Dedication

I began working for Dr. P. Michael Conn in his research laboratory in September 1984, and had continued to work with him until his untimely passing in November 2016. Dr. Conn was a superb mentor, friend, and human being. He mentored numerous postdoctoral fellows, graduate students, and staff throughout his research career, and, in turn, many of the fellows and students have successful careers and hold Dr. Conn in very high regard.

Dr. Conn was known for his research involving the mechanisms of action of gonadotropin-releasing hormone in the pituitary, and therapeutic approaches that restore misfolded protein functioning. He authored and coauthored over 350 publications in his field and wrote and edited over 200 books, including texts in neurosciences, molecular biology, and endocrinology. He was recognized with a MERIT Award of the National Institutes of Health; the J.J. Abel Award of the American Society for Pharmacology and Experimental Therapeutics; the Weitzman, Oppenheimer, and Ingbar Awards of the Endocrine Society; the Miguel Aleman Prize; Mexico's National Science Medal; and the Stevenson Award of Canada. He was the recipient of the Oregon State Award for Discovery, the Media Award of the American College of Neuropsychopharmacology, and was named distinguished Alumnus of Baylor College of Medicine in 2012. Dr. Conn served as the editor of numerous professional journals and book series: *Endocrinology*, *Journal of Clinical Endocrinology and Metabolism*, *Endocrine*, *Methods*, *Progress in Molecular Biology and Translational Science*, and *Contemporary Endocrinology*. He was an advocate for the value of animal research and the dangers posed by animal extremism. He was the coauthor of *The Animal Research War* (2008) and wrote many opinion editorials for the public and academic community, which appeared in *The Washington Post*, *The LA Times*, *The Wall Street Journal*, the *Des Moines Register*, and elsewhere.

I am honored that I spent 32 years learning and working with Dr. Conn, a true friend.

Dr. P. Michael Conn will be sorely missed. Rest in peace my friend!

Preface

The key to use animal models is to select ones that have similarities to human tissues or disease states. Some models have the advantage that the reproductive, mitotic, development, or aging cycles are more rapid compared with those in humans, facilitating study; others are utilized because individual proteins may be studied in an advantageous way and have human homologs. Other organisms are facile to grow in laboratory settings, lend themselves to convenient analyses or have defined properties that are important.

The collection of systems represented in this volume is an effort to reflect the diversity and utility of models that are used to study human disease. That utility is based on the consideration that observations made in particular organisms provide insight into the workings of other, more complex systems. Even the cell cycle in the simple yeast cell has similarities to that in humans and regulation with similar proteins occurs.

We have included sections on ethics and animal care, and the ethics of research; both are important in our view.

Some models will have been omitted due to page limitations and we have encouraged the authors to use tables and figures to make comparisons of models so that observations not available in primary publications can become useful to the reader.

We thank the authors for the timely submission of chapters so that this volume could be published while it is still fresh and to the staff at Academic Press for shepherding the process of publication.

P. Michael Conn

Ethics in Biomedical Animal Research: The Key Role of the Investigator[a]

Jerrold Tannenbaum

University of California Davis, Davis, CA, United States

[a]Some content in this chapter has been reproduced from Tannenbaum, J., 2017. Ethics in the Use of Animal Models of Seizures and Epilepsy. In: Pitkänen, A., et al. (Eds). Models of Seizures and Epilepsy, Chapter 5, pp. 47-68.

1 NATURE AND SCOPE OF THE CHAPTER

This chapter presents an overview and explanation of ethical principles that are of crucial importance in the use of animal models for the study of human disease. The chapter is intended primarily for, and is written from the perspective of, scientists who conduct biomedical animal research. Like the other chapters in this volume, the discussion of animal research ethics presented here focuses on matters that are directly relevant to the design and implementation, by investigators, of animal research projects.

The chapter begins with a consideration of the nature of biomedical animal research ethics. The chapter reviews the reasons investigators should engage in ethical assessment of their work, and explains why they are uniquely qualified to do so. The discussion presents a number of fundamental principles of biomedical animal research ethics, and offers guidelines for putting these principles into practice. The chapter then highlights several ethical issues regarding which members of the biomedical research community have exhibited some lack of clarity or disagreement. The discussion concludes with recommendations for participation by investigators in ethical discussion of their work, and of biomedical animal research generally.

The chapter does not provide a detailed description of ethical theories that have been applied to biomedical animal research by academic philosophers or legal theorists. Nor does the chapter summarize the large (and growing) scholarly literature in animal research ethics. I suggest below that animal researchers become familiar with some of this literature. However, attempting to present comprehensive descriptions of ethical theories or the animal research ethics literature would preclude a discussion that is useful to investigators. Aside from the fact that many different arguments and conclusions have been offered by different thinkers, much of the animal research ethics literature focuses on a question that has *already* been answered by scientists who conduct biomedical animal research, and by society generally. As stated by one philosophical discussion, "at the heart of the wide-ranging and seemingly unending controversy over the use of animals in biomedical science, whether in basic or applied research, toxicity testing, drug production, or education, is one burning question: Are we humans ethically *justified* in such a use of animals, in general and in particular cases?" (Donnelly and Nolan, 1990, p. 8) Clearly, there would be no need for this chapter, or more importantly for biomedical animal research ethics, if there were no significant ethical issues relating to the use of animals in biomedical research. However, it is simply a fact that among the most fundamental ethical tenets of contemporary society is not just that humans *are* justified in using animals to understand and combat human disease, but that we are often ethically *obligated* to do so.

As used in the chapter, the term "investigator" refers to principal and coprincipal investigators, and also includes scientific colleagues who participate significantly in formulating the goals and design of an animal research project. The central theme of the chapter is that investigators—not animal care and use committees, attending veterinarians, or government agencies—play the primary role in ensuring the ethical conduct of biomedical animal research.

2 THE SUBJECT MATTER OF BIOMEDICAL ANIMAL RESEARCH ETHICS

Biomedical animal research ethics has three essential features in addition to its concern with the use of animals in scientific research.

First, biomedical animal research ethics involves issues that pertain to whether animals employed in research are

used and treated properly from an ethical standpoint in ways that accord with human ethical obligations *to the animals*. Many important ethical questions raised by uses of animals in biomedical research are not issues of biomedical animal research ethics. For example, potential employment of the CRISPR gene editing technique to produce animals with transplantable human organs has raised questions about whether the technique itself could lead to the editing of the human germ line and to the engineering of humans with supposedly desirable characteristics (Baltimore et al., 2015; Lanphier et al., 2015), or could result in unintended organisms that might harm public health or the environment (Caplan et al., 2015). These are not questions of biomedical animal research ethics because they do not ask whether the animals in such research are being used properly, from the standpoint of the interests of the animals themselves. In contrast, it would be a matter of biomedical animal research ethics to ask whether animals produced using CRISPR will experience problematic pain or distress: during research procedures, as a result of their genetic make up, or because of how they might be bred and raised to provide human organs or tissues (Combes and Balls, 2014; Hyun et al., 2007).

Second, biomedical animal research ethics addresses questions that pertain to animals employed in research intended to address *medical* issues in humans or animals. Biomedical animal research ethics is a subset or branch of animal research ethics, which deals with ethical obligations to animals used in all kinds of scientific animal research, including, for example, use of animals to test the safety of household products, chemicals used in industrial processes, and cosmetics; research intended to understand how various species can be preserved in the wild; and agricultural experiments aimed at breeding animals that produce nutritious and palatable food. These uses of animals sometimes involve facts, ethical issues, and ethical principles that are significantly different from those that pertain to using animal models to study human disease. Biomedical animal research ethics considers research directed at improving animal health because animals are sometimes intended beneficiaries of animal research (Quimby, 1998).

Third, as generally defined, biomedical animal research ethics (like animal research ethics) relates to the use and treatment of *live* animals that are *sentient*, in the sense of being capable of experiencing unpleasant or pleasant sensations or feelings. Questions in biomedical animal research ethics can be asked regarding whether live animals should be killed. For example, some people believe that certain species (e.g., chimpanzees) should never be killed in research, and it can be asked whether it is morally wrong (and not just a waste of resources) to euthanize many more mice for their tissues than is required for a given study. These are questions in biomedical animal research ethics because they ask whether there is an ethical obligation to certain animals to allow them to live.

This chapter considers issues in biomedical animal research ethics relating to the proper treatment of animals employed in scientific research that aims at discovering methods of preventing, alleviating, or curing human disease.

3 WHY INVESTIGATORS SHOULD CARE ABOUT BIOMEDICAL ANIMAL RESEARCH ETHICS

Some investigators may be suspicious of advice (sometimes offered by nonscientists) that they should devote valuable time and energy to ethical assessment of their research. Biomedical research is science, and science deals with objectively verifiable facts and hypotheses. In contrast, ethics is a matter of value judgments, about which there can be disagreement, even when there is an agreement about the facts. For example, some people believe that it is unethical to use animals in research, even when such research results in the prevention or cure of serious disease (Regan, 2004). It is difficult enough to conduct productive scientific research, the results of which *are* subject to objective empirical verification. Leave us alone to do our experiments, some investigators might say, and let others worry about demonstrating that what we do is ethical.

3.1 Investigators are Already Committed to High Ethical Standards

One reason investigators should engage in ethical assessment of their work is that they have *already* committed themselves to high ethical standards in their use of animals. Biomedical animal research is founded on an enormously important ethical principle (which is discussed in detail later in the chapter): *It is among the most noble and imperative of human endeavors to employ scientific research to prevent, alleviate, and cure the pain, suffering, distress, fear, anxiety, disability, infirmity, and death associated with human disease.* The decision to use animals to fight disease is motivated by this high ethical ideal. Having already committed themselves to engaging in one of the most virtuous endeavors known to humankind, investigators who use animal models are logically and unavoidably committed to ethical behavior in all aspects of their work, including their use and treatment of animals.

3.2 Ethical Treatment of Animals is Required by Law

Perhaps the most immediate and direct reason investigators should want to adhere to high ethical standards is that they must follow the laws of their respective countries relating to animal research. Many of these laws

impose straightforwardly *ethical* requirements. Failure to comply with these requirements can result in disapproval of a proposed animal research project by an institutional animal care and use committee (IACUC) or in some countries a government official or licensing authority; disciplinary action, such as public censure or a fine; or in extreme cases termination of research (APHIS, 2016a; Home Office, 2014; NIH, 2015a, Part II §8.5).

3.2.1 General Commitment to Ethical Behavior

Laws in many countries assert a general commitment to ethics in the use and care of research animals. For example, the 2010 *European Directive on the Protection of Animals Used for Scientific Purposes* (*EU Directive*), which represents the official policies of the European Parliament and the Council of the European Union, states that "(a)nimals have an intrinsic value which must be respected" (European Union, 2010, Preamble para. 12). In the United States, the National Resources Council *Guide for the Care and Use of Laboratory Animals* (the *Guide*) (NRC, 2011) must be followed in all research on live vertebrates that is funded by one of the institutes or centers of the National Institutes of Health (NIH) [HREA, 1985, §289d(c)]. In a section titled "Ethics and Animal Use," the *Guide* reminds investigators that they do not have a legal right to conduct animal research. The use of animals is a *privilege* afforded by government, which it can withdraw. As the *Guide* observes, this privilege is conditioned on the use and care of research animals in accordance with ethical standards, some of which exceed those specifically required by law:

> The decision to use animals in research requires critical thought, judgment, and analysis. Using animals in research is a privilege granted by society to the research community with the expectation that such use will provide either significant new knowledge or lead to improvement in human and/or animal well-being. (references omitted). It is a trust that mandates responsible and humane care and use of these animals. ... Ethical considerations discussed here and in other sections of the *Guide* should serve as a starting point; readers are encouraged to go beyond these provisions. NRC (2011, p. 4)

3.2.2 Legal Requirements Reflecting General or Specific Ethical Principles

Many laws, regulations, and government agency policies that pertain to animal research state explicitly, or reflect, very general ethical ideals or requirements. Underlying the US Animal Welfare Act (AWA, 2013), for example, is the general principle of biomedical animal research ethics that investigators must minimize pain or distress experienced by animal subjects. The *EU Directive* requires that any harm caused to animals in a research project must be justified by expected benefits of the research [European Union, 2010, Art. 38 para. 2(d)]. A well-known

set of nine general ethical principles for biomedical animal research (some of which are included in substance in the fundamental ethical principles presented later in the chapter) is enunciated in the *US Government Principles for the Utilization and Care of Vertebrate Animals Used in Testing, Research, and Training* (*US Principles*) (OLAW, 2015b, pp. 4–5), which must be followed by investigators conducting research governed by the Health Research Extension Act of 1985 (HREA) and its incorporated *Public Health Service Policy on Humane Care and Use of Laboratory Animals* (*PHS Policy*) (OLAW, 2015b, para. I). Certain laws state more specific ethical rules, such as the requirement of the US AWA [AWA, 2013, §2143(a)(3)(B)] and the AWA Regulations [AWAR, 2015, §2.31(d)(1)(ii)] that investigators consider alternatives to procedures likely to produce pain or distress in research animals. Some laws state even more specific ethical requirements, such as the requirement of the AWA that, unless scientifically necessary, animals should not be subjected to multiple major invasive procedures [AWA, 2013, §2143(a)(3)(D)].

3.3 Ethical Treatment of Animals Promotes Sound Scientific Results

As is discussed in this chapter, among the central principles of biomedical animal research ethics are that animals should not experience more pain or distress than necessary for the scientific aims of an experiment, and that they should be provided housing environments and general care that are appropriate for their species and contribute (consistent with experimental aims) to their health and comfort. Studies have long established that unnecessary animal pain or distress during experiments can affect and invalidate experimental results (Russell and Burch, 1959), and that removal of stressors from housing environments can improve the validity and repeatability of data (Garner, 2005; Weed and Raber, 2005).

3.4 Ethical Treatment of Animals is Required by Funding Bodies

Government agencies that fund animal biomedical research require adherence to ethical standards as a condition of support. In the United States, applicants to the NIH must certify that projects will meet the ethical requirements of the Vertebrate Animals Section of the grant application (OLAW, 2016b), which includes the pain and distress minimization principle (discussed below) and justification of the use of animals and the proposed species. Moreover, no NIH-funded animal research may begin, or continue, without determination by the IACUC that the project complies with the ethical standards of the *PHS Policy* (OLAW, 2015b, para. II), and of the *Guide* [OLAW, 2015b, para. IV(A)(1)]. Animal research funded

by the National Science Foundation must also meet the standards applied by the *PHS Policy* to NIH-funded animal research (OLAW, 2015a).

Private funding bodies also require grant recipients to meet various ethical standards. For example, the American Cancer Society (ACS, 2016, p. 6), the American Epilepsy Society (AES, 2016), and the American Heart Association (AHA, 1985) require applicants to certify that animal research projects have received approval from their IACUC, which in the United States includes a determination that all legally required ethical standards will be followed. These organizations also specifically require adherence to the *PHS Policy* and its ethical standards. In the United Kingdom, major funding organizations, including the Association of Medical Research Charities (AMRC, 2015), the Biotechnology and Biological Sciences Science Council (BBSRC, 2013), the Medical Research Council (MRC, 2016), and the Wellcome Trust (2016) require that animal research be conducted only when no feasible nonanimal alternative exists; that applicants employ the "3Rs" of replacement, reduction, and refinement (discussed below), and that appropriate Home Office licenses and certificates are followed. These organizations also require grantees to follow the ARRIVE Guidelines of the UK National Centre for the Replacement Refinement & Reduction of Animals in Research (NC3Rs, 2010), which are intended to assist investigators in preparing manuscripts submitted for publication and are considered below.

3.5 Ethical Treatment of Animals is Required by Peer-Reviewed Journals

Virtually all journals that publish reports of animal research require that authors state, when submitting manuscripts or sometimes in the manuscripts themselves, that they have adhered to specified ethical standards. These journals always include in such standards, observance of all applicable laws and approval of the research by the investigator's IACUC or other legally required review body or government official. As noted earlier, these laws contain fundamental principles of biomedical animal research ethics. Some journals include ethical standards adherence to which might not be legally required in given cases. For example, although the HREA requires that NIH-funded projects follow the ethical standards of the *PHS Principles* and the *Guide*, many journals require adherence to the ethical standards in these documents for all research on live vertebrates, however funded. Some journals mention specific ethical requirements already implied by the general requirement of following all laws and government agency policies. Such journal requirements typically include that the minimum number of animals was

used (e.g., Journal of Neuroscience; PLoS One) and that animal pain, suffering, or distress were prevented or minimized (e.g., Neuroscience; Neuroscience Research; PLoS One). Some journals require adherence to the ethical standards of the professional association under whose auspices these journals are edited. The *Journal of Neuroscience*, for example, requires that all reported animal experimentation be conducted in accordance with the Society for Neuroscience *Policies on the Use of Animals in Neuroscience Research* (SfN, 2016), which mandate observance of the *PHS Policy* and the *Guide* for all experiments on live vertebrate animals.

3.5.1 The ARRIVE Guidelines

The ARRIVE Guidelines (NC3Rs, 2010), mentioned earlier, contain a checklist of 20 directives for the preparation of manuscripts reporting animal research projects. The Guidelines are widely regarded as an effective vehicle not just for promoting standardized, transparent descriptions of animal use that can be evaluated by the scientific community, but also for facilitating the use of animals in ethically as well as scientifically sound ways (du Sert, 2011; Eisen et al., 2014; Reynolds et al., 2012; Rice et al., 2013.) Among the directives of the Guidelines are that the investigator "(e)xplain how and why the animal species and model being used can address the scientific objectives and, where appropriate, the study's relevance to human biology" (NC3Rs, 2010, para. 3b); "(p)rovide details of the animals used, including species, strain, sex, developmental stage (e.g., mean or median age plus age range) and weight (e.g., mean or median weight plus weight range)" (para. 8a); "(p)rovide details of housing (type of facility, e.g., specific pathogen free (SPF); type of cage or housing; bedding material; number of cage companions; tank shape and material etc. for fish)" (para. 9a); "(e)xplain how the number of animals was arrived at. Provide details of any sample size calculation used." (para. 10b); "(p)rovide details of the statistical methods used for each analysis" (para. 13a); "(d)escribe any implications of your experimental methods or findings for the replacement, refinement or reduction (the 3Rs) of the use of animals in research" (para. 18c); and "(c)omment on whether, and how, the findings of this study are likely to translate to other species or systems, including any relevance to human biology" (para. 19).

At the time of this writing, more than 600 journals have recommended that authors follow the ARRIVE Guidelines (Cressey, 2016). However, relatively few journals require compliance, and one study found that few investigators followed the Guidelines even when encouraged to do so (Baker et al., 2014). In light of the support of the ARRIVE Guidelines by journal editors, it seems inevitable that all high-impact journals eventually will make compliance mandatory. It is, therefore,

at the very least prudent for investigators to become used to incorporating the Guidelines into their experiments and manuscript preparation. More importantly, following the ARRIVE Guidelines will assist investigators in conducting scientifically and ethically sound experimentation.

3.6 Ethical Treatment of Animals is Essential for Public Support

A very important reason investigators should be sensitive to ethical aspects of their work is that without public support most biomedical animal research would cease. The great majority of this research is funded by government agencies (FASEB, 2016a), which receive the money they disburse from the public. Moreover, underlying government acceptance and regulation of animal research is the general view of society that biomedical animal research is valuable and is conducted ethically. Were the public to reject this view, it would likely demand an end to government funding, and perhaps to biomedical animal research altogether.

Public approval of biomedical animal research cannot be taken for granted and in some countries may be declining. Polls conducted by the Pew Research Center (2015, p. 141) found that in 2009, 52% of US adults "favored," and 43% "opposed," "the use of animals in scientific research." By 2014, those in favor dropped to 47%, and those opposed rose to 50%. The annual Gallup Poll on moral attitudes of Americans (Gallup, 2016) found that in 2016, 53% of the public believed that "medical testing on animals" is "morally acceptable" and 41% that it is "morally wrong." In 2006, the percentages were 61 and 32%, respectively.

Governments worldwide have recognized that public support for animal research depends upon the public's knowledge that experimental animals are treated in accordance with high ethical standards. For example, in enacting the 1985 amendments to the AWA (2013), the US Congress declared (Public Law 99-198, 1985) that "measures which help meet the public concern for laboratory animal care and treatment are important in assuring that research will continue to progress." In passing the HREA (1985) Congress stated (House Conference Report, 1985, p. 747) that although humane standards of animal care "will change in the future as science advances ... the consultation inherent in the review of the care and treatment of animals by animal care committees is essential. Within such a framework, the public can have confidence that the proper sensitivity, whatever the sensitivity may be, to the care and treatment of animals will occur." The *EU Directive* recognizes the importance of "the ethical concerns of the general public as regards the use of animals in procedures" (European Union, 2010, Preamble para. 12).

3.7 Ethical Treatment of Animals is the Right Thing to Do

Finally, and surely most importantly, investigators should conduct ethical animal research because this is simply the right thing to do. If animals are to be used to understand human disease, they should always be used for ethically sound reasons and in ethically appropriate ways. We owe this to them, as well as to the humans who benefit from their use in research and who should rest assured that this use is ethically appropriate.

4 ASPECTS OF ANIMAL USE AND CARE RELEVANT TO BIOMEDICAL ANIMAL RESEARCH ETHICS

Most issues in biomedical animal research ethics pertain to the conduct of individual animal research projects, that is, to how experiments or research procedures are designed and executed. Ethical questions can arise in all stages of a project, beginning with whether there is sufficient rationale for the use of animals or a particular species, to whether the project treats the animals appropriately during experimental procedures, to when and how the animals' lives may or should be ended, to what should be done with animals that survive experimentation. Although such questions typically arise in the context of particular projects, biomedical animal research ethics sometimes address them generally. Thus, one can ask when certain kinds of physical restraint might be unacceptable for certain species, or when it is ethically acceptable to withhold pain relief from animals (Tannenbaum, 1999). Answers or general approaches to such questions may then sometimes be applied in particular animal research projects.

Biomedical animal research ethics is also concerned with the treatment of animals when they are not undergoing research procedures. Many, perhaps most, research animals spend the majority of their time housed in facility animal quarters, before or after procedures are conducted on them. To be sure, many animals are never off-study, if, for example, effects on their physiology or behavior while in the animal quarters are of direct interest in the research, or if what they are fed or how they are housed is part of the study. However, even these animals can be affected by conditions of housing and care that are not part of the research. Ethical issues relating to housing and general care of animals include whether the size, constituent materials, and physical layout of cages or other enclosures are sufficient to meet certain behavioral needs, whether animals receive adequate care from veterinarians and support staff to address health or welfare problems,

and whether and to what extent research facilities are ethically obligated to provide enriched housing environments.

Biomedical animal research ethics also deals with general issues that pertain to whether it is ethically acceptable to use certain kinds of animals in any, or in various kinds of, research. One such issue is whether chimpanzees may be used in biomedical research (IOM, 2011). Another is whether researchers are ethically obligated to use purpose-bred cats or dogs rather than random-source former pets obtainable from shelters or commercial dealers (NRC, 2009b). These are questions in animal research ethics because they ask whether using such animals in research or in certain kinds of research would accord with investigators' or society's ethical obligations to these animals.

5 USE OF PRIVATELY OWNED ANIMALS IN BIOMEDICAL RESEARCH

It is helpful at this stage of the discussion to consider two general aspects of biomedical animal research: use of privately owned animals, and the nature of basic animal research.

Presently, the vast majority of biomedical animal research is conducted in facilities on animals owned by these facilities or investigators. Recently there has been an increase in the use of privately owned animals, primarily pet cats and dogs, that aims at understanding medical problems not just of these species, but also of humans (Alvarez, 2014; Christopher, 2015a,b; Khanna et al., 2009; Kol et al., 2015; Lairmore and Khanna, 2014). Among the advantages of this research are said to be that certain diseases are already present in many pets and thus need not be induced in laboratories in healthy animals; that certain kinds of ailments of humans and pets are sometimes easier to study in pets; and that what can be learned about certain kinds of diseases in privately owned animals can shed light on identical or virtually identical human ailments (Kol et al., 2015).

Biomedical research on pets is subject to some of the same ethical requirements explored in this chapter, for example, the pain and distress and harm minimization principles. However, there are distinctive ethical issues raised by research on such animals. These issues include how investigators should obtain informed consent from pet owners who may be more interested in helping their animals than contributing to soundly designed experiments; whether and when investigators may enroll an animal in an experiment if there already exists an effective treatment for the animal's condition, or a treatment the success of which is predictably at least as good as that of the experimental procedure; whether a beloved pet should be kept on an experimental treatment that is not working or is not working as well as a treatment other animals in a study are receiving; and whether owners are ethically entitled to a portion of profits that might result from the development of drugs or techniques based on use of their animals.

Also central in the ethical assessment of research projects using privately owned animals is the issue of when these animals are good experimental subjects from a *scientific* standpoint. As is discussed later in this chapter, an important rule of biomedical animal research ethics is that sound science contributes to the ethical use of animals and poor science is likely to cause ethical problems. For example, as will be noted below, if in an experiment too few animals are used to obtain valid results, the use of any of the animals will be pointless at best and at worst could cause pain or distress that is unjustified. There are surely often scientific advantages in employing laboratory animals, such as the ability to use a sufficient number of animals with characteristics (including genetic make-up or disease condition) tailored to an experiment; to perform all scientifically appropriate procedures (including production of a precise disease state and use of controls); and to euthanize animals at scientifically appropriate times.

As of this writing, a few published articles have addressed some of the ethical issues raised by use of privately owned animals in research also aimed at understanding human disease (Baneux et al., 2014; Habing and Kaneene, 2011; Kol et al., 2015, p. 6.) However, there is not yet anything approaching a developed literature on these issues. One reason may be the fact that, at least in the United States, laws governing biomedical animal research do not apply to experiments conducted by veterinary clinicians on privately owned animals. As is discussed earlier, legal requirements relating to animal research tend to express fundamental, widely accepted ethical principles regarding how animals should be treated. In the absence of laws relating to research on privately owned animals, the scientific community may lack strong motivation to address all the ethical issues this kind of research can raise.

Proponents of the use of privately owned animals are hopeful that much of this work will produce important knowledge that can lead directly to clinical trials in humans, and that will produce important advances in understanding human diseases (Kol et al., 2015). Time will tell whether this will be so, and whether ethical questions raised by such research will receive sufficient attention. The remainder of this chapter considers ethical issues that relate to animal experimentation conducted in laboratories, which currently constitutes the great preponderance of biomedical animal research.

6 THE NATURE OF BASIC ANIMAL RESEARCH

Many investigators who use animals in biomedical research describe their research as "basic." It is important that they are clear about what they mean by this term. There are two different senses of "basic" research commonly employed in the scientific literature, which raise very different ethical issues.

6.1 "Basic" Research as the Search for Knowledge for its Own Sake

Historically the first, and possibly still the predominant, definition characterizes basic research as "directed towards increase of knowledge … where the primary aim of the investigator is a fuller knowledge or understanding of the subject under study, rather than a practical application thereof" (NSF, 1959, p. 368); as "uncommitted research, prompted by disinterested curiosity, and aimed primarily at the extension of the boundaries of knowledge" (American Council on Education, 1954, p. 49); as aimed at "the extension of knowledge for its own sake" (OECD, 1966, p. 24); or as motivated by "intellectual curiosity (where) the motivating force is not utilitarian goals, but a search for a deeper understanding of the universe and of the phenomena within it" (Seaborg, 1963, p. 1383). I shall call this the *subjective* sense of "basic" research because it identifies investigators' *motivation* as the key factor in whether their research is so classified.

There is a long-standing and sizeable body of thought that rejects intellectual curiosity and knowledge for its own sake as acceptable reasons for animal experimentation, and certainly for causing experimental animals any pain, suffering, or distress (Bowd, 1980; Midgley, 1981; Rollin, 1992, p. 170; Ryder, 1971). Although these thinkers accept knowledge for its own sake as a justification for scientific inquiry, and accept some curiosity-driven research that does not cause animals pain (e.g., purely observational studies of animals in natural habitats), they argue that it is profoundly unethical to cause an animal any pain or distress so that scientists can obtain and enjoy knowledge for its own sake. Louis Goldman, who for many years led the Royal Society for the Prevention of Cruelty to Animals (RSPCA), expressed this view as follows.

> Experiments which cause pain and suffering demand special justification. That special justification cannot merely be that scientists are entitled to do anything that might increase the sum total of knowledge or bring about a medical advance in the remote future. There has to be a direct benefit, a good and immediate relevant reason—one which most people would accept as adequate.
>
> I believe that most people would accept the use of animals to test a new vaccine or a new drug before it is given to man.

> I believe that most people accept that new surgical procedures like transplant operations should first be tested on animals. … (But) some scientific problems are not really worth solving. We don't really need proof that inhaling a mixture of air and alcohol produces a state of addiction in mice. Nor do we need proof that animals can be trained to avoid a part of a cage where they received electric shocks to their feet. The link between the experiment and a possible benefit to mankind is so remote as to be almost invisible. Goldman (1979, pp. 191–2).

This viewpoint is, I would suggest, widespread. Many people are unlikely to accept experiments that cause animals pain or distress in order to discover something that is solely of intellectual interest, and that does not offer *some* possibility of ultimately benefiting humankind.

Appreciating the general hostility to curiosity-driven research that can cause animals pain or distress, some defenders of such research argue that it will *eventually* benefit human health (Miller, 1985; Morrison, 2009; Thomas, 1974). According to sleep investigator Adrian Morrison, for example,

> the basic researcher seeks to understand a biological phenomenon for the sake of understanding it, not in an attempt to solve a particular problem. … Nonetheless, basic research is the very first step toward solving a clinical problem, often without a specific disease in mind, because so many bits of information from varied and often improbable sources will ultimately come together to provide a solution to a diseased condition. In other words, good and successful basic research will usually end up solving a problem that the researcher did not originally intend to solve. Morrison (2009, p. 69)

Morrison and others find support for this view in the famous study of physiologists Julius Comroe and Robert Dripps (1976), which concluded that many important clinical advances treating cardiac and pulmonary disease resulted from animal experiments in which investigators had no interest in discovering knowledge with potential clinical relevance. However, this study was retrospective, and was able to identify successful experiments that did lead to clinical advances. The claim that all or most curiosity-driven animal research will in the future benefit human health is not supported by the Comroe and Dripps (1976) study, and seems intuitively false. There is surely no connection *simply* between *any* researcher's *interest* in certain biological phenomena and any probability that the research will lead to health benefits. A number of recent literature surveys has shown that, in fact, many animal experiments (whether or not classified as "basic") have not yet translated into clinical applications (Hackam and Redelmeier, 2006; Henderson et al., 2013; van der Worp et al., 2010). It is important to note that the studies just cited do not claim, or show, that animal research is not necessary or useful in combating human disease. Rather, the authors of the studies call for better understanding of aspects

of animal projects that might increase their probability of discovering effective clinical applications. One of the primary aims of the new and rapidly expanding science of translational medicine is not only finding potential clinical applications of completed animal research, but identifying kinds of animal research that might lead to clinical applications (Reed et al., 2012; Zerhouni, 2007; Zucker, 2009). This new science recognizes, as have investigators in a number of fields of biomedical research (Galanopoulou et al., 2013), that the record of translation of animal studies has sometimes been disappointing and that it is no longer acceptable to support animal experiments on the grounds that one cannot predict what discoveries will eventually contribute to clinical applications.

6.2 "Basic" Research as the Search for Fundamental, Underlying Mechanisms, and Causes

There is another sense of the term "basic" research employed by scientists that does not tie basic animal research, by definition, to the search for knowledge for its own sake. "Basic" research in this second sense is sometimes referred to as "fundamental" research, because it seeks to understand foundational, underlying mechanisms or causes that it is hoped might eventually explain much, if not all, of a wide range of phenomena. So defined, basic research typically does not expect to quickly make discoveries with specific relevance to practical results, precisely because the research seeks to find causes and explanations of matters that are not yet well understood. It is sometimes said that basic research in this sense seeks to discover knowledge that is widely applicable to multiple scientific fields, or is so significant and central to a specific field that it might contribute to a changed and greatly improved way of looking at that field (Calvert, 2006; Kidd, 1959; Reagan, 1967). I shall call this the *objective* sense of "basic" research because it identifies features of research itself and not investigators' motivation as the key factor in whether research is classified as basic. An animal experiment that constitutes basic research in the objective sense can have as *part* of its motivation the discovery of knowledge for its own sake, but this is not what makes such research basic. Basic research in the objective sense can—and in the biomedical sciences almost always does—aim at fighting disease and improving health. It is the objective sense of "basic" research, coupled with this practical aim, that the NIH employs when it states (NIH, 2015b) that its "mission is to seek fundamental knowledge about the nature and behavior of living systems and the application of that knowledge to enhance health, lengthen life, and reduce illness and disability."

6.3 What Investigators Mean by "Basic" Animal Research

Some investigators who characterize their animal research as "basic" do not indicate clearly what they mean by the term. Scientists who conduct biomedical animal research almost always have as their ultimate goal understanding and conquering human or animal disease. Therefore, if asked which definition of the term "basic" they employ, most investigators would likely endorse the objective sense. However, like Morrison in the passage quoted earlier, some animal researchers who comment about the nature of basic animal research do appear to employ the subjective sense of "basic research," although they go on to express confidence that curiosity-driven animal research will eventually lead to clinical advances. Some scientists who speak about the nature of basic animal research seem to want to employ both the subjective and the conflicting objective sense of the term. For example, the eminent epilepsy animal researcher Philip Schwartzkroin appears to adopt the objective definition when he writes that "technological invention drives modern science, and the findings from 'basic' laboratory (and clinical) research drive technical innovation. … It is *often* the technological advance that is the ultimate goal of even the most basic forms of research" (Schwartzkroin, 2012, pp. 2–3, author's italics). However, he also asserts that the primary if not the sole motivation for many epilepsy researchers who use animals is intellectual curiosity. He states that "many young researchers are attracted to epilepsy research *simply* because the problems are intellectually fascinating, the phenomena are dramatic, and the potential experimental approaches allow/encourage the use of a broad array of technical weaponry" (p. 4, author's italics). He also writes that "(o)btaining knowledge for its own sake is an old and sacred pursuit … Because of the uncertainty about what insights might become important in the future, because what seems irrelevant or unusable at one time might provide the basis for important future developments, 'basic research' without specific practical rationale should be encouraged and supported" (p. 3).

6.4 Recommendations

The view that it is wrong to cause animals pain, distress, or other severe harms in experiments that are motivated solely or primarily by curiosity does not imply that it is wrong for investigators who conduct basic animal research in the objective sense to enjoy solving intellectual problems, or to believe that biological knowledge is worth obtaining for its own sake. Nor, for reasons discussed below, do all ethically conducted basic animal research projects require a demonstration of immediate or likely clinical applications. However, in

light of the hostility that many have to animal experimentation that causes animals pain or distress and is motivated by the desire to discover knowledge for its own sake, several things seem clear. First, investigators should not express or endorse the subjective definition of "basic" animal research out of a mistaken assumption that basic research must be defined as motivated by the search for knowledge for its own sake. Second, in communicating with members of the public, funding agencies, government regulators, and IACUCs, investigators should make clear that they are using the objective sense of "basic" research. Finally, even if intellectual curiosity comprises part of their motivation for using animals in basic research, investigators should indicate clearly that the primary and ultimate aim of their research is, as the NIH characterizes its mission in funding fundamental research, "to enhance health, lengthen life, and reduce illness and disability" NIH (2015b). This statement surely reflects how the vast majority of biomedical animal researchers who conduct basic studies view their work.

7 WHY INVESTIGATORS PLAY THE KEY ROLE IN ENSURING THE ETHICAL CONDUCT OF ANIMAL RESEARCH PROJECTS

Some investigators may be reluctant to become involved in ethical discussion of their work, or of biomedical animal research generally because their distinctive professional expertise relates not to ethical theory but to scientific investigation. In fact, animal researchers are uniquely qualified and situated to engage in ethical evaluation of biomedical animal research.

7.1 The Nature of Principles of Biomedical Animal Research Ethics

A helpful starting point for investigators who may think that their scientific background does not qualify them to engage in ethical assessment of animal research, is to consider the nature of fundamental ethical principles that apply to biomedical animal research. Most such principles are general and require *factual* information to be applied to actual circumstances. For example, as discussed later, one of the central principles of animal research ethics (which I call "the pain and distress minimization principle") is that *an animal research project should cause no more pain or distress to the animals than is necessary to achieve the scientific goals of the research.* This principle sometimes requires investigators to ask questions about procedures used in experiments, and may sometimes necessitate changes in project design and implementation. However, the principle cannot by itself generate any specific conclusions or courses of action without the

asking of questions that are empirical in nature and the consideration of which involves scientific knowledge and expertise.

For example, one issue to which the pain and distress minimization principle applies is whether in a given experiment, it is ethically acceptable to allow animals to die on their own, in pain or distress, or whether they should be euthanized at some point prior to death. What the pain and distress minimization principle requires when this question is asked will depend on a number of facts about the experiment, which can include the following: (1) what the project aims to discover; (2) whether the animal model used in the study is a good model from a scientific standpoint to achieve the project's goals; (3) whether the study correctly employs the model; (4) whether the model, or the results sought in the study, require death as the endpoint or can allow the euthanasia of at least some of the animals; and (5) how much pain or distress the animals actually experience. These are all empirical questions, consideration of which does not involve value judgments.

7.2 The Need for Scientific Expertise in Applying General Ethical Principles

The pain and distress minimization principle illustrates why animal researchers should not be reluctant to consider ethical issues relating to their work. First, the principle is (like the other fundamental ethical rules presented in this chapter) immediately and intuitively compelling. Although more can be said about the ethical foundations of the principle, a great deal of theoretical discussion is not required to demonstrate its persuasiveness. Investigators should be entirely comfortable endorsing and applying it. Second, the pain and distress minimization principle cannot be applied correctly to an animal research project without knowledge and expertise possessed uniquely by *scientists* who are familiar with the kinds of questions asked by the project; with the applicability to these questions of various kinds of experiments or research techniques; with the nature and effects of possible ways of using the animals on what they experience; and with techniques for preventing or minimizing their pain or distress. These are all matters of science and not ethical theory.

7.3 The Investigator as Captain of the Experimental Ship

The primary reason investigators must play the *central* role in ensuring the ethical conduct of animal research projects is that they play the central role in determining project goals, and in designing and implementing their experiments to achieve these goals.

7.3.1 Primacy of Project Goals

One crucial reason the investigator plays the key role in ensuring that an animal experiment is ethically appropriate is that the investigator formulates the aim or aims of the experiment. Even if a government official or funding agency, for example, is authorized to, or might convince, an investigator to modify a project's goals for scientific or ethical reasons, it is the investigator who must accept these goals if the project is to be conducted. Likewise, animal housing and care, even if modified by an IACUC or facility veterinarian for welfare reasons, must be consistent with the investigator's experimental goals.

Intuitively, it is clear that the goals of an animal research project must determine how the animals are used. For the primary purpose of an animal experiment aimed at understanding a human disease is not to use or treat animals in certain ways, but to understand the disease. Animals used in research projects must be treated ethically, and as is discussed below, it can be possible that a research project ought not to be done because how it treats the animals is not justified by the value of the project. Nevertheless, how animals are used will always remain subservient to, and be controlled by, project goals.

W.M.S. Russell and R.L. Burch, who introduced the concepts of the "3Rs," (discussed below) recognized the primacy of project goals in the ethical design and implementation of biomedical animal experiments. As they stated in their original discussion of the 3Rs, the "central problem" faced by investigators is how to minimize animal pain and distress "without prejudice to scientific and medical aims" (Russell and Burch, 1959, p. 14). This means that the scientific aims of an experiment must determine whether, to what extent, and how pain or distress can be minimized. Put another way, an investigator must *first* determine the aims of an experiment, support these aims on scientific grounds, and *then*, consistent with these aims, ask whether pain or distress can be eliminated or lessened. Put yet another way, elimination or lessening of pain or distress, or other harms to animals, is not an independent goal that is to be balanced *against* the aims of an experiment, so that the aim of a project should be changed if there is another aim that might cause less animal pain or distress. If live animals must be used in an experiment that is justifiable scientifically, they should be used. If they must be caused some pain, distress, or other harm it will be appropriate to cause such harm, provided the harm is minimized consistent with project aims and this minimized harm is ethically justified.

The formulation of scientifically sound project goals, before minimization of pain or distress is implemented, is both a scientific and ethical requirement. It is a scientific requirement because changing or compromising project aims to lessen animal pain or distress could produce results that are not scientifically valuable, or not as valuable as those that would be produced by pursuing the original aims. It is an ethical requirement because causing animals pain or distress in a poorly designed experiment that likely will not produce good scientific results is causing unnecessary and unjustifiable pain or distress, and even when there is no pain or distress can involve a waste of resources and a pointless ending of animals' lives.

Russell and Burch's insistence on the primacy of experimental aims is reflected in the requirement of the US AWA that each "principal investigator considers alternatives to any procedure likely to produce pain to or distress in an experimental animal" [AWA, 2013, §2143(a)(3)(B)]. To enforce this provision, the US Department of Agriculture (USDA) has adopted the following policy that defines and sets forth requirements for investigators regarding consideration of such "alternatives."

> Alternatives or alternative methods, as first described by Russell and Burch in 1959, are generally regarded as those that incorporate some aspect of replacement, reduction, or refinement of animal use in pursuit of the minimization of animal pain and distress *consistent with the goals of the research*. These include methods that use non-animal systems or less sentient animal species to partially or fully replace animals (for example, the use of an in vitro or insect model to replace a mammalian model), methods that reduce the number of animals to the minimum required to obtain scientifically valid data, and methods that refine animal use by lessening or eliminating pain or distress and, thereby, enhancing animal well-being (for example, the use of appropriate anesthetic drugs). However, *methods that do not allow the attainment of the goals of the research are not, by definition, alternatives.* USDA (2016, Policy #12, p. 12.1, author's italics)

7.3.2 Design and Implementation of Experimental Procedures

It is also the investigator who designs and implements the scientific procedures employed to fulfill project aims. If an IACUC, review body, or government official is authorized to demand a modification in experimental procedures, the investigator must be satisfied that changes will not compromise the scientific goals of the project. It is also the investigator and the investigator's research staff who perform experimental procedures and are, therefore, responsible for ensuring that all scientifically and ethically appropriate procedures are carried out.

7.3.3 The Importance of Sound Science in Ensuring Ethical Animal Experimentation

There is another, and critically important, reason investigators play the key role in ensuring that their projects are conducted ethically. As will be discussed in detail later, the central ethical question raised by any biomedical animal experiment is whether what is done with or to the animals is justified by the *value* of the experiment.

For reasons explained later in the chapter, the key task in ensuring that an animal research project has sufficient value to justify its use of animals is typically designing and implementing a project that is *scientifically* sound. It is the investigator, in setting project goals and designing and implementing the experiment to achieve these goals, who ultimately determines its level of scientific soundness.

