morpholinos to block the translation in embryos of the Psen1 and Psen2 proteins. Blockage of Psen1 translation (Nornes et al., 2003) causes phenotypes similar to those seen for loss of Psen1 in knockout mice (Shen et al., 1997) that are thought to reflect loss of Notch signaling. However, unlike in mice (Steiner et al., 1999), loss of Psen2 function

also appears to have major effects on Notch (Nornes et al., 2009). The idea that Psen2 shows greater redundancy of function with Psen1 in zebrafish than the orthologs of these genes show in humans/mammals is supported by the fact that zebrafish lacking *psen1* activity is viable (Sundvik et al., 2013) while mice lacking Psen1 activity show an embryonic lethal phenotype similar to loss of Notch signaling (Shen et al., 1997). Zebrafish lacking endogenous Psen1 activity could be manipulated transgenically to express Presenilin proteins that include human Alzheimer's disease mutations. Note, however, that such fish would not strictly model human Alzheimer's disease mutations since the human mutations are always observed in a heterozygous state together with wild-type alleles. Alternatively, the genome editing technologies of TALENs and CRISP/Rs could be utilized to generate Alzheimer's disease-like mutations in the endogenous zebrafish *psen1* gene and these fish could then be studied as heterozygotes.

Relevant to this discussion is the paper by Leimer et al. (1999) in which they expressed zebrafish Psen1 protein in human HEK293 cells and saw an increase in the level of $A\beta_{42}$ produced relative to total cellular $A\beta$. This is similar to observations of $A\beta_{42}$ production in human cells with Alzheimer's disease mutations in PSEN1 [reviewed by Wolfe (2007)]. However, this is not surprising since zebrafish *psen1*, when expressed in human cells, can be regarded as equivalent to a human PSEN1 protein bearing a large number of missense mutations and small in-frame insertions and deletions. Thus, changes in the relative level of $A\beta_{42}$ would be expected.

Interestingly, loss of Psen2 specifically affects the production of a particular type of early neuron in the developing spinal cord—the dorsal longitudinal ascending (DoLA) interneurons. Loss of Psen1 does not affect DoLA numbers while loss of Psen2 does (Nornes et al., 2009). This observation provided the first in vivo bioassay for Psen2 function and was later exploited to show functional interaction between Psen1 and Psen2 [(Nornes et al., 2008) see later].

A fascinating aspect of Alzheimer's disease mutations in the *PSEN* genes is that, almost without exception, none of the over 200 known mutations cause truncation of Presenilin proteins [discussed in Jayne et al. (2016)]. Most of the mutations are missense mutations changing amino acid residues or internal insertions or deletions that preserve the open reading frame (ORF). Even Alzheimer's disease mutations that affect transcript splicing always produce at least one transcript form possessing an ORF that includes C-terminal codons [e.g., Dermaut et al. (2004)]. We previously attempted to model these PSEN splicing mutations in zebrafish embryos by injecting morpholinos targeting splice acceptor sites. The intention was to cause exon skipping to produce transcripts lacking exons 8 or 9 similar to the effects of the human PSEN1

L271V (Kwok et al., 2003) and Δ9 (PerezTur et al., 1995; Prihar et al., 1996) mutations, respectively. By targeting morpholinos to the splice acceptor sites of zebrafish *psen1* exons cognate with human *PSEN1* exons 8 and 9 we hoped to induce exclusion of these exons. However, the predominant products were transcripts that failed to splice out introns 7 and 8, respectively. This led to truncation of the ORF after exons 6 and 7 sequences (Nornes et al., 2008). We have also found that a general characteristic of morpholinos that affect splicing is that they simultaneously appear to inhibit the process of nonsense mediated decay. Thus, aberrant transcripts caused by morpholinos can be translated into truncated protein molecules that commonly have dominant effects on cell biology (Newman et al., 2014). Indeed, for zebrafish *psen1* transcripts we found that truncation of the ORF after exons 6 and 7 resulted in dominant negative effects on Psen1 activity (Nornes et al., 2008). By counting DoLA neurons in developing zebrafish embryos we were also able to observe that these dominant negative effects extended to suppression of Psen2 activity (Nornes et al., 2008).

The effects of interfering with splicing either via mutations or using morpholinos can be complex. For example, the G183V mutation in the splice donor site of exon 6 of human PSEN1 (that appears to cause FTD but not Alzheimer's disease) causes formation of a full-length transcript that includes the G183V missense mutation but also transcripts that lack either exon 6 or exons 6 and 7 (Dermaut et al., 2004). A morpholino binding over the cognate donor site of zebrafish *psen1* transcripts causes inclusion of intron 5 and/or part of intron 6 (it is not known whether these inclusions are simultaneous) (Nornes et al., 2008). Therefore, to validate that dominant effects are due to the ORF of a particular splice product, it can be useful to attempt to replicate the phenotype by injection of an mRNA engineered to encode only that ORF. mRNAs for injection into zebrafish embryos are typically synthesized using the pcGlobin2 vector (Ro et al., 2004) which includes untranslated β-globin sequences that stabilize the transcripts. If the relevant phenotype only occurs after 24 h, this can be difficult to phenocopy using mRNA injection due to the instability of the mRNA (Nornes et al., 2008). In such cases it may be possible to use transient transgenesis with the Tol2 vector and a suitable promoter to drive expression of the mRNA (Kawakami, 2004). Injection of mRNA encoding a *psen1* ORF truncated after exon 7 was able to replicate the early (24 h postfertilization, hpf) but not later (48 hpf) phenotypes seen due to injection of a morpholino that blocked the splice acceptor site of exon 8 (Nornes et al., 2008).

The production of *psen1* transcripts with truncated ORFs is not irrelevant to understanding Alzheimer's disease. Recently, a first ORF-truncating mutation that apparently causes Alzheimer's disease, *K115Efx10*, was

isolated in the human PSEN2 gene (Jayadev et al., 2010). This dinucleotide deletion results in a frameshift and premature stop codon that putatively truncates the PSEN2 protein in its first luminal loop. Interestingly, this truncated protein (if it is expressed) would closely resemble the PS2V isoform of PSEN2 that is generated in neurons under hypoxia and is observed in the brains of people with late onset, sporadic Alzheimer's disease (Sato et al., 1999; Smith et al., 2004). We have used mRNA injection into zebrafish embryos to show that the putative peptide produced by *PSEN2* mutation *K115Efx10* can stimulate γ-secretase activity and suppress the unfolded protein response (UPR) (Moussavi Nik et al., 2015) in a manner similar to that observed for PS2V by Sato et al. (2001). This suggests that the *K115Efx10* mutation that truncates PSEN2 may be pathogenic due to stimulation of Aβ production from APP and supports increased Aβ levels as a common link between *K115Efx10* early-onset Alzheimer's disease and late-onset sporadic Alzheimer's disease. Interestingly, by injecting mRNA coding for PS2V together with morpholinos blocking translation of either endogenous zebrafish Psen1 or Psen2 protein we were able to show that PS2V's action on γ-secretase activity requires Psen1 but not Psen2 activity (Moussavi Nik et al., 2015). In this study we also demonstrated that zebrafish possess a PS2V-like isoform, PS1IV, that is produced from the fish's *PSEN1* rather than *PSEN2* orthologous gene. The molecular mechanism controlling formation of PS2V/PS1IV was probably present in the ancient common ancestor of the *PSEN1* and *PSEN2* genes. Even though human PS2V and zebrafish PS1IV have highly divergent structures we were still able to demonstrate conserved function, in that PS1IV is also able to stimulate γ-secretase activity and suppress the UPR under hypoxia. In a recently published study (Ebrahimie et al., 2016), we used a morpholino to specifically block the induction of PS1IV that normally occurs under hypoxia. Through analysis of the subsequent microarray data we identified gene regulatory networks that are modulated by PS1IV. When PS1IV is absent under hypoxia-like conditions, we observed changes in expression of genes controlling inflammation (particularly sporadic Alzheimer's disease-associated *IL1B* and *CCR5*), vascular development, the UPR, protein synthesis, calcium homeostasis, catecholamine biosynthesis, TOR signaling, and cell proliferation. Our results imply an important role for PS2V in sporadic Alzheimer's disease as a component of a pathological mechanism that includes hypoxia/oxidative stress.

3.2.2 Other Components of γ-Secretase

In humans, γ-secretase complexes include three components other than a PSEN1 or PSEN2 protein. The three components are ANTERIOR PHARYNX DEFECTIVE 1A or 1B encoded by *APH1A* and *APH1B*, respectively;

NICASTRIN encoded by *NCSTN* and PRESENILIN Enhancer 2; *C. ELEGANS*, HOMOLOG OF encoded by *PSENEN* (previously known as *PEN2*). Zebrafish apparently possess orthologous genes *aph1b* (but not *aph1a*) (Francis et al., 2002), *ncstn* (Lim et al., 2015; Strausberg et al., 2002), and *psenen* (Campbell et al., 2006; Francis et al., 2002). Only *psenen* has been subjected to functional investigation of any depth. Xia's laboratory used a morpholino to block translation of Psenen and saw increased destabilization of Psen1 protein, reduced neuron formation and defective somitogenesis as expected for the loss of Notch signaling caused by loss of γ-secretase activity (Campbell et al., 2006). A similar somatic phenotype was seen when translation of Aph1b was blocked (Campbell et al., 2006). Interestingly, blockage of Psenen translation caused much greater induction of apoptosis in developing embryos than blockage of Psen1, Psen2, or Aph1b translation and this apoptosis could be blocked by simultaneous blockage of p53 translation [indicating that induction of the apoptosis was via the p53 pathway (Campbell et al., 2006)]. The same laboratory also used coinjection of Psenen morpholino and Psenen mRNA (engineered to lack the morpholino-binding site) to show that the cytosolic loop domain of Psenen was essential to inhibit the caspase-dependent apoptosis seen when Psenen expression is lost. They also showed that loss of NF-κB function (via blockage of translation of NF-κB component p65) could block this apoptosis (Zetterberg et al., 2006).

3.2.3 Assays for γ-Secretase Activity in Zebrafish

Over 70 proteins are known to be substrates of γ-secretase (Lleo and Saura, 2011) and changes in γ-secretase activity can affect some substrates but not others (Wolfe, 2012). There are, as yet, no published assays in zebrafish that directly observe γ-secretase cleavage activity. To date, analysis of γ-secretase activity in zebrafish has exploited changes in the transcription of genes that are known to be the downstream target of Notch signaling, such as *hairy-related 6* (*her6*) (Arslanova et al., 2010; Bernardos et al., 2005; Campbell et al., 2006) and *neurogenin1* (*neurog1*) (Campbell et al., 2006). However, the transcriptional control of these genes varies in different regions of the embryo (Arslanova et al., 2010; Campbell et al., 2006), so it is not informative to use qPCR on whole embryos to assay their expression in response to factors changing γ-secretase activity. For this reason, changes in the expression of Notch target genes are observed by in situ transcript hybridization in particular tissues (Arslanova et al., 2010; Campbell et al., 2006; Nornes et al., 2008). However, in situ transcript hybridization is a very difficult technique to use quantitatively since the staining of embryos that indicates gene transcription is sensitive to fixation conditions, permeabilization, and incubation times in reagents, etc.

Assessment of γ-secretase cleavage of APP in manipulated zebrafish embryos by monitoring of endogenous Appa cleavage is difficult since the α- or β-secretase cleaved forms of Appa (that are the substrate for γ-secretase cleavage) cannot be detected before 48 hpf. For this reason Wilson and Lardelli (2013) have developed an assay where a modified fragment of Appa (equivalent to the membrane embedded remnant after β-secretase cleavage) fused to GFP is expressed in embryos by mRNA injection or transient Tol2 vector transgenesis. This construct is coexpressed with free GFP and then the ratio of Appa:GFP to free GFP is quantified. Use of this assay system has shown that PSEN2 truncated by the *K115Efx10* mutation boosts APP cleavage in a similar manner to PS2V (Moussavi Nik et al., 2015).

3.2.4 Assays for Autophagy in Zebrafish

Recently, it was discovered that Presenilin proteins apparently play a major role in autophagy since they are required for the acidification of lysosomes (Lee et al., 2010) [although another report disputed this Zhang et al. (2012a)]. FAD mutants of human PSEN1 are defective for this autophagy function. Interestingly, the autophagy function of PSEN1 appears to be dependent on the PSEN1 holoprotein rather than on the endoproteolysed form of PSEN1 that is active in γ-secretase complexes. An inhibitor of γ-secretase also had no effect on autophagy (Lee et al., 2010). He et al. (2009), He and Klionsky (2010) have shown that autophagy can be analyzed in fish by analyzing induction of LC3-II protein (one of the major biochemical markers of autophagy) by immunoblotting using an antibody against human LC3 that cross-reacts with the zebrafish protein. Ganesan et al. (2014) validated the LC3-II immunoblot autophagy assay in the presence of chloroquine (a lysosomal proteolysis inhibitor). He et al. (2009), He and Klionsky (2010) have also developed a transgenic zebrafish expressing GFP coupled to LC3 that can be used in autophagy assays. The ability to manipulate Presenilin protein expression and assay autophagy in zebrafish might rapidly reveal more about the involvement of Presenilins in autophagy and how this relates to their other role in γ-secretase activity (Ganesan et al., 2014).

3.2.5 APP

For the two zebrafish APP paralogs, *appa* and *appb* in situ transcript hybridization analysis detects their expression during embryogenesis after the start of gastrulation. By 24 hpf, their transcripts are found in the developing brain and other tissues with only appb expressed in the spinal cord (Musa et al., 2001). The expression of these genes has also been examined in other ways. Lee and Cole (2007) fused ~8.5 kb of appb sequence upstream of and including the *appb* promoter to GFP and followed this with 5 kb of sequence from the first *appb*

intron. They observed expression in neural and other tissues including in developing vasculature (intersomitic vessels). The observations of vascular expression did not correspond to what had been seen from in situ transcript hybridization other than for expression in the dorsal aorta (Lee and Cole, 2007). Subsequently, Shakes et al. (2008) used GFP-enhancer trapping within a BAC clone of *appb* to analyze transcriptional regulation of this gene. In effect, they generated a series of deletions within the BAC clone and this was then introduced into zebrafish embryos to observe the pattern of GFP expression. They did not mention observation of vascular expression but they found that an enhancer within intron 1 of *appb* also required sequences far upstream of the gene to generate expression resembling that of the endogenous gene.

Recently, Liao et al. (2012) isolated insertions of gene traps containing GFP in the *appa* gene and the related gene *aplp2*. For both genes, the gene traps caused fusions to GFP of the extracellular domains of the proteins they encode. Interestingly, the fusion proteins of both genes were found in vasculature but in situ transcript hybridization could not detect transcription of these genes in endothelial cells of the vasculature. It appears that the proteins are synthesized in neuronal tissue but that their extracellular domains subsequently accumulate in vasculature. This observation suggests that the belief that mammalian APP is transcribed in vasculature may be inaccurate.

Translation-blocking morpholinos and mRNA injection into embryos have also been used to analyze the function of the zebrafish Appa and Appb proteins. Inhibition of Appa translation in developing embryos had little effect. However, it was demonstrated that Appb is required for correct convergent extension cellular movements (Abramsson et al., 2013; Joshi et al., 2009) and normal neural development (Song and Pimplikar, 2012) with axon outgrowth defects corresponding with cytoskeletal organization being observed (Song and Pimplikar, 2012). Coinjection of the morpholino blocking Appb expression with mRNA encoding human APP (that cannot bind the morpholino) rescued the embryonic defects and demonstrated the conservation of function in development between the human and zebrafish proteins (Abramsson et al., 2013; Joshi et al., 2009; Song and Pimplikar, 2012). Interestingly, the convergent extension defects could also be rescued by injection of mRNA encoding only the extracellular domain of human APP usually released by α-secretase cleavage but not by a larger protein including the transmembrane domain but lacking the last 18 C-terminal residues that include the EYNPTY motif or by APP containing the Swedish mutation (APP_{SWE}). Morpholino knockdown studies of *appb* have also demonstrated the importance of Appb in motor neuron patterning and formation (Abramsson et al., 2013), neurogenesis, notch signaling,

and in the formation of a specific cell type, the Mauthner cell, in the developing hindbrain (Banote et al., 2016).

3.2.6 Modeling Aβ Toxicity

The small size of zebrafish embryos and larvae means that individuals can be placed in the wells of microtiter plates and these then used for screening the effects of chemical libraries (Lessman, 2011). This strategy can be used to discover therapeutic compounds for disease states when these states can be modeled in fish. The amyloid hypothesis of Alzheimer's disease supposes that the Aβ peptide or its aggregates can be toxic and so considerable effort has been expended to find compounds to suppress Aβ production or to counter this toxicity. To date, the only published attempt to generate a transgenic model of Aβ toxicity in fish involved expression of $Aβ_{42}$ fused to an optimized secretory signal sequence in the melanin-containing pigment cells of zebrafish (melanophores/melanocytes) using the promoter of the gene *mitfa* (*nacre*) (Newman et al., 2010). It was hoped that this would produce an easily visible but viable phenotype of a disrupted surface pigmentation pattern. Unfortunately, a disrupted pattern only became evident after 16 months by which time the fish were aged adults and effectively sterile.

An alternative strategy for observing Aβ toxicity is simply to expose developing embryos to Aβ in their aqueous support medium. $Aβ_{40}$ (2.5 μM) caused defective development including of the vasculature and accelerated cell senescence (Donnini et al., 2010) as indicated by staining for β-galactosidase activity (Kishi et al., 2008). In their prion protein (PrP) morpholino knockdown model, Sempou et al. (2016) treated 5 hpf embryos with 0.5 μM of oligomeric Aβ. It has been reported that PrP transduces neurotoxic signals from Aβ oligomers in Alzheimer's patients through a not well-defined mechanism (Larson et al., 2012; Um et al., 2012). The treatment of embryos with Aβ oligomers induced biochemical changes consistent with their defined PrP gain-of-function phenotype. More recently, $Aβ_{42}$ peptides were directly injected into the 24 hpf zebrafish brain (Nery et al., 2014). At 5 days postfertilization (dpf), the injected larvae displayed cognitive deficits (demonstrated via a decreased response to avoid an aversive stimulus) and increased Tau phosphorylation. These effects were not accompanied by an increase in apoptosis and could be reversed by lithium treatment. These Aβ toxicity model systems could be useful for future pharmacological screening to alleviate the observed effects.

3.2.7 Hypoxia

Considerable evidence supports that hypoxia may be an important early factor in the etiology of Alzheimer's disease. For example, serum biomarkers of hypoxia can differentiate between people with mild cognitive impairment (MCI) that progress to Alzheimer's disease and those who do not (Oresic et al., 2011), and Aβ levels in serum can be greatly increased after cardiac arrest (Zetterberg et al., 2011). Hypoxia causes the electron transport chain of mitochondria to increase free radical production thus producing oxidative stress (Bell et al., 2007), and cardiovascular risk factors [that are also risk factors for Alzheimer's disease (Kotze and van Rensburg, 2012)] would be expected to affect oxygenation of the brain. Zebrafish are an excellent system for analysis of the biological effects of hypoxia [reviewed by van Rooijen et al. (2011)] and have been proposed as a model for hypoxic–ischemic brain damage (Yu and Li, 2011). Zebrafish embryos and adults can be placed in water depleted of oxygen, and Moussavi Nik et al. (2011) have shown that exposure of embryos and larvae to sodium azide can be used to mimic the effects of hypoxia. Hypoxia produces changes in the splicing of the zebrafish *psen1* gene that are functionally equivalent to human PS2V formation (Moussavi Nik et al., 2015), and Moussavi Nik et al. (2012) showed that, as in humans, the zebrafish *psen1*, *psen2*, *appa*, *appb*, genes as, well as *bace1* (that encodes β-secretase) are upregulated by hypoxia in larvae and adult brain. This supports that production of Aβ is a protective response to hypoxia although Aβ itself has not yet been detected in zebrafish. Interestingly, this study showed that F2-isoprostanes (caused by peroxidation of arachidonic acid) are not suitable as a marker for oxidative stress in zebrafish because of the much lower levels of arachidonic acid in zebrafish compared to mammals. Upregulation of *catalyse* gene expression is an alternative marker of oxidative stress (Jin et al., 2011; Moussavi Nik et al., 2012; Tseng et al., 2011).

3.2.8 APOE

The APOEε4 allele is the main genetic risk factor for late-onset, sporadic Alzheimer's disease. According to Genin et al. (2011), APOE should be considered "a major [Alzheimer's disease] gene with semidominant inheritance." APOE activity is important for clearance of Aβ from the brain [reviewed in Huang and Mucke (2012)] and recent evidence suggests that the pathological ε4 allele may undermine blood–brain barrier integrity (Bell et al., 2012). In zebrafish, the *apoe* genes, *apoea* and *apoeb*, have been analyzed in a variety of contexts. Both *apoea* (Raymond et al., 2006) and *apoeb* (Pujic et al., 2006) show expression in the developing retina and in the yolk syncytial layer of the developing zebrafish. Expression of *apoeb* has also been observed in a variety of other tissues/cell types, such as microglial cells (Veth et al., 2011), developing fins, and epidermis (Monnot et al., 1999; Tingaud-Sequeira et al., 2006), macrophages (Lien et al., 2006), liver, intestine, and ovary (Levi et al., 2012). Expression of *apoeb* has also been observed in regenerating fin tissue

(Monnot et al., 1999). Although little research on APOE function in zebrafish has been performed to date, zebrafish lend themselves to analysis of vascular development and function, for example, through the existence of GFP-labeled vasculature, such as provided by fli1a:EGFP transgenic fish (Lawson and Weinstein, 2002), so we expect to see future work in this area.

3.2.9 MAPT/tau

Alzheimer's disease is classed as a tauopathy and Bai and Burton (2011) have previously discussed the use of zebrafish to analyze this class of diseases. The same laboratory has successfully used the promoter of the *enolase2* gene, *eno2*, to drive expression of a human *MAPT* gene encoding 4 tubulin-binding repeats (R), MAP-Tau4R, in neurons (Bai et al., 2007) at levels eightfold higher than in human brain. Since changes in the ratio of 3R to 4R isoforms of MAPT may be important in some tauopathies (Liu and Gong, 2008), such overexpression of a single isoform might generate pathological states. Another example of MAPT overexpression was the work by Paquet et al. (2009) in which cDNA encoding a mutant form of human MAPT associated with FTD, TAU-P301L, was expressed in zebrafish neurons using a binary and bidirectional transgenic system. A *HuC* promoter was used to drive expression of a Gal4:VP16 fusion protein and this protein then bound to UAS sites in a bidirectional promoter transcribing a fluorescent marker protein gene (DsRed) and the TAU-P301L transgene. This transgenic system is only active in the progeny of fish bearing Gal4:VP16 when these are mated with fish bearing the TAU-P301L transgene. This allows the separate transgenic lines to survive when the combined action of the two transgenes causes a neurodegenerative phenotype. The system is also notable for the fact that the neurons expressing the TAU-P301L transgene could easily be identified due to the coexpression of DsRed in those cells. Paquet et al. were able to use the neurodegenerative phenotype to test the efficacy of inhibitors of GSK-3β that phosphorylate the mutant human TAU in this system. They also exploited the system to investigate whether they could observe any ameliorative effect of the compound methylene blue (van Bebber et al., 2010) that has been proposed to be possibly efficacious in treating Alzheimer's disease [reviewed by Oz et al. (2009)]. They did not observe any ameliorative effects of methylene blue on their transgenic system. Note that, since no comparison was made between the phenotype caused by expression of nonmutant versus mutant MAPT in the fish, it is not certain whether the neurodegenerative phenotype observed is due to the P301L mutation or to overexpression of the human protein, or both. There was also no attempt to quantify the expression of the human protein relative to the expression of the endogenous zebrafish *mapt* genes.

The transient expression of tau-GFP (zebrafish and human) under the control of the HuC promoter in zebrafish embryos also results in high levels of neuronal death (Wu et al., 2016). Treatment of these embryos with either signaling factors (Bcl2-L1, Nrf2, and GDNF) or chemical compounds exhibiting antiapoptotic, antioxidative, or neurotrophic effects can prevent the tau-GFP neuronal cell death. This transient tau-GFP system could be used to discover novel drugs against tauopathies.

GWAS have identified *PICALM* as a locus associated with increased Alzheimer's disease risk. In experiments performed in HeLa cells, Moreau et al. (2014) demonstrated that PICALM modulates autophagy and alters the clearance of tau (a known autophagy substrate). They confirmed this function of PICALM in vivo, using zebrafish transgenic tau models. In their first model, they generated an expression construct comprising a green-red photoconvertible fluorescent protein fused to human tau that was mosaically expressed in the epithelial and muscle cells of the zebrafish. Mosaic tau zebrafish were imaged before and after photoconversion to determine the clearance of the photoconverted red fluorescently tagged tau protein. They confirmed that tau clearance is predominantly mediated by autophagy (through immunoblotting for LC3 levels). Subsequent overexpression of PICALM in the mosaic zebrafish reduced clearance of Tau through inhibition of autophagy. In their second model, they examined the effect of PICALM overexpression on tau toxicity in transgenic zebrafish expressing EGFP-tagged human tau under the control of the rhodopsin promoter that drives expression in the rod photoreceptors (rho:GFP-tau). Through comparisons to transgenic zebrafish expressing rho:GFP (i.e., no tau), they demonstrated neurodegeneration through an increase in apoptotic cells in the retina of the rho:GFP-tau zebrafish. Overexpression of PICALM specifically in the photoreceptors (through electroporation of PICALM DNA) resulted in an acceleration of the neurodegeneration previously observed and in increased tau phosphorylation in the rho:GFP-tau zebrafish only. Rapamycin treatment of rho:GFP-tau zebrafish was able to rescue photoreceptor degeneration in the unelectroporated eyes but not in the PICALM electroporated eyes suggesting that the effect of PICALM on tau toxicity is autophagy dependent. This study is an excellent example of how the zebrafish model can be utilized to answer specific questions about the mechanisms behind Alzheimer's disease in an in vivo setting. Their zebrafish models provided support for the demonstrated mechanistic link of an Alzheimer's disease GWAS risk factor (PICALM) with tau accumulation and autophagy.

The zebrafish genes *mapta* and *maptb* were identified by Chen et al. (2009) who noted their similar but not completely overlapping patterns of expression in developing embryos. In particular, only *maptb* is strongly

expressed in the trigeminal ganglion and dorsal sensory neurons of the developing spinal cord during embryogenesis. Interestingly, *mapta* is expressed as 4R–6R isoforms while *maptb* is predominantly expressed as 3R isoforms. This suggests that manipulation of the expression of these two genes may be informative for understanding the role of the 3R:4R ratio in tau pathogenesis and this contrasts with the mouse which mainly expresses 3R forms of *Mapt*. In unpublished work, Chen et al. have shown that manipulation of *mapta* and *maptb* expression can cause abnormalities in axonogenesis from the trigeminal ganglion. We have assessed the splicing of transcripts of the *mapt* genes in the adult zebrafish brain under hypoxic conditions. We find that hypoxia causes increases in the *mapta* and *maptb* transcript isoforms, particularly the 6R and 4R isoforms of *mapta* and *maptb*, respectively. Expression of the zebrafish ortholog of human *TRA2B*, *tra2b* (that encodes a protein that binds to *MAPT* transcripts to regulate splicing), was reduced under hypoxic conditions, similar to observations in Alzheimer's disease brain. Overall, these findings indicate that hypoxia can alter splicing of zebrafish *MAPT* coorthologs promoting formation of longer transcripts and possibly generating Mapt proteins more prone to hyperphosphorylation. This supports the use of zebrafish to provide insight into the mechanisms regulating *MAPT* transcript splicing under conditions that promote neuronal dysfunction and degeneration (Moussavi Nik et al., 2014).

3.2.10 The Future for Zebrafish Models

Whether the zebrafish can be employed to model a late-onset disease like Alzheimer's disease is debatable since zebrafish have a profound capacity for regeneration and this must impact on the development of neurodegenerative phenotypes. Neurogenesis in the adult zebrafish brain is much more abundant than is observed in mammals (Kizil et al., 2012), consequently making analysis of neuronal loss difficult. However, zebrafish do have high physiological and genetic homology with humans and a similar central nervous system with many behaviors being evolutionarily conserved between zebrafish and mammals. As discussed by Kalueff et al. (2014), the zebrafish is an emerging model for studying a number of complex brain disorders.

Even though the zebrafish has primarily been used to analyze how genes involved in human disease play roles during early zebrafish development; the zebrafish adult brain is becoming increasingly used to investigate Alzheimer's disease. For example, assessment of embryo lead exposure on latent neurological alterations was analyzed in 12-month-aged zebrafish brains (Lee and Freeman, 2016). Microarray analysis of these brains revealed female-specific gene expression changes in the Alzheimer's disease-related genes *APP*, *APOE*, and *SORL1*. This group also demonstrated gender-specific expression changes in Alzheimer's disease-related genes in untreated zebrafish (Lee et al., 2016). Female adult brains showed an upregulation of *appa*, *appb*, and *psen1*, and a downregulation of *apoea* and *apoeb* in 12-month brains compared to 6-month brains. This was not observed in male adult fish brains. Furthermore, Nada et al. (2016) proposed that they had developed a drug-induced Alzheimer's disease zebrafish model by using okadaic acid. Although these drug exposure models still require further validation, it demonstrates the potential utility of the adult zebrafish.

The zebrafish provides unique advantages for modeling single FAD mutations and for transcriptomic and proteomic analysis of gene expression in mutant brains. Single, whole brains provide sufficient RNA or protein for "omics" analyses. The genetic noise that influences human brain transcriptome analyses due to genetic and environmental variation can be greatly reduced by analyzing multiple inbred sibling zebrafish raised in the same tank. Furthermore, zebrafish larvae are the most versatile available vertebrate model system for the screening of chemical libraries to find candidate drugs to treat disease (Rennekamp and Peterson, 2015). Therefore, the development and subsequent analysis of FAD genetic zebrafish models will potentially reveal underlying causes of Alzheimer's disease and also open up new pathways to the development of anti-Alzheimer's disease drugs.

4 MAMMALIAN MODELS OF ALZHEIMER'S DISEASE

Invertebrates provide us with excellent opportunities to decipher the biochemical roles of genes and the implications of genetic mutations in a minimalistic system. Nonmammalian vertebrates enable deciphering of the roles of these genes in disease pathogenesis in relatively simplistic and highly manipulable systems. However, neurodegeneration related to specific human diseases is not a global event and initiates in specific brain compartments. For example, FTD is characterized by prominent neurodegeneration in temporal and/or frontal lobes of the brain (Rabinovici and Miller, 2010), while neurodegeneration in Alzheimer's disease is located to hippocampus, forebrain, and cortex (Bilbul and Schipper, 2011). Thus nonmammalian vertebrates with simpler brain structures cannot faithfully emulate the neurodegeneration observed in human disease. Furthermore, although studies of the cognitive abilities of nonmammalian vertebrates have gained traction in recent years (Marder, 2002), they are yet not very well established. Thus, in some situations, higher order vertebrates with greater homology to human physiological processes and

anatomical structures can be more appropriate for neurodegenerative disease modeling.

The obvious choice to model human neurodegeneration would be the genetically proximal and anatomically similar nonhuman primates (NHP). NHPs have similar brains, cellular metabolomics, and share many of the physiological and behavioral characteristics of humans (Chan, 2004; Lane, 2000). In addition, NHPs show similar age-related cognitive impairment (Joly et al., 2014; Nagahara et al., 2010) and cerebral pathology as observed in human aging (Heuer et al., 2012; Ndung'u et al., 2012), thus NHPs can serve as a model for spontaneous disease development. However, the high costs associated with maintenance of NHPs make large-scale studies prohibitive. In addition, currently it is difficult to generate transgenic NHPs, limiting the use of NHPs in modeling human neurodegeneration (Chen et al., 2012a). Nevertheless, NHPs have been employed as an intermediary animal model when translating research from rodent models to humans (Verdier et al., 2015) [for a review on NHPs see Camus et al. (2015), Huang et al. (2016)]

In contrast to NHPs, mammalian rodent models are more amenable to transgenic techniques, easier to maintain, cost effective, and have a relatively short life span. Although, in comparison to NHPs, rodents are genetically distant to humans, in terms of evolutionary history they are more closely related to humans than the nonmammalian vertebrates (Jucker, 2010), and they can show gene expression profiles similar to humans (Chan et al., 2009; Strand et al., 2007; Zheng-Bradley et al., 2010).

Mouse models currently are the most popular choice for modeling Alzheimer's disease, as mouse transgenic techniques are well established (Doyle et al., 2012) (enabling easy generation of transgenic mice). Mice also have a shorter life span (enabling quick assessment of experiments), have multiple progeny (enabling quick transgenic family expansion), with a relatively short gestation period of ~21 days (enabling large-scale and generational studies). Their husbandry and maintenance costs are also lower than for other mammals. Thus mouse models can be more suitable and practical for modeling human neurodegeneration (Leung and Jia, 2016). In addition, the cognitive abilities of rodent models have been very well characterized and faithfully emulate neurodegeneration along with associated cognitive and behavioral changes (Webster et al., 2014). Murine models of Alzheimer's disease have played an important role in providing significant insight into mechanisms underlying the amyloid hypothesis and are the most commonly used in vivo tool for screening in preclinical drug trials. However, it must be noted that rodents themselves are poor natural models of Alzheimer's disease and do not exhibit pathological hallmarks of the disease, partly due to differences to human Aβ and tau species and aggregation states of these proteins. Thus, transgenic mice expressing human genes have been employed to study familial Alzheimer's disease-related mutations in genes involved in Aβ metabolism (i.e., APP and/or the PSEN genes) and/or tau (MAPT). These transgenic mice have been generated using both random transgene integration and knock-in techniques. In addition, knockout models have also been used to examine the implications of certain Alzheimer's disease-related genes, such as PSEN1/2, APOE, and BACE (see later) in disease pathogenesis.

While murine models have been assumed to be excellent models of autosomal dominant familial forms of Alzheimer's disease, their relevance to the more common, sporadic, late-onset form of the disease has been more contentious. Although genetic predisposition is associated with sporadic Alzheimer's disease, environmental, metabolic, and lifestyle risk factors are thought to play a more important role in disease pathogenesis (Chakrabarti et al., 2015; Piaceri et al., 2013; Stozicka et al., 2007). Further limitations to murine models of Alzheimer's disease include levels of transgene expression (Epis et al., 2010), variations due to genetic background (Lehman et al., 2003a), and the presence of both human and endogenous murine Aβ and tau confounding the interpretation of results (Howlett and Richardson, 2009). Thus to investigate pathogenesis of sporadic Alzheimer's disease, there is an increasing interest in developing nontransgenic animal models for Alzheimer's disease.

In addition to NHPs, other higher mammalian models have been investigated for Alzheimer's disease research as alternatives to the mouse and rat. Polar bears, dogs, and dolphins have all been reported to exhibit age-related pathological features, such as amyloidosis, neuronal-fibrillary deposition, and cognitive deficits similar to humans (see later). The obvious disadvantages of these animals are difficulty of maintenance and the length of time (years to decades) before pathology is observed. Smaller nontransgenic animal models, such as guinea pigs and rabbits are alternatives. Like mice and rats, guinea pigs and rabbits are experimentally amenable but, unlike mice or rats, they show higher sequence conservation to humans in important Alzheimer's disease-associated genes and their Aβ sequence is identical to that of humans. The subsequent section details the characteristics of the most commonly utilized transgenic mouse models for Alzheimer's disease and relevant knock-in and knockout models. Limitations of these mouse models and the growing interest in utilizing nontransgenic models as a more representative model for sporadic Alzheimer's disease will also be discussed.

4.1 Transgenic Rodent Models

4.1.1 Transgenic Mouse Models

The major attribute that has established the mouse as a mainstream model in Alzheimer's disease research is its ability to be genetically manipulated using well-developed transgenic technologies. Various transgenic techniques have been employed to investigate the role of autosomal dominant Alzheimer's disease mutations in mice. In contrast, although rats are more amenable to surgical interventions and cognitive training and are more relevant to human disease from a neuropsychological perspective, transgenic techniques are still under development.

Both random and targeted transgenic methods have been used to develop Alzheimer's disease transgenic models. In the former case, FAD-associated mutations are introduced to the existing murine genetic background (i.e., with the murine endogenous gene expressing simultaneously), using either small cDNA-based expression constructs or artificial chromosomes. Small cDNA-based transgenic models are most commonly driven by a strong neural-specific promoter, such as the platelet derived growth factor-beta (PDGP) promoter (Hsia et al., 1999; Mucke et al., 2000), hamster prion promoter (PrP) (Borchelt et al., 1996; Chishti et al., 2001; Hsiao et al., 1996), or thymocyte antigen promoter (Thy1.2) (Lewis et al., 2000; Richards et al., 2003) which allow ~3- to 30-fold overexpression of the Alzheimer's disease-associated transgene (depending on the promoter applied and genetic background) (Jankowsky et al., 2005). Regionally restricted promoters, such as the calcium calmodulin kinase II (CamKII) promoter (forebrain-specific expression) have also been used (Jankowsky et al., 2005). The development of artificial chromosome-based technology has allowed the introduction of transgenes incorporating large genomic fragments (including the *cis*-acting elements required to regulate gene expression) into models. The transgenes are thus expressed under the control of "native" promoters and transcriptional effectors, which can recapitulate more closely the normal expression patterns of the endogenous gene.