7.4 The Role of Review Committees and Government Officials in Assessing the Ethical Appropriateness of Animal Experiments

In some countries, local or national review committees or government officials are legally authorized to assess the ethical appropriateness of biomedical animal research projects, and can deny investigators permission to conduct an experiment that in their view does not meet certain ethical requirements. In the European Union, one foundation of such legal authority is the provision of the 2010 *EU Directive* that "the project evaluation" must include "a harm-benefit analysis of the project, to assess whether the harm to the animals in terms of suffering, pain and distress is justified by the expected outcome taking into account ethical considerations, and may ultimately benefit human beings, animals or the environment" [European Union, 2010, Art. 38 para. 2(d)]. The UK ASPA requires that the Home Office official who must license a procedure "carry out a harm-benefit analysis of the programme of work to assess whether the harm that would be caused to protected animals in terms of suffering, pain and distress is justified by the expected outcome, taking into account ethical considerations and the expected benefit to human beings, animals or the environment" [ASPA, 1986, §5B(3)(d)].

7.4.1 Ethical Review in the United States

In recent years there appears to have been increasing acceptance in the United States of the view that IACUCs are legally authorized, and indeed required, to engage in ethical assessment of proposed animal research projects. Some commentators believe that language in the AWA and the HREA requiring the humane or proper treatment of animals authorizes IACUCs to reject animal research projects they find to be scientifically and hence ethically unjustifiable, on the grounds that animals cannot be treated humanely or properly if they are used in scientifically unsound experiments (Mann and Prentice, 2004). Acceptance of the view that American IACUCs are constituted by law as ethics review committees appears to have been furthered by the official position of the Association for Assessment and Accreditation of Laboratory Animal Care International (AAALAC) that an IACUC in its accredited institutions must conduct a "harm/benefit analysis," in which it would "weigh the potential

adverse effects of the study against the potential benefits that are likely to accrue as a result of the research" (AAALAC, 2015). To support this position, AAALAC cites (Newcomer, 2012, p. 296) the statement in the *Guide* that "due to their potential for unrelieved pain or distress or other animal welfare concerns," in certain protocols "the IACUC is obliged to weigh the objectives of the study against other potential animal welfare concerns" (NRC, 2011, p. 27). Conferences and workshops on animal research in the United States routinely include sessions on how IACUCs should engage in harm–benefit analysis and ethical review of research protocols.

It is beyond the ability of this discussion to settle definitely whether IACUCs are permitted or obligated by US law to reject biomedical animal experiments they find ethically unjustified. This matter may need to be resolved by the courts, the conclusions of which are not always predictable. However, a discussion of ethical assessment of biomedical animal research in the United States would be remiss if it did not observe that Congress, in enacting both the HREA and the AWA, expressed its intention that IACUCs must never review the ethical appropriateness of animal research projects. The HREA directs the NIH to issue guidelines to ensure "(t)he proper *care* of animals to be used in biomedical and behavioral research" [§289d(a)(1), author's italics] and "the proper *treatment* of animals while being used in such research" [§289d(a)(2), author's italics]. The statute also states that any guidelines or regulatory actions "shall not be construed to prescribe methods of research" [§289d(a)(2)]. In explaining the meaning of these provisions, Congress declared that "the animal care committees have *no authority to interfere with research decisions, goals, or methods*. The committees have *no authority to 'second guess' or review the appropriateness of research*. The authority of the committees is limited to review of the care and treatment of animals pursuant to guidelines established by the NIH" (House Conference Report, 1985, pp. 746, author's italics).

Likewise, the AWA prohibits the USDA from promulgating "rules, regulations, or orders with regard to the design, outlines, or guidelines of actual research or experimentation by a research facility as determined by such research facility" [AWA, 2013, §2143(a)(6)(A)(1)(i)]. The USDA policy on alternatives, quoted earlier, reflects the guiding principle of the AWA that IACUCs may review and require changes in scientific aspects of animal research projects, but only when, *consistent with the scientific goals of a project*, modifications in project design or implementation would better fulfill the animal welfare aims of the statute. In further explaining its policy on alternatives quoted earlier, the USDA states that investigators must demonstrate to the IACUC that they have searched relevant databases and other appropriate sources for alternatives. If an adequate search would identify "a bona fide alternative method (one that could

be used to *accomplish the goals of the animal use proposal*), the IACUC may and should ask the PI to explain why an alternative that had been found was not used. The IACUC, in fact, can withhold approval of the study proposal if the Committee is not satisfied with the procedures the PI plans to use in his study" (USDA, 2016, Policy #12, p. 12.1, author's italics). However, if any methods that might lessen pain or distress would interfere with the attainment of project goals, these methods need not be used; as indicated in the policy statement quoted earlier, they would not be called "alternatives" (id.).

There are a number of arguments supporting the wisdom of Congress' prohibition of IACUC ethical assessment of experimental goals. As is discussed below, the scientific soundness or merit of an animal experiment is a central determinant in whether it is ethically justified. IACUCs in the United States typically do not have the scientific expertise to assess the scientific merit of all protocols they must consider. Regarding experiments covered by the HREA, those with the responsibility for scientific merit review—and who have expertise to conduct such review—are NIH-appointed scientific review groups (SRGs) (NIH, 2016b).

More importantly, allowing IACUCs to reject project goals on ethical grounds would likely lead to discord and confusion in the biomedical research community, and could hinder potentially beneficial experimentation. There are as yet no universally accepted or legally mandated standards of what constitutes ethically good or bad goals for animal experiments. Moreover, some ethical issues relating to the ethical appropriateness of animal research are difficult, complex, and contentious in their own right. Thus, different IACUCs with different ethical views could reach different conclusions about whether the same or similar kinds of animal experiments would be permitted in their institutions.

Imagine, for example, a hypothetical project that proposes to simulate cigarette smoking in monkeys to determine whether various new potential therapeutic agents can alleviate or reverse the resulting emphysema in these animals, and ultimately in people. The IACUC at one institution regards the goal of the experiment and what will be done to the animals as ethically justified, on the grounds that many people around the world smoke cigarettes, develop emphysema, and need relief. An IACUC at another institution rejects precisely this kind of study. This IACUC maintains that smoking-related emphysema can most effectively be eliminated or reduced if people simply stop smoking, and believes it is not fair to monkeys to give them the disease to help people who should not have smoked in the first place. However, this IACUC tells the investigator that if monkeys are to be used, the animals will have to be subjected to the equivalent of secondhand smoke; such an experiment would be ethically justifiable, this IACUC believes, because many

people (such as children of smokers) who contract lung disease as a result of smoking by others cannot be held responsible for their illness. An IACUC at a third institution rejects this latter kind of study as unethical, on the grounds that nonhuman primates should not be used in any kind of tobacco research, but tells the investigator that if the experiment is modified to study first- or secondhand smoke in mice, it would be ethically justified and would be approved. Another IACUC will approve only studies of secondhand smoke on mice, for the same reason the second IACUC mentioned earlier rejects firsthand smoke studies on monkeys. These hypothetical IACUCs (like many actual IACUCs) concede that they are unqualified to assess the scientific merit of these experiments. Their conclusions reflect their differing views about whether, all things considered, it is *right* to use the animals in the studies, or put another way, whether what is done to these animals would be justified ethically by the value of the experiments.

The claim advanced here is not that there would be disparities in IACUC ethical determinations relating to all or even most kinds of biomedical animal research projects. As is clear from the discussions in this chapter, there is a great deal of agreement in the research community about general fundamental ethical principles relating to biomedical animal research and about how these principles should be applied in many kinds of circumstances. However, there are many kinds of ethically difficult or societally controversial animal experiments regarding which different IACUCs could, and probably will, come to different ethical conclusions about whether experiments will be permitted. Funding agencies might be prevented by IACUC ethical disapprovals from considering studies they would find to be of high scientific merit. Investigators might be forced to leave institutions with IACUCs that reject their work on ethical grounds. Perhaps some institutions would compete for investigators on the basis of their IACUCs' acceptance of certain kinds of animal research, or would appoint IACUC members whose ethical views will not chase away investigators and funding. At some institutions, whether certain kinds of research are approved or rejected could continually change, as different people with different ethical opinions about such research become IACUC members.

To prevent such disparities and changes, government authorities would presumably need to find a way of ensuring consistent IACUC ethical conclusions. Perhaps the *PHS Policy* or the AWA regulations would contain rules not only relating to research animal care and treatment, but also setting forth ethically acceptable research goals and methods. One commentator (who recognizes that current US law does not allow IACUC review of ethical merit) argues that the best way to ensure nationwide ethical consistency is for Congress to establish a national

commission that would issue ethical policies and rules binding on all IACUCs and investigators in the country (Brody, 1989).

One argument sometimes offered to support the legality of IACUC ethical review in the United States is the claim that such review is required by Principle II of the *US Principles* (OLAW, 2015b, pp. 4–5). This principle states that "(p)rocedures involving animals should be designed and performed with due consideration of their relevance to human or animal health, the advancement of knowledge, or the good of society." As is explained below, Principle II is reasonably interpreted to express the most general ethical principle of animal research ethics: whatever is done to animals in a research project must be justified by the project's value. IACUCs are required by the HREA to ensure that research projects covered by the statute conform to the *PHS Policy* (OLAW, 2015b, para. IV.C.1, p. 13), and the *PHS Policy* is "intended to implement and supplement" the *US Principles* (OLAW, 2015b, para. I, p. 7). Therefore, it might seem plausible to conclude that the *PHS Policy*, via the *US Principles*, requires IACUCs to determine whether the goals of animal research projects are sufficiently worthy to justify how these projects use and treat animals.

The *US Principles* were adopted in 1985 by a number of federal agencies (including the NIH) primarily for use in animal research conducted intramurally by these agencies (Laboratory Animal Welfare, 1985). Congress subsequently passed the HREA, which applies to NIH-funded animal research conducted in nongovernment institutions. The HREA directed the NIH to establish guidelines for enforcing the statute [HREA §289d(a)]. The NIH adopted the *US Principles* and the *PHS Policy*, originally intended to apply in its own facilities, as guidelines for NIH-funded animal research in nongovernment institutions. In exercising the authority given to it by Congress, the NIH could not then, and cannot now, contradict or override the legislative intent of Congress in passing the HREA, including Congress' stated prohibition of IACUC review of scientific goals and ethical appropriateness of animal research projects. This means that nothing in the *US Principles* or the *PHS Policy* can allow or require an IACUC to reject or demand changes in a project because in the IACUC's view the project does not provide sufficient ethical justification for its use of animals.

Proponents of IACUC ethical review also point to the *Guide* and certain statements by the NIH Office of Laboratory Animal Welfare (OLAW), which administers the HREA and the *PHS Policy*. One statement in particular in the *Guide* is thought by some to require IACUC review. As noted earlier, the *Guide* asserts that "due to their potential for unrelieved pain or distress or other animal welfare concerns," in certain protocols "the IACUC is obliged to weigh the objectives of the study against other potential animal welfare concerns" (NRC, 2011,

p. 27). As discussed below, this is a statement of what I call the harm justification principle, one of the most important principles of biomedical animal research ethics. OLAW has also indicated that it expects experiments to be rejected if found by IACUCs to be scientifically and hence ethically inappropriate. For example, OLAW asserts that

> Although not intended to conduct peer review of research proposals, the IACUC is expected to include consideration of the U.S. Government Principles in its review of protocols. Principle II calls for an evaluation of the relevance of a procedure to human or animal health, the advancement of knowledge, or the good of society. Other PHS Policy review criteria refer to sound research design, rationale for involving animals, and scientifically valuable research. Presumably a study that could not meet these basic criteria is inherently unnecessary and wasteful and, therefore, not justifiable. OLAW (2016a, D.12)

Time will tell to what extent IACUCs in the United States reject experiments on ethical grounds; whether investigators and institutions that feel aggrieved by such determinations challenge them administratively or in the courts; and what the results of any such challenges might be. If, as has been argued here, in enacting the HREA and the AWA Congress forbade IACUCs from rejecting or modifying research projects or goals on ethical grounds, the ability or obligation of IACUCs to engage in such behavior cannot be conferred by any language contained in the *US Principles*, the *PHS Policy*, the *Guide*, or any document or policy statement issued or endorsed by the NIH or the USDA.

Although IACUCs do not appear to be permitted to reject or demand modifications of project goals they find unethical, current US law does assign crucial ethical functions to IACUCs. By requiring, consistent with project goals, minimization of pain and distress, IACUCs ensure application by investigators of the pain and distress minimization principle (discussed below). IACUCs in the United States also have legal authority to assure compliance with the species-appropriate housing and appropriate care principles (discussed below). Correct application of these fundamental principles of biomedical animal research ethics is essential in ensuring that animal experiments are conducted ethically.

US law, as characterized here, leaves it ultimately to the investigator to choose project goals that, together with experimental procedures to implement these goals (which IACUCs do have limited authority to modify), provide sufficient ethical justification for a project's use of animals. As already noted, court decisions are sometimes unpredictable. It is, therefore, worth observing that even if the US legal system should determine that the HREA or the AWA allows or obligates IACUCs to reject or modify animal experiments they find ethically unjustified, it would still be the investigator who is best able to articulate why a project has sufficient scientific value

to justify its use and treatment of animals. It would still be the investigator who sets project goals, and who must accept any modifications of these goals if the project is to proceed. It will still be the investigator who is responsible for putting into effect an experiment with sufficient value to assure that it justifies its use of animals.

8 SOURCES OF GUIDANCE FOR INVESTIGATORS IN CONDUCTING ETHICAL RESEARCH

In designing and applying an animal model, an investigator will want to consult accurate and up-to-date published sources (such as the chapters in this book) that consider the value of the model in studying the disease or aspect of the disease under investigation. Readers of this chapter are also likely, and reasonably, to ask what published sources they can consult to evaluate *ethical* claims about animal research, and to make sound decisions regarding ethical issues relating to their projects.

8.1 Scientific Resources

Most published sources animal researchers will want to consult to ensure that their projects are ethically sound are wholly scientific in nature, and are indeed very same kinds of materials investigators already consult. These are resources that address issues pertaining to the scientific soundness of the design and implementation of a project, including the choice of project goals that are appropriate to investigating a given disease or aspect of a disease, the animal model to be employed, and experimental means of applying the model. Such materials assist investigators in designing projects that are strong from a scientific, and for reasons discussed later, are therefore likely to be strong from an ethical, standpoint. Investigators already consult scientific sources that are relevant to ensuring that projects meet legal requirements relating to animal welfare, such as publications that indicate whether there are available methods that would lessen animal pain or distress consistent with project goals.

8.2 Ethical and Ethically Relevant Resources

There are numerous resources that address ethical issues more directly and that investigators will find helpful in considering how to apply various ethical principles in developing and employing animal models.

8.2.1 Legally Mandated Ethical Principles

As observed earlier, one important source of ethical rules relating to biomedical animal research are the ethical requirements that government agencies impose on researchers, IACUCs, and research facilities. Most ethical standards relating to animal research required by law in the United States are set forth in statutes, primarily the AWA (2013) and the HREA (1985); in regulations or rules that are applied by the government agencies that administer these statutes, for the AWA, the AWA Regulations in the Code of Federal Regulations (AWAR, 2015), and for the HREA, the *PHS Policy* (OLAW, 2015b); and in various policies adopted by these agencies, for the AWA, by the USDA Animal and Plant Health Inspection Service (APHIS), and for the HREA, by OLAW. In the United Kingdom, ethical as well as technical standards are contained in the general statute governing animal research, the Animals (Scientific Procedures) Act 1986 or ASPA (1986). The Home Office, which enforces the Act, issues guidance documents and policy statements to assist investigators and to explain legally mandated ethical and technical animal research standards to the public (Home Office, 2014, 2015, 2016a,b). In the European Union, the fundamental legal documents governing animal research are the *European Convention for the Protection of Vertebrate Animals Used for Experimental and Other Scientific Purposes* (*European Convention*) (Council of Europe, 1986) and the *EU Directive* (European Union, 2010), which contain ethical principles member nations are expected to acknowledge and enforce.

Only a representative sampling of legally mandated ethical principles can be provided here. The AWA indicates [AWA, 2013, §2143(b)(3)] that its general aim is to ensure that "(p)rocedures involving animals will avoid or minimize discomfort, distress, and pain to the animals." To achieve this ethical goal the AWA and AWA Regulations impose a number of more specific ethical requirements. These include requirements that the "principal investigator considers alternatives to any procedure likely to produce pain to or distress in an experimental animal" [AWA, 2013, §2143(a)(3)(B)]; "(t)he principal investigator has provided written assurance that the activities do not unnecessarily duplicate previous experiments" [§2.31(d)(1)(iii)]; "(p)rocedures that may cause more than momentary or slight pain or distress to the animals will … (b)e performed with appropriate sedatives, analgesics or anesthetics, unless withholding such agents is justified for scientific reasons, in writing, by the principal investigator and will continue for only the necessary period of time" [§2.31(d)(1)(iv)(A)]; paralytics without anesthesia shall not be used [§2143(a)(3)(C)(iv)]; "(n)o animal will be used in more than one major operative procedure from which it is allowed to recover, unless ... (j)ustified for scientific reasons by the principal investigator, in writing" [AWAR, 2015, §2.31(d)(1)(x)]; and "(a)nimals that would otherwise experience severe or chronic pain or distress that cannot be relieved will be painlessly euthanized at the end of the procedure or, if appropriate, during the procedure" [§ 2.31(d)(1)(v)].

Perhaps the best-known legally mandated ethical rules for animal research in the United States are the *US Principles* (OLAW, 2015b, pp. 4–5). The *Principles* include statements that "(p)rocedures involving animals should be designed and performed with due consideration of their relevance to human or animal health, the advancement of knowledge, or the good of society" (Principle II); "(t)he animals selected for a procedure should be of an appropriate species and quality and the minimum number required to obtain valid results. Methods such as mathematical models, computer simulation, and in vitro biological systems should be considered" (Principle III); "(p)roper use of animals, including the avoidance or minimization of discomfort, distress, and pain when consistent with sound scientific practices, is imperative. ..." (Principle IV); "(p)rocedures with animals that may cause more than momentary or slight pain or distress should be performed with appropriate sedation, analgesia, or anesthesia. Surgical or other painful procedures should not be performed on unanesthetized animals paralyzed by chemical agents" (Principle V); "(a)nimals that would otherwise suffer severe or chronic pain or distress that cannot be relieved should be painlessly killed at the end of the procedure or, if appropriate, during the procedure" (Principle VI); "(t)he living conditions of animals should be appropriate for their species and contribute to their health and comfort. ..." (Principle VII); and "(i) nvestigators and other personnel shall be appropriately qualified and experienced for conducting procedures on living animals ..." (Principle VIII).

The Preamble of the *EU Directive* (European Union, 2010) contains a large number of general principles of animal research ethics. These include statements that "(n)ew scientific knowledge is available in respect of factors influencing animal welfare as well as the capacity of animals to sense and express pain, suffering, distress and lasting harm. It is therefore necessary to improve the welfare of animals used in scientific procedures by raising the minimum standards for their protection in line with the latest scientific developments" (para. 6); "(w)hile it is desirable to replace the use of live animals in procedures by other methods not entailing the use of live animals, the use of live animals continues to be necessary to protect human and animal health and the environment" (para. 10); "(t)he methods selected should avoid, as far as possible, death as an end-point due to the severe suffering experienced during the period before death" (para. 14); "(f)rom an ethical standpoint, there should be an upper limit of pain, suffering and distress above which animals should not be subjected in scientific procedures. To that end, the performance of procedures that result in severe pain, suffering or distress, which is likely to be long-lasting and cannot be ameliorated, should be prohibited." (para. 23); "(t)o ensure the ongoing monitoring of animal-welfare needs, appropriate

veterinary care should be available at all times and a staff member should be made responsible for the care and welfare of animals in each establishment" (para. 30); and "(t)he accommodation and care of animals should be based on the specific needs and characteristics of each species" (para. 34).

8.2.2 Nongovernmental Documents Adherence to Which is Required by Law

As already noted, the *Guide* (NRC, 2011), though published by the nongovernmental National Research Council (NRC), is required by the *PHS Policy* to be followed in all research covered by the HREA (OLAW, 2015b, para. I, p. 7). The *Guide* (NRC, 2011, Appendix B, pp. 199–200), mandates adherence to the ethical rules in the *US Principles*. Most of the standards of animal use and care enunciated in the *Guide* are not ethical rules like those enunciated in the *Principles*. However, the *Guide* contains discussions that are relevant to considering ethical questions raised by various aspects of animal research. Among the many subjects with ethical implications considered in the *Guide* are choice of endpoints (pp. 27–28); physical restraint (pp. 29–30); multiple survival surgical procedures (p. 30); food and fluid regulation (pp. 30–31); pain and distress (pp. 120–121); anesthesia and analgesia (pp. 121-123); euthanasia (pp. 123–124); and environment, housing, and management in general and relating to various species (pp. 41–88). Investigators conducting research governed by both the AWA (USDA, 2016, Policy 3) and the *PHS Policy* (OLAW, 2015b, para. IV.C.1.g) must employ methods of euthanasia approved in the American Veterinary Medical Association (AVMA) *Guidelines on Euthanasia* (AVMA, 2013). This document contains discussions of ethical questions relating to when euthanasia should be performed in various circumstances. Although current US law requires investigators to use a euthanasia *method* approved in the AVMA guidelines, (and does not mandate adherence to ethical suggestions in the document), investigators will find its discussions of ethical issues useful.

8.2.3 Publications of Workshops, Study Committees, and Nongovernmental Entities

Another source of guidance in ethical assessment of animal research projects are publications of groups or special committees of nongovernment bodies that are requested or consulted by their respective governments. In the United States, these groups include the NRC of the National Academies of Science, and the NRC Institute for Laboratory Animal Research (ILAR). These publications tend not to offer detailed discussion of or arguments for ethical principles. However, these publications provide useful information about how to apply certain accepted ethical principles (such as the pain and distress minimization principle) to various situations

faced by researchers. Among such publications are the reports of the ILAR Committee on well-being of nonhuman primates on *The psychological well-being of nonhuman primates* (ILAR, 1998); the NRC Committee on *Guidelines for the care and use of mammals in neuroscience and behavioral research* (NRC, 2003); the NRC Committee on *Recognition and alleviation of distress in laboratory animals* (NRC, 2008); the NRC Committee on the *Recognition and alleviation of pain in laboratory animals* (NRC, 2009a); and the Federation of Animal Science Societies *Guide for the care and use of agricultural animals in research and teaching* (FASS, 2010). Discussion of general issues relating to the use or availability of certain animals for research can be found in the NRC report on *Scientific and humane issues in the use of random source dogs and cats in research* (NRC, 2009b) and the Institute of Medicine (IOM) report on the *Use of chimpanzees in biomedical and behavioral research* (IOM, 2011). The RSPCA has written or published a number of documents discussing ethical assessment of animal experiments, including *A resource book for lay members of ethical review and similar bodies worldwide* (Jennings and Smith, 2015). A useful, comprehensive treatment of animal research ethics is *The ethics of research involving animals*, published by the UK Nuffield Council on Bioethics (2005). An invaluable source of discussions with implications for ethical issues in biomedical animal research is the *ILAR Journal*, the leading-peer reviewed periodical in the United States focusing on research animal welfare. Issues of the journal are dedicated to specific human diseases, animal models, research techniques, or species of research animal.

8.2.4 Ethical Guidelines of Professional Associations

Among the most helpful sources of published principles in biomedical animal research ethics are official statements and policies of professional associations of scientists, laboratory animal veterinarians, and research animal care specialists. These statements sometimes assert ethical principles that focus on particular kinds of research, and sometimes apply general ethical principles to certain kinds of animal research or species. Investigators need not be a member of a particular association to find its ethical statements applicable to their research projects.

Among general ethical statements by professional scientific associations are those of the American Physiological Society (APS, 2016), the American Psychological Association (APA, 2012), the American Society of Primatologists (ASP, 2001), the Federation of American Societies for Experimental Biology (FASEB, 2016b), the Society for Neuroscience (SfN, 2016), and the Society of Toxicology (SOT, 2008).

Statements of veterinary associations of ethical principles relating to biomedical animal research,

sometimes accompanied by detailed suggestions for their application, can be found in statements or documents of, for example, the American College of Laboratory Animal Medicine (ACLAM, 2001, 2006, 2012a,b), the American Society of Laboratory Animal Practitioners (ASLAP, 2007, 2008, 2009), the AVMA (2016), the British Veterinary Association (BVA, 2016), and the Laboratory Animal Veterinary Association of the BVA (LAVA, 2016).

Professional associations whose focus is on the wide range of research animal use and care offer general ethical policies and sometimes specific guidance in implementing these policies. Such organizations include the American Association for Laboratory Animal Science (AALAS, 2014), the Basel Declaration Society (Basel Declaration, 2010), the Canadian Council on Animal Care (CCAC, 1989), the Federation of European Laboratory Animal Science Associations (FELASA, 2005; Guillen, 2012), and the International Council for Laboratory Animal Science (ICLAS, 2012). AAALAC (2016) includes in its accreditation requirements a number of its own ethical policies, as well as adherence to other documents containing ethical standards for animal research, including the *Guide* (NRC, 2011) and the *European Convention* (Council of Europe, 1986).

9 DEVELOPING USEFUL ETHICAL GUIDELINES

Whether contained in laws, regulations, or professional association documents, most current statements of principles of biomedical animal research ethics enunciate a relatively small number of ethical rules. Moreover, multiple ethical rules contained in many of these documents express the pain and distress minimization principle, either stating this principle generally or applying the principle to certain kinds of situations in which it is relevant. The latter is the intent, for example, of the third through the sixth of the *US Principles* (OLAW, 2015b), and of similar statements in the AWA and ethical guidelines of scientific and veterinary associations cited earlier. The ethical rules contained in current legal and professional documents also tend to be extremely general and often omit certain specific kinds of research or research procedures that, it can be argued, ought to be mentioned explicitly in any useful set of ethical rules. For example, one can ask whether statements of ethical principles that invoke the pain and distress minimization principle should at least mention—or perhaps include much more specific rules regarding—various issues that raise distinctive applications of the principle, such as choice of humane endpoints, physical restraint, and tumor burden.

That statements of biomedical animal research ethics tend to present a small number of very general principles allows these statements to apply to a wide range of research: on different diseases, employing different models and research procedures, and using different species. The generality of the principles also adds to their credibility. It is usually more difficult to find counter-examples to a very general rule (e.g., that research animal pain and distress should be minimized consistent with project goals) than to very specific guidelines that may not be persuasive in some situations (e.g., a rule that death as an endpoint may be used only in specified kinds of studies).

The major shortcoming of a limited number of general ethical principles is that general rules provide little practical guidance. Animal researchers might benefit from statements of ethical principles that are more detailed than those provided in current legal and professional documents. A useful set of principles probably should not contain a large number of very specific ethical rules. Too many specific rules might distract investigators from the necessary task of carefully examining the particulars of each project, and from considering how the project treats the animals during all of its stages. On the other hand, investigators might find it helpful to have dedicated ethical rules dealing with certain animal models, research techniques, or species. This might make ethical assessment of particular projects more persuasive and efficient by focusing attention on recurring ethical questions and by presenting possible answers to such questions.

Current legal and professional documents that enunciate ethical principles for biomedical animal research also do not provide supporting ethical *arguments* for these principles—perhaps because the principles are widely accepted in the biomedical research community and seem unquestionably correct to investigators and government regulators alike. However, as is demonstrated below, it is important to consider underlying ethical and empirical arguments for principles of biomedical animal research ethics. These arguments can be helpful in explaining the meaning of the principles and in motivating investigators to follow them.

It cannot be known what a more comprehensive set of principles of biomedical animal research ethics will contain until sustained work is done to offer and evaluate such principles. The rules presented in the remainder of this chapter serve as a core for the articulation of additional principles and practical guidelines. Absence in this discussion of any rule currently mandated by law or included in professional association ethical documents is not meant to suggest that such rules should not be followed by investigators, or should not be included in a comprehensive set of fundamental principles of biomedical animal research ethics.

10 FUNDAMENTAL PRINCIPLES OF BIOMEDICAL ANIMAL RESEARCH ETHICS

The following discussion presents 13 principles that express basic truths about animal research or about how it should be conducted. An ethical evaluation of any individual animal research project is likely not only to involve the application of one or more of these principles, but also to employ these principles to support the most important ethical conclusions relating to the project. Additionally, each of these principles applies to different aspects of many kinds of animal experiments. Thus, the principles can be said collectively to form the fundamental structure on which the ethical conduct of biomedical animal research rests. The principles are listed in Table 1.1, and for convenience of discussion are designated as F1–F13.

F1. The Biomedical Research Principle

It is among the most noble and imperative of human endeavors to employ scientific research to prevent, alleviate, and cure the pain, suffering, distress, fear, anxiety, disability, infirmity, and death associated with human disease.

What I call *the biomedical research principle*, deserves a prominent place in biomedical animal research ethics. The principle does more than reflect the central motivation of biomedical science in using animals to understand human disease. The principle also does more than commit animal researchers to conduct research for ethically sound reasons and in ethically sound ways—by proclaiming that biomedical research is driven by the highest of ethical ideals at its core. The biomedical research principle, together with the accompanying next two fundamental principles discussed below, implies a truth of critical importance. As indicated by the quotation early in the chapter from a philosophical discussion of animal research (Donnelly and Nolan, 1990, p. 8), many philosophers think that the primary question in biomedical animal research ethics is whether or to what extent the use of animals in research is justified. If what must be shown is that animal research *is* justified, the burden of argument is on those who think it is justified. However, if as is surely the case it is a noble and imperative endeavor to employ scientific research to understand and combat human disease, and if as is surely the case the development of knowledge necessary to understand and combat human disease often requires in vivo animal experimentation (see Principle F2 below), and if as is surely also the case animals should be used before humans in research on human disease when scientifically appropriate (see Principle F3 below), the ethical burden of proof is on those who think that biomedical animal research is *not* justified.

TABLE 1.1 Fundamental Principles of Biomedical Animal Research Ethics

1. *The biomedical research principle.* It is among the most noble and imperative of human endeavors to employ scientific research to prevent, alleviate, and cure the pain, suffering, distress, fear, anxiety, disability, infirmity, and death associated with human disease.
2. *The animal research principle.* "The development of knowledge necessary for the improvement of the health and well-being of humans, as well as other animals requires in vivo experimentation with a wide variety of animal species." Preamble, *US Principles* (OLAW, 2015b, p. 4).
3. *The Nuremberg principle.* Medical research on human subjects "should be so designed and based on the results of animal experimentation and a knowledge of the natural history of the disease or other problems under study that the anticipated results will justify the performance of the experiment." (Nuremberg Code, 1947, para. 3).
4. *The pain and distress minimization principle.* An animal research project should cause no more pain or distress to the animals than is necessary to achieve the scientific goals of the research.
5. *The pain and distress justification principle.* Any pain or distress that an animal research project will cause the animals must be justified by the value of the project, and the more pain or distress an animal research project will cause animals, the greater must be the value of the project to justify this pain or distress.
6. *The harm justification principle.* Any harm (including pain or distress) that an animal research project will cause the animals must be justified by the value of the project, and the greater the harms an animal research project will cause animals, the greater must be the value of the project to justify these harms.
7. *The harm minimization principle.* An animal research project should cause no more harm (including pain or distress) to the animals than is necessary to achieve the scientific goals of the research.
8. *The general justification principle.* Whatever is done with or to animals in a research project (including but not restricted to causing harms, such as pain and distress) must be justified by the value of the project.
9. *The 3Rs principle.* In designing and implementing animal experiments investigators should practice the "3Rs" of replacement, reduction, and refinement.
10. *The species-appropriate housing principle.* "The living conditions of animals should be appropriate for their species and contribute to their health and comfort." *US Principles*, Principle VII (OLAW, 2015b, p. 5).
11. *The appropriate care principle.* While housed in the research facility, animals must receive appropriate veterinary supervision and care, and the conscientious attention of trained animal care staff.
12. *The appreciation principle.* Research animals should be treated with kindness, compassion, and gratitude.
13. *The translation principle.* Investigators should support, stay informed about, and when appropriate engage in scientific and professional efforts aimed at improving the translation of animal experiments to clinical applications.

This does not mean that all animal research is ethically justified. Nor does it mean that for any given animal research project there is a presumption that the project is ethically appropriate, and that someone who might think otherwise has the burden of proving that this is so. For reasons explained below, it is primarily the task of investigators and others who are part of the general biomedical animal research endeavor to ensure that individual research projects are ethically appropriate.

F2. The Animal Research Principle

"*The development of knowledge necessary for the improvement of the health and well-being of humans as well as other animals requires in vivo experimentation with a wide variety of animal species.*" Preamble, *US Principles* (OLAW, 2015b, p. 4).

This statement, which I shall call *the animal research principle*, opens the *US Principles*. The animal research principle, together with the biomedical research principle, provides a critically important foundation for regarding animal research as generally ethically justified. For if it is imperative to understand and combat human disease, and if doing so requires animal research, then it is imperative (subject to additional scientific and ethical considerations) to conduct biomedical animal research. The animal research principle does not imply that all animal research projects are necessary for the improvement

of human health. It is incumbent on investigators to conduct animal research that *does* have the potential to understand and combat disease.

F3. The Nuremberg Principle

Medical research on human subjects "should be so designed and based on the results of animal experimentation and a knowledge of the natural history of the disease or other problems under study that the anticipated results will justify the performance of the experiment." (Nuremberg Code, 1947, para. 3).

The quoted portion of this principle is a key provision of the Nuremberg Code, widely regarded as the historical foundation of internationally accepted ethical principles relating to the use of humans in medical research (Annas and Grodin, 1992). I shall therefore call this *the Nuremberg principle.* The Nuremberg Code was written by the American judges who presided over the post-World War II trials of the so-called "Nazi doctors" who were prosecuted for crimes against humanity for conducting torturous experiments on concentration camp inmates. The Code's insistence on scientifically appropriate animal research prior to human experimentation reflects the recognition that animal models often facilitate the understanding of human disease. The Nuremberg Code also expresses the view that that research on humans that is conducted with the voluntary consent

of research subjects must—in fairness to these human subjects—have at least some possibility of discovering something useful. There must be good reason to ask these people to possibly forego an available treatment, or to experience potential pain, distress, or discomfort, or feelings of anticipation, hope, or disappointment that can be associated with participating in a clinical trial.

The Nuremberg Code also expresses the widely held view that humans are of greater worth and value than animals. What horrified the Nuremberg judges, and the entire civilized world, when evidence of the experimental atrocities was presented during the trials, was that the Nazi experimenters had no respect for the value of human life. As the chief prosecutor told the judges (Taylor, 1992, pp. 89–90), the experimenters did not even treat their human victims like animals; they treated them worse than research animals could be treated under German law. In requiring that animals be used before humans when scientifically appropriate, the Nuremberg Code reflects the view that certain things may and should first be done with animals because they are animals and not humans.

The Nuremberg principle does not condone subjecting animals to the pointless torture the Nazi experimenters inflicted on people. The Nuremberg Code was strictly a proclamation of *human* rights. The conduct of ethical animal research was not one of its concerns. The ethical requirement of proper treatment of animals in research preceding human testing was added to international research standards in the Declaration of Helsinki (World Medical Association, 2013), which expands upon the Nuremberg Code and is regarded as the most important contemporary comprehensive exposition of ethical principles relating to medical research on humans (Perley et al., 1992). Paragraph 21 of the Declaration states that "(m)edical research involving human subjects must conform to generally accepted scientific principles, be based on a thorough knowledge of the scientific literature, other relevant sources of information, and adequate laboratory and, as appropriate, animal experimentation. The welfare of animals used for research must be respected."

The Nuremberg principle calls upon investigators to employ animal models that *do* further the understanding of human diseases. For if a model that does not assist in understanding a particular disease leads to human clinical trials, and if investigators know or should know prior to such trials that this is not a good model for the disease, the human trials will not have sufficient scientific rationale, and human subjects who volunteer for these trials will not be treated fairly.

Because the Nuremberg principle is a statement about fundamental human rights as much as it is a foundation of biomedical animal research, in communicating with the public about their work (which is urged below),

animal researchers would do well not just to explain how animal research can help people who suffer from terrible diseases. Investigators should also emphasize that in using animal models they are seeking to protect the interests and rights of *people* whose participation in clinical trials is essential for progress in combating human disease.

F4. The Pain and Distress Minimization Principle

An animal research project should cause no more pain or distress to the animals than is necessary to achieve the scientific goals of the research.

This is what I have called *the pain and distress minimization principle*. Due to its prominence in rules of animal research ethics enunciated by government bodies and professional scientific associations, it is fair to say that the pain and distress minimization principle is often regarded in the biomedical research community as the most important principle of animal research ethics. For reasons explained below, this is not the case, although the principle is a key rule of animal research ethics and often figures centrally in the ethical assessment of individual animal experiments.

F4.1 Ethical Foundations of the Pain and Distress Minimization Principle

Although the principle is intuitively persuasive, it is useful to examine its ethical foundations. As I discuss in the context of pain research on animals (Tannenbaum, 1999), the ethical basis of the pain and distress minimization principle is the fact that, as significantly unpleasant experiences, pain and distress are harms or evils in themselves. Although pain is sometimes beneficial in signaling the presence of a problem, such as an injury, the experience of pain is bad in itself, which is why humans as well as animals do not like it and try to avoid it. If one is asked to explain *why* feeling pain or distress is a bad thing (a question that is rarely asked because its answer is obvious) one would respond that these experiences are bad because of how they feel: they are bad because they are pain or distress. In other words, one cannot provide a further reason why pain and distress are bad, it is just self-evident that they are evils and harms in themselves. Because pain and distress are evils, one ought not inflict them on animals unless one has a justification for doing so. A basic principle of ethics is that it is wrong to harm or cause an evil to a being without a justifiable reason.

From these considerations, it follows that if an investigator can achieve the scientific goals of an animal research project in a way that would cause animals less pain or distress than would another way of achieving these goals, the investigator is ethically obligated to choose the way that causes less pain or distress. To cause more pain or distress than is necessary to achieve these goals is to

cause pain or distress that is provided no legitimate reason or justification by the goals of the research.

F4.2 Qualifications to the Pain and Distress Minimization Principle

The pain and distress minimization principle requires two important qualifications to be applied persuasively.

UNCERTAINTY REGARDING MINIMIZATION

If an investigator knows with certainty that one practicable method of pursuing a project's aims will cause less pain or distress to the animals than another, it will be wrong to use the latter method. However, it may sometimes be impossible to *know* that a given method will in fact minimize pain or distress. For example, a research procedure may be so novel that one can only surmise but not be certain that one has designed the procedure so as to minimize the animals' pain or distress. In such a case, it would be unreasonable to criticize an investigator who has made good-faith efforts, based on available scientific and veterinary knowledge, to minimize the animals' pain or distress. In other words, reasonably interpreted, the pain and distress minimization principle sometimes obligates an investigator to *attempt* to cause no more pain or distress to animals than is necessary for the purposes of the research. Although one sometimes cannot fairly ask more of investigators than this, in accordance with typical statements of the pain and distress minimization principle, I have not phrased the principle in terms of making attempts. A good reason for this approach, I would argue, is that stating the obligation in terms of attempts rather than success might be interpreted by some as an expression of satisfaction with merely trying, and as lessening the importance of the need to try to *ensure* that pain and distress are minimized.

IMPRECISION IN ESTIMATES OF ANIMAL PAIN OR DISTRESS

It is also often impossible to apply the pain and distress minimization principle with a high degree of precision. Sometimes it will be clear that pain is being minimized. If, for example, an animal is fully anesthetized during surgery, its pain will be minimized during anesthesia. However, when animals must experience some unrelieved pain or distress because of research goals, it will sometimes be impossible to know whether a procedure has been designed or executed so as to cause *absolutely* the *minimum* amount of pain or distress necessary to pursue project goals. Animals are not capable of verbally expressing precisely the nature, duration, and severity of their pain or distress. Much has been and continues to be learned about pain and distress in various species (NRC, 2008, 2009a). Perhaps some day research into chemical and physiological aspects of animal pain and distress will enable very precise measurements, so that investigators can know that by employing some procedure or using some drug or behavioral technique, they can reduce the pain or distress of research animals even by just a small amount. However, at least at present, investigators must sometimes settle for somewhat imprecise estimates of how much and what kinds of pain or distress research animals experience.

F4.3 The Incompleteness of the Pain and Distress Minimization Principle

Despite its persuasiveness and importance, the pain and distress minimization principle can never be sufficient to justify any animal research project that causes animals pain or distress. For it can conceivably be the case that an experiment causes no more pain or distress to the animals than is necessary for accomplishing a project's scientific aims, but the project aims at discovering such unimportant knowledge that the discovery of this knowledge does not seem to justify causing animals *any* pain or distress. It can also conceivably be the case that an animal research project causes so much animal pain or distress that, even though this amount is the minimum required for accomplishing the project's scientific aims, and even though the project aims to discover something that would be regarded as having some value, the value of this knowledge does not seem to justify this amount of animal pain or distress.

F5. The Pain and Distress Justification Principle

Any pain or distress that an animal research project will cause the animals must be justified by the value of the project, and the more pain or distress an animal research project will cause animals, the greater must be the value of the project to justify this pain or distress.

To support any given animal research project that causes animals pain or distress, the pain and distress minimization principle must be supplemented by Principle F5, which I shall call *the pain and distress justification principle*. To be ethically acceptable, the value of a project must justify the pain or distress experienced by the animals, even if this pain and distress is the minimum necessary to achieve the goals of the research. Additionally, because more or more severe pain or distress is a greater evil for animals than less or less severe pain or distress, the more pain or distress an animal research project will cause animals, the stronger must be the justification for causing this pain or distress. Expressed another way, the more the pain or distress, the more the project must be *worth* the pain and distress from an ethical standpoint, that is, the greater must the *value* of the research (Tannenbaum, 1999).

F6. The Harm Justification Principle

Any harm (including pain or distress) that an animal research project will cause the animals must be justified by the value of the project, and the greater the harms an animal research project will cause animals, the greater must be the value of the project to justify these harms.

It is important in considering how the pain and distress justification principle functions in assessing the ethical appropriateness of research projects, to consider the more general principle of which the pain and distress justification principle is a specific application. This is Principle F6, which I call *the harm justification principle.*

The pain and distress minimization and justification principles derive their persuasiveness from the more general ethical principles that it is wrong to cause a harm or evil to an animal without justification for doing so, and that the greater the harm one causes an animal the stronger must be the justification. Pain and distress are harms or evils for animals. However, they are not the only possible harms to animals that may sometimes need to be justified by the value of animal research projects. For example, as Morton (1995) observes, there are unpleasant feelings or emotions other than pain or distress that at least some research animals seem capable of experiencing, such as severe stress, fear, boredom, and anxiety. If the negative feelings of pain and distress experienced by research animals must be justified by the value of research, and must be minimized, there seems to be no reason why other feelings that can be at least as unpleasant do not also require justification and minimization.

F6.1 Determining the Value of a Research Project

For the purpose of determining whether a project's value justifies any harms it may cause animals, it is useful to separate the value of animal research projects into two components, what I shall call their *medical value* and their *scientific value*.

MEDICAL VALUE OF THE PROJECT

In asking whether an animal research project justifies any harms it may cause animals, the first thing many people probably will want to consider is its "medical value." I use this term to refer to the value or importance of understanding the disease or aspect of the disease the project investigates. In determining the level of a project's medical value, one would consider the nature, severity, and duration of the pain and suffering, distress, discomfort, fear, anxiety, and infirmity associated with the disease. One would also consider, among other things, whether the disease or aspect of the disease under investigation is life threatening or terminal; it impairs the ability of sufferers to enjoy a decent quality of life; there are a large number of sufferers; the disease is transmissible or easily transmissible to others; it impairs the ability of

sufferers to be gainfully employed; there are currently effective treatments; the disease is currently treatable only with methods that have serious risks or side effects; changes in lifestyle and behavior can prevent people who do not yet have the disease from contracting it; how it affects family members of sufferers; and the extent to which the disease currently or will in the future impose financial costs on the healthcare system or the economy.

SCIENTIFIC VALUE OF THE PROJECT

Clearly, to justify any harms a project may cause to the animals, an animal research project must do more than seek to understand a disease or an aspect of a disease that it is important to understand. A study that has high medical value in seeking, for example, a cure for a currently incurable form of cancer, begins with a goal that *if reached* would justify a great deal more animal pain or distress than would a project that seeks to discover something trivial or unimportant. However, the former project would not justify *any* animal pain, distress, or other significant harm if it seeks to achieve its important goals by asking questions that are not scientifically relevant to achieving these goals, or by employing methodologies that are not scientifically appropriate to answering questions that are relevant to achieving these goals.

To comply with the harm justification principle, an animal research project must have something more than medical value. The project must also have "scientific value," by which I mean that it must be sound from a scientific standpoint. The concept of scientific soundness (often called *scientific merit*) is complex and impossible to define succinctly. Indeed, one of the most important and difficult questions that scientists ask is how to determine whether various kinds of research are scientifically sound. However, it can be said that in determining the extent to which a project's scientific value justifies any harms it causes to animals, among the things one would ask are whether (1) the scientific questions addressed by the project are relevant to understanding the disease or aspect of the disease under investigation, (2) the animal model is appropriate to this task, (3) the project design applies the model correctly, and (4) the experimental procedures have some likelihood of answering the questions posed by the project.

- **Relevance of the NIH Concept of "Scientific and Technical Merit"** Investigators who have sought funding from one of the institutes or centers of the NIH are familiar with the NIH concept of "scientific and technical merit" (to which I shall refer as *scientific merit*). A detailed discussion of this concept is not possible here. Nevertheless, it is important to note that the concept of "scientific value" employed here incorporates many—but not all—elements of the NIH concept of scientific merit.

As defined by the NIH (2016b, First Level of Review, para. B, Peer Review Criteria and Considerations), the scientific merit of a research project is comprised of five general major characteristics: significance, investigator(s), innovation, approach, and environment. During SRG peer review of a grant proposal, each of these aspects receives a separate score, which are used to reach a final score for the project's scientific merit. Significance and innovation pertain to the quality or value of the scientific goals of the project. Approach, investigator(s), and environment relate to the likelihood that the project will fulfill these goals. Because applying these criteria is complex, difficult, and impossible to capture in brief definitions or rules that do justice to the variety of projects that are reviewed, the NIH lists several questions that an SRG should ask in assessing a project's value for each of the five general considerations. In assessing *significance*, reviewers are to ask: "Does the project address an important problem or a critical barrier to progress in the field? Is there a strong scientific premise for the project? If the aims of the project are achieved, how will scientific knowledge, technical capability, and/or clinical practice be improved? How will successful completion of the aims change the concepts, methods, technologies, treatments, services, or preventative interventions that drive this field?" The following questions are listed for assessment of *innovation*: "Does the application challenge and seek to shift current research or clinical practice paradigms by utilizing novel theoretical concepts, approaches or methodologies, instrumentation, or interventions? Are the concepts, approaches or methodologies, instrumentation, or interventions novel to one field of research or novel in a broad sense? Is a refinement, improvement, or new application of theoretical concepts, approaches or methodologies, instrumentation, or interventions proposed?" Questions reviewers are to ask about *investigator(s)* include "Are the PD/PIs, collaborators, and other researchers well suited to the project? If Early Stage Investigators or New Investigators, or in the early stages of independent careers, do they have appropriate experience and training?" Questions relating to *approach* include whether "the overall strategy, methodology, and analyses (are) well-reasoned and appropriate to accomplish the specific aims of the project" and whether "potential problems, alternative strategies, and benchmarks for success (are) presented." Questions relating to *environment* include whether "the scientific environment in which the work will be done contribute to the probability of success? Are the institutional support, equipment, and other physical resources available to the investigators adequate for the project proposed?"

As is apparent from the questions relating to significance and innovation, the NIH concept of scientific merit includes some measure of "medical value" as I have defined it. For example, one reason an SRG might determine that a project "addresses an important problem" is that the disease the project investigates causes suffering and death to many people. One reason peer reviewers may favor a project that could "shift current research or clinical practice paradigms" is that current approaches used to understand and treat a devastating disease have not been successful. At least as applied to biomedical animal research (which typically seeks to provide scientific foundations for subsequent human trials), most of the questions used by the NIH in determining scientific merit relate to what I have called scientific value. This is not surprising. An SRG might review a number of proposed projects that seek to understand the same disease or aspect of a disease. It must, therefore, often be the quality of the science of these projects that distinguishes those with greater scientific merit and likelihood of funding from those with less.

The inclusion of what I have termed a project's "medical value" and "scientific value" in the NIH concept of "scientific merit" doubtlessly works well for the intended primary function of the NIH concept, which is to facilitate decisions about which of the competing grant proposals will receive funding (NIH, 2016b). However, for the purpose of *ethical* assessment of animal research projects, it is useful to assess a project's medical value and scientific value independently and separately. Determining the importance of understanding a disease involves considering issues about such matters as how many people suffer from a disease, the nature of this suffering, and the economic costs of the disease on the healthcare system and the general economy. Such questions range far beyond the design of an animal research project. Careful consideration and assessment of the medical value of the disease that an animal research project seeks to understand is more likely to occur if such consideration is kept separate from addressing questions that deal exclusively with the scientific soundness of the project, and that can be answered by considering the scientific quality of the questions the project asks and the methodologies it employs.

In sum, the definition of "scientific value" employed here for the purposes of applying the harm justification principle includes the NIH definition of "scientific merit," with the exception of considerations that relate to what I have called medical value. This understanding of scientific

value is not intended to restrict scientific value to components of the NIH definition of scientific merit. What constitutes scientific value is a matter for scientists to determine. However, it is useful to incorporate elements of the NIH concept of scientific merit that relate to scientific soundness in any understanding of the scientific value that must play a role in the ethical assessment of animal research projects. The NIH concept of scientific merit is widely accepted by scientists as providing criteria for determining sound science. Moreover, many animal researchers are already seeking to design projects that have high scientific value as defined here because they are already seeking to design projects that have scientific merit as defined by the NIH.

F6.2 Determining Whether the Value of a Project Justifies any Pain, Distress, or Other Harms Caused to the Animals

There has thus far been relatively little consideration in the biomedical animal research ethics literature regarding precisely how one should determine whether the value of a project justifies any pain, distress, or other harms it will cause to animals. The following discussion attempts to provide some guidance in approaching this difficult but nonetheless ethically imperative task.

ASSESSING THE PROJECT'S MEDICAL VALUE

In applying the harm justification principle to a research project, an investigator might begin by reviewing its medical value. This would involve considering the criteria for determining medical value discussed earlier, including the number of people who suffer from the disease or condition; the pain and suffering, distress, fear, anxiety, infirmity, or death associated with the disease; the need for further understanding of the disease; its impacts on society; and so on. For all the diseases discussed in this book, this process will result in a determination of high medical value.

ASSESSING THE NATURE AND EXTENT OF HARMS TO THE ANIMALS

To ensure that any pain or distress experienced by animals is justified by the value of the project, an investigator must determine as accurately as possible whether and to what extent the animals will experience pain, distress and other kinds of significant harms. This is to be sure an immensely important and sometimes difficult task.

THE PROJECT'S SCIENTIFIC VALUE AS THE JUSTIFICATORY LINK BETWEEN MEDICAL VALUE AND HARMS TO THE ANIMALS

There is still one major missing piece that must be provided before it can be determined whether the value of a project justifies any harms it causes the animals. There must be a connection or link between the medical value of the project on the one hand, and any pain, distress, or other harms to the animals on the other, which allows the former to justify the latter. This connection is provided *by the project itself and by its scientific value*. If a project does not ask scientifically sound questions that would assist in understanding the disease or aspect of the disease under investigation, does not propose scientifically appropriate methodologies to answer such questions, or cannot succeed because the investigator does not have adequate facilities or staffing, the medical value of understanding the disease and of the project will be disconnected as it were from any pain or distress or other harms the project may cause the animals. It will, therefore, be impossible to appeal to the medical value to justify the harms. In contrast, if a project asks scientifically relevant questions, proposes sound methodologies, and has some likelihood of answering its questions, it will have a high level of scientific value. There will then be a scientific link between the project's medical value and any harms caused to the animals that will allow a determination of whether the former justifies the latter. Although the project may be unable to promise likely clinical applications at the time it is proposed (see discussion below), if it is scientifically sound it might provide knowledge that eventually could contribute to a clinical application. Moreover, the higher the scientific value of the project, the more likely the project will seem worth how it uses and treats the animals. A project with indisputably very high medical value and with exceptionally high scientific value that causes animals little or no unrelieved pain or distress will seem clearly justified; and such a project is likely to seem justified, even when there is some unrelieved pain or distress, and even if such pain or distress is significant, if this pain or distress is necessary to achieve project goals.

PREDICTABILITY OF RESULTS AND SCIENTIFIC VALUE

It is beyond the scope of this discussion to consider in detail the many ways in which various kinds of biomedical animal research can have significant scientific value. For purposes of understanding the harm justification principle, it is helpful, however, to note the relevance of the predictability of results to the scientific value and justifiability of biomedical animal experiments. As is recognized by several of the NIH criteria for scientific merit, an animal experiment *will* have very high scientific value if it *is* likely to lead to an important clinical application, such as a new and effective cancer drug. However, investigators who employ animal models can rarely claim their experiments are likely to result in clinical applications in humans, not because there is necessarily something wrong with their experiments, but because biomedical animal experiments rarely can promise likely

clinical applications. There are several reasons for this, which relate to the nature of biomedical research itself.

LIKELY LIMITED IMPACT OF SUCCESSFUL EXPERIMENTAL RESULTS

First, it will almost always be inaccurate and inappropriate to try to justify the harm any single animal research project may cause animals by claiming that this harm will be outweighed by the benefits associated with understanding and being able to combat the disease under study. No one project is likely to result in a complete understanding or treatment of a disease. Many experiments that investigate a disease about which much more needs to be learned will likely, even when successful, discover something that will add only a limited amount of knowledge to the understanding of the disease. However, even this limited value can justify harms the project does to the animals. The best that most individual projects *can* do is to achieve limited understanding of a disease. Moreover, if a project does contribute to understanding and conquering a disease, it will often be the results of the experiment, *together with the results of other animal research projects often of other investigators as well*, that will lead to understanding the disease. It is, therefore, unrealistic to demand, as does philosopher Bernard Rollin (1992, p. 140), that an animal research project is ethically justifiable only if "the benefit to humans (or to humans and animals) clearly outweighs the pain and suffering experienced by the experimental animals."

VALUE OF UNSUCCESSFUL PROJECTS

Science sometimes progresses by not succeeding. A hypothesis that one hopes to verify may prove incorrect, a general line of inquiry may not lead to fruitful results. Animal research projects that can be described as unsuccessful for such reasons may clear the way for eventual success by ruling out certain hypotheses, theories, or general approaches. Therefore, that an animal research project that seemed worth doing and ethically justifiable when begun fails to achieve its goals, does not imply the project was really not worth doing and did not justify harms it caused to animals. Unfortunately, it is usually difficult for investigators to learn, before doing an experiment, that a kind of experiment or procedure has been conducted by someone else and failed to yield valid or useful results. Journals usually do not publish reports of negative findings or failed experiments (unless included in reports of approaches that succeeded). Some investigators might understandably be reluctant to want to publish accounts of unsuccessful experiments. One of the major recommendations of the 2012 International Translational Research Task Force on epilepsy research, which was established to improve translation of animal experiments to clinical treatments of the epilepsies, was the exploration of acceptable and useful ways of disseminating negative experimental results (Galanopoulou et al., 2013).

UNPREDICTABILITY OF THE IMPACT OF RESEARCH RESULTS

An animal research project aimed at understanding a human disease may obtain results, the significance of which is unclear at the time of discovery. As Comroe and Dripps (1976) demonstrated, it often takes years, sometimes decades, for knowledge discovered by animal research to contribute to the understanding of a disease, in part because discoveries must sometimes await the results of research yet to be conducted. If an animal experiment aimed at understanding a human disease yields results that are not clearly applicable in understanding this (or another) disease, it would be unreasonable to conclude that years or decades may need to pass before it can be determined whether the project was ethically appropriate.

F6.3 Problematic Expressions of the Harm Justification Principle: "Harm–Benefit Analysis"

Investigators must pay careful attention to the harm justification principle, and not just because some procedures cause unrelieved pain, distress, or other harms. A widely endorsed interpretation of the principle appears to make it impossible for many experiments to justify the pain, distress, or harms they sometimes must cause animals. It is, therefore, essential that animal researchers, especially those engaged in basic research, insist that the harm justification principle not be interpreted improperly.

The *Guide* asserts the harm justification principle when it states (NRC, 2011, p. 27) that "due to their potential for unrelieved pain or distress or other animal welfare concerns," in certain protocols "the IACUC is obliged to weigh the objectives of the study against other potential animal welfare concerns." Although this statement does not use the words "harm" or "value" it clearly intends to ask that harms to animals be weighed against the value of experiments. In speaking of animal welfare concerns *other* than unrelieved pain or distress, the *Guide* recognizes that harm is the more general category of welfare problems to which research animals can be subjected, and that pain and distress, though critically important, are not the only possible harms that must be justified.

The *Guide's* statement of the harm justification principle does not attempt to specify or restrict the kinds of value that would justify various uses of animals. However, major difficulties for biomedical animal experimentation are created by some well-known expressions of the harm justification principle. These statements of the principle use the term "benefits" to refer to what *must* justify harms research animals experience, and they use the term "harm–benefit analysis" to refer to the process of justifying these harms. Moreover, by "benefits" these statements of the

harm justification principle usually mean *practical benefits*, such as discovery of a treatment for a disease. Additionally, these statements of the harm justification principle not only require "benefits" in this sense, but also require any experiment that harms animals to have, at the time it is proposed, a *high probability* or *likelihood* of resulting in such benefits. For example, as noted earlier, AAALAC interprets the statement from the *Guide* quoted previously to require an IACUC to conduct a "harm/benefit analysis," in which it would "weigh the potential adverse effects of the study against the potential *benefits* that are *likely to accrue* as a result of the research" (AAALAC, 2015, author's italics). The *EU Directive* demands a high probability of practical benefits when it asserts that investigators and review committees must engage in "a harm-benefit analysis of the project, to assess whether the harm to the animals in terms of suffering, pain and distress is justified by the *expected outcome* taking into account ethical considerations, and may ultimately *benefit human beings, animals or the environment*" (European Union, 2010, Art. 38 para. 2(d), author's italics). According to the Federation of European Laboratory Animal Associations (FELASA), "ethical evaluation should take the form of a harm-benefit assessment" (FELASA, 2005, p. ii), which consists of "considering ethical justification in terms of the balance of *likely benefit* over harm" (*id*., p. 20, author's italics).

WHY THE HARM JUSTIFICATION PRINCIPLE WHEN PROPERLY INTERPRETED SHOULD NOT REQUIRE LIKELY BENEFITS

If interpreted to require that any animal experiment project that causes animal pain, distress, or other harms must be likely to result in practical benefits, the harm justification principle would reject a great deal of potentially important biomedical animal research as unethical. Much of animal research is basic (in the objective sense) and cannot promise practical benefits at the time an experiment is proposed. Paradoxically, because some of the knowledge that basic animal research would discover will play a role in eventual clinical advances, requiring all animal research that might harm animals to be likely to produce clinical advances, will ensure that many clinical advances will never be made.

Moreover, even in the rare instance in which an investigator has good reason to think that an animal experiment, before it is begun, might lead to a clinical treatment for humans, it will often be impossible to maintain that there is a *likelihood* that this treatment will result from the experiment. Indeed, even after an animal experiment has been completed, and appears to have discovered a successful treatment in experimental animals, it will often be impossible to predict, before human trials are conducted, that the experiment will likely result in an effective and safe clinical application for humans. This is why human clinical trials are conducted.

PROBLEMATIC RESPONSES TO THE PROBLEM FOR THE HARM–BENEFIT ANALYSIS OF BASIC ANIMAL RESEARCH

Investigators should avoid and oppose two common and persistent responses to the problem that so-called "harm–benefit" analysis could eliminate much if not all basic animal research. Some have attempted to solve the problem by expanding the definition of "benefits" to include knowledge that is valuable for its own sake irrespective of whether it might ever contribute to practical benefits. It is also claimed that all, most, or (typically) an unspecified proportion of basic biological research will eventually contribute to clinical applications.

For example, in interpreting the UK ASPA, the Animal Procedures Committee (APC) established by the Act states that

> The "advancement of knowledge in biological or behavioural sciences" is a permissible purpose under Section 5(3) of the Act. Moreover, under the Act, such gains in knowledge are considered to be intrinsically valuable, and do not have to be instrumentally beneficial in order to provide an acceptable reason for using animals. In other words, they are considered to be actual benefits; they are not being judged simply on the basis of the potential or possible benefits to which they might lead. APC (2003, p. 49)

As discussed earlier, the view that it is permissible to cause animals harms, such as pain or distress, to obtain "intrinsically valuable" knowledge is abhorrent to many people, and could result in substantial public opposition to animal research if widely endorsed in the scientific community.

The APC also states that sometimes,

> although particular practical applications are not envisaged in research classified as fundamental, such research is usually carried out in areas identified as being of strategic importance, in which better knowledge can influence work more obviously directed at a practical application. For example, work to understand central nervous system receptor sites for chemicals produced in the brain could be classified as fundamental research, because the work is not directed towards any clearly identified practical application. But it is nevertheless apparent that the knowledge generated by such work could be used in research that is directed towards particular health care benefits in the future. APC (2003, p. 49)

This kind of general justification of basic animal research accords entirely with the general account of the harm justification principle presented in this chapter. In proposing the sort of experiment discussed by the APC, an investigator would—doubtlessly—characterize the potential medical value of the project by identifying a number of specific brain diseases the understanding of which the kind of knowledge sought in the project might advance. The investigator would also—correctly— observe that because these diseases involve or can be

affected by the functioning of brain chemical receptor sites, some of the knowledge the project might discover could some day assist in treating one or more of the specified diseases. What is problematic about the APC's characterization of this kind of experiment is the claim that the project is justified by harm–benefit analysis, as delineated by the UK ASPA, the *EU Directive*, and other statements of harm–benefit analysis quoted earlier. It is simply incorrect, and unhelpful, to try to make the case that the study described by the APC can promise *likely* or *expectable* practical benefits. About such a project one can and should say that it is in a *general area* of research in which *some* experiments can be expected, for good scientific reasons, eventually to contribute to the understanding of certain neurological disorders. It is for this reason that such a project can have high scientific value, if it asks clearly relevant or innovative questions about chemical receptors in the brain and if it proposes and can implement scientifically sound procedures to address these questions. It is on such matters relating to medical and scientific value that a determination of ethical appropriateness will focus, not on speculative and unverifiable claims of likely or expected benefits.

In 2016, a working group convened by AALAS and FELASA released a two-part report intended to explain and provide guidance to review bodies and investigators regarding "harm–benefit analysis" (Brønstad et al., 2016; Laber et al., 2016). The report will stimulate a good deal of useful discussion. Although it is beyond the scope of this chapter to examine the report in detail, two of its contentions are noteworthy here.

According to the report, "(b)enefits for human, animal or environment health are regarded as acceptable benefits to justify animal use as long as there are no alternatives. The intrinsic uncertainty whether promised benefits will be realized or not, must be compensated by strengthening the quality of the study to optimize the possibility of reliable known benefits" (Brønstad et al., 2016, p. 17). The second sentence appears to accord with the account of the harm justification principle presented in this chapter, as long as it is understood that "optimize" does not mean "make highly probable or likely." However, the AALAS–FELASA report also maintains that among what it calls "primary benefits" that can directly justify harming animals in research is "the intrinsic value of knowledge itself and the relevance of this knowledge in applications that are directly beneficial to humans and other species or the global environment and that sustain the quality and diversity of life" (p. 8). This statement appears to assert that intrinsically valuable knowledge itself sometimes justifies harming animals. The report also includes among "secondary" benefits that can justify harming animals when there also present a likely primary benefit, the "quest for knowledge" (p. 17), respect for which reflects "recognition of the intellectual arena,

the exercise of our creative imagination, rationality and problem-solving skills in the pursuit of the animal-based branch of science, which is part of our culture" (p.10).

It is not clear from the report when intrinsically valuable knowledge is supposed to constitute a primary or a secondary benefit. Nor is it clear when knowledge and associated intellectual activities are a secondary benefit, how strongly they can add to the justification of animal research harms. However, as noted earlier, a great many people believe that it is *never* appropriate to cause an animal pain, distress, or other harm in the pursuit of knowledge for its own sake. This view does not preclude using animals in research part of the *motivation* of which is pursuing knowledge for its own sake. However, this view does not countenance knowledge for its own sake as a sufficient or supplementary ethical *justification* for causing animals pain, distress, or other serious harms.

Like some others who attempt to reconcile basic animal research with the harm–benefit analysis, the AALAS–FELASA report also appears to make the fallacious claim that because many currently available clinical advances would not have been developed without past basic animal experimentation, current basic animal experiments can be counted on eventually to produce practical benefits. According to the report, "(w)hile basic research is burdened with some uncertainty regarding direct benefits, we have a long history of experience showing that basic research is beneficial for the development of society, especially with regard to taking advantage of technological progress" (p. 14).

F6.4 Further Needed Discussion of the Harm Justification Principle

In sum, I have suggested that what is needed is not harm–benefit analysis, but harm–*value* analysis, which includes but is not restricted to considering likely or expected benefits as a justification for causing animals pain, distress, or other harms. Much more discussion is needed to explain and apply such an analysis, and the harm justification principle. For example, as is observed below, there is some disagreement regarding what constitutes "harms" as understood by the principle, and greater consideration is needed regarding kinds of "value" that can justify various experimental uses of animals.

Another general issue that would be useful to consider is the extent to which projects that have higher scientific value, thereby justify causing more harm to animals. Determining scientific value (or "scientific merit" as understood by the NIH minus what I call medical value) is complex and requires balancing different criteria. For example, of two projects, *A* and *B*, that both seek to understand the same disease or aspect of the disease and thus have the same level of medical value, *A* might be judged by peer reviewers to have somewhat

more scientific value than *B* because, while both projects score well for significance, *A* is more innovative, because it examines novel methodologies for treating the disease. In such a case, it might not seem reasonable to conclude that because project *A* has somewhat higher scientific value than *B*, project *A* is justified in causing a somewhat higher amount of pain or distress to animals. On the other hand, if project *A* has a great deal more scientific value than *B* because of *A*'s innovativeness, *A* might well seem justified in causing significantly more pain to animals than *B*. Addressing such questions probably would require consideration of a large number of examples of research projects that involve varying levels of the components of scientific value. We might conclude that it is sometimes impossible to correlate different levels of scientific value with correspondingly higher or lower levels of justified animal pain or distress. It may sometimes or often be possible only to conclude that a given animal research project has *sufficient* value to cause certain harms to animals.

F7. The Harm Minimization Principle

An animal research project should cause no more harm (including pain or distress) to the animals than is necessary to achieve the scientific goals of the research.

This principle, which I shall call *the harm minimization principle*, is the more general and underlying foundation of the pain and distress minimization principle (F4), just as the harm justification principle (F6) is the more general and underlying foundation of the pain and distress justification principle (F5). The harm minimization principle holds that whenever a project causes animals something that would be classified as a harm, this harm should be minimized consistent with the project's goals. This principle follows from the ethical principles, discussed earlier, that one should not cause a harm or evil to an animal without a justifiable reason for doing so, and that to cause animals more harm than is necessary to achieve a project's goals is to cause harm that is provided no legitimate reason or justification by the goals of the research.

F8. The General Justification Principle

Whatever is done with or to animals in a research project (including but not restricted to causing harms, such as pain and distress) must be justified by the value of the project.

Questions about ethical justification of animal research typically involve research that causes or can cause harms to animals. The focus of ethical analysis in such cases is usually on whether the value of the research justifies these harms. As is discussed below, there are disagreements regarding what should be included in the definition of a "harm" to research animals. The term is typically used to refer at least to pain or distress, and not to much less

unpleasant experiences, such as very slight and brief discomfort. Merely using animals in a research project is not generally regarded as harming them, nor is euthanasia. If this is how harming research animals is understood, the majority—surely the great majority—of biomedical animal research projects do not cause *any* harm to animals. The only statistics available in the United States regarding how many animals experience pain or distress are compiled by the USDA for AWA-covered animals, which presently do not include mice and rats. In 2015, 445,972 or approximately 58% of the 767,622 AWA-covered animals did not experience any pain or distress and were not given any drugs to eliminate any pain or distress; 252,618 or approximately 33% would have experienced pain had drugs not been administered; and 69,032 or approximately 9% experienced some unrelieved pain or distress (APHIS, 2016b). Statistics issued by the UK Home Office (2016b, pp. 17–18), which include all vertebrate species, as well as cephalopods, indicate that for all procedures completed in 2015, 24% involved what the Home Office classifies as causing "moderate" harms (defined as causing "a significant and easily detectable disturbance to an animal's normal state, but this is not life threatening. Most surgical procedures carried out under general anaesthesia and with good post-operative analgesia (i.e., pain relief) would be classed as moderate"). Six percent of all procedures were assessed as "severe" (defined as causing "a major departure from the animal's usual state of health and well-being. It would usually include long-term disease processes where assistance with normal activities such as feeding and drinking are required or where significant deficits in behaviours/activities persist. It includes animals found dead unless an informed decision can be made that the animal did not suffer severely prior to death").

It is not the case that an animal research project that does not cause animals any harms is necessarily ethically justified. If a project has absolutely no scientific value, it is difficult to see how it is appropriate to use animals at all—even if the project would not cause the animals any harms, such as pain or distress. An animal experiment might lack scientific value because, for example, using animals will clearly not assist in answering the questions posed by the project; the questions the project seeks to address using animals are not relevant to the disease or condition supposedly under investigation; or the project repeats without variation an experiment that has been done before and regarding which no rationale can be provided for such repetition. One can object to such experiments on the grounds that they would involve a waste of money and animals that could be allocated to potentially valuable research. It also seems reasonable to think that employing animals in projects in which there is no legitimate scientific rationale for doing so constitutes an inherent misuse of the animals themselves,

a complete waste of them and of their lives if they are euthanized.

There is a well-known and widely accepted ethical principle that expresses the need to ensure that all animal research projects—those that do and those that do not harm the animals—are ethically justified. This is Principle F8, which I call *the general justification principle.* This ethical rule is stated in Principle II of the *US Principles* (OLAW, 2015b, pp. 4–5), discussed earlier. In asserting that "(p)rocedures involving animals should be designed and performed with due consideration of their relevance to human or animal health, the advancement of knowledge, or the good of society," Principle II does not explicitly or implicitly speak of harms. Principle II is reasonably interpreted as declaring that *whatever* is done to research animals must be justified by the value of the research. (To be sure, Principle II also identifies goods that, in its view, comprise the categories of research value; these are not included in the broad statement of the general justification principle offered here.) The general justification principle is the most general fundamental principle of animal research ethics. For the general justification principle includes the pain and distress and harm justification principles, and additionally includes *anything* that could require justification by the value of a research project.

F8.1 Applying the General Justification Principle to Projects That do and Those That do not Cause Animals Harm

When applying the principle to projects that cause harms to research animals, one would employ the harm justification principle component of the general justification principle, using an appropriate methodology for applying the harm justification principle. When applying the general justification principle to animal research projects that do not harm animals, one would apply a similar general methodology. One could begin by assessing the medical value of a project, and identify the use or treatment of animals the project must justify. One could then determine whether the project has sufficient scientific value to provide a connection between its medical value and the animal use that allows the former to justify the latter.

F8.2 Why Many Projects That do not Harm Animals Will be Easily Justified

When the general justification principle is applied to research that does not cause animals harm, it will very often be relatively easy to conclude that the research is justified, precisely because the treatment of animals to be considered does not rise to the level of a harm. As is discussed below, some people believe that a stronger showing of the value of a project is required to use or kill certain species in research (e.g., nonhuman primates), even if the research does not cause the animals any

"harms" as usually defined. However, for many research animals (e.g., mice and rats), most people would surely say that to justify simply the use of animals, and even their euthanasia, in a project that will cause them no pain or distress, there is not a great deal that the medical and scientific value of the project must justify. All the project must have is a legitimate scientific rationale for the animal use, that is, a scientifically sound reason for thinking that the project requires the use of animals, and that the project may answer questions relevant to an aspect of the disease under investigation.

To illustrate, consider the following example of a common use of animals that does not cause them "harms" as usually defined: obtaining cells or tissue for examination or further experimentation. An experiment with the general aim of understanding vision in mammals and eventually humans, euthanized mice after their arrival in the laboratory and harvested their retinas (Coombs et al., 2006). The investigators sought to determine whether certain staining techniques are superior in studying mouse retinal ganglion cells, and hoped to discover morphological patterns in these cells common to mice. One rationale for using mice was the investigators' view that because of possibilities of genetic manipulation of mice, the mouse retina may prove to be a valuable model for vision research. Although the project obtained the desired results, it was clearly ethically justified when proposed by its scientifically supportable and potentially successful aim of furthering understanding of the structure of the mouse retina. That the experiment would not cause any animal pain or distress ensured that the project's treatment of the animals was justified by its demonstrable scientific and medical value. Indeed, this project would have seemed ethically justified even if the investigators could provide just *some* reason for thinking they *might* discover *something* that might *some day* prove relevant to understanding mammalian and thus perhaps ultimately human vision.

This experiment illustrates why discussions of animal research ethics tend to focus on projects or kinds of research that cause animals harms, such as pain or distress. Nevertheless, it would be useful to consider a range of examples of experiments that do not cause animals harm. Such an examination might reveal that the threshold of justification for such projects is very low, and that the strongest objection against using animals in scientifically pointless experiments usually is that doing them is a waste of resources that could be allocated to valuable research.

F9. The 3Rs Principle

In designing and implementing animal experiments investigators should practice the "3Rs" of replacement, reduction, and refinement.

The so-called "3Rs," introduced by Russell and Burch in 1959, are so widely accepted, and are featured so prominently in laws and statements of principles of biomedical animal research ethics worldwide, that they must be regarded as belonging in the fundamental principles of biomedical animal research ethics. However, as is discussed in detail elsewhere (Tannenbaum and Bennett, 2015), there is considerable misunderstanding regarding what Russell and Burch meant by replacement, reduction, and refinement. There is also significant lack of clarity and disagreement about how the 3Rs ought to be defined, and about their underlying ethical justifications.

For the purposes of this discussion, it is sufficient to emphasize that Russell and Burch viewed all 3Rs as tools for minimizing research animal pain, distress, and fear. Their discussion of the 3Rs begins with

> consideration of the ways in which inhumanity can be and is being diminished or removed. These ways can be discussed under the broad headings of Replacement, Reduction, and Refinement. … Replacement means the substitution for conscious living higher animals of insentient material. Reduction means reduction in the numbers of animals used to obtain information of given amount and precision. Refinement means any decrease in the incidence or severity of inhumane procedures applied to those animals which still have to be used. Russell and Burch (1959, p. 64)

As is indicated by the beginning of this passage, for Russell and Burch, the *only* purpose of *all* the 3Rs is to diminish or remove what they call "inhumanity." They define "inhumanity" as "pain or fear inflicted on animals by man" (p. 15), as well as "distress of a certain degree (of whatever origin) … *which, if protracted, would lead to the physiological stress syndrome*" (p. 24). This is why their definition of "refinement" refers to a decrease in the incidence or severity of "inhumane procedures." (They understand "humanity" or "humaneness" as the absence of pain, fear, or severe distress.) For Russell and Burch, refinement aims, by definition, at minimizing pain, fear, and distress. Reduction can minimize pain, fear, and distress by using fewer animals that experience pain, fear, or distress. Replacement aims at minimizing pain, fear, and distress by substituting "conscious living higher animals" with "insentient material" that cannot experience pain, fear, or distress. Russell and Burch did *not* define "replacement" as not using animals; accordingly, they included in replacement the use of completely anesthetized vertebrates that do not experience any pain or distress during experimentation (p. 70). Additionally, although Russell and Burch are commonly said to have used the term "alternatives" to refer to the 3Rs, the word does not appear in their book. Indeed, Russell (who was responsible for most of the volume) never accepted the term because his overriding goal was not finding experimental methods that are alternatives to using animals,

but preventing or lessening research animal pain, distress, or fear (Tannenbaum and Bennett, 2015).

F9.1 Redefinition of "Replacement"

More recently, many—often citing Russell and Burch—have defined "replacement" as not using animals in research. For example, in its official policy on animal research, the AVMA states that it "endorses the principles embodied in the '3R' tenet of Russell and Burch (1959)," and defines replacement as "replacement of animals with nonanimal methods wherever feasible" (AVMA, 2016). The UK National Centre for the Replacement Refinement & Reduction of Animals in Research, sponsor of the ARRIVE Guidelines, defines "replacement" as "methods that avoid or replace the use of animals defined as 'protected' under the Animals (Scientific Procedures) Act" (NC3Rs, 2016). The *EU Directive* defines "replacement" as ensuring that "wherever possible, a scientifically satisfactory method or testing strategy, not entailing the use of live animals, shall be used" (European Union, 2010, Art. 4, para. 1). Such definitions appear to view replacement not as, or not just as, a means of eliminating or minimizing animal pain or distress, but as an aim that should be sought in its own right (Tannenbaum and Bennett, 2015). Rowan, for example, states that the "three Rs provide a broad-based approach to reducing both laboratory animal numbers *and* laboratory animal suffering" (Rowan, 1984, pp. 261–262, author's italics).

Those who define and promote replacement in the sense of not using animals rarely explain *why* investigators should try to use no animals, independently of the goal of minimizing pain and distress. It can be maintained that using no animals would reduce the expense of research, and that this would be a good thing in itself or might allow more research using the same financial resources; indeed, in enacting the AWA, Congress stated [Public Law 99-198, 1985, §1751(3)] that "measures which eliminate or minimize the unnecessary duplication of experiments on animals can result in more productive use of Federal funds." It can be argued that using no (or fewer) animals is preferable because using animals in research can be difficult, time consuming, or inefficient. It can be argued that eliminating use of animals in research is preferred by the public and thus would enhance public support for biomedical research. Perhaps the reason that no animals should be used is supposed to be that research animals are confined, or that many of them are killed. One or more of these arguments, or others, might well support not using animals. However, proponents of "replacement" as not using animals typically advance no reasons for this position. Perhaps some believe that it is just self-evident that it is better not to use animals in research than to use them.

Importantly, those who view replacement as a goal entirely independent of the aim of minimizing pain or distress appear to think replacement in this sense must be a goal of *all* animal research. It is supposed to be ethically obligatory to use no animals even if animals that are used experience no pain or distress, have a much better life than they would in natural environments, are "happy" when used in research, or are not killed during or after research. Some who define "replacement" as not using animals appear to believe that it is inherently wrong to use animals in biomedical research, and that when animals must be used because there is no alternative way of understanding a disease process, such research is an unfortunate necessary evil. It is clear why people would view using animals in biomedical research as inherently wrong if they believe that *all* uses of animals for any human purposes (such as for food) are unethical on the grounds that any human use of animals violates their moral rights (Regan, 2004.) However, this latter position does not seem to be held by many people in the research community who view not using animals in research as an end in itself. Their reasons for holding this view need to be made clear and explained.

F9.2 Redefinition of "Refinement"

Some people have adopted definitions of "refinement" that also depart from Russell and Burch's original definition. The *Guide*, for example, defines "refinement" to include not only minimization of pain or distress, but also providing animals "well-being" (NRC, 2011, p. 5), by which the *Guide* sometimes appears to mean the presence of positive, pleasant experiences. Such a definition seems to reflect a view that those who use animals in research have a general ethical obligation to provide these animals positive experiences, irrespective of the ability of such positive experiences to prevent or counter pain or distress (Tannenbaum, 2001; Tannenbaum and Bennett, 2015). The *Guide* does not indicate *why* well-being should be included in the goals of refinement. Buchanan-Smith et al. (2005, p. 382) concede that Russell and Burch restrict the purpose of refinement to the elimination of adverse experiences, such as pain or distress, and propose a new definition of "refinement" that includes providing positive experiences, such as well-being and happiness. One reason for this inclusion, they maintain, is that a purpose of refinement is improving the quality of research results, and in their view, happy and healthy animals increase the value, validity, and accuracy of scientific results. They also claim, without further explanation, that their revised definition is "in line with new developments in animal ethics and animal welfare science" (p. 384). For reasons outlined below, the claim that research animals are entitled to well-being or happiness is hardly self-evident and requires considerable clarification and supporting argument.

F9.3 The Need for Clarity and Argument

It would be useful for the field of biomedical animal research ethics to consider in depth how the 3Rs should be defined and what their goal or goals should be (Tannenbaum and Bennett, 2015). Sustained ethical discussion might demonstrate the advisability of including some pleasurable feelings among the goals of refinement, and might provide persuasive reasons for viewing replacement and reduction as ethically obligatory, independent of their capacity to minimize pain or distress. However, the only support that proponents of such views tend to offer are citations to Russell and Burch, who in fact did not view the 3Rs as anything other than tools for eliminating or reducing research animal pain, fear, and distress.

F10. The Species-Appropriate Housing Principle

"The living conditions of animals should be appropriate for their species and contribute to their health and comfort." US *Principles*, Principle VII (OLAW, 2015b, p. 5).

This rule, which I shall call *the species-appropriate housing principle*, is included in many professional association statements of principles of animal research ethics, as well as in governmental documents, such as the *US Principles*. One persuasive ethical basis for the principle is the pain and distress minimization principle. Species-appropriate living conditions often prevent pain or distress that might result when animals do not live or behave in certain ways that are natural to their species. However, it is possible to argue that research animals deserve species-appropriate housing that contributes to health and comfort because such housing does more than prevent or minimize pain and distress. For this reason, the species-appropriate housing principle raises conceptual, scientific, and ethical questions that require attention.

F10.1 Definitions of and Ethical Arguments for Research Animal "Well-Being"

One source of questions regarding the species-appropriate housing principle is the contention, which appears to be widely accepted in the research community, that a purpose of providing species-appropriate living conditions is to promote and enhance animals' "well-being." The *Guide*, for example, is replete with statements to the effect that "(t)he design of animal facilities combined with appropriate animal housing and management are essential contributors to animal well-being, the quality of animal research and production, teaching or testing programs involving animals, and the health and safety of personnel" (NRC, 2011, p. 41). The *Guide* further states that "(t)he primary aim of environmental enrichment is to enhance animal well-being by providing animals with sensory and motor stimulation, through structures and resources that facilitate the

expression of species-typical behaviors and promote psychological well-being through physical exercise, manipulative activities, and cognitive challenges according to species-specific characteristics" (pp. 52-53). Although the *Guide* contains definitions of many terms, it does not define or indicate clearly what it means by "well-being." The omission is important not just because the term is used frequently in the document, but because there are two different conceptions of animal "well-being" that have been used in the animal research community. Each of these conceptions reflects a different underlying *ethical* argument for providing well-being and species-appropriate housing for research animals.

WELL-BEING AS ABSENCE OF PAIN OR DISTRESS

Some commentators define research animal "well-being" as the absence of pain or distress. For example, Reinhardt (1993, p. 1) interprets the 1985 amendment to the AWA mandating environments for nonhuman primates conducive to their "psychological well-being" to require "that the barren cage environment of laboratory non-human primates must be enriched in order to ameliorate the adverse effects attendant upon chronic understimulation." Weed and Raber (2005, p. 120) define "refinement" (which will be considered further below) as "the use of methods that lessen or eliminate pain and/or distress and therefore enhance an animal's well-being." The NRC *Guidelines for the care and use of mammals in neuroscience and behavioral research* offers the identical definition (NRC, 2003, p. 10). Likewise, "comfort" provided by species-appropriate environments can be understood to mean the absence of discomfort or other kinds of distressful or negative feelings. Those who adopt such definitions of "well-being" or "comfort" employ the pain and distress minimization principle to justify the species-appropriate housing principle. They believe that one way of minimizing pain or distress animals can experience in research facilities is by affording them species-appropriate housing.

WELL-BEING AS INCLUDING POSITIVE FEELINGS AND EXPERIENCES

In contrast, "well-being" is sometimes understood to mean not just absence of pain or distress, but also the presence of positive experiences, such as certain pleasures, contentment, or happiness. Likewise, "comfort" can be understood as including certain positive experiences and not just absence of feelings of distress or discomfort. Those who employ definitions of "well-being" and "comfort" that include positive or pleasurable feelings believe that research animals deserve living conditions appropriate to their species and conducive to their comfort, in addition to, and independently of, their entitlement to minimization of pain or distress. For example, Buchanan-Smith et al. (2005, p. 382) use "the term 'well-being' to relate to both the physical health of the animal and to its psychological wellbeing." "The aim," they say, "should be not only to avoid or minimise adverse effects, but also to maximise well-being. This means that we must take a proactive approach in promoting the positive elements of welfare, such as companionship, comfort, and security." Indeed, they hold that one component of well-being is research animal *happiness*, asserting that "the enhancement of well-being has potential benefits to the science; 'happy' and healthy animals increase the validity and accuracy of scientific results." Rollin maintains that "all animals kept in confinement for human benefit" should be provided environments conducive to their psychological well-being and that accordingly the research community must "begin to seek animal-friendly housing, care, and husbandry systems that allow the animals to live *happy lives* while being employed for human benefit" (Rollin, 1995, Preface, n.p.).

The *Guide* sometimes rejects housing conditions that are not species-appropriate on the grounds that they result in pain, distress, or other significantly unpleasant experiences. For example, it is stated (pp. 50–51) that "(e)nvironments that fail to meet the animals' needs may result in abnormal brain development, physiologic dysfunction, and behavioral disorders … that may compromise both animal well-being and scientific validity. The primary enclosure or space may need to be enriched to prevent such effects." However, the *Guide* appears to adopt a concept of "well-being" that includes more than absence of pain or distress. It defines "refinement" as "modifications of husbandry or experimental procedures to enhance animal well-being *and* minimize or eliminate pain and distress" (NRC, 2011, p. 5, author's italics.). The *Guide* does not indicate what kinds of positive feelings or experiences it presumably includes within animal "well-being" and endorses as a reason for providing species-appropriate living conditions.