The development of sophisticated gene-targeting technologies underpinned the use of the transgenic mouse as the dominant organism for modeling Alzheimer's disease. These powerful technologies allowed reproduction of the disease features by engineering of existing endogenous genomic loci rather than introduction of exogenous genes. Knockout models have been generated to examine the null phenotypes of particular Alzheimer's disease-related genes, such as *PSEN1* (Dewachter et al., 2002; Shen et al., 1997), *PSEN2* (Herreman et al., 1999), *APOE* (Piedrahita et al., 1992), and *BACE* (Cai et al., 2001). Chimeric models expressing human Alzheimer's disease-associated mutations have also been generated (Jankowsky et al., 2005; Reaume et al., 1996). In these models, key sequences of Alzheimer's disease-related genes were "humanized" and FAD-associated mutations were introduced by targeted point mutation. In such models, the mouse genome remains mostly unchanged except for one or more mutated amino acids. This form of model avoids potential problems resulting from gene overexpression, disrupted spatial and temporal expression, and coexistence of endogenous orthologous genes as seen in other transgenic models. However, the introduction of multiple simultaneous mutations into a genetic locus can still, potentially, confound analysis. Later, we discuss some of the mouse models that express Alzheimer's disease-relevant genes including APP, PS1, tau, apoE, or BACE.

4.1.2 Transgenic APP Models

Modeling of Alzheimer's disease in transgenic mice has been pursued largely under the influence of the amyloid hypothesis, whereby Aβ aggregation is a pivotal event in the disease pathogenesis driving neurodegeneration. However, initial attempts to recapitulate cerebral amyloid accumulation through overexpression of wild-type APP were of little success. Although a number of strategies were pursued (Fukuchi et al., 1996; Lamb et al., 1993; Neve et al., 1996), overexpression of wild-type APP did not result in cerebral deposition of amyloid plaques and cognitive deficits, or overt neuronal loss. Attention was rapidly redirected into the generation of a mouse model expressing FAD-causing mutations.

4.1.3 cDNA-Based Transgenic APP Models

The first success in developing a transgenic FAD-based model came from Games et al. (1995), who generated the PDAPP mouse. In this model, the APP Indiana mutation (V717F) was driven by a strong neuronal-specific PDGF promoter. Under the regulation of such a highly active promoter, the transgenic APP level was approximately 10-fold higher than that of the endogenous mouse APP. The Indiana mutation results in high Aβ$_{42}$ production and age-dependent accumulation of Aβ. In heterozygous mice, deposition of human Aβ begins at 6–9 months in the hippocampus, corpus callosum, and cerebral cortex. Condensed thioflavin S-positive senile plaques resembling those seen in Alzheimer's disease brains were seen after 9 months. Although widespread neuronal loss was absent, impairments in spatial memory and object recognition in young PDAPP mice were reported (Chen et al., 2000; Dodart et al., 1999; Huitron-Resendiz et al., 2002).

Similarly, the Tg2567 mouse was generated by overexpression of a human APP gene containing the Swedish mutation (KM670, 6711L) transcribed from the PrP promoter. The Swedish mutation is located on the N-terminal flanking region of the Aβ, and results in an increase

in $A\beta_{40}$ and $A\beta_{42}$ (Haass et al., 1995). In the Tg2567 mouse, the expression level of the mutant human APP was elevated more than fivefold above the endogenous mouse APP. In the brains of these mice the $A\beta_{40}$ and $A\beta_{42}$ peptides accumulate in an age-dependent manner. Deposition of amyloid plaques commences at 11–13 months in frontal, temporal cortex, hippocampus, presubiculum, subiculum, and cerebellum in a pattern reminiscent of that seen in human Alzheimer's disease. The mice demonstrated memory impairments and deficits in long-term potentiation typical of neuronal dysfunction. However, neuronal loss was not evident (Hsiao et al., 1996). Additionally, cerebrospinal fluid (CSF) $A\beta_{42}$ levels were reduced with the formation of amyloid plaques (Kawarabayashi et al., 2001), resembling the scenario that occurs in Alzheimer's disease patients (Blennow et al., 2006). Due to these characteristics, the Tg2567 line has been widely used in Alzheimer's disease research and for the preclinical evaluation of potential therapeutics. This mouse model also has been commonly used to cross with other transgenic mice containing mutations in PS1 or tau to accelerate amyloid deposition or generate mice containing both senile plaques and NFTs (discussed further subsequently).

Additional APP transgenic models have been generated using strategies similar to that implemented for generation of the PDAPP and Tg2567 lines, where cDNA-based single or double FAD APP mutants were overexpressed by a neuronal-specific promoter. These models often exhibit high expression of the human FAD APP mutation, $A\beta$ accumulation, and deficits in spatial and learning memory. However, the phenotypic features differed based on different mutations under investigation, the promoter used for expression, and the genetic background of the mouse line. For example, whereas the PDAPP line shows accumulation of $A\beta_{42}$, plaques in the Tg2567 line are mostly comprised of $A\beta_{40}$ (Johnson-Wood et al., 1997; Kawarabayashi et al., 2001). Similarly, in transgenic lines harboring the Dutch (APP^{E693Q}) mutation, more extensive accumulation of $A\beta$ in cerebral blood vessels in the form of cerebral amyloid angiopathy (CAA) and cerebral hemorrhage were reported (Herzig et al., 2004). While it is beyond the scope of this chapter to discuss every model, a brief summary of the characteristics of the more commonly used transgenic lines can be found in Table 40.3.

The cDNA-based transgenic lines provide a valuable system to replicate human cerebral amyloidosis in mice and have demonstrated cognitive deficits associated with accumulated $A\beta$. However, these models do not accurately reflect the pathologic condition of human FAD possibly due to the heterologous regulation and overexpression of APP and FAD mutant APP, which deviate considerably from the human conditions. To overcome these issues, transgenic mice have been created whereby an APP transgene is under the control of a native mouse promoter.

4.1.4 YAC/BAC-Based Models

Yeast artificial chromosomes (YACs) and BACs can accommodate large gene inserts including distant regulatory elements and, unlike cDNA-based expression systems, allow for a more spatial and temporally controlled expression of transgenes. Both YACs (Lamb et al., 1993, 1997) and BACs (Chiocco et al., 2004) have been used to express wild-type and clinical mutants of APP in mice. Using these artificial chromosome technologies, transgenic mice containing either the Swedish (swe) and/or London (lon) mutations were created where a more specific and accurate spatial and temporal expression of mutant APP was observed. In a transgenic mice referred to as J1.96 (containing human APP with both the Swedish and London mutations), a single copy of the *APPswe/lon* mutation was detected and the transcriptional expression of this transgene was similar to that of endogenous mouse *APP*. Expression levels of the full-length APP protein remained steady, but levels of the C-terminal fragment (C99) and $A\beta_{42}$ peptide increased twofold over that generated in a transgenic line expressing human wild-type APP (Py8.9) using the same strategy (Lamb et al., 1997).

In another mouse model containing the human *APPswe* mutation (R1.40), multiple copies of the transgene were identified and resulted in two- to threefold overexpression of the mutant APP. While the expression of full-length APP was constantly threefold above that of endogenous APP, the ratio of β/α-cleaved C-terminal APP fragments was dramatically increased. The levels of both $A\beta_{40}$ and $A\beta_{42}$ were proportionally elevated, providing in vivo evidence that the Swedish mutation facilitates β-site cleavage and that the London mutation is able to shift the γ-site toward the 42 aa form of $A\beta$ (Lamb et al., 1997). Comparisons with the cDNA-based transgenic mouse line Tg2567 revealed that both APP holoprotein expression and $A\beta$ production in the R1.40 line was much lower in the hippocampus. Abundant $A\beta$ deposition in the hippocampus was detected in the Tg2567 line at 13.5 months but not in the R1.40 mouse at the same age. In the cortex, the level of $A\beta_{40}$ was similar in both lines, although a significantly higher level of full-length APP was expressed in Tg2567. In the homozygous R1.40 line, $A\beta$ deposition occurred primarily in the frontal cortex at 13–16 months and spreads into hippocampus with age. Unlike the Tg2567 mouse line, cognitive deficits were not observed in both the J1.96 and R1.40 lines (Lehman et al., 2003b). Overall these results suggest that although the YAC/BAC-based systems allow more specific and accurate spatial and temporal expression of mutant APP, greater amyloid deposition and cognitive deficits are achieved by using heterologous promoters.

TABLE 40.3 Examples of Transgenic Mouse Models

Line	Transgene/promoter	Age of plaque onset (months)	CAA	NFTs	Behavioral phenotype	References
PDAPP	APP717I minigene/PDGF-β	6–8	*	—	Impaired spatial memory (3–4 months) Cued fear conditioning (11 months)	Games et al. (1995)

Chem. 271 (38), 23380–23388.

The reason(s) for the differences in Aβ deposition and cognitive state in these two transgenic lines harboring the same FAD mutations are not clear. One possible explanation may be the region-specific regulation of different promoters and the distinct transcriptional profile of the mutant human APP (i.e., the Tg2567 line only expressed the APP_{695} isoform, but all APP isoforms were present in the R1.40 line) (Lehman et al., 2003a).

4.1.5 Knock-Ins

A more elegant way to mimic the pathology of human FAD mutations and to avoid issues surrounding overexpression using specific promoters is to generate a knock-in model. Andrew et al. established the first human APP-swe knock-in line, termed APP SWE-KI in 1996. In this line, targeted mutagenesis technology was employed to introduce the Swedish mutation and "humanize" the mouse endogenous Aβ peptide by altering the three amino acids that differ from human Aβ. The expression level of the mutant APP was equivalent to that of wild-type, endogenous mouse APP, but generation of the APP β-CTF was greatly enhanced, accompanied by a nine-fold elevation of the level of Aβ (Reaume et al., 1996). However, amyloid pathology and associated cognitive deficits were not prominent, even by 22 months of age (Flood et al., 2002). In another knock-in model carrying the APP London mutation (V642I), an increased level of $Aβ_{42}$ was observed but amyloid plaque deposition was absent. Deterioration of long-term memory was evident in very old mice (27–29 months), while short-term working memory was preserved (Kawasumi et al., 2004).

The major difference between the knock-in model and other transgenic models is the absence of endogenous mouse Aβ. It has been shown that human Aβ can coaggregate with rodent Aβ in vivo with the potential to alter the structural conformation of Aβ plaques (Pype et al., 2003). This notion was supported by the finding that the Aβ peptide generated in the brains of Tg2567 transgenic mice lacks modifications, such as N-terminal degradations and levels were ~tenfold greater than that seen in human brains (Kalback et al., 2002). The knock-in models exclude the potential effect of interactions between human and rodent Aβ peptides on the development of pathology. Nevertheless, such studies have demonstrated that Aβ levels can be significantly elevated solely by the Swedish mutation without overexpression of APP in vivo. However, the absence of further histological pathology and behavioral changes in the knock-in mouse models possibly suggests that the pathology observed in other transgenic mice is due to the overexpression of the mutant transgenes and not to the effects of FAD-associated APP mutations themselves.

More recently, however, an APPKI mouse model has been generated that unlike previous attempts exhibit Alzheimer's disease pathology and cognitive deficits.

The model is referred to as the APP^{NL-F} mouse model and was generated by Takaomi Saido's laboratory from the RIKEN brain institute. The Aβ sequence of mouse APP was humanized and the Swedish mutation (KM670/671NL) and Beyreuther/Iberian mutation (I716F) were introduced into exons 16 and 17 of the mouse APP gene (Saito et al., 2014). These mice exhibited increased levels of $Aβ_{42}$ (with a high $Aβ_{42/40}$) ratio and plaque formation at 6 months of age, with similar pathology to that seen in human Alzheimer's disease brain (Saito et al., 2014). Other hallmarks were also exhibited including neuroinflammation, synaptic alterations, and cognitive impairment was observed at 18 months of age. Inclusion of the Arctic mutation (E693G) into exon 17 of mouse APP (APPNL-G-F), resulted in an accelerated pathology, with plaques. This model circumvents the intrinsic problems associated with APP transgenics [see review Nilsson et al. (2014)] and crossbreeding with other KO, KI mice could provide relevant insights into downstream neurodegenerative pathways.

4.1.6 Presenilin Models and Crosses

The Presenilin proteins (PSEN1 and PSEN2) are considered to be the catalytic components of the γ-secretase enzyme that promotes the final cleavage of APP to generate Aβ. Mice lacking PSEN1 die before birth and the embryos display severe skeletal and brain deformities while heterozygotes exhibit tau hyperphosphorylation, markedly reduced Aβ levels, massive neuron loss, and hemorrhages in the CNS (Rozmahel et al., 2002; Shen et al., 1997). These severe phenotypes due to the lack of PSEN1 have been associated with PSEN1's essential function in facilitating Notch signaling. Mice lacking PSEN2 on the other hand only develop a mild pulmonary fibrosis and hemorrhages with age (Herreman et al., 1999; Steiner et al., 1999), consistent with suggestions that PSEN2 is less efficient at γ-secretase activity than PSEN1 (Acx et al., 2014; Bentahir et al., 2006; Mastrangelo et al., 2005; Meckler and Checler, 2014, 2016).

The majority of FAD-associated mutations are located in the *PSEN1* gene. Most of these are associated with severe amyloid pathology in humans as a result of accumulation of the longer, more pathogenic $Aβ_{42}$ peptide species. As such, mice harboring *PSEN1* mutations have been generated, mainly for the purpose of crossing with APP transgenic mice to accelerate pathology. A few transgenic lines containing FAD-associated *PSEN2* mutations have also been generated. Similar transgenic approaches and promoters (such as the PDGF, PrP, and Thy1.8 promoters) were employed in the construction of PSEN1/2 transgenic lines. Although increases in endogenous murine $Aβ_{42}$ levels have been reported in a few PSEN transgenic lines, these mice do not exhibit an Alzheimer's disease-like neuropathology including

amyloid deposition, most likely due to the lower propensity of the endogenous rodent Aβ to aggregate (Duff et al., 1996; Wen et al., 2002). To promote cerebral amyloid deposition, mice expressing PSEN1/2 have been crossed with APP transgenic lines. These mice show accelerated plaque formation and some exhibit neuronal loss. One example is the model developed by Casas et al. who crossed the APP751SL line (harboring APP London and Swedish mutations), with a knock-in model expressing the PSEN1 mutations M233T and L235P. This model developed amyloid plaques at 6 months and exhibited neuronal loss at 10 months (Casas et al., 2004). Interestingly, the neuron loss observed in this model was not associated with extracellular amyloid plaque load, but closely correlated with the presence of intraneuronal Aβ (Casas et al., 2004).

A more aggressive amyloid pathology has been reproduced in a 5xFAD line, which expresses the APP Swedish, Florida, and London mutations, and the PSEN1 M146L and L286V mutations from a Thy1 promoter (Oakley et al., 2006). The combination of these mutations led to a >25-fold increase in the $A\beta_{42}/A\beta_{40}$ ratio in a 9- to 12-month-old mouse compared to the Tg2576 transgenic at a similar age. The accumulation of Aβ commences as early as 2 months of age (compared to Aβ deposition in the Tg2576 mouse that commences at 9–12 months). Formation of plaques initiated in the deep layer of the cortex and subiculum and spread to extensive areas of the cortex, subiculum, and hippocampus, which is similar to other Thy1 promoter driven APP transgene (Oakley et al., 2006). At 4–6 months of age, impairment in hippocampal-related function was evident (Kimura and Ohno, 2009; Ohno et al., 2004, 2006). At 9 months of age these mice show reduced synaptic function and neuronal loss, which correlates with accumulation of intraneuronal Aβ (Oakley et al., 2006; Youmans et al., 2012a). The 5xFAD mice have also recently been crossed to mice expressing APOEε4 and ε3. These mice develop plaques around 6 months of age and provide the opportunity to assess therapeutics in the presence of the major genetic risk factor for sporadic Alzheimer's disease, APOEε4 (Youmans et al., 2012b). Recently, cerebrovascular pathology, such as cerebral microbleeds and CAA have been shown to be exacerbated in female 5xFAD APOEε4 mice (Cacciottolo et al., 2016). These sex-biased APOEε4 effects on the cerebrovascular system were in contrast to observations in human Alzheimer's disease/dementia clinical cohorts, emphasizing the need for caution when interpreting sex-specific effects on pathology seen in these models.

4.1.7 Triple Transgenic Model (3xTg)

As discussed previously, rodent models expressing FAD-associated APP/PSEN1/PSEN2 single or multiple mutations do not successfully reproduce the tau pathology observed in the brains of Alzheimer's disease patients. Therefore, mice expressing mutations in the tau protein, associated with FTD were crossed with mice expressing FAD-associated mutations to achieve both cerebral amyloid deposition and tau pathology. In the APP2576/TauJNPL3 (P301L) transgenic line, increased tau tangle pathology was observed in the limbic system and olfactory cortex, and extended to the subiculum, hippocampus, and occasionally isocortex (Lewis et al., 2001). These are regions that do not exhibit tau pathology in mice bearing only tau transgenes. However, the presence of the mutated tau did not alter Aβ deposition (Lewis et al., 2001). Similarly, injection of Aβ peptide directly into the brains of transgenic mice possessing tau mutations can exacerbate tau pathology (Gotz, 2001). In a 3xTg mice line (with APPSWE, Tau-P301L, and PSEN1 M146V), selective reduction of early-stage tau pathology was evident when anti-Aβ antibodies were injected into the mice brains. However, later-stage tau pathology seemed to be resistant to this treatment (Oddo et al., 2004). Reduction of levels of the tau pathology also appeared to improve the Aβ-related memory impairment and reduced the susceptibility to excitotoxicity in the PDAPP mouse, without altering the high Aβ level (Roberson et al., 2007). The exact mechanism behind the synergistic toxic effect of Aβ and tau is not yet fully elucidated. However, Götz's laboratory showed that deficiency of tau may reduce Aβ toxicity by disrupting the postsynaptic targeting of Fyn, a kinase that acts on the NMDA receptor (Ittner et al., 2010).

Double or triple transgenic models with tau mutations shown a wider spectrum of pathologies resembling that in Alzheimer's disease and have provided valuable insights into the interaction between Aβ and tau pathology. However, NFTs found in Alzheimer's disease brain consist of hyperphosphorylated wild-type tau protein (not mutant tau) through activation of kinases/phosphatases. Tau pathology in the aforementioned mouse lines is induced by mutations in tau characteristic of other dementias including FTD and thus may not truly reflect the consequences of tau/Aβ pathology in Alzheimer's disease.

4.1.8 Crosses With APOE

Crossing of FAD transgenic mice with mice overexpressing or lacking genetic risk factors for sporadic Alzheimer's disease has provided insight into how risk factors influence cerebral amyloidosis. Another motivation behind generation of FAD mice expressing these genetic risk factors has been to attempt to provide more relevant models for sporadic Alzheimer's disease. The ε4 allele of apolipoprotein E (APOE) is by far the strongest genetic risk factor found in most populations studied and accounts for ~50% of Alzheimer's disease cases (Martins et al., 2009). The three major alleles of APOE gene encode

the three major isoforms of the apoE protein, denoted as apoE2, apoE3, and apoE4, which aid in the transport of triglyceride-rich lipoproteins (chylomicrons and VLDL), phospholipid, and cholesterol into cells. Although studies have shown apoE to mediate Aβ production and toxicity, the interactions of its isoforms with Aβ have been the most widely studied. The apoE4 isoform has been shown to bind Aβ poorly and to impair its clearance (Deane et al., 2008). These are two mechanisms by which it is thought to promote amyloid deposition and contribute to the Alzheimer's disease risk associated with the *APOEε4* allele.

The *APOE* knockout mouse model has been crossed to a number of amyloidogenesis models, such as the APPV717F (Holtzman et al., 1999), PDAPP (Fryer et al., 2003), APPswe (Fryer et al., 2003), and Tg2567 (Fryer et al., 2005) mice. In all of these models, the lack of mouse *APOE* appeared to reduce the level of Aβ, delay amyloid deposition, and prevent the development of CAA. Furthermore, the expression of human *APOE* (either the E4 or E3 isoform) in APPV717F, Tg2576, and APPswe mice delayed the development of amyloid deposition compared to mice expressing endogenous mouse *APOE*. Compared to the APPsw lines expressing *APOE E4*, the expression of *APOE E3* reduced amyloid plaques and prevented the formation of CAA.

A study in the PDAPP/TRE transgenic line [in which *APOE* is humanized (Bales et al., 2009)] suggested *APOE* isoform-dependent clearance of Aβ in brain interstitial fluid (Castellano et al., 2011). In mice expressing human *APOEε4* (*APOEε4*-targeted replacement mice), we have recently shown reduced peripheral clearance and reduced uptake of intravenously injected Aβ by two major organs that clear Aβ from the periphery, the liver, and kidney (Sharman et al., 2010). It was also found that levels of the Aβ degradation enzyme, insulin degradation enzyme (IDE) were reduced in the brain and kidney of mice harboring the *APOEε4* allele. The decreased capacity of apoE ε4 to clear/degrade Aβ from the periphery and the associated lower levels of IDE, particularly in the brain, suggested an explanation for the greater brain Aβ accumulation and Alzheimer's disease pathology in Alzheimer's disease individuals with APOEε4 alleles.

4.1.9 Transgenic Rat Models

Although the mouse model is commonly used, efforts have also been made to develop transgenic rat models. Rats offer an advantage over mice that they are closer to humans in terms of genetics (Gibbs et al., 2004), physiology (Jacob and Kwitek, 2002; Lin, 1995), and neurohistology (Tesson et al., 2005). In addition, rats perform better than mice in behavioral tests and the larger bodies of rats are more amenable to surgical procedures, electrophysiology, and neuroimaging, thus facilitating

easier neurological assessments following interventions (Tesson et al., 2005). Furthermore, and similar to humans, the rat possesses six isoforms of tau protein (Hanes et al., 2009), and rat apoE shares considerable (>73%) homology and biochemical properties with human ApoE protein (McLean et al., 1983; Tran et al., 2013). Thus it appears that rat models of Alzheimer's disease should allow for a more accurate assessment of various Alzheimer's disease pathologies implicated in cognitive decline.

Before the advent of rat transgenics, aged rats were used as a model of Alzheimer's disease. However, they failed to faithfully recapitulate Alzheimer's disease pathologies, such as Aβ deposition (Anderson et al., 1999; Echeverria et al., 2004b; Ruiz-Opazo et al., 2004), pronounced deficits in cholinergic and dopaminergic functions (Gilad and Gilad, 1987), and hippocampal degeneration (Greene and Naranjo, 1987).

Initial hAPP (wt or FAD mutant) transgenic rat models failed to show robust extracellular Aβ deposits. However, in these models the accumulation of intracellular Aβ deposition in the neocortical and cortical neurons and hippocampus triggered tau phosphorylation (Folkesson et al., 2007; Kloskowska et al., 2010) and dysregulation of hippocampal proteins involved in memory and learning (Echeverria et al., 2004a,b; Lopez et al., 2004; Vercauteren et al., 2004) leading overall to cognitive dysfunction. These initial rat studies reaffirmed the role of oligomeric Aβ in Alzheimer's disease pathogenesis [reviewed in Do Carmo and Cuello (2013)].

Flood et al. (2009) were the first to successfully generate a transgenic rat model showing robust amyloid deposition. They coexpressed the APP Swedish and London mutations in rats and this resulted in formation of amyloid deposition at 17–18 months. Amyloid deposition was accelerated by the introduction of a third human mutation, PSEN1 M146V, causing plaque formation to be evident by 7 months (Flood et al., 2009). In addition, this triple transgenic rat model showed impaired long-term potentiation accompanied by deficits in spatial learning and memory and this correlated with the level of Aβ in the hippocampus.

More recently, Leon et al. (2010) reported a novel transgenic rat model that appears to display a wide range of Alzheimer's disease-like pathology caused by a single transgene (hAβPPswe, ind). This mutation of human APP was expressed from the murine neuron-specific Thy1.2 promoter (Leon et al., 2010). Extracellular amyloid deposition was detected from 6 months of age in homozygous lines, starting from subiculum and spreading to the rest of the hippocampus and eventually the neocortex. Cognitive impairment was evident at 3 months of age in homozygous animals and correlated with the level of Aβ oligomers. Although the formation of NFTs has been demonstrated in rats expressing trun-

cated human tau protein (t151-391) (Stozicka et al., 2010; Zilka et al., 2006), a transgenic model that exhibits both amyloid plaques and NFTs is yet to be developed.

4.1.10 Modeling the Impact of Risk Factors in Alzheimer's Disease Pathology in Rodents—Type 2 Diabetes

The aforementioned rodent models are generated through incorporation of human genetic mutations that cause FAD, to induce relevant pathology. However, they have been utilized to provide insight into how risk factors contribute to the more common sporadic cases to promote pathology and Alzheimer's disease onset. Unlike FAD, sporadic Alzheimer's disease is multifactorial involving genetic, environmental, and life-style risk factors. Type 2 diabetes mellitus (T2DM) is one such risk factor, where nontransgenic and transgenic rodent models have been utilized to provide insight into underlying mechanisms as well as to evaluate the potential of antidiabetic medications in the treatment of Alzheimer's disease.

Like sporadic Alzheimer's disease, T2DM occurs more commonly in older age with a high prevalence in people >65 years of age. T2DM is characterized by several metabolic abnormalities, chronic inflammation, and cellular insulin resistance leading to elevated blood glucose levels. Similarly, Alzheimer's disease patients are typically hyperinsulinemic with concomitant reduced insulin sensitivity and reduced insulin receptor expression (Carro and Torres-Aleman, 2004a,b; De Felice, 2013a,b; de la Monte, 2012a,b; de la Monte et al., 2012; Steen et al., 2005; Talbot et al., 2012), metabolic stress and inflammation (Verdile et al., 2015). High glucose levels increase the risk of Alzheimer's disease (Crane et al., 2013) and Alzheimer's disease patients show severe dysregulation of glucose metabolism (Abolhassani et al., 2016; Arrieta-Cruz and Gutierrez-Juarez, 2016; Calsolaro and Edison, 2016; Carbonell et al., 2016; Chen and Zhong, 2013; Daulatzai, 2016; Jimenez-Bonilla et al., 2016; Li et al., 2016; Liguori et al., 2016; Minoshima et al., 1997; Morris et al., 2016; Mosconi, 2005; Mosconi et al., 2005, 2006; Oh et al., 2016; Tramutola et al., 2016). Brain imaging studies in T2DM cohorts have shown that diabetes is associated with brain atrophy (Moran et al., 2015) and cerebral glucose hypometabolism (Roberts et al., 2014; Thambisetty et al., 2013). One cross-sectional study of normal, nondiabetics has shown that higher insulin resistance is associated with increases in brain amyloid as measured by the amyloid radiotracer, C11PIB-PET (Willette et al., 2015). This is in contrast to the aforementioned studies in T2DM cohorts (which show no such associations). In human studies there is not yet a coherent explanation regarding how T2DM may promote the progression of Alzheimer's disease pathology. Amyloid deposition may be associated with early stages of insulin resistance whereas, with

the onset of T2DM, cerebral hypometabolism and neuronal dysfunction are main features. Larger, longitudinal studies with other biomarkers of disease are required to provide further insight. However, studies in various models of diabetes and, more recently, models of diabetes and Alzheimer's disease have provided insight into potential mechanisms.

Nontransgenic T2DM rodent (rat) animal models on a high fat/high sugar diet show hyperglycemia, whole body insulin resistance, hepatic steatosis, and defects in lipid and glucose metabolism (Buettner et al., 2006). These T2DM models also present brain inflammation (Pistell et al., 2010) with concomitant reduction in hippocampal brain-derived neurotrophic factor leading to reduced neuronal plasticity (Molteni et al., 2002) and cognitive impairment (Winocur and Greenwood, 2005; Winocur et al., 2005) and increased brain Aβ levels (Pedrini et al., 2009). In addition, a high fat/high sugar diet exacerbates Alzheimer's disease pathology in transgenic mice (Barron et al., 2013; Julien et al., 2010; Kadish et al., 2016; Knight et al., 2014; Kohjima et al., 2010; Ma et al., 2009; Martin et al., 2014; Petrov et al., 2015; Sajan et al., 2016; Shie et al., 2002; Tang et al., 2015; Vandal et al., 2014), either through altering APP processing (Refolo et al., 2001) or by reducing the activity of enzymes that degrade Aβ (Leissring et al., 2003). In these models reduction in brain insulin and insulin signaling are also features which can promote Aβ accumulation and tau hyperphosphorylation [recently reviewed in Verdile et al. (2015)].

The aforementioned studies induce an acute diabetic phenotype with diet manipulation in rodent models, but some researchers model the phenotype chemically, through administering streptozotocin (STZ) which induces islet β-cell failure (Wang et al., 2010) and thus failure to secrete insulin resulting in a type 1 diabetes phenotype. However, intracerebroventricular (ICV) injections of STZ in wistar rats can induce impairments in brain glucose metabolism (hyperglycemia) (Chen et al., 2012b; Heo et al., 2011; Lee et al., 2014) and glucose uptake (Heo et al., 2011) resulting in cognitive deficits (learning and memory loss) (Knezovic et al., 2015; Lannert and Hoyer, 1998; Mehla et al., 2014; Peng et al., 2013; Rodrigues et al., 2010; Shingo et al., 2012; Shonesy et al., 2012), reduced acetyl-CoA media neuronal transmission (Terwel et al., 1995) reduction in neuronal growth function (Duelli et al., 1994; Grunblatt et al., 2006), neuronal loss (Shingo et al., 2013), increased and hyperphosphorylation of tau (Chu and Qian, 2005; Peng et al., 2013), increased phosphorylated GSK-3β (Plaschke and Kopitz, 2015), reduced O-glycanation, increase APP secretases (Park et al., 2015), increased aggregated Aβ (Deng et al., 2009; Lin et al., 2014a; Salkovic-Petrisic et al., 2006), increased neuroinflammation (Chen et al., 2013), mitochondrial dysfunction (Correia

et al., 2013; Paidi et al., 2015), cerebral vascular amyloidosis (Salkovic-Petrisic et al., 2011), and increased oxidative stress (Mehla et al., 2012; Tahirovic et al., 2007a,b) [for more information see Correia et al. (2011), Salkovic-Petrisic and Hoyer (2007), Salkovic-Petrisic et al. (2013), Wang et al. (2014)]. Similarly, ICV administration of STZ in classical Alzheimer's disease transgenic animals, such as those described previously exacerbates Alzheimer's disease pathology (Chen et al., 2012b; Chen et al., 2013, 2014; Plaschke et al., 2010).

These models of diabetes, however, do not reflect the chronic nature of T2DM since they do not take into account the factors that promote progression to overt diabetes in subjects with insulin resistance, which occurs in a majority of type 2 diabetics. Islet amyloid formation and subsequent β-cell destruction has an important role in the progressive decline in insulin secretion and rising blood glucose levels typical of T2DM (Hoppener et al., 1999; Kahn et al., 1999). Islet amyloid is a characteristic pathologic feature of the pancreas in T2DM where >95% of patients have visible islet amyloid at autopsy which correlates with disease severity (Westermark, 1972).

A more chronic model of insulin resistance and hyperglycemia is the homozygous "obese" mouse (ob/ob). These mice develop insulin resistance and diabetes due to a mutation of the leptin gene and, when crossed with Alzheimer's disease (APP23) transgenic mice, Alzheimer's disease pathology and associated cognitive deficits are enhanced (Takeda et al., 2010). However, ob/ob mice still do not model all the pathological conditions of chronic T2DM, as rodent IAPP does not aggregate and thus islet amyloid does not accumulate and no β-cell death is observed (Hoppener et al., 1999).

Accumulation of islet amyloid, islet β-cell failure, and the resulting hyperglycemic conditions can be achieved in mice overexpressing human islet amyloid polypeptide (hIAPP, also called amylin) in pancreatic islet cells (Hoppener et al., 1999; Verchere et al., 1996). These features of the IAPP transgenic mouse model make it a more relevant model to mimic the human chronic condition. A mouse model with overlapping Alzheimer's disease and T2DM pathologies would be useful in providing insight into not only how T2DM accelerates Alzheimer's disease pathology but also how Alzheimer's disease pathology may impact on the diabetes, for which there is growing evidence (Zhang et al., 2012b; Zhang et al., 2013). Such an animal model would also be important as a preclinical model to assess the efficacy of current/novel antidiabetic drugs at slowing down/preventing the progression of Alzheimer's disease in the presence of comorbidities, such as diabetes [reviewed in Verdile et al. (2015)].

4.1.11 Limitations of the Transgenic Rodent Models

The transgenic rodent models of Alzheimer's disease have played an important role in providing significant insight into mechanisms consistent with the amyloid hypothesis and are still currently the most commonly used in vivo tool for screening in preclinical drug trials. Although there are a wide variety of Alzheimer's disease transgenic models, all are based on the presence of single or multiple (up to five) FAD-causing mutations. In reality, Alzheimer's disease patients never inherit multiple pathogenic mutations in *APP*, *PSEN1*, or *tau*. Thus none of the transgenic mice fully mimic the genetics of familial Alzheimer's disease. The relevance of these models to the more common later onset forms of Alzheimer's disease where a heterogeneous etiology occurs is questionable. The results to date indicate limitations of using mice and rats to model a human disease that takes several decades to develop. Furthermore, discrepancies in neuropathology and behavior between transgenic mouse models and human disease suggest caution when interpreting results. These discrepancies include plaque loads greater in older transgenic mice than those found in human Alzheimer's disease brains simultaneous with neurodegenerative effects that are smaller than seen in post mortem brains (Arendash et al., 2001; Kelly et al., 2003). The real question is whether these mice mimic Alzheimer's disease or are models of amyloid deposition and a recent paper by Hargis and Blalock suggests that only the latter may be the case. These researchers examined the concordance between brain gene expression changes seen in transcriptomic data from humans and rodents during normal ageing and in human Alzheimer's disease and in five distinct transgenic mouse models of this disease. Good concordance was seen for ageing in these organisms with very different life spans and between individual cases of sporadic Alzheimer's disease. However, there was little concordance between human Alzheimer's disease and the mouse models or even between the various mouse models themselves (Hargis and Blalock, 2016). This casts doubt over the relevance to sporadic Alzheimer's disease of these transgenic mouse models.

As one might expect from the comparisons of transcriptomic data described previously, another problem with many transgenic rodent models is that they do not encompass the full spectrum of Alzheimer's disease pathology. An example is one of the models discussed previously, the commonly used mouse transgenic line Tg2576 expressing the *APPswe* mutation. Although Aβ deposition is prominent and widespread in this transgenic line, NFT formation and overt neurodegeneration is absent (Hsiao et al., 1996). In more aggressive models in which multiple FAD mutations are coexpressed, neuron loss can be detected (although not to the extent seen in an Alzheimer's disease brain) (Casas et al., 2004; Oakley et al., 2006). In addition, the deposition of amyloid plaques and the decline of cognitive function appear to be highly dependent on the extraordinarily high

expression level of mutant APP, while phenotypic amyloidogenesis and cognitive deficits are not prominent in models expressing a physiological level of the same APP mutation (Flood et al., 2002). Transgenic models that exhibit both amyloid deposition and accumulation of NFTs can only be generated through coexpression of FAD-causing mutations together with tau mutations that cause tauopathies, such as FTD. However, tau mutations do not occur in the human Alzheimer's disease condition where, instead, tangle formation is triggered by the hyperphosphorylation of native tau isoforms. Thus, once again the relevance of these transgenic models to the human Alzheimer's disease condition is questionable.

Although FAD-associated mutations are known to cause Alzheimer's disease, there is no evidence that the proteins from these mutant genes are overexpressed in humans. In addition, it is difficult to separate the contributions of transgenes and normal aging to the cognitive deficits seen in these mice. Furthermore, transgene expression or gene deletions may affect behavior of the animals. Other confounding factors, such as genetic background [see next Owen et al. (1997)] linkage disequilibrium (Crusio, 1996; Gerlai, 1996) and the role of disease modifier genes (Kent et al., 1997) should also be taken into account. The use of nontransgenic littermates is required to better discern any pathogenic effects of mutations over those due to transgene overexpression. Furthermore, most transgenic systems use heterologous promoters. Consequently, the resulting pathology follows the spatial and temporal pattern of the expression of the transgene, which is often different to the progression of pathology seen in humans (Epis et al., 2010).

The expression of the transgene also influences experimental design. For example, insufficient randomization or numbers among experimental groups can lead to false-positive/-negative results, since the expression levels of transgenes can vary greatly between individual animals due to the differences in gender, generation, and genetic background. Loss of transgene copies can occur over generations and this can ameliorate the phenotype of later generations. Outbreeding with mice of different genetic backgrounds can also alter the susceptibility of a line to the transgene. These variables add further complexity to experimental design but cannot be ignored.

The genetic background of transgenic mice may also influence pathology and behavior, as became evident with some of the first transgenic lines which were created on a FVB/N background. This background was later discovered to be unsuitable for learning experiments due to their background visual and learning impairments. This necessitated crossing the transgene into other wild-type backgrounds (i.e., C57Bl6) or generating transgenic mice in genetic strains more suitable for behavioral assessments (Chapman et al., 1999; Johnstone et al., 1991; Moechars et al., 1999).

Overexpressing the APP Swedish mutation in mice of different genetic background has been shown to result in different levels of APP-CTF and Aβ levels, despite similar levels of the APP holoprotein. This indicates that genetic background significantly influences Aβ metabolism (Lehman et al., 2003a). Here, it should be considered that transgenic mice contain endogenous APP and APP-processing enzymes that may interfere with the production of different Aβ species. Another example is the R1.40 transgenic mouse that expresses the APPswe mutation. Despite similar levels of the APP holoprotein, the levels of APP C-terminal fragments and Aβ were found to be altered in the R1.40 mouse when it was backcrossed into three different inbred strains. As a result, the age at which Aβ deposition occurs varies between these three lines (Lehman et al., 2003a). The effect of genetic background on the onset of cerebral amyloidosis has also been reported in other transgenic lines, including Tg2567 (Carlson et al., 1997) and TgCRND8 (Chishti et al., 2001). Genetic background has also been reported to affect vulnerability to excitotoxins, which may contribute to observed variations in pathology onset and development (Schauwecker, 2002; Shuttleworth and Connor, 2001).