QUESTIONS ABOUT PROVIDING POSITIVE EXPERIENCES TO RESEARCH ANIMALS

Because the pain and distress minimization principle is unquestionably persuasive, it provides convincing ethical support for the species-appropriate housing principle. However, serious questions must be asked about the contention that research animals are entitled to positive experiences, such as pleasure, contentment, or happiness (Tannenbaum, 2001). These questions include how terms, such as "pleasure," "contentment," and "happiness" should be defined as applied to animals; whether and when it can confidently be said that research animals of various species experience these mental states; and whether, when, and how possibly

greater or lesser amounts of these states can be determined for various species. It must also be asked whether requiring pleasures or happy lives for research animals, assuming we know what this means and how to provide it, would hinder or preclude valuable research by greatly increasing its economic cost. Moreover, if providing a "happy life" or even more limited pleasures for *all* research animals is ethically obligatory, any experiment that must cause some unrelieved pain or distress, or is not consistent with animal happiness, might be unethical. Perhaps sustained ethical discussion will demonstrate that it is conceptually and ethically appropriate to interpret the species-appropriate housing principle to require positive feelings of pleasure, contentment, or happiness, for all or for some research animals. However, this interpretation should not be accepted without clearly expressed and persuasive arguments.

F10.2 Environmental Enrichment

A second source of the need for further thinking about the meaning and ethical foundations of the species-appropriate housing principle is the fact that providing such housing is now widely understood to require not just basic conditions, such as clean air and water and sufficient cage space, but also environmental enrichment. Although the AWA requires enrichment only for nonhuman primates [AWA, 2013 §2143(a)(2)(B)], the *Guide* maintains (NRC, 2011, pp. 52–54) that species-appropriate housing includes environmental enrichment for all species covered by the *PHS Policy*. In the biomedical research community generally, understanding and applying enrichment techniques to all species used in research is regarded as a major priority (Wolfle, 2005).

DIFFERING DEFINITIONS OF "ENRICHMENT"

One reason inclusion of enrichment in the species-appropriate housing principle raises issues regarding how and why the principle should be applied is that there is disagreement about how "enrichment" should be defined. As Newberry (1995, p. 230) observes, the term is sometimes used to refer to certain kinds types of environmental change (such as group housing or various kinds of feeding mechanisms), is sometimes defined as an increase in environmental complexity, and sometimes refers to positive outcomes for the animals' welfare. Lack of uniformity in definitions can make it difficult to engage in a discussion of enrichment and its ethical foundations.

DIFFERING VIEWS OF THE AIMS OF ENRICHMENT

Another source of difficulty in considering whether and why certain kinds of enrichment might be ethically obligatory is the fact that proponents of enrichment differ about whether enriched environments are ethically obligatory solely because these environments can prevent or ameliorate pain or distress, or also because they may sometimes result in positive experiences, such as pleasures, contentment, or happiness. All the authors quoted earlier regarding the nature of and ethical arguments for animal "well-being" are discussing not just well-being, but environmental enrichment, which they view as promoting well-being. Thus, inclusion of enrichment in the species-appropriate housing principle raises the same issues discussed earlier regarding whether and why providing certain kinds of positive experiences to research animals might be ethically obligatory.

POTENTIAL EFFECTS ON RESEARCH RESULTS

Also important in considering when investigators may be ethically required to provide enriched environments is the fact that there have been conflicting claims regarding whether enrichments of various kinds impact research results positively, negatively, or not at all (Bayne, 2005). There is evidence that at least in certain kinds of studies and for certain kinds of animals, enrichment can lessen deleterious effects of captive environments and can improve the validity, reliability, and replicability of research results (Garner, 2005; NRC, 2011, p. 54). On the other hand, various ways in which enrichment can make the housing environment more complex are sometimes not conducive to animal welfare, or can introduce variables that might adversely affect the quality of experimental data. Benefiel et al. (2005, p. 103) concluded, after reviewing a wide range of enrichment techniques in various kinds of research, that "not all—and maybe not most—forms of supplementation are beneficial for laboratory animals or good for research." As is discussed earlier, the strongest justification for using animals in a research project, and for causing pain or distress when necessary, is that the project has medical and scientific value. If enriched housing conditions would jeopardize the scientific results of a project, the justification for using the animals can be weakened. Assuring that enriched environments are good for the research, as well as for the animals is, therefore, an ethical, as well as scientific imperative.

F11. The Appropriate Care Principle

While housed in the research facility, animals must receive appropriate veterinary supervision and care, and the conscientious attention of trained animal care staff.

This principle, which I shall call *the appropriate care principle*, is based at the very least on the pain and distress minimization principle. Insofar as animals may be ethically entitled to positive experiences, such as certain pleasures, contentment, or happiness, it can be argued

that these experiences constitute part of the reason they should be afforded good veterinary care and skilled attention from animal care staff. The ethical obligation to provide such care and attention is also implied by Principle F12, because being kind, compassionate, and grateful to research animals involves attending to their medical and behavioral needs.

F12. The Appreciation Principle

Research animals should be treated with kindness, compassion, and gratitude.

What I call *the appreciation principle* reflects the fact that research animals do not volunteer for experiments. Additionally, most are kept in confinement, few can exhibit all their natural behaviors, and some experience unrelieved pain or distress. This is almost always done not for their benefit, but ours. Although research animals are incapable of volunteering, or of understanding or entering into a contract or bargain, surely in return for what they give up and provide, they are entitled to kind and compassionate treatment and care.

Gratitude for what research animals make possible is also important. One cannot express gratitude to animals in ways that they would understand as gratitude. However, there are tangible ways, aside from proper treatment during research and in housing and general care, in which gratitude sometimes can be expressed. One issue of increasing interest in the research community is whether, to what extent, and how investigators and research facilities should deal with animals that survive research projects. Aside from euthanasia, possible options for animals that are not diseased or disabled can include transfer to another investigator in the facility for use in research; transfer to another research institution; resettlement in a sanctuary where they will not be used in research (as has been the case for some nonhuman primates); or for some kinds of animals, adoption as pets. A survey of research institutions in the United States found that 71 of 177 IACUCs permitted adoption of animals as pets after use in research under specified circumstances (Huerkamp and Archer, 2007, p. 222). Adoption can be a tangible way of thanking some animals for their service to research. Difficult questions can be raised about adoption and other options that do not involve killing animals, for example, about appropriate criteria for choosing adoptive owners; about who should pay for or engage in efforts to adopt or place animals no longer needed by an investigator or institution; and about whether and when it may not be ethically acceptable to subject usable animals to still more research (and the possibility of pain or distress) by reusing or sending them to another research institution.

F13. The Translation Principle

Investigators should support, stay informed about, and when appropriate engage in scientific and professional efforts aimed at effecting translation of animal experiments to clinical applications.

The most significant general development in recent years in biomedical research arguably has been the emergence and development of the field of translational science and medicine. This general scientific endeavor is universally endorsed by investigators, government regulators, and funding agencies. However, what I call *the translation principle* is not yet routinely included in government or professional association statements of fundamental rules of biomedical animal research ethics. The principle belongs in any such statement. The translation principle is as important as any ethical rule relating to biomedical animal research because following the principle will likely facilitate application of the pain and distress and harm justification principles.

In light of the inherent complexity of disease, and the ways in which biomedical research progresses, it is unrealistic and unreasonable to demand that all animal experiments, when proposed, be likely to result in clinical applications for humans. However, as observed earlier, any likelihood that an experiment will lead to clinical applications will enhance its scientific value in justifying harms it might cause to animals. Therefore, if investigators could know that certain kinds of animal experiments or certain kinds of experimental procedures might be likely—or more likely than other kinds of experiments or procedures—to lead to clinical applications, they might be able to conduct experiments that provide increased justification for using animals, and for harms the animals might experience. Similarly, if investigators could know that certain kinds of experiments or procedures are not likely—or less likely than other kinds of experiments or procedures—to lead to clinical applications, they might be able to spare animals unjustifiable harms by not conducting such experiments.

It cannot be known at present whether advances in translational science will lead to a decrease in the total number of animals used in biomedical research, and thereby to a decrease in the total amount of research animal pain, distress, and other harms. Perhaps improved translation will reduce research animal numbers. However, it is possible that in certain areas of research, use of animals will become so much more productive in developing and testing clinical applications that more and not fewer animal experiments will be conducted. There may also be forces independent of translatability that could lead to use of more animals in total, such as the need to breed large numbers

of transgenic mice; required testing of advances suggested by experiments on this or other species on animals higher on the phylogenetic scale; or the development of kinds of animal experimentation that are at present unpredictable. On the other hand, more efficient translation might lead to a lessening of even these numbers.

The translation principle not only aims at properly treating animals, it also seeks to benefit and ensure the ethical treatment of humans. In areas where translation from animal studies to clinical applications has thus far been disappointing, development of treatments can be hindered by the reluctance of pharmaceutical companies and other funders to invest in animal experiments that will be needed to develop and test such treatments (O'Brien et al., 2013). Generally, conducting animal experiments that are more likely to produce clinical applications should allow government and private funding agencies to allocate available resources more efficiently, so that experiments can be directed toward the widest possible range of disease states, and can be conducted by as many talented investigators as possible.

As noted earlier in the discussion of the Nuremberg principle, humans are not only beneficiaries of biomedical animal research, we also occupy an essential role in the link between animal experiments and clinical applications. At least at present, it can rarely be known with certainty what most human clinical trials will find. However, the more probable that animal studies on which such trials are based will lead to clinical applications, the stronger the case that can be made to enroll human volunteers in associated clinical trials. Moreover, the more that can be learned about potential translation of animal studies on which human clinical trials are based, the more that can be told to potential volunteers about possible risks and benefits to them, so that they can exercise the best possible informed consent before they participate in these studies (Kimmelman and London, 2011).

11 PRACTICAL ETHICAL GUIDELINES FOR INVESTIGATORS

The preceding discussion suggests a number of practical ethical guidelines for investigators. These practical guidelines are designated as P1–P10.

P1. Approach all phases and aspects of an animal research project with the aim of making the project ethically as well as scientifically sound

Particularly good times to review the ethical soundness of a project are when one is thinking about the project as a whole; for many investigators this will be during the preparation of a grant proposal and of an IACUC animal use application. After a project has begun, anything that would require notification to the IACUC of a significant change in the nature of the research, such as a change in project goals, procedures, or numbers of animals [AWAR, 2015, §2.31(d); OLAW, 2015b, para. IV.B.7, p. 13], should be accompanied by consideration of whether any of these changes would affect the project's ethical appropriateness.

P2. Appreciate that as the source of the project's scientific goals, you play the key role in determining whether the project will be conducted ethically

See the discussion of the ethical importance of project goals and of the harm justification principle (Principle F6) earlier in this chapter.

P3. Keep in mind that the central question in the ethical assessment of a project is whether its value justifies its use and treatment of animals; that the value of a project consists of its medical and scientific value; and that the greater the value of the project, the more likely the project will justify its use and treatment of the animals

See the discussion of the harm and general justification principles (Principles F6 and F8) earlier.

P4. To be able to make the strongest case for the medical value of the project, always keep up-to-date information and documentation, which is readily understandable by laypersons, regarding the nature, effects, and need for further understanding about the disease or the aspect of the disease under investigation

An investigator who conducts serious animal research regarding one of the diseases discussed in this book will already have extensive knowledge about why it is important to gain further understanding of the disease or the aspect of the disease under study. However, it is useful to be able to include in a complete argument for the ethical justification of a project current information and documentation that can establish its medical value beyond a doubt. A comprehensive and detailed account of a project's medical value, in language that is understandable by laypersons, can also help investigators explain to members of the public why their work is important.

P5. Design the project with the maximum possible scientific value, by framing sound scientific questions that relate to the medical value of the project, by designing scientifically sound research procedures aimed at answering these questions, and by assembling facilities and staff that will enable the project to achieve its goals

This is what biomedical scientists always seek to do in the conduct of high-quality science. See the discussion of the harm and general justification principles (Principles F6 and F8) earlier.

P6. If the project has the potential to cause harms to animals, specifically pain or distress, but also any other significant unpleasant experiences, assure yourself that these harms are not only necessary to achieve project goals, but are ethically justified in light of the value of the project

See the discussion of the pain and distress justification principle (Principle F5) and the harm justification principle (Principle F6) earlier.

P7. In designing and conducting the project, take all reasonable steps to minimize any pain or distress that the animals may experience, consistent with project goals

As I have suggested, minimization of pain or distress may well be a subject regarding which investigators would find it helpful to have a number of specific ethical rules. Aspects of project design and execution that the pain and distress minimization principle can impact are numerous, and include the following: animal identification methods; anesthesia during surgery; use of analgesics for pain prevention or relief; methods of sampling blood and other tissues; injection sites and methods; kinds and duration of physical restraint; tumor size and location; forced exercise; aversive behavioral stimuli; use of adjuvants; deprivation of food or water; minimization of pain and distress in control animals; determination of humane endpoints; euthanasia; and training of researchers and research staff regarding appropriate handling of animals in experimental procedures. In the absence of more specific practical ethical guidelines for minimizing pain or distress—and perhaps even if such guidelines become available—investigators might consider the general approach suggested by Carbone (2007, p. 163):

> First, visualize every step in the animal's life from the initial point of contact (birth at the facility or arrival into the facility) until the animal's euthanasia or departure from the institution.

List every reasonable source of significant pain or distress, whether related to housing or the experimental procedures. Each of these potential sources of pain or distress should then be addressed, whether in a targeted literature search, consultation with peers who have published on the methodology, or consultation with veterinarians and animal care specialists, and with as much creative thinking as the investigator can muster.

P8. Regard your attending veterinarian as a constant source of information and guidance during all stages of the project

Laboratory animal veterinarians have expertise in minimization of pain and distress and in animal housing and care. As members of or advisors to IACUCs, they keep abreast of regulatory requirements. They have knowledge of kinds of biomedical research and experimental techniques and effects of these techniques on research animals. Consultation with a veterinarian during project design can help ensure that subsequent modifications required by legal standards will not be necessary. Veterinarians can also help ensure that a project is conducted ethically by assisting in eliminating or minimizing potential harms to animals in a project's design or implementation.

P9. Collect, read, and regularly consult publications that enunciate or apply ethical principles relevant to your research

See the earlier discussion of sources ethical guidance in conducting ethical research.

P10. Although you should follow legal requirements applicable to the project, when such requirements impose only minimum ethical standards, appreciate that conducting research ethically may involve exceeding these standards

As observed earlier, legal requirements sometimes impose important, but nevertheless minimum, ethical standards. Investigators should not ignore or put aside reasonable ethical questions relating to a research project on the grounds that the project may meet all ethical expectations that are required by law. The fundamental ethical imperative of using animals for good reasons and treating them properly and the importance of assuring public support of animal research are the only two reasons for trying to exceed legal standards if ethical requirements demand more. Another is that if investigators are thought by regulators or the public to be violating ethical standards that are not yet mandated by law, the result may be additional regulations and government supervision of research. This may not always

be salutary for ethical discussion, much less for research. Some issues in animal research ethics are difficult and complex. Regarding such issues, ethical deliberation may sometimes be best left open to debate, with possible approaches emerging widely and voluntarily, after extended consideration of varying viewpoints, rather than being imposed by legal edict.

12 SOME CURRENT DIFFICULT ISSUES IN ANIMAL RESEARCH ETHICS

There are issues in biomedical animal research ethics regarding which there is a lack of clarity or disagreement in the research community, and that require considerable thought because of their complexity and potential implications. One such issue, discussed earlier, is whether, to what extent, and why research animals might be entitled to positive experiences, such as pleasures, contentment, or happiness. Other ongoing ethical issues include the following.

12.1 The Nature and Weight of Harms to be Justified by the Value of Animal Research Projects

The harm justification principle holds that any harm (including pain or distress) that an animal research project will cause animals must be justified by the value of the project, and the more harm an animal research project will cause animals, the greater must be the value of the project. There are difficult issues regarding what counts as "harms" to research animals and how much weight such harms should be given in determining whether they are justified by animal research projects.

Unpleasant Experiences Other Than Pain and Distress

Pain and distress are clearly harms to research animals, and their nature, intensity, and duration must be weighed against the value of a research project. I suggest earlier that if pain and distress count as harms that must be justified by the value of animal research projects, some other negative experiences, such as fear (which is included by Russell and Burch among such harms), anxiety, and boredom sometimes might also have to be counted as harms. Whether and to what extent research animals, or some research animals can experience such emotions is a matter for further empirical investigation (Tannenbaum, 2001). Ethical discussion is also needed to determine the extent to which such experiences would constitute harms, and the value that various kinds of animal experimentation might need to outweigh these harms.

Frustration of an Animal's Nature or Telos

Some philosophers and animal welfare advocates believe that, as Rollin (1992) argues, the inborn nature or to use the Aristotelian term *telos* of animals is entitled to respect by people who use animals for their benefit. According to this view, preventing animals from engaging in certain kinds of natural activities harms them, in addition to and independently of any pain, distress, or other unpleasant feelings they may experience as a result. Though sympathetic to this view, Thompson (2010) concedes it has problems, the significance of which have not yet been adequately examined. For example, allowing animals to engage in natural behavior is sometimes inimical to their welfare by subjecting them to risks of injury or disease. It is also doubtful, I would suggest, that natural tendencies, irrespective of distress or severe discomfort their frustration might cause, are entitled to respect in their own right. Humans are programmed by our inborn nature to grow old and die. Yet much of medical science seeks not only to change this process from what it would be if nature were allowed to take its course, but to postpone and perhaps even eliminate this natural process altogether. If some natural behaviors or tendencies are good and others are bad, it cannot be just the fact that they are natural that make them so. If there is something wrong in restricting some natural behaviors of research animals, other than the fact that animals may experience pain, distress, or other unpleasant feelings, what this is needs to be identified and explained. If preventing research animals from engaging in certain behaviors is in itself harming them, it also would have to be determined how strong such harms are and how strongly they might count against conducting certain kinds of research.

Killing Research Animals

There is a disagreement in the animal ethics and animal welfare literature regarding whether death in itself (i.e., death irrespective of whether it occurs with pain or distress) constitutes a harm to animals. Some thinkers (Regan, 1983, pp. 99–103) argue that death is a misfortune or harm for animals and that killing inflicts harm on them because it prevents them from having a future life. Others (Cigman, 1981, pp. 53–59; Webster, 1994, p. 15) maintain that killing animals does not harm them or their welfare because they do not have a concept of life and a desire to live, or a concept or a fear of death. The prevalent view in the research community appears to be that whether or not killing animals harms them, the fact that a research project kills animals is not relevant to determining whether the project is ethically justified. Cancer researcher Harold Hewitt (1981, pp. 169–170) accurately characterizes the prevailing position.

I must confess that my own concern is really not with the number of animals (used in an experiment), in the sense that I should be more upset by my having caused one animal to suffer by my neglect or ineptitude than I should be by administering euthanasia to 50 at the termination of an experiment in which none had been caused suffering. The question the prospective animal experimenter has to ask himself is whether he considers that the painless taking of animal life is itself an immoral act. For me it is not. ... I do not see the moral distinction between the taking of an animal life in the laboratory, in the slaughter house, or in the course of pest control.

This view is reflected in the AWA and HREA, neither of which requires that killing animals be justified on scientific grounds, and regarding killing require only that killing be done without causing pain or distress [AWAR, 2015, §1.1, §2.31(d)(xi); OLAW, 2015b, para. IV.C.1.g, p. 14]. In many years discussing animal research ethics with investigators, IACUC members, and veterinarians, I have encountered an increasing number of people who believe that killing certain kinds of animals, specifically nonhuman primates and cats and dogs, necessitates a stronger justification than does killing mice, rats, or fish, for example. If this view represents a trend in the research community and society generally, the issue of the ethical relevance of species will become increasingly important in discussions of biomedical animal research ethics.

12.2 Ethical Relevance of Species and Species Characteristics

The IOM Chimpanzee Report

In 2011, a committee appointed by the NRC IOM issued a report on the use of chimpanzees in biomedical and behavioral research (IOM, 2011). The committee recommended that chimpanzees be used in research only if the "knowledge gained is necessary to advance the public's health" and only if there is "no other research model by which the knowledge could be obtained, and the research cannot be ethically performed on human subjects." (p. 4) The committee also stated (p. 15) that "imposing requirements for justifying the use of higher species is an implicit recognition that use of higher animals comes at higher moral costs." In 2016, exceeding the restrictions on chimpanzee research recommended by the IOM report, the NIH (2016a) decided not to fund any new projects or renewals or revisions of ongoing projects involving chimpanzees, with the exception of projects involving noninvasive research. Among the matters the NIH regards as "noninvasive" are "visual observation," "behavioral studies designed to improve the establishment and maintenance of social groups," and "collections of biological materials (e.g., saliva, oral or other cavity specimens, urine, feces, or hair) obtained voluntarily from a chimpanzee that has been trained through positive reinforcement to cooperate in the collection. This excludes venipuncture or other more invasive methods."

The Relative Moral Cost View

Whether one agrees with the IOM committee's recommendations or the NIH's decision regarding chimpanzees, there are some, probably many, people who believe that using certain species in research requires stronger ethical justification than does using other species. I shall call this the "relative moral cost view." This view does not imply that harms, such as pain and distress, are less important to minimize and justify in certain species than in others. Pain and distress are evils for any animal that can experience them, and investigators are ethically obligated to cause only the minimum necessary amount of justifiable pain or distress to achieve research goals. Nor does the relative moral cost view involve the claim that because of their mental capacity some species (e.g., nonhuman primates) may be capable of experiencing more pain or distress than other species, and research causing pain and distress in these animals may, therefore, require a higher value to justify this higher level of pain or distress. As commonly expressed, the relative moral cost view holds that a stronger justification—that is, a higher value of a research project—is required simply to use or kill certain species, even if the research causes these animals no pain or distress.

Criteria for Ranking Species

The relative moral cost view raises many difficult questions. First, if species are to be ranked, persuasive criteria are needed for such ranking. In speaking of "higher animals," the IOM report appears to suggest that the criteria to be used relate to characteristics, such as mental sophistication and complex emotions. These criteria may effectively distinguish nonhuman primates from other animals, but may not do justice to all discriminations that many people seem to want to make. For example, doubtlessly many people think a stronger showing of the value of a research project must be made for using and killing dogs than pigs. However, pigs are extremely sophisticated mentally and socially, perhaps no less so than dogs. What seems to distinguish pigs from dogs is not that dogs are "higher" animals, but that in many countries dogs are beloved pets and pigs are food. Rowan and I have suggested (Tannenbaum and Rowan, 1985) a number of criteria for distinguishing species in ways that support demanding a stronger showing of the value of research in using certain species. These criteria include whether animals exhibit self-awareness, their mental complexity, the complexity of their natural social behavior, and whether and how they interact with human beings. These criteria support the widely held view that using

monkeys, cats, and dogs, for example, requires a stronger justification than using mice or rats. Moreover, the criteria suggest that many peoples' inclination to require a stronger justification for using dogs than pigs in research is supported by the regular (and often emotional) involvement of people with dogs. However, it is not clear why this cultural and historical preference for dogs over pigs would *justify* requiring a higher value of research for one of two species with comparable mental and behavioral capacities.

Number of Ranked Categories

If species are to be ranked, it must also be decided how many categories of ranking should be employed. It can be argued that if it makes scientific and ethical sense to rank species for the purpose of justifying their use, we should separately rank *all* species commonly used in research. This might involve placing all species along a spectrum, presumably with chimpanzees at the high end, with amphibians and fish, for example, far down the scale. One might then assign a different level of moral cost to the research use of each species, and require a stronger justification for use in research the closer each species is located toward the chimpanzee end of the spectrum. One can only begin to imagine the arguments this approach would engender. Some people might argue, for example, that baboons should be distinguished from and ranked higher than other monkeys. Some might argue that rabbits are higher on the scale than hamsters or guinea pigs, or that hamsters or guinea pigs are or are not higher than rats or mice, that rats are or are not higher than mice, and so on.

Alternatively, one could argue for a smaller number of ranked categories, some or all of which would consist of multiple species. Such an approach might place chimpanzees in the first category, other nonhuman primates next, dogs and cats in the next category, and then perhaps all other species. Perhaps baboons would be distinguished from other monkeys and placed in a separate category closer to the chimpanzee end of the spectrum. Perhaps rabbits would be recognized as a separate category closer to chimpanzees than guinea pigs or hamsters. These and other possible ways of recognizing ranked categories would presumably be based on whatever criteria are regarded as appropriate for ranking. There could well be vigorous disagreements about how many groupings there should be, and the species membership of these groups.

Research Implications of Species Rankings

Finally, if species are to be ranked, it must be determined how much moral cost is associated with each ranked group or species, so that it can be determined how much value a given animal research project must

have to outweigh this cost. Moreover, it might be necessary to determine whether certain ranked groups or species may be used in certain, but not other kinds of research. For example, it might be deemed appropriate to use monkeys in research aimed at understanding diseases, such as AIDS and Ebola, but not in certain kinds of behavioral studies.

The aim of this discussion is not to reject ranking or some ranking of research animals. What is needed is a great deal of further discussion and supporting argument, *if* we want persuasively and consistently to rank various species for the purpose of determining how strong a showing must be made of the value of experiments before these species may be used in research or certain kinds of research.

13 GENERAL SUGGESTIONS FOR INVESTIGATORS

The following suggestions are offered to investigators for engaging in activities beyond the laboratory setting.

S1. Communicate to the public the nature and potential benefits of your research, and the ethical values and standards you apply in all phases of your work

As observed earlier, public support is essential for the continued conduct and funding of biomedical animal research. No one can speak more knowledgeably and persuasively about the nature, potential benefits, and ethical conduct of biomedical animal research than investigators. No one can speak more knowledgeably and persuasively about the value and ethical appropriateness of individual biomedical animal experiments than the investigators who conduct these experiments (Nature, 2011; Ringach and Jentsch, 2009).

S2. Become familiar with some of the animal research ethics literature

Some investigators may find the animal research ethics literature inaccessible or unwelcoming. Much of this literature employs specialized philosophical or legal terminology and theories with which scientists may be unfamiliar. Moreover, as one philosopher (a critic of animal research) correctly observes, "more is written in moral opposition to animal experimentation than in its support" (Nobis, 2011, p. 298).

There are a number of reasons animal researchers should not avoid or ignore the academic animal research ethics literature. Animal activists who seek to eliminate all animal research derive their opposition and many of

their public relations and political tactics from the views of academic philosophers and lawyers (Conn and Parker, 2008; Miller, 2011; Regan, 2004; Smith, 2010). At the very least, researchers should be familiar with the underlying beliefs of animal research opponents.

Additionally, there is much in the animal research ethics literature to which investigators can respond on empirical grounds. Two fundamentally different approaches have been adopted by opponents of animal research. What is typically called the "animal rights" approach, maintains that using animals for the benefit of humans or other animals is an inherent violation of these animals' moral rights, whatever benefits such uses might bring to humans or other animals (Francione, 2000; Regan, 1983, 2004; Wise, 2001). There is some disagreement among proponents of this approach regarding what kinds of animals have such rights and why. However, all such animal rights proponents agree that is wrong to use mammals in research, even if this research results in medical benefits for people or animals, and even if the research causes the animals no pain or distress, or does not involve killing them. However, there are philosophers and other critics of animal research who base their opposition on what they claim in fact results from or happens to animals in research. For example, Peter Singer, the author of *Animal liberation* (1975), objects to animal research on the grounds that in his view it results in no medical benefits, or that benefits it does bring to people or animals are greatly outweighed by pain and suffering which (he claims) experimentation causes animals. Using their knowledge of animal research and of their own projects, investigators can argue against this kind of objection by pointing to what animal research has discovered and how research animals are actually treated.

Finally, as discussed earlier, there are unresolved difficult ethical issues in animal research ethics. Contributions to discussions of these issues by advocates of *all* viewpoints will be encouraged, if animal researchers take an active and continuing interest in philosophical and legal debates about animal use in general and animal research in particular.

There are publications that investigators will find accessible and that can ease one into the animal research ethics literature. Among these are general accounts of current and historical controversies (Conn and Parker, 2008; Rudacille, 2000; Smith, 2010), collections of papers that discuss general ethical issues in animal research (Kraus and Renquist, 2001; Paul and Paul, 2001), and the autobiography of a prominent animal researcher (Morrison, 2009). These publications are more sympathetic to biomedical animal research than is much of the philosophical literature, but for this reason provide good starting points for further reading.

S3. Participate in discussions of ethical issues relating to biomedical animal research

Investigators play the key role in ensuring the ethical conduct of biomedical animal research. It is, therefore, essential that you participate in discussions of ethical issues relating to animal research and contribute your perspectives and expertise to the debates. If you are at an academic institution, organize, participate in, or attend courses or lecture series that discuss animal research. If you are at an academic institution or conduct research in a corporation or a government agency, encourage your colleagues to sponsor seminars and discussions about biomedical animal research ethics. Organize or attend sessions on animal research ethics at meetings of professional associations. Wherever and whenever you can—as you conduct your projects, among scientific colleagues, in interactions with the public—be eager and ready to think and talk about the ethical principles that motivate and guide your work.

1 INTRODUCTION

Behavioral management is a term that entered the lexicon of animal care at the end of the last century (Weed and O'Neill-Wagner, 2006). Broadly, it refers to animal care practices and items that we provide to captive animals to manage their psychological and behavioral needs. It incorporates both social and nonsocial environmental enrichment, as well as positive reinforcement training (PRT), facilities design, positive interactions between caretakers and animals, and behavioral monitoring and assessment to promote psychological well-being

for captive animals (Bloomsmith and Else, 2005; Keeling et al., 1991; Weed and Raber, 2005). All animals evolved distinct behavioral patterns and repertoires, including social behaviors, foraging behaviors, and antipredator behaviors, to promote survival in a complex environment. Compared to natural environments, captive settings are usually rather simple, and do not always allow for the expression of all of these behaviors, which can lead to frustration, boredom, stress, and even the development of abnormal behaviors. Enrichment provides a way to functionally simulate the natural environment of captive animals, in an effort to increase opportunities for the expression of species-specific behaviors.

Environmental enrichment (EE) is just one component of a comprehensive behavioral management program for addressing the behavioral and psychological needs of captive animals. Most institutions devote considerable resources to ensure that varied and species-appropriate behavioral management programs are provided for their animals. Further, many organizations, particularly those that house nonhuman primates (NHPs), have one or more staff members dedicated to providing enrichment for their animal subjects (Baker, 2016). Enrichment is now provided to all vertebrate animals; not only to mammals, but also to birds (Meehan et al., 2004; Nager and Law, 2010), reptiles (Almli and Burghardt, 2006), amphibians (Tinsley, 2010; Torreilles and Green, 2007), and fish (Kihslinger and Nevitt, 2006; Williams et al., 2009).

Enrichment as a field of scientific inquiry has undergone considerable growth over the past few decades. In the past, toys or other items were given to animals without much thought. Today, enrichment programs are recognized as integral components of animal care practices (National Research Council, 2011). Further, they are often approached from an empirical scientific perspective, with many, particularly those involving NHPs, overseen by PhD-level staff (Baker et al., 2007). The past decade or so has seen a dramatic increase in the number of published scientific papers that address environmental enrichment (Simpson and Kelly, 2011). A recent (2016) PubMed search using the keyword "environmental enrichment" produced over 1500 results, of which over 1100 were published in the past 10 years (unpublished data). Interestingly, the majority of these manuscripts were not authored by animal welfare scientists, but rather by biomedical scientists (de Azevedo et al., 2007), illustrating the dual applied and basic science natures of enrichment. Animal welfare scientists, including behaviorists, zoo biologists, and others, examine enrichment and its effects on the psychological well-being of captive animals, in an effort to improve the lives of these animals. Neuroscientists, and other biomedical scientists, utilize enrichment to model environmental effects on a variety of behavioral, neurobiological, and physiological outcome measures.

In this chapter we examine the use of environmental enrichment in both applied and basic science contexts; as a welfare tool and as an experimental model. We will briefly discuss whether enrichment increases variability in research protocols, and will present some practical tips on ways to implement an effective enrichment program for laboratory animals.

2 ENRICHMENT AND WELFARE

2.1 Why Enrich?

Two of the primary goals of enrichment are to reduce stress and improve the psychological well-being of research subjects. Animals living in a laboratory are exposed to a variety of stressors in their daily lives (Morgan and Tromborg, 2007). Some experimental procedures to which these animals are exposed can be aversive, and even common husbandry practices, such as cage changes or physical restraint, may be stressful. Environmental factors, such as lighting, noise, and temperature, may also cause stress for some species or individuals (Morgan and Tromborg, 2007). In addition, laboratory animals often live in enclosures that restrict their ability to express species-typical behaviors. EE can help alleviate the effects of potential stressors associated with captive conditions, enhancing both physical and mental health for subjects. Importantly, in addition to reducing stress, enrichment can also foster resiliency to stress (Novak and Suomi, 1988). It is neither possible nor, in many cases, desirable to eliminate all stress experienced by animals. Stressors are not intrinsically detrimental (Novak and Suomi, 1988), and can even be adaptive, relieving boredom, and helping animals learn to cope with various factors in their environment (Newberry, 1995). Enrichment and behavioral management techniques have been shown to mitigate stress responses to aversive stimuli (including predator odors) in a variety of species, including rodents (Benaroya-Milshtein et al., 2004), birds (Reed et al., 1993), and snakes (Almli and Burghardt, 2006). Enriched animals show less fear and are less responsive, both behaviorally and physiologically, to negative events, such as exposure to predators or certain experimental procedures, compared to animals in a nonenriched environment (Barbelivien et al., 2006; Klein et al., 1994; Moncek et al., 2004; Sampedro-Piquero et al., 2016). Responding appropriately to stress is widely considered an important indicator of well-being in captive animals (Novak and Suomi, 1988; Overall and Dyer, 2005). Not only can enrichment modulate the stress response, but it also may help to reverse the effects of early adverse experiences on hypothalamic-pituitary-adrenal (HPA) function (Francis et al., 2002).

There are both ethical and scientific motivations to provide the best possible environment for laboratory animals. Scientists using animal models in research recognize their ethical responsibility to attend to, and enhance, the psychological well-being of their subjects (Coleman, 2011; National Research Council, 2011). In addition, the reduction of potentially confounding captivity-related stressors, through the use of enrichment, can improve the quality and utility of animal models. It has long been established that highly stressed animals are not reliable subjects for most scientific studies except, perhaps, for those examining the effects of stress. Psychosocial and environmental stressors can alter the HPA axis, as well as cardiovascular function (Gerber et al., 2002; von Holst, 1998) in laboratory animals. Reproductive and immunological functions may also be compromised by emotional stress (Bethea et al., 2008; Rogers et al., 1999). These physiological and immunological changes can affect a variety of research outcomes. Because individuals can vary widely in their physiological and behavioral response to stress, it can increase experimental variability (Schapiro, 2000; Weed and Raber, 2005). Additionally, stressed or emotionally compromised animals have a greater risk of becoming ill or developing maladaptive behaviors, such as self-directed aggressive behavior (Novak, 2003), which can also adversely affect research. Therefore, identifying ways to reduce stress for laboratory animals is important to maximize scientific validity.

Not only does enrichment help to improve well-being, but it can also result in improved safety for caregivers. Working with calm, cooperative animals is safer for care staff than working with highly stressed, and potentially reactive, animals (Bloomsmith, 1992). Van de Weerd et al. (2002) found that mice from an enriched environment were easier to handle (e.g., exhibited more relaxed behavior) compared to mice from a standard environment. Dogs reared in an environment in which they were enriched with a great deal of human interaction were more outgoing, easier to work with, and less likely to bite handlers compared to those reared without human interaction (Adams et al., 2004; Fox and Stelzner, 1966).

2.2 Common Abnormal Behaviors Seen in Captivity

As mentioned earlier, one goal of enrichment is to reduce abnormal, or maladaptive, behaviors. Abnormal behaviors are generally defined as behaviors that deviate from those that are typical of the species (Garner, 2005). They can also include normal behaviors expressed at unnatural levels or at inappropriate times (Garner, 2005). Abnormal behaviors in laboratory animals can take many forms; it is beyond the scope of this chapter to provide a comprehensive review of these behaviors. Instead, we will provide a brief overview of those abnormal behaviors that are most common and/or most problematic to laboratory animals.

One of the more pervasive maladaptive behaviors seen in captive animals is stereotypical behavior (Garner, 2005). Stereotypies, often defined as repetitive behaviors without obvious function (Mason, 1991), are seen in numerous species of animals that live in a variety of captive settings, including zoos, sanctuaries, and research facilities (Mason and Latham, 2004). Pacing, or repetitive movement over the same path, and other whole-body locomotor behaviors, such as jumping, twirling, and rocking are common stereotypical behaviors for laboratory animals. Variations of these behaviors are seen in NHPs (Gottlieb et al., 2013a, 2015; Lutz et al., 2003), rodents (Garner, 2005; Latham and Mason, 2010; Würbel et al., 1998), pigs (Puppe et al., 2007), and birds (Meehan et al., 2004; Polverino et al., 2015), and have even been reported in fish (Kistler et al., 2011). Bar biting or mouthing is relatively common in rodents and pigs. Stereotypies can also include self-directed behaviors, such as hair pulling, eye poking, and self sucking, which have been reported in NHPs and dogs (Lutz et al., 2003). Regardless of its manifestation, the most commonly posited etiology is thought to be suboptimal housing conditions, such as a barren environment with insufficient external stimuli to meet the animals' behavioral needs (Meehan et al., 2004; Swaisgood and Shepherdson, 2006). For example, captive gerbils housed without substrate conducive to digging (an intrinsic behavior) often develop stereotypic digging behavior (Wiedenmayer, 1997).

Alopecia, or loss of hair, fur or feathers, is a relatively common condition for captive animals (Novak and Meyer, 2009). There are many potential etiologies for such loss of hair or fur, including bacterial or fungal infections, parasitic infestations, compromised immune function, and nutritional deficiencies (Honess et al., 2005; Kramer et al., 2010; Novak and Meyer, 2009; Steinmetz et al., 2005), as well as certain behavioral patterns. Behavioral etiologies for hair loss include self-epilating behaviors, such as hair pulling in primates (Honess et al., 2005), barbering in rodents (Garner et al., 2004; Kalueff et al., 2006), and feather pulling in birds (Garner et al., 2006; Grindlinger and Ramsay, 1991). Group-housed animals may execute these behaviors on conspecifics. Psychogenic alopecia, thought to arise from excessive grooming due to anxiety and conflict, is relatively common in dogs and cats (Gross et al., 2005). Social or environmental stresses have also been hypothesized as potential underlying factors in the development of alopecia (Reinhardt, 2005; Reinhardt et al., 1986; Steinmetz et al., 2006), although this is not a universal finding (Kramer et al., 2010). Regardless, alopecia, particularly in NHPs, is highly visible to

regulatory inspectors (e.g., USDA in the United States) and is thus of concern for many facilities.

The maladaptive behavior of greatest concern for laboratory animals is self-injurious behavior (SIB). Seen most commonly in NHPs, SIB includes behaviors such as self-biting, head banging, damaging hair plucking, and other behaviors that could cause injury to the individual (Novak, 2003). SIB can result in significant tissue or muscle damage and infection, and thus can compromise the well-being and welfare of the individual. Inadequate socialization early in life (e.g., rearing in a nursery without the mother) has been identified as the biggest risk factor for the development of SIB in macaques and other primates (Bellanca and Crockett, 2002; Novak, 2003; Rommeck et al., 2009). Common husbandry practices, such as relocating animals to new rooms, can exacerbate bouts of SIB in animals with a history of the behavior (Davenport et al., 2008). In rodents, SIB is typically induced by exposure to caffeine and other stimulants (Kies and Devine, 2004).

2.3 Types of Enrichment

Enrichment is often broken down into five basic and overlapping categories (Bloomsmith et al., 1991; Keeling et al., 1991); social (housing gregarious species in groups or pairs), physical (perches, platforms, huts, toys, and other objects that can be explored or manipulated), food (novel food items, or objects that increase foraging time), sensory (televisions, radio), and occupational (physical and mental activity, including PRT). These enrichment options are not utilized equally by all species. For example, television and radios are often provided for NHPs, but may not be of value to mice and rats. Ideally, laboratory animals should receive multiple forms of enrichment. In the following sections we provide selected examples of these types of enrichment, with some benefits and potential costs for each.

2.3.1 Social Enrichment

Most common laboratory animals are social, and live in complex societies in the wild [e.g., fish, rodents (Baumans, 2010; Koolhaas, 2010), rabbits (Cowan, 1987), dogs (Serpell, 1996), New (Fragaszy et al., 2004; Williams et al., 2010), and Old (Wolfensolm, 2010) World monkeys, and chimpanzees (Wrangham et al., 1994)]. For these species, housing them with compatible conspecifics is one of the most effective forms of enrichment. Such housing allows individuals to engage in many species-typical behaviors, including social play and social grooming (Hutchinson et al., 2005). It has also been shown to reduce abnormal behaviors in rabbits (Chu et al., 2004), dogs (Hubrecht et al., 1992), and NHPs (Reinhardt, 1999; Weed et al., 2003), and to improve wellness in NHPs. Rhesus macaques housed in groups (i.e., with social

enrichment) have enhanced immune function compared to those living in individual cages (Schapiro et al., 2000). Importantly, social housing can prevent abnormal behaviors (including SIB) from occurring in a number of species, including NHPs (Lutz and Novak, 2005), rabbits (Chu et al., 2004), and sheep (Dwyer, 2009). Further, social companionship can buffer individuals against external stresses (Balcombe, 2006; Epley, 1974; Gerber et al., 2002; Gust et al., 1994) and reduce cortisol levels (Fuentes and Newgren, 2008).

Social housing can be accomplished by housing animals in pairs or in groups. It is important to understand the behavioral biology of the target species before making decisions about how best to engage them in social housing. While many Old World monkey species live in multimale, multifemale groups, Hamadryas baboon groups have a harem structure, with only one male; multimale, multifemale groups in captivity would likely result in unacceptable levels of aggression.

While social housing can greatly improve the well-being of captive animals, it is not without risk, and can lead to aggression, as individuals establish their place in the dominance hierarchy. A certain degree of aggression is to be expected. Individuals do not always need to be separated at the first sign of fighting, even if there is some minor wounding. The benefit of social companionship often outweighs the cost of minor wounds to the individual. However, this may not be true for severe trauma or escalated aggression. The degree of "acceptable" aggression depends on many factors, including the species and the type of individuals (e.g., aggression might be less tolerable when infants or frail animals are involved). Refer to Olsson and Westlund (2007) for a review of social housing for rodents and NHPs.