Another example of the complexity involved with interpretation of mouse models of Alzheimer's disease is the interaction between rodent and human forms of Aβ accumulating in transgenic animals overexpressing human mutant APP and a PSEN1 transgene (van Groen et al., 2006). Rodent Aβ was associated with human Aβ with its localization in dystrophic neurons surrounding plaques containing human Aβ. Why this occurs is uncertain and it may reflect a situation in which human Aβ acts as a seed for aggregation of rodent Aβ, or increased human Aβ saturates the clearance mechanisms for human (and rodent) Aβ leading to accumulation of both (Howlett and Richardson, 2009). However, the potential problems associated with the presence of endogenous APP and Aβ is somewhat negated with the recent creation of APP KI mice (Saito et al., 2014).

Problems have also occurred with replication of data where experimental results using the same transgenic lines cannot be replicated between different labs. For example, two independent groups, Chen et al. (2000) and Dodart et al. (1999), have characterized the behavior of PDAPP mice. Although both groups observed age-independent behavioral impairments, Dodart et al. (1999) reported impairment of object recognition memory performance, which was not observed by Chen et al. (2000) even in old aged mice. These differences in results may occur due to the genetic background of the mice used or the design of the particular behavioral assessments.

The complexity that occurs with the majority of mouse models and their questionable relevance to Alzheimer's disease, (particularly the sporadic forms where there

is mixed etiology) has prompted investigation of possible nontransgenic mammalian models of Alzheimer's disease.

4.2 Nontransgenic Animal Models

Alzheimer's disease studies using most nontransgenic mammalian models are focused on the highly conserved human APP sequence and, in particular, the complete sequence identity that humans and many other mammals show within their Aβ domains (Beck et al., 1997). Mammals as diverged as polar bears and dolphins share sequence identity with human Aβ but NHPs, dogs, rabbits, and guinea pigs are more commonly used in Alzheimer's disease research. Later, we outline the literature that describes the characterization of Alzheimer's disease pathology in these nontransgenic animals. We examine their role in providing insight into Alzheimer's disease pathogenesis and, in particular, how they may provide better models for sporadic Alzheimer's disease than transgenic rodents (Lecanu and Papadopoulos, 2013; Sarasa and Pesini, 2009; Stephan and Phillips, 2005).

4.2.1 Nonhuman Primates

NHPs have great value in Alzheimer's disease research since they share relatively close common ancestry (and thus genetics) with humans. Therefore, they have comparable brain structures and cognitive capabilities. Age-related cerebral amyloidosis has been demonstrated in a few species of monkey and great ape (Beck et al., 1997; Gearing et al., 1994, 1997; Price et al., 1991; Selkoe et al., 1987). In aged great apes, Aβ deposition can be detected in cerebral blood vessels (as CAA), and in cortex and hippocampus (as diffuse plaques), resembling the pathology observed at early stages of the human Alzheimer's disease condition (Gearing et al., 1994). Dense neuritic amyloid plaques are seldom seen but have been reported in old rhesus monkeys (Gearing et al., 1994). As in humans, the deposition of Aβ within plaques colocalizes with APOE. However, the deposition of various Aβ species (Aβ$_{40}$ and Aβ$_{42}$) within plaques is notably distinct between humans and other primates. For example, in the human Alzheimer's disease brain, Aβ$_{42}$ is the predominant component of amyloid plaques, and is deposited early, while deposition of Aβ$_{40}$ protein occurs at later stages of the disease. In aged orangutans, chimpanzees, and rhesus monkeys, Aβ$_{40}$ is the major species even from a relatively early stage of cerebral amyloidosis to form diffuse plaques (Gearing et al., 1994, 1997). The reason for the differences in Aβ species profile in plaques observed in aged primates and humans is not clear. One possibility may relate to APOE-Aβ metabolism. In both rhesus monkey and chimpanzee, the *APOE* gene is ε4-like (Gearing et al., 1994; Morelli et al., 1996; Poduri et al., 1994). Genetic-association studies have shown that

APOE4 may contribute to the increase of Aβ$_{40}$-positive plaques (Gearing et al., 1996; Schmechel et al., 1993).

Tau hyperphosphorylation and formation of NFTs has only been detected in a few species of NHPs, despite the high homology of their *MAPT* gene with that of humans (e.g., 100% identity in chimpanzees, 99.5% in gorillas, and 96.7% in rhesus monkey). Formation of tau paired helical filaments has been reported in one 41-year-old chimpanzee, but their distribution was mainly within cortical neurons and only rarely in hippocampus, which is distinct from the pattern observed in human Alzheimer's disease (Rosen et al., 2008). Additionally, tau pathologies have also been observed in baboons in neurons and glial cells (Schultz et al., 2000). Similar to amyloid deposition, accumulation of tau is age related, increasing from 31% at 11–20 years to 91% in 26- to 30-year-old baboons (Schultz et al., 2000). In grey mouse lemurs, Alzheimer's disease-like tau pathology was observed in association with brain atrophy, abundant amyloid plaque deposition, and cholinergic neurons loss (Kiatipattanasakul et al., 2000).

Consistent with the age-related cognitive and memory impairment observed in aged humans, aged NHPs exhibit deficits in visuospatial learning (Petrides and Iversen, 1979), recognition memory (Herndon et al., 1997; Moss et al., 1988; Presty et al., 1987), and cognitive processes, such as reversal learning (Bachevalier et al., 1991; Lai et al., 1995; Rapp and Amaral, 1989), working memory, and set-shifting (Moore et al., 2003, 2006). These impairments indicate a decline in function of the frontal cortex and hippocampus and are associated with pathology present in these regions, similar to that shown in human Alzheimer's disease brain (Braak and Braak, 1997; Braak et al., 1998).

The evidence to date indicates that NHPs may represent the closest natural animal model for human Alzheimer's disease. Although they have been utilized in Alzheimer's disease studies, particularly in the evaluation of anti-Alzheimer's disease drugs [reviewed in De Felice and Munoz (2016)], the high cost of maintaining NHPs, their relatively long life span, and limited access to these experimental animals restrict their wider use as Alzheimer's disease models.

4.2.2 Dogs

Similar to NHPs, aged dogs have proven to be useful models for human Alzheimer's disease since they show age-related cognitive decline and amyloid plaques. However, dogs are much more widely available, cheaper, and easier to maintain than primates. The relevance of aged dogs to modeling of sporadic, late-onset human Alzheimer's disease, makes them useful to assess nonpharmacological strategies, dietary and environmental risk factors, and for validating the efficacy of pharmacological treatments.

The most commonly used dog in laboratories is the beagle, which has a median life span of 12–14 years and is considered aged when older than 9 years (equivalent to >68 years in a human (Albert et al., 1994; Lowseth et al., 1990; Patronek et al., 1997). Similar to humans, the cognitive function of aged beagles varies significantly between individuals and can be categorized into "successful aging," "mildly impaired," and "severely impaired," equivalent to cognitively normal, MCI, and dementia in humans (Adams et al., 2000a,b). Similar to humans, the visuospatial (Chan et al., 2002; Studzinski et al., 2006) and executive functions (Callahan et al., 2000; Milgram et al., 2002; Tapp et al., 2003) of dogs are most vulnerable in age-related cognitive decline, while, simple rule-based learning and procedural learning are largely preserved (Milgram et al., 1994).

The Aβ sequence of dog is identical to that of humans (Johnstone et al., 1991; Selkoe et al., 1987), and the pattern of amyloidosis during aging is similar (but not exactly same) to that observed in the human Alzheimer's disease brain, where accumulation of Aβ is initiated in the prefrontal cortex and spreads to the entorhinal and parietal cortices. (Cummings et al., 1996a; Head et al., 2000). The amyloid deposits are predominantly the diffused subtype composed mainly of $A\beta_{42}$ (Cummings et al., 1996b) (and so are distinct from those seen in NHPs where, as mentioned previously, the major Aβ species is $A\beta_{40}$). Accumulation of Aβ within the cerebral blood vessels in the form of CAA has also been observed (Ishihara et al., 1991; Uchida et al., 1990; Yoshino et al., 1996) and is distributed in a similar spatial pattern to that seen in the Alzheimer's disease brain (Attems et al., 2005). In addition, in aged dogs accumulation of cerebral Aβ correlates with cortical atrophy (Gonzalez-Soriano et al., 2001; Kimotsuki et al., 2005), reduced cortex volume (Tapp et al., 2004), neuronal loss (Siwak-Tapp et al., 2008), and cognitive decline (Colle et al., 2000; Cummings et al., 1996a; Head et al., 1998) similar to the human Alzheimer's disease brain.

Aged dogs model sporadic Alzheimer's disease-like pathology and thus have been a valuable model in assessing nonpharmacological and pharmacological interventions for Alzheimer's disease. Being more genetically and physiologically similar to humans than mice and rats, dogs appeared to be better predictors for negative outcomes in preclinical trials. For example, the potential Alzheimer's disease drugs, amapkine (an AMPA receptor), and selegiline (an irreversible monoamine oxidase B inhibitor) showed beneficial effects on cognitive function in rodent models. However, evaluating these agents in dogs revealed similar findings to those in human clinical trials for Alzheimer's disease, where cognitive functioning was not significantly improved. (Studzinski et al., 2005). Furthermore, the outcomes of active immunization trials in dogs were similar to those in human

clinical trials. Despite immunization therapy having success in improving learning and memory in transgenic mouse models exhibiting amyloid pathology (Dodart et al., 2002; Hartman et al., 2005; Kotilinek et al., 2002) improvements were not observed when Aβ immunization was administered to dogs. In aged dogs (8.4–12.4 years old), no improvements in complex learning, spatial memory, and attention were detected in response to the Aβ immunization treatment, although Aβ plaque load was reduced (Head et al., 2008). On the basis of the benefits shown with active immunization in mouse models, commencement of the first human trials (AN1792) showed some now well-documented unwanted side effects, such as increased CAA, serious signs of CNS inflammation including increased T lymphocyte infiltration in the brain and leukoencephalopathy in 18 of 300 patients (6%) which led to the termination of phase II trials [Gilman et al. (2005), reviewed in Foster et al. (2009)]. Twelve of the patients recovered, while 6 suffered from disabling cognitive and neurological deficits. However, as with the mouse models, dogs also failed to reveal the adverse autoimmune responses that occurred in human patients (Head et al., 2008). Aged dogs have also been useful for assessing the impact of nonpharmacological interventions including the benefits of dietary antioxidants and behavioral enrichment in delaying cognitive decline and dementia (Milgram et al., 2002, 2004, 2005; Nippak et al., 2007; Opii et al., 2008; Siwak et al., 2005).

4.2.3 Sheep

Sheep have also been used in studies of neuropathology including the neurodegenerative prion disease scrapie (Hunter, 2007) and as a model for the effect of traumatic brain injury on APP expression (Anderson et al., 2003). Sheep are one of the few animals that, during normal aging, develop NFTs closely resembling those seen in the Alzheimer's disease brain (Braak et al., 1994; Nelson and Saper, 1995; Nelson et al., 1993, 1994). This makes them useful for the study of tau neuropathology. Additionally, there is high homology between sheep and human forms of apolipoprotein (APOE) (Komatsu et al., 1998), unlike rodent APOE. In humans, polymorphisms of APOE are recognized as an important risk factor for the development of Alzheimer's disease (Corder et al., 1993). Whereas no similar polymorphisms have been found in sheep APOE (Komatsu et al., 1998), the high homology between sheep and human APOE makes research easier to translate between the species. In addition, the sheep Aβ sequence is identical to that of humans (Johnstone et al., 1991). ThioS-positive neuritic plaques have been identified in the brains of sheep (Nelson et al., 1994) and soluble levels can be detected by ELISA (Barron et al., 2009).

Similarities between sheep reproduction and human reproduction have provided the opportunity to assess

the impact on Alzheimer's disease-related pathology of the Alzheimer's disease risk factor age and the related reductions in sex hormones. Sheep have proven very useful as a model for human reproduction and metabolism due to similarities in estrus periodicity, breeding, and metabolic rate. The sheep estrus cycle lasts approximately 17 days, more closely approximating the length of the human menstrual cycle than rodents, which have an estrus cycle lasting approximately 4 days. Furthermore, sheep, like humans, are generally limited to one or two offspring, unlike other mammals, such as rodents or dogs that are prolific breeders. As such, sheep are thought to better reflect hormonal regulatory mechanisms of ovulation than prolific breeders. Ovariectomy of sheep has been a very successful model for the study of menopausal symptoms and conditions including hot flushes (MacLeay et al., 2003), heart disease (Gaynor et al., 2000), bone density loss (Newton et al., 2004), and arthritic changes (Cake et al., 2005). On the basis that ovariectomized sheep are a relevant model of human menopause, a study investigated the impact of estrogen depletion and supplementation on Aβ accumulation and oxidative stress in sheep brain (Barron et al., 2009). Neither depletion nor supplementation of estrogen impacted on levels of Aβ or oxidative stress. Evidence from rodent animal studies indicate that, under certain conditions, treatment with supraphysiological concentrations of estrogen can modulate Aβ levels (Levin-Allerhand et al., 2002; Zheng et al., 2002). However, the circumstances necessary to elicit these effects and their relevance to the clinical setting remain unclear.

4.2.4 Guinea Pigs and Rabbits

Guinea pigs and rabbits are small-sized mammalian models that show greater conservation in important Alzheimer's disease-related genes than mice or rats. They are also experimentally more amenable compared to large-sized mammal models, such as primates and dogs. Guinea pig APP protein is 97% identical to human APP and exhibits a similar pattern of transcriptional splicing (Beck et al., 1997). Notably, the Aβ sequence of guinea pigs is identical to that of human (Beck et al., 1997; Sharman et al., 2013). Furthermore, guinea pig Aβ has a demonstrated capacity to form higher order molecular structures, such as oligomers, widely considered to be the principal contributor to neurotoxicity in Alzheimer's disease pathogenesis (Beck et al., 2000). Guinea pigs also share sequence similarities with other Alzheimer's disease-related human genes, such as the presenilins. Indeed, the formation of the PSEN2 truncation, PS2V, which is upregulated in human Alzheimer's disease brains and in neurons under hypoxic conditions, was identified in guinea pig brain and shown to be upregulated in brains from cholesterol-fed animals (Sharman et al., 2013). Intriguingly, the PS2V isoform is not

produced by the PSEN genes of mice or rats (Moussavi Nik et al., 2015). In addition, similar to normal aging in humans, aging in wild-type guinea pigs leads to hyperphosphorylation of Tau in discreet brain regions including the hippocampus. Traumatic brain injury increases the vulnerability of the hippocampus and dysregulation of Alzheimer's disease-related proteins, similar to what is observed in humans (Bates et al., 2014).

Guinea pigs are the only small animal model known to mimic closely human lipoprotein and cholesterol metabolism (Fernandez, 2001) (see later). As such they have been demonstrated to be an excellent nontransgenic model for studies attempting to elucidate the effect of cardiovascular risk factors and drug interventions on the development of Alzheimer's disease. They are also an excellent model for evaluation of dietary interventions as they show aortic plaque accumulation when challenged with a hypercholesterolemic diet (Sharman et al., 2008; Torres-Gonzalez et al., 2008).

High-cholesterol diets have been shown to increase the risk of Alzheimer's disease and the correlation between cholesterol metabolism and amyloidogenesis has been explored in transgenic and nontransgenic animal models (George et al., 2004; Refolo et al., 2000; Sparks et al., 1994; Umeda et al., 2012). However, most of the commonly used rodents and other species have distinct cholesterol profiles compared to humans. For example, rabbits are deficient in hepatic lipase and carry the majority of their cholesterol as VLDL (Badimon et al., 1990). Rats and mice lack plasma cholesterol ester transfer protein and use HDL as the major cholesterol carrier (Moghadasian, 2002). In comparison, the majority of cholesterol in guinea pigs is transported via LDL as in humans (Fernandez, 2001). Therefore, guinea pigs may be a more appropriate model compared to other rodents to study the relationship between cholesterol metabolism and Alzheimer's disease in a physiological context. It is therefore rather surprising that the guinea pig has not been widely used to assess the impact of such dietary interventions on Alzheimer's disease-related pathology, such as Aβ accumulation. Recent failures of drugs in clinical trials indicate that further studies using more appropriate animal models are warranted (De Strooper and Chavez Gutierrez, 2015). Thus, in recent years, the guinea pig has been used to test the efficacy of numerous Alzheimer's disease drug due to its genetic similarity to humans (Brodney et al., 2011; Davtyan et al., 2013; Eketjall et al., 2013; O'Hare et al., 2014; Pohanka et al., 2012; Portelius et al., 2014).

Of course, guinea pigs also have limitations as an Alzheimer's disease model. Compared to rats and mice, guinea pigs are considered to be less suitable to perform learning and memory tasks (Beck et al., 1997). However, a few groups have had success in undertaking behavioral assessments, such as the Morris water

TABLE 40.4 Comparison of Mammalian Models

Model organisms	Husbandry cost	Anatomical similarity to humans	Molecular and genetic similarity to humans	Similarity of pathology to humans	Transgenic technology	Feasibility of large-scale experiments	Affordability of large-scale studies	Availability of antibody reagents

*, Least optimal; **, less optimal; ***, optimal; ****, most optimal.

maze with guinea pigs (Dringenberg et al., 2001; Lewejohann et al., 2010). Other limitations associated with the use of guinea pig as a potential model include that breeding and maintenance costs remain relatively high compared to rats and mice and that less-developed gene and protein identification databases are available compared to those for the commonly used rodents. In addition, whether or not guinea pigs can model NFT formation remains to be determined. There is a distinct lack of knowledge of what tau (MAPT) isoforms exist in guinea pigs and whether they are hyperphosphorylated. Only one published study has investigated tau isoforms in guinea pig brain tissue. Takuma et al. (2003) applied an antibody produced against human tau to examine tau isoforms in guinea pig brain and only detected the 1N isoform. They also identified differences in amino-terminal inserts in tau between mice and rats where 1N and 2N insert types are dominant in rats, while 0N and 1N are dominant in mice. The reasons for these species differences in tau amino-terminal isoforms (and indeed the function of these isoforms) remain unclear. However, the dominance of the 1N isoform in humans, mice, rats, and guinea pigs suggest a conserved role for tau containing this particular N-terminal insert.

Like guinea pigs, rabbits do not develop amyloid deposition with age. However, Alzheimer's disease-like pathologies, such as cortical Aβ deposition, loss of neurons in frontal cortex, hippocampus, and cerebellum, and impairments in learning complex tasks, can be induced by a combination of a trace amount of copper and a high-cholesterol diet in rabbits (Sparks and Schreurs, 2003; Woodruff-Pak et al., 2007). This Alzheimer's disease-like pathology can be ameliorated by removing cholesterol from the diet or by cholesterol-lowering treatment (Sparks, 2008). These results indicate that rabbits are suitable models for assessing copper and high-cholesterol intake as risk factors for Alzheimer's disease. Unlike guinea pigs, Alzheimer's disease-like NFT pathology has been identified in rabbits, but only under cholesterol-fed

conditions. One study showed that administering 1% cholesterol for 7 months resulted in Aβ deposition and NFT-like changes in female rabbits (Ghribi et al., 2006). A more recent study showed that total plasma tau levels were increased in cholesterol-fed rabbits and that NFT-like pathology was greatest in cholesterol-fed animals administered distilled water (Sparks et al., 2011). Interestingly, NFT-like pathology was reduced in cholesterol-fed rabbits administered water containing copper (0.12 ppm) and an even greater reduction was observed with tap water (estimated to contain 0.2 ppm copper). The inverse was observed for Aβ pathology, indicating separate mechanisms by which metals in water alter Alzheimer's disease pathology (Table 40.4).

4.2.5 Hibernating Mammals Provide Insight Into tau Phosphorylation in Alzheimer's Disease

Hibernating mammals, such as the Arctic ground squirrel, Syrian hamster, and black bear are interesting animal models for investigating tau pathology in Alzheimer's disease. Hyperphosphorylation of tau protein and formation of NFTs are found in these animals during hibernation and can be reversed after euthermia (Arendt et al., 2003; Hartig et al., 2007; Su et al., 2008). The level of tau phosphorylation in these animals seems to be related both to body temperature and hibernation status (Stieler et al., 2011). Higher degrees of phosphorylation were demonstrated in animals with lower body temperature during hibernation, with the inverse observed under euthermia (Stieler et al., 2011).

Phosphorylation of tau induced by hibernation mostly occurs during early stages of torpor and does not proceed further during the course of torpor. Partial dephosphorylation of tau protein has been observed in aroused Arctic ground squirrels under conditions of sporadic euthermic arousals, but complete dephosphorylation only occurred after euthermy (Su et al., 2008). In hibernating animals, phosphorylation of tau occurs at similar residues as seen for human tau in Alzheimer's disease

patients (T231/S235, T212/S214/T217, S396/404). However, the kinases involved in hibernation and the development of Alzheimer's disease pathology appeared to be distinct. Alzheimer's disease-associated hyperactivation of GSK-3β and SAPK/JNK was not observed in hibernation. In contrast, GSK-3β and SAPK/JNK was largely deactivated due to the low body temperature during hibernation, while, cdk5 and ERK1 seemed to play a vital role in hyperphosphorylation of tau during hibernation (Stieler et al., 2011).

The hyperphosphorylation of tau during hibernation has been proposed to be a protective mechanism to reduce the demand for energy to maintain basic cellular functions during famine (Arendt et al., 2003). Similar hyperphosphorylation of tau was reported in animals under starvation, anesthesia, and cold water stress (Okawa et al., 2003). Under hibernation, tau hyperphosphorylation has been shown to be isolated to the cholinergic neurons in the basal forebrain projection system, but not the gamma-aminobutyric acid (GABA)-ergic neurons, a pattern that is similar to that seen in Alzheimer's disease brain (Hartig et al., 2007).

Neuronal hypometabolism is a feature of Alzheimer's disease and other dementias. It has been suggested to occur early in Alzheimer's disease, possibly prior to the onset of symptoms (Reiman et al., 1996, 2004; Small et al., 2000) and can be a possible predictor of cognitive dysfunction (Devous, 2002; Kim et al., 2005). Stieler et al. (2011) have hypothesized that hyperphosphorylation of tau may represent a physiological response to hypometabolism, occurring in the early stages of Alzheimer's disease pathogenesis. However, due to the persistence of the hypometabolic state of the Alzheimer's disease brain, tau hyperphosphorylation continues resulting in the formation of tangles and eventual neuronal death (Stieler et al., 2011). Animals that hibernate may provide a valuable platform to investigate the physiological functions, molecular pathways, and mechanisms of tau hyperphosphorylation, and its relevance to Alzheimer's disease pathogenesis under conditions of neuronal inactivity.

5 CONCLUSIONS

An animal model can never reflect completely the pathology of a human disease. This applies particularly to modeling of Alzheimer's disease since this condition affects the most complex biological structure in existence—the human brain. Nevertheless, investigating Alzheimer's disease in animal models, including animals highly diverged from humans, such as the invertebrates, is very worthwhile because the discovery of conserved normal and pathological processes in widely diverged organisms indicates the fundamental importance of those processes.

The current uncertainty about the cause(s) and progression of Alzheimer's disease means that we must be particularly cautious in how we interpret information we obtain from modeling this condition. A huge amount of data has been collected regarding the genes, cellular processes, and neurophysiological events that may be involved in development of Alzheimer's disease but no consistent, unifying mechanistic explanation has yet emerged. The reason for this may lie, in part, in the dominant use of mice and rats for Alzheimer's disease modeling and the relatively rapid evolution of Alzheimer's disease-related genes in these rodents (family Muridae) compared to other rodents and mammals. Alternatively, the hypotheses we currently use to guide our experimentation in this area may be inappropriate to a greater or lesser degree. We must also remember that, despite their apparent common histopathology, the inherited and sporadic forms of this disease may be fundamentally different. Since sporadic, late-onset Alzheimer's disease is overwhelmingly more common than the inherited, early-onset form; there should be a greater focus on analyzing Alzheimer's disease-like pathologies and Alzheimer's disease risk factors in nontransgenic mammals. Also, the functions of the genes/proteins identified as associated with sporadic Alzheimer's disease (e.g., by GWAS) should be analyzed in genetically manipulable model organisms including non-Muridae mammals, vertebrates, and invertebrates. Hopefully, these and other strategies will mean that the coming decade produces greater advances in understanding, ameliorating, and preventing Alzheimer's disease than the last.

Abbreviations

AADC	L-Amino acid decarboxylase
ADL	Activities of daily life
AMPT	α-Methyl p-tyrosine
BBB	Blood–brain barrier
BDNF	Brain-derived neurotrophic factor
Cdk-5	Cyclin-dependent protein kinase 5
[^{11}C]CIT-FP	N-3-Fluoropropyl-2-β-[O-methyl-^{11}C] carbomethoxy-3-β-(4-iodophenyl)-tropane
COMT	Catechol-O-methyl transferase
COX-2	Cyclooxygenase 2
DA	Dopamine
DAT	Dopamine transporter
DARPP-32	Dopamine- and cAMP-regulated neuronal phosphoprotein 32 kDa
DMSO	Dimethylsufoxide
DOPAC	3,4-Dihydroxy-phenylacetic acid
L-dopa	L-3,4-Dihydroxyphenylalanine
[^{18}F]-DTBZ (AV-133)	9-Fluoropropyl-(+)-dihydrotetrabenazine
ER	Endoplasmic reticulum
[^{18}F]FECNT	2β-Carbomethoxy-3β-(4-chlorophenyl)-8-(2-[^{18}F]-fluoroethyl)-nortropane
FGF-2	Basic fibroblast growth factor 2
GDNF	Glial cell line-derived neurotrophic factor
GFAP	Glial fibrillary acidic protein
GPe	External segment of globus pallidus
GPi	Internal segment of globus pallidus
GSH-PX	Glutathione peroxidase
HPLC	High-performance liquid chromatography
HVA	Homovanillic acid
IL-1β	Interleukin 1β
IL-6	Interleukin 6
iNOS	Inducible nitric oxide synthase
JNK	c-Jun N-terminus kinase
LRRK2	Leucine-rich repeat kinase 2
LTF	Latency to fall
MAO-B	Monoamine oxidase B
MDA	Malondialdehyde
MEMRI	Manganese-enhanced magnetic resonance imaging
MPP$^+$	1-Methyl-4-phenyl-pyridinium
MPTP	1-Methyl-4-phenyl-1,2,3,6-tetrahydropyridine
MSNs	Medium spiny neurons
NAT	Noradrenaline transporter
NeuN	Neural nuclei
NF-κB	Nuclear factor-κB
NO	Nitric oxide
6-OHDA	6-Hydroxydopamine
PD	Parkinson's disease
PET	Positron emission tomography
PINK-1	PTEN-induced putative kinase 1
PQ	1,1'-Dimethyl-4-4'-bipyridinium (paraquat)
RNS	Reactive nitrogen species
ROS	Reactive oxygen species
SNpc	Substantia nigra pars compacta
SNr	Substantia nigra pars reticulate
SPECT	Single photon emission computerized tomography
SOD	Superoxide dismutase
STN	Subthalamic nuclei
TH	Tyrosine hydroxylase
TLR2	Toll-like receptor 2
TNF-α	Tumor necrosis factor-α
UPDRS	Unified Parkinson's disease rating scale
VMAT	Vesicle monoamine transporter

1 INTRODUCTION

In 1817, a British clinician James Parkinson described his six patients as showing shaking palsy (Parkinson, 1817), currently known as an extrapyramidal syndrome, and it was the first case report of "Parkinson's disease (PD)" later named by a French neurologist Jean-Martin Charcot (Chacot, 1880). Tretiakoff (1919) showed PD was associated with degeneration of the neurons in substantia nigra pars compacta (SNpc), and Carlsson (1959) showed the neurotransmitter of the nigrostriatal neuron was dopamine (DA). Ehringer and Hornykiewicz (1960) proposed PD was caused by a significant decrease of the striatal dopamine. Thus, PD can be defined as a common neurodegenerative disorder characterized by a slowly progressive motor dysfunction associated with loss of the nigrostriatal dopaminergic neurons resulting in depletion of the striatal dopamine. It was proposed that PD symptoms were expressed when approximately 60% of the dopaminergic neurons in SNpc had died (German et al., 1989), and approximately 70 ~ 80% of dopamine in the striatum had been lost (Jankovic and Marsden, 1988; Ma et al., 2002).

In the striatum, dopaminergic afferent makes synapses to the GABAergic medium spiny neurons (MSNs), which receive dopamine with D_1 or D_2 receptors. The former excites and the latter inhibits the activity of MSNs, respectively. Glutamatergic input from the cortical neurons and cholinergic axons of the striatal interneurons also innervate to MSNs, both of which mainly excite MSNs. In PD, inhibition via D_2 receptor is lost by depletion of dopamine, resulting in hyperactivation of MSNs, which strongly inhibits their target neurons in the external segment of globus pallidus (GPe) (GPe), which are normally innervating to subthalamic nuclei (STN), internal segment of globus pallidus (GPi), and substantia nigra pars reticulata (SNr), respectively (Fig. 41.1). Both STN and GPi are known as targets for the electrodes of deep-brain stimuli therapy in PD (Krack et al., 2010).

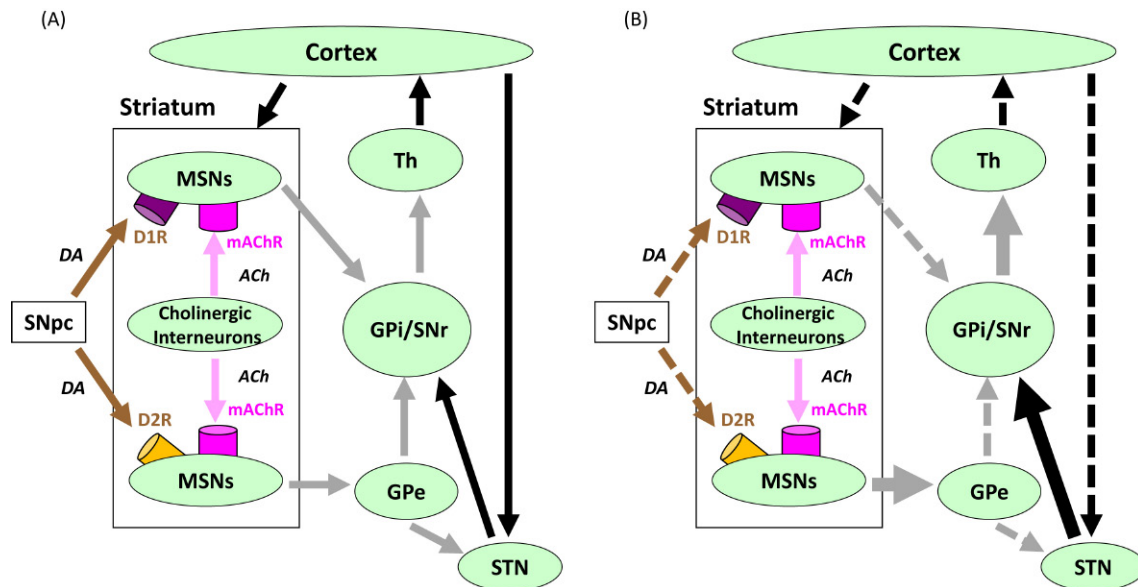
For a pharmaceutical treatment of PD, L-3,4-dihydroxyphenylalanine (L-dopa) is most commonly applied as a precursor of dopamine together with an inhibitor for peripheral aromatic L-amino acid decarboxylase (AADC), such as carbidopa. It has been over 40 years since L-dopa in combination with AADC were established as a standard pharmacotherapy of PD (Rascol et al., 2011) Despite some side effects, such as drug-induced dyskinesia (Encarnacion and Hauser, 2008), L-dopa is still a gold standard for PD treatment because of its powerful efficacy on the motor dysfunctions in PD patients. The following drugs are also applicable, although some of them are restricted to


FIGURE 41.1 **Schematic diagrams of the neuronal circuit related to Parkinson's disease (PD).** (A) In normal condition. (B) In PD state. *Arrows* indicate the neurons as follows: *black*, glutamatergic; *gray*, GABAergic; *brown*, dopaminergic; *pink*, cholinergic; broken, decreased; enlarged, hyperactivated, respectively. *ACh*, Acetylcholine; *DA*, dopamine; *GPe*, external section of globus paridus; *GPi*, internal section of globus paridus; *mAChR*, muscarinic acetylcholine receptor; *MSNs*, medium spiny neurons; *SNpc*, substantia nigra pars compacta; *SNr*, substantia nigra pars reticulare; *STN*, subthalamic nuclei; *Th*, thalamus.

apply together with L-dopa: dopamine agonists (mainly for D_2 receptor), such as bromocriptine, pergolide, talipexole, cabergoline, pramipexole, ropinirole, and rotigotine; selegiline, an inhibitor for monoamine oxidase B (MAO-B); entacapone, an inhibitor for catechol-O-methyl transferase (COMT); amantadine, originally developed as an antiinfluenza therapeutic, increases synaptic release of endogenous dopamine and inhibits NMDA receptor; anticholinergic drugs, such as trihexyphenidyl, biperiden, profenamine, and metixene; zonisamide, originally developed as an antiepileptic agent, is proposed to have multiple therapeutic actions; istradefyline, adenosine A2A receptor inhibitor. In Fig. 41.2, we summarize some typical therapeutic agents and their proposed pharmacological targets.

Animal models for PD are essential to understand the detailed pathophysiological mechanisms of PD, and to develop novel therapeutics including pharmaceutical treatments. These models can also be utilized for screening effective substances having therapeutic and/or neuroprotective (disease modifying) effects on PD-related neuronal system, such as the nigrostriatal neurons (Fig. 41.3, based on the molecular pathophysiology of PD discussed later on). In general, favorable animal models should satisfy the following three validities with human PD: face, constructive, and predictive (Trivedi and Jarbe, 2011). Although it is difficult to establish such a model satisfying all of these validities, various animals as PD models have been used to date: nonhuman primates from big monkeys, such as baboons (Kishima et al., 2004)

and macaques (Saiki et al., 2010) to small ones, such as common marmosets (Choudhury et al., 2010), rodents especially rats and mice, rabbits (Ghiribi et al., 2003), dogs (Choi et al., 2011), cats (Schneider and Rothblat, 1991), frogs (Barbeau et al., 1985) and nonvertebrates, such as drosophila (Park et al., 2005) and nematode (Braungert et al., 2004). Among them, nonhuman primates are especially valuable because of their genetic, anatomical, and functional similarities to humans, although there are some difficulties regarding availability, habitation, handling, and experimental techniques. The most frequently used animals are rats and mice as they are readily available and easy to handle. Considering these facts, in this chapter, we focus on the mouse as a rodent and the common marmoset as a nonhuman primate model, respectively, since both of them are relatively easy to handle for their size and availability.

To establish an appropriate animal model, several chemicals/neurotoxins inducing PD-like symptoms are often used, also with increasing use of the transgenic and knockout mice models of specific genes related to familial PD, such as mutated α-synuclein, parkin, PTEN-induced putative kinase 1 (PINK-1), DJ-1, leucine-rich repeat kinase 2 (LRRK2), and so on (Crabtree and Zhang, 2012). Among them, a neurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) is commonly used since it causes a selective loss of dopaminergic neurons and induces typical PD-like symptoms in rodents, amphibians, nonhuman primates, and humans (Barbeau et al., 1985; Blandini and Armentero, 2012; Langston et al., 1983).

Using MPTP, the authors have studied the molecular details of PD and actions of some therapeutic/neuro-protective drugs in mice and in common marmosets (Araki et al., 2001; Choudhury et al., 2010; Kadoguchi et al., 2014; Kikuta et al., 2015; Muramatsu et al., 2002; Nomoto et al., 1998; Tanabe et al., 2014; Yamamura et al., 2013; Yokoyama et al., 2010a,b).

In this chapter, we first overview the clinical symptoms and characteristics observed in PD patients and in animal models, followed by summarizing the neurotoxins used to establish PD models. Then we describe the practical experimental methods and applications with some results relevant to PD both in mice and in common marmosets.

2 CLINICAL CHARACTERISTICS OF PD AND THEIR RELEVANT SYMPTOMS IN ANIMAL MODELS

To evaluate the animal models of human disease, it is important to understand the clinical characteristics and symptoms of the disease. In this section, we summarize the epidemiological and clinical characteristics of PD briefly, comparing with behavioral and molecular characteristics of animal models for PD.

2.1 Epidemiological Background

PD is the second most common neurodegenerative disorder after Alzheimer's disease (de Lau and Breteler, 2006). The prevalence of PD is about 0.3% of the whole population in first world countries. PD is more common in the elderly and prevalence rises from 1% in those over 60 years of age to 4% of the population over 80 (de Lau and Breteler, 2006). The mean age of onset is around 60 years, although 5%–10% of cases, classified as young onset, begin between the ages of 20 and 50 (Samii et al., 2004). Based on these facts, the use of adult animals rather than juvenile ones for PD models sounds reasonable. Some studies have proposed that PD is more common in men than women, but others failed to detect any differences between the two sexes (de Lau and Breteler, 2006).

Many risk factors and protective factors have been proposed, sometimes in relation to theories concerning possible mechanisms of the disease, however, none have been conclusively related to PD by empirical evidence. When epidemiological studies have been carried out in order to test the relationship between a given factor and PD, they have often been flawed and their results have in some cases been contradictory (de Lau and Breteler, 2006). The most frequently replicated relationships are an increased risk of PD in those exposed to pesticides, such as rotenone, paraquat, and maneb (de Lau and Breteler, 2006). Exposure to these pesticides can double the risk of PD, and indirect measures of exposure, such as living in rural environments, have also been found to increase the risk of PD. As we describe later, in fact, these pesticides are successfully used to produce a PD model in experimental animals.

On the other hand, it was reported that the risk of PD was reduced in smokers down to a third when compared to nonsmokers (de Lau and Breteler, 2006). The basis for this effect is not known, but possibilities include an effect of nicotine as a dopamine stimulant (de Lau and Breteler, 2006; Quik et al., 2009). Tobacco smoke contains compounds that act as MAO inhibitors that also might contribute to this effect (Castagnoli and Murugesan, 2004). Other substances reported to reduce PD risk were caffeine (Bankiewicz et al., 1999), estrogens, antiinflammatory drugs, and so on (de Lau and Breteler, 2006).

2.2 Clinical Stages of PD

Although clinical experts describe symptoms and stages of PD differently, it sometimes is classified based on the daily-life disabilities with three stages as early, moderate, or advanced: Early, the stage when a person has a mild tremor or stiffness but is able to continue work or other normal daily activities. This often refers to a person who has been newly diagnosed with PD; Moderate, the stage when a person begins to experience limited movement. A person with moderate PD may have a mild to moderate tremor with slow movement; Advanced, the stage when a person is significantly limited in his or her activity, despite treatment. Daily fluctuations in symptoms, medicinal side effects that limit treatment, and loss of independence in activities of daily living are common. A person with advanced PD may have significant and frequent changes in posture and movement with speech difficulties.

The severity of PD may also fall into the following five stages known as Hoehn and Yahr's scale: Stage I, symptoms affect only one side of the body; Stage II, both sides of the body are affected, but posture remains normal; Stage III, both sides of the body are affected, and there is a mild imbalance during standing or walking. But the person remains independent; Stage IV, both sides of the body are affected, and there is disabling instability while standing or walking. The person in this stage requires substantial help; Stage V, severe, fully developed disease is present. The person is restricted to a bed or chair. Dementia is also observed in 20 ~ 30% of PD patients, although it only appears in the later stage.

Further detailed ratings established in 1987 known as Unified Parkinson's Disease Rating Scale (UPDRS), a worldwide standard scale of PD, evaluates both motor and nonmotor symptoms subdivided into total 42 subjects, rating each of them with 5 stages. UPDRS consists

of five parts: I, evaluation of mentation, behavior, and mood; II, self evaluation of the activities of daily life (ADL), such as speech, swallowing, handwriting, dressing, hygiene, falling, salivating, turning in bed, walking, cutting food; III, evaluation of motor function scored by clinician; IV, Hoehn and Yahr's scaling of PD severity; V, ADL scaling of Schwab and England. Although it takes time for scoring all the subjects, it is also utilized to evaluate drugs in clinical trial or the result of surgery.

2.3 Clinical Symptoms in PD Patients

The most common symptoms in PD include the following four: (1) bradykinesia which is a slowness of voluntary movement and associated with reduction in automatic movement, such as swinging of the arms during walking, is the most disabling feature. The voice is hypophonic and poorly modulated, which is called monotonous speech. A reduction of the facial muscles movements and blinking lead to the characteristic expressionless masked face; (2) Resting Tremor, the 4–6-Hz "Pill rolling," is typically the most characteristic sign and seen in 60% of the patients with PD. Initially, the tremor may appear in just one arm or leg or only on one side of the body. The tremor may also affect the chin, lips, and tongue. Emotional and physical stresses tend to make the tremor more noticeable. Sleep, complete relaxation, and intentional movement or action usually reduce or diminish the tremor; (3) Rigidity, is defined as an increase in muscle tone of passive movement responding to applied force. PD patients mostly express the lead-pipe type of rigidity and cogwheel type occasionally. Rigidity is used as an indicator to determine the efficacy of the medications; (4) Difficulty with walking (gait disturbance) and balance (postural instability). A person with PD is likely to take small steps and shuffle with his or her feet close together, bend forward slightly at the waist (stooped posture), and have trouble turning around. Balance and posture problems may result in frequent falls. But these problems usually do not develop until later in the course of the disease.

2.4 Symptoms in Nonhuman Primates

Many clinical symptoms described earlier can be reproduced in the experimental nonhuman primates probably because they are in the same species with us. Parameters to be analyzed are: tremor, freezing, locomotion, fine motor skills, akinesia, balance, posture, startle response, gross motor skills, and so on (Bankiewicz et al., 1999). They are usually classified from 0 (normal) to 3 ~ 5 subclasses according to the severity. Alternatively, a scale of clinical rating ranged from 0 to 32 are also applicable (Swanson et al., 2011). In some cases, fine motor skills are evaluated with computerized touch-

panel systems (Swanson et al., 2011). Detailed examples of MPTP-treated common marmoset will be described in the later section.

2.5 Symptoms in Rodents

Although it is well known that rodent models for human diseases are favorable with genetic, biochemical, and anatomical studies, it does not always reflect exact behavioral parameters with symptoms of the disease, because of the differential anatomy, biochemistry, and functions with human. Despite this discrepancy, researchers have developed many useful paradigms to assess motor dysfunctions of rodents as we describe in the later section. It is important to be aware that one experimental paradigm does not always reflect one specific parameter of human exactly. For this reason, multiple paradigms are recommended to examine in each experimental project.

After administrating neurotoxins or chemicals described later, animals show akinesia- and/or bradykinesia-like symptoms, such as freezing, and abnormal movement of limbs with tremor, slowness, rigidity, and so on. Behavioral tasks to analyze these motor dysfunctions will be described later.

3 MOLECULAR PATHOPHYSIOLOGY OF PD

As we mentioned in the previous sections, PD is associated with degeneration of the nigrostriatal dopaminergic neurons. It means a significant reduction of the striatal dopamine with its metabolites and molecular markers for dopaminergic neurons, such as tyrosine hydroxylase (TH) are observed with anatomical and/or biochemical analysis (Nagatsu and Sawada, 2007). It is also known that formation of the acidophilic inclusions called Lewy body with a high amount of α-synuclein and ubiquitin proteins are observed in the cytoplasm of the remaining but degenerated neurons, together with some characteristic small projections called Lewy neurites (Forno, 1996). In fact, increasing evidence suggested impaired proteolytic systems of ubiquitne-proteasome and/or lysosome contributed to the accumulation of α-synuclein, causing endoplasmic reticulum (ER)-stress with progression of the dopaminergic cell death (Cox and Cachón-González, 2012; Wang and Takahashi, 2007). Parkin, a ubiquitin E3 ligase, and its upstream protein kinase PINK1 are known to be involved in the removal of damaged mitochondria by ubiquitinating various substrate proteins in the depolarized mitochondria, and its genetic deficiency is correlated to PD occurrence (Kitada et al., 1998; Matsuda et al., 2010). Parkin is also phosphorylated by c-Abl

tyrosine kinase at tyrosine 143 residue to be inactivated (Ko et al., 2010) and a c-Abl inhibitor nilotinib protected dopaminergic neurons in MPTP mice (Karuppagounder et al., 2014). Thus inhibitors of c-Abl are suggested to be possible disease-modifying agents for PD. Mitochondrial dysfunctions and impaired calcium homeostasis are also related to the apoptotic cell death of dopaminergic neurons (Calí et al., 2011), generating free radicals, reactive oxygen and nitrogen species (ROS/RNS), which in turn cause oxidative stress to neurons. Furthermore, inflammatory and immunological reactions mediated by activated glial cells are strongly suggested to participate in the progression of dopaminergic cell death (Collins et al., 2012). In the activated astrocytes, upregulation of inflammatory cytokines, such as tumor necrosis factor-α (TNF-α) occurs, which triggers the apoptotic signaling of dopaminergic neurons by activation of TNF receptor. In the activated microglia, upregulation of inducible nitric oxide synthase (iNOS) occurs with increasing NO, which also contribute to generate highly toxic radicals, such as $ONOO^-$ (Tieu et al., 2003). Involvement of cyclooxygenase 2 (COX-2) facilitating inflammatory reactions is also known (Minghetti, 2004). Overall, each of these molecular events contributing to aggression of the PD pathology will be a possible protective (disease modifying) and/or therapeutic target of PD (Fig. 41.3), although most of the therapeutic drugs in clinical use today target for the synapse between nigrostriatal dopaminergic neurons and MSNs in the striatum, and none of the protective (disease modifying) drugs inhibiting the progression of PD are practically used yet. In the later section, we discuss the relevancy of these pathophysiological details of human PD and those of MPTP-induced animal model on a molecular level.

4 NEUROTOXINS FOR MAKING PD MODELS

All the agents used to prepare PD models ultimately result in the depletion of the striatal dopamine to express PD-like dysfunctions. In this section, we overview some typical neurotoxins and chemicals for PD models including MPTP in experimental animals.

4.1 6-OHDA

The first neurotoxin for PD model introduced by Ungerstedt (1968) was a hydroxylated analog of DA, 6-hydroxydopamine (6-OHDA). Using Sprague-Dawley rats, he reported a unilateral application of 6-OHDA into the nucleus caudatus putamen or the substantia nigra caused loss of monoaminergic terminals and dopaminergic cell bodies, respectively, with a marked motor asymmetry known as hemi-Parkinsonism, typically characterized by a rotational behavior to the impaired side (Ungerstedt and Arbuthnott, 1970). To date, the 6-OHDA model has been utilized by many researchers to examine pathophysiological hypothesis and possible novel treatment of PD and dyskinesia. Because of low permeability to blood–brain barrier (BBB), however, 6-OHDA must be applied directly into specific region of brain (typically in substantia nigra, medial forebrain bundle, or striatum) using stereotactic apparatus. For this reason, rats are most frequently used and less applied in nonhuman primates (Betarbet et al., 2002). It also requires pretreatment with an inhibitor for noradrenaline transporter (NAT), such as desipramine when selective loss of dopaminergic neurons is desired, because 6-OHDA is effectively incorporated into catecholamine neurons through NAT in addition to dopamine transporter (DAT) (Duty and Jenner, 2011). Furthermore, 6-OHDA can easily be degraded by MAO-B, so pretreatment with an MAO-B inhibitor, such as pargyline is also required to protect 6-OHDA from the oxidative breakdown. Once incorporated into catecholamine neurons, 6-OHDA rapidly gives oxidative stress to form ROS and/or RNS (Duty and Jenner, 2011), and also inhibits mitochondrial respiratory chain by interacting directly with complexes I and IV (Duty and Jenner, 2011). These events are thought to induce the catecholaminergic neurons to die. Although it is one popular experimental model for PD, 6-OHDA does not satisfy all the characteristics of the disease, such as progression of PD and formation of cytoplasmic Lewy body-like inclusions with increased α-synuclein protein (Duty and Jenner, 2011).

4.2 MPTP

The potency of MPTP to utilize in PD-model was found by chance when a synthesized heroin analog meperidine, containing a high amount of MPTP as a by-product, was administrated intravenously by seven individuals. They showed PD-like symptoms, such as akinetic rigidity, and were recovered by L-dopa (Langston et al., 1983). Further studies showed systemic administration of MPTP into nonhuman primates (Langston et al., 1984) and mice (Ricaurte et al., 1987) caused an irreversible and selective degeneration of dopaminergic neurons in the substantia nigra, and elicited PD-like symptoms. Because MPTP is a highly lipophilic molecule, it can easily cross BBB and be converted into the hydrophilic metabolite 1-methyl-4-phenyl-pyridinium (MPP^+) by MAO-B expressed in astrocytes (Figs. 41.4 and 41.5). MPP^+ is selectively incorporated into dopaminergic neurons via DAT, and is taken up into mitochondria, inhibiting complex I of the respiratory electron transfer chain. This leads to impairment of ATP production, elevated intracellular Ca^{2+} levels, and generation of ROS/RNS, eliciting apoptotic cell death of the dopaminergic neurons (Fig. 41.5).
FIGURE 41.4   **Chemical structures of MPTP and its toxic metabolite MPP$^+$.**

Thus, MPP$^+$ is primarily a mitochondrial toxin to specifically disrupt the respiratory system of dopaminergic neurons (Yokoyama et al., 2011a). MPP$^+$ also triggers inflammatory reactions starting from activation and proliferation of astrocyte and microglia (Yokoyama et al., 2011b). It facilitates synthesis and secretion of inflammation-related molecules including cytokines, such as TNF-α, interleukin 1β (IL-1β) and IL-6, chemokines, and prostagrandines. In microglia, upregulation of iNOS also occurs, resulting in increase and release of NO, which attacks neurons with generating toxic ROS and RNS. These events are well consistent with what happened in the brain of PD patients mentioned earlier.

To date, a wide variety of animals including nematodes (Wang et al., 2007), frogs (Barbeau et al., 1985), mice (Sunderström et al., 1990), rats (Laret et al., 2002), rabbits (Ghiribi et al., 2003), cats (Schneider and Rothblat, 1991), dogs (Choi et al., 2011), and nonhuman primates (Nomoto et al., 1998) were demonstrated to have sensitivity to MPTP. Among them, nonhuman primates with the highest MPTP sensitivity are ideal to use, though rodents are still the most widely used because of convenience. Mice are more favorably used than rats because the latter show a relatively high peripheral MAO activity (Kakaria et al., 1987) causing conversion of MPTP to MPP$^+$ before crossing BBB, failing to enter brain. If a researcher prefers to use MPTP in rats, it is necessary to inject MPTP or MPP$^+$ directly into the brain with a stereotactic apparatus as like 6-OHDA (Heikkila et al., 1985). Alternatively, intranasal administration of MPTP has developed recently (Predinger et al., 2012), though its efficiency and specificity should be examined more.

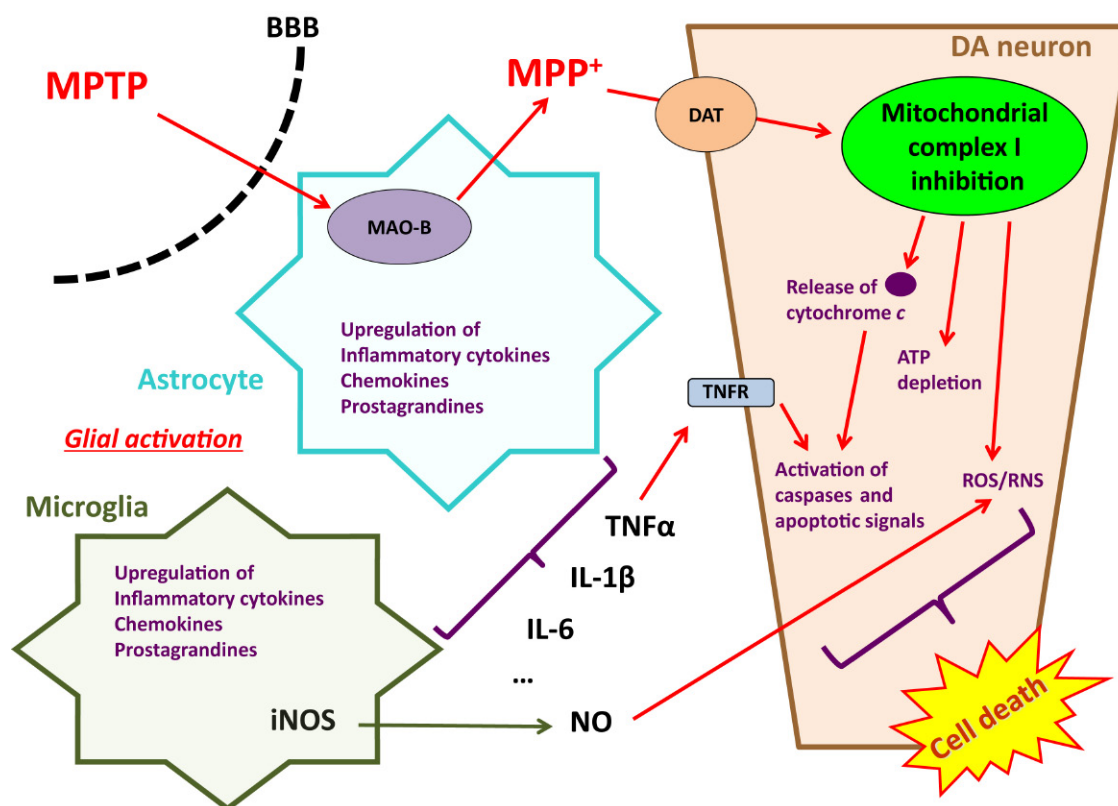
It should be noted that one significant difference of MPTP model with human PD is absence of Lewy body. Even by examining three different schedules of MPTP administration (acute, semichronic, and chronic), none of the obvious Lewy body-like inclusions were found


FIGURE 41.5   **Schematic diagram of action of MPTP in SNpc.** *BBB*, Blood–brain barrier; *DAT*, dopamine transporter; *IL*, interleukin; *iNOS*, inducible nitric oxide synthase; *MAO-B*, monoamine oxidase; *NO*, nitric oxide; *ROS*, reactive oxygen species; *RNS*, reactive nitrogen species; *TNF*, tumor necrosis factor.

in mice brain (Shimoji et al., 2005). It was also reported in a study that using two monkeys which survived over 10 years demonstrating severe PD-like symptoms after MPTP treatment in their youth had no Lewy body-like inclusions in brain, even though expression of α-synuclein protein was increased significantly (Halliday et al., 2009). We will discuss this discrepancy in the later section.

4.3 Pesticides

As we described in the previous section, exposure to pesticides, such as rotenone, paraquat, and maneb was shown to have a positive correlation to the risk of PD. Rotenone is one of the lipophilic phenylpropanoid compounds. Because of its selective inhibitory effect on the mitochondrial respiratory complex I similar to MPP⁺ (but have no cell-type specificity), it was expected to be utilized as a chemical for PD model. In fact, chronic, but not acute, systemic administration of rotenone in rats with 2.5 mg/kg/day for 7 ~ 33 days caused a loss of the nigrostriatal dopaminergic neurons, appearance of the cytoplasmic inclusions reminiscent to Lewy body which contained α-synuclein and ubiquitin proteins, and motor dysfunctions including hypokinesis, hunched posture, rigidity, and tremor (Betarbet et al., 2000). This is quite an attractive model with matching face and constructive validities with human PD, however, rotenone also has cardiovascular and other systemic toxicities in addition to the toxicity for central neurons, probably because of its cell-type nonspecific inhibition of mitochondrial complex I, resulting in a relatively high rate of mortality (~30%) where the results tend to vary (Duty and Jenner, 2011).

Different from rotenone, paraquat (1,1′-dimethyl-4-4′-bipyridinium: PQ) does not cross BBB. It is transported into the brain by a neutral amino acid transporter, and incorporated into dopaminergic neurons with a sodium-dependent uptake system (Shimizu et al., 2001). As its chemical structure resembles MPP⁺, it is thought to inhibit mitochondrial respiratory complex I, resulting in a mild loss of the nigrostriatal dopaminergic neurons, although paraquat was reported to have no specificity to DAT (Richardson et al., 2005). On the other hand, however, a recent report showed that paraquat could be incorporated via DAT when it was converted to a monovalent cation PQ(+) rather than a native divalent cation state PQ(2+) (Rappold et al., 2011). This and further studies are expected to clarify a precise mechanism of the selective toxicity of paraquat on dopaminergic neurons.

Manganese ethylene-bis-dithiocarbamate, also called maneb, is known to inhibit mitochondrial respiratory complex III (Zhang et al., 2003). It is frequently used in geographically overlapping areas with paraquat, and it was reported that combined administration of them enhanced the toxicity than the cases of sole use, in fact (Thiruchelvam et al., 2000). In addition, 30 mg/kg of maneb was reported to enhance the neurotoxicity induced by 50 mg/kg MPTP in mice examined with locomotor activities and catalepsy test (Takahashi et al., 1989). Thus, it can be considered that combination of neurotoxins usually enhance the expression and progression of PD-like symptoms with degenerating the nigrostriatal dopaminergic neurons, although an exception was also reported (Aoki et al., 2010).

4.4 Others

Chemicals other than neurotoxins listed earlier—mainly interacting with molecules for dopaminergic neurotransmission, biosynthesis, and metabolism—are also used for PD models, although many of their effects are transient and do not cause a selective degeneration of dopaminergic neurons: Reserpine, an inhibitor for vesicle monoamine transporter (VMAT), resulting in a depletion of synaptic dopamine; Methamphetamine, it also causes a depletion of the striatal dopamine at synaptic terminals; Haloperidol, an inhibitor for D₂ receptor typically causes the antipsychotic drugs-induced extrapyramidal syndrome; α-methyl *p*-tyrosine (AMPT), an inhibitor for TH.

5 MPTP-INDUCED MICE MODEL OF PD

Here we describe practical methods to produce MPTP-induced PD model of mice and how to analyze them with behavioral, immunohistochemical, and biochemical manners. We also discuss the relevance of molecular details between human PD and this model.

5.1 Animal Selection

Among the strains of mice examined in, such as CD-1, C57BL/6, BALB-c, CBA/Ca, NMRI, and Swiss Webster, C57BL/6 is now considered to show the highest sensitivity to MPTP (Filipov et al., 2009; Muthane et al., 1994; Sedelis et al., 2000; Sunderström et al., 1987, 1990). Some researchers tried to explain the reasons for the differential sensitivity among the strains with difference of molecular details, including the activity of MAO-B (Walsh and Wanger, 1989), c-Jun N-terminus kinase (JNK) signaling with COX-2 expression (Boyd et al., 2007), glial functions (Smeyne et al., 2001), and so on, although no conclusive result has been obtained yet.

For the age of mice used, adult ones ranging from 7 ~ 8 weeks to much older—up to ~12 months—are favored, and older animals showed higher MAO-B activity causing their increased sensitivity to MPTP (Walsh and Wanger, 1989).

5.2 Drug Administration

Researchers should carefully handle MPTP in a safety cabinet by wearing gloves, a goggle, and a mask to avoid unexpected inhalation. MPTP can be dissolved in water or saline (150 mM NaCl) with up to 10 mg/mL. It can also be dissolved in dimethyl-sufoxide (DMSO). Subcutaneous or intraperitoneal administration of MPTP is generally performed using a 1 mL disposable syringe. Various schedules and amounts of MPTP administration are reported, it may be roughly classified into three categories: acute, subacute (semichronic), and chronic. Following is the frequently used dosing: 10–20 mg/kg for 4 times with 1 ~ 2-h intervals as an acute model; 30 mg/kg/day for 4 ~ 5 days as a subacute model; 2 times of 25 mg/kg with 250 mg/kg of probenecid in a week for 5 weeks as a chronic model (Shimoji et al., 2005). In fact, various substances including clinically approved ones were successfully evaluated with this model. Some of the typical substances analyzed by us are as follows: L-dopa, cabergoline, perindopril, riluzole, 7-nitroindazole, benzamide, zonisamide, imatinib, nilotinib, mirtazapine, and so on (Araki et al., 2001; Choudhury et al., 2010; Kadoguchi et al., 2014; Kurosaki et al., 2004; Muramatsu et al., 2002; Nomoto et al., 1998; Tanabe et al., 2014; Yamamura et al., 2013; Yokoyama et al., 2010a,b). Acute and subacute models are especially favorable for screening therapeutic substances efficiently with analyzing their molecular details of pharmacology. On the other hand, subacute and chronic administration of MPTP would reflect the processes of PD progression, suitable to analyze its molecular pathophysiology and screening protective (disease modifying) substances. In case of a protective (disease modifying) substance to be applied chronically, subacute (semichronic) protocol of MPTP administration described earlier is also applicable.

It should be noted that differential dosing results in differential effects on behavioral, anatomical, and neurochemical parameters. For example, our previous study (Kuroiwa et al., 2010) with various schedules and dosing of MPTP to 8 weeks old male C57BL/6N mice resulted in differential amounts of the striatal dopamine and its metabolites 3,4-dihydroxy-phenylacetic acid (DOPAC) and homovanillic acid (HVA), even in the cases of the same total 80 mg/kg dosing with four different schedules (Kuroiwa et al., 2010). In this study, we scheduled as follows: (1) 4 × 10 mg/kg/day for 2 consecutive days; (2) 1 × 20 mg/kg/day for 4 consecutive days; (3) 2 × 20 mg/kg/day for 2 consecutive days; (4) 4 × 20 mg/kg in a day. The striata were dissected out in 1, 2, and 3 weeks after MPTP administration. As a result, reduction of the amount of striatal dopamine varied between the four groups: (1) showed a constant reduction to ~40% throughout the periods of examination; (2) only decreased to ~70% in 1 week, then recovered to ~85%; (3) decreased to ~35% in 1 week, but recovered to ~70% after 2 weeks; (4) significantly decreased to ~20%, and the effect was sustained throughout the 3 weeks examined. The magnitude of reduction was (2) < (3) < (1) < (4), showing acute administration with frequent injections resulting in the most effective and prolonged reduction of the striatal dopamine.

5.3 Behavioral Analysis

After administrating MPTP, evaluations of the functional motor coordination and/or balance are usually performed with various behavioral tasks. As we mentioned earlier, multiple tasks are recommended to examine each experimental project.

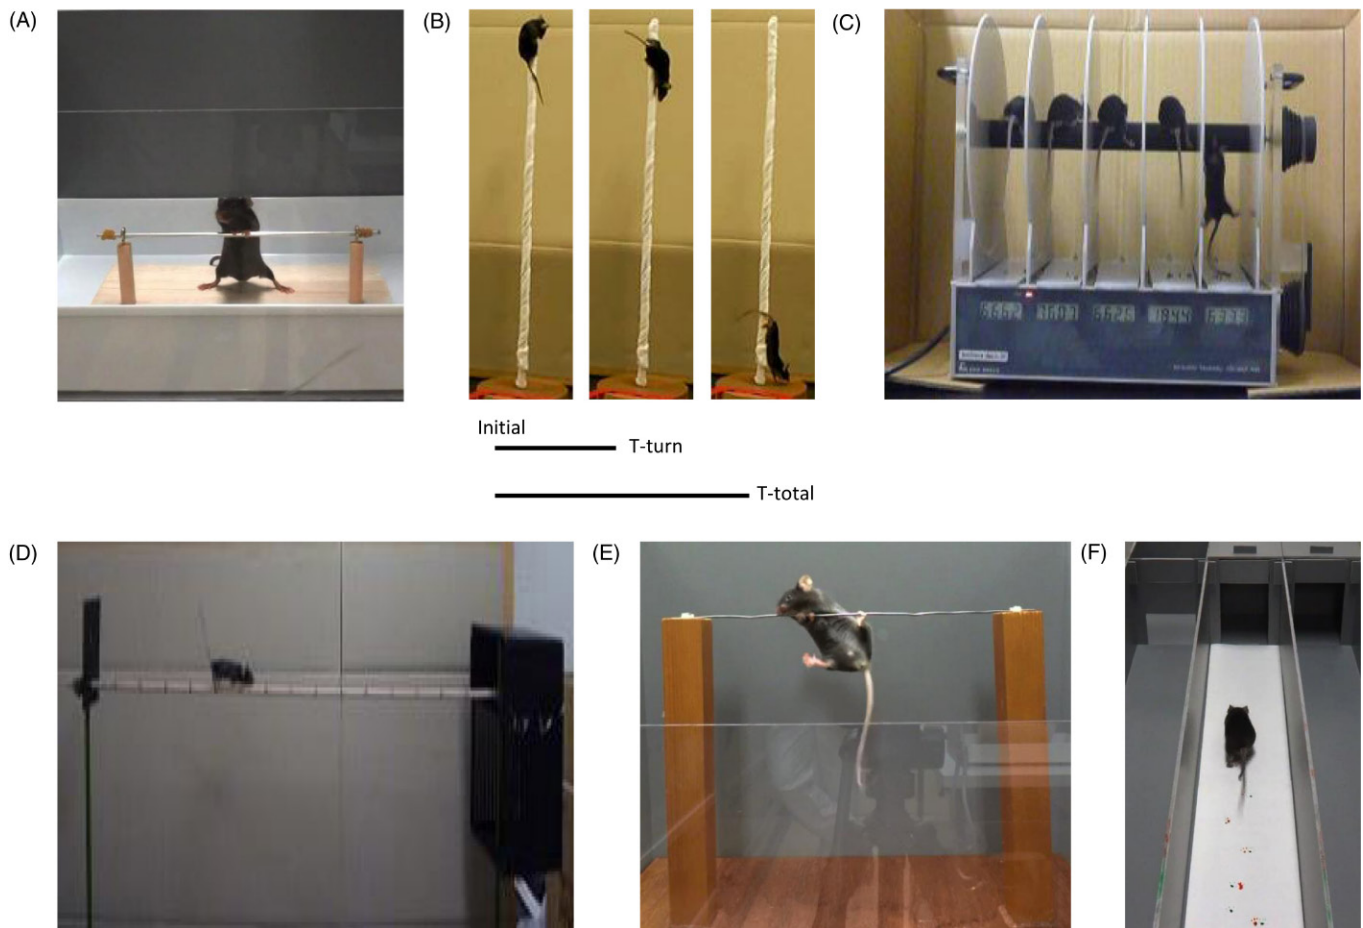
Generally, behavioral assessments are performed from a few hours to days after MPTP treatment. It should be noted that MPTP sometimes has an acute inhibitory effect on skeletal muscles, probably by inhibiting peripheral nicotinic acetylcholine receptors in the neuromuscular junctions (Hsu et al., 1994). For this reason, it is highly recommended to start the analysis at least with a 24-h interval after the final MPTP treatment, especially when a researcher wants to examine a therapeutic effect of a substance or so. We usually perform behavioral evaluations on or over 3 days after MPTP administration (20 mg/kg × 4 times, total 80 mg/kg with 2-h intervals in a day), when we want to examine the therapeutic effect of a substance, such as L-dopa, because numbers of the nigrostriatal dopaminergic neurons become minimum and those of activated astrocytes and microglia are in maximum (Aoki et al., 2009). Also in our case examining a protective substance, we usually apply MPTP with 10 mg/kg × 4 times with 1-h intervals (total 40 mg/kg) and the substance to be examined is applied 30 min before and 90 min after the first administration of MPTP, then perform behavioral tasks and biochemical examinations on or over the next day of MPTP administration (Yano et al., 2009). Alternatively, MPTP may be administered with 30 mg/kg/day for 4 ~ 5 days, and the substance to be examined would be start to be applied 1 day before starting MPTP administration, followed by daily application until stopping MPTP administration. Another issue is a behavioral recovery despite significant neurodegenerative changes on the nigrostriatal dopaminergic neurons. A study showed, the differential time course of recovery was seen between the different strains of mice (Sedelis et al., 2000). It may also depend on which type of behavioral tasks to apply. Thus, researchers should optimize the schedule of dosing, type of the tasks applied, and the timing to analyze carefully by a pilot experiment. Following behavioral tasks are frequently used to evaluate PD-like motor dysfunctions in mice. We show some pictures of typical experimental apparatuses in Fig. 41.6.


FIGURE 41.6 **Experimental apparatuses to assess motor dysfunctions of mice.** (A) Catalepsy bar test. (B) Pole test. (C) Rota-rod test with a falling mouse on the right. (D) Beam-walking test. (E) Horizontal wire test. (F) Footprint test.

5.4 Catalepsy Bar Test

It requires a relatively simple apparatus consisting of a horizontal bar (typically ranging from 0.2 to 1 cm diameter) made of wood or a stainless steel wire, spanning between two pillars with a typical height of 5–20 cm from the grounding platform (Fig. 41.6A). The period during which the mice keep an immobile posture when putting their forepaws on the bar and hind paws on the ground, known as catalepsy, is recorded until they quit keeping the posture (Watanabe et al., 2008). Similar paradigm called grip test is also applicable (Sedelis et al., 2000). Usually, naive or vehicle-treated animals show a few seconds of catalepsy period, while MPTP-treated mice show a typically prolonged period with three- to five-folds (Watanabe et al., 2008). When the mice quit the immobile posture, some of them may put all their paws on the ground, may lift their hind paws up on the bar and may move on it. The difficulty of this task is a relatively large variation of individuals especially in MPTP-treated animals which cause a failure to detect significance, even though the results show a good tendency. Finally, researchers should also note that catalepsy not only reflects an extrapyramidal syndrome but also psychotic and hypnotic conditions in some cases.

5.5 Pole Test

This paradigm was originally developed to detect MPTP-induced bradykinesia in 1987 (Ogawa et al., 1987), and was also proven to be effective especially for detecting antipsychotic drugs-induced extrapyramidal syndrome with D_2R inhibition (Ohno et al., 1994). The apparatus used consists of a vertical pole fully taped with gauze typically $40 \sim 50$ cm in height standing on a basement platform (Fig. 41.6B). Mice are first settled on the top of the pole with their heads looking upward. Mice then turn their heads downward within a few seconds, and the latency of this is called T-turn. Mice are subsequently moved down along with the pole, and the latency to reach to the ground platform is called T-total. Although both T-turn and T-total can be parameters to evaluate, the latter is more frequently used. MPTP prolongs both of the parameters significantly, such as 2–3 times longer, and is recovered by a therapeutic drug, such as L-dopa (Ogawa et al., 1987).

5.6 Rota-Rod Test

This is a frequently applied paradigm to assess the motor coordination of rodents (Fig. 41.6C) (Kadoguchi et al., 2014; Tanabe et al., 2014; Yokoyama et al., 2010b). The rota-rod apparatus with constant and/or variable speeds can be purchased from many companies selling behavioral apparatuses. It consists of a rotating rod with a few cm of diameter and usually covered by a rubber on its surface, divided into $4 \sim 5$ individual sections so that multiple animals can be assessed in one trial. Mice are put on the rotating rod with a constant speed, typically ranging from 15 to 32 rpm in a trial session, for an appropriate cut off duration, such as 10 min, and the latency to fall on the ground (LTF) is recorded. Alternatively, the rotating speed may be increased during the session, such as from 5 to 30 rpm with a constant increment. A well-trained mouse without drugs can endure to keep walking on the rod for over 10 min even with 32 rpm. MPTP usually shorten the LTF significantly to the extent, such as from half to one-third of the control. It requires some training sessions to minimize the variable of individuals. For this purpose, $1 \sim 2$ training sessions/day for successive $2 \sim 3$ days with a relatively lower speed than the trial session should be performed before MPTP administration.

5.7 Open-Field Test

It is one of the most popular apparatuses to evaluate a locomotor activity and exploratory behavior of rodents in an open box surrounded by walls (Sedelis et al., 2000). The field is usually ~ 2500 cm^2 (50 cm $\times$ 50 cm) divided into 25 areas by drawing lines onto it. There are a wide variety of apparatuses and analysis used, though essentially evaluating the spontaneous activity of the animals with horizontal (distance travelled) and vertical (rearing) directions for various durations. Automated recording systems using an infrared beam and/or video-based tracing are convenient to use. Alternatively, just counting numbers of transition between the divided areas and of rearing frequencies are also acceptable. To minimize the variety of individuals and to exclude an exploratory behavior in a novel field, pretrial habitations may be required. When the effect of MPTP in mice is fully expressed, both horizontal and vertical activities are decreased. This paradigm, however, is highly affected by emotional biases (Belzung and Griebel, 2001), so researchers have to make sure whether the results are caused only by alternation of motor functions.

5.8 Wheel Activity Test

This test allows to evaluate spontaneous locomotor activity during the active cycle of the mouse using an activity wheel (15 cm in diameter). The distance traveled is measured by the total number of wheel rotations completed during an active cycle.

5.9 Elevated Plus Maze

This paradigm is often used for screening anxiolytic drugs, such as benzodiazepines (Belzung and Griebel, 2001). As with open-field test, it can also be used to evaluate spontaneous locomotor and exploratory activities, and is highly affected by emotional biases. The maze is settled with a height, such as 45 cm with pillars standing from the ground floor. The maze consists of four arms of pathways crossing at the center stage with a right angle, and the two paths facing each other have walls, while the other two have no wall. The numbers of arm entry and rearing are convenient indexes of the horizontal and vertical activities, respectively. When the mouse feels anxiety, it tends to remain in the arm with a wall, so the time spent in each arm is also recorded. Frequencies of arm entries decrease in motor impaired mice.

5.10 Beam-Walking Test

The purpose of this test is to measure the traversing speed of mice on the horizontal bar (Fig. 41.6D), evaluating a sensorimotor coordination and the integrity of the vestibular senses (Dean et al., 1981; Sato et al., 2008). The bar with a square or a circular shape, typically $50 \sim 60$ cm in length, is positioned at a height of 50 cm supported by two pillars, having a box at the goal end so that the mice can take rest after traversing. It requires some training sessions (e.g., 3 trials in a day for 2 successive days) before the trial. In the training session, the bar with a relatively large diameter or width, such as $12 \sim 16$ mm is used. In the trial session after MPTP administration, mice are settled at the starting end of the bar with a diameter of $6 \sim 8$ mm, and the time required to reach the box is measured. The traversing speed of MPTP-treated mice tends to delay, and will be recovered by administrating a therapeutic drug, such as L-dopa. It seems to have a higher sensitivity than other paradigms, although some of the mice especially treated with MPTP stop traversing in the middle of the bar (freezing) for several times, which is also considered to reflect one aspect of akinesia.

5.11 Horizontal Wire Test

This test estimates motor coordination and muscle relaxation (Burkard et al., 1985; Vanover et al., 1999). The testing apparatus consists of a solid wire (typically $0.1 \sim 0.2$ cm diameter, $20 \sim 30$ cm length) horizontally stretched $20 \sim 30$ cm above the grounding platform (Fig. 41.6E). Mice are lifted by the tail and allowed to

grasp the wire with their forepaws, and then are released. A mouse passes the task if it grasps the wire with at least one hindpaw within a few (3 ~ 10) seconds. If a mouse takes over the prescribed time to grasp the wire with a hindpaw, or can't grasp the wire, it fails. Mice are trained to pass the task 2 ~ 3 times before MPTP administration. The parameter determines the rate of mice passing the task in each group. The pass rate of control group is approximately over 75%, while the rate of MPTP-treated group decreases to less than half of the control.