Thus, it is important to find compatible partners. Many factors can influence compatibility, including the species, strain (Crawley et al., 1997), and sex (Latham and Mason, 2004) of the animals. Within rodent species, mice tend to be more aggressive than rats. Further, female mice tend to fight less than male mice, particularly during mating season. Adding enrichment (e.g., nesting material) can reduce aggression in socially housed male mice (Van Loo et al., 2002). Intrinsic traits, such as temperament, may also influence compatibility, at least in macaques. Female rhesus macaques tend to be more compatible with temperamentally similar, rather than temperamentally dissimilar, conspecifics (Capitanio et al., 2017; Coleman, 2012).

Humans can also serve as social enrichment for laboratory animals, particularly dogs and NHPs. Dogs are unique among laboratory animals in that they have evolved a well-developed bond with humans. As such, positive interaction with human handlers is an effective form of enrichment for laboratory dogs (Overall and Dyer, 2005). Socializing dogs with humans, particularly

when they are puppies, allows them to learn appropriate social cues and behaviors (Adams et al., 2004). It has also been shown to reduce stress in dogs. Simply petting a dog can increase affiliative neurotransmitters, including beta endorphins, for both the dog and the human (Odendaal and Meintjes, 2003). Further, socialization with humans can help to prevent the development of behavior problems (Hubrecht, 1995). NHPs can also benefit from positive interactions with human caretakers. Such interactions have been shown to reduce abnormal behavior, increase species-appropriate behaviors, such as grooming, and improve well-being in marmosets, macaques, and chimpanzees (Baker, 2004; Bayne et al., 1993a; Manciocco et al., 2009; Reinhardt, 1997; Waitt et al., 2002), among others. These relationships can also promote coping skills (Rennie and Buchanan-Smith, 2006) and help mitigate stress reactivity toward potentially stressful situations. Miller et al. (1986) found that chimpanzees were less anxious when confronted with novelty in the presence of their trusted caretaker than when the caretaker was absent. While less is known about the effects of human interactions on other animals, early handling by care staff can help reduce stress in rodents (Caldji et al., 2000; Cloutier et al., 2012; Plotsky and Meaney, 1993), pigs (Zupan et al., 2016), and rabbits (Swennes et al., 2011).

Because of the importance of socialization, social pairs or groups should remain intact and stable whenever possible. While most species of laboratory animals are gregarious in nature, some, such as sheep, are highly social. These animals can become extremely agitated in response to separation from the group (Dwyer, 2009), and are prone to displays of stereotypic behavior. The effects of such separations on such species can be attenuated by ensuring that other members of the social group are in visual contact.

2.3.2 Physical Enrichment

Physical enrichment generally refers to items designed to increase the complexity of the environment and promote species-normative behaviors. It includes substrate, nesting material, climbing structures, places to hide or rest, toys, and objects on which subjects can gnaw, to list just a few. These objects provide animals with choice (e.g., they can choose to use them or not) and some degree of control over their environment (Joffe et al., 1973). As with social enrichment, decisions concerning the utilization of specific enrichment items should be guided by an understanding of the natural behavior of the species. For example, many laboratory animals, including rodents and rabbits, are prey species, which shapes much of their behavior. When confronted with an aversive or frightening stimulus, their first reaction is to hide or burrow. Providing the animals with shelter (e.g., tunnels or huts) or substrate in which they

can dig, affords them with the ability to withdraw from aversive situations, which can alleviate fear and stress (Hutchinson et al., 2005). Fig. 2.1 illustrates some examples of structural enrichment.

Effective physical enrichment encourages species-typical behaviors, such as exploration and manipulation, play, nesting, burrowing, rooting, dust bathing, and locomotion. Certain items, such as visual barriers, can provide protection from aggressive conspecifics (Archard, 2012). Enrichment has also been shown to increase fecundity in fish (Wafer et al., 2016) and learning in elderly dogs (Milgram et al., 2005), and to induce positive affect in rats (Brydges et al., 2011; Richter et al., 2012) and pigs (Douglas et al., 2012). Enriched mice have higher natural killer cell activity levels (Benaroya-Milshtein et al., 2004) compared to mice that are not enriched, suggesting better immune function. Physical enrichment has even been found to improve wound healing rates in rats (Vitalo et al., 2012).

The benefits of enrichment may be related to the novelty and complexity of the items. Animals often lose interest in enrichment items with continuous exposure (Hubrecht, 1993; Lutz and Novak, 2005), and thus rotating and/or replacing items can promote their use (National Research Council, 2011; Rawlins et al., 2004). Complexity of enrichment may also be important. Recent work by Abou-Ismail and Mendl (2016) assessed the effect of enrichment novelty versus complexity in newly weaned male Wistar rats. Socially housed rats were exposed to five novel enrichment items (e.g., ladders, crawl balls, wood blocks, shelter, Nylabones) over a 5-week period. These enrichment items were either presented sequentially (novelty condition) or simultaneously (complexity condition). Rats in the novelty condition were provided with five copies of one enrichment item (e.g., five wood blocks) for 1 week, five copies of a different enrichment item (e.g., five Nylabones) the following week, and so on, while those in the complexity condition were provided with one of each of the five enrichment items for the entire 5 week period. The authors found that the animals in the complexity condition showed more signs of positive welfare, such as weight gain and species-normal behaviors, and fewer indicators of poor welfare, such as aggression and vocalizations, compared to those in the novelty condition. These results suggest that diversity of objects may be important to well-being (Abou-Ismail and Mendl, 2016).

Physical enrichment may also decrease abnormal behavior in a variety of species, including rodents and rabbits (Balcombe, 2006; Chu et al., 2004; Marashi et al., 2003; Renner and Rosenzweig, 1986; Wemelsfelder, 1990), pigs (Beattie et al., 1996), and NHPs (Gottlieb et al., 2014; Kessel-Davenport, 1998; Lam et al., 1991; Schapiro and Bloomsmith, 1995). For example, moving to an outdoor environment, which is arguably more

FIGURE 2.1   **Examples of housing with physical enrichment (including toys and structures for climbing, resting, and hiding)** (A) Enriched housing for guinea pigs, (B) enriched housing for dogs, (C) play structure for group housed rhesus macaques, *Macaca mulatta*, and (D) a "porch" on a rhesus macaque cage. *Source: (A) Photo courtesy of the Oregon National Primate Research Center; (B) photo courtesy of Novo Nordisk A/S, and reprinted from Ottesen, J.L., Weber, A., Gürtler, H., Mikkelsen, L.F., 2004. complex and stimulating than an indoor environment, has been shown to reduce stress (Honess et al., 2005; Schapiro et al., 1995) and SIB in macaques (Fontenot et al., 2006). Further, there is some evidence that exposing mice to an enriched environment early in life can help prevent the development of stereotypical behavior when the mice are older, even after enrichment has been removed (Gross et al., 2012). However, these results are not universal. Several studies have found no discernible effect of simple enrichment devices on abnormal behavior (Line et al., 1991; Novak et al., 1998) or that the benefit was limited to the time till the apparatus was present (Lutz and Novak, 2005).

Care must be taken to avoid injuries related to enrichment items. Animals can injure themselves on certain types of hooks that are used to attach enrichment devices to the outside of cages. For example, juvenile or infant monkeys often put items in their mouths, and can injure themselves on "S-shaped" hooks. Ropes and wire used to hang devices or swings should be short and/or covered with a material (PVC tubing) that reduces the potential of the rope or wire accidentally encircling the animal's neck. Handmade devices should be sturdy, to minimize the likelihood of breakage and the exposure of sharp edges. It is important to ensure that enrichment items can be easily cleaned, to avoid spreading disease (Bayne, 2005; Bayne et al., 1993b). There may be other untoward consequences of physical enrichment, potentially increasing aggression among socially housed animals (Marashi et al., 2003), due to competition over favored

items. Providing multiple enrichment items and dispersing them, as opposed to clustering them, can also help reduce enrichment-related aggression (Akre et al., 2011).

2.3.3 Food Enrichment

Foraging, which includes searching for, procuring, and manipulating food (e.g., opening seeds), is a major part of the behavioral repertoire of many animals in the wild. Animals can spend more than 50% of their waking hours engaged in this behavior. Time spent foraging and eating is greatly reduced in a laboratory setting, where processed food items (biscuits, chow, pellets) are typically provided only once or twice a day, or even less frequently; rodent chow is often placed in a hopper at the top of the cage weekly. Feeding enrichment includes procedures and devices designed to increase time spent feeding and foraging. This kind of enrichment is almost universally utilized by animals. Indeed, given a choice, rodents and other animals will often choose to work to obtain their food, even if they could get it for "free" (Carder and Berkowitz, 1970), a concept known as "contrafreeloading."

Food enrichment can be as simple as hiding food in the substrate to promote foraging behaviors or providing whole foods to promote processing behaviors. Since the goal of food enrichment is to encourage species-typical foraging behaviors, food treats should be provided in ways that extend the time to find and procure food, and not simply handed to the animal.

Specialized manipulanda are often used to provide food enrichment for laboratory animals. These devices, which typically have a small opening for food, are manipulated by the animal to remove the food. While most commonly used for NHPs, similar manipulanda can be used for most species, including dogs and pigs (Huntsberry et al., 2008; Lutz and Novak, 2005; Figure 2.2). Foraging manipulanda have been found to decrease the occurrence of some abnormal behaviors, including stereotypies (Novak et al., 1998) and over-grooming (Schapiro and Bloomsmith, 1995) in NHPs, when they remain attached to the cage. However, the undesired behaviors tend to return after time, likely due to decreased interest in devices that remain attached to cages indefinitely.

With all feeding enrichment, care must be taken not to provide items that are high in "empty" calories. Weight gain and even obesity can be a problem for certain laboratory animals, particularly if they are not given ample opportunities to exercise. Further, if too many treats are provided to animals, they may not consume the nutritionally balanced components of their diets. There are ways to provide food enrichment without adding problematic additional calories. Putting a desired treat in ice can be effective feeding enrichment for dogs and NHPs. The animal's chow may also be provided in such a way as to be "enriching." For example, hamsters and gerbils

hoard their food naturally. For these species, scattering food on the substrate, as opposed to using a hopper, provides them with multiple opportunities to search for, gather, transport, and then hoard their food.

2.3.4 Sensory Enrichment

Animals in the wild are exposed to a variety of visual, auditory, tactile, gustatory, and olfactory stimuli, the diversity of which is often greatly reduced in laboratory conditions. Sensory enrichment is typically designed to provide stimulation for one or more of these senses. As with most other types of enrichment, it is important to take the species' capabilities into account when providing sensory enrichment. Olfactory stimuli are very important to certain species, but are of only minimal consequence to others. While many laboratory species, including rodents, rabbits, dogs, prosimians, and New World monkeys rely heavily on scent marking, it is not common in other species, such as birds, Old World monkeys, and apes.

Auditory enrichment often consists of music or natural habitat sounds. In addition to being used as enrichment, auditory stimuli may also be used to mask other, presumably stressful, sounds (e.g., animal handling and/or cage cleaning procedures). While certain kinds of music have been shown to be anxiolytic in humans (Wells, 2009), the results in animal studies are less clear. Music has been found to be reduce anxiety in mice (Chikahisa et al., 2007), guinea pigs (Wells, 2009), and dogs (Wells et al., 2002). It may also reduce aggression and agonistic behavior in chimpanzees (Howell et al., 2003). However, when given a choice, chimpanzees, tamarins, and marmosets frequently chose silence over "music" (McDermott and Hauser, 2007; Richardson et al., 2006). Further, while it is often assumed that "natural" sounds (i.e, those from an animal's natural environment) are enriching, this is not always the case. Such sounds may not be meaningful to the animals, or may actually be stressful (Wells, 2009). Auditory enrichment is subject to the greatest potential for "abuse" by animal caregivers. It is often difficult to determine whether the musical stimulation being provided is intended to enrich the subject animals or the humans responsible for their care (personal observation).

Visual enrichment can be provided in a variety of forms, including television or videos, computer screen savers and similar applications, or even simply a window. Several species of NHPs will watch videos presented to them (Bloomsmith and Lambeth, 2000; Platt and Novak, 1997), with individually housed primates spending more time "actively" watching than socially housed animals (Bloomsmith and Lambeth, 2000). Whether or not this kind of enrichment affects the welfare of subjects may depend on the degree of control available to subjects. The presentation of video stimuli over which

the animals have no control has not been shown to dramatically affect either the promotion of species-typical behavior or the reduction of abnormal behavior (Bloomsmith and Lambeth, 2000; Platt and Novak, 1997). However, Ogura and Matsuzawa (2012) found that visual stimuli that changed frequently and could be controlled by the subjects did reduce abnormal behavior in Japanese macaques. Television may be aversive if stressors, such as predators, appear on the screen.

2.3.5 Occupational Enrichment

Occupational enrichment includes physical activity and cognitive tasks. It provides opportunities for animals to obtain physical and/or mental stimulation. One of the most common forms of occupational enrichment for small laboratory animals is exercise. There is a large body of evidence suggesting that exercise can help reduce stress, improve overall health, and improve memory and learning in captive animals (Penedo and Dahn, 2005; Santos-Soto et al., 2013; Van Praag, 2009). While many laboratory animals will readily exercise when given the opportunity, others are less eager to do so. Further, providing opportunities for exercise can be challenging for some species. While providing exercise for dogs is mandated by the Animal Welfare Act (1991), it can be challenging to implement. Simply giving the dog an area in which to play may not be enough to promote exercise. Dogs generally do not exercise unless they have the stimulation of humans or other animals (Campbell et al., 1988).

Housing NHPs in large enclosures is one way to provide them with exercise. When this is not possible, activity cages can be utilized to provide exercise to NHPs (Wolff and Rupert, 1991). Indeed, the *Guide for Care and Use of Laboratory Animals* (National Research Council, 2011) recommends the intermittent use of such activity units for NHPs housed in cages, particularly if they are singly housed. These cages have been found to reduce abnormal behavior in baboons (Kessel and Brent, 1995), vervet monkeys (Seier et al., 2011), and rhesus macaques (Griffis et al., 2013), at least for the time that the animals are able to use them.

Cognitive-based enrichment provides animals with opportunities to solve problems. Such enrichment, often accomplished with computers or tablets, is gaining in popularity, at least for NHPs. In particular, tablets provide NHPs access to a wide range of games, known as apps, which can be easily changed and updated (O'Connor et al., 2015). There is currently a paucity of studies examining the effects of this kind of cognitive enrichment; however, a small number of studies have shown that tablets and apps positively affect welfare in NHPs and pigs. Pigs exposed to cognitive challenges showed decreased stereotypical behavior (Puppe et al., 2007) and fewer behavioral and physiological indices of stress compared to nonenriched pigs (Zebunke et al., 2013). Computer tasks have been found to reduce levels of stereotypies and other behavioral problems in rhesus and bonnet macaques (Lincoln et al., 1995; Platt and Novak, 1997; Washburn and Rumbaugh, 1992).

Another form of cognitive/occupational enrichment is positive reinforcement training (PRT). PRT techniques are a form of operant conditioning (Skinner, 1938) in which subjects are rewarded with something desirable (e.g., a food treat) for performing specific behaviors on command. The animals are not punished if they do not perform the behavior; they are simply not rewarded. In PRT, the subject is presented with a stimulus (e.g., a verbal command), responds by performing a specific behavior (e.g., move to the front of the cage and remain stationary), and is provided with reinforcement (e.g., food treat) when it has completed the specific behavior. Refer to Laule et al. (2003) and Pryor (1999) for an overview of PRT.

The use of PRT is recognized as an important tool for promoting well-being in captive species. It is most often used with dogs (Fugazza and Miklósi, 2015; Pryor, 1999) and NHPs (Coleman et al., 2008; McKinley et al., 2003; Prescott et al., 2005; Schapiro et al., 2003; Schapiro et al., 2005), although other species may benefit from this kind of training as well. Laboratory animals have been successfully trained to perform various husbandry or clinical tasks, including moving to a new part of an enclosure (Veeder et al., 2009), presenting a body part for an injection or another procedure (Priest, 1991; Schapiro et al., 2003), taking oral medications (Klaiber-Schuh and Welker, 1997) and remaining stationary for blood sampling (Coleman et al., 2008; Laule et al., 1996; Figure 2.3).

There are many benefits to using PRT. By allowing individuals to cooperate with various procedures, PRT can

reduce the stress associated with these procedures (Bassett et al., 2003; Laule et al., 2003; Schapiro et al., 2003). It can also increase well-being by decreasing boredom, and increase mental stimulation for subjects (Laule et al., 2003). Trained animals are often easier to work with than are untrained animals (Adams et al., 2004). In addition, training has been used to reduce abnormal behaviors, such as stereotypic behavior in NHPs (Coleman and Maier, 2010). While it may take time to train animals for specific tasks, the time invested will likely result in significant time savings when conducting procedures with trained subjects (McKinley et al., 2003; Veeder et al., 2009).

3 ENRICHMENT AND ANIMAL MODELS

Researchers have utilized EE as a model for the ways in which environmental factors affect physiological and biological outcomes for over 70 years, ever since Donald Hebb examined learning in the rats he kept as pets in his home. Compared to rats kept in cages in the laboratory, rats allowed to live as pets when young had better problem solving abilities later in life (Hebb, 1947). Since Hebb's studies, there have been many publications demonstrating that rats and mice living in an enriched

environment perform better than nonenriched conspecifics on a variety of standardized tests of memory and spatial learning, including the Morris water maze (Morris, 1984). Rodents provided with an enriched cage (including some sort of substrate, toys rotated on a regular basis, objects on which to climb, and a hut or other shelter), either with or without social partners, tend to perform better on these tests than do nonenriched conspecifics (Falkenberg et al., 1992; Renner and Rosenzweig, 1986; Schrijver et al., 2002).

Learning is certainly not the only area of research in which enrichment is used as a model. The effect of enrichment on research outcomes has been tested in many, if not most, models of human diseases. However, enrichment is a relative term; the exact characteristics of an "enriched environment" for rodents are not consistent across studies (Fox et al., 2006; Simpson and Kelly, 2011). Rodent enrichment can include items such as large cages, nestlets, or other material in which the rodents can nest, different types of substrates, toys, climbing structures, tunnels, wood objects on which the animals can gnaw, and exercise wheels. In some studies, the enriched condition consists of a few toys added to the cage, while in others, enrichment consists of large cages with structural complexity, including running wheels and other opportunities for exercise (Fox et al., 2006). In at least one study (Landers et al., 2011), the environmentally enhanced rodents lived in outdoor enclosures, and in others (Sparling et al., 2010) animals in an enriched environment had access to several floors of caging. Similarly, there is also variation in unenriched, control groups across studies, ranging from relatively barren enclosures with virtually no enrichment to enclosures with bedding and nestlets. Interestingly, this seems to be changing over time; what was considered an "enriched" condition in older studies is often considered the "control" condition today. Social enrichment (i.e., having more than one animal in the enclosure) also varies, with some authors considering "social enrichment" to be two animals cohoused, and others considering "social enrichment" to be larger groups (Simpson and Kelly, 2011). Despite these differences, there are many commonalities among studies involving EE. We present representative and relevant examples of some of this research below. For more exhaustive and comprehensive reviews of EE as a model for specific human conditions, see Bayne and Würbel (2012), Fox et al. (2006), Nithianantharajah and Hannan (2006), Renoir et al. (2013), Simpson and Kelly (2011), van Praag et al. (2000), and Will et al. (2004).

3.1 Neuroplasticity and Neurogenesis

There is a wealth of data demonstrating that environmental enrichment can increase brain plasticity through a variety of mechanisms (Simpson and Kelly, 2011).

EE has been shown to increase brain size and weight (Greenough, 1975) and increase the number of synapses per neuron (Benefiel and Greenough, 1998) in rodents. Further, several studies have demonstrated that enrichment can promote cell proliferation and neurogenesis in mice, rats (Kempermann et al., 1997; van Praag et al., 2000), and guinea pigs (Rizzi et al., 2011), which may also promote plasticity. Voluntary running on an exercise wheel promotes neurogenesis in the rat dentate gyrus at the same level as cage enrichment (van Praag et al., 1999), suggesting that several kinds of enrichment can affect neurogenesis. This neurogenesis in response to enhanced environmental conditions has also been observed in invertebrate species, including crickets (Lomassese et al., 2000) and crayfish (Ayub et al., 2011), suggesting it has been conserved across species. In addition to promoting neurogenesis, enrichment can decrease apoptosis or cell death (Young et al., 1999) in rodents and aged dogs (Siwak-Tapp et al., 2008).

The hippocampus, an area of the brain involved in learning, appears particularly sensitive to the effects of an enriched environment (Brown et al., 2003; Kempermann et al., 1997; Zhu et al., 2006). Kempermann et al. (2002) found that hippocampal neurogenesis in adult mice exposed to long-term enrichment was five-fold higher than nonenriched controls. Living in an enriched environment following early insult, such as neonatal alcohol exposure, can promote neurogenesis in the hippocampal dentate gyrus and reverse associated learning deficits (Hamilton et al., 2014). In contrast, lack of social enrichment (i.e, social isolation) can impair adult neurogenesis in the dentate gyrus (Lieberwirth et al., 2012).

The effects of enrichment on plasticity can be long lasting. EE has been found to mitigate age-related changes in neurogenesis (Kempermann et al., 1997, 2002), gliogenesis (Soffie et al., 1999), cortical thickness, and dendritic branching (Mohammed et al., 2002). These changes have been associated with improved learning and memory in aged rodents (Bennett et al., 2006; Kempermann et al., 2002) and dogs (Milgram et al., 2005).

3.2 Neurological Disorders

EE has also been used as a model to study the ways in which the environment interacts with specific neurological diseases. EE has been found to be neuroprotective when provided after insult in models of seizures (Dhanushkodi and Shetty, 2008), stroke (Mering and Jolkkonen, 2015), and Parkinson's disease (Faherty et al., 2005). It has also been found to be protective when provided prior to the insult (Williamson et al., 2012). In general, EE improves functional recovery after brain damage in a variety of models (Will et al., 2004), and has important implications for studies on degenerative

diseases, such as Alzheimer's (Jankowsky et al., 2005) and Huntington's disease (HD) (van Dellen et al., 2000). Exposure to enrichment has been shown to delay the onset of motor deficits (van Dellen et al., 2000), decrease cognitive deficits (Nithianantharajah et al., 2008), and decrease depressive behaviors (Pang et al., 2009) associated with HD in a transgenic mouse model. In addition, exercise (Pang et al., 2006) and cognitive enrichment (Martinez-Coria et al., 2015) have been found to have beneficial effects on HD, although the effects are often not as profound as those associated with physical enrichment (Mazarakis et al., 2014). Larger and more complex caging has also been found to mitigate detriments in learning and working memory associated with Alzheimer's disease (Arendash et al., 2004; Jankowsky et al., 2005). Studies such as these provide insight into the effects of environmental conditions on disease progression (Nithianantharajah and Hannan, 2006).

3.3 Affective Disorders

Affective and other psychiatric disorders often have an environmental component, and thus environmental enrichment is often used as a model in these studies. There are several studies examining the anxiolytic role of EE, both in applied and basic science. EE has been found to reduce behavioral and physiological signs of anxiety in rats (Ashokan et al., 2016; Mychasiuk et al., 2012), mice (Benaroya-Milshtein et al., 2004; Chapillon et al., 1999), and fish (Manuel et al., 2015). For example, mice living in an enriched environment appear less anxious in tests assessing anxiety, including the elevated plus maze and open field tests than to those in standard housing (Benaroya-Milshtein et al., 2004; Chapillon et al., 1999). Not only can enrichment function preventatively, it can also be therapeutic (Sampedro-Piquero et al., 2016). These findings are not universal. Leal-Galicia et al. (2007) found no difference in exploratory behavior between enriched and control animals on the open field test. However, the animals in this study were not provided with continuous enrichment, suggesting that enrichment may need to be continuous to be completely effective in this model (Simpson and Kelly, 2011).

Not only does enrichment affect the development of anxiety in animal subjects, but it can also affect the subjects' progeny. Mychasiuk et al. (2012) found that offspring of rats living in a highly enriched environment (i.e., large cages with toys, climbing structures, and food treats) showed more exploratory behavior in an open field than did offspring of rats living in standard housing. Pups from enriched parents also showed reduced global DNA methylation (which implies increased gene expression) in the hippocampus and frontal cortex compared to pups of control parents (Mychasiuk et al., 2012). This study suggests that prenatal enrichment can induce

epigenetic changes that can affect behavioral trajectories of offspring (Mychasiuk et al., 2012).

Relatively few studies have examined the effects of EE on other psychiatric disorders; however, EE has been shown to impact addiction. Several studies have demonstrated enriched animals self-administer decreased amounts of amphetamine compared to controls (Bardo et al., 2001; Green et al., 2002), and show reduced impulsivity-related behaviors when nose poking for a sucrose reward (Wood et al., 2006). Enrichment has also been shown to reduce schizophrenic-like behaviors in a mouse model for schizophrenia (Burrows et al., 2015; Santos et al., 2016).

3.4 Obesity

Researchers who study obesity often examine food intake. Unlike many other models of human behavior, there are a number of studies that demonstrate that exposure to enrichment has no effect on food intake. For example, Beale et al. (2011) found that environmental enrichment, consisting of chew sticks and/or black tubes, did not affect food intake, body weight, or behavior in rats. Similarly, Teske et al. (2016) found no difference in food intake between rats provided with bedding, a relatively basic form of enrichment, and those housed on a wire-bottom cage, nor did they find differences in hyperphagia following administration of orexin-A after animals were given a chewable enrichment device (Nylabone). However, in both of these studies, rats in the "enriched" condition were singly housed and had only basic enrichment (bedding and a toy). Thus, the lack of effect could be due to the relatively low levels of enrichment provided and/or the lack of social companionship.

In support of this concept, mice socially housed with additional enrichment had higher food intake and enhanced leptin sensitivity compared to those in a nonenriched environment (Mainardi et al., 2010). Interestingly, the effect of enrichment on food intake was only found when enrichment was provided to adult mice; mice reared in an enriched environment from birth did not differ from others in food intake. Thus, it is also possible that the timing of EE is important to food intake.

Regardless of the effect enrichment has on food intake, several authors have demonstrated that enriched animals tend to be leaner than their unenriched conspecifics (Cao et al., 2011). While exercise is known to reduce adiposity (Mainardi et al., 2010), physical enrichment, such as cage complexity, is also important to this process. Mice provided with an enriched environment, including toys, nesting material, and running wheels, showed significant reduction in white adipose tissue compared to both nonenriched mice and those given only a running wheel (Cao et al., 2011). It has been posited that the cognitive and physical stimuli associated with environmen-

tal enrichment promote transformation of white adipose tissue to brown adipose tissue through activation of brain-derived neurotrophic factor mediator(s) (Foglesong et al., 2016).

Enrichment can also help to mitigate some of the other negative consequences of obesity. EE can help reverse cognitive deficits caused by a high-fat diet in rats (Gergerlioglu et al., 2016). It can also reduce obesity-related liver streatosis and insulin resistance (Foglesong et al., 2016). Animals in an enriched environment are also less likely to suffer from various cancers associated with obesity than are control animals (Cao et al., 2010).

3.5 Cancer

EE has been found to be protective against certain types of cancer. Mice provided with a highly enriched environment, including both social and structural complexity, showed inhibited tumor growth in a melanoma and a colon cancer model (Cao et al., 2010). The effect of EE on the tumors was both preventative and therapeutic. Interestingly, this effect did not extend to exercise; voluntary wheel running in the absence of other enrichment was not found to have the same tumor suppressive effect as an enriched environment for mice in this study (Cao et al., 2010). EE has also been shown to augment the efficacy of immunotherapy in B cell lymphoma (Benaroya-Milshtein et al., 2007). Immunized mice housed in an enriched environment produced higher levels of antibodies and had more attenuated tumor growth compared to those in a standard environment.

Studies have also examined the effect of EE on models of breast cancer. EE reduced tumor growth in mice (Nachat-Kappes et al., 2012). Further, mammary gland development has been shown to be influenced by EE. Mice maintained in a highly enriched environment had fewer cyclooxygenase-2 (COX-2) positive cells, proinflammatory mediators implicated in the development of breast cancer, compared to those housed in a standard environment (Nachat-Kappes et al., 2012). Interestingly, mammary gland development in mice living in the standard environment was similar to that of mice fed with a high-fat diet, another known risk factor for tumor development (Nachat-Kappes et al., 2012).

While the aforementioned study examined the effects of physical enrichment on cancer, similar results have been found with social enrichment. Singly housed mice (Williams et al., 2009) and rats (Hermes et al., 2009) demonstrated increased cancer development compared to socially housed conspecifics. Similarly, lack of social companionship augments angiogenesis in colon cancer (Wu et al., 2000). In both cancer models, the reduction of stress associated with social and/or environmental enrichment was posited as the likely reason for the improvement.

4 ENRICHMENT AND EXPERIMENTAL VARIABILITY

The use of environmental enrichment and/or exercise is mandated by the Animal Welfare Act (1991) for captive primates and dogs, and therefore these animals tend to receive a fair amount of enrichment. However, despite the plethora of studies demonstrating the beneficial effects of EE on welfare and specific disease outcomes, enrichment for rodent species is still often rudimentary, frequently consisting of little more than bedding and some sort of shelter (e.g., hut). This minimal enrichment for rodents is due, in large part, to the concern that differences in enrichment practices across, and even within, laboratories will lead to increased variability in the data and an inability to replicate findings (Benefiel et al., 2005). It is believed that if environmental conditions are kept constant, reproducible results will follow (Richter et al., 2009, 2010). However, the *lack* of enrichment can also produce variability across laboratories (Weed and Raber, 2005). As discussed previously, enrichment can help attenuate stress responses to aversive stimuli. Given that individuals can vary greatly in their response to stress (Bartolomucci et al., 2005; De Kloet, 2004; Meaney et al., 1991), lack of enrichment can increase an animal's vulnerability to various stressors and thus, overall experimental variability (Weed and Raber, 2005). The provision of enrichment and other behavioral management techniques can reduce fear and anxiety associated with experimental procedures and the development of stress-related problems, and thereby increase the validity of experimental results. In addition, managing aspects of the behavioral environment can minimize the effects of previously uncontrolled factors that may confound the research project.

There is mounting evidence suggesting that the provision of enrichment does not lead to experimental variability. Richter et al. (2009, 2010) argue that environmental standardization may actually cause poor reproducibility in experimental outcomes. Wolfer et al. (2004) examined whether enrichment influenced between-laboratory variation in the behavior of female mice tested on four commonly utilized behavioral assessments (water maze, open field, object exploration, and elevated maze). There was significant within-group variation in behavioral measures, regardless of degree of enrichment. However, they did not find significant effects of the individual laboratory, suggesting that enrichment did not increase variation *across* laboratories (Wolfer et al., 2004).

It is also important to point out that living in a barren environment can interfere with normal brain development and behavior (Benefiel and Greenough, 1998; Renner and Rosenzweig, 1986) and can lead to the development of maladaptive behavior (Würbel, 2001).

Therefore, it can be argued that animals in these conditions are not appropriate subjects for neurobiological research, which should focus on modeling normal brain development (Olsson et al., 2003). In short, good science depends on animals that are physically and psychologically healthy. EE is a key component in accomplishing these goals.

5 IMPLEMENTING AN ENRICHMENT PLAN

It is beyond the scope of this chapter to describe how to implement enrichment plans for all laboratory species. There are many published papers and books that provide excellent overviews concerning methods for implementing enrichment, including Bloomsmith et al., 1991; Keeling et al., 1991; Markowitz, 1982; Ottesen et al., 2004; Shepherdson et al., 1998; Stewart, 2004; Young, 2003. Table 2.1 provides additional resources for some commonly utilized laboratory species. However, while specifics may change across species, there are general tenets of enrichment. We describe these in the following sections. We also present an example of an enrichment plan for a nontraditional species.

5.1 Understand the Natural History of the Species you are Trying to Enrich

As detailed throughout this chapter, one of the first and most important steps in designing an enrichment program is to understand the behavioral needs of the species to be enriched. Every species evolved under different environmental conditions, resulting in unique species-specific behavioral patterns. Most species retain these behavioral repertoires in captivity. Even rodents, which have been bred in laboratories for many generations, still maintain behaviors similar to their wild counterparts (Boice, 1977; Hutchinson et al., 2005), including nest-building, burrowing, hiding, and foraging. Therefore, knowledge of the natural behavioral biology of the species is important for the establishment of a successful enrichment program, and should inform decisions concerning the specific enrichment opportunities to be provided. For instance, while most rodents are social, golden hamsters are not, and should not be housed in groups. Owl monkeys (*Aotus sp.*) utilize nests in the wild, and should be provided with nest boxes in captivity; such nest boxes would be of little value to most macaque species. The Animal Welfare Information Center (United States Department of Agriculture) website (http://awic.nal.usda.gov/publications/bibliographies-and-resource-guides) contains useful information regarding the natural history and behavior of various laboratory animal species (Table 2.1).

TABLE 2.1 Resources on Behavioral Biology/Natural History and Enrichment Programs for Some Commonly Utilized Laboratory Animals

Animal	Behavioral biology	Overview of EE
Fish	Engeszer et al. (2007); Spence et al (2008)	Williams et al. (2009)
Amphibians	Tinsley (2010); Hayes et al. (1998)	Archard (2012)

EE, Environmental enrichment.

Even within a species, enrichment needs may also vary by strain (Van de Weerd et al., 1994), age (Newberry, 1995), or gender (Welberg et al., 2006). In many species, young animals tend to be more exploratory and active than older animals, and should be provided with increased opportunities to explore and play. Other factors, such as individual temperament, may also play a role in the behavioral needs of animals. Most EE plans incorporate some sort of novelty. Toys and other items are often replaced and/or rotated on a regular basis, in an effort to promote the use of, and hence, the value of the enrichment (Hubrecht, 1993). However, highly anxious or inhibited individuals may respond to constant changes of EE differently than less inhibited conspecifics (Coleman, 2012; Fox and Millam, 2007; Freeman and Gosling, 2010). For these neophobic animals, frequent changing of enrichment items may actually cause, rather than reduce, stress (Coleman, 2012). Enrichment programs should account for these differences to the extent possible.

There is one caveat to this tenet, however. While it is important to keep in mind the natural history of the species, it is equally important to remember that the captive environment has limitations, particularly in terms of space and the ability to escape, which can preclude the expression of naturalistic behavior. Social behaviors may be especially vulnerable to captive conditions. For example, wild rabbits are known to be gregarious, but in captivity, adults, especially males, are often aggressive toward one another, making social introductions challenging (Morton et al., 1993). Conversely, hamsters are naturally solitary. However, captive hamsters seem to prefer social housing, spending more time in social contact with others than alone (Arnold and Estep, 1990). It is important to balance natural history with published literature on best care practices.

5.2 Devise Enrichment Plans With Specific Behavioral Outcomes in Mind

EE should be goal-based. In other words, it should be implemented so that it addresses particular needs. As an example, foraging, including food procurement and processing (e.g., finding food, opening shells, or coverings) is a significant part of the behavioral repertoire of many animals. The presentation of a pelleted diet in captivity is likely to substantially reduce time spent in these behaviors. Therefore, the goal of food enrichment should be to increase the amount of time animals spend finding, processing, and eating their food. It is not intended simply as a way to give animals treats. To meet food enrichment-related goals, desired food treats should not be handed out, but should be hidden or presented in ways that extend foraging time.

5.3 Do no Harm

As detailed earlier, an important factor to consider in providing enrichment is safety. Certain enrichment items may be problematic for specific individuals. While nesting material is used without problem in many rodent species, it can cause conjunctivitis in some genetically modified mice (Bazille et al., 2001). Therefore, enrichment options should be carefully researched prior to implementation, to ensure that they are appropriate for the species and strain being utilized. Further, new enrichment options should be tested in a small number of individuals prior to widespread implementation, to determine whether they are safe and/or may affect experimental outcomes.

5.4 Consider the Costs of the Enrichment

Enrichment should balance the benefits to the animals with the cost of the device. Some enrichment, including larger cages, exercise wheels, and commercially available devices can be prohibitively expensive. One way to provide such costly items is to allow animal's access to them on a rotating basis. Alternatively, many enrichment items (e.g., rodent tunnels) can easily be made with inexpensive and commonly available materials, such as PVC tubing. Cardboard tubes can also be used as an inexpensive enrichment device for rodents (Würbel et al., 1998).

Another cost associated with enrichment is the time of care staff. Enrichment should be somewhat challenging for the animals (to meet the goal of occupying their time), but not too challenging for the animal care staff to maintain. Enrichment items that take a longer time for staff to fill, put up, and clean than the time it takes the animals to use should be reconsidered. That being said, the human cost should not be overemphasized. Effective environmental enrichment programs must establish a workable balance between human convenience and the needs of the animals. Animal needs should be the primary factor driving decisions about enrichment programs.

5.5 "Listen" to the Animals to Determine Whether They Find the Enrichment Enriching

As detailed earlier, environmental enrichment should be goal-oriented. Typically, goals of enrichment, if not used as part of an experimental paradigm, include increasing behavioral diversity and decreasing or preventing abnormal behaviors. Enrichment offerings should be empirically evaluated to ensure they are meeting these goals. Items that do not have a demonstrable effect upon the well-being of the animals should be reconsidered, and probably replaced (Newberry, 1995). Enrichment items that are shown to have untoward effects (e.g., decreased reproduction, illness, maladaptive behaviors) should be eliminated. Even enrichment that has been effectively used for long periods should be regularly evaluated to ensure it is still achieving its desired behavioral goals.

Evaluation can be accomplished in several ways. Taking systematic observations on a subset of individuals is one way to evaluate the effectiveness of enrichment. These types of observations tend to assess whether the enrichment is affecting the expression of both normal and abnormal behaviors, as well as whether it is being utilized at all. As some individuals change their behavior in the presence of a human observer (Iredale et al., 2010), utilizing video cameras can be useful for these sorts of observations, with the caveat that analysis of video data is often quite time consuming. In addition to direct observations, the value of enrichment can be inferred from some physiological measurements. If multiple animals get hurt or sick from the enrichment, then obviously removal of the enrichment is likely to be necessary. Another way to evaluate enrichment is through the use of consumer demand approaches, such as preference tests, to determine how hard animals are willing to work to gain access to specific enrichment opportunities (Schapiro and Lambeth, 2007). Items for which animals are not willing to work should be reconsidered.

Recently, investigators have begun to use cognitive bias testing to evaluate how animals perceive enrichment (i.e., positively or negatively). Cognitive bias refers to the influence of affective state on information processing (Mendl et al., 2009). Multiple studies have demonstrated that, in humans, self-reported emotional states can influence cognitive processes, including attention, memory, and judgment. Specifically, individuals in a negative affective state show increased vigilance to threatening stimuli, are quicker to recall negative memories, and are more likely to have negative assumptions about future events or ambiguous stimuli compared to those in a positive emotional state (Eysenck et al., 1991).

Researchers have exploited this bias in information processing to develop cognitive bias tests to indirectly measure emotional states in nonhuman animals. These tests have been used to assess emotionality in animals living in enriched compared to unenriched environments in a variety of species, including rats (Brydges et al., 2011; Richter et al., 2012), pigs (Douglas et al., 2012), and starlings (Matheson et al., 2008). These studies demonstrated that enrichment induced positive emotionality. While still relatively new, this kind of testing offers a promising tool for assessing the effects of various kinds of enrichment.

5.6 Predictability is Important

As detailed earlier, there are many stressors in the environment of laboratory animals. Husbandry events, such as room cleaning, presence of new care staff, or sudden noises can be stressful for animals. Even "positive" events, such as feeding and provision of enrichment, can be a source of chronic stress to some individuals. These events occur daily, but their timing is often unpredictable for animals, leading to prolonged anticipation of husbandry events resulting in chronic stress. Making such events more predictable to animals can decrease stress and improve well-being (Gottlieb et al., 2013b; Stella et al., 2014; Ulyan et al., 2006; Waitt and Buchanan-Smith, 2001). Simply feeding animals their chow at the same time every day can effectively decrease behavioral indicators of stress in caged rhesus macaques (Gottlieb et al., 2013b). Thus, to the extent possible, provision of enrichment should be somewhat predictable to the animals. Similarly, it should also be consistent. Because enrichment can affect many research outcomes, care must be taken to ensure enrichment is given uniformly, and not haphazardly. Enrichment should be considered an integral part of animal care, and not as something extra to be done "when there is time" (Stewart, 2004).

5.7 Document

While not necessarily a tenet of enrichment, another important part of an enrichment plan is documentation. Information such as when and what kind of enrichment is provided should be recorded. Maintaining these records serves as a way to show that the animals have received enrichment opportunities. Further, systematic documentation can be used to help address unexpected results, and provides a way to ensure that enrichment is consistently being delivered.

Documentation can take several forms. Enrichment can be written on daily logs (Coleman et al., 2012), if they are utilized, or can also be entered directly into spreadsheets.

6 EXAMPLE OF AN ENRICHMENT PLAN: BLACK-TAILED PRAIRIE DOGS (CYNOMYS LUDOVICIANUS)

Enrichment plans should be tailored for each species housed in the laboratory. The point of writing an enrichment plan is to address the potential display of species-specific behavior while animals are housed under laboratory conditions. Inclusion into a study or protocol should not exclude animals from receiving EE or prevent them from displaying normative behavior for the duration of the project. The following is an example of an enrichment plan for a nontraditional laboratory species (adapted from the Compatative Medicine Branch, CDC, Behavioral management plan, 2015).

Prairie dogs are diurnal, burrowing rodents. They are a social species and may concentrate their burrow locations in one area and defend home burrows from neighboring colonies. Prairie dogs are primarily herbivorous and cache their food (Fink, 2004; Hoogland, 1995).

Coloniality is a hallmark of prairie dog societies. Each colony is made up of territorial family groups called a coterie. Thus, social housing (in groups) should be one of the first considerations in implementing an enrichment program for this species. Such housing allows individuals to engage in many species typical behaviors, including play and grooming. Groups of prairie dogs can be housed in relatively large indoor enclosures. If they must be single housed for scientific reasons approved by the Institutional Animal Care and Use Committee (IACUC), they should be arranged in a manner that permits animals to have visual, auditory, and possibly olfactory contact with conspecifics. Single housing should be the shortest duration possible.

Prairie dogs should be housed on Envirodry or similar type bedding which allows for the expression of burrowing and nest-building behavior. Providing the animals with shelter (e.g., tunnels or houses) or substrate in which to burrow affords them the ability to withdraw from aversive situations, which can alleviate fear and stress and tunnels. Many of these items (e.g., tunnels) can easily be made with commonly available materials, such as PVC tubing or cardboard sections cut from longer commercially available tubes.

In the wild, prairie dogs forage from dawn to dusk (Hoogland, 1995), and thus food enrichment is an important part of their enrichment program. Feeding enrichment can be as simple as hiding food in the substrate, which promotes foraging. This kind of enrichment should be provided as often as possible (i.e., at least 3–5 days a week). In the laboratory, food enrichment can include items such as apples, carrots, sweet potato, hay, sunflower seeds, peanuts, and mealworms. Mealworms can be placed into paper bags prior to delivery and tossed onto the floor of each colony room prior to feeding.