5.12 Footprint and Stepping Test

As described earlier in Section 2.3, a PD patient tends to have trouble walking and balancing, taking small steps with his or her feet close together with abnormal balance. Similar symptoms are also observed in MPTP-treated mice. Footprint test and a recently developed stepping test evaluate these abnormalities (Blume et al., 2009; Mohanasundari et al., 2006).

The footprint apparatus consists of a runway, usually 50 ~ 60 cm length, with a dark goal-box at the end (Fig. 41.6F). Mice are trained to walk straight to the gaolbox on the white paper before the trial. After administrating drugs, the forepaws and hindpaws of the mice are painted with different colors (e.g., forepaws with red and hindpaws with green). Then the mice are made to walk on the paper. The footprint patterns are analyzed for three parameters (stride length, stride width, and overlap). Stride length, usually 5 ~ 7 cm, is determined by measuring the distance between each step of the same side of the body. MPTP decrease the length for a half to a third compared to the control mice. Stride width, usually 2 ~ 2.5 cm, is measured as the distance between the right and left footprint, which often increases in MPTP mice. Overlap, usually 0.5 ~ 0.7 cm, is measured as the distance between the center of frontpaw and hindpaw footprints on the same side, which also increase in MPTP mice.

In the stepping test (Blume et al., 2009), a mouse is allowed to settle at one edge of the table with 1.2 m length, typically with all limbs on the table. The experimenter would lift the hind legs up by pulling the tail up with only the forepaws touching on the table. At a steady pace of approximately 1 m in 3 ~ 4 s (for a total distance of 1 m), the experimenter pulled the animal backward by the tail, down toward the other edge of the table, and the number of adjusting steps from both forepaws is computed. A significant decrease in this is observed in MPTP-treated mice when compared to the saline group.

5.13 Immunohistochemical and Biochemical Evaluations With Relevancy to PD

Anatomical and immunohistochemical evaluations can be applied after mice have been fixed with 4% para-

formaldehyde, with preparing paraffin-embed, frozen, or free-float sections, according to researcher's choice.

Most of the anatomical studies are performed in SNpc and in the striatum where dopaminergic neurons with their axons are lost by MPTP treatment. In SNpc, immunostaining with antibodies for TH, DAT, or neural nuclei (NeuN) reliably detect the significant decrease in the number of dopaminergic neurons after MPTP treatment. Our previous study in case of the acute MPTP administration with 4 times of 20 mg/kg with 2-h intervals in a day (total 80 mg/kg) resulted in nearly 60% of TH-positive neurons being lost within 3 days, although around 10% were recovered in 3 weeks after MPTP treatment, probably showing a recovery of TH protein expression in the remaining neurons (Aoki et al., 2009). Similarly in the striatum, the density of TH-positive fibers was decreased significantly, indicating a degeneration of the dopaminergic axons after MPTP administration (Yokoyama et al., 2010b).

The neuronal death in SNpc includes apoptosis because the immunoreactive neurons to the antibody for single-strand DNA, a marker for apoptosis, significantly increased within 5 h till 3 days after MPTP treatment (Aoki et al., 2009). It was also reported in SNpc that MPTP increased the protein expression of cleaved caspase 3, one of the critical executers of apoptosis, and the effects of MPTP were significantly decreased when the gene coding caspase 3 was disrupted (Yamada et al., 2010). Many other studies also reported MPTP-induced apoptosis of the dopaminergic neurons in SNpc, and the apoptotic neurons were also found in SNpc of the postmortem brain of PD patients (Mochizuki et al., 1996), showing a good relevancy between this model and human PD.

MPTP also affects the activation of glial cells. Numbers of both astrocytes detected by antiglial fibrillary acidic protein (GFAP) or S100β antibodies and microglia detected by isolectin B$_4$ or anti-Iba-1 antibody were significantly increased in the same conditions above (Aoki et al., 2009; Himeda et al., 2006; Yokoyama et al., 2010b). These glial cells abundantly express cytokines and chemokines, such as IL-1β, IL-6, and TNF-α, related to inflammatory and immunological reactions, possibly mediating progression of neurodegeneration both in human and this model. Similarity of the time courses of p65 nuclear factor-κB (NF-κB) expression in the reactive astrocytes and ssDNA immunoreactivity in neurons was observed after MPTP treatment (Aoki et al., 2009). Because NF-κB activation was found in both postmortem PD brains and neurotoxin-induced animal models, it is also thought to be a key molecule to induce neuronal apoptosis (Ghosh et al., 2007; Langston, 2002).

MPTP also elicits oxidative stress which is another factor to cause dopaminergic degeneration (Fig. 41.2). In fact, activities of superoxide dismutases (SODs) and glutathione peroxidase (GSH-PX) were decreased, and

malondialdehyde (MDA), the end product of lipid peroxidation, was significantly increased after MPTP administration (Li and Pu, 2011). Further, reduction of lipoamide dehydrogenase and metallothionein in MPTP-treated mice was reported (Dhanasekaran et al., 2008). Involvement of the oxidative stress in PD progression is well known as mentioned previously (Calí et al., 2011), so this is another relevant factor between animal model and human disease, and substances which upregulate these antioxidative proteins would be possible disease modifying agents to slow down PD progression.

As we described in the previous section, formation of Lewy body including accumulated α-synuclein protein oligomers and ubiquitin probably caused by an abnormal ubiquitin-proteasome systems is a characteristic pathology in PD. In contradiction, however, many reports denied the formation of a Lewy body-like inclusion in MPTP-treated mice (Betarbet et al., 2002; Blandini and Armentero, 2012; Halliday et al., 2009; Shimoji et al., 2005; Ungerstedt, 1968). In addition, a proteasome inhibitor failed to induce or enhance neurotoxicity on the nigrostriatal dopaminergic neurons (Kadoguchi et al., 2008a,b). From these results, researchers may suspect MPTP can not mimic the steps of protein degeneration caused by ER-stress in PD. However, MPTP, when administered chronically using osmotic minipump but not with sporadic administration, was reported to form neuronal inclusions containing both increased α-synuclein and ubiquitin proteins (Fornai et al., 2005). Another report also showed that oligolmerization of α-synuclein mediated by fatty acid-binding protein 3 (FABP3) was increased by MPTP treatment with 25 mg/kg for 5 days in mice (Shioda et al., 2014). Though further examinations will be necessary, these reports would open new insight to support the validity of MPTP model reproducing accumulation and oligomerization of α-synuclein, impairment of proteolytic system, and ER-stress elicited in PD.

Many researchers are interested in the protective potency of neurotrophic factors including brain derived neurotrophic factor (BDNF) (Ding et al., 2011; Hung and Lee, 1996; Nagahara and Tuszynski, 2011) and glial cell line-derived neurotrophic factor (GDNF) (Rangasamy et al., 2010) with their receptors. The mesolimbic dopaminergic neurons originated from ventral tegmental area innervated to nucleus accumbens shows less vulnerability to MPTP than the nigrostriatal dopaminergic neurons, and expression of mRNA of BDNF was higher in the former than the latter pathway, possibly explaining the differential sensitivity to the neurotoxin (Hung and Lee, 1996). Furthermore, a study using Fluoro-Jade, a fluorescent detector of neurodegeneration, and other antibodies showed the neurons expressing both TH and TrkB, a receptor of BDNF, were less sensitive to MPTP than other TH-positive neurons in SNpc (Ding

et al., 2011). Mice transplanted bone marrow stem cells expressing recombinant GDNF showed resistance to MPTP on behavioral, immunohistochemical, and biochemical levels (Biju et al., 2010), demonstrating successful delivery of GDNF with macrophage-mediated manner had a protective effect on MPTP neurotoxicity. Nicotine was reported to upregulate both basic fibroblast growth factor 2 (FGF-2) and BDNF in the striatum, with protective effects on MPTP-induced neurotoxicity (Maggio et al., 1998). It suggests the reason why smokers show lower risk of PD mentioned earlier. All of these studies utilized MPTP model, suggesting the possibility of future therapeutics using exogenous or endogenous neurotrophic factors.

In association with loss of nigrostriatal dopaminergic neurons, amounts of the striatal dopamine and its metabolites, DOPAC and HVA, are significantly decreased. They are usually quantified by a high-performance liquid chromatography (HPLC) (Kadoguchi et al., 2014; Kuroiwa et al., 2010; Yokoyama et al., 2010b). Turnover rate of dopamine is expressed with dopamine/(DOPAC + HVA), which can also be regarded as an indirect index of the released dopamine (because it is degraded after released from synaptic vesicles) (Hollerman and Grace, 1990), although inhibition of MAO-B and/or COMT also increases this value. It is also utilized to assess TH activity indirectly. L-dopa could be an indirect index of TH activity under the condition of AADC converting L-dopa to DA is inhibited (Perrin et al., 2004). NSD-1015A, a BBB-permeable AADC, when applied on 30 min prior to sacrifice the mice, can inhibit TH in brain, thus L-dopa is accumulated. The accumulated L-dopa is decreased significantly by MPTP treatment, indicating activity of TH was decreased in association with reduction of TH protein expression (Perrin et al., 2004). HPLC is also combined with a microdialysis to quantitate dopamine and its metabolites in the extracellular fluids of a specific brain region, such as the striatum in living animals, which enables researchers to measure the released dopamine directly (Olive et al., 2000).

Quantification of changes of the protein amount is easily detected by Western blot analysis with higher sensitivity than histochemical methods. It is frequently used to detect the toxicity of MPTP in SNpc and a presynaptic component of the striatum with downregulation of markers for the dopaminergic neurons TH, DAT, and VMAT2, together with upregulation of the glial markers, such as GFAP and Iba-1 (Yokoyama et al., 2010b), although it should be combined with an immunohistochemical analysis when the information of cellular and subcellular localization of the molecule is also necessary. Finding a protein marker reflecting MPTP toxicity in postsynaptic MSNs should also be considered because they will be a good index for the resulting effects of loss of dopamine in the striatum. Moreover, it will be a possible therapeu-

tic target in MSNs (Fig. 41.3). For example, c-Fos protein is one of a product of immediate early genes induced by neuronal activity (Chen et al., 2001). We have recently found a phosphorylated form of cyclin-dependent protein kinase 5 (Cdk5) at tyrosine 15 residue (Cdk5-pTyr15) by c-Abl was abundantly expressed in the striatal matrix compartment (Morigaki et al., 2011), and was negatively regulated by D_2 receptor activation, as well as acute administration of c-Abl inhibitors, such as imatinib (Yamamura et al., 2013) and nilotinib (Tanabe et al., 2014), suggesting the possibility of Cdk5-pTyr15 and its substrate dopamine- and cAMP-regulated neuronal phosphoprotein 32 kDa (DARPP-32) phosphorylated at Thr 75 residue (DARPP32-pThr75) to be pathological protein markers reflecting activity of MSNs. Other reports suggested involvement of of c-Abl in PD progression mentioned earlier (Karuppagounder et al., 2014; Ko et al., 2010). Considering all of these reports, c-Abl inhibitors may be applicable both as PD modifying and as therapeutic agents.

Because MPTP affects both sides of brain hemisphere, researchers can utilize each hemisphere for different purposes: one side for HPLC and the other side for Western blot or RT-PCR, for example.

Thus, MPTP-induced mice model of PD shows most of the pathological characteristics with human PD except for the formation of Lewy body, and has been frequently utilized for drug screening and analysis of pathophysiological and pharmacological mechanisms of PD, its protection and therapeutics.

5.14 Functional Imaging in Mice

Recent advances in imaging technologies have enabled to apply positron emission tomography (PET) to MPTP-treated mice. The first study that applied PET in MPTP mouse was reported in 2001 (Ishiwata et al., 2001), showing decreased presynaptic ligand-DAT binding with N-3-fluoropropyl-2-β-[O-methyl-^{11}C] carbomethoxy-3-β-(4-iodophenyl)-tropane ([^{11}C]CIT-FP) and compensatory upregulation of postsynaptic D_2 receptors with [^{3}H]raclopride after MPTP treatment. Since then, studies using PET have been gradually increasing, especially within the past few years. It has been primarily utilized to visualize the process of progressive degeneration of dopaminergic neurons by MPTP treatment with a DAT ligand 2β-carbomethoxy-3β-(4-chlorophenyl)-8-(2-[^{18}F]-fluoroethyl)-nortropane ([^{18}F] FECNT) (Honer et al., 2006) and a VMAT2 ligand 9-fluoropropyl-(+)-dihydrotetrabenazine ([^{18}F]-DTBZ or AV-133) (Chao et al., 2012; Toomey et al., 2012). Although its application is still limited, PET imaging will be a powerful tool to understand the molecular events of PD and pharmacology of therapeutics in living animals.

A recent study revealed that manganese-enhanced magnetic resonance imaging (MEMRI) was applicable on MPTP mice, showing a correlation between the highly active area in a brain identified with the manganese ion accumulated and severity of nigrostriatal dopaminergic neuronal degeneration quantified with TH immunoreactivity (Kikuta et al., 2015). This may also be applicable for future PD diagnosis.

Microglial activation during and after MPTP treatment had been visualized using bioluminescence in vivo imaging with Toll-like receptor 2-luciferase/green fluorescent protein (TLR2-luc/gfp) reporter mice. This study showed a transient activation of TLR2 signaling during MPTP administration, returned to the basal level within 3 h (Drouin-Ouellet et al., 2011). Using such a cell type specific signaling molecule as a reporter, bioluminescence study will explore further detailed pathophysiological mechanisms of PD in a time-dependent manner in vivo.

6 MPTP-INDUCED COMMON MARMOSET MODEL FOR PD

6.1 General Information to Use Common Marmosets

Common marmoset (*Callithrix jacchus*) is a nonhuman primate belonging to *Cebidae Callitrichinae*, a family of New World monkeys, having a body length of approximately 20 cm with a tail of about 25 cm, and an adult body weight over 240 g. Because of its size, easiness of handling compared to other monkeys, and good reproduction, it is a useful and favorable animal model for human diseases. A recent study of gene expression analysis comparing 26 genes between mice and common marmosets distinguished some shared and different molecules expressed during developmental stages of brain (Mashiko et al., 2012), possibly causing structural and functional differences between them.

6.2 Housing and MPTP Administration

Animals should be purchased from a reliable dealer of experimental animals. In general, both male and female animals with ages 2 ∼ 4 years, 240 ∼ 400 g weight are used for experiments. Usually two animals per cage are housed under controlled temperature (28 ± 1°C) and humidity (50 ± 5%) with a 12-h light/dark cycle. Before starting MPTP treatment, the animals are maintained with free access to food and water. After MPTP treatment, each animal must be fed with milk artificially twice daily when they are unable to voluntarily ingest sufficient food. After MPTP administration, the behavioral studies of Parkinsonism usually are performed by close observation with video camera. MPTP administration is usually done with a variety of doses by a subcutaneous injection. Repeated administration with 24-h

intervals is usually performed. According to the doses injected, the following symptoms are observed.

6.3 Progression of Abnormal Symptoms

The acute effects of MPTP include abnormal movements and alterations of motor behavior and posture. These effects may be observed by the systemic or local administration of MPTP and several dosing regimens (Table 41.1) have been used in many studies (Choudhury et al., 2010; Fox et al., 2002; Jenner et al., 1984; Philippens et al., 2013; Rose et al., 1993). The abnormalities become more striking after each successive dose. They occur within 5 min of drug administration and, initially, may last for 15 ~ 30 min. After four or five doses, some of the acute motor effects may persist. The first motor signs to appear, usually after the third dose, will be intermittent eyelid closure, a decrease in spontaneous movements, including loss of facial expression, and postural tremor. The animals will be awake, however, and may respond to loud noises by opening their eyes, looking at the examiner, and making weak threatening movements. The tremor will be intermittently present, moderate in amplitude, and slow in frequency, and involve the proximal muscles of the extremities. A postural tremor of the head or jaw may be observed in some animals. These acute motor effects may last up to 30 min. Motor signs that appear only after four or five doses include abnormal facial movements and changes in posture, muscle tone, and deglutition. Twitching of the facial muscles and facial grimacing may be prominent effects seen in all of the animals. Extension of the head, rigidity of the upper and lower extremities may be demonstrated by passive range-of-motion testing and may be sustained (turning to one side were observed in some of the animals). Some animals may also have difficulty swallowing, as may be evidenced by drooling and the accumulation of food biscuits in their mouth pouches. Rotatory movements of the eyes may be observed in some animals. In all of the animals, eyelid closure, decreased spontaneous motor activity, rigidity, postural tremor, and difficulty swallowing may persist with a cumulative dose of about 1.7 mg/kg. Abnormal facial movements, head extension, and rotatory eye movements, however, may be observed only during the 30 min immediately after drug administration. After the 5-day period of drug administration, other signs of motor impairment may appear. These include general slowness of movement, a flexed posture, loss of hand dexterity, and "freezing" episodes. The animals remain seated, with marked flexion of the neck, thoracic spine, and upper and lower extremities. There may be evident difficulty in picking up food biscuits, which may be subsequently dropped while being carried to the animal's mouth. Episodes of "freezing" or stopping in the

middle of a motion may be observed in some animals. Motor function deficits may appear to increase during the initial 2-week period after the last dose of the drug (Burns et al., 1983). In Table 41.2, we summarized PD-related symptoms observed in marmosets after MPTP treatment referred from two reports (Ando et al., 2008; Pearce et al., 1999).

When a researcher wants to get a short-term maximal effect of MPTP, it will be administered at a dose of 2.5 mg/kg subcutaneously with 3 times at intervals of

(A)

(B)

Before MPTP
After MPTP

FIGURE 41.7   **Common marmosets.** (A) Normal condition. (B) 14 days after MPTP-treatment at a dose of 2.5 mg/kg subcutaneously with 3 times at intervals of 24 h.

24 h (Choudhury et al., 2010). In Fig. 41.7, we show a picture of normal and MPTP-treated common marmosets.

6.4 Locomotor Activity

Evaluation is usually performed in a monitoring cage unit for locomotor activity with multiple infrared beams covering the inside of the entire cage to automatically detect spontaneous activity of the animal. After a habituation period of ~1 h, an interruption of an infrared beam by a moving marmoset was automatically recorded as a single locomotor count, accumulated over 10 min for up to 8 h.

6.5 Scoring of Severity

The akinesia-like symptom develops, which can be classified with 0 ~ 5: 0 = The animal shows normal behavior; 1 = The animal appears quiet but shows a normal repertoire of movements; 2 = The animal can move freely, but is clumsy when making complicated movements; 3 = The animal makes few slower movements and is obviously clumsy in executing complex movement; 4 = The animal makes few movements unless disturbed, and then movement is slow and limited to a small region of the cage; 5 = The animal is akinetic and does not move even when disturbed (Rose et al., 1993). A well-trained observer scores while the locomotor activity is recorded through a one-way mirror. Besides this, many reports (Annett et al., 1994; Eslamboli et al., 2005; Henderson et al., 1998; Montoya et al., 1990; Palmér et al., 2012; Philippens et al., 2000; Przybyszewski et al., 2006; Roberts et al., 1994; Verhave et al., 2009; Yamane et al., 2010) have been published describing several behavioral tests for this model (Table 41.3).

6.6 Immunohistochemical, Biochemical Analysis

Basically the same protocols as mice can be applied for immunohistochemical and biochemical analysis. Namely, immunostaining, HPLC, western blot, RT-PCR, and so on.

6.7 Functional Imaging in Common Marmosets

Although PET and single photon emission computed tomography (SPECT) studies using MPTP on nonhuman primates have been reported (Ashkan et al., 2007; Ballanger et al., 2016; Doudet et al., 1989; Eberling et al., 1999; Hantraye et al., 1986), any functional imaging study on MPTP-treated common marmosets has yet to be reported except for the one by Ando et al. (2012). As various radiolabeled analogs interacting with molecules of dopaminergic systems have been developed (Minuzzi et al., 2006), they will be examined in common marmosets in the near future.

7 CONCLUDING REMARKS

Here we have described the characteristics and methodological details of MPTP-induced mouse and common marmoset models of PD. As we have seen, these reliable models have a lot of merits compared to other models with well satisfying the face, constructive, and predictive validities of human PD. As a face validity, bilateral motor dysfunctions related to extrapyramidal syndrome have been well reproduced especially in nonhuman primates including common marmoset, and many behavioral tasks for mice have also been developed. As constructive validities, following characteristics observed in human PD are well reproduced: specific cell death of nigrostriatal dopaminergic neurons; decrease of the striatal dopamine and its metabolites; activation of astrocytes and microglia; oxidative stress caused both by mitochondrial dysfunction and activated glial cells; inflammatory reactions. Although only one exception that does not match to human PD in MPTP model is the formation of Lewy-like inclusion bodies containing α-synuclein and ubiquitin proteins, it may also be reproduced under a certain condition of MPTP administration, probably by continuous delivery with osmotic minipump or by longer administration for at least 5 days. As a predictive validity, many of the drugs in clinical use for PD are also effective in the MPTP model. To understand pathophysiological and pharmacological details, to develop novel therapeutics, and to screen possible substances for protective (disease modifying) and therapeutic drugs of PD, its applications including functional imaging will continue to expand further.

1 INTRODUCTION

Neurodegenerative diseases are a major cause of disability and premature death among older people worldwide and result from the progressive death of neurons, which over time leads to movement and/or cognitive impairment (Bird et al., 2003; Huisman et al., 2011; Savica et al., 2013). The majority of neurodegenerative diseases are clinically heterogeneous and genetically complex. This is especially true for the two most common neurodegenerative diseases, that is, Alzheimer's disease (AD) and Parkinson's disease (PD), in which >90% of cases are not linked to a single mutation. It is worth mentioning that Huntington's disease (HD) is a purely genetic disorder (Lansbury, 2004).

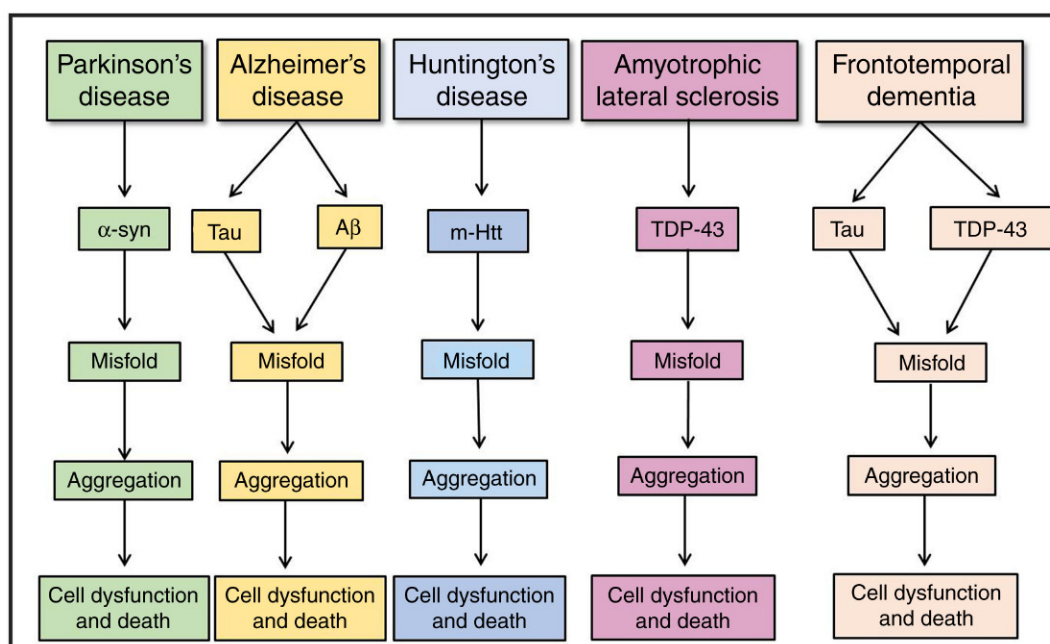
Despite the diversity of clinical phenotypes, neurodegenerative disorders share common features including clinical course and molecular mechanisms of pathogenesis. Preferential subsets of neurons are affected in neurodegenerative diseases which arise insidiously, progress endlessly, and are frequently age related (Byrne et al., 2011). Neurodegenerative diseases also share some pathological hallmarks: accumulation of characteristic proteins into insoluble aggregates within and/or between neurons along with synaptic loss and neuronal death (Fig. 42.1). These proteins includes α-synuclein (α-syn) of Lewy bodies (LBs) and Lewy neurites in PD, β-amyloid (Aβ) of senile plaques, and tau of neurofibrillary tangles (NFTs) in AD, polyglutamine (polyQ)-rich huntingtin inclusions in HD, TDP-43 aggregates in amyotrophic lateral sclerosis (ALS) and TDP-43 aggregates and tau in frontotemporal dementia (FTD) (Guo and Lee, 2014). Proteins aggregate due to their altered conformation which may result from a primitive


FIGURE 42.1 **Neurodegenerative diseases share common pathological hallmarks: accumulation of characteristic proteins into insoluble aggregates within and/or between neurons, along with cell dysfunction and neuronal death.**

mutation in the coding gene or from an injury as induced, for instance, by excitatory neurotransmitters, cytokines, or environmental toxins (Vidoni et al., 2016). For instance, oxidized protein aggregates may accumulate progressively over time as a consequence of chronic exposure to prooxidative neurotoxins, such as pesticides (e.g., rotenone), herbicides (e.g., paraquat), or recreational drugs (e.g., amphetamine) (Janda et al., 2012, 2015).

So far, there are no treatments capable of modifying the course of neurodegenerative diseases. The identification of effective drugs depends on the understanding of the pathophysiological mechanisms underlying each disease (Ribeiro et al., 2013). One step into this direction depends on the availability of animal models that can mimic the neuropathological and clinical features of each neurodegenerative disease (Duyckaerts et al., 2008). In the current chapter we will provide an overview of the main animal models of AD, PD, HD, ALS, and FTD.

2 PARKINSON'S DISEASE

PD is the second most common neurodegenerative disease and the main cause of parkinsonism, a clinical syndrome characterized by bradykinesia, rigidity, postural instability, and resting tremor. Its prevalence varies from 1% to 4% in people over 60 years (de Rijk et al., 1997; Wright Willis et al., 2010). The neuropathological hallmarks of PD are the loss of dopaminergic neurons in the *substantia nigra pars compacta* (SNpc) and the formation of intraneuronal proteinaceous inclusions called LBs in

affected brain areas. LBs are composed of unbranched α-synuclein (α-syn) filaments and ubiquitin, and most likely result from ineffective protein degradation (Braak et al., 2000, 2003a). *Postmortem* analyses have shown that α-syn inclusions emerge in a predictable order in different parts of the brain and might be linked to the progressive clinical stages of PD (Braak et al., 2004). As the disease advances, neuronal loss is observed in other brain regions, such as the cholinergic nucleus basalis of Meynert, thalamus, amygdala, and the serotoninergic neurons of the raphe nucleus (Braak et al., 2000, 2003b; Jellinger, 1991). Interestingly, clinical studies have shown that nonmotor symptoms may antedate the onset of typical motor signs in PD, stressing the need for understanding the molecular pathways that may trigger the related neurodegenerative process (Obeso et al., 2010).

The etiopathogenesis of PD is rather complex, involving environmental and genetic factors. However, clear genetic factors respond to only a small proportion of cases, the so-called genetic parkinsonism. Point mutations affecting the ubiquitin–proteasome pathway proteins are implicated in these cases (McNaught et al., 2001). Other genetic factors related to mitochondria function and oxidative stress may influence sporadic cases (Palacino et al., 2004; Winklhofer and Haass, 2010). Neuroinflammation is also considered to play a role in PD pathogenesis, and increase levels of inflammatory cytokines are detected in *postmortem* specimens, cerebrospinal fluid, and blood from patients with PD (Mogi et al., 1994; Scalzo et al., 2009).

Therapeutic strategy for PD is based on dopamine analogs, dopamine-degrading enzyme inhibitors, and

deep brain stimulation, all aiming at the improvement of motor symptoms secondary to dopaminergic impairment, but no strategy so far is able to halt the progressive neuronal death (Lees et al., 2009).

2.1 Animal Models of Parkinson's Disease

There are genetic and neurotoxin-based models of PD. Either toxic- or genetic-based models have their own advantages and disadvantages. Indeed, the use of the two in combination would be quite interesting. Accordingly, a multigene modulated transgenic model in combination with a reliable and effective neurotoxin might allow a better modeling PD phenotype. In coming years, we expect to see better models for basic understanding of PD and also for improved high-throughput drug discovery.

2.1.1 Genetic Models

The genetic basis for several forms of PD and related parkinsonian disorders has been elucidated in the past 2 decades. Although the great majority of PD cases cannot be explained by a single mutation, the identification of risk loci, genes, and mutations in PD has provided new insights into disease pathogenesis and indicated new study approaches (Lee et al., 2012).

Genetic models of a disease usually can be made of a mutant gene involved in the development of the disease or a gene that might not be validated in the disease but can recapitulate some key features of the disease in the model system (Jagmag et al., 2015). Five genes are frequently targeted as disease model for PD and they all have been associated with familial PD.

2.1.1.1 α-SYNUCLEIN MODELS

The α-synuclein gene (SNCA gene, designated as PARK1) is linked to a dominant type of familial early-onset PD. The α-syn is the main component of LB observed in the brains of PD patients (Iwatsubo, 2003). Mutations in five locations (A30P, A53T, S129D, S87, E46K) have been identified in familial PD to date. The severity and age of onset of disease depend on the promoter and levels of transgene expression.

Aiming to further investigate the role of α-syn in the pathogenesis of PD, transgenic mice overexpressing human α-syn were generated (Masliah et al., 2000). These models are instructive for studying the molecular mechanisms by which α-syn aggregation as well as neurodegeneration occurs in vivo. However, most of these models failed to show loss of dopaminergic neurons, the key pathological feature of PD, although there are subtle functional abnormalities in the nigrostriatal system and neurodegeneration in other anatomical circuits (Fernagut and Chesselet, 2004; Oliveras-Salva et al., 2013). Also, α-syn transgenic mice overexpressing human α-syn display mitochondrial abnormalities in degenerating neurons (St Martin et al., 2007). The mechanism of α-syn-induced mitochondrial dysfunction might involve sequestration of mitochondrial proteins or yet-unidentified pathways (Olzscha et al., 2011). In addition to mitochondrial dysfunction, a DNA damage response leading to cell death might be one downstream consequence of α-syn aggregation. Although the animal models of PD focused on α-syn are useful and validated, the exact function of this protein is still a matter of debate. Available data suggests that α-syn might be a presynaptic regulator of dopamine release, synthesis, or storage (Maries et al., 2003; Proukakis et al., 2013). Moreover, inflammatory signs were observed in a transgenic mouse overexpressing human α-syn, intracellular accumulation of α-syn within the striatum might induce a different immune response compared to other brain regions (Khandelwal et al., 2010).

As there is no loss of dopaminergic neurons in the substantia nigra of most α-syn transgenic mice, mechanistic studies of dopaminergic neurons death by α-syn have been obtained through the investigation α-syn expression following MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine) administration (Nieto et al., 2006; Song and Jung, 2004). Mitochondrial dysfunction appears to be sufficient to induce α-syn aggregation and downstream toxicity for dopaminergic neurons in MPTP mouse models. As expected, dopaminergic neurons of α-syn transgenic mice show more sensitivity for mitochondrial toxins (Nieto et al., 2006).

2.1.1.2 LEUCINE-RICH-REPEAT-KINASE 2 (LRRK2) MODELS

Mutations in the leucine-rich-repeat-kinase 2 (LRRK2) gene (PARK8) are the most common genetic causes of both familial and sporadic PD (Funayama et al., 2002; Paisan-Ruiz et al., 2013). Structurally, LRRK2 is a very interesting protein which has GTPase and kinase domains in addition to leucine-rich repeat domains, forming a large protein kinase. In addition, LRRK2 has several functional motifs and has been implicated in a variety of cellular processes including mitochondrial function, signal transduction, cell death pathways, vesicle trafficking, neurite outgrowth, autophagy, and cytoskeleton assembly (Tsika and Moore, 2012). Several groups have generated LRRK2-related PD mouse models expressing LRRK2 wild-type or PD-associated mutant LRRK2 to simulate aberrant kinase activity (Dawson et al., 2010). Overexpression of wild-type LRRK2 in transgenic mice causes an enhancement of DA release from the striatum and motor hyperactivity owing to this excess DA. On the other hand, overexpression of mutant LRRK2G2019S mice decreases the release and uptake of DA, thereby suggesting a role for LRRK2 in DA transmission (Li et al., 2009). Transgenic mice overexpressing mutant LRRK2R1441G show progressive and age-dependent motor deficits that progress to immobility that can be reversed by levodopa or apomorphine, similar

to what happens in PD (Kumar and Cookson, 2011). Qing Xu et al. generated human bacterial artificial chromosome (BAC)-mediated transgenic mouse models expressing mutant LRRK2 that robustly recapitulate pathological features of PD. These animals develop an age-dependent decrease in motor activity that is progressive and responds to treatment with levodopa. Pathologically, the most salient phenotype is premature axonopathy of nigrostriatal dopaminergic neurons accompanied by hyperphosphorylated tau. These mice also exhibit a consistent dopamine transmission deficit in acute brain slices and live freely moving animals (Xu et al., 2012).

2.1.1.3 PARKIN MODELS

Parkin (*PARK2*) mutations have been seen in cases of familial early-onset PD (autosomal recessive inheritance). Parkin is an integral ligase protein in the ubiquitin–proteasome system and it is widely expressed in most tissues including the brain (Lucking et al., 2000). Most parkin transgenic rodents, that is, *Parkin* KO animals, do not exhibit loss of dopaminergic neurons in the SNpc (Goldberg et al., 2003; Itier et al., 2003; Palacino et al., 2004). Nevertheless, some recently developed transgenic rodent models have demonstrated modest loss of dopaminergic neurons (Dave et al., 2014; Kitada et al., 2009; Van Rompuy et al., 2014). The transgenic parkin mice overexpressing the protein exhibit deficits in behavioral tasks previously shown to be sensitive to nigrostriatal dysfunction. In addition, proteomic studies using parkin-null mice showed marked reduction of mitochondrial respiratory chain proteins and stress response proteins when compared with littermate controls. Surprisingly, MPTP intoxication in parkin-null mice caused a similar level of dopaminergic neuronal toxicity compared with wild-type mice, although parkin overexpression provides protection against MPTP (Paterna et al., 2007; Perez et al., 2005; Thomas et al., 2007). A compensatory remodeling in parkin deficient dopaminergic neurons may have complemented parkin-related protective roles against mitochondrial dysfunction. Moreover, studies have shown that parkin deficiency in mice increases the risk of inflammation and neuronal death loss, suggesting a specific role for parkin in neuroprotection against inflammation-induced degeneration (Frank-Cannon et al., 2008).

2.1.1.4 DJ-1 MODELS

DJ-1 is molecular chaperone that, under an oxidative environment, plays a role in inhibition of α-syn aggregate formation (Shendelman et al., 2004). *DJ-1* (*PARK7*) mutations are linked to autosomal recessive and early-onset PD. *DJ-1* KO models present decreased dopamine release in the striatum but no loss of dopaminergic neurons in the SNpc, and a hypoactivity upon amphetamine challenge (Andres-Mateos et al., 2007; Goldberg et al., 2005). Dopaminergic neurons from *DJ-1* KO mice exhibited elevated mitochondrial oxidant stress due to compromised uncoupling of

mitochondria following basal pacemaker potential (Guzman et al., 2010). In a *Drosophila* homozygous mutant model, severe defects in locomotor ability without loss of dopaminergic neurons were observed, consistent with studies in *DJ-1* KO mice (Goldberg et al., 2005). A new model, the DJ1-C57 mouse, shows promise with significant unilateral loss of dopaminergic (DA) neurons in the SNc that progresses to bilateral degeneration of the nigrostriatal axis with aging and mild motor behavior deficits (Rousseaux et al., 2012). Still, consistent with DJ-1 protective role against stress, dopaminergic neurons with *DJ-1* deletion present increased susceptibility to MPTP toxicity. However, *DJ-1* KO mice do not present increased vulnerability to inflammation-related nigral degeneration (Nguyen et al., 2013).

2.1.1.5 PINK1 MODELS

Mutations in the *PTEN-induced putative kinase 1* (*PINK1*) gene (*PARK6*) result in early-onset PD (autosomal recessive inheritance). PINK1 codes for a mitochondrial kinase which recruits parkin from the cytosol to the mitochondria, increases the ubiquitination activity of parkin, and induces parkin-mediated mitophagy (Lazarou et al., 2013). The phenotypes of *PINK1* and *Parkin* KO mice are very similar as PINK1 and parkin are in the same pathway. Animals present reduced locomotion, but no change on rotarod performance. In addition, neither dopaminergic neurons abnormalities nor LB formation have been observed in *PINK1* KO mice. However, they present mitochondrial functional defects and increased sensitivity to oxidative stress (Kitada et al., 2007). A recently developed *PINK1* KO rat exhibiting dopaminergic neurons loss and motor impairment mimics more closely the PD phenotype (Dave et al., 2014).

2.1.2 Neurotoxic Models

The called neurotoxin-based models of PD are the most effective in reproducing dopamine deficit in primates and rodents. The most widely used compounds for animals models of PD are MPTP, rotenone, and 6-OHDA (6-hydroxy-dopamine).

2.1.2.1 MPTP

MPTP is a neurotoxin precursor of 1-methyl-4-phenylpyridinium (MPP+) which causes damage to the nigrostriatal pathway with a significant loss of dopaminergic neurons in the striatum and SNpc, similar to what it is seen in PD. MPP+ has a high affinity for the membrane dopamine transporter with comparatively lower affinities for the norepinephrine and serotonin transporters (Javitch et al., 1985). Furthermore, MPP+ interacts with the mitochondrial complexes I–III–IV, inhibiting the electron transport chain and inducing ATP depletion and oxidative stress (Bezard and Przedborski, 2011). MPP+ is also linked to impairment of glutamate uptake by astrocytes and neuronal apoptosis (Hazell et al., 1997).