7 CONCLUSIONS

Animal models of human disease are key to finding new treatments, cures, and preventative measures for those afflicted. As such, captive animals will continue to play a key role in these efforts. We are morally, ethically, and, for many species legally responsible for providing the highest quality of care for the animals that contribute to our understanding of these disease processes and their treatments. The requirement that environmental enrichment be part of a comprehensive care program at any institute where animal research is conducted is a relatively new concept (Weed and O'Neill-Wagner, 2006), but it is one that has received a great deal of attention. With the publication of the 8th edition of the *Guide for Care and Use of Laboratory Animals* (National Research Council, 2011) the Association for the Assessment and Accreditation of Laboratory Animal Care, International (AAALAC, International), the NIH Office of Laboratory Animal Welfare (OLAW) and others have reiterated the importance of addressing the well-being of those animals used in research.

EE is an important refinement to many laboratory procedures. Along with *Reduction* and *Replacement*, *Refinement*, or practices that minimize stress and distress experienced by animals, make up Russell and Burch's 3Rs (Russell and Burch, 1959). The 3Rs have long been accepted as guiding principles for the ethical and humane use of animals in biomedical research (National Research Council, 2011). EE represents a significant refinement, insofar as it improves psychological well-being and welfare, and reduces stress for subjects.

Attending to the behavioral needs of animals also helps research endeavors. To provide the most reliable and valid data, subjects must be provided with the best physical and social environment conditions possible within the framework of the research. With few exceptions, animals evolved to live in complex environments, which can substantially differ from those experienced in captivity. Lack of environmental stimulation can cause stress for animals, which in turn can affect a wide range of physiological outcomes. Not only can this negatively impact welfare, but it can impact the research on which these animals participate. Addressing the species-specific needs of laboratory animals enhances the work conducted with every animal model, improves our understanding of basic biomedical questions and enhances our ability to seek valid answers and appropriate treatments.

O U T L I N E

1 ANIMAL MODELS

In order to gain insight into human behavioral dysfunctions and neurologic and psychiatric disorders, it is of utmost importance that appropriate animal models are used in the behavioral neurosciences, such as neurobiology, biopsychology, neurology, and psychiatry. Animal model approaches have a long history in biomedical (Ericsson et al., 2013; Franco, 2013) and neuroscience research (Cowan et al., 2000), where the models have been developed to investigate brain–behavior relations. The aim has been to gain insight into human behavior and its underlying neuronal and neuroendocrinological processes, their role in neurological and neuropsychiatric diseases and their treatment.

Animal models in neuroscience research are mainly used for two purposes:

- for gaining insight in the processes and mechanisms underlying neurobehavioral disorder, which is primarily an area of basic research, but may also be a first step in translational research, and
- for identifying new therapeutic options and testing their efficacy and safety (van der Staay, 2006; van der Staay et al., 2009, 2014). For evaluating the safety and efficacy of interventions, translational research using (large) animal models alongside clinical trials is necessary (Drolet and Lorenzi, 2011).

In this chapter, we shall address the subject "large animal models." First, the theoretical framework of performing animal experimental studies will be discussed and a definition of animal models will be given. Then, the position of (large) animal models in the translational chain will be discussed. Next, we direct our attention to selecting an appropriate animal model for addressing a scientific question. Some aspects of performing research using large animal models are challenging, compared to rodent models. We will address these challenges and their implications. Large model animal species need an adapted infrastructure for housing and testing. Also, we pay particular attention to methodological questions associated with the use of large animal models, such as considerations about the experimental unit. The most efficient use of large animal models may imply multiple testing and multiple readouts to obtain a maximum of information. Similarly, reuse of animals within a study and/or reuse in successive (possibly unrelated studies) is discussed. Finally, the advantages and disadvantages of studies with large model animal species will be contrasted.

2 WHY ANIMAL EXPERIMENTAL STUDIES?

The possibilities to investigate the processes underlying behavioral dysfunctions and psychiatric disorders in the brain of humans are restricted, except when they are assessed in a clinical setting with patients as subjects. However, the extent and location of the damage [although emerging imaging techniques broaden the possibilities (Mier and Mier, 2015)], and its "history," are often unclear, and the neurobiological variables associated with behavioral dysfunctions cannot be controlled sufficiently to achieve meaningful and interpretable results. Comparative approaches (Brenowitz and Zakon, 2015; Mehta and Gosling, 2008) relying on animal models could be used to answer questions about behavioral dysfunctions and their underlying neural substrate. Animals with a known and reproducible dysfunction or damage may help us to understand brain dysfunctions and their effects on behavior (Blanchard et al., 2013).

The comparative approach is based on the evolutionary theory and the assumption that fundamental aspects of the behavior of humans have a genetic basis with a common evolutionary trajectory that are shared with other species. A central intention of comparative behavioral sciences is to identify "(…) animal species with behavioral or psychological repertories similar to humans so that the results of experiments with these animal models may throw light on seemingly related behavior in human beings" (Lickliter, 2004, pp. 27–28). Whereas animals are in most instances intended as a model for humans, one animal species may also serve as model organism for another species. Studies, however, which

explicitly compared behavior across species, are rare in neuroscience (Sharbaugh et al., 2003).

We define animal models of neurobehavioral disorders as follows:

> An animal model with biological and/or clinical relevance in the behavioral neurosciences is a living organism used to study brain–behavior relations under controlled conditions, with the final goal to gain insight into, and to enable predictions about, these relations in humans and/or a species other than the one studied, or in the same species under conditions different from those under which the study was performed. *van der Staay, 2006*, *pp. 133–134*

3 ANIMAL MODELS IN BIOMEDICAL RESEARCH

Animal models are used during the entire cascade from proof of concept (POC) through efficacy testing, safety, teratology, and toxicology evaluations of candidate drugs to translational research to product-related research. POC, also called proof of principle (POP) is objective evidence supporting the functionality of a principle, concept, or theory and its potential for real-world application. In preclinical trials using appropriate animal models, the efficacy and safety of a drug is determined (Lalonde et al., 2007). Safety pharmacology aims to detect the liability of adverse effects, determine safety margin calculation, and monitor clinical safety (Pugsley et al., 2008). Teratology or developmental toxicology assesses agent-induced abnormal development (Vorhees, 1989), whereas toxicology is the study of the effects of (putative) poisonous chemicals or drugs on living beings. Finally, product-related research is performed during experimental research preceding and/or following the introduction of, for example, a therapeutic drug into the market. Its purpose is to fully tap the potential of a therapeutic substance at advanced stages in the clinical development and of the products that have already been launched onto the market (to our knowledge, this element of the cascade has not yet been addressed in scientific publications). All steps in the cascade of drug development are performed using animals as subjects, in particular rodent species. However, large animal models are increasingly being used and may change the cascade of animal experiments from basic research to research intended to develop new therapeutic principles.

4 CONCERNS ABOUT THE TRANSLATABILITY OF FINDINGS FROM ANIMAL EXPERIMENTAL STUDIES

The relevance of results from preclinical animal studies for developing new therapeutics and the translational value of preclinical animal studies has been criticized (Plath et al., 2011; Pratt et al., 2012). Many putative new therapeutics turn out to be ineffective or not effective enough in clinical trials, whereas they showed good efficacy and safety in animal models (Gribkoff and Kaczmarek, in press; Macleod, 2011; van der Worp et al., 2010). Consequently, the translatability of result of animal studies to humans has been described as poor (Garner, 2014; Ioannidis, 2008; Macleod, 2011; van der Worp et al., 2010).

Many putative causes have been identified for the poor translatability of results from animal experimental studies (Sabroe et al., 2007), in particular ascribed to methodological flaws, such as underpowered studies, low group sizes, and/or lack of blinding, to name only a few (van der Worp et al., 2010). Awareness is increasing that animal studies can be flawed in multiple ways, and recommendations to increase the predictive validity of animal model-based research have been published (Ioannidis et al., 2014). Notably, it has hardly ever been questioned in this distending stream of critical reviews addressing lack of translatability, whether the appropriate model animal species have been used and whether a change of animal model species from rodents to large animals may improve translatability (presumably not in all, but probably in some areas of neuroscience research).

5 TRANSLATIONAL RESEARCH

Whereas research for identifying new therapeutic principles and putative therapeutics may be considered as basic research, using validated animal models to develop novel therapeutics may be considered translational research, where translation refers to the process in which knowledge generated in one area of research is applied in another area of research to advance goals in that area (Abernethy and Wheeler, 2011).

McGarland Rubio et al. defined translational research as follows:

> Translational research fosters the multidirectional integration of basic research, patient-oriented research, and population-based research, with the long-term aim of improving the health of the public. T1 research expedites the movement between basic research and patient-oriented research that leads to new or improved scientific understanding or standards of care. T2 research facilitates the movement between patient-oriented research and population-based research that leads to better patient outcomes, the implementation of best practices, and improved health status in communities. T3 research promotes interaction between laboratory-based research and population-based research to stimulate a robust scientific understanding of human health and disease. *McGartland Rubio et al., 2010*, *p. 471*

The European Society for Translational Medicine (TM) defined translational medicine as "an interdisciplinary branch of the biomedical field supported by

three main pillars: benchside, bedside and community. The goal of TM is to combine disciplines, resources, expertise, and techniques within these pillars to promote enhancements in prevention, diagnosis, and therapies." (Cohrs et al., 2015, p. 88).

Animal models are the first step in the translational continuum that has been described as consisting of three (Abernethy and Wheeler, 2011; Drolet and Lorenzi, 2011; McGartland Rubio et al., 2010), four (Lander and Atkinson-Grosjean, 2011), or five (Waldman and Terzic, 2010) distinct stages (Trochim et al., 2011). For our

purposes, the first translational stage(s) (T0 and T1) are of relevance. Fig. 3.1 depicts the chain of research from basic to translational. Nowadays, many if not most researchers using animal models in biomedical research denote their work as "translational." The T0 stage (Waldman and Terzic, 2010) in Fig. 3.1 may cover this use of "translational."

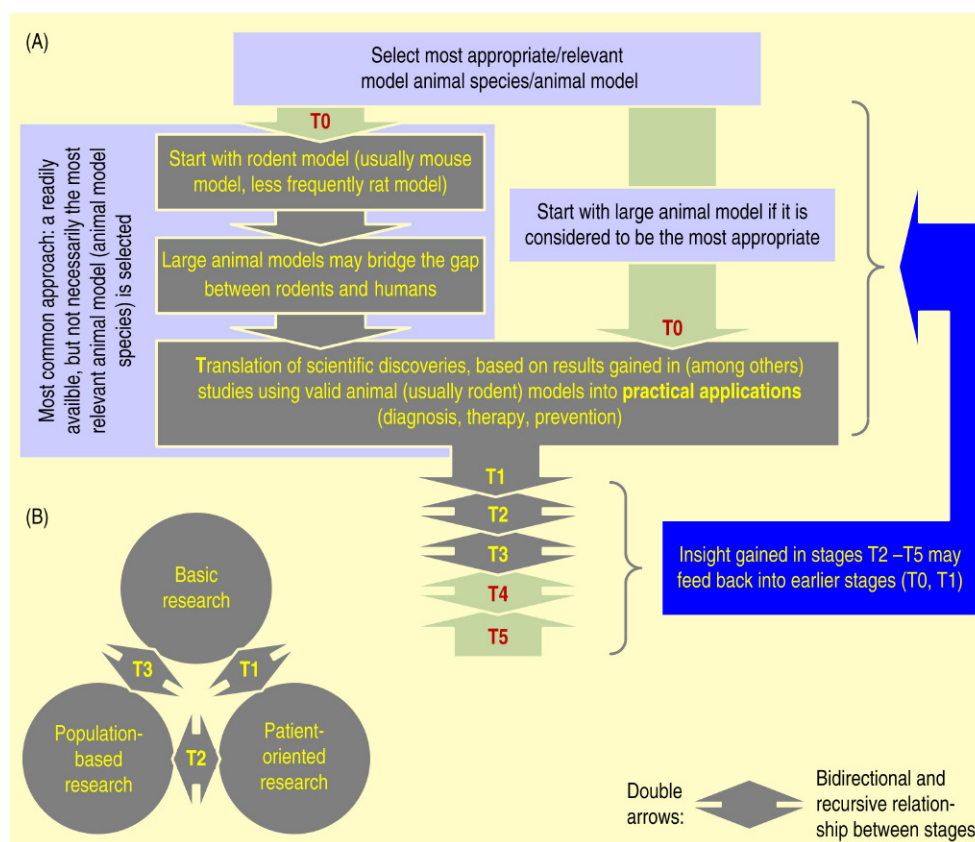
Translational animal models can be considered as a subset of the more general concept of "generalizability." The "translational value" and "translational relevance" of an animal model, and the concept of "predictive validity" are connected, or may be conceived as basically


FIGURE 3.1   **The position of animal models in the stages from basic (bench) to applied (bedside) translational research and the decision about the animal model species/animal model(s) to be used.** Translational research distinguishes different stages, most commonly T1–T3 [panel (B) Drolet and Lorenzi, 2011; McGartland Rubio et al., 2010, p. 472], which may be considered as the basic concept. Others, however, distinguish more stages, for example, T1–T4 (Trochim et al., 2011), or T0–T5 (Waldman and Terzic, 2010). In all systems, the first stage (T1) or the first two stages (T0, T1) involve animal experimental research (in particular proof of concept research, Hostiuc et al., 2016). Proof of concept research may start using rodent experiments [panel (A) upper left] or may be performed using large animals, if the large animal model is considered as more appropriate/relevant, eventually completely skipping rodent experiments [panel (A) upper right]. T1 is "the transfer of new understandings of disease mechanisms gained in the laboratory into the development of new methods for diagnosis, therapy, and prevention and their first testing in humans" (Woolf, 2008, p. 211). Waldman and Terzic (2010) suggested to add the stages T0, preclinical research (in vitro research and in vivo animal model-based research), which may start as basic research, and T5, improving the wellness of populations by reforming suboptimal social structures. Basic research is performed for gaining scientific insight without the primary intention of practical application of the knowledge, whereas T0 already considers practical applicability. The bidirectional and recursive relationship between animal models, translation to applications, and reverse translation to animal models is indicated by the *double-headed arrows*. Also, insight gained in later stages may feed back to the first stage(s) of translational research (T0 or T1, depending on the classification of stages used). Stages T0, T4, and T5, which have been added to the original concept of three translational stages shown in panel B, are depicted as *green arrows* or *double arrows* in panel A. *Source: Panel (A) modified from van der Staay, F.J., Arndt, S.S., Nordquist, R.E., 2014. Developing mouse models of neurobehavioral disorders: when is a model a good model? In: Pietropaolo, S., Sluyter, F., Crusio, W.E. (Eds.), Behavioral Genetics of the Mouse, vol. 2. Cambridge University Press, United Kingdom, pp. 3–17; panel (B) modified from McGartland Rubio, D., Schoenbaum, E.E., Lee, L.S., Schteingart, D.E., Marantz, P.R., Anderson, K.E., et al., 2010. Defining translational research: implications for training. Acad. Med. 85 (3), 470–475.*

the same concept. "Translational," however, has a clear focus on applicability (diagnosis, therapy, prevention). By comparing the effects of a new therapeutic with a compound with proven efficacy in the clinic, the predictive validity of an animal model can be determined experimentally. Likewise, the "translational value" or "translational relevance" of a (large) animal model is determined retrospectively: insights derived by using the animal model must successfully be translatable to practice.

Using models with proven construct validity may increase the probability of successful translation of animal research-based preclinical findings to clinical applications (Kimmelman and London, 2011; Pratt et al., 2012). The translatability can further be increased by using a broader range of relevant models (Pratt et al., 2012), for example, by using animals that show comorbidity (Libby, 2015), by applying a treatment regime that closely matches that of clinical practice (Green et al., 2011), and by applying appropriate behavioral tests that can distinguish between different behavioral domains and endophenotypes (Homberg, 2013). The "translational value" and "translational relevance" of large animal models largely depends on the degree to which they mimic the dysfunction/disease under study and the availability of reliable testing methods.

Translational research is bidirectional (Donaldson and Hen, 2015). It may start with clinical observations and characterizing disease-relevant endophenotypes in patients which are then reverse translated to animal models, that is, clinical findings inseminate basic research (Holschneider et al., 2011). This can be considered as a process of induction in the process of developing animal models (van der Staay, 2006). Sinha et al. (2011) assessed whether neuropharmacological findings in humans yield new insights, that is, whether they can be reverse translated to investigating underlying mechanisms in an appropriate animal model. Reverse translational approaches thus may contribute to conceiving and developing new animal models or to refining established ones. For developing translationally relevant animal models (Pratt et al., 2012), an intensive interaction of animal research scientists and clinical researchers is fundamental (Markou et al., 2009).

"The model's circular structure suggests that research is a continuing cycle, and its bidirectional arrows emphasize that new knowledge and hypotheses are generated at each step. Some basic research and population-based research is translational, but neither type of research is by definition translational. In contrast, patient-oriented research fundamentally addresses issues that have the potential to translate to clinical practice and, therefore, affect health." (McGartland Rubio et al., 2010, p. 472).

Animal models intended for use in basic research and animal models in translational research should,

in principle, fulfill the same criteria to be valid and relevant. However, translational animal models may need to fulfill additional criteria if they are applied in translational stage 1 (T1) (van der Staay et al., 2014). Whereas the key definitions per stage may differ for different classifications of the translational continuum, they all describe translational research as a process that moves from basic/preclinical research [T1 or T0/T1 that include(s) animal models] to the clinical application of the knowledge gained in animal experiment, and finally, to public health (Fig. 3.1). This process is bidirectional (Trochim et al., 2011) and in some instances, can be recursive.

6 CHOICE OF APPROPRIATE ANIMAL MODEL

In most instances, if authors reflect on the choice of an appropriate animal model, they are looking for models with rodents, and do not consider *nonrodent* species, that is, they usually mean *rodent model*, or *mouse model* when referring to *animal model*. Manger et al., 2008 discussed the consequences of the disproportionate use of rodent model, and particularly mouse models in basic neuroscience research. This extreme bias may hinder "(...) the discovery of novel aspects of brain structure and function that would be of importance in understanding both the evolution of the human brain and in selecting appropriate animal models for use in clinically related research." (Manger et al., 2008, p. 2).

There has been a steady increase of using rodent species, mainly mice, whereas in nonrodent species, in this decade, the use of pigs has overtaken that of rabbits and dogs as model species in biomedical research (Ericsson et al., 2013; Table 3.1). Recently, the use of large animal models appears to increase owing to the development of genetically modified farm animals. For example, genetically modified pigs are being developed as models for human diseases, such as Alzheimer's disease (Søndergaard and Herskin, 2012).

The reasons for sticking to rodent models, where nonrodent models might be more appropriate are mainly nonscientific:

- The researcher is mainly experienced with performing rodent studies. Rand (2008) cautions against selecting an animal model solely based on the familiarity of the researcher with a model, its availability and its costs.
- The question "which model species is the most suited for my research" very often is not even asked. This should, however, be one of the first questions when planning to perform animal experimental studies (Rand, 2008; von Rechenberg, 2012),

TABLE 3.1   Advantages and Disadvantages of the Reuse of Animals in Different Tests in the Same Study, Yielding Multiple Readouts From the Same Animals, or of the Same Animals in Successive, Unrelated Studies

	Disadvantages	
Advantages	Reuse of animals in one study (multiple tests and/or repeated testing)	Reuse of animals in successive, unrelated studies (which may comprise of one test or multiple tests, and eventually, repeated testing)
Fewer animals are needed for research (Reduction)	If nonrepresentative samples of the population are used, then this may affect the results of all experiments and/or tests with the same animals	If the samples are not representative for the population from which they were drawn, then this may affect all experiments/tests performed with the same animals
Animals are handled and accustomed to being tested; less habituation or training trials are needed; animals are used to be handled and tested; lower stress level	Animals may not be "test naïve" in later tests or experiments, that is, previous testing may affect results of subsequent tests and/or experiments; excessive reuse of animals may compromise their welfare (depending on the degree of discomfort induced by the testing methods used, Festing et al., 1998)	Excessive reuse of animals may compromise their welfare (depending on the degree of discomfort induced by the testing methods used, Festing et al., 1998); reuse may necessitate transportation, mixing (introduction into a new group due to random assignment to treatment conditions), housing in an unfamiliar animal room
Animals are test experienced. Successive testing provides opportunities to adapt to different environmental demands and challenges; behavioral consistency may increase with age, due to experience with testing (Bell et al., 2009); less likely "Casper Hauser" individuals with unchallenging life (van der Staay et al., 2010)	Animals may not be "test naïve" in later tests or experiments; altered behavioral baseline; prior testing may alter effects of treatment (Holmes et al., 2001b); this may complicate comparison with studies that used test naïve animals; previous testing may interfere with subsequent testing (proactive interference)	Animals may not be "test naïve" in later tests and/or experiments; prior testing may alter effects of treatment (Holmes et al., 2001b); this may complicate comparison with studies that used "test naïve" animals; previous testing may interfere with subsequent testing (proactive interference)
Knowledge accumulates with each test/ experiment, providing a more complete picture, and allowing investigation of relationships between variables (readouts) (Reduction, Refinement)	Animals are older in successive tests (age cannot strictly be controlled); animals may reach "ceiling" performance level, reducing sensitivity to detect treatment effects; correction of P-values for multiple comparisons may reduce sensitivity to detect (subtle) effects	Animals are inevitably older in each successive study (age cannot strictly be controlled)
Testing may act as enrichment	Testing per se may overshadow the effects of experimental manipulations (Westlund, 2014a,b)	Testing per se may overshadow the effects of experimental manipulations (Westlund, 2014a,b)

where the appropriateness of the selected animal model species should be the first consideration (Held, 1983).

- Conservatism of rodent researchers may withhold them from considering alternative animal model species. In this connection, Libby (2015) coined the term *Murine "model" monotheism*, which is a nice label for the bias toward rodent models.
- Neglecting publications that used nonrodent animal models (perhaps best described as "reading bias").
- In most research institutes, facilities other than those needed for housing and testing rodents are unavailable.

Instead, the selection of rodent and nonrodent species for preclinical assessment of, for example, the efficacy and/or safety of new putative therapeutics, should

always be based on scientific and ethical justifications. Animal models must fulfill a set of scientific criteria and should thoroughly be validated (Belzung and Lemoine, 2011; Markou et al., 2009; van der Staay, 2006; van der Staay et al., 2009, 2014). Of course, these criteria are closely connected with the research question(s) that the animal study is supposed to answer. Besides this very specific consideration, general questions must be addressed to help finding the animal model best fitting one's research question(s). This implies that the selection of an animal model species and the animal model should be considered on a case-by-case basis (Colleton et al., 2016; Rand, 2008). Based on Rand's (2008) listing of scientific and practical criteria, the following questions need to be answered before selecting an animal model and starting a study. The first questions are related to the experimental approach to be chosen:

- What is known about the problem under consideration (based on a thorough review of the scientific literature, for example, via a systematic review, Hooijmans and Ritskes-Hoitinga, 2013, or via less time-consuming rapid reviews, Featherstone et al., 2015)?
- Has the selected model been validated and is it deemed to be the most appropriate for answering the research question(s)? How closely, for example, does the animal replicate the human disease (Søndergaard and Herskin, 2012)?
- What kind of model is it: does the model animal express naturally occurring or experimentally induced deficits (for different classifications of "animal models," see Rand, 2008; van der Staay, 2006)?
- What are the ethical implications of this choice (similar considerations as, e.g., for stroke models in primates Sughrue et al., 2009, may be relevant in other large animal model species)?
- How many animals are needed to answer the research question(s), that is, which group sizes are needed to ensure sufficient power?

Next, questions concerning availability, animal housing, and animal care must be answered, such as:

- Is the animal model species chosen readily available. In most instances, availability should not be a major problem in research using large farm animals.
- Can the animals be housed appropriately? This may be a concern in large animal research because they may need considerably more space and must be housed in stables/pens that fulfill their species-specific needs.
- Are the researchers and animal caretakers trained to work with large model animal species and provide special care, if necessary?

Finally, a number of specific questions must be answered:

- Do animals with genetic homogeneity or heterogeneity best serve the research question(s)? Most large model animal species are heterogeneous lines/breeds, that is, homogeneous (inbred) lines are not yet readily available. However, for most farm animal species, a large variety of breeds is available.
- Is the selected model animal species testable, both in terms of ease of handling, as well as in terms of availability of well-established and validated test methods and test equipment (see also Chapter 39)?
- Does the size of the animal facilitate taking samples from the animal (blood, hair, tissues)? Is it crucial that organ size is similar to that of humans?

- Should the animal be tested during ontogeny, (e.g., early postpartum, as juvenile), as adult, or during senescence. Whereas large animal species may be specially suited for pre-, peri-, and early postnatal experimental manipulations, they may be less suited for aging research, due to poor availability of aged subjects and the high life expectancy of many of these species.
- Recently, the "sex bias" in neurosciences and biomedical sciences in general attracts increasing attention (Beery and Zucker, 2011; Zakiniaeiz et al., 2016). It has to be decided whether males, females, or both sexes should be included. Due to the extra space, special equipment, well-trained personnel needed to perform experiments using large model animal species, inclusion of both sexes may overburden available resources.

7 WHERE IN THE PROCESS OF MODELING HUMAN DISEASES AND DEVELOPING PUTATIVE THERAPEUTICS HAVE LARGE ANIMAL MODELS BEEN USED?

Large animal models may be relevant for research that aims to improve production of animal-derived products (not considered further in this chapter), for animal health and welfare, and for translational biomedical research (Gonzalez-Bulnes et al., 2016; Ireland et al., 2008; Koopmans and Schuurman, 2015), that is, they can be considered as multiple purpose models. Large animal models are well accepted in the area of orthopedic and xenotransplantation research (Cook et al., 2014; Gregory et al., 2012; Harding et al., 2013). They are, however, only sporadically used in neuroscience, where they are mainly applied in stroke and traumatic brain injury studies (Boltze et al., 2008; Duhaime, 2006; Margulies et al., 2015; Mehra et al., 2012; Platt et al., 2014; Wells et al., 2012).

Most of the efficacy, toxicology, teratology, and safety studies use rodents species as subjects. However, in particular in toxicology, teratology, and safety studies a considerable proportion of animals used are large animals (e.g., dogs and miniature pigs). In particular in safety pharmacology/toxicology/teratology studies, the minipig is gaining importance (Bode et al., 2010; Forster et al., 2010a,b,c; Svendsen, 2006; van der Laan et al., 2010).

Other than in risk assessment studies, the use of large animal model species is still negligible in drug testing, be it in POC studies or in studies, which aim to test the efficacy of a new compound preclinically, compared with rodents.

8 WHICH MODEL ANIMAL SPECIES ARE CLASSIFIED AS LARGE IN SCIENTIFIC RESEARCH?
One may distinguish between "small (e.g., mouse, rat)," "midsized" (e.g., dove, chicken, rabbit, guinea pig, marmoset, cats) and "large" (e.g., pig, dog, rhesus monkey, baboon, chimpanzee) animals. However, Hagen et al. (2012) categorize companion animals, such as cats, dogs, rabbits, and ferrets, farm animals, such as pigs, goats, sheep, cows, and horses, chickens, ducks, goose, etc. as "large" animals, if compared with the most commonly used species in scientific research, mice and rats (Fig. 3.2).

The designation of specific species as "small," "midsized," or "large" animals depends in part on the system under study. Rodents are virtually always considered "small" animals, while dogs, sheep, swine, and primates are typically considered "large" animals. Chickens and cats can be included in either group, depending on the specific system studied.

For purposes of brain research, it may be useful to ask which feature in humans one is attempting to reconstruct in a given model. In a study of experimentally induced brain injury one may, for example, try to model one or more of the following features: the mechanistic forces that caused the brain injury, the resultant morphological changes in the brain, the effects of age (maturation) and aging on these changes, and/or the effects of treatment with putative therapeutics on the development and final extent of the damage (Duhaime, 2006).

The size of the model animal species and of its brain may crucially determine the resolution at which these changes in the afflicted brain can be studied. Consequently, big is sometimes better. For example, bigger brains contain more tissue for analysis, nuclei and areas

(A)	(B)	Species		Approximate brain weight	Gyri and sulci
		Human	5 cm	1300–1400 g	Gyrencephalic
Large animal model species	Large animal model species	Cow		480 g	Gyrencephalic
		Sheep		175 g	Gyrencephalic
		Pig		80–180 g (large variation between breeds)	Gyrencephalic
		Dog		70–130 g (large variation between breeds)	Gyrencephalic
	mid-sized	Cat		30 g	Gyrencephalic
small*		Chicken		2.5–4.5 g (large variation between breeds)	Lissencephalic
	small*	Rat		2 g	Lissencephalic
		Mouse		0.5 g	Lissencephalic

aNote: quail and pigeons may be considered as small model animal species

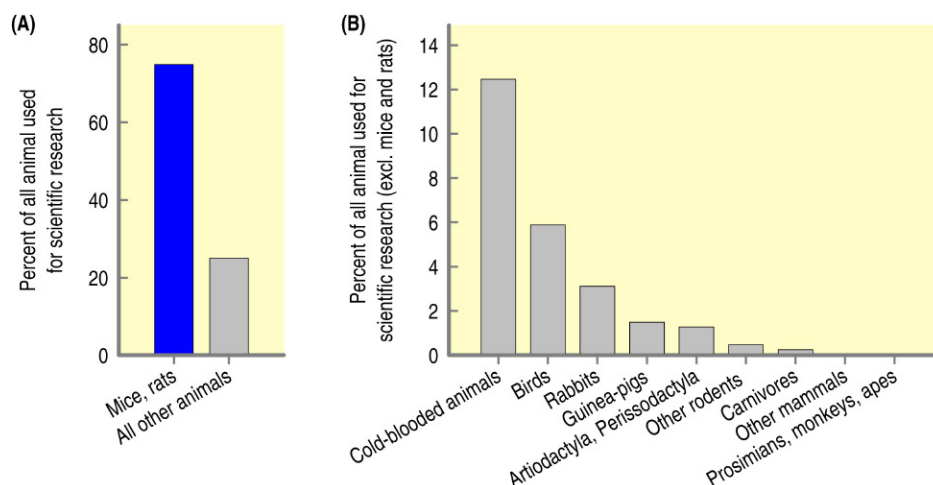
FIGURE 3.2 Classification of animal model species as large, midsized, or small (columns A and B), and weight (g) of the brain of adults of these species, from mice to humans. In pigs and dogs, the variability is high, due to selection on, among others, body size. *Source: Silhouette of brains of human, sheep, pig, dog, cat, rat, mouse, and chicken redrawn from photographs: Welker, W., Johnson, J. Modified from Gieling, E.T., Schuurman, T., Nordquist, R.E., van der Staay, F.J., 2011. The pig as a model animal for studying cognition and neurobehavioral disorders. Curr. Top. Behav. Neurosci. 7, 359–383.*


FIGURE 3.3 **Animal use in the European Union in 2011.** Panel (A) shows that the majority of studies are performed using mice and rats. In panel (B), "All other animals" from panel (A) is subdivided. Note that chickens are included in "Birds." The Perissodactyla include horses, donkeys, and their crossbreds. The Artiodactyla include pigs, goats, sheep, and cattle (European Commission, 2013). Unfortunately, the different reporting schedules, classifications of model animal species, and inclusion/exclusion of model species preclude a one-to-one comparison between statistics about experimental animal use in the EU and the USA (USDA, 2015).

of interest are bigger, allowing more precise lesioning of target structures, local injections of test compounds via cannulas, electrophysiological stimulation or recordings in deep brain structures, or electroencephalography from the surface of the brain or skull.

The use statistics of different animal model species in scientific research in the European Union in 2011 (European Commission, 2013) are depicted in Fig. 3.3. Large animal use represents only a very low percentage of the total use of experimental animals.

9 WHICH TYPES OF (LARGE) ANIMAL MODELS ARE AVAILABLE?

A number of classifications of animal models have been proposed. These classifications typically distinguish between normal animals, animals with spontaneously occurring deficits, and animals with experimentally induced deficits (Gamzu, 1985; van der Staay, 2006), but other classifications have also been proposed (Rand, 2008). The classification can be applied to rodent and nonrodent (e.g., farm animal) models.

Normal subjects, that is, animals without observable (behavioral) deficit are useful for assessing the safety/toxicology risk of putative therapeutics (Dixit and Boelsterli, 2007), for assessing the putative abuse liability of a compound, and for investigating the neurobiological specificity of compounds and their mechanisms of action.

Spontaneous models are, for example, old animals, animals showing spontaneously and endogenously

occurring psychiatric or neurological conditions, spontaneously occurring mutations, genetic lines (inbred strains and their crossings), and lines resulting from selective breeding, and selected extremes from a particular animal population (Hudler, 2007; van der Staay, 2006).

Induced models are healthy animals in which the pathological condition is induced experimentally, for example, transgenic and knockout animals, selection lines resulting from selective breeding, animals with disruptions induced, for example, by stimulation with electric currents, pharmacological treatments, or by inducing hypoxia or anoxia. This class also includes animals with neuro- or immunotoxic, radiofrequency, cryogenic CNS-specific lesions, and lesions induced by aspiration or ablation (knife cuts). Finally, this class contains animals with experimentally induced cerebral ischemia or hemorrhagic stroke.

Rand (2008) in addition distinguishes negative models and orphan models. Negative models may be useful to investigate the mechanisms behind disease resistance because they are characterized by insusceptibility to disease or chemical stimulation. The opposite of negative models are orphan models. These animals show a disease/deficiency/dysfunction for which no correspondence has yet been described in humans. As soon as a similar disease has been identified in humans, an orphan model may become the basis of a spontaneously or naturally occurring, or an induced model (e.g., sheep suffering from scrapie, now may serve as model human spongiform encephalopathies).

A considerable number of rodent models have been developed for at least the first three classes. However,

they have not yet been established broadly in large model animal species.

Already 4.5 decades ago, Douglas (1972) summarized arguments why the pig may be a useful animal model species for human biomedical research, predominantly based on hematological and organ similarities between pigs and humans. However, he also noted that "Apart from the biological side, the pig must not be considered stupid. The pig can be used for the observation of many well-defined patterns of individual and group behavior (…)" (Douglas, 1972, p. 232), a first hint that this species may also be useful in neuroscience research. Reasons why large animal models should be used are given by Bähr and Wolf (2012), de Groot et al. (2005), Gieling et al. (2011b), Reynolds (2009), and Roberts et al. (2009). They all agree that "(…) the validity of an animal model as a predictor of human response depends on how closely the model resembles humans for the specific characters being investigated." (Festing and Altman, 2002, p. 246).

10 SPECIAL ASPECTS IN USING LARGE FARM ANIMAL MODELS

Large animal models need more housing and testing space than rodent species (Fig. 3.4, panel A). Also, test procedures and equipment must be adapted from rodent studies or must be developed and validated.

New equipment and new tools for large animal models are being developed. For example, stereotaxic atlantes and stereotaxic frames (Marcilloux et al., 1989; van Eerdenburg and Dierx, 2002) are available for many large animal species. For about a decade, the stereotaxic, histology-based atlas by Félix et al. (1999) and the magnetic resonance imaging-based atlas by Watanabe et al. (2001) were the only source of stereotaxic coordinates of the pig brain. Recently, higher resolution three-dimensional representation of the pig brain have been published (Göttingen minipig, Andersen et al., 2005; neonatal pig, Conrad et al., 2014; commercial pig, Saikali et al., 2010). A stereotaxic atlas for the chicken brain has been published a decade ago (Puelles et al., 2007), whereas for sheep (and for a number of other species), three-dimensional representations became recently available online (Johnson et al., 2016).

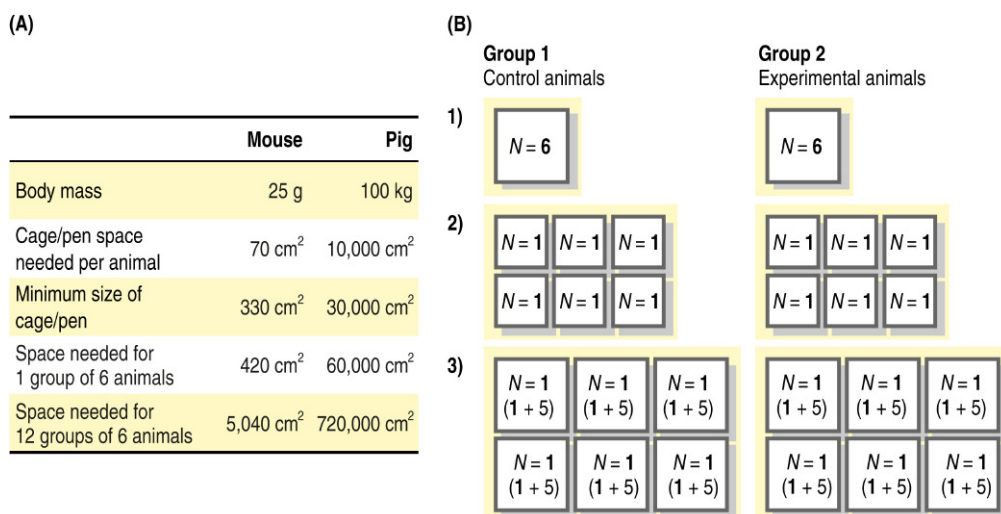
For pigs, a large number of tests to assess emotion (reviewed by Murphy et al., 2014) and cognition (reviewed by Gieling et al., 2011a) have been developed. Similarly, an increasing repertoire of behavioral test is being developed for sheep (e.g., judgment bias, Doyle et al., 2011; face and object discrimination learning, Kendrick et al., 1996, 2001; spatial learning, Lee et al., 2006), although progress is slow. The repertoire of tests for assessing learning and memory in chicks is still limited, but expanding (e.g., the spatial holeboard task, Nordquist et al., 2011; Tahamtani et al., 2015; Fig. 3.5, panel B).


FIGURE 3.4 **Space requirements and examples of different experimental setups of the same study.** In panel (A), the space requirements for housing 6 mice or pigs individually or as group are tabulated in cm^2. In the example depicted in the panel (B), each of 12 animals is randomly assigned to one of two treatment groups (assuming that a group size of 6 animals is sufficient to address the scientific questions of the experiment). Although it cannot be excluded that cage is a confound variable that might codetermine or even cause differences between treatments in setup 1, the mere assumption leads to a huge increase in animals used, if a "state of the art" experimental setup (setup 3) is applied. Note, that the 6 pens per condition in setup 3 do not provide 100% identical environments for the 6 experimental animals per treatment group. Instead, strict standardization of the housing conditions (i.e., of the two cages in setup 1) could be applied, reducing the number of animals to 12. In social species, setup 1, but not setup 2 is an alternative for setup 3. Note: none of the setups is able to control all putative intervening variables. The number of control or experimental animals per cage/pen is printed bold (the *squares* representing cage/pen areas are on scale and correspond to the tabulated values; based on Forbes et al., 2007).
FIGURE 3.5 Comparison of holeboard arena's used to test spatial learning in two large animal model species [(A) pigs, Antonides et al., 2015a; Gieling et al., 2013; (B) chickens, Nordquist et al., 2011; Tahamtani et al., 2015] and two small animal model species [(C) rats, van der Staay, 1999; (D) mouse, Kuc et al., 2005].

Many of these tests have been developed for assessing cognitive functions in farm animal species, and have only sporadically been used in biomedical studies. They still need scientific validation but they provide a basis for testing learning and memory in disease models using large animal model species. However, it is obvious that additional tests must be developed to increase the usability and relevance of large animal models of neurobehavioral and psychiatric disorders.

The test equipment for large animals must fulfill a number of special requirements. First, obviously, it must fit the size of the animal species to be tested (Fig. 3.5). This may require a room which exceeds the size of a standard rodent laboratory. Second, the equipment must be stable enough to resist destruction by the tested animals. Our test apparatuses for pigs (Fijn et al., 2016; Gieling et al., 2014; Murphy et al., 2013; van Eck et al., 2016) were constructed by a stable builder according to our specifications, using standard material that normally is used to construct pig pens. Stable builders know how to construct pig-proof equipment.

Also, testing procedures and methods need to be suited for the species to be tested. For example, pigs must thoroughly be habituated to the test environment, the experimenter(s), and to being alone in the test apparatus (Gieling et al., 2011a; Murphy et al., 2014) (see also Chapter 39). The habituation and training period can be time consuming, before formal testing starts.

11 EXPERIMENTAL UNIT

Most animal experimental studies do not explicitly define the experimental unit. It needs to be stressed that *experimental unit is not* the same as *unit of analysis*. Depending on the experimental design used, there may be multiple units of analysis. Whereas in a basic single-level experiment the *experimental unit* would be considered the *unit of analysis*, a multilevel design may have more than one unit of measurement (Festing, 2006; Festing and Altman, 2002; Perrett, 2012).

An "experimental unit" is defined as the smallest division of the experimental material that allows any two experimental units to receive different treatments (Festing, 2006, 2011), or as Bate and Clark define it, "An experimental unit for a treatment factor is the smallest unit which a level of the treatment can be applied to." (Bate and Clark, 2014, p. 37). An experimental unit is one member or a set of animals that are initially similar on the measure(s) of interest, with each animal then subjected to one of several experimental treatments (Fig. 3.6, panels A–D). An experimental unit can also be a part of an animal (e.g., skin patches that undergo different treatments; Fig. 3.6, panel E). Each treatment represents one of a set of different experimental conditions. The effects of these different conditions are assessed experimentally.