MPTP model on primates presents the most closely pathological features of PD. In this model, motor symptoms are very similar to those observed in humans (bradykinesia, rigidity, and postural abnormalities), except for resting tremor. Although no typical LBs are observed in this model, α-syn immunoreactivity is enhanced in the nigrostriatal system and in other brain areas, such as the striatum and caudate nucleus (Purisai et al., 2005). Symptoms are also reversible by dopaminergic drugs known to be effective in PD. This model has been widely used to investigate new pharmacological treatments for PD as well as strategies to avoid treatment-related dyskinesias.

MPTP is more often used in mice models than in primates largely due to its very high cost in the latter. Primate models are preferred for testing drug treatment protocols just before human studies (Antzoulatos et al., 2010; Verhave et al., 2012). Mice treated with MPTP do not show typical PD behavior; however, motor alterations are observed when significant dopaminergic neuron loss is present (Jackson-Lewis and Przedborski, 2007). Rats have proven to be resistant to MPTP-induced toxicity (Riachi et al., 1990). The reason for this resistance has been speculated to be due to its differential MPP+ sequestration (Schmidt and Ferger, 2001).

MPTP is mainly administered via systemic route through subcutaneous, intravenous, or intracarotid injections. As MPTP is lipophilic, it can cross the blood–brain barrier, allowing greater ease in administration. However, it is very toxic, posing significant concerns with his manipulation and/or administration.

2.1.2.2 ROTENONE

Rotenone is a compound that occurs naturally in several plants and it has been used as abroad spectrum insecticide and pesticide. Rotenone blocks the mitochondrial electron transport chain through the inhibition of complex I, as seen in MPTP. Rotenone is highly lipophilic and easily crosses the blood–brain barrier (Talpade et al., 2000). Rotenone cytotoxicity is based on oxidative stress and reactive oxygen species (ROS) production (Sherer et al., 2003). High doses of rotenone can induce generalized neurodegeneration, so studies have been directed to chronic low-dose regimen in systemic administration of this compound in rodents. In this condition, α-syn positive LBs are observed in the nigrostriatal system (Tieu, 2011). Despite demonstrating slow and specific loss of dopaminergic neurons, this model is difficult to replicate due to the high mortality observed in animals treated with rotenone (Fleming et al., 2004). The route of administration of rotenone can vary. Chronic systemic (intravenous) exposure induces nigrostriatal dopaminergic neurodegeneration. Bilateral stereotaxic injection of rotenone into the medial forebrain bundle of rats causes a depletion of dopamine in the nigrostriatal system with associated rigidity and decreased motor activity, which can be reversed by levodopa therapy (Alam et al., 2004). Rotenone has also been tested in mice through chronic intragastric administration, which is able to induce α-syn accumulation in the enteric nervous system, the dorsal motor nucleus of the vagus, the intermediolateral nucleus of the spinal cord, and the SNpc (Pan-Montojo et al., 2010).

2.1.2.3 6-OHDA

6-OHDA is a selective neurotoxin that was first reported to cause lesions in nigrostriatal dopaminergic neurons in rats (Ungerstedt, 1968), but it has been subsequently shown to work in other animals, such as mice. 6-OHDA does not cross the blood–brain barrier and it needs to be injected into the brain. 6-OHDA is taken up by dopaminergic neurons due to its high affinity to dopamine transporter. Once inside neurons, 6-OHDA is readily oxidized in ROS leading to electron transport chain inhibition and oxidative stress (Mazzio et al., 2004). 6-OHDA is usually injected unilaterally in the SNpc or in the striatum. The unilateral injection causes neuron cell death and molecular changes in the lesion hemisphere compared with the intact hemisphere. In addition, systemic administration of apomorphine or amphetamine-induced rotations in unilateral lesioned in the animals. This model has been used to evaluate motor deficits and behavioral symptoms. However, neither LB nor olfactory deficits were observed in 6-OHDA treated animals (Duty and Jenner, 2011). Furthermore, this model has been useful to study glial involvement in the neurodegenerative process. For instance, studies have shown that microglia activated by overexpression or aberrant expression of α-syn secretes inflammatory cytokines and reactivates oxygen species that contribute to neurodegeneration (Saura et al., 2003). Despite its limitations, the 6-OHDA lesion is a highly reproducible model and has been to test new therapeutic strategies in PD.

3 ALZHEIMER'S DISEASE

AD is the main neurodegenerative disease and the most common cause of dementia, accounting for approximately two thirds of all dementia cases and afflicting more than 35 million individuals worldwide (Querfurth and LaFerla, 2010). AD affects mainly people over 60 years old and its initial presentation is usually memory impairment, but later symptoms include visuospatial, language, and executive dysfunctions (Querfurth and LaFerla, 2010). The vast majority of AD cases is sporadic, and whose causes remain unknown. The histopathological hallmark of AD is the accumulation of NFTs and amyloid plaques in addition to widespread synaptic loss, inflammation, oxidative damage, and neuronal death (Esch et al., 1990; Querfurth and LaFerla, 2010). NFTs are formed by aggregates of hyperphosphorylated tau protein. Extracellular amyloid

plaques are formed from β-amyloid peptides (Aβ), which are fragments formed by cleavage of amyloid precursor protein (APP) (Esch et al., 1990). APP can be processed by α-and γ-secretases, generating a nonamyloidogenic product, or by β- and γ-secretases, generating Aβ peptides, which are amyloidogenic and are likely to form plaques. There is no direct correlation between the number of cortical plaques and cognitive deficit in AD patients, and many individuals have amyloid plaques without cognitive impairment or dementia (Duyckaerts et al., 2009). Furthermore, the quantity and the structure of the senile plaques are not correlated with the severity of dementia, and the amyloid deposition seems to remain stable during the progression of the disease (Jack et al., 2010). While clinical progression of AD symptoms does not correspond to the progression of the amyloid deposition in the human brain, it seems closely related to the progression of tau pathology (Hyman, 2011). Accordingly, factors other than amyloid deposits might have a role in disease progression (Terry et al., 1991). Aβ is a potent mitochondrial poison, especially affecting the synaptic pool (Mungarro-Menchaca et al., 2002). In a transgenic mice model with overexpression of mutant human APP, exposure to Aβ inhibits mitochondrial enzymes in the brain and in isolated mitochondria (Hauptmann et al., 2006; Reddy and Beal, 2008), and cytochrome c oxidase is specifically susceptible (Caspersen et al., 2005). As a consequence, electron transport, ATP production, oxygen consumption, and mitochondrial membrane potential all become impaired.

Although the hypotheses concerning mechanisms underlying AD pathogenesis led to the development of drugs that have been tested in large clinical trials, the results of the trials completed so far are disappointing (Reitz, 2016). At present, there is no effective disease-modifying strategy in AD, and the available drugs are indicated to improve cognitive and behavioral symptoms (Querfurth and LaFerla, 2010).

3.1 Animal Models of Alzheimer's Disease

Animal models have significantly advanced the understanding of AD pathogenesis, but gaps in the knowledge regarding the causes of AD turn difficult to develop a model that recapitulates all aspects of the disease (Ribeiro et al., 2013). To date, animal models used in preclinical studies can be distinguished in: (1) transgenic models of AD consisting in single or multitransgenic animals overexpressing APP, PS (Presenilin) and/or Tau mutations; (2) nontransgenic models obtained by toxins injection in the brain, including direct injection of Aβ or tau, and models of aging (Puzzo et al., 2015).

3.1.1 Transgenic Models

The first transgenic animal built to mimic AD was based on the amyloid hypothesis, thus reproducing the deposits of Aβ in the brain by overexpressing the isoform

β-APP751 (Higgins et al., 1994; Quon et al., 1991). This model is a good model of Aβ hyperproduction, but the animals do not exhibit other features of AD, such as neuronal and/or synaptic loss (Lamb et al., 1993). These are excellent models to better understand the pathophysiologic role of Aβ in AD or to test drugs expected to modulate or reduce Aβ levels.

In 1995, Games et al. created the PDAPP mouse expressing high levels of human APP cDNA with a FAD-associated mutation (substitution of valine at position 717 with phenylalanine). Those animals expressed high levels of APP and developed several characteristics of human AD, such as extracellular amyloid fibrils organized in plaques, apoptosis, dystrophic neuritis subcellular, degenerative changes, synaptic loss, and gliosis that spread progressively from hippocampus to cortex (Games et al., 1995). More importantly, PDAPP mice had memory impairment, the main clinical feature of AD. One year later, Hsiao et al. (1996) created another transgenic mouse model of AD, the Tg2576 line, carrying the double Swedish mutation (K670N and M671L). These mice have increased APP production with consequent overproduction of Aβ40 and Aβ42, and plaques formation in different regions of the brain. Also, hyperphosphorylated tau occurs at old age when animals are around 11–13 months. Conversely, they did not present significant cognitive impairment (King and Arendash, 2002). This model has some advantages that consist in a well-characterized model and the relatively simple management of the colony. The disadvantage is that the AD phenotype occurs late. Indeed, it is usually necessary to wait 2 months to perform experiments to be sure that animals present both synaptic and memory dysfunction (Puzzo et al., 2015).

A model containing three different mutations—3XTg—such as APPSwe, PS1 M146V, and hyperphosphorylated tau (tauP301L) have been generated in mice (Oddo et al., 2003). This model is the only one to exhibit both Aβ and tau pathology that is characteristic of the human form. These animals exhibited Aβ pathology at 6 months of age (increased Aβ40 and Aβ42 levels, intracellular accumulation of Aβ, and amyloid plaques) that preceded tau pathology with NFTs formation at about 1 year old of age. Memory impairment was also evident (Billings et al., 2005; Kazim et al., 2014; Oddo et al., 2003). In addition, this model showed an increase of inflammatory mediators in the hippocampus (Cantarella et al., 2015).

3.1.2 Nontransgenic Models

Nontransgenic models for studying AD are mainly obtained by injecting Aβ or tau directly into the brain via intracerebroventricular (i.c.v.) or intrahippocampal injections (Balducci and Forloni, 2014; Puzzo et al., 2014). The advantages of the use of nontransgenic models include the possibility of (1) investigating Aβ and tau effects in animals different than mice or for which transgenic models are not available, (2) excluding the confounding

effects of overexpression of APP and its fragments, (3) investigating the different role of Aβ and tau species (monomers vs. oligomers vs. insoluble) at different concentrations, (4) investigating the difference between an acute or a chronic administration, and to clarify aspects of the molecular mechanisms underlying Aβ and tau pathology that cannot be investigated using transgenic models (Puzzo et al., 2015). However, acute models do not reproduce the gradual increase in Aβ deposition or tau pathology throughout the years as in humans.

It is worth mentioning that both transgenic and nontransgenic models do not reproduce the entire clinical features of human AD, but we have a number of very interesting tools to study AD. Although with their limitations, both models allow investigating memory, synaptic plasticity, histopathological changes, and molecular mechanisms underlying the disease. They represent an important tool to better understand the pathophysiology of the disease and to establish therapeutic strategies.

4 HUNTINGTON'S DISEASE

HD is an autosomal dominant genetic disorder characterized by progressive motor dysfunction, cognitive decline, and behavioral symptoms (Novak and Tabrizi, 2011; Ready et al., 2008). HD has a prevalence of 5–10 per 100,000 in South America, North America, Australia, and most European countries and countries of European descent, being significantly less prevalent in Africa and Asia with an estimated number of 0.5:100,000 in Japan and China (Walker, 2007). HD affects males and females at the same frequency, and the mean age of onset is around 40 years, although it can be as early as 4 and as late as 80 years of age. In the United States alone, there are about 30,000 patients with HD and there are about 150,000 people at risk of developing the disease (Margolis and Ross, 2003; Walker, 2007).

HD is caused by an expanded CAG repeat in the exon 1 of the *Huntingtin* gene which encodes an expanded polyglutamine stretch near the N-terminus of the 350 kDa huntingtin protein (Htt) (Consortium, 2012). The presence of more than 40 CAGs invariably causes the disease within a normal lifespan, and longer repeats accelerate disease onset (Langbehn et al., 2010). Although the primary factor that determines whether and when a person will develop HD is the length of the expanded CAG tract, the precise clinical manifestations, and onset of the disease are, to some extent, also influenced by environmental and genetic modifiers. While it is commonly acknowledged that the correlation of repeat size accounts for about 70% of the variation in age of onset (Gusella and MacDonald, 2009), there is higher variation in age of onset among patients with repeat lengths below 55 (Myers, 2004).

Mutant Htt is widely expressed, and believed to induce neurodegeneration through abnormal interactions with other proteins. This leads to several cellular alterations, including abnormal vesicle recycling, loss of signaling by brain-derived neurotrophic factor (BDNF), excitotoxicity, perturbation of Ca^{2+} signaling, decrease in intracellular ATP levels, alteration of gene transcription, inhibition of protein clearance pathways, mitochondrial and metabolic disturbances, and ultimately cell death (Zuccato et al., 2010). In addition, microglial activation and the associated neuroinflammation appear to be a prominent pathological feature of HD (Tai et al., 2007). Activated microglia are increased in cortex, striatum, and globus pallidus from patients with HD, and their frequency increases with neuronal loss (Pavese et al., 2006; Sapp et al., 2001). Similarly, the expression of inflammatory mediators is increased specifically in the striatum in HD, presumably in activated microglia, but not in cortex or cerebellum (Silvestroni et al., 2009).

Although the onset of HD is clinically diagnosed on the basis of motor performance, symptoms of psychiatric disorders, such as anxiety, irritability, impulsivity, aggression, apathy, and depressed mood are prevalent among HD gene carriers and patients with HD (Rosenblatt, 2007). Around 40%–50% of patients with HD are found to experience depression (Duff et al., 2007). Also, suicide is four- to sixfold more common in patients with HD than in the general population (Schoenfeld et al., 1984).

Despite the fact that the HD gene was identified over 20 years ago, there is no effective disease-modifying therapy for HD to date. Current pharmacological therapeutics are exclusively symptomatic, aiming at improving motor, cognitive and psychiatric symptoms.

4.1 Animal Models of Huntington's Disease

HD is a genetic disease caused by a single gene mutation. Accordingly, it is highly feasible to develop animal models with genetic manipulations that closely recapitulate HD pathology. Rodents are by far the most commonly used animals for modeling HD. These models include transgenic mice and knock-in (KI) mice. Mouse is the most commonly used mammalian genetic model due to its efficiency, economy, and ease of manipulation. These animal models have been important tools to investigate the pathogenesis of the disease and to try develop therapeutic strategies.

4.1.1 Transgenic Mouse Models

4.1.1.1 R6/1/R6/2

R6/1 (116 CAG repeats) and R6/2 (144 CAG repeats) mice were the first HD mouse models to be developed expressing the exon 1 of human Htt under the control of 1 kb human Htt promoter (Mangiarini et al., 1996). Importantly, all transgenic models also express the two

normal alleles of the murine *Huntingtin* gene. R6/2 is the most extensively studied rodent model of HD, exhibiting a robust phenotype and severe neurological symptoms, including motor deficits, such as lack of motor coordination, abnormal walk, and learning impairment (Carter et al., 1999; Mangiarini et al., 1996). Motor changes start at 4 weeks, and R6/2 mice only survive for 12–13 weeks (Mangiarini et al., 1996). Depression-like behavior has been demonstrated in female R6/2 mice using the forced swimming test (Pang et al., 2009). R6/2 mice also exhibit an increase in anxiety-like behavior (Menalled et al., 2009). Procedural learning deficits have been shown in this model (Cayzac et al., 2011), as well a muscle atrophy (Ribchester et al., 2004). This model is vastly used for drug testing due to its rapid onset. Aggregate formation is very pronounced in this model and intranuclear inclusions are very similar to those observed in biopsy from HD patients and happening prior to the development of symptoms (Davies et al., 1997). However, nuclear Htt aggregates are widely distributed in several brain substrates of R6/2 mice, including the hippocampus and cerebellum, two regions that are relatively spared in HD (Li et al., 2001). Finally, aberrant peripheral immune system activation has been demonstrated in this model. Despite of its robust phenotype, R6/2 mice do not represent a precise model of HD, as this model only expresses the amino-terminal region of the Htt protein, which is mainly composed of polyglutamines. In this regard, R6/2 mice can also be used as a model of polyglutamine diseases including genetic ataxias and spinobulbar muscular atrophy (Ribeiro et al., 2013).

4.1.1.2 YAC128/BACHD

YAC128 and BACHD are transgenic HD mouse models that express full-length human Htt containing 128 and 97 polyglutamines, respectively (Gray et al., 2008; Slow et al., 2003). These mice were created using yeast artificial chromosome (YAC) and BAC technology. BACHD and YAC128 exhibit milder clinical deficit and slower progression compared to R6/2 (Menalled and Chesselet, 2002). Notably, these mice develop selective striatal and cortical atrophy at the age of 12 months, thus recapitulating to some extent the regional selectivity of adult-onset HD. These mice also present electrophysiological abnormalities suggestive of an alteration at glutamatergic synapses (Hodgson et al., 1999). Although BACHD and YAC128 exhibit similar phenotype, there are some differences between them. For instance, the BACHD CAG tract is half CAG and half CAC, providing resistance to polyQ expansions and contractions (Gray et al., 2008). On the other hand, only 7% of the YAC128 CAG tract is CAC (Pouladi et al., 2012b). Moreover, the mRNA levels of DARPP-32, enkephalin, dopamine receptors D1 and D2, and cannabinoid receptor 1 are

significantly decreased in YAC128, but not in BACHD mice (Pouladi et al., 2012b). BACHD mice exhibit reduced levels of Htt aggregates as compared to YAC128 (Gray et al., 2008; Pouladi et al., 2009), but Htt aggregates can be clearly detected in the cortex and striatum of BACHD mice (Gray et al., 2008). BACHD and YAC128 mice develop progressive motor and cognitive and behavioral deficits (Gray et al., 2008; Pouladi et al., 2009; Van Raamsdonk et al., 2005). Deficits in learning and memory have been assessed using a number of sensitive behavioral paradigms, which include tests of procedural learning, spatial learning, associative and nonassociative (habituation) learning, discrimination, episodic learning, and strategy shifting. Deficits in motor learning have been demonstrated during the training phases of the running wheel and rotarod tasks (Pouladi et al., 2012a; Van Raamsdonk et al., 2005). Increases in anxiety-like behavior have been shown in YAC128 and in BACHD mice using the open-field test (Menalled et al., 2009). Furthermore, peripheral immune system activation has been demonstrated in YAC128 mice and impaired macrophage migration has been shown in BACHD mice (Kwan et al., 2012).

4.1.2 HD Knock-In Mouse Models

KI models should be optimal to reproduce human pathology because they are the most faithful reproduction of the genetic mutation and do not overexpress Htt or disrupt endogenous genes by deleterious integrations into the genome (Menalled and Chesselet, 2002). Several KI models with expanded CAG repeats or human mutant Htt exon 1 replacing the corresponding sequences in the endogenous murine Htt gene locus have been generated (Heng et al., 2008; Shelbourne et al., 1999; Wheeler et al., 2000). The most studied mutant Htt-KI models include HdhQ111, CAG140, and HdhQ150 mice, which are suitable for studying HD pathogenesis and testing therapies. All these HD KI mice showed late-onset phenotype and progressive, but mild pathology (Shelbourne et al., 1999; Wheeler et al., 2000). Behavioral abnormalities in this KI model were similar but milder than transgenic mouse models (Woodman et al., 2007). For instance, HdhQ150 mice exhibit late-onset motor changes, including motor task deficit and gait abnormalities (Woodman et al., 2007). These animal present deficits in the novel objection recognition test of episodic memory (Giralt et al., 2012). Depression-like behavior and anxiety-like behavior have also been demonstrated (Orvoen et al., 2012). Although HD KI mice do not develop a phenotypes as robust as those in transgenic mice expressing N-terminal mutant Htt, they recapitulate an important pathological change seen in the brain of the HD patient, which is the preferential accumulation of mutant Htt in striatal neurons (Wheeler et al., 2000).

4.1.3 Transgenic Large Animal Models of HD

Research using large animal models of HD has been very limited. The potential use of large animal models in HD research has been refocused recently with the development of three transgenic large animal models of HD, a nonhuman primate model (rhesus monkey) (*Macaca mulatta*) (Yang et al., 2008), a sheep model (*Ovis aries*) (Jacobsen et al., 2010), and a Tibetan miniature pig model (Yang et al., 2010). The rhesus macaque and pig models were generated using fragments of human *HTT* that included a CAG repeat expansion. By contrast, the sheep model used the full-length human coding sequence of *HTT* that is expressed from a transgene. The symptoms exhibited by each species of HD animal reflect the transgene construct used. HD transgenic monkeys with 84Q can die postnatally, and this early death is associated with the levels of mutant Htt (Yang et al., 2008). Despite their early death, some transgenic monkeys developed key clinical HD features including dystonia, chorea, and seizures (Yang et al., 2008), which have not been replicated by mouse models or other small animal models. Studies of transgenic large animals also showed that smaller N-terminal mutant Htt is more toxic. Transgenic pigs (Baxa et al., 2013) and sheep (Jacobsen et al., 2010) that express much larger Htt fragments develop nondetectable or very mild phenotypes. Thus, even in large animals, expression of small N-terminal mutant Htt fragments appears to be necessary to facilitate disease progression.

5 AMYOTROPHIC LATERAL SCLEROSIS

ALS is a fatal late-onset neurodegenerative disorder that is characterized by a progressive loss of motor neurons of the CNS leading to muscle weakness, wasting, and spasticity (Robberecht and Philips, 2013). Patients with ALS develop progressive muscle weakness along with fasciculation, hyperreflexia, and muscle. Patients with ALS usually die within 3–5 years after the diagnosis (Cudkowicz et al., 1997). For a long time, ALS was regarded as a motor neuron-specific disease. It is now clear that mild cognitive deficits and FTD are common in ALS (Therrien et al., 2016).

There is no familial history of ALS in the majority of cases which are classified as sporadic ALS (sALS). A clear familial history of the disease is present in approximately 10% of patients whose cases are known as familial ALS (fALS). Familial cases of ALS are usually inherited in an autosomal dominant way, although there are some autosomal recessive and X-linked forms. Mutations in more than 10 different genes have been identified to date (Renton et al., 2014). The most common mutations are found in the genes encoding superoxide dismutase 1 (SOD1), fused in sarcoma (FUS), and TDP-43 (TARDBP).

Recently, a hexanucleotide repeat expansion (GGGGCC) in the *C9ORF72* gene was identified as the most frequent cause of fALS (around 40%) in the Western population (DeJesus-Hernandez et al., 2011; Renton et al., 2011). Besides genetic factors, environmental factors seem to play a role in disease pathogenesis, such as toxins, but the evidence comes primarily from experimental models (Ingre et al., 2015).

ALS is a heterogeneous disease not only genetically, but also clinically. The age of onset, the rate of progression, and the presence of cognitive dysfunction are variable. In some patients, neurons in the prefrontal and temporal cortex are affected, leading to cognitive and/or behavioral problems. FTD is present in about 15% of patients with ALS (Lillo and Hodges, 2009; Ringholz et al., 2005). Conversely, 15% of FTD patients show signs of motor neuron disease (Burrell et al., 2011; Lomen-Hoerth et al., 2002).

Different mechanisms have already been suggested to play a role in the pathogenesis of ALS. These include astrocytosis, neuroinflammation, mitochondrial dysfunction, deregulated autophagy, and axonal transport dysfunction and retraction. Modulating these different disease processes could have a positive effect on disease progression, and modifying these pathological mechanisms could be translated into therapeutic strategies.

In 1995, riluzole was approved by the US Food and Drug Administration (FDA) for the treatment of ALS (Bensimon et al., 1994). Two decades later, this drug remains the only approved treatment for ALS. Riluzole increases the life span of the patients by an average of 2–3 months (Miller et al., 2007, 2012). Several preclinical studies have been performed in rodent models of ALS to prevent, reverse, or modulate the disease process. So far, none of these therapeutic strategies has been successfully replicated in clinical trials. As a consequence, besides riluzole, only symptomatic treatments are applied to improve the quality of life of ALS patients.

5.1 Animal Models of Amyotrophic Lateral Sclerosis

The identification of the genetic causes of ALS was critical for advancing the understanding of the pathophysiology of this disorder since these mutations form the basis of the development of experimental models for the disease. There are different mouse models for ALS, such as transgenic and KO mice (Mancuso and Navarro, 2015).

5.1.1 SOD1 Models

Mutations in the *SOD1* gene on chromosome 21 were the first identified causes of autosomal dominant fALS (Rosen, 1993). SOD1 is a ubiquitous cytoplasmic and mitochondrial enzyme which functions in a dimeric state to catalyze the breakdown of damaging ROS, preventing

oxidative stress. Due to the harmful effects of ROS and their association with neurodegenerative diseases, it was originally proposed that pathogenic mutations in SOD1 could cause ALS as a result of a loss of dismutase activity (Rosen, 1993). Subsequent investigation failed to associate mutant SOD1 activity with pathogenicity (Borchelt et al., 1995) and in *SOD1* KO mice do not present motor dysfunction, at least up to 6 months of age (Reaume et al., 1996). More recent characterization of the *SOD1* KO mice has revealed that although they do not exhibit any motor neuron loss, they have significant distal motor axonopathy, indicating a major role of SOD1 in normal neuronal function (Fischer et al., 2011).

Transgenic mouse model (SOD1G93A) of SOD1–ALS was initially developed expressing approximately 20–24 copies of the human coding sequence with the G93A mutation under control of the human *SOD1* promoter (Gurney, 1994). Since the development of this model, over 20 other SOD1 models have been proposed, and SOD1 transgenic mice have been used as the primary rodent models of ALS. Mutant *SOD1* transgenic mice recapitulate many features of ALS, including axonal and mitochondrial dysfunction, progressive neuromuscular dysfunction, gliosis, and motor neuron loss (Bruijn et al., 1997; Chang-Hong et al., 2005; Gurney, 1994). Transgenic SOD1 rodent models may vary the age of disease onset and rates of disease progression. Development of ALS-like symptoms in these mice is known to be mainly dependent of specific factors, including: SOD1 mutation; transgene expression level; gender, and genetic background (Heiman-Patterson et al., 2011; Mancuso et al., 2012).

In order to rule out the possibility that the disease phenotype may be the result of overexpression of SOD1 per se, lines of transgenic mice overexpressing the human wild-type protein have also been created. This so-called wt-hSOD1 mouse model might cause progressive motor neuron degeneration. Homozygous expression of a human wild-type SOD1 transgene resulted in a reduced lifespan, with a median survival of 367 days, accompanied by slow weight gain after birth and more significant weight loss in older male mice (Graffmo et al., 2013). Also, these animals developed an ataxic staggering gait with abnormal hind limb reflexes (Graffmo et al., 2013). Gliosis and misfolded SOD1 were detected in the spinal cord at 100 days of age, as well as signs of vacuolization and axonal damage which are typical of SOD1 overexpression (Jaarsma, 2006; Jaarsma et al., 2000). By end stage, around 40% of motor neurons in the thoracic spinal cord had been lost (Graffmo et al., 2013).

5.1.2 TDP-43 Models

TDP-43 is a 43 kDa nuclear protein originally discovered due to its effects on human immunodeficiency virus transcription (Bento-Abreu et al., 2010). It is encoded by the *TARDBP* gene on chromosome 1, and contains a nuclear-localization signal, two RNA-binding motifs, and a glycine-rich region, which contains a "prion-like" domain and mediates protein and heterogeneous nuclear ribonucleoproteins (hnRNP) interactions. It is within this glycine-rich domain that the majority of pathogenic mutations for ALS have been identified (Kabashi et al., 2008; Sreedharan et al., 2008). In vitro and in vivo studies have identified a variety of aberrant cellular dysfunctions caused by mutant TDP-43, including abnormal neuronal function and synaptic defects (Godena et al., 2011), deleterious effects on mitochondria (Braun et al., 2011; Shan et al., 2010), and proteasome dysfunction. Although it remains unclear how mutations in TARDBP cause ALS, both loss and gain of function mechanisms have been proposed (Tsao et al., 2012). The development of disease phenotypes in the model TDP-43-ALS in rodents is highly dependent upon the promoter used and the level of transgene expression. However, these models display mostly axonal damage with relatively mild motor neuron cell death. In marked contrast to SOD1 transgenic mice, overexpression of human wild-type TDP-43 has been shown to cause significant neurodegeneration (McGoldrick et al., 2013).

5.1.3 FUS Models

FUS was identified because of its oncogenic properties following a chromosomal translocation resulting in the fusion of truncated FUS protein with the transcription factor CHOP (Crozat et al., 1993; Rabbitts et al., 1993). The *FUS* gene is located at 16p11.2 and comprises 15 exons encoding a multifunctional 526 amino-acid protein (Prasad et al., 1994) with a complex domain structure. FUS is ubiquitously expressed in all cells. Some rodent data suggest that expression outside the CNS decreases with age, being absent in mouse skeletal muscle, liver, and kidney from 80 days of age (Huang et al., 2010). FUS binds DNA and RNA, and presents primarily a nuclear localization (Bosco and Landers, 2010; Gal et al., 2011).

Mutations in *FUS* have been described as contributing in similar proportion of fALS cases (FUS-ALS) as TDP-43 mutations. FUS may function downstream TDP-43 and in parallel to other RNA-binding proteins (Kabashi et al., 2011). Developing models of FUS-ALS is essential to clarify the mechanisms by which mutations in this protein cause ALS and how aberrant RNA metabolism may lead to neurodegeneration.

There are four transgenic rodent lines overexpressing FUS: transgenic mice which overexpress HA-tagged human wild-type FUS under control of the mouse prion promoter (Mitchell et al., 2013); somatic brain transgenic mice expressing V5-tagged human wild-type FUS, mutant R521C and FUS lacking its nuclear localization signal (D14) (Verbeeck et al., 2012); transgenic rats which conditionally express human wild-type or mutant FUS under the tetracycline response element system TRE

(Huang et al., 2011); and transgenic rats which express mutant FUS under the CaMKIIa promoter with a TRE (Huang et al., 2012). These models display different phenotypic manifestations ranging from different levels of motor involvement with muscle denervation, axonopathy, and spinal degeneration, to cognitive deficits with memory impairment and hippocampal neuronal death.

5.1.4 C9ORF72 Models

Since the discovery of C9ORF72 hexanucleotide expansions as one of the most frequent causes of ALS, significant efforts has been dedicated for developing animal models based on this mutation. C9ORF72 was modeled in zebra fish by knocking down the zC9ORF72. Loss of function of the zC9ORF72 transcripts causes both behavioral and cellular deficits related to locomotion but without major morphological abnormalities (Ciura et al., 2013). More recently, C9ORF72 transgenic mice have been developed by expressing the abnormal hexanucleotide expansion (G4C2)66, throughout the nervous system by means of somatic brain transgenesis mediated by an adeno-associated virus. Resulting mice presented neuronal nuclear inclusions of poly(Gly-Pro), poly(Gly-Ala), and poly(Gly-Arg) dipeptide repeat proteins, as well as TDP-43 pathology and neuronal loss. Transgenic mice developed behavioral changes resembling those of c9FTD/ALS patients, including hyperactivity, anxiety, antisocial behavior, and motor deficits (Chew et al., 2015).

5.1.5 VCP Models

The identification of mutations in the valosin-containing protein (VCP) as contributing for ALS (Shaw, 2010) and inclusion body myosytis with Paget's disease of bone and frontotemporal lobar degeneration (IBMPFD) (Mehta et al., 2013) has led to the development of mouse models of these diseases (Badadani et al., 2010; Custer et al., 2010). VCP is an AAA-ATPase which has a range of cellular functions (Meyer et al., 2012; Yamanaka et al., 2012). Studies have examined whether KI of the R155H mutation in VCP, which causes ALS (Shaw, 2010), could cause motor neuron degeneration in heterozygosity or homozygosity (Nalbandian et al., 2012; Yin et al., 2012). In heterozygote KI mice, the R155H mutation in VCP did not affect lifespan (Yin et al., 2012). However, these mice developed progressive weakness from 9 months of age and showed significant weight loss by 24 months of age (Yin et al., 2012). Consistent with this motor neuron degeneration, electromyography of hind limb muscles at 24 months of age showed evidence of denervation and neurogenic changes (Yin et al., 2012). Pathological analysis of the spinal cord revealed gliosis, oxidative stress, and cytoplasmic accumulation of mitochondria in motor neurons (Yin et al., 2012). Compared to the heterozygous KI mice, homozygous expression of human mutant VCP resulted in a much more aggressive phenotype, with early lethality and very few pups surviving to 21 days of age (Nalbandian et al., 2012). Although mutations in VCP have complex effects and phenotypes in transgenic mice may not be exclusively due to motor neuron degeneration, study of VCP models has clearly shown the deleterious effects of mutant VCP on motor neuron survival.

6 FRONTOTEMPORAL DEMENTIA

FTD is the third most common form of dementia across all ages, after AD and vascular dementia, and is a leading cause of early-onset dementia. FTD is characterized by progressive deficits in executive function, behavior, and language (Vieira et al., 2013). Due to the similarity of behavioral changes in patients with FDT to those seen in patients with major psychiatric disorders, diagnosis is frequently challenging.

The estimate is that FTD rates will double every 20 years, reaching 115.4 million in 2050. In a metaanalysis of 73 articles of early-onset dementia (patient age <65 years), FTD is the third most prevalent dementia subtype in most studies, with a prevalence ranging from 3% to 26% (Vieira et al., 2013). Also, FTD is still misdiagnosed, and most numbers probably underestimated the true incidence. FTD is classified into three clinical variants: behavioral-variant FTD, which is associated with behavioral and executive deficits; nonfluent variant primary progressive aphasia, with progressive deficits in speech, grammar, and word output; and semantic variant primary progressive aphasia, which is a progressive disorder of semantic knowledge and naming (Gorno-Tempini et al., 2011; Rascovsky et al., 2011). When FTD progresses and the initially focal degeneration becomes more diffuse, affecting larger regions in the frontal and temporal lobes, the symptoms of the three clinical variants can converge. Over time, patients develop global cognitive impairment and motor deficits, and may include parkinsonism and motor neuron disease in some patients. Individuals with end-stage disease have difficulty in eating, moving, and swallowing. Death usually happens about 8 years after the onset and is typically caused by pneumonia or other secondary infections (Bang et al., 2015).

Until 2004, tau was the only molecule known to accumulate in the brain of patients with FTD, and mutations in the *Microtubule Associated Protein Tau (MAPT)* gene were the only known genetic cause of FTD. Since then, two new neuropathological substrates (TDP-43 and FUS) and six new FTD genes (*GRN, C9ORF72, VCP, FUS, CHMP2B,* and *TARDBP,* the gene for TDP-43) have been identified. These advances have created new opportunities to study FTD using rodent models, and to use this important tool for studying pathophysiology of neurodegenerative disorders and new targets for treatment (Roberson, 2011).

No approved disease-modifying drugs are available for the treatment of FTD. Treatment is mainly focused on management of behavioral symptoms. For instance, agitation, aggressiveness, impulsivity, and aberrant eating behavior can improve with the use of selective serotonin reuptake inhibitors (Lebert et al., 2004) and/or low doses of atypical antipsychotics (Asmal et al., 2013). Cholinesterase inhibitors and memantine, drugs use for the treatment of AD, are not beneficial and can even worsen behavioral abnormalities seen in patients with FTD (Mendez et al., 2007).

6.1 Animal Models of Frontotemporal Dementia

Different FTD models have been developed in the past few years. Here, we review recent progress with mouse models based on tau, TDP-43, progranulin, VCP, and CHMP2B.

6.1.1 Tau Models

Tau was the first molecule linked to FTD, both by neuropathology and by genetics. More than 25 lines of transgenic mice have been created that express human tau with mutations linked to FTD. Tau transgenic mice have provided important insights and raised new questions about mechanisms of tau-mediated neurotoxicity.

The first models showed that expressing mutant tau was sufficient to cause both aggregated tau pathology and neuronal death. In both the rTg4510 and hTau lines, neuronal tau aggregates are formed, but neurons without aggregates are more susceptible to death. (Andorfer et al., 2005; Santacruz et al., 2005). Both aggregated tau pathology and neuronal death have been dissociated from the functional deficits in tau mouse models. Another interesting lesson from tau models was that the synapse is not just a target for tau, but a likely site of spreading pathology. It has been proposed that the propensity of neurodegenerative diseases to target large-scale networks is most likely due to transneuronal spread (Zhou et al., 2008).

Not all lineages display the pronounced neurodegeneration seen in the human disease, but among those that do, deficits in synaptic plasticity, and cognitive dysfunction precede neurodegeneration (Yoshiyama et al., 2007). Studies in mice have shown that neurodegeneration and cognitive deficits can be dissociated from neurofibrillary tangle pathology (Santacruz et al., 2005). These findings point to the importance of identifying the species of tau responsible for synaptotoxicity and neurotoxicity in mice and determining whether these tau species also occur in human neurodegenerative diseases.

6.1.2 TDP-43 Models

TDP-43 is connected to FTD by both neuropathology and genetics, but the neuropathologic link is much stronger. TDP-43 is a multifunctional nuclear protein that binds to DNA and RNA (Barmada et al., 2010). Models with deletion of TDP-43 are embryonic lethal early in gestation (Sephton et al., 2010; Wu et al., 2010). Heterozygous mice have normal TDP-43 protein levels and no evident neuropathology, limiting their utility (Sephton et al., 2010; Wu et al., 2010). The first models used heterologous promoters to drive human TDP-43 expression throughout the nervous system developed a sever phenotype marked by significant motor impairment leading to death in weeks to months (Wegorzewska et al., 2009; Wils et al., 2010). In each of these TDP-43 lines, in which brain pathology was examined, frontal cortex was selectively vulnerable to development of ubiquitinated neuronal inclusions, astrogliosis, and neuron loss (Wegorzewska et al., 2009; Wils et al., 2010). Subsequent models were engineered with more restricted promoters to better isolate the forebrain effects of TDP-43 from the motor phenotypes seen in pan-neuronal lines.