For some, it must be possible to treat an animal independently from all other animals involved in the study *at any time*, that is, "The experimental unit may be defined
FIGURE 3.6 **Experimental units in animal research.** "Condition" refers to experimental condition (treatment or control). While it is unusual to depict pigs instead of rodents as experimental animals, studies with large animals may pose additional challenges that need to be addressed when designing and performing an experiment. *Source: Modified from Gieling, E.T., Schuurman, T., Nordquist, R.E., van der Staay, F.J., 2011. The pig as a model animal for studying cognition and neurobehavioral disorders. Curr. Top. Behav. Neurosci. 7, 359–383, Fig. 4.*

as the object independently treated in an experiment." (Perrett, 2012, p. 3). For others, this may refer to random assignment or placement to one of the experimental conditions *at the start of an experiment*, before the animals undergo their assigned experimental manipulations. According to Cheng, following a definition of Cox from 1958 "In general, an experimental unit can be defined as the smallest division of the experimental material such

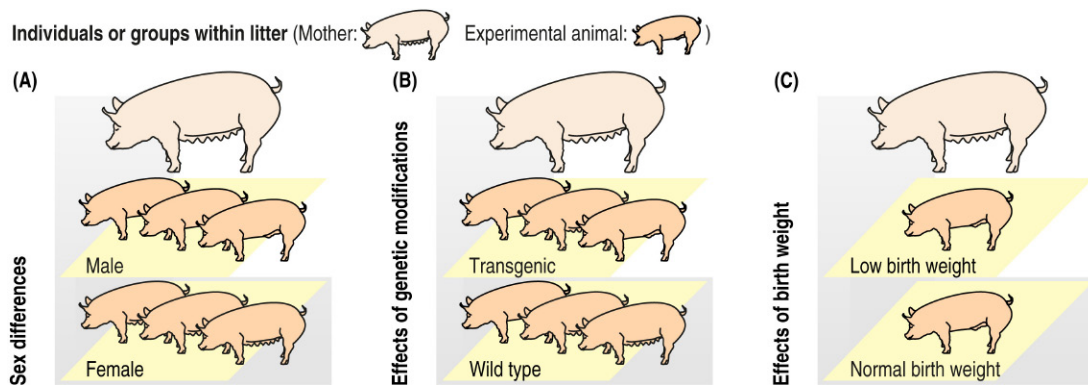
that different units may receive different treatments." (Cheng, 2013, p. 1) (see Figs. 3.6 and 3.7 for schematic overviews of experimental units). Random assignment is the procedure by which animals are allotted to different treatment groups (treatment conditions), or to an untreated control group (control condition; note that some studies comprise more than one control group). It is assumed that as a result of random assignment to


FIGURE 3.7 **Examples of individuals or groups within litter (i.e., offspring of the same sow) are shown, where litter is the experimental unit.** Instead of litter, the experimental unit may be pen, herd, compound in a zoo, etc. In (A) male and female pigs are selected from the same litter for assessing sex differences. In (B) transgenic and wild-type pigs are derived from the same litter to investigate the effects of genetic manipulations, whereas in (C) low birth weight (LBW) and normal birth weight (NBW) pigs are selected for investigating the effects of birth weight. In all examples, a study comprises a number of litters. Note that in these examples, random assignment of individuals to a group is not possible, but random selection of animals from a larger pool (e.g., selection of one or a few males in a litter from a larger number of male littermates) to a study is possible.

treatment conditions, the different treatment groups will be initially similar; differences between the treatment groups (conditions) are likely not due to differences between the groups that already existed before the start of the experimental manipulations. Once an individual has been assigned to a particular experimental condition, it may be impossible to treat that individual animal independently from the other animals in the same group during the term of the experiment. Due to space requirements and space restrictions, this is a problem inherent in studies using large animal model species.

Most large model animal species produce litters with multiple offspring. It is advisable to use this in designing experiments. There are two ways to assign littermates to experimental groups (conditions): either all littermates are assigned randomly to the same experimental group, a nested design, or the littermates are randomly assigned to different experimental groups, a randomized blocks design (Denenberg, 1984). In the nested design (Fig. 3.6, panel B and Fig. 3.7) litter must be considered as experimental unit because littermates are not independent. As Lazic and Essioux (2013) pointed out, litter effects are common and usually large. Consequently, replication of findings is difficult if this source of variation is ignored when analyzing the data and the translational value of the study may be low.

Mixed model analyses of variance may be used to account for nested effects. They have been developed to account for "nested (multiple observations within a single subject/animal in a given condition) and crossed (subjects/animals observed in multiple conditions) structure of the data" (Boisgontier and Cheval, 2016). Unfortunately, this statistical approach has not yet been fully appreciated in the neurosciences.

In the randomized block design of a one-factorial study consisting of an experimental and a control condition one might use pairs of littermates from a number of different litters equal to the number of animals per group used. Then, one sibling per pair is assigned randomly to the experimental group, the other to the control group. Fig. 3.7 (panels A–C) shows a different design in which a *group of littermates within litter* is assigned randomly to the experimental condition, and *another group of littermates within the same litter* to the control condition. In these designs, accounting of litter effects helps to obtain a better estimate of the effects of the experimental manipulation (Denenberg, 1984; Healy, 1972).

12 EXPERIMENTS USING SOCIAL ANIMALS REQUIRING GROUP HOUSING

Fig. 3.4 (panel B) shows a schematic overview of different experimental setups for studying the effects of experimental manipulations on social animals (here: pigs). Assuming that six animals per treatment condition are sufficient for sound statistical interference about the effects of the experimental intervention(s) and that a group size of six animals fulfills the need to live in a group, and strictly following the previously given definition of "experimental unit" (Festing, 2006), the state of the art setup of the study is depicted as setup 3. Note, that this setup needs 5 times more animals than the 2×6 animals assigned randomly to the treatments groups in setups 1 and 2. In setups 2 and 3, each of the 2×6 experimental animals can be treated independently. In large animal research, setup 3 may already exceed the possibilities of appropriate housing of the animals. Instead,

one may house each of the 2 × 6 animals individually in smaller pens (Fig. 3.4, panel B, setup 2), adhering to the postulation of independent treatment. However, still the space requirements for housing all animals are high (Fig. 3.4, panel A). In addition, welfare of the animals may be at stake because social animals should be housed in groups.

In setup 1, all animals of the same treatment group are housed in one pen. In this case it is impossible to treat each individual animal independently from the pen mates, that is, the other animals undergoing the same experimental intervention. Consequently, according to the definition, the pen is the experimental unit and it is impossible to perform proper statistics on the effects of the experimental manipulation(s), as $N = 1$. However, the animals are housed socially and not individually as in setup 2, and no surplus animals are used, as in setup 3.

We discuss the implications of the definition of experimental unit, of housing animals in groups, and of repeated testing and/or reuse of animals against the background of principles of two (Reduction, Refinement) of the 3Rs (the third one being Replacement: Russell and Burch, 1959).

What are the consequences for the majority of studies performed, in which animals are housed in groups? For example, pigs are group housed in a barren or an enriched pen to assess the effects of environmental enrichment (Bolhuis et al., 2013; Grimberg-Henrici et al., 2016). A strict definition of "experimental unit" may have major implications for studies with socially housed animals, and may lead to an undesirable increase in the number of animals used. It also may considerably increase the costs of a study, in particular if large animals are involved (e.g., pigs, sheep, cattle, horses), but also if rodents are kept under special condition, such as isolators or ventilated cages.

Finally, we address the question what the welfare consequences are of collecting a multitude of measures in the same animal, of testing the animal repeatedly in the same study, and of reusing the animal in subsequent (unrelated) studies.

13 PUTATIVE ADVANTAGES AND DISADVANTAGES OF GROUP HOUSING

Group housing and environmental enrichment are common measures to improve the welfare of social animals. Most large animal model species (in particular the farm animals, such as chickens, pigs, sheep) are social animals that live in groups/herds (Estevez et al., 2007). Compulsory group housing might reduce the number of experimental units (i.e., cages/pens) and may consequently increase the number of animals needed (even if a

part of the penmates are not tested). Individual housing of these animals with the aim to increase the number of experimental units, compromises their welfare (Fig. 3.4, panel B, setup 2).

When using social animals, it is mandatory to apply group housing from an animal welfare perspective. Some Ethics Committees routinely demand group housing, even in cases where individual housing would be more appropriate, for example, if highly aggressive male mice are used in a study, despite the fact that this practice may compromise the experimental results (Poole, 1997). Older, sexually mature minipig boars, for example, should be housed individually to prevent fierce fighting, whereas younger boars can be kept in groups (Ellegaard et al., 2010).

One of the disadvantages of group housing and testing more than one member of the group or all group member, effects of test order, have been documented by Kask et al. (2001) for rats and by Arndt et al. (2009), and Takao et al. (2016) for mice. In rats, cohort removal induced anxiogenic like effects (Kask et al., 2001). In the study by Takao, cohort removal induced an increase in body temperature, pain sensitivity, and anxiety-like behavior in mice. Cohort removal also increased the plasma corticosterone concentration in mice (Takao et al., 2016). Arndt et al. (2009) observed a within cage order effect on the hormonal stress response (corticosterone) in socially housed female C57BL/6 mice. Whether similar effects may occur in other group-housed animals species as well (Fig. 3.4, panel B, setup 1) needs to be investigated. A thorough habituation of group-housed animals to the test environment and to being tested alone might help to forestall test-order effects.

14 PRINCIPLES OF THE 3R—REPLACEMENT, REDUCTION, REFINEMENT

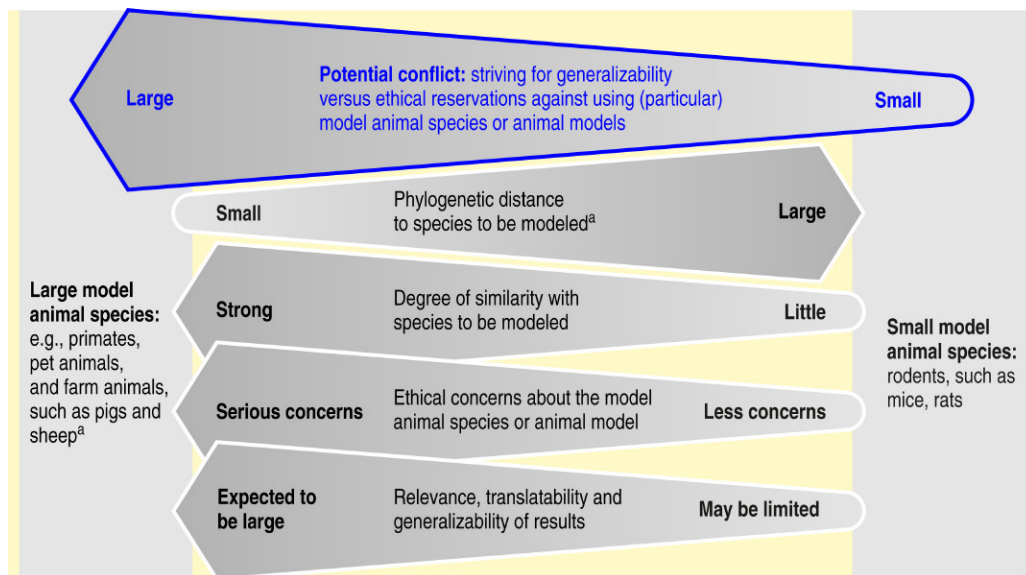
Replacement is the "the use of non-animal methods, such as cell cultures, human volunteers and computer modeling instead of animals to achieve a scientific aim." (Richmond, 2000, p. 84). Under certain conditions, in vitro studies may replace in vivo studies, or insentient lower creatures may replace higher animals, that is, it should be obvious that we are not dealing with Replacement when discussing large animal models. Using, for example, pigs instead of dogs in regulatory toxicology studies cannot be seen as Replacement according to the 3Rs, as they do not replace or avoid animal use (Russell and Burch, 1959; Webster et al., 2010). However, many people have severe objections against using pet animals, such as dogs (Hasiwa et al., 2011) in scientific research laboratories. These objections may be less severe if pigs are used instead (Fig. 3.8).


FIGURE 3.8   General characteristics of large animal models versus rodent models for studying human disease, area of potential conflict between the model animal species/animal model, and the expected degree of generalizability of results are compared. [a]Note that the phylogenetic distance between some large animal model species, such as domestic artiodactyls (which include cattle and pigs) and humans is larger than that between rodents and humans (Varga, 2012), whereas they may share more anatomical and physiological similarities with humans than rodents (Bähr and Wolf, 2012). *Source: Modified from van der Staay, F.J., Arndt, S.S., Nordquist, R.E., 2009. Evaluation of animal models of neurobehavioral disorders. Behav. Brain Funct. 5, 11., Fig. 4.*

Reduction is "Any approach in scientific research, product testing or education that leads directly or indirectly to a decrease in the number of animals used while meeting the scientific requirements." (Consensus definition in: de Boo and Hendriksen, 2005, p. 376). Reduction thus refers to the minimum number of animals necessary to answer a scientific question. The National Centre for the Replacement, Refinement, and Reduction of Animals in Research adds to this definition methods that enable researchers to obtain comparable levels of information from fewer animals or to obtain *more information from the same number of animals*, thereby avoiding further animal use (Wellcom Trust, 2013).

Refinement is "Any approach which avoids or minimizes the actual or potential pain, distress and other adverse effects experienced at any time during the life of the animals involved, and which enhances their wellbeing" (Buchanan-Smith et al., 2005, p. 381). Remarkably, Refinement does not include the measures that improve the quality of experiments, which, by reducing the number of poor experiments, reduces the number of animals that is necessary for gaining solid scientific insight.

Note that the 3Rs are a somewhat one-sided view on the use of animals in scientific experiments (for critical notes about the 3Rs see Ibrahim, 2006). Refinement, for example, is considered exclusively in the context of pain, distress, adverse effects. However, Refinement of procedures and methods may yield clearer, replicable results which answer the research questions without the need of performing an endless series of additional experiments. Using the most appropriate animal model species thus may in fact reduce the use of animals as well. Approaches to the evaluation and improvement of animal models have extensively been described (Belzung and Lemoine, 2011; van der Staay, 2006; van der Staay et al., 2009, 2010). Developing valid large animal models may contribute to reducing animal experimentation in the long run.

15 GETTING THE MOST OUT OF AN ANIMAL EXPERIMENTAL STUDY

Experiments should be designed in a way that a maximum of relevant information can be derived. This may have considerable implications for the study design, the number of animals used, and the statistical analysis of data. Repeated testing and/or reuse in related or unrelated experiments are means to increase the amount of information derived from the same animal, and to reduce the number of animals in experimental research. Repeated testing may also be applied for determining onset, progression of neurobehavioral dysfunctions, neurologic and psychiatric conditions, their duration, and their reversibility by treatment with putative therapeutics. Similarly, this testing schedule may be used for assessing onset, progression, duration, and reversibility of neurotoxic injury (Henck et al., 2016).
FIGURE 3.9 **Example of multiple readouts (dependent variables) in a single animal experimental study.** After chronic exposure to stressors, pigs are subjected to behavioral tests of emotion and cognition, each of which may reveal a large number of measures. In addition, saliva, blood, and hair samples are collected to determine stress markers ex vivo. The animals are sacrificed at the end of the study, and brain and organ samples are taken for a variety of analyses, for example, for assessing the correlation between stress markers and cognitive performance.

An advantage of measuring multiple variables is that more information can be gained from a study, without increasing the number of animals needed (see Fig. 3.9 for a hypothetical example, which, however, is inspired by Antonides et al., 2015a). The approach may be considered as contributing to Refinement and Reduction according to the principles of the 3Rs.

In an attempt to reduce the number of animals employed in experimental studies, one may decide to reuse animals. Reuse may refer to using animals in one particular study in successive experiments to address additional scientific questions within the study or in successive studies that may address scientific questions unrelated to those of the first study. The gain of information must be weighed ethically against an increase of discomfort that the animal may experience, as must be any reuse of the same animals in subsequent studies. Festing (1998) cautions against possible welfare consequences of the wish to reduce animal use, for example, through excessive reuse of animals. Such a practice may threaten the animal's welfare, depending on the discomfort caused by each of the tests employed. The reuse of animals has a number of advantages and disadvantages (Table 3.1).

16 NEED TO CORRECT FOR MULTIPLE COMPARISONS?

Without doubt, there is a higher probability of false positive results in studies with multiple dependent variables. On the statistical level, multiple read-out variables and multiple testing in the same study (Fig. 3.9) imply that the P-values must be corrected for multiple comparisons, that is, that the P-value for accepting the alternative hypothesis (incorrect rejection of the null hypothesis) becomes more stringent. Consequently, when performing a large number of statistical tests of significance, a correction for multiple testing (e.g., the Bonferroni correction for multiple testing) must be applied. This approach, however, leads to a loss of sensitivity (Benjamini et al., 2001; Storey, 2002). Therefore, a more sophisticated

approach, such as controlling the "false discovery rate" (FDR) is indicated (Benjamini and Yekutieli, 2001).

In studies with an exploratory character, all differences/correlations with associated probabilities <0.05 are considered, without making provisions for multiple testing through applying a Bonferroni correction or controlling the FDR (Bender and Lange, 2001; Sainani, 2009).

17 REPLICATION STUDIES

The risk of false positive results for the main question(s) of a study (e.g., does an experimental intervention affect working memory and/or reference memory performance in a cognitive holeboard task, Antonides et al., 2015a,b), is unaffected by analyzing additional variables obtained from the same subjects. These ancillary variables may provide valuable information about the study (Gaines Das, 2002) and thus may help to understand and discuss the results of a study. The additional variables measured might be treated as "exploratory."

Subsequent replication studies must be performed to corroborate the effects found in the exploratory studies (van der Staay et al., 2010), that is, the repeatability and robustness of findings across studies should be investigated. One should consider all findings as tentative, until they have been corroborated in additional, independent studies (Feise, 2002; van der Staay et al., 2010). Replication studies help to determine the generalizability of previous findings (van der Staay et al., 2010). These studies should, however, not be exact replications. Instead, they should be extended replications (partial, systematic or differential, conceptual, or quasireplications; van der Staay et al., 2010). Extended replications are based on a wider notion of replication, namely the repetition of a test of a hypothesis or a result of earlier work with different methods (Schmidt, 2009).

In "partial" replications (slight) procedural modifications are introduced whereas all other aspects closely mimic the original study. "Conceptual replications"

investigate the same relationships/constructs as the original study, using different procedures. "Systematic or differential replications" induce variations in major independent variables, for example, in rearing, housing, and/or test conditions, or gender. This type of replication may even extend to seminatural or natural environments. In "quasireplications" species different from the one used in the original study are tested (Palmer, 2000). Quasireplications are often performed using large animal models to fill the gap between rodent studies and humans.

For example, in a study addressing the effects of different levels of environmental enrichment, all animals undergoing the same level of environmental complexity may be housed in the same cage/pen/enclosure. Under this condition, of course, the level of environmental enrichment cannot be manipulated per individual animal (Fig. 3.4, panel B). Comparing the effects of experimental manipulations in wildlife populations in different territories or in groups of animals in different zoos suffers from the same restriction.

18 IDENTIFICATION OF POSSIBLE CONFOUNDS

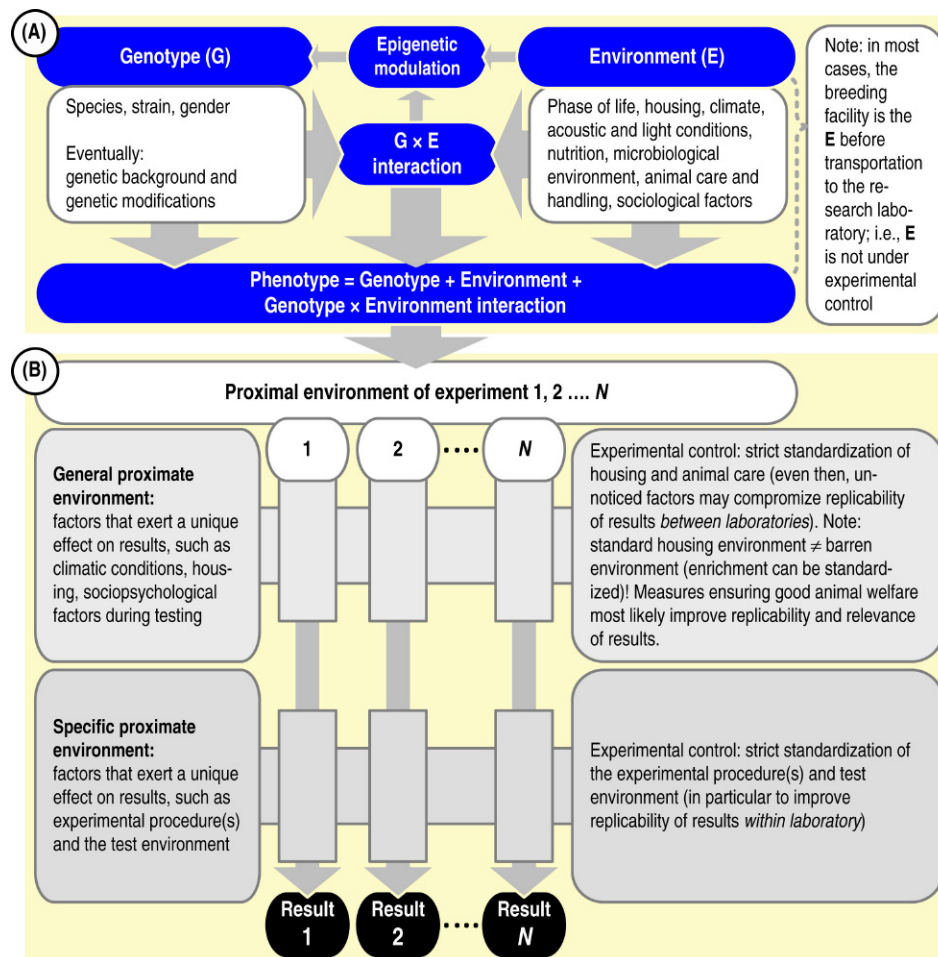
"A primary function of research design is to maximize the validity of the conclusions (…), i.e. to minimize the number of alternative hypotheses that are consistent with the data." (Altmann, 1974, p. 15). A main purpose of designing the experimental conditions is the identification and marginalization of the influence of confounding variables (MacVittie, 2014), for example, through a systematic inventory of the factors that affect an animal during its life that may affect its behavior in a study (Hendrick, 1991) (Fig. 3.10, panel A). Unfortunately, some of these putative confounds are not under control of the experimenter, and their effects may remain undetected


FIGURE 3.10 **Factors affecting results of animal experimental studies, and how to control them.** Variations in responses to experimental conditions are caused by the interplay between the phenotype and the effects of the response-eliciting proximate environment that in turn consists of the testing environment and testing procedures (Nomura et al., 2008; Russell and Burch, 1959). *Source: Modified from van der Staay, F.J., Arndt, S.S., Nordquist, R.E., 2014. Developing mouse models of neurobehavioral disorders: when is a model a good model? In: Pietropaolo, S., Sluyter, F., Crusio, W.E. (Eds.), Behavioral Genetics of the Mouse, vol. 2. Cambridge University Press, United Kingdom, pp. 3–17.*
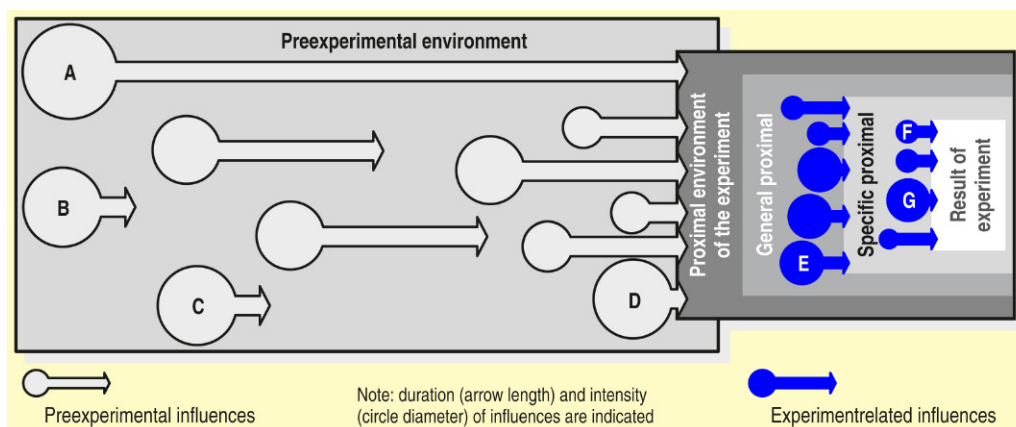

FIGURE 3.11   **Factors affecting experimental results (Fig. 3.10B).** Factors are, for example, (A) housing conditions and animal care routines, (B) maternal care, (C) weaning and mixing, (D) transport from breeder to animal laboratory, (E) construction clatter due to structural alteration works in the building housing the laboratory, (F) change of experimenter during testing, (G) order of testing animals housed in the same cage (Arndt et al., 2009; Takao et al., 2016). Note that, although a factor may have affected the experimental animals during a narrow time period, its effects may extend into the testing phase.

or defy statistical control, that is, their contribution to test results cannot properly be estimated.

Other factors are part of the proximate experimental environment (Gáspár et al., 1991; Fig. 3.10, panel B). Already more than half a century ago, Russell and Burch (1959) directed attention to the role of the testing environment and testing conditions, using the concept called "dramatype." More recently, these thoughts were adopted in the elaboration of the concept of "response action pattern" by Nomura et al. (2008).

Both concepts—"dramatype" and "response action pattern"—are poorly defined, nor have they broadly been adopted by animal behavioral scientists. According to Hino (2004), they stand for how the animal presents itself in the experiment as evidenced by the test results derived from it. Nevertheless, this concept has focused attention on the *general* and *specific proximate environment* of an experiment (Fig. 3.10, panels A and B, and Fig. 3.11).

In brief, both concepts act on the assumption that the variations in responses to experimental conditions are caused by the interplay between the phenotype and the effects of the response-eliciting proximate environment that in turn consists of the testing environment and testing procedures (Nomura et al., 2008; Russell and Burch, 1959). Since even slight variations in the proximate environment may affect the results of an experiment, it is important to identify, and eventually control these factors (Fox, 1986; Russell and Burch, 1959; van der Staay et al., 2010, 2014). Schellinck et al., 2010 summarized the potential confounding factors in mouse studies. Many of these factors may also act as confounds in animal studies using other species than the mouse. Recently, Nevalainen (2014) directed attention to the effects of laboratory animal husbandry praxis as an integral

part of the experimental design. It can cause major interference with the results, whereas these influences can easily be overlooked (Fig. 3.11). If these confounds are undetected but relevant for the test scores obtained, then only robust effects may be detectable (van der Staay et al., 2010), or the study may yield false positive or false negative results.

The genetic makeup of the experimental animal is relatively stable and thus controllable; in particular if animals with a defined genotype are used, such as inbred strains or the first filial generation (F1) form crossings between inbred strains. However, even then they may be subject to epigenetic modulation. The environment is less well controllable and subject to change (Hino, 2004).

For studies using large animal model species, availability of inbred strains is still extremely limited (Fang et al., 2012; Meurens et al., 2012). Developing inbred strains in farm animals, that is, strains established by brother by sister mating for 20 or more consecutive generations (Staats, 1976) can be a long-standing undertaking, in particular due to the slow succession of generations in many large species (Bähr and Wolf, 2012).

19 EFFECTS OF OBESITY ON EXPERIMENTAL RESULTS

A putative intervening variable in animal experimental research, that has been neglected, is obesity in the experimental animals. Martin et al. (2010) discussed the effects of obesity in laboratory rodents on the results of scientific experiments. Instead of moving around and foraging during the major part of the period of wakefulness, rodents in the laboratory live in a very restricted area, with food and water available *ad libitum*. Under

FIGURE 3.12 **Minipigs are prone to becoming obese.** The left panel shows a lean and an obese minipig side by side. The right panel shows group housing of Göttingen minipigs. *Source: Photographs courtesy Ellegaard Göttingen Minipigs, DK.*

these conditions, they are overweight to obese. A direct consequence is that laboratory rodents may develop insulin resistance, hypertension, and that their life expectancy is reduced (Gibbs and Smith, 2016), compared with animals living in a larger enriched cage, fed a restricted diet where food is provided intermittently. Restricted feeding retards the development of neurological disorders (e.g., Parkinson's and Huntington's disease), compared with overfed conspecifics. Also, the brains of overfed rodents may be more vulnerable to stroke and traumatic brain injury. All these factors may affect the outcome of drug testing and may contribute to a lack or translatability of results to humans (Martin et al., 2010) and consequently, overfeeding and obesity should be avoided.

In particular commercial pigs and minipigs (Fig. 3.12) are also prone to obesity if fed *ad libitum* (making them interesting animal models in obesitas research, Johansen et al., 2001; Koopmans and Schuurman, 2015). Even more pronounced this is also true for the parental lines of broiler chickens. To control their weight gain and to avoid obesity-associated problems, these birds are kept on a strict and severe diet. Until they reach adulthood, they are fed ≤50%, then approximately 90% of the quantity that they would consume if feed were available *ad libitum* [broiler breeder may be interesting for studying (abnormal) regulation of feed intake, Buzała et al., 2015; D'Eath et al., 2009; Richards et al., 2010]. This may lead to similar effects as discussed for rodent studies. Therefore controlled restricted feeding to prevent obesity is indicated in minipigs (Bollen et al., 2005; Boonen et al., 2014). Restricted feeding can induce a chronic sensation of hunger that may reduce welfare, but not health (Bollen and Ritskes-Hoitinga, 2007). However, the sensation of hunger per se does not impair welfare: it is a natural motivational state that triggers foraging and eating behavior (Tolkamp and D'Eath, 2016). Therefore contrary to the Farm Animal Welfare Council (FAWC, 2103) that defined welfare as, among others, "freedom from hunger and

thirst", we assume that animal welfare is not at stake as long as an animal can adequately react to hunger, thirst, or incorrect food (Ohl and van der Staay, 2012).

20 TESTING UNDER UNIFORM CONDITIONS IN THE LABORATORY VERSUS TESTING IN A HETEROGENEOUS ENVIRONMENT, SUCH AS A FARM

If experiments are not highly standardized, environmental influences, in particular the proximal environment of the experiment, are probably the major source of variation between experiments (Nomura et al., 2008). This may reduce the replicability of results (van der Staay et al., 2010) *within* and *between* laboratories (Fig. 3.13).

The reason why setup 1 in Fig. 3.4, panel B is not considered appropriate is that pen or cage may act as confound. "For example, if one cage held all the control animals and another all the animals treated with some test substance and a difference was found between the means of the two cages for some character of interest, this might be due to the effect of the treatment, or it might be because the animals in one cage had been fighting, or had a sub-clinical infection not found in the other cage. In such cases any treatment effect is "confounded" or inextricably mixed with an environmental effect." (Festing, 2011, p. 3). Unfortunately, this is a procedure that is used in a large proportion of animal experimental studies, either because this is common use in a laboratory [especially in research using (mutant) mice as subjects and in research in which rodents are kept in ventilated cages], or because of space restrictions, for example, in biomedical studies using large animals, such as farm animals.

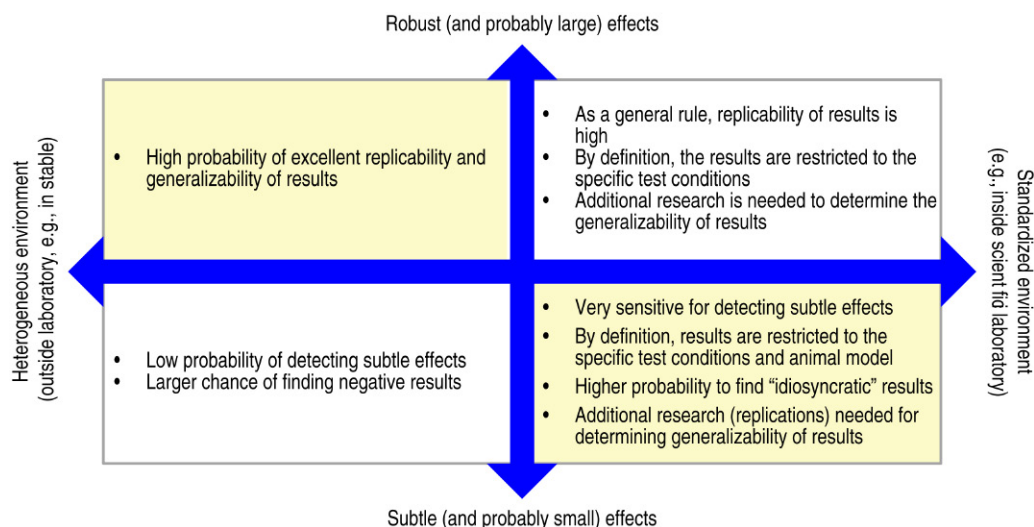
When deciding which experimental setup to choose—more pens with fewer animals or fewer pens with more animals, or many pens with many animals of which only


FIGURE 3.13 **Consequences of strict standardization versus heterogenization of the experimental environment for the detection of effects of experimental manipulations.** Highly standardized conditions can be realized in a laboratory setting, whereas, for example, experiments on farm are more likely performed under heterogeneous (and less well controllable) environmental conditions.

one serves as experimental animal (Fig. 3.4, panel B)—two sources of (uncontrolled) variation may affect the results:

1 between pen variation (Demétrio et al., 2013), which may be experimentally controlled by strict standardization of housing and testing conditions, and
2 between animal within-pen variation (Demétrio et al., 2013), which may be controlled by random assignment or random matched assignment of animals to the pens/conditions, on characteristics that might imbalance the groups, such as the weight of the animals, age (which often correlates with weight), or the sex ratio in the group.

Consequently, experimental control through strict standardization (van der Staay, 2006; van der Staay and Steckler, 2002; van der Staay et al., 2009, 2010) may increase the confidence in the conclusions drawn from an experiment. Unfortunately, this problem is more complex and the setup of an experiment depends on whether the expected effects are large or small, and on the desired degree of generalizability of results (Fig. 3.13).

21 TRAINING AND TESTING MAY ACT AS ENVIRONMENTAL ENRICHMENT

Coleman et al., 2013 distinguish between different classes of enrichment, among them social, physical, food, sensory, and occupational enrichment, the latter including mental activity and training). If, for example, training and testing act as (cognitive) enrichment, they may overshadow the effects of experimental manipulations, such as housing in barren versus enriched environments

(Grimberg-Henrici et al., 2016; Westlund, 2014a,b). Cognitive enrichment may improve animal welfare (Boissy and Lee, 2014; Boissy et al., 2007; Špinka and Wemelsfelder, 2011). It may also ameliorate disease-associated cognitive deficits, similar to the effects of environmental enrichment. More research is needed to learn about the effects of (extended) behavioral training and testing. To circumvent this putative confound in large animal models of neurobehavioral deficiencies, new, short-lasting cognitive tests are urgently needed, that do not necessitate extended training before testing can start (Roelofs et al., 2016).

22 MODELING EARLY LIVE EVENTS THAT AFFECT SUBSEQUENT DEVELOPMENT

Large animal models may be especially suited for investigating long-term effects of pre-, peri-, and early postnatal adverse events on functioning later in life, for example, events that might adversely affect (brain) development (see also Chapter 39), which is already vulnerable during gestation. The gestation length is approximately 21 days in rats, varies between 142 and 152 days in sheep, is approximately 115 days in pigs, and 280 days in humans (Fig. 3.14). Moreover, within the framework of neurobiological investigations on factors affecting early brain development, rodents deviate more from humans than, for example, pigs and sheep. If a study aims to investigated the effects of putative adverse factors on brain development during its most vulnerable period, the brain growth spurt, then pigs are especially suited as model for humans. The growth spurt in pigs starts prenatally and peaks around birth, similar
FIGURE 3.14 **Brain growth spurt in rats, sheep, pigs and humans.** Whereas the brain growth spurt in rats occurs after birth, it starts before birth in sheep, pigs and humans, and pigs. Note that the timing of events between conception and birth within species is quite invariable, but may vary considerably between breeds and individuals within breeds of pigs and sheep postnatally. Also in humans, the variability is large postnatally. Rats can be considered as postnatal brain developers, sheep are prenatal brain developers, whereas pigs and humans might be categorized as perinatal brain developers, with the strongest brain growth spurt peaking around birth (Dobbing and Sands, 1979). Note that for proliferation, synaptogenesis, subplate neurons and myelination of rats, sheep and humans, a similar overview is given by Yager (2004, Fig. 3.1, p. 33). The natural life expectancies of pigs and sheep have not systematically been documented and are therefore estimates primarily based on anecdotal evidence.

to that in humans. On the other hand, the growth spurt in sheep starts and peaks much earlier during pregnancy, and in rodent species, such as rats it starts after birth (Dobbing and Sands, 1979). Using more advanced techniques, this proposed timing of events in brain development seems generally to be corroborated (Clancy et al., 2001). Clancy et al., 2007 created a website that enables fast comparison of neurodevelopmental stages in a number of mammalian species (unfortunately, chickens and pigs are not included).

23 BRAIN INFARCTION, HEMORRHAGE, TRAUMATIC BRAIN INJURY

Large animal models have proven relevance in research on brain infarction, hemorrhage, and traumatic brain injury. Cai and Wang (2016), Mehra et al. (2012), and Mergenthaler and Meisel (2012) compared the advantages and disadvantages of using rodent versus large animal models for studying stroke. Duhaime (2006) performed a similar comparison for models of traumatic brain injury. Regional imaging techniques, such as nuclear magnetic resonance spectroscopy and imaging, and functional imaging, are easier to perform in large gyrencephalic animals, that is, in animals with a cerebral cortex that has convolutions (gyri). Also, advanced physiological monitoring can repeatedly and simultaneously be performed, eventually supplemented with neurological examinations, neurobehavioral tests, and neurochemical and neuropathological analyses (Traystman, 2003). Many techniques to induce infarc-

tion [e.g., middle cerebral artery occlusion (MCAO), Platt et al., 2014], hemorrhage (James et al., 2008), and traumatic brain damage (Margulies et al., 2015) have been developed. Large animal models may be especially suited to assess the effects of early (neonatal) stroke (Duhaime, 2006) and traumatic head injury (Friess et al., 2007, 2009).

24 AGING AND AGING-RELATED DISEASES

Aging research using large (farm) animal species may not easily be realized. For farm animal species, the anticipated average life is unknown, and estimates are based on anecdotal evidence at the best (Fig. 3.14). Aged pet animals could provide an alternative. With their owners consent, these animals could be used in noninvasive and nonaversive studies to assess naturally occurring age-related and/or disease (e.g., beta amyloid pathogenesis)-related neurobehavioral dysfunctions and putative therapeutic options to treat them (e.g., dogs, Martin et al., 2011).

Combined with an *Animal donor codicil* (Faculty Veterinary Science, University Utrecht, 2016), this approach may even make postmortem examinations possible. This approach, arguably, would only be applicable for a restricted number of research questions because it largely depends on the cases presented in a veterinary practice, the willingness of the pet owner to allow scientific investigations on his/her animal, the existence of a signed codicil, and timely offering of the dead animal to the research institution. Postmortem MRI

and other suitable techniques may then provide insight into the brain tissue integrity (Dawe et al., 2016). This approach may allow to investigate the effects of sex, age, strain, and comorbidities, to name a few. Although this approach can be considered as "Reduction" in the spirit of the 3Rs, as it spares laboratory animal use (Russell and Burch, 1959), many putative intervening variables cannot properly be controlled (Fig. 3.11).

25 TRANSGENIC LARGE ANIMAL MODELS

The development of techniques for experimentally manipulating genes gave a boost to the use of mice in biomedical and translational research. Newly developed and validated techniques for manipulating genes in large animal model species (Aigner et al., 2010; Bähr and Wolf, 2012; Klymiuk et al., 2012), in particular swine, could stand at the cradle of developing sophisticated, translatable large animal models of human disease. Transgenic pig models of neurodegenerative diseases, such as Huntington's disease (Baxa et al., 2013), Parkinson's disease, and Alzheimer's disease are under development or have been developed (Holm et al., 2016). The development of inducible gene expression in large model animal species is a further milestone for deriving at relevant and translational biomedical models (Klymiuk et al., 2012) of human diseases.

26 DISCUSSION

26.1 State of Large Animal Model Development and Research

Appropriate animal experimental studies can contribute to unraveling mechanisms and processes underlying human diseases, and to detecting and developing putative therapeutics for the treatment of these diseases. Recently, the lack of translatability of animal experimental studies to humans has severely been criticized. "(…) livestock models have been underutilized in translational research. This has been partially due to the slow realization of their advantages and value and to the perceived expense and difficulty of using livestock models." (Roth and Tuggle, 2015, p. 5).

Can large animal models fill the gap between rodent studies and clinical testing in humans? For example, in stroke research, lissencephalic rodents are generally used, rather than gyrencephalic species (Fig. 3.2). The brains of gyrencephalic species show a greater resemblance with the human brain (Gribkoff and Kaczmarek, in press).

We are just beginning to appreciate the value of large animal model species for biomedical research and for

gaining insight into disease processes and their cure. The available knowledge about a putative animal model species is a determining factor in the choice of using this species (Clancy et al., 2007). Also, available information that helps to closely compare results between species (preferentially including humans) affects the selection of an animal model species. Comparative studies provide valuable information to close this gap (Clancy et al., 2007; de Vere and Kuczaj II, 2016; MacLean et al., 2012; Workman et al., 2013) and facilitate interpretation and generalization of results.

26.2 Factors Specifically Associated With Large Animal Models

False positive or negative findings may be caused by use of an inappropriate animal model (Belzung and Lemoine, 2011; van der Staay, 2006; van der Staay et al., 2009), an inappropriate experimental design, and/or inappropriate statistical analyses. In principle, the criteria with respect to the reliability and validity of rodent models also apply to large animal models. However, researchers using large animal models are confronted with practical questions, which are related to the specific infrastructure needed, such as space for housing and testing the animals. These practical problems and their solutions may also raise methodological/scientific questions, such as about the experimental unit, the reuse of animals in order to reduce the number of animals needed and/or to collect as much information as possible from a study.

Provided an appropriate animal model was used and effects of an experimental intervention were demonstrated, then replicability of result may be compromised by differences in the proximal experimental conditions in subsequent studies (van der Staay et al., 2010). We have proposed a replication strategy to corroborate (and extend) experimental findings (van der Staay et al., 2010), depending on the type of replication (Nuzzo, 2014).

In this chapter, we focused on methodological and practical considerations with respect to the development and application of large animal models for biomedical research and for human neurobehavioral and psychiatric disorders. A number of these considerations may also be relevant for rodent models, and as such are not specific and unique for large animal models. However, because large animal models need an infrastructure for performing studies that cannot be delivered by the standard rodent housing and testing facilities, many of the points raised in this chapter are of special relevance for studies using large animal model species.

26.3 Small Sample Sizes and Reuse of Animals

Owing to the infrastructure needed and higher costs, group sizes in experiments using large animal models are generally small. Reduction of animal use is one

of the principles of the 3Rs (Russell and Burch, 1959). However, these principles are not objectives in itself, but directed by the goal of the experiment. This set of principles should not restrict the validity and generalizability of results by, for example, reducing the number of subjects per treatment group to such an extent that an experiment becomes underpowered (Button et al., 2013). Such underpowered experiments, that is, experiments designed with a too small number of animals, run an increased risk of failing to detect an effect of the treatment (false negative result) or to detect an effect that essentially is a chance finding (false positive result) (Eisen et al., 2014). Consequently, the animals in underpowered experiments have been used/sacrificed unnecessarily. This type of studies thus only contributes to increasing the number of subjects needed to answer a question scientifically because additional (and better) experiments with sufficient statistical power will be required.

On the other hand, reuse of animals reduces the number of animals for animal experimental studies. Repeated testing within a study can be considered as a special variant of reuse of animals. This approach introduces an extra dimension, namely within subject comparisons, sometimes on a timeline (e.g., progress of learning across training sessions; changes due to aging processes, due to therapeutic interventions, etc.).