Some neuronal populations were more vulnerable than others. In a line expressing wild-type human TDP-43 around 75% of dentate granule neurons were lost, whereas CA1 pyramidal neurons were resistant, and deep cortical layers were more affected than superficial layers (Igaz et al., 2011). When wild-type or mutant TDP-43 was expressed, astrocytosis developed before 5 months of age, and learning/memory and motor deficits developed around 7 months.

6.1.3 Progranulin Models

Mutations in the progranulin gene (GRN) have recently been identified as a cause of about 5% of all FTD, including some sporadic cases. Recent studies using mouse models has defined the expression of PGRN in the brain (Petkau et al., 2010). PGRN is expressed late in neurodevelopment, localizing with markers of mature neurons. PGRN is expressed in neurons in most brain regions, with highest expression in the thalamus, hippocampus, and cortex. Microglia cells also express progranulin, and the level of expression is upregulated by microglial activation.

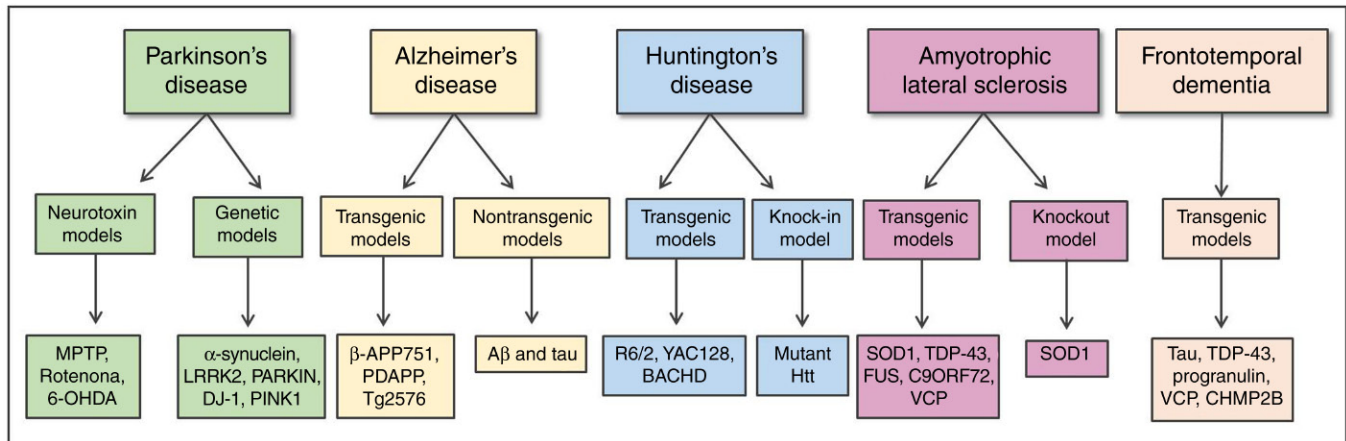
Around 70 different GRN mutations have been identified in FTD and all reduce progranulin levels or result in loss of progranulin function. Several different lines of progranulin KO mice have been developed. Each had early abnormalities in social behavior without impairment in overall health or motor function (Kayasuga et al., 2007). Evidence for protein mishandling in mice includes accumulation of ubiquitinated protein, lipofuscin, and phosphorylated TDP-43 (Ahmed et al., 2010; Kayasuga et al., 2007). The evidence for neuroinflammation is even stronger with all lines showing high levels of astrogliosis and microgliosis (Ahmed et al., 2010; Kayasuga et al., 2007). The foremost task is to establish the mechanistic basis of the FTD-related behavioral deficits in progranulin-deficient mice, including testing whether the observed protein mishandling or neuroinflammation phenotypes are causally related to neuronal dysfunction, and/or whether other mechanisms are in play.


FIGURE 42.2   **Animal models of neurodegenerative diseases.**

6.1.4 VCP Models

Mutations in *VCP* which encodes VCP (VCP in humans or p97 in mouse) can cause pure FTD, but more commonly cause a syndrome with muscle and bone diseases. This rare disorder is called inclusion body myopathy with Paget's disease of bone and frontotemporal dementia (IBMPFD) (Watts et al., 2004). VCP/p97 has numerous functions, including regulating protein degradation through the ubiquitin–proteasome system, endoplasmic reticulum-associated degradation, and autophagy. The clinical presentation of FTD in IBMPFD includes both bvFTD and semantic variant-type progressive aphasia with an age of onset in the mid to late 50s. (Kim et al., 2012; van der Zee et al., 2009). Neuropathologically, FTD caused by VCP mutations is associated with FTLD-TDP type D, a distinct subtype that is not seen in sporadic FTD or with other mutations.

Two transgenic and one KI line are available as models of VCP-related FTD. The transgenic models express human VCP with either the R155H or A232E mutation from a ubiquitous promoter at levels two- to threefold higher than the endogenous gene (Custer et al., 2010). Each of these models exhibits age-dependent muscle, bone, and brain disease related to human. Neuronal dysfunction in the transgenic lines includes increased anxiety-related behavior and impaired novel object recognition (Custer et al., 2010). On *postmortem* examination, all three models had age-dependent gliosis and loss of nuclear TDP-43 with accumulation of ubiquitinated TDP-43 in the cytoplasm (Badadani et al., 2010; Custer et al., 2010).

6.1.5 CHMP2B Models

Mutations in CHMP2B are the rarest cause of FTD, with four proven pathogenic mutations identified in five families to date. In addition, the neuropathology is unique, representing a small cluster of FTD cases with ubiquitinated neuronal cytoplasmic inclusions that do not contain tau, TDP-43, or FUS. (Holm et al., 2009). CHMP2B encodes charged multivesicular protein 2B, which is involved in trafficking endosomes to degradation in lysosomes. Mice expressing CHMP2B Intron promoter develop inclusions of ubiquitinated proteins that are negative for TDP-43 and FUS, as in the FTLD-UPS pathology in patients with CHMP2B mutations (Skibinski et al., 2005). The mice also develop axonal swellings and have reduced survival (Fig. 42.2).

7 CONCLUSIONS

Although the pathophysiology of different neurodegenerative disease shares common mechanisms, especially pathological protein aggregation, these disorders present significant clinical and genetic heterogeneity. Several fundamental issues remain unanswered. What is responsible for triggering the generation of misfolded proteins that initiate disease-related cascades? Why do only certain proteins aggregate in a disease-specific manner if the common final pathway is the impairment of protein homeostasis? What is the factor underlying the selective vulnerability of different brain regions? What is the role played by glial cells in the transmission of protein aggregates? The precise nature of each one of these proteins in the aggregation pathway and their relevance for discrete human diseases require further studies. In this regard, animal models have provided significant contribution to the understanding of the pathophysiology of neurodegenerative diseases. Nevertheless, animal models only recapitulate part of the complex and heterogeneous nature of neurodegenerative diseases. There is still a great challenge ahead to establish new animal models that can truly contribute to the development of preventive and/or disease-modifying therapeutic strategies (Table 42.1).

TABLE 42.1 Main Animal Models of Neurodegenerative Diseases

Disease	Models	Mechanisms	Advantages	Disadvantages
Parkinson's disease	α-Synuclein	*Genetic model*: mutation on A30P, A53T, S129D, S87, E46K in α-*syn* gene and KO model	Decreases in striatal DA. Inclusion bodies. Motor impairments	Not show loss of dopaminergic neurons
	LRRK2	*Genetic model*: mutation on R1441G, G2019S, exon 29, 30 in *LRRK2* gene, KO model	Enhancement of DA release from the striatum. Motor hyperactivity	Different results depending on the mutation used
	PARKIN	*Genetic model*: transgenic overexpression parkin and KO model	Behavioral deficits, mitochondrial dysfunction	Not exhibit loss of dopaminergic neurons
	DJ-1	*Genetic model*: KO model	Defects in locomotor, decreased dopamine release in the striatum	Usually, no loss of dopaminergic neurons in the SNpc
	PINK1	*Genetic model*: KO model	Reduced locomotion, no change on rotarod performance, mitochondrial dysfunction	No dopaminergic neurons abnormalities and LB formation
	MPTP	*Neurotoxic model*: interacts with mitochondrial complexes and increase oxidative stress	Reproduce lesion formation, dopaminergic neuron loss, systemic administration	No LB formation, typical PD behavior not observes, high toxicity
	Rotenone	*Neurotoxic model*: increase oxidative stress and reactive oxygen species production	Reproduce lesion formation, dopaminergic neuron loss, LB formation, systemic administration	Difficult to replicate due to the high mortality
	6-OHDA	*Neurotoxic model*: 6-OHDA is oxidized in reactive oxygen species leading to electron transport chain inhibition and oxidative stress	Reproduce lesion formation, dopaminergic neuron loss	No LB formation. Need inject into the brain
Alzheimer's disease	Transgenic models	*Genetic model*: single or multitransgenic animals overexpressing APP, PS and/or Tau mutations	Usually, mice presented impairment in memory and the main feature of a patient with AD	AD phenotype occurs late. Just in mice
	Nontransgenic models	*Neurotoxic model*: toxins injection in the brain, including Aβ or tau	Use other animals than mice. Investigate the difference between an acute or a chronic administration	Acute models do not reproduce the gradual increase in Aβ occurring in many years in humans
Huntington's disease	R6/1 R6/2	*Genetic model*: R6/1 (116 CAG repeats) and R6/2 (144 CAG repeats) mouse models that were developed, expressing the exon 1 of human Htt under the control of 1 kb human Htt promoter	Severe neurological symptoms, rapid onset, intranuclear inclusions very similar to those observed in biopsy from HD	Only expresses the amino-terminal region of the Htt protein nuclear Htt. Aggregates are widely distributed in several brain substrate
	YAC128/ BACHD	*Genetic model*: mouse express full-length human Htt containing 128 and 97 polyglutamines, respectively	Develop selective striatal and cortical atrophy at the age of 12 months. Progressive motor, cognitive deficits, psychiatric disturbance peripheral immune activation	Milder deficit and slower progression
	HD knock-in	*Genetic model*: models with expanded CAG repeats or human mutant Htt exon l HdhQlll, CAG140, and HdhQ150	Preferential accumulation of mutant Htt in striatal neurons that are mostly affected in HD. Depression-like behavior and increase in anxiety-like behavior	Late-onset phenotype and progressive but mild pathology. Not develop a phenotypes as robust as those in transgenic mice

Amyotrophic lateral sclerosis	SOD1	*Genetic model*: KO model and transgenic SOD1 models	In KO, significant distal motor axonopathy. In transgenic mice many features of ALS, axonal and mitochondrial dysfunction, progressive neuromuscular dysfunction, gliosis, and motor neuron loss	KO does not present motor dysfunction, at least up to 6 months of age. Transgenic have variable ages of disease onset and rates of disease progression
	TDP-43	*Genetic model*: remains unclear which TDP-43 mutations cause ALS	Models display mostly axonal phenotypes with relatively mild motor neuron cell death and significant neurodegeneration	Phenotypes are highly dependent upon the promoter used and the level of transgene expression
	FUS	*Genetic model*: four transgenic rodent lines overexpressing FUS	Motor involvement with muscle denervation, axonopathy and spinal degeneration, cognitive deficits, memory impairment, and hippocampal neurons death	All four models display different phenotypic manifestations
	C9ORF72	*Genetic model*: transgenic mice been expressed abnormal hexanucleotide expansion (G4C2)66 and KO model	Transgenic mice has neuronal nuclear inclusions of poly(Gly-Pro), poly(Gly-Ala), and poly(Gly-Arg) dipeptide repeat protein and neuronal loss	KO mice did not induced degeneration, defects in motor function, or altered survival
	VCP	*Genetic model*: KI of the R155H mutation in VCP	In heterozygosity progressive weakness from 9 months of age and weight loss by 24 months of age. Homozygous resulted in a much more aggressive phenotype, early lethality	Phenotypes in transgenic mice, may not be exclusively due to motor neuron degeneration
Frontotemporal dementia	Tau	*Genetic model*: 25 lines of transgenic mice have been created that express human tau with mutations	Aggregated tau and neuronal death, deficits in synaptic plasticity and cognitive dysfunction and neurodegeneration	Not all lines display the pronounced neurodegeneration seen in the human disease
	TDP-43	*Genetic model*: transgenic and KO model	Astrocytosis developed before 5 months of age, and learning/memory and motor deficits developed around 7 months	None of these features correlates well with the presence of functional deficits across different lines
	Progranulin	*Genetic model*: several different lines of progranulin KO mice	Early abnormalities in social behavior without impairment in overall health or motor function, neuroinflammation	Different results in different lines KO model
	VCP	*Genetic model*: two transgenic and one KI line are available as models of VCP- related	Models exhibit age-dependent muscle, bone, and brain disease related to human	Mutation on VCP can cause pure FTD but more commonly cause a syndrome of FTD with muscle and bone disease
	CHMP2B	*Genetic model*: expressing CHMP2B Intron promoter	Develop axonal swellings and have reduced survival	Neuropathology is unique, representing the small cluster of FTD cases

AD, Alzheimer's disease; ALS, amyotrophic lateral sclerosis; APP, amyloid precursor protein; FTD, frontotemporal dementia; FUS, fused in sarcoma; HD, Huntington's disease; KI, knock-in; LB, Lewy body; LRRK2, leucine-rich-repeat-kinase 2; MPTP, 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine; 6-OHDA, 6-hydroxy-dopamine; SNpc, substantia nigra pars compacta; SOD1, superoxide dismutase 1; PS, Presenilin; VCP, valosin-containing protein.

1 INTRODUCTION

Bipolar disorder (BD) is a chronic, severe, and disabling psychiatric condition characterized by recurrent mood switches, including mania and depression, which often increase in severity and frequency over time (APA, 2013). The estimated prevalence in general population is 3% with the mean age of first mood episode around 20 years old (Bauer et al., 2010; Perlis et al., 2009). Apart from the core dysfunction in mood regulation, BD is often associated with high rates of medical and psychiatric comorbidities as well as dysfunction in cognition, endocrine, autonomic, and circadian rhythm, all which ultimately related with poor quality of life and

premature mortality (Krishnan, 2005; Sierra et al., 2005; Swartz and Fagiolini, 2012). Increased risk of suicide has been reported in approximately 10%–20% of patients with BD (Novick et al., 2010).

Although depressive symptoms tend to overcome manic and hypomanic episodes in the long-term course of the illness, mania is regarded as the clinical hallmark of BD with the cardinal diagnostic feature being the occurrence of at least one episode of mania and/or hypomania during the lifetime (Angst et al., 2003). Clinically, a manic episode is generally defined by euphoria, hyperactivity, impulsivity, increased risk-taking behavior, increased reward seeking, and decreased need for sleep. The consequences of mania are devastating and include

a significant social and economic burden (APA, 2013). Recurrent episodes of mania might be associated with BD progression, that is, a greater susceptibility for subsequent episodes, treatment resistance, cognitive and functional decline (Fries et al., 2012; Kapczinski et al., 2014). Moreover, there is evidence that effectively treating mania and preventing recurrent manic episodes might minimize depression burden in part by decreasing the risk of postmanic depressive cycling (Sachs and Gardner-Schuster, 2007; Zarate et al., 2001).

Effective treatments as lithium, anticonvulsants, and antipsychotics have improved the prognosis of BD, but a significant number of patients does not respond well to these drugs. These available pharmacological strategies to treat BD were either discovered via serendipity or resulted from testing drugs previously approved for other clinical conditions like the antipsychotics and the anticonvulsants (Gould et al., 2004; Maletic and Raison, 2014). The limited understanding of the cellular and molecular mechanisms involved in BD pathogenesis and physiopathology is a major constraint to the development of effective therapies for the illness. However, a growing body of studies has aimed to unravel the mechanisms underlying the pathophysiology of mania and, ultimately, to identify potential therapeutic targets for BD.

Animal models are valuable tools for the study of underlying neurobiological mechanism of diseases as well as for the assessment of candidate novel strategies in preclinical settings (Lipska and Weinberger, 2000). The development of appropriate animal models of human diseases is a task of major importance and at least three criteria must be met: face, construct, and predictive validities. Face validity is the ability of the model to mimic behavioral changes comparable to those in the human illness, while for the construct validity the pathophysiological alterations must be the same as, or at least similar to, the human condition. Finally, for predictive validity, conventional drugs used to prevent and/or reverse the behavioral problem in humans should be able to do the same in the animal model (Machado-Vieira et al., 2004; Robbins and Sahakian, 1980).

To date, there are no ideal animal models for BD, that is, a model that covers the full spectrum of the disease by mimicking mood/emotional state changes across manic and depressive poles. Current experimental models only allow the independent investigation of manic or depressive-like episodes (Valvassori et al., 2013). Moreover, the available models are not able to emulate the cumulative burden of recurrent spontaneous mood swings, even within the same pole. The lack of valid biomarkers of the illness, uncertainty regarding the mechanisms of action of the existing mood-stabilizing drugs, and the highly complex genetic basis of BD have hampered the development of BD models (Gould and Einat, 2007).

Over the past decades, pharmacological, environmental, and genetic models have been developed in an attempt to unveil mania pathophysiology and to discover future generation of mood-stabilizing compounds. Herein, we will discuss emerging evidence regarding animal models of mania, their contributions, and potential limitations.

2 INSIGHTS FROM PHARMACOLOGICAL ANIMAL MODELS OF MANIA

Pharmacological models of mania are usually easy to induce and, despite their major limitations, have been repetitively employed to investigate mania pathophysiology and novel therapeutic targets with potential mood-stabilizing properties (Einat, 2006; Young et al., 2011). Psychostimulants drugs, especially amphetamines (AMPHs), are the most used pharmacological model to induce mania. However, other compounds with distinct mechanism of actions have also been used to model mania, including Quinpirole, ouabain, GBR 12909, ketamine (Fig. 43.1), and cholera toxin (El-Mallakh et al., 1995; Ghedim et al., 2012; Kofman et al., 1998; Shaldubina et al., 2002; Young et al., 2010). These compounds mimic hyperactivity, one core facet of mania that can be easily measured in behavioral sets. Moreover, psychostimulants may induce reduced sleep and risk-taking behavior that are also important features of mania (Berridge and Stalnaker, 2002; Einat et al., 2003). Cognitive decline was reported following amphetamine and Quinpirole administration, indicating that these models are able to reproduce a different aspect of the illness (Agmo et al., 1997; Einat and Szechtman, 1993; Fries et al., 2015). Other variables that had been included in the behavioral repertoire related to mania are hole exploration by mice (Perry et al., 2009; Souza et al., 2016) and appetitive high frequency ultrasound vocalization (USV) in rats (Pereira et al., 2014).

Other drugs, such as trimethyltin, imidazole, clonidine, testosterone, corticosterone, among others, can induce manic symptoms, such as irritability, aggression, and increased sexual drive. However, their validity as pharmacological models of mania needs to be further addressed (for review see Einat, 2006).

2.1 Psychostimulants—Amphetamines

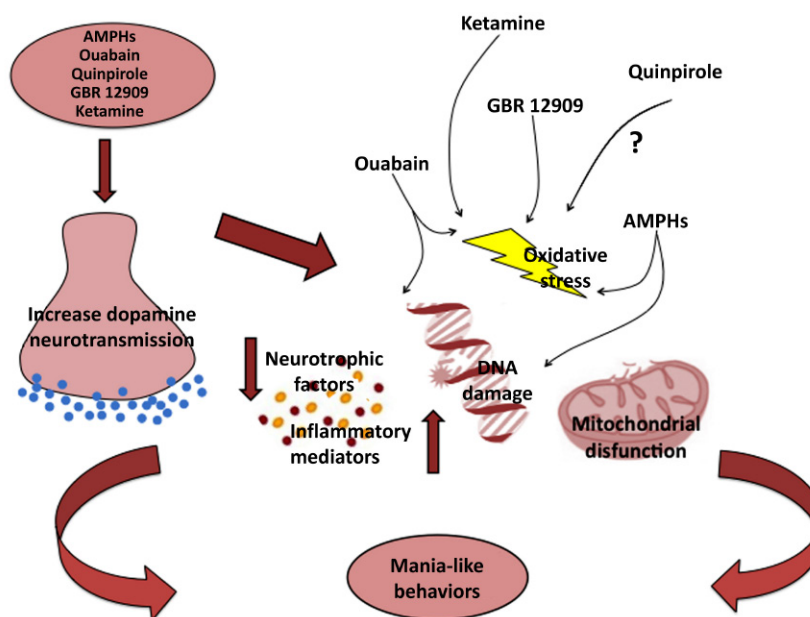
The hypothesis that dopamine (DA) is involved in the neurobiology of mania proposed in the 1970s (Serra et al., 1979) fostered the development of animal models based on pharmacological changes of the dopaminergic neurotransmission. For instance, BD patients presented modifications in an allele of the DA transporter encoder in the *substantia nigra*, which may contribute to


FIGURE 43.1 **Proposed mechanisms of action for pharmacological animal models of mania.** Pharmacological agents that currently present some face, construct, and preditive validities as animal models of mania include: amphetamines *(AMPHs)*, ouabain, GBR 12909, Quinpirole, and ketamine. The administration of these compounds often leads to an increase in the dopaminergic neurotransmission. Dopamine presents a significant redox potential, and high levels of this neurotransmissor have been associated with oxidative damage to proteins, lipids, and DNA in neurons. Besides inducing dopamine release, both AMPHs and ouabain can lead to CNS impairment by increasing oxidative stress, DNA damage, inflammation, mitochondrial dysfunction, and decreasing neurotrophic support, all of which implicated in bipolar disorder (BD) pathophysiology. Oxidative stress has also been demonstrated in GBR 12909 and ketamine models of mania. Evidence regarding the potential of Quinpirole to induce features of BD pathophysiology is still missing, limiting the construct validity of this pharmacological model of mania.

the increase in dopaminergic transmission found in BD (Pinsonneault et al., 2011). A significant increase in the expression of the dopamine receptor D1 was also found in the hippocampus of BD patients, reinforcing the involvement of DA in the pathogenesis of this condition (Pantazopoulos et al., 2004). Psychostimulants act on the central nervous system (CNS) by increasing DA efflux, inhibiting DA reuptake as well as its degradation by the enzyme monoamine oxidase. The result of dopaminergic hyperactivity following the psychostimulants administration in rats is the change in behavior also observed in manic episodes in humans, notably hyperlocomotion (Fiorino and Phillips, 1999).

A diagnostic criterion of DSM-5 for mania is the increased activity presented in nearly all acute manic states (APA, 2013). Although hyperactivity does not reflect the full spectrum of mania, it is an essential component of it. Pharmacological induction of hyperactivity in rodents, usually with psychostimulants such as amphetamine (AMPH) and cocaine, is still the most employed model to study mania since it can be quickly induced, easily measured, and is reliable in its response to the prototypic mood stabilizer lithium (Lerer et al., 1984; Smith, 1981) and valproate (Kuruvilla and Uretsky, 1981; Post and Weiss, 1989; Shaldubina et al., 2002), and antipsychotics (Young et al., 2011). Another important component of mania is cognitive dysfunction, that is, impairment

of attention, memory, and executive functioning that can be easily and reliably rated in laboratory (Burdick et al., 2007). There is consistent evidence that psychostimulants are capable of inducing cognitive impairment in rodents (Fries et al., 2015). In this line, methylphenidate increases hole exploration in mice submitted to holeboard, an effect that was blocked by lithium administration (Souza et al., 2016). Amphetamine also increases high frequency (50 kHz) USV in rats, which is associated with increase in positive affect (Pereira et al., 2014; Rippberger et al., 2015). This effect of amphetamine in 50 kHz USV is blocked by lithium and tamoxifen (Pereira et al., 2014).

Amphetamine (AMPH) is a psychostimulant drug of the phenethylamine class mostly employed and generally accepted in preclinical settings to model mania (O'Donnell and Gould, 2007). AMPH induces release of DA from presynaptic nerve terminals in addition to inhibiting reuptake (Seiden et al., 1993). DA release in response to AMPH occurs by a transporter-mediated release mechanism named reverse transport, which is impulse-independent and has little calcium dependence (Pierce and Kalivas, 1997a; Sulzer et al., 1995). Acute administration of AMPH increases DA levels in striatal slices of rat (Paszti-Gere and Jakus, 2013) and also induces symptoms, such as enhanced mood, racing thoughts, high energy, and restlessness in both

healthy or euthymic BD subjects, supporting the use of those compounds as a model of BD (Anand et al., 2000; Strakowski and Sax, 1998).

In rodent animal models, both AMPH and synthetic compounds with a similar structure, known as amphetamines (AMPHs) including methamphetamine, dextroamphetamine (d-amphetamine), lisdexamfetamine dimesylate (LDX), 3,4-methylenedioxymethamphetamine (MDMA) share a common dopamine-enhancing activity inducing locomotor hyperactivity and psychomotor agitation (Berk et al., 2007; Kara and Einat, 2013). It has been reported that AMPHs-mediated toxicity and behavioral dysfunction involve mesocorticolimbic dopaminergic neurons, which project from the ventral tegmental area (VTA) to the nucleus accumbens (NAc) and prefrontal cortex (PFC) (Pierce and Kalivas, 1997b). For instance, microinjections of D-amphetamine in the NAc and *ventral pallidum* of adult male Sprague–Dawley rats significantly increased locomotor activity and conditioned reward responses (Fletcher et al., 1998). Furthermore, AMPH injected in the NAc also increases 50 kHz USV. The mood stabilizer lithium as well as selective dopamine antagonists, such as haloperidol and chlorpromazine reverse the acute hyperactivity and the increase in 50 kHz USV induced by AMPHs (Gould et al., 2001; Rippberger et al., 2015; Tohen et al., 2003; Vieta and Sanchez-Moreno, 2008).

Apart from increased dopaminergic neurotransmission, oxidative stress, mitochondrial dysfunction, and DNA damage have also been associated with BD pathogenesis (Andreazza et al., 2007, 2008a; Beauvais et al., 2011; Konradi et al., 2004). Considering the redox potential of DA, increased levels of this neurotransmissor lead to oxidative damage to proteins, lipids, and DNA in the neurons (Gluck et al., 2001; Rees et al., 2007). Components of oxidative stress, such as the reactive oxygen species (ROS) are mainly produced in the brain by mitochondrial complexes of the electron transport chain. Thus, an imbalance in the oxidant/antioxidant processes may inhibit electron transport chain complexes, leading to energy metabolism deregulation including decreases in ATP production and ultimately cellular dysfunction (Calabrese et al., 2001; Mattiasson et al., 2003).

In this scenario, Gluck et al. (2001) were the first to show that methamphetamine administration leads to ROS-mediated oxidative stress to proteins and lipid peroxidation, as indicated by a significant increase in the concentration of thiobarbituric acid reactive species (TBARs) and protein carbonyls in the hippocampus and striatum of the methamphetamine-treated mice (Gluck et al., 2001). Similar findings were also reported following acute and repeated exposure to d-amphetamine, which were associated with increased locomotor activity in the open field test (Frey et al., 2006a). Further, they also reported that the oxidative stress induced by acute

or chronic injections of *d*-amphetamine might results of an imbalance between superoxide dismutase (SOD) and catalase (CAT) activities in brain areas like PFC, hippocampus, and striatum, disrupting the antioxidant defense promoted by those enzymes (Frey et al., 2006b). Moreover, an increase of TBARS and superoxide production in submitochondrial particles of the PFC and hippocampus following chronic *d*-amphetamine exposure suggests that AMPHs induce oxidative stress through mitochondrial ROS generation (Frey et al., 2006c). Importantly, the mood stabilizers lithium and valproate reversed and prevented hyperactivity and brain oxidative damage in response to both *d*-amphetamine and methamphetamine administration, supporting a role of oxidative stress in the pathophysiology of BD and the use of these psychostimulant drugs as validity models of mania (Frey et al., 2006d; da-Rosa et al., 2012).

An abnormal cellular energy state affects neuronal function, plasticity, and brain circuit ultimately leading to mood changes (Angst et al., 2003) and cognitive impairment (Quraishi et al., 2009), important features of BD. Mitochondria is the principal source of cellular energy in form of ATP, indicating a potential involvement of this organelle in BD (Kato and Kato, 2000). Acute administration of amphetamine leads to a quickly depletion of ATP levels by 20% in the striatum 1.5 h following the psychoactive drug administration, which were restored within 24 h (Chan et al., 1994). A fast decrease of cytochrome oxidase enzymatic activity, a marker for alterations in mitochondrial function, was also found in rat's striatum (23%–29%) NAc (29%–30%) and *substantia nigra* (31%–43%) 2 h following administration of both methamphetamine and MDMA. Similarly to the Chan et al. (1994) findings, the reduction in cytochrome oxidase activity was transient and returned to control levels within 24 h (Burrows et al., 2000). Significant dysfunction in CNS energy metabolism as indicated by disruption in the activities of Krebs cycle enzymes (citrate synthase and succinate dehydrogenase) and mitochondrial respiratory chain complexes (I–IV) in several brain regions (PFC, amygdala, hippocampus, and striatum) following methamphetamine and *d*-amphetamine exposure was also recently reported (Feier et al., 2012). Accordingly, impairment of mitochondrial complex I activity and oxidative damage to mitochondrial proteins were found in *postmortem* studies of PFC of BD patients (Andreazza et al., 2010). Importantly, mood stabilizers lithium and valproate reversed and prevented AMPHs-induced inhibition of mitochondrial respiratory chain activity and brain energetic metabolism dysfunction (Feier et al., 2013; Valvassori et al., 2010). Altogether, these studies support the hypothesis that disruption in mitochondrial function, possibly in response to an increase in DA levels, is involved in BD pathophysiology.

Oxidative stress and mitochondrial activity impairment may directly damage cellular proteins, DNA, and lipids, thereby compromising cellular function (Gluck et al., 2001; Rees et al., 2007). Indeed, lost in DNA integrity has previously been reported in patients with BD (Andreazza et al., 2007; Frey et al., 2007) in proportion with increased oxidative stress in such patients (Andreazza et al., 2007). Accordingly, rats that received *d*-amphetamine presented both peripheral (blood) and hippocampal DNA damage, which correlated positively with lipid peroxidation. Lithium and valproate treatments restored the oxidative balance and prevented transient damage to the DNA, indicating that AMPHs-induced mania might be an interesting model to investigate the role of DNA impairment in BD (Andreazza et al., 2008b).

Emerging evidence suggests that inflammation underlies BD (Barbosa et al., 2014; van den Ameele et al., 2016). High levels of inflammatory mediators like the cytokines TNF, IL-1β, and IL-6 were found in the serum (Barbosa et al., 2011a; Modabbernia et al., 2013) as well as in the cerebral spinal fluid of BD patients (Söderlund et al., 2011). A role for the immune system in BD was also supported by *postmortem* studies that demonstrated increased expression of the cytokines IL-1β, its receptor (IL-1R), TGF β, as well as astroglial and microglial markers (glial fibrillary acidic protein, inducible nitric oxide synthase, c-fos, and CD11b) in the PFC of BD (Bezchlibnyk et al., 2001; Rao et al., 2010). Apart from enhanced locomotor activity, treatment with *d*-amphetamine increased the levels of the cytokines IL-4, IL-6, IL-10, and TNF in the frontal cortex, striatum, and serum of male Wistar rats. The hyperactivity along with inflammatory alterations was reversed by lithium, supporting the involvement of the immune system in the neurobiology of mania (Valvassori et al., 2015a).

Neurotrophic factors are proteins that mediate neuronal survival, proliferation, and differentiation, being critically involved in mnemonic and emotional processes. Particularly, the Brain-derived neurotrophic factor (BDNF) is abundantly expressed in the hippocampus and cerebral cortex, brain areas thought to be critical for the control of mood, emotion, and cognition (Chao, 2003). There is growing evidence that decreased levels of BDNF are associated with cognitive decline in BD patients (Fernandes et al., 2011). Importantly, significant decrease in BDNF peripheral levels was found during acute episodes of mania, which were prevented by lithium treatment (de Sousa et al., 2011; Tramontina et al., 2009). Altogether these studies provided evidence that peripheral BDNF could be used as a biomarker of mood states and progression of BD.

Resembling the findings in clinical studies with BD patients, a significant decrease in BDNF levels in several brain regions including hippocampus, cortex, amygdala, and *striatum* was also found following *d*-amphetamine

exposure (Cechinel-Recco et al., 2012; Frey et al., 2006e; Macêdo et al., 2012). BDNF reduction as well as hyperactivity induced by *d*-amphetamine was reversed by lithium and valproate (Cechinel-Recco et al., 2012; Frey et al., 2006e). Cognitive impairment associated with BDNF alterations in rat's hippocampus, PFC, and amygdala was also reported following subchronic (7 days) and chronic (35 days) repeated amphetamine injections (Fries et al., 2015). The aforementioned studies support the role of BDNF in mania and reinforce that AMPHs model fulfills adequate face, construct, and predictive validity as an animal model of mania.

Behavioral sensitization, a process whereby repeated intermittent administration of a psychostimulant increases the behavioral response over time, has also been regarded as a classic validated animal model of mania. Repeated intermittent administration of AMPHs in rodents gives rise to the behavioral sensitization phenomena argued to have similarities to the sensitization found in humans (Post, 2007; Robinson and Berridge, 1993). Behavioral sensitization and kindling responses resembling mania along with increased vulnerability to recurrence following successive episodes were initially described by Robert Post following repeated cocaine administration (Post and Weiss, 1989). Further studies confirmed the occurrence of behavioral sensitization following repeated injections of amphetamine and methamphetamine (Cappeliez and Moore, 1990; Kuribara and Uchihashi, 1993; Namima et al., 1999). A potential predictive validity of AMPH sensitization as a behavioral model of mania was proposed as antimanic drugs, such as lithium, valproate, carbamazepine, and lamotrigine were able to reverse *d*-amphetamine sensitization-induced hyperactivity in rodents (Dencker and Husum, 2010). This behavioral sensitization phenomenon has been proposed as a valuable model to explain the chronicity and cyclic course of BD (Post et al., 2001).

Although, psychostimulants are classically employed to model mania in preclinical settings and has provided valuable insights regarding mania pathophysiology and potential therapeutic targets, these pharmacological models have major limitations. Besides not mimicking the full spectrum of the disease, these models are also used as models of drug abuse or addiction and schizophrenia. Moreover, their pathophysiological mechanisms overlap with other major mental disorders, such as schizophrenia and attention deficit hyperactivity disorder, which may compromise their construct validity (Young et al., 2011).

2.2 Amphetamine and Chlordiazepoxide Mixture

The combination of the AMPH psychostimulant *d*-amphetamine with the benzodiazepine derivative chlordiazepoxide (CDP), which presents anxiolytic and

sedative effects, has been proposed as an animal model of mania. Despite the biological mechanisms underlying the potent effects of the AMPH–CDP mixture remain unknown, it results in higher levels of hyperactivity compared to levels triggered by either compound alone, supporting a model face validity (Arban et al., 2005; Aylmer et al., 1987; Kelly et al., 2009).

Some predictive value was also provided by studies showing that acute administration of mood stabilizers, such as lithium and valproate reversed AMPH + CDP-induced hyperactivity (Aylmer et al., 1987; Cao and Peng, 1993). However, the predictive validity of this model is questionable and remains to be fully established. For instance, Arban et al. (2005) conducted a study to investigate the effect of several antimanic drugs, including lamotrigine and carbamazepine, in the hyperactivity caused by AMPH + CDP. Although the antimanic agents successfully decreased hyperactivity, it was unclear whether this effect was due to mood stabilizers action or simply reflected a potentiation of the activity-suppressant effect of CDP by the antimanic drugs (Arban et al., 2005). In an independent study also suggested that the AMPH + CDP might not be an ideal model to investigate novel putative therapies for mania (Kelly et al., 2009). A practical problem with this model is the large number of control groups needed to conclude about the potential antimanic-like effect of experimental drugs (Young et al., 2011).

2.3 Ouabain

In 1983, El-Mallakh first described a potential involvement of the sodium, potassium-activated adenosine triphosphatase (Na$^+$, K$^+$-ATPase) membrane pump in BD pathophysiology. A decrease in the activity of the Na$^+$, K$^+$-ATPase, a major plasma membrane transporter for sodium and potassium that maintains and reestablishes the electrochemical gradient of the neuron, was associated with both phases of BD (El-Mallakh, 1983). Disruptions in Na, K-ATPase activity can lead to both mania and depression by increasing membrane excitability and decreasing neurotransmitter release, affecting neuronal excitability and activity (El-Mallakh and Wyatt, 1995). Accordingly, reduction in Na$^+$, K$^+$-ATPase enzymatic activity in the blood and in the expression of its α2 isoform in the brain temporal cortex of BD patients has been reported (Antia et al., 1995; Huff et al., 2010; Li and El-Mallakh, 2004; Rose et al., 1998).

In this scenario, ouabain (OUA), a potent Na$^+$, K$^+$-ATPase inhibitor, was proposed as a promise pharmacological model of mania. Indeed, intracerebroventricular (ICV) administration of subconvulsive doses of OUA-induced hyperactivity in rodents (El-Mallakh et al., 1995; Li and El-Mallakh, 2004), which were prevented by lithium and valproate, supporting the validity of OUA as a pharmacological model of mania (Jornada et al., 2010a; Li and El-Mallakh, 2004).

Likely psychostimulants, OUA administration also leads to CNS impairment by increasing oxidative stress, DNA damage, inflammation, mitochondrial dysfunction, and decreasing neurotrophic support in several brain regions, including hippocampus, frontal cortex, *striatum*, and amygdala (Freitas et al., 2010; Jornada et al., 2010b; Riegel et al., 2009, 2010; Tonin et al., 2014; Varela et al., 2015). The OUA-induced brain damage was also reversed or prevented by the mood stabilizers lithium and valproate, reinforcing the predictive validity of this model (Banerjee et al., 2012; Freitas et al., 2011; Jornada et al., 2010a, 2011; Valvassori et al., 2015b; Varela et al., 2015).

A recent study showed that ICV injections of OUA impair synaptic plasticity and alter DA release in the rat medial prefrontal cortex (mPFC), a brain area critically involved in cognition. OUA-induced changes in mPFC were prevented by pretreatment with lithium. These findings indicate advantages of this model that, besides inducing behavioral changes, also mimics significant pathophysiological mechanisms of the disease, such as decrease in Na$^+$, K$^+$-ATPase activity and increase in extracellular DA (Sui et al., 2013). Although widely employed to study mania, as a pharmacological model OUA faces some clear limitations. This model cannot fully mimic human BD and to date only one facet of the manic spectrum, hyperlocomotion, was investigated, and future studies are needed to investigate other better behaviors, such as sleep, sexual drive, and aggressivity (Herman et al., 2007).

2.4 Quinpirole

A potential pharmacological model for mimicking mania in animals is the administration of the dopamine D2/D3 receptor agonist, Quinpirole (Einat and Szechtman, 1993; Shaldubina et al., 2002). Increase in locomotor activity as well as cognitive decline following Quinpirole injections has been described (Einat and Szechtman, 1993). Quinpirole induces a biphasic locomotor response, starting with inhibition and followed by excitation, which resembles the oscillating nature of BD (Shaldubina et al., 2002). Mood-stabilizing anticonvulsants, such as valproate, phenytoin, and carbamazepine attenuated Quinpirole-induced hyperactivity without effects on the hypoactive phase (Shaldubina et al., 2002), providing some predictive validity to the model. Since these drugs reversed only the hyperactive state, some authors suggested that the Quinpirole model may not be more advantageous than the AMPHs-induced models (Shaldubina et al., 2002).

In an extended approach of this model, Quinpirole was administered following dopaminergic supersensitivity

induced by chronic treatment with the antidepressant imipramine to mimic the antidepressant-related manic switch. Both lithium and valproate failed to prevent the development of such behavioral supersensitivity, but carbamazepine was effective in preventing imipramine-induced behavioral sensitization (D'Aquila et al., 2000, 2006). Since lithium, carbamazepine, and valproate are all considered poorly effective in the treatment of antidepressant-related mania, the predictive validity of this model is debatable, and cannot be based only on the carbamazepine results (D'Aquila et al., 2001).

2.5 GBR 12909

Manic episodes in BD are associated with increased activation of brain DA systems, which is consistent with genetic linkage studies connecting dopamine transporter (DAT) abnormalities to this disorder (Greenwood et al., 2001; Hayden and Nurnberger, 2006). For instance, genetic modified mice presenting reduced DAT levels exhibited significantly increased extracellular DA activity similarly to BD patients (Vawter et al., 2000; Zhuang et al., 2001). Accordingly, the selective DA transporter reuptake inhibitor, GBR 12909, has been proposed as a potential pharmacological model of mania.

The GBR 12909 administration as a promise candidate of an animal model of mania was also based in a reverse-translational approach. This approach proposed to stratify the complex multifaceted behaviors associated with hyperactivity in animals and translated this response to human. By employing a behavioral pattern monitor (BPM) technique, it was found that BD patients presented motor and exploratory behavior pattern very distinctly from those observed in schizophrenia patients. The striking difference between manic BD and schizophrenia patients in this task highlights the relevance of multivariate assessment of behavior, which may improve the diagnostic differentiation between these two conditions that can be indistinguishable during acute states (Pini et al., 2004; Young et al., 2007). Mice that received AMPH, a mania model criticized for sharing pathophysiological features with schizophrenia models, presented increased motor activity, but reduced exploratory behavior as measured by the BPM (Young et al., 2010). Interestingly, methylphenidate, which also blocked DAT, increased mice hole exploration in the holeboard test (Souza et al., 2016). On the other hand, the administration of GBR 12909 increased activity and exploratory behaviors, a phenotype consistent with the behavior of BD patients in the human BPM (Perry et al., 2009; Young et al., 2010). The selective inhibition of DAT by GBR 12909 was independently of the mice strain and presented a long-lasting (3 h) effect, supporting the face validity of this model.

A recent study found that a single injection of GBR 12909 induced hyperlocomotion and increased exploratory behavior. These behavioral changes were associated with decreased levels of the antioxidant enzyme glutathione (GSH) and increased lipid peroxidation in the hippocampus and striatum, consistent with the oxidative stress role described in BD pathophysiology (Queiroz et al., 2015). Further studies are needed to better address the involvement of inflammation, DNA, and mitochondrial damage, among other factors already reported in pharmacological models and often implicated in BD neurobiology (Fig. 43.1).

Acute administration of valproate and lithium prevented GBR 12909 behavioral and prooxidative alterations (Queiroz et al., 2015). Chronic treatment with valproate partially attenuated the behavior effects of functional decrease of DAT observed in genetic modified mice and following GBR 12909 acute injections (van Enkhuizen et al., 2013). Altogether, these studies provided evidence of the potential predictive validity of this promise model of mania.

In this line, mood stabilizers also blocked methylphenidate-induced hyperlocomotion (Barbosa et al., 2011b; Pereira et al., 2011; Souza et al., 2016; Tonelli et al., 2013) and hole exploration (Souza et al., 2016).

2.6 Ketamine

Ketamine, an antagonist of *N*-methyl-D-aspartate glutamatergic receptor, is also used as a pharmacologically based mania model. Ketamine induced hyperlocomotion in rodents (Gazal et al., 2014, 2015; Ghedim et al., 2012) and there is a case report of manic-like symptoms induced by ketamine (Ricke et al., 2011). Ketamine-induced hyperlocomotion is blocked by lithium and valproate (Gazal et al., 2014, 2015; Ghedim et al., 2012), showing its predictive validity. Moreover, this effect is associated to increase oxidative stress (Gazal et al., 2014, 2015; Ghedim et al., 2012). However, as other psychostimulant models, ketamine challenge is also used to model schizophrenia (Young et al., 2011).

3 INSIGHTS FROM ENVIRONMENTAL MODELS

A significant limitation reported for pharmacological models is that they reflect only one facet of mania, that is, hyperlocomotion, that is also commonly observed in other conditions like schizophrenia and drug abuse (Young et al., 2011). As mania is a complex disorder influenced by environmental and genetic factors, it is reasonable to assume that manipulations of these factors might induce behaviors in animals that resemble human manic states rather than only hyperactivity (Gould and Einat, 2007). Moreover, pharmacological models can give false results (positive or negative) if a significant

pharmacokinetic interaction occurs between induction drug and test drug.

Environmental models of mania in rodents include sleep deprivation, the resident-intruder test, and the dominant–submissive behavior paradigms (Malatynska and Knapp, 2005; McClung, 2011; Miczek et al., 2001). The rodent sleep deprivation model is based in the circadian rhythm changes associated with mania (McClung, 2011). This model presents significant relevance regarding face validity since sleep disruption is one of the hallmarks of mania (Mansell and Pedley, 2008), and sleep deprivation can trigger mania in bipolar patients (Wehr, 1992). Moreover, sleep deprivation reproduces several manic-like behaviors, such as insomnia, hyperactivity, aggressive actions toward other animals, hypersexuality (an increase in mounting behavior), and stereotypy (sniffing and rearing) (Abrial et al., 2015; Fratta et al., 1987; Gessa et al., 1995; Hicks et al., 1979). Increase in protein kinase C (PKC) activity in the PFC of sleep-deprived animals along with changes in glutamatergic signaling supports some construct validity to the model. Furthermore, sleep deprivation increases oxidative stress, which correlated positively with increase in locomotor activity (Kanazawa et al., 2016). Additionally, predictive validity is also suggested since lithium, aripiprazole, and tamoxifen attenuated manic-like behaviors (Abrial et al., 2015; Kanazawa et al., 2016; Szabo et al., 2009).

The resident-intruder test models provocative, intrusive, or aggressive behaviors frequently observed in manic patients (Einat, 2007a). This test consists of introducing an intruder rodent into the home cage of an isolated mouse or rat, and quantifying both the aggressive acts from the resident and the defensive acts and postures exhibited by the intruder (Miczek et al., 2001). Manic-like behaviors, including biting, threatening postures, and tails rattling may be augmented by prolonged isolation or exposure to foot shock applied to the resident rodents (Miczek and O'Donnell, 1978). Although treatment with lithium, valproate, and antipsychotics reduced resident aggression toward intruders (Einat, 2007b; O'Donnell and Gould, 2007), similar effects have been demonstrated following anxiolytics administration (Vassout et al., 2000; Yang et al., 2015), indicating limited predictive validity and specificity to mania.

The dominant–submissive behavior is a more recent proposed environmental model of mania. In this model, subordinate animals, similar to depressed humans, presented increased defensive behavior and reduced activity. On the other hand, dominant animals, similar to manic episodes, exhibited self-confident, assertive and aggressive behavior (Malatynska and Knapp, 2005). Lithium, valproate, and carbamazepine reversed the dominant behavior in a time course similar to that observed in BD patients. For instance, lithium and carbamazepine treatment reduced rodent dominance after 2–3 weeks of treatment (Malatynska and Knapp, 2005; Malatynska et al., 2007). Similar to the resident-intruder test, the dominant–submissive behavior paradigms are also sensitive to the effects of anxiolytic and anxiogenic drugs limiting its construct and predictive validity as a mania model (Vassout et al., 2000).

4 INSIGHTS FROM GENETIC MODELS

BD is a highly heritable disorder that possibly involves multiple genes. In this context, genetic models of mania have been proposed to define specific neurobiological processes and associated behaviors that are involved in the pathways connecting genes and manic symptoms (Gould and Einat, 2007). Due to the possibility of identifying potential behavioral endophenotypes, genetic models might present greater construct validity compared to pharmacological and environmental models (Gould and Einat, 2007; Malkesman et al., 2009).

Rodent genetic models of mania include genes coding for DAT (Ralph-Williams et al., 2003), circadian locomotor output cycle kaput (CLOCK) (Roybal et al., 2007), glutamate receptor 6 (GluR6) (Shaltiel et al., 2008), GSK-3β (Prickaerts et al., 2006), circadian gene D-box binding protein (DBP) (Le-Niculescu et al., 2008), pituitary adenylate cyclase-activating polypeptide (PACAP) (Hattori et al., 2012), extracellular signal-regulated kinase 1 (ERK1) (Engel et al., 2009), postsynaptic density protein (PSD) SHANK3 (Han et al., 2013), inositol-monophosphatase (IMPA)1 (Damri et al., 2015), and B-cell lymphoma 2 (Bcl-2) (Lien et al., 2008). Although genetic models might be promising to understand the neurobiological mechanisms underlying mania and to develop potential therapeutic strategies, further studies are needed to confirm their face and predictive validities (Young et al., 2011).

5 CONCLUSIONS

Pharmacological models of mania have been widely employed to investigate mania pathophysiology and potential therapeutic agents. Apart from their significant limitations, accumulating evidence had supported face, predictive, and construct validities. Moreover, these models had been useful to investigate potential drugs for mania, such as *N*-acetylcysteine plus deferoxamine, curcumin, sulfate magnesium, folic acid, and diphenyl diselenide (Arent et al., 2015; Barbosa et al., 2011b; Brocardo et al., 2010; Brüning et al., 2012; Gazal et al., 2014). It is worth mentioning that many studies investigated the acute effect of antimanic drugs to provide some predictive validity. Although these studies showed positive effects in behavioral pharmacological terms, mania is a

long-term condition that requires chronic therapeutic approaches. Therefore, studies that investigate chronic treatment responses are more likely to exhibit predictive validity for treatment in subjects with BD (Young et al., 2011). Anyway, the pharmacological models of mania aroused interest in this field and may prompt the development of more complex and valid models.

The models based on environmental and genetics manipulations, which are less studied and validated, are promising and apparently overcome some limitations of pharmacologically based models. Finally, new behavioral variables that had been proposed (hole exploration by mice and high frequency USVs in rats) can refine mania models and increase their content validity, making possible the assessment of different facets of the illness.

1 INTRODUCTION

Severe stress in humans is a risk factor for major depression and anxiety disorders (Charney and Manji, 2004; Duman, 2009; Heim et al., 2010; Krishnan and Nestler, 2008). Consequently, deleterious effects of stress are commonly considered in mental health research. Far fewer studies have addressed the discovery that mild but not minimal nor severe stress exposure promotes subsequent coping and emotion regulation as described by U-shaped functions (Russo et al., 2012; Sapolsky, 2015; Seery et al., 2010). Historical reasons for this imbalance in stress research are discussed by Petticrew and Lee (2011).

In addition to the qualities or intensities of stress exposure, temporal aspects further contribute to the production of stress vulnerability versus resilience (Burchfield, 1979). Prolonged chronic stress leads to vulnerability (Brosschot, 2010), whereas intermittent stress exposures interspersed with undisturbed periods of recovery provide repeated opportunities to learn, practice, and improve coping with subsequent gains in emotion regulation and resilience (Brockhurst et al., 2015; Lee et al., 2014; Lyons et al., 2010a,b). Variously described in studies of humans as inoculating, steeling, or toughening (Dienstbier, 1989; Garmezy et al., 1984; Russo et al., 2012; Rutter, 2006), the notion that learning to cope with stress builds resilience is supported by nonhuman primate research.

In natural and seminatural conditions, squirrel monkey mothers and other group members periodically leave newly weaned offspring beginning at 3–6 months of age to forage for food on their own (Lyons et al., 1998). At this stage of development, offspring are approximately half their adult body size. Initially, brief mother–infant separations studied in controlled experimental conditions elicit distress peep-calls and increase plasma levels of the stress hormone cortisol with partial habituation of these measures observed over repeated separations (Coe et al., 1983; Hennessy, 1986). Later in life, monkeys exposed to intermittent separations show fewer behavioral indications of anxiety, diminished stress-levels of cortisol, and enhanced glucocorticoid feedback regulation of

the hypothalamic–pituitary–adrenal (HPA) axis compared to monkeys not exposed to intermittent separations (Levine and Mody, 2003; Lyons et al., 1999; Lyons et al., 2010b; Parker et al., 2004, 2006). Similar examples have been reported for human children studied in the context of separation stress (Poulton et al., 2001), work-related stress (Mortimer and Staff, 2004), family stress (Hagan et al., 2014), and other diverse stressful life events (Boyce and Chesterman, 1990).

Coping with stress is not, of course, limited to critical or sensitive periods in primate postnatal development. Learning to cope in adult monkeys increases hippocampal neurogenesis and enhances expression of genes involved in cell proliferation and survival (Lyons et al., 2010a). Learning to cope also protects adult monkeys against subsequent stress-induced deficits in behavior on tests of emotionality and diminishes the HPA axis neuroendocrine stress response (Lee et al., 2014). Adult humans who survive earthquakes or floods subsequently respond to natural disasters with diminished anxiety (Norris and Murrell, 1988) and less depressed affect (Knight et al., 2000) compared to inexperienced human survivors.

Here we describe new models of stress coping and resilience in mice (Brockhurst et al., 2015; Lee et al., 2016). Instead of screening for the presence of traits that occur in resilient individuals or the absence of vulnerability to stress (Feder et al., 2009; Russo et al., 2012), we focus on learning to cope with stress and the process of building resilience. Considering resilience as a process implies that it can be modified and improved in humans with or without preexisting psychopathologies (DiCorcia and Tronick, 2011; Masten, 2001; Waugh and Koster, 2015). Humans may more closely resemble various nonhuman primates, but the availability of research tools for dissecting causal pathways that link behavior and brain are far greater in mice compared to monkeys (Gerits and Vanduffel, 2013; Huang and Zeng, 2013). Therefore, mouse models offer essential opportunities to bridge the gap between basic and applied research in psychiatry and behavioral neuroscience.

2 LEARNING TO COPE TRAINING

Adult C57BL/6 male mice weighing ~25 g (range 22–28 g) are maintained in same-sex groups of 2 or 3 animals per cage in climate-controlled rooms with an ambient temperature of 26°C and lights on from 07:00 to 19:00 h (Brockhurst et al., 2015). Food and drinking water are provided *ad libitum*. After 2 weeks of acclimation, mice are randomized to experimental learning to cope sessions of training or a control treatment condition. In the control condition, mice remain undisturbed in their

FIGURE 44.1 **Learning to cope with stress training sessions.** Mice are removed from the home cage every other day for 21 days and individually placed for 15 min behind a mesh-screen barrier in the cage of a larger, same-sex resident mouse breeder. The mesh-screen barrier prevents fighting and physical injury during all 11 training sessions but allows for noncontact interaction. Four C57BL/6 mice are depicted in the home cages of four Swiss Webster resident mouse breeders.

home cage and receive ordinary animal facility care. Age-matched mice in the learning to cope training condition are intermittently exposed to a social stress protocol developed by other investigators (Golden et al., 2011) and modified as follows.

Every other day for 21 days between 2 and 4 h after onset of lights on, mice in the learning to cope condition are removed from their home cage and individually placed for 15 min behind a mesh-screen barrier in the cage of a larger, same-sex, resident Swiss Webster mouse breeder (Fig. 44.1). Each subject is repeatedly exposed to the same resident stranger with different residents used for different subjects to avoid idiosyncratic effects induced by any particular resident. The mesh-screen barrier prevents fighting and physical injury during all 11 training sessions but allows for noncontact interaction. After each training session, mice are immediately returned to their home cage.

3 LEARNING TO COPE IS STRESSFUL

Plasma levels of the stress hormone corticosterone were initially assessed in undisturbed home cage baseline conditions and then immediately after the 1st, 3rd, 7th, and 11th learning to cope training sessions (Brockhurst et al., 2015). Corticosterone levels were also assessed after restraint stress tests conducted 2, 6, and 13 days following completion of learning to cope and control treatment conditions (Brockhurst et al., 2015). Restraint stress tests consisted of confinement for 15 min every other day for seven total sessions in plastic conical 50 mL tubes perforated with ventilation holes. Blood samples for corticosterone measures were collected via the tail vein (refer to http://www.

nc3rs.org.uk/mouse-tail-vessel-microsampling-non-surgical) between 2 and 3 h after onset of lights on to control for circadian variation. Plasma extracted from blood samples was assayed in duplicate for corticosterone using a radioimmunoassay without knowledge of the treatment conditions.

Learning to cope training sessions consistently elicited robust corticosterone responses (Fig. 44.2) as discerned by ANOVA (F(4,28) = 13.19, P < 0.001). Learning to cope also diminished subsequent corticosterone responses to restraint (Fig. 44.3) as indicated by a treatment main effect (F1,14) = 15.57, P = 0.001), sample condition main effect (F(3,42) = 91.33, P < 0.001), and treatment-by-sample condition interaction (F(3,42) = 5.33, P = 0.003). Learning to cope has previously been reported to diminish subsequent HPA axis stress hormone responses in juvenile (Parker et al., 2006) and adult (Lee et al., 2014) monkeys. During restraint, we informally noted more struggling and less behavioral immobility in mice trained to cope compared to controls. Follow-up studies were therefore conducted to test this hypothesis in another sample of mice to rule out blood sampling effects on measures of emotional behavior.

4 LEARNING TO COPE REDUCES SUBSEQUENT BEHAVIORAL MEASURES OF EMOTIONALITY

After completion of learning to cope and control treatment conditions, we administered tail-suspension tests counterbalanced with open-field and object-exploration tests to control for test order (Brockhurst et al., 2015). Behavioral tests were conducted 2–13 days after completion of the learning to cope and control treatment conditions between 2 and 3 h after onset of lights on. Video records

were scored by a trained observer using Noldus Observer XT without knowledge of the treatment conditions.

Tail-suspension tests followed a standard protocol (Cryan et al., 2005) with total time spent immobile scored as a measure of behavioral despair. Open-field tests were then conducted repeatedly with each mouse on two consecutive days according to a modified protocol as described by Gould et al. (2009). Mice were individually placed in a white plastic open-field box (40 × 40 × 42 cm) for each daily 10-min test session and the box was cleaned after every test session. Time spent freezing in the open-field box was scored as the absence of all movement except respiration and is considered a measure of anxiety-like behavior in mice (Ahn et al., 2013).

After 2 days of acclimation to the open-field, object-exploration tests were conducted in the same open-field box with a familiar white plastic cap that was continuously maintained in the home cage and a novel black plastic pipe. Both objects were attached to the floor of the open field for each 10-min object-exploration test session. The next day, exploration tests were repeated with the location of objects reversed to control for place preferences. The open-field box and objects were cleaned after every test session. Latencies to explore either of the objects were scored when the animal's head was located within 1 cm of the familiar or novel object.

Mice trained to cope spent significantly less time immobile as a measure of behavioral despair on tail-suspension tests compared to controls (F(1,21) = 6.38, P = 0.021; Fig. 44.4A). Anxiety-like behavior indexed by mean freezing scores from two open-field test sessions was also diminished by learning to cope training compared to controls (F(1,21) = 5.98, P = 0.023; Fig. 44.4B). Learning to cope training has previously been reported
FIGURE 44.4 Learning to cope training subsequently decreases (A) immobility on tail-suspension tests and (B) freezing in the open field (mean ± SEM, *n* = 12, **P* < 0.05 Fishers protected *t*-tests following ANOVAs described in the text). *Note*: different *y*-axis time scales for each graph. *Source: Modified from Brockhurst, J., Cheleuitte-Nieves, C., Buckmaster, C.L., Schatzberg, A.F., Lyons, D.M., 2015. to diminish anxiety-like behavior (Parker et al., 2004) and stress-induced anhedonia (Lee et al., 2014) in monkeys.

During object-exploration tests, object type and treatment main effects were discerned for latency scores as depicted in Fig. 44.5. Shorter exploration latencies were evident for the familiar compared to novel object ($F_{(1,21)}$ = 9.02, *P* = 0.007) and mice trained to cope explored objects faster than controls ($F_{(1,21)}$ = 6.06, *P* = 0.023). Learning to cope training has previously been reported to enhance novel object exploration in monkeys (Parker et al., 2007). Although the object type-by-training treatment interaction was not significant for mice, exploration latencies were significantly diminished by learning to cope training compared to controls for the novel object ($F_{(1,21)}$ = 6.76, *P* = 0.017) but not the familiar object (Fig. 44.5). Shorter exploration latencies were scored on the first compared to the second test day ($F_{(1,21)}$ = 5.06, *P* = 0.035), but the test day-by-training treatment and test day-by-treatment-by-object type interactions were not significant (data not shown).

5 LEARNING TO COPE INCREASES ANTERIOR CINGULATE CORTEX STARGAZIN GENE EXPRESSION

In an unbiased search for neural markers of learning to cope with stress, we discovered increased stargazin (also called TARP gamma-2) gene expression in anterior cingulate cortex of adult monkeys (Lee et al., 2016). Anterior cingulate cortex is involved in learning, memory, cognitive control, emotion, and HPA axis regulation (Etkin et al., 2011; Herman, 2013; Ochsner et al., 2012; Wang et al., 2012; Weible, 2013). Stargazin modulates glutamate receptor signaling via AMPA receptor trafficking (Chen et al., 2000; Jackson and Nicoll, 2011; Vandenberghe et al., 2005) and plays a role in synaptic plasticity (Huganir and Nicoll, 2013) as a mechanism for learning considered functionally in terms of behavior change. Results from monkeys were subsequently tested for reproducibility in mice.

Three days after completion of the behavioral tests described previously, brain tissues from mice were collected after onset of lights on to control for circadian variation (Lee et al., 2016). Responses attributable to behavioral testing were distinguished from prior learning to cope training effects by investigating mice that were and were not behaviorally tested for emotionality after randomization to coping and control treatment conditions. A training treatment main effect ($F_{(1,43)}$ = 6.23, *P* = 0.016) was discerned for anterior cingulate cortex stargazin expression in mice but neither the behavioral testing main effect nor behavioral testing-by-training treatment interaction was significant (Fig. 44.6).

As evidence of learning to cope effects distinct from stress exposures per se, increased anterior cingulate
FIGURE 44.6 Anterior cingulate cortex stargazin expression in mice randomized to learning to cope training sessions versus a no-training treatment control. Mice from each training treatment are either exposed or not to subsequent behavioral tests of emotionality (*N* = 11–12 per condition; mean ± SEM; **P* = 0.016). *Source: From Lee, A.G., Capanzana, R., Brockhurst, J., Cheng, M.Y., Buckmaster, C.L., Absher, D., Schatzberg, A.F., Lyons, D.M., 2016. Learning to cope with stress modulates anterior cingulate cortex stargazin expression in monkeys and mice. Neurobiol. Learn. Mem. 131, 95–100. Copyright 2016 by Elsevier.*

cortex stargazin expression correlated inversely with diminished behavioral measures of emotionality in mice. Specifically, increased anterior cingulate cortex stargazin expression correlated with diminished latencies to explore a novel object ($r = -0.53$, df 21, $P = 0.009$) and with diminished immobility on tail-suspension tests ($r = -0.50$, df 21, $P = 0.016$). Increased stargazin expression in anterior cingulate cortex did not correlate with freezing in the open field, and stargazin expression was not measured in mice monitored for corticosterone.

Increased stargazin expression induced by coping in mice was also nearly significant in amygdala ($F(1,21) = 3.09$, $P = 0.093$) but not hippocampus (data not shown). Increased amygdala stargazin expression correlated inversely with diminished tail-suspension immobility ($r = -0.42$, df 21, $P = 0.044$) but not novel object-exploration latencies nor freezing in the open field. Stargazin expression in hippocampus was not correlated with any behavioral measure of emotionality in mice.

6 DISCUSSION

Results demonstrate that learning to cope sessions of training acutely stimulate corticosterone and subsequently enhance active forms of coping behavior in mice. Stargazin gene expression in a brain region involved in learning is increased by coping and stargazin expression correlates inversely with behavioral measures of emotionality. Results in mice parallel our findings from monkeys and support the hypothesis that an aspect of learning to cope with stress is mediated by a common neural mechanism.

Convergence in monkeys and mice reduces the risk of false positive findings and enhances translational relevance (Ciesielski et al., 2014; Lee et al., 2016). Translation has commanded considerable attention because of recent uncertainties about generalization across different species given inevitable biological variation, the use of diverse experimental manipulations, and various ways to operationalize complex outcomes of interest (Institute of Medicine, 2013). Reproducibility across distinct models that utilize different species may help to ensure that observed behavioral and neurobiological effects generalize to broader contexts.

Learning to cope training sessions were designed on the basis of evidence that mild but not minimal nor severe stress exposure provides opportunities to learn, practice, and improve coping as described by U-shaped functions (Russo et al., 2012; Sapolsky, 2015; Seery et al., 2010). Intermittent social separations used in our models of coping in monkeys are described by Lee et al. (2014) and Lyons et al. (2009, 2010a) and a standard social stress protocol was modified to create experimental training conditions for studies of learning to cope in

mice (Brockhurst et al., 2015; Lee et al., 2016). Instead of daily and direct exposure to an aggressive same-sex resident (Golden et al., 2011), learning to cope training sessions for mice were conducted every other day behind a mesh-screen barrier in the cage of a same-sex resident stranger (Fig. 44.1). The mesh-screen barrier prevented fighting and physical injury but allowed for noncontact interaction. Immediately after each training session, subjects were returned to their home cage to allow ample time for recovery and consolidation of learning and memory in familiar undisturbed conditions. Learning to cope training sessions in mice subsequently diminished immobility as a measure of behavioral despair on tail-suspension tests (Fig. 44.4). Learning to cope also subsequently diminished freezing in the open field, decreased novel object-exploration latencies, and reduced corticosterone responses to restraint (Figs. 44.3–44.5).

These results concur with little known studies conducted in the 1950s. Based on Freud's theory that early life stress contributes to the development of subsequent emotional instability, Seymour Levine expected to find that rats exposed to intermittent foot shocks sufficient to elicit evasive movements would show signs of subsequent emotional instability later in life (Levine, 1962; Levine et al., 1956). Levine's findings were not supportive of Freudian theory and he concluded that intermittent exposure to stress "results in the capacity for the organism to respond more effectively when confronted with novel situations or, in other words, to exhibit a diminished emotional response" (Levine, 1962). Levine also found that handling without foot shocks diminished subsequent emotionality in rats and postnatal handling has received considerable research attention in developmental psychobiology (Fernández-Teruel et al., 2002).

Additional indications that stress is not necessarily destructive come from human psychotherapies. Intermittent exposure to mildly stressful situations is a feature of stress inoculation training for people who work in conditions where performance in the face of adversity is required, for example, medical and military personnel, police, firefighters, and rescue workers (Meichenbaum and Novaco, 1985; Saunders et al., 1996; Stetz et al., 2007). Exposure psychotherapies likewise train patients to imagine a graded series of stress inducing situations and encourage interaction with stressors in vivo (McNally, 2007). These procedures promote learning (Craske et al., 2008) and provide opportunities to practice acquired coping skills (Serino et al., 2014).

Animal models of exposure psychotherapies often focus on learned extinction of conditioned fear (Davis et al., 2006; Milad and Quirk, 2012). Extinction occurs when a conditioned stimulus (CS) that was previously paired with an unconditioned stimulus (US) is repeatedly presented on its own. Repeated presentation of the CS alone results in new learning and subsequent inhibition

of the conditioned fear response (Bouton et al., 2006; Milad and Quirk, 2012). Far less researched, but of equal importance, are indications that repeated presentation of the US alone also inhibits conditioned fear responses by devaluing or reducing the impact of the US through a process called US habituation (Rauhut et al., 2001; Rescorla, 1973; Storsve et al., 2010).

Inhibitory effects of CS extinction do not generalize to contexts that differ from those in which CS extinction learning occurred (Bouton, 2002; Harris et al., 2000; Rauhut et al., 2001). Context specificity limits the utility of animal models for exposure psychotherapies based on CS extinction (Craske et al., 2008; McNally, 2007). In contrast, certain models of US habituation are minimally responsive to modulation by contextual cues (Churchill et al., 1987; Evans and Hammond, 1983; Grissom et al., 2007; Hall and Honey, 1989; Jordan et al., 2000; Nyhuis et al., 2010; Rauhut et al., 2001). With respect to minimal modulation by contextual cues, US habituation resembles aspects of learning to cope training for monkeys and mice.

Learning to cope training for mice entails repeated exposure to a larger, same-sex, resident stranger. Training effects then generalize to completely different test contexts as exemplified by diminished immobility during tail suspension, less freezing in the open field, decreased novel object-exploration latencies, and reduced corticosterone responses to restraint (Figs. 44.3–44.5). Learning to cope training effects likewise generalize in studies of monkeys and are minimally responsive to modulation by contextual cues. Intermittent social separations used to train coping in monkeys diminish behavioral and neuroendocrine indications of anxiety and increase novelty seeking behavior in test contexts that differ completely from those in which learning to cope training occurred (Lee et al., 2014; Lyons et al., 2010b; Parker et al., 2007).

Despite similarities in generalization, learning to cope differs from US habituation. Early studies found that habituation during intermittent social separations used to train coping in monkeys occurs much faster for behavioral than glucocorticoid stress hormone responses (Coe et al., 1983; Hennessy, 1986). Learning to cope training likewise acutely increases the primary glucocorticoid stress hormone in mice (i.e., corticosterone) without indications of neuroendocrine habituation over repeated training sessions (Fig. 44.2). Although repeated exposure to homotypic stressors generally results in habituation of the glucocorticoid response in rodents (Herman, 2013), repeated exposure to same-sex social strangers appears to be resistant to neuroendocrine habituation for ten or so sessions in mice (Brockhurst et al., 2015; Warren et al., 2013). Learning to cope training instead has delayed incubation effects (Poulos et al., 2016) insofar as corticosterone responses to subsequent restraint stress

tests are diminished after completion of training compared to no-training controls (Fig. 44.3).

Glucocorticoids are translated into genomic outputs by binding intracellular glucocorticoid receptors that translocate to the nucleus and interact with DNA to regulate the expression of numerous genes (Oakley and Cidlowski, 2013; Zalachoras et al., 2013). Many genes differentially expressed in anterior cingulate cortex of monkeys trained to cope appear to interact with glucocorticoids according to our recent bioinformatics analysis (Lee et al., 2016). Although publicly available data in GEO (http://www.ncbi.nlm.nih.gov/geo/) confirm transcription regulation by glucocorticoids in brain, temporal patterns of glucocorticoid exposure that mimic intermittent sessions of learning to cope are not available for gene expression profiles in GEO. Intermittent versus chronic glucocorticoid exposure differentially regulates the expression of specific genes (Conway-Campbell et al., 2012), and broader profiles of gene expression from diverse brain regions are needed to determine whether differential gene expression profiles explain divergent psychobiological effects of intermittent versus chronic stress.

The gene that encodes stargazin appears to be regulated by glucocorticoids and anterior cingulate cortex stargazin expression is increased by learning to cope in monkeys (Lee et al., 2016). Learning to cope likewise increases anterior cingulate cortex stargazin expression in mice randomized to coping with or without subsequent behavioral tests of emotionality (Fig. 44.6). Increased anterior cingulate cortex stargazin expression induced by coping in mice correlates inversely with behavioral measures of emotionality. Increased stargazin expression induced by coping in mice is also nearly significant in amygdala but not hippocampus.

Although numerous studies confirm that stargazin facilitates synaptic plasticity (Huganir and Nicoll, 2013), few investigations have linked stargazin to learning and memory considered functionally in terms of behavior change. One report indicates that eyeblink conditioning increases stargazin expression in rat cerebellum (Kim and Thompson, 2011), and another study shows that spatial navigational learning increases stargazin expression in rat hippocampus (Blair et al., 2013). We found that learning to cope with stress increases stargazin expression in anterior cingulate cortex of both monkeys and mice (Lee et al., 2016). Stargazin is involved in AMPA receptor trafficking (Chen et al., 2000; Jackson and Nicoll, 2011; Vandenberghe et al., 2005), and pharmacological blockade of AMPA receptors in anterior cingulate cortex impairs assimilation of new information into established mental schemas or associative frameworks (Wang et al., 2012). Nevertheless, all reports connecting stargazin with learning considered functionally in terms of behavior change are

correlational and further studies are needed to establish causal links between learning reflected in behavior and increased stargazin expression in relevant regions of brain. Molecular genetic research tools developed for mice are ideally suited to address this gap in our knowledge.

7 LIMITATIONS

Our findings should be interpreted along with other potential limitations. Results from males may or may not hold true for females. Although learning to cope training sessions enhance subsequent emotion regulation in adult female monkeys (Lee et al., 2014), learning to cope in female mice has not yet been explored. Repeated exposure to a lactating same-sex resident stranger (Jacobson-Pick et al., 2013) may be more effective for training female mice to cope compared to the nonlactating same-sex resident stranger that we used here for males. In home cage conditions, social versus individual housing (Panksepp and Lahvis, 2016) may likewise alter the impact of encounters with a resident stranger for learning to cope training in mice.

Learning to cope training and subsequent tests of emotionality were both conducted shortly after onset of lights on and this schedule may have altered circadian aspects of emotionality. Training and testing also both required transfer of mice from their home cage into new environments. Studies of habituation or extinction during repeated transfers alone are needed but contextual differences between training and testing generally enhance behavioral and neuroendocrine measures of arousal (Bouton et al., 2006; Herman, 2013) instead of producing observed reductions in emotionality. Correlations between behavior and glucocorticoids are not presented because these measures were collected from different mice to control for potential blood sampling effects on behavior. Lastly, the pursuit of convergent evidence in mice and monkeys may minimize false positive findings and enhance translational relevance (Ciesielski et al., 2014), but this approach also increases the risk of falsely disregarding species differences as negative or unimportant results.

8 CONCLUSIONS

Here we describe new mouse models of stress coping and resilience. Learning to cope training sessions acutely increase corticosterone and diminish subsequent immobility on tail-suspension tests. Learning to cope also subsequently diminishes freezing in the open field, decreases novel object-exploration latencies, and reduces corticosterone responses to restraint. Learning to cope increases stargazin expression in anterior cingulate cortex, and stargazin correlates inversely with behavioral measures of emotionality. Stargazin modulates glutamate receptor signaling and plays a role in synaptic plasticity as a mechanism that mediates learning and memory considered functionally in terms of behavior change.

These findings suggest new strategies for research in translational psychiatry and behavioral neuroscience. In addition to investigating how the effects of severe stress damage behavior and brain (Charney and Manji, 2004; Duman, 2009; Nestler, 2014), we propose a complementary approach focused on learning to cope with stress and the process of building of resilience. Mechanisms of learning to cope with stress identified in animal models may provide preventive or therapeutic targets for interventions designed to treat stress disorders in humans. Pharmacological mimicry or facilitation of coping is a novel approach that shifts attention from neuropathology to consider the mechanisms that mediate coping as new targets for programs to build resilience. While not fully complete, this framework supersedes narrower views that regard stress as solely destructive and overlook its broader role in neurobiology, behavior, and human mental health.

# Animal Models for the Study of Human Disease

Edited by **P. Michael Conn**

Second Edition

Animal Models for the Study of Human Disease, second edition identifies important animal models and assesses the advantages and disadvantages of each model for the study of human disease. This new edition provides much needed information on model sharing, animal alternatives, animal ethics, access to databanks of models, and brings together common descriptions of models for busy researchers across biomedical and biological sciences.

Offering easily searchable advantages and disadvantages for each animal model, organized by disease topics, this resource aids researchers in finding the best animal model for research in human disease.

Key Features:

- Organized by disease orientation for ease of searchability

- Provides information on locating resources, animal alternatives, and animal ethics

- Covers a broad range of animal models used in research for human disease

- Contributed by leading experts across the globe

- Expanded coverage of diabetes and neurological diseases