26.4 Practical and Methodological Consequences of Mandatory Group Housing

Farm animals, such as chickens, sheep, goats, and pigs are social, living in groups, often with a well-established hierarchy (Estevez et al., 2007). Testing of group-housed animals consists of separating one group member at the time from the group, and returning it to the group after testing. It has been shown in group-housed mice, that sequential removal of an individual for testing and reintroduction into the group may have adverse effects, such as stress or anxiety (Arndt et al., 2009; Takao et al., 2016). Similar effects might be expected to occur in large social, group-housed farm animals, such as sheep, goats, and pigs (although systematic studies about this topic in using farm animals are still missing). Minimizing the effects of testing outside the group may necessitate extensive habituation of the animals to the housing conditions, the experimenters, the testing environment and the test procedures (Antonides et al., 2015a). Some of these factors are depicted under "general proximal environment and "specific proximal environment" in Fig. 3.10, panel B).

26.5 Multiple Readout Parameters

For a better understanding of an animal's behavior in a test, but also to derive maximal advantage of experiments with large animal species, we may need to consider multiple variables, which may represent multiple underlying mechanisms, such as learning, memory, motivation, and sensorimotor capacities (Kapadia et al., 2016; van der Staay et al., 2012). Many behavioral tests yield more than one read-out parameter. For example, holeboard-type tasks may provide dependent parameters that reflect different components of spatial memory, such as working and reference memory, or the food search strategy adopted, the animal's motor abilities and their motivation (van der Staay et al., 2012). More than one readout parameter may necessitate correction for multiple measurements, that is, the P-values may be corrected to more stringent testing of effects.

26.6 Advantages and Disadvantages of Using Large Animal Models

Using large animal models has a number of advantages and disadvantages both at the scientific and the practical level (Rand, 2008). Is should be noted, that the subsequent lists of advantages and disadvantages are not exhaustive. Depending on future developments, more items may be listed or items may be delisted because problems may be solved.

Advantages of the use of farm animals as model species:

- Larger farm animal species (e.g., pig, sheep) show a closer resemblance to humans (size matters) with presumably higher translational value than the usual rodent models, although the phylogenetic distance between large animal model, such as domestic artiodactyls (which includes cattle and pigs) and humans is larger than that between rodents and humans (Varga, 2012) (Fig. 3.8). This also holds true for the phylogenetic distance between Galliformes (e.g., chickens, junglefowl, turkeys, quails, and pheasants) and humans (Maximino et al., 2015). However, large model animal species may be more similar to humans than rodents in many respects (e.g., physiology, anatomy) (Gieling et al., 2011b). Mammalian large model species may more faithfully replicate human disease than do rodent species (Pinnapureddy et al., 2015).
- Many large animal model species have larger, *gyrencephalic* brains, in which the cerebral cortex has convolutions formed by gyri and sulci, than the commonly used rodent species, which have *lissencephalic brains,* in which the cerebral cortex is smooth, without gyri and sulci (Figs. 3.2 and 3.8). Gyrencephalic brains are generally larger than lissencephalic brains and thus provide higher resolution images using, for example, imaging techniques, such as MR, positron emission tomography, and CT scanners (Mehra et al., 2012).

- Large farm animal models may serve as "second species" in preclinical drug development, in particular in risk assessment studies (Hasiwa et al., 2011), filling the gap between rodents and humans. Minipigs, for example, may replace dogs as frequently used species in risk assessment studies (e.g., safety pharmacology, toxicology, Bode et al., 2010; Forster et al., 2010c; Swindle et al., 2012; Vamathevan et al., 2013; van der Laan et al., 2010). As far as prenatal development is concerned, chickens may also be useful for safety studies (Bjørnstad et al., 2015).
- Large animals may be used in comparative approaches to identify and characterize differences and similarities between various species. "The standard model species represent a vanishingly small percentage of the total biological diversity." (Brenowitz and Zakon, 2015, p. 273). "Convergence on selected model species often carries an implicit assumption that mechanisms observed in one species are characteristic of all related species. A focus on any single species, however, fails to encompass the diversity of mechanistic adaptations present in even closely related species that differ behaviorally." (Brenowitz and Zakon, 2015, p. 274).
- The number of behavioral tests for assessing emotion and cognition in a number of farm animal species is increasing (Gieling et al., 2011a; Kornum and Knudsen, 2011; Murphy et al., 2014).
- Generalizability and translatability of results may increase through replication studies with other species than the rodent species that most likely were used previously (van der Staay et al., 2010).
- Nearly unrestricted availability of a large number of species/strains from controlled suppliers and well-defined sources (e.g., for Göttingen minipigs see Simianer and Köhn, 2010).
- Unlike rodent studies in which experiments are short lasted because of the short life expectancy, experiments with large animal models can be long lasting. This allows performance of longitudinal studies in, for example, the area of gene therapy (Casal and Haskins, 2006).
- Large animal model species, such as chickens (approximately 275 eggs per layer hen per year) and pigs (approximately 30 piglets per sow per year) produce many progenies.
- Special miniature pig and commercial pig breeds are available for biomedical research (Smith and Swindle, 2006) with known/controlled health status [e.g., conventional, specific pathogen free, or gnotobiotic, that is, germ-free or formerly germ-free animal with fully defined composition of its associated microbial flora (Miniats and Jol, 1978)].
- Higher level of acceptance of general public—in particular if farm animals are used as large animal model instead of primates or pet animals, such as cats and dogs (Hagen et al., 2012; Ormandy and Schuppli, 2014; van der Staay et al., 2009) (Fig. 3.8). Moreover, farm animals may be returned to the food chain for human consumption provided they were not treated with compounds that might endanger the human consumer.
- Studies using large model animal species extend knowledge about farm animals that may be relevant for farm animal health and welfare (Reynolds et al., 2009).

Large animal models are less well established than rodent models. This entails some disadvantages, in particular caused by gaps in our knowledge, such as lack of comprehensive ethograms. A number of the listed disadvantages are expected to dissipate with increasing experience and use of these models:

- Less "historical" data are available for large farm animal model species than for "classical" model species [e.g., rodents (efficacy, safety, toxicology), dogs (safety)], although relevant information is increasingly available for pigs (in particular Göttingen minipigs) in risk assessment (teratology, toxicology) research (Swindle et al., 2012).
- Lack of external funding opportunities for research and technological development (Chiba et al., 1994; Golden et al., 2012; Ireland et al., 2008; Reynolds, 2009; Roberts et al., 2009).
- Lack of validated models, that is, models that have survived a validation process (van der Staay, 2006; van der Staay et al., 2009).
- Lack of validated tests (e.g., for pigs reviewed by Gieling et al., 2011a; Murphy et al., 2014).
- Lack of test equipment; only very few commercial suppliers offer test equipment for large animals; testing equipment very often is custom made (see also Chapter 39). Special demands regarding the testing equipment, for example, pig-proof apparatus (e.g., barn builders have expert knowledge for constructing pig-proof equipment).
- The current education of scientists and technicians is "rodent" centered (Libby, 2015). Using large model animal species increases the need for trained technicians.
- Large model animal species require special housing conditions, such as large stables and pens. Nearly all farm animal species are social (Estevez et al., 2007), requiring group housing.
- Associated with group housing in cages/pens is the issue of "experimental unit" (Fig. 3.6 and 3.7).
- Studies using large-animal models may be more expensive than studies using rodent models (e.g., purchase of the animals, housing facilities, testing equipment).

- Many large animal model species grow fast (e.g., the daily weight gain of pigs in the grower-finisher period: approximately 800–1000 g, Pardo et al., 2013; Vautier et al., 2013, and the brain volume of pigs doubles between 2 and 24 weeks of age, Conrad et al., 2012). Moreover, the high body mass in adulthood, for example, in pigs (Lind et al., 2007) may thwart their handling, drug administration (voluntary oral administration may be preferred, Turner et al., 2011), and behavioral testing.

- Compared with rodent research, large amounts of investigational drugs are needed when testing efficacy, safety, and toxicology in large animal models. In neuropharmacological research, it is worthwhile to investigate whether this may eventually be solved by intracerebroventricular (ICV) administration of centrally acting drugs. Such an approach may also prevent development of peripheral side effects. A disadvantage of ICV injections is the need to supply the animal with a cannula (Yao et al., 2014), which will need surgical interventions (e.g., stereotaxic placement), and which, in fast-growing species, eventually may grow out if implanted before they are full grown.

- One of the largest risk factors for many human diseases is aging (Harman, 1991; Niccoli and Partridge, 2012). Unfortunately, the life expectancy and longevity of large animal model species has not yet been documented well, but appears to be much higher than that of rodent species, making aging research with large animal models less feasible (Mitchell et al., 2015) (Fig. 3.14). Avian species, such as chickens are estimated to have a life expectancy considerably exceeding that of equally sized mammals (Holmes et al., 2001a; Wasser and Sherman, 2010).

Summarizing, existing models need to be modified to better serve their goals and new models need to be developed. They must undergo rigorous evaluation to ascertain their reliability and validity (Belzung and Lemoine, 2011; van der Staay et al., 2009). They must also measure up to high standards of preclinical evaluation to improve and ensure their translational value. "There is no single, perfect animal model that can completely predict the outcome of clinical trials. The challenge is to collect relevant and sufficient information from as many models as are required to make an informed decision regarding the potential benefits and risks to patients." (Cibelli et al., 2013, p. 274). We are not advocating the use of large animal models *instead* of rodent models. We advocate use of the animal model that best suits the aim of a study and that best informs the researcher.

1 INTRODUCTION

Cataract is the leading cause of blindness worldwide and accounts for approximately half of all forms of vision loss (Bourne et al., 2013). Currently, the only way to treat cataracts is by surgery. However, with an aging population and an increase in the number of people affected by diabetes, the demand for surgery and the need for cost-effective alternative solutions are growing exponentially. To reduce the need for cataract surgery, alternative medical therapies to delay cataracts are urgently required, as it has been predicted that delaying the onset of cataract by 10 years will halve its incidence (Brian and Taylor, 2001).

Research with human tissue offers the best possibilities of designing an anticataract therapy that is effective in humans. Unfortunately, there are a myriad of difficulties associated with working with human donor lenses. This includes the limited availability of human donor lenses and intact cataractous lenses, the narrow age range, postmortem delay between death and tissue processing, and the inherent variability between donors (genetic variation, systemic disease, cause of death, exposure to environmental risk factors). As a result, this has led to researchers to turn to animal models of lens cataract to investigate the mechanisms underlying cataract formation and to test the efficacy of therapies for their potential use in humans.

There is a large number of animal models currently in use, and with the uptake of transgenic technologies, this number is increasing. These models have been used to either study the cataract pathogenesis or to trial anticataract therapies with the long-term view to reduce the incidence of cataract in humans. While one experimental system cannot entirely replicate the cataract process in humans, investigators need to be mindful of selecting an appropriate animal model. However, it is often unclear what form of human cataract these animal models are trying to replicate.

As a recent review has assessed and evaluated animal models for studying age-related nuclear cataract (Lim

et al., 2016), the aim of this chapter is to focus on identifying the most appropriate animal models for studying diabetic cataract. To do this, we will describe reported changes in human diabetic lenses in terms of lens physiology, cellular structure, and biochemistry, and then use this set of parameters to determine which animal models are the most appropriate for mimicking the cataract process in humans.

2 CATARACT TYPES

Clinically four main forms of lens cataract are recognized in humans. Three of these: nuclear, cortical, and subcapsular are named on the regions in the lens where the light-scattering cataract first originates (Fig. 4.1). While the light scattering normally originates in one of these three regions of the lens, over time, the cataract may spread to other lens regions to produce a mixed-cataract phenotype, the fourth major class of cataract.

Of these four subtypes of cataract, nuclear cataract is the most common (Age-Related Eye Disease Study Research Group, 2001). Age is the major risk factor for nuclear cataract formation and accounts for 50% of the total cataract cases. Age-related nuclear (ARN) cataract is characterized by the depletion of the antioxidant glutathione (GSH) in the lens nucleus, resulting in the extensive oxidation of proteins and lipids in this region of the lens (Truscott, 2005), without any obvious damage to the lens fiber structure (Al-Ghoul et al., 1996). ARN cataracts involve the gradual opacification of the lens nucleus, and are graded by the extent of nuclear brunesence (Fig. 4.2) and nuclear opalescence (Chylack et al., 1984). While age is also a risk factor for cortical and posterior subcapsular (PSC) cataracts, both of these cataract subtypes are also strongly associated with diabetes (Bron et al., 1993). Cortical cataracts initially appear in the lens cortex, often with wedge-shaped spokes (Fig. 4.2); however, as the cataract matures, the entire lens becomes opaque (Bron et al., 1993). PSCs are disc-shaped opacities that develop

at the posterior pole of the lens. They appear as a dense, circular plaque in the central posterior part of the lens (Fig. 4.2) and are surrounded by vacuoles and smaller areas of degenerated lens material (Adrien Shun-Shin et al., 1989).

3 AGE-RELATED NUCLEAR CATARACT

In this section, we will briefly describe the pathogenesis of ARN cataract in humans, as it is the most common cataract type. The pathophysiological mechanisms that lead to ARN cataract formation are well established in the human lens, and as a result, we have a firm understanding of changes to lens physiology (Duncan and Bushell, 1975), cellular structure (Al-Ghoul et al., 1996; Costello et al., 1992), and biochemistry (Fujii et al., 2012; Garner and Spector, 1980a,b; Hooi et al., 2013a,b; Lou, 2003; Lou and Dickerson, 1992; Spector and Roy, 1978; Takemoto, 1996; Truscott and Augusteyn, 1977a,b,c) that occur during ARN cataract formation. These changes have been extensively reviewed by many (Lim et al., 2016; Lou, 2003; Michael and Bron, 2011; Truscott, 2005) and are, therefore, only summarized in this chapter (Table 4.1).

It is well established that oxidation is the hallmark of ARN cataract and that depletion of GSH, the principal antioxidant in the lens, specifically in the nucleus (<2 mM), but not the lens cortex, appears to trigger a cascade of events that precedes cataract formation (Truscott, 2005). This includes the extensive loss of protein sulfhydryl groups, with over 90% of cysteine residues and ~50% of methionine residues oxidized in nuclear proteins in lenses obtained from patients with ARN cataract (Garner and Spector, 1980a; Spector and Roy, 1978; Truscott and Augusteyn, 1977a,b). This loss of protein sulfhy-

dryl groups is accompanied by an increase in protein-thiol mixed disulfides (Lou and Dickerson, 1992; Lou et al., 1990, 1999), and an increase in the water-insoluble fraction (Pirie, 1968; Truscott and Augusteyn, 1977a), which culminate in the formation of protein–protein disulfides (PSSP), and other cross-linkages that lead to protein aggregation, light scattering, and ultimately cataract.

As a number of ARN cataract animal models have been recently reviewed and assessed for their ability to replicate changes in human ARN cataract (Lim et al., 2016), we will concentrate on the mechanisms of human diabetic cataract formation and the identification of the most appropriate animal models for studying human diabetic cataract in the following sections.

4 DIABETIC CORTICAL CATARACT

Diabetes is characterized by chronic hyperglycemia resulting from defects in insulin secretion, insulin action, or both. There are different types of diabetes with the most common types being type 1 and type 2 diabetes.

Type 1 diabetes is most commonly diagnosed in children in a rapidly progressive form, but can be detected as a slowly progressive form in adults. Type 1 diabetes is an autoimmune disease that leads to the destruction of the insulin-producing pancreatic β cells, resulting in insulin deficiency (King, 2012). Type 1 diabetic patients are usually not obese, and there is a genetic predisposition for the autoimmune destruction of β cells.

Type 2 diabetes is most commonly diagnosed in middle-aged adults and while there is a hereditary component, the risk of development of type 2 diabetes increases proportionally with increasing body mass index

TABLE 4.1   Summary of Human Lens-Related Changes in ARN and Diabetic Cataract

Human lens changes	ARN cataract	Diabetic cataract
Morphology	• No major fiber disruptions or extracellular debris in the lens nucleus • Signs of intracellular space distension between adjacent fibers with electron microscopy • Increased frequency of multilamellar bodies	• Distinct localized zone of cell swelling in the lens cortex • Globular bodies, water clefts, vacuoles in the deeper cortex region, with unaltered structural changes in the superficial cortex and nuclear layers
Physiology	• No changes in Na^+, K^+, and Ca^{2+} in the lens nucleus	• Increased Na^+ and Ca^{2+} and decreased K^+
Biochemistry	• Depletion of GSH in the lens nucleus • Significant loss of PSH groups • Increase in protein mixed disulfides bound to GSH (PSSG) or cysteine (PSSC) formation • Significant loss of water-soluble protein in the lens nucleus • Cataract-specific modifications to crystallin proteins	• Increase in glucose and sorbitol • Decrease in GSH • Activation of Ca^{2+}-dependent proteases • Cleavage of cytoskletelon proteins • Decrease in Na^+/K^+ ATPase activity • Increase in glycated proteins (AGEs) • Increase in disulfide cross-linked proteins • Decrease in ATP and NADPH • Decrease in amino acid uptake and amino acid content

GSH, Glutathione; PSH, protein sulfhydryl; PSSC, protein–cysteine disulfide; PSSG, protein–glutathione disulfide.

(Lehtovirta et al., 2010). Type 2 diabetes is associated with insulin resistance and a lack of appropriate compensation by the β cells, leading to insulin deficiency (King, 2012).

A frequent complication of both type 1 and type 2 diabetes is cataract. Diabetic patients are at a greater risk, 2–5 times, for cataract formation and are more likely to get cataracts at an earlier age (Klein et al., 1995a,b). A number of epidemiological studies (Delcourt et al., 2000; Klein et al., 1995a; Leske et al., 1999; Rotimi et al., 2003; Rowe et al., 2000) have reported up to a fivefold increase in the prevalence of cortical and/or PSCs in diabetic subjects (type 1 and type 2) compared with nondiabetics. In addition, the onset of cataract develops at an earlier age (Leske et al., 1991) and progresses faster in diabetics compared to nondiabetics (Caird and Garrett, 1962).

4.1 Mechanism of Action

In contrast to those of ARN cataract, the mechanisms of human diabetic cataract formation have largely been determined using animal models. Historically, two animal models in particular have been responsible for our understanding of the molecular pathways involved in diabetic cataract formation. These two models are the streptozotocin (STZ) rat, a model used to chemically induce type 1 diabetes by destroying pancreatic β cells (Bond et al., 1996; Chatzigeorgiou et al., 2009; Obrosova et al., 2010; Perry et al., 1987; Suryanarayana et al., 2005, 2007; Varsha et al., 2014; Wang et al., 2016), and galactose-fed animals, a model for obese type 2 diabetes (Bond et al., 1996; Kador, 1988; Kador et al., 1979, 2006, 2007; Perry et al., 1987; Robison et al., 1990, 1995; Sato et al., 1998; Sippel, 1966; Suryanarayana et al., 2005, 2007; Varsha et al., 2014; Wang et al., 2016). These models have been very popular with researchers because diabetes or galactosemia can be induced rapidly and effectively in animals resulting in formation of "fast" sugar lens cataract. These acute models replicate the fast development of cataract that occurs in diabetic patients with uncontrolled hyperglycemia. However, most diabetic patients are able to control their blood glucose reasonably well and, therefore, such acute cataract development is rarely seen.

From these animal models, however, a general consensus was reached among researchers on the mechanism of diabetic cataract formation in humans. The long-standing traditional view has been that high levels of the impermeable osmolyte, sorbitol, produced from excess glucose by the enzyme aldose reductase (AR), initiates osmotic stress, resulting in the attraction of fluid, lens fiber cell swelling, and tissue liquefaction (Kinoshita, 1965, 1974). Based on this view, considerable attention was focused on the development and testing of AR

inhibitors. These inhibitors have proven to be very successful in ameliorating diabetic cataract in rats and dogs (Drel et al., 2008; Kador et al., 2006, 2007, 2010, 2016; Matsumoto et al., 2008), but an anticataract therapy in humans remains elusive.

Rodents and, in particular, rats have been the most commonly employed experimental model for studying diabetic cataract. However, distinct biochemical differences exist between humans and rats with respect to AR activity and polyol accumulation. Adult rat lenses have very high levels of AR activity and low levels of SDH activity (Jedziniak et al., 1981; Varma and Kinoshita, 1974). This is the opposite of human lenses, which exhibit low AR activity and high SDH activity (Jedziniak et al., 1981; Varma and Kinoshit, 1974). In addition, the amount of sorbitol present in human diabetic cataractous lenses is considerably less than that found in STZ-injected and galactose-fed rats (Chylack et al., 1979).

While these animal models have undoubtedly been instrumental in identifying enzymes and signaling pathways involved in the pathogenesis of diabetic cataract, they have also led to a misleading view, particularly on the importance of AR in the human lens. More recent research is now focused on identifying additional pathways that may contribute to cataract formation and, as a result, has prompted a reevaluation of the current animal models of diabetic cataract. However, to determine which animal models are most likely to be of relevance for studying human diabetic cataract, it is important to first identify the key changes to the human lens as a result of diabetic cataract formation.

4.2 Lens Changes in Human Diabetic Cataracts

In this section, we describe changes at the physiological, morphological, and biochemical level of lenses from diabetic patients and have summarized these findings in Table 4.1.

4.2.1 Physiology

Studies on human lenses have shown that there is an increase in the membrane permeability of lens cells with age that leads to an increase in internal sodium and calcium content (Duncan et al., 1989). In cortical cataract, there is a progressive alteration in ionic content, with lens sodium and calcium content further increasing (Duncan and Bushell, 1975). The effects of increased intracellular calcium have been studied using organ-cultured human donor lenses incubated in the presence of inomycin, a calcium ionophore (Sanderson et al., 2000). In this study, the increased calcium content increased lens wet weight, activated calcium-dependent cleavage and cross-linking of vimentin by calpain and transglutaminase, and induced cortical opacification (Sanderson et al., 2000).

Interestingly, this was also accompanied by an efflux of protein into the media and a loss of soluble lens proteins (Sanderson et al., 2000). This finding is consistent with a study from mature human cortical cataracts, which exhibited a loss of crystallins from the soluble fraction by insolubilization and efflux into the aqueous humor (Sandberg, 1976).

4.2.2 Morphology

While sorbitol accumulation in adult human diabetic lenses is unlikely to be sufficient to initiate osmotic stress over the entire lens, it is proposed that localized osmotic stress cannot be ruled out (Kador et al., 2016). In support of this, morphological analyses of human diabetic lenses reveals that the major cellular damage is typically observed in a localized zone in the deeper lens cortex that is surrounded by relatively undamaged cells in the superficial cortex and nucleus (Obrosova et al., 2010). The major damage to the restricted area fiber is suggested to correlate with the high levels of expression of AR in the epithelium and cortex and, therefore, the localized accumulation of sorbitol (Jedziniak et al., 1981). Numerous morphological alterations have been documented. These include globular bodies, such as extracellular Morgagnian globules or intracellular globules containing α-, β-, and γ-crystallin and actin (Creighton et al., 1978); cellular degeneration and breakdown of lens fibers (Vrensen, 2009); swelling of the broken ends of cortical fibers (Vrensen, 2009); undulating and folded fibers at the borders between the cortex and nucleus (Michael et al., 2008); and small fluid-filled water clefts close to the folded fibers (Michael et al., 2008). These changes tend to be present in the deeper cortex with no changes in the fiber cell morphology and cytoplasmic texture evident in the nuclear regions (Al-Ghoul and Costello, 1996). Several reports have also documented a decrease in cell density in the lens epithelium of type 2 diabetic patients (Takamura et al., 2000; Tkachov et al., 2006).

4.2.3 Biochemistry

A correlation between AR gene markers and susceptibility to develop complications among diabetic patients has been reported, suggesting that AR is also involved in the pathogenesis of diabetic complications in humans (Chung and Chung, 2003). However, in contrast to animal studies, there is currently no direct evidence of AR in the pathogenesis of human diabetic cataract. However, it is likely that the polyol pathway does play a contributory role. Recent studies suggest that the polyol pathway activity contributes to diabetic lesions in a number of ways, including osmotic, glycation, and oxidative stress (Chung and Chung, 2003; Nakamura et al., 2001; Szwergold et al., 1990). Each of these is discussed further.

4.2.3.1 INCREASED POLYOL PATHWAY ACTIVITY

It has been proposed that excess glucose enters the sorbitol pathway in diabetes, where AR catalyzes the NADPH-dependent reduction of glucose to its sugar alcohol, sorbitol. Sorbitol dehydrogenase (SDH) then catalyzes the NAD-dependent oxidation of sorbitol to fructose. As sorbitol does not readily diffuse out of the cells, and its oxidation to fructose is slow, the accumulation of sorbitol as a result of hyperglycemia increases the intracellular osmotic pressure, promoting cell swelling. Although it is well established that the sorbitol pathway leads to sugar cataract in animal lenses (Kinoshita, 1974), its role in the etiology of diabetic cataract in human lenses is uncertain. This is due to conflicting results on the levels of sorbitol and fructose measured in human lenses obtained from diabetic and nondiabetic patients, and from inconsistent and limited data regarding the levels of enzyme activity of AR and SDH in human lenses [summarized by Jedziniak et al. (1981)]. Some studies report comparable levels of sorbitol and fructose in both nondiabetic lenses and diabetic lenses (Heaf and Galton, 1975; Kuck, 1965; Pfaffenberger et al., 1976), while other studies found no sorbitol and decreased levels of fructose in nondiabetic lenses, but increased levels of sorbitol in the diabetic lens (Pirie and Vanheyningen, 1964; Varma et al., 1979). In cases where sorbitol has been measured in the human diabetic lens, the amounts of sorbitol detected have been quite low, and in some studies, deemed insufficient on a lens mass basis to account for the observed osmotic damage (Varma et al., 1979). Fructose levels are increased in human diabetic lenses and appear to be related to the degree of blood glucose levels (Jedziniak et al., 1981; Varma et al., 1979) and the extent of circulating hemoglobin glycation (Lerner et al., 1984). Consistent with this finding of higher fructose in diabetic human lenses, measurement of the enzymes involved in the polyol pathway has shown AR activity to be very low in human lens and SDH activity to be high, relative to animal lenses, indicating that the sorbitol pathway in the adult human lens is different from that in the animal lenses (Jedziniak et al., 1981). Comparison of the AR and SDH activity between human nondiabetic lenses and diabetic lenses revealed that AR and SDH levels were not significantly higher in the diabetic lenses relative to the nondiabetic lenses (Jedziniak et al., 1981). The lack of elevated AR activity in human diabetic lenses is in stark contrast to studies performed on diabetic rat lenses (Varma and Kinoshit, 1974). However, it has been postulated that despite low AR activity in the human lens, significant osmotic effects could be generated if the sorbitol was localized to specific regions of the lens. The localization and activity of AR in the human lens is highest in the epithelium and superficial cortical fiber cells (Jedziniak et al., 1981). Such a specific localization of AR and the associated localized accumulation of sorbitol

could explain the localized cellular swelling observed in the diabetic lens.

4.2.3.2 NONENZYMATIC GLYCATION

Nonenzymatic glycation has been implicated in the pathogenesis of diabetic cataract (Obrosova et al., 2010), and occurs when free amino groups of proteins react nonenzymatically with the acyclic form of glucose via an Amadori rearrangement (John and Lamb, 1993). Over time, the Amadori product undergoes dehydration and cleavage reactions in a process known as the Maillard reaction, in which the product forms stable adducts on proteins known as advanced glycation end products (AGEs) that manifest as protein brunescene and/or an increase in the fluorescent properties of the glycated protein (Bucala et al., 1992). Lens proteins, in particular crystallin proteins, are particularly susceptible to AGE formation for two reasons. First, as the lens is not dependent on insulin for glucose uptake, it is constantly exposed to high glucose concentrations (Pokupec et al., 2003), and second, as crystallin proteins have little or no turnover, they are particularly susceptible to posttranslational changes, such as modification by AGE formation (Pokupec et al., 2003). Advanced glycation occurs during normal aging in the human lens, but is significantly increased in diabetic cataract (Ahmed, 2005; Vlassara et al., 1994), with an overall increase in fluorescence in lens proteins and an increase in nonenzymatic lens brunescene (Monnier and Cerami, 1981; Oimomi et al., 1988; Stevens et al., 1978). AGEs have been shown to accumulate in human diabetic lenses (Ahmed et al., 2003; Franke et al., 2003; Pokupec et al., 2003), and include pentosidine and carboxymethyllysine (AGES formed oxidatively) and imidazolone (AGE formed nonoxidatively) (Franke et al., 2003). However, in another study, no differences in carboxymethyllysine content were identified between nondiabetic and diabetic lenses (Lyons et al., 1991). AGE structures modify crystallin proteins and in doing so cause conformational changes that lead to altered structure and function (Luthra and Balasubramanian, 1993). Modification of α-crystallin, for example, by the AGE precursor methylglyoxal, causes altered chaperone-like activity, partial protein unfolding, enhanced proteolysis, and subsequent protein insolubilization (Biswas et al., 2006, 2008). The glycation of lens proteins in vitro has been shown to result in the formation of dimers, trimers, and polymers, as well as high–molecular weight protein aggregates (Liang and Rossi, 1990), which would act to scatter light and result in cataract formation (Kasper and Funk, 2001).

4.2.3.3 OXIDATIVE STRESS

Oxidative stress is detected in the human diabetic lens and manifests early as a depletion of GSH (Ozmen et al., 1997). The depletion of GSH is most likely due to a decrease in the availability of NADPH, which is necessary for its regeneration from glutathione disulfide (GSSG) by glutathione reductase (GR) (Fig. 4.3). The depletion of NADPH results from its excessive consumption during the conversion of glucose to sorbitol (Bron et al., 1993). This implies that the pentose phosphate pathway, which is the main regenerative source of NADPH, fails to restore NADPH levels. This view is supported by the observation that the activity of glucose-6-phosphate dehydrogenase, the key regulatory enzyme of the pentose phosphate pathway, decreases in the diabetic lens (Donma et al., 2002; Nishikawa et al., 2000). Other signs of increased oxidative stress in the diabetic lens includes the accumulation of lipid peroxidation products, such as malondialdehyde (MDA) (Altomare et al., 1995); an increase in GSSG (oxidized GSH), depletion of other nonenzymatic antioxidants, such as ascorbate and taurine (Anthrayose and Shashidhar, 2004); as well as a decrease in activity of antioxidant defense enzymes, such as superoxide dismutase, catalase, and glutathione peroxidase (Donma et al., 2002; Ozmen et al., 2002). In diabetic patients, it is suggested that the efficiency of these enzymes might be compromised due to decreased availability of GSH, NADPH cofactors, and/or reduced activity of the these enzymes by AGE formation that is known to cause structural changes that reduce enzyme activity (Shin et al., 2006). While there is evidence to show that diabetic cataract in humans is associated with increased oxidative stress, the source of this oxidative stress remains unclear. Glucose autoxidation and nonenzymatic glycation are thought to contribute to an increase in free radicals in the diabetic lens (Ansari et al., 1996; Nagaraj et al., 1991; Wolff and Dean, 1987), which interestingly in turn, further accelerate the process of glycation (Loske et al., 2000). SDH, the second enzyme in the polyol pathway that converts sorbitol to fructose has also been suggested to contribute to oxidative stress. The oxidation of sorbitol to fructose increases the rate of formation of NADH, resulting in an increased cytosolic ratio of free NADH to NAD. As NADH is a substrate for NADH oxidase, an increase in NADH results in the generation of reactive oxygen species (ROS). In addition, large increases in NADH will also inhibit glycolysis (Rose and Warms, 1966), and thus limit the availability of pyruvate for the regeneration of NAD. Due to the inhibition of glycolysis, more glucose will enter the polyol pathway, further altering the cytosolic NAD:NADH ratio. Finally fructose and its metabolites fructose-3-phosphate and 3-deoxyglucosone are more potent nonenyzmatic glycation agents than glucose (Chung et al., 2003). Therefore more glucose entering the polyol pathway increases AGE formation and exacerbates oxidative stress.

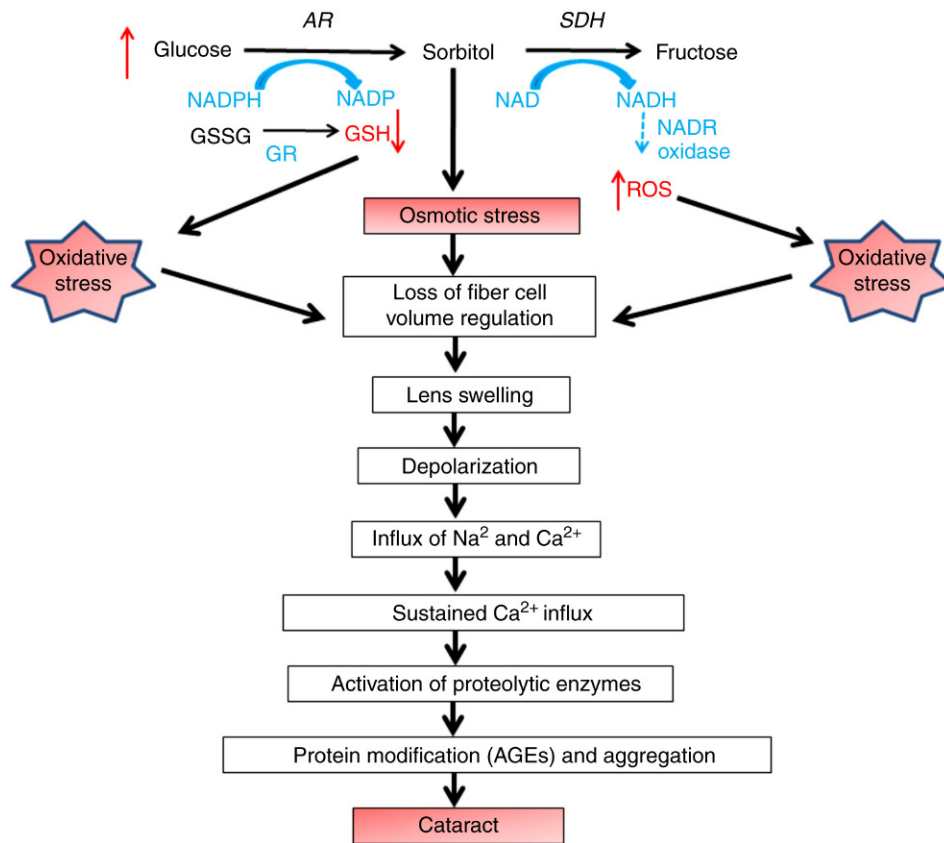
Taken together, it is clear that osmotic stress alone does not account for the slow development of cataracts


FIGURE 4.3 **Molecular mechanisms involved in the pathogenesis of diabetic cataract.** Osmotic and oxidative stress work synergistically to result in loss of fiber cell volume regulation. This triggers a series of events that lead to cell swelling, depolarization, and an influx of sodium and calcium ions. The accumulation of calcium ions results in the activation of calcium-dependent proteases, which targets cytoskeletal and crystallin proteins. In parallel, proteins are further modified by the formation of advanced glycation end products (AGEs), which are known to alter the structure and function of crystallins. As a result, there is an increase in insoluble proteins, the subsequent formation of high–molecular weight aggregates, and ultimately cataract. *AR*, Aldose reductase; *GR*, glutathione reductase; *GSSG*, glutathione disulfide; *NADP*, nicotinamide adenine dinucleotide phosphate; *NADPH*, reduced form of nicotinamide adenine dinucleotide phosphate; *ROS*, reactive oxygen species; *SDH*, sorbitol dehydrogenase.

that is typically seen in the majority of adult diabetic patients (Chan et al., 2008). Rather, the emerging view is that hyperglycemia results in increased polyol activity, which generates osmotic stress and oxidative stress in the diabetic lens (Chung et al., 2003). While the initiating mechanism in the development of diabetic cataract results in osmotic stress, there is evidence that the lens is able to regulate its volume through an osmoregulatory mechanism that can accommodate small changes in cellular osmotic pressure (Cammarata et al., 2002). However, over time, the ability of the lens to actively regulate its volume becomes impaired (Chan et al., 2008), and coupled with oxidative stress, these two pathways converge and contribute to cataract formation (Fig. 4.3). With this new view of diabetic cataract formation, we will now assess and evaluate current diabetic animal models for their ability to replicate the slow development of cataract formation observed in the human lens.

5 ANIMAL MODELS OF DIABETIC CATARACT

The STZ rat and galactose-fed animals both represent acute models for replicating the fast development of cataract that occurs in some diabetic patients with uncontrolled hyperglycemia. It is clear that these models possess similar hallmarks of human diabetic cataract and have increased our understanding of the contribution of the polyol pathway to osmotic stress in diabetic cataract significantly. However, moving forward, to develop anticataract therapies that will be effective in humans, we must identify diabetic animal models that develop slow-forming cataracts, which represent a more typical scenario in adult diabetic cataract formation than the traditional acute models. In humans, diabetic cataract can take 10–20 years to develop. Therefore, in animal cataract models where cataracts develop slowly, it is unlikely that these lenses would experience a rapid and

significant increase in polyol accumulation that would cause serious osmotic stress. Rather, the contribution of oxidative stress from increased polyol pathway activities is likely to be an important factor for chronic cataract development.

Excellent reviews of animal models in diabetes research are described by Chatzigeorgiou et al. (2009) and King (2012). From these diabetic animal models, a small subset has been used to study diabetic cataract and of this subset, a few describe the development of slow-forming cataracts. These models are discussed further.

5.1 Obese Models of Type 2 Diabetes

Animal models of type 2 diabetes tend to include models of insulin resistance and/or models of β cell failure (King, 2012). Many animal models of type 2 diabetes are obese, which reflects the human condition where obesity is closely linked to type 2 diabetes development. From these obese models, there were two models in particular that caught our attention due to the development of slow-forming cataracts, as well as the exhibition of morphological and biochemical changes reminiscent of that in human diabetic cataract.

5.1.1 Zucker Diabetic Fatty (ZDF) Rat

The Zucker fatty rat is used as a model of human obesity accompanied with hyperlipidemia and hypertension. Inbreeding of the Zucker fatty rat for hyperglycemia gave rise to the ZDF rat strain, which are less obese than the Zucker fatty rat, but have more severe insulin resistance (Pick et al., 1998). Diabetes develops in males at 8 weeks of age, but females do not develop overt diabetes (Peterson et al., 1990; Srinivasan and Ramarao, 2007; Wohlfart et al., 2014). Cataract in male ZDF rats is observed at ~15 weeks with the appearance of peripheral vesicles in the lens, which progress to cortical opacities and the development of a mature cataract by 21 weeks (Kim et al., 2011a,b; Shibata et al., 2000) Immunohistochemistry of ZDF lenses revealed large areas of tissue liquefaction, fiber cell swelling, as well as multiple membrane ruptures in the cortex (Kim et al., 2011b). At the biochemical level, lenses of the ZDF rats exhibited 3-fold increase in glucose and fructose, and a 22-fold increase in sorbitol levels (McCaleb and Sredy, 1992), as well as significantly higher AR activity relative to control rats. Lenses also exhibited a decrease of GSH (2.5-fold) in the ZDF rats relative to control rats (Coppey et al., 2002). Labeling for argpyrimidine, a methylglyoxal-derived AGE, and apoptotic molecules revealed that AGEs were highly accumulated in the epithelium (Kim et al., 2012). In addition, expression of the apoptotic factor nuclear factor kappaB (NFκB) was increased in the lens epithelium, as well as the mRNA expression of iNOS (Kim et al., 2010), indicating the involvement of the AGEs/NFκB/iNOS in the alteration of lens epithelial cells in diabetes.

5.1.2 Otuska Long Evans Tokushima Fatty (OLETF) Rat

The OLETF rat develops obesity-induced diabetes, but compared to other obese rodent models, the OLETF rat is only mildly obese. The OLETF rat comes from an outbred colony of Long Evans rats. Male OLETF rats are more susceptible to developing type 2 diabetes, with diabetes apparent at 18–25 weeks (Kawano et al., 1992). Hyperglycemia and hyperinsulinemia are exhibited in the early phases of the disease as a result of islet cell hyperplasia and peripheral insulin resistance (Ishida et al., 1995; Sato et al., 1995). As such OLETF rats are used as a model of human type 2 diabetes (Kawano et al., 1992, 1994). However, very few studies have used the OLETF rat as a model to study diabetic cataract (Bhutto et al., 2002; Kubo et al., 2001; Nagai et al., 2011). In the studies that have been reported, all male OLETF rats develop bilateral cortical cataracts after 60 weeks of age (Bhutto et al., 2002). At 40 weeks, swelling of the lens fibers was observed in the anterior and PSC fibers (Kubo et al., 2001), and at 60 weeks, vacuoles and cell swelling were observed in the equatorial cortex and supranuclear fibers (Kubo et al., 2001) These morphological changes in the OLETF rats resemble those in the galactosemic- and STZ-induced diabetic rats (Fukushi et al., 1980; Kinoshita, 1974), but occur much later in the OLETF rat. Sorbitol levels and AR and SDH activity in the lenses of OLETF rats were also increased (Kubo et al., 2001). Interestingly, SDH activity was greater than AR activity in the 60-week-old OLETF rat lens and this resulted in a net sorbitol conversion to fructose (Kubo et al., 2001), demonstrating that the polyol pathway is a factor in the development of sugar cataract. Other studies, which examined apoptosis and epithelial cell density in OLETF rat lenses have reported that markers of apoptosis, such as interferon-γ (IFN-γ) and interlukin-18 (IL-18), were markedly increased in the OLETF lenses relative to control (Nagai et al., 2011). This indicates that the decreased lens epithelial cell density reported in human diabetic cataract may be due to activation of IL-18 (Awasthi and Wagner, 2004; Nagai et al., 2011) Given that cataract becomes apparent in older animals and that a number of morphological and a few biochemical changes are apparent that resemble those observed in human diabetic cataract, the OLETF rat may be a potentially useful model for studying the chronic pathways that lead to cataract formation in type 2 diabetic patients.

5.2 Nonobese Models of Type 2 Diabetes

As type 2 diabetes can also manifest in the absence of an obese phenotype, the development of nonobese

models is also important for studying the etiology of this disease. Of the nonobese models commonly used by researchers, there are two particular models that slowly develop lens cataract formation and exhibit some evidence of the physiological, morphological, and biochemical features that are the hallmarks of human diabetic cataract.

5.2.1 Spontaneous Diabetic Torri (SDT) Rat

SDT rats spontaneously develop hyperglycemia and glucose intolerance due to decreased insulin secretion and accompanying β cell degeneration. The male SDT rat develops diabetes from about 20 weeks of age (Masuyama et al., 2003), while female SDT rats develop diabetes from 40 weeks of age (Shinohara et al., 2004). In male and female SDT rats, cataracts were observed at 40 weeks of age or older. Lens clouding begins at the posterior pole of lens and progresses to mature cortical cataract in which severe swelling, vacuolation, disintegration of the lens fibers, and formation of Morgagnian globules in the lens cortex are observed (Sasase, 2010). Eventually nuclear sclerosis and opacification of the lens cortex are both observed (Sasase, 2010), along with the extrusion of the lens nucleus into the vitreous chamber as a result of rupture of the posterior lens capsule (Shoda et al., 2007). Few female rodent models currently exist for type 2 diabetes, as in most diabetic models, it is only the males who develop diabetes. Therefore, the female SDT rat may be a useful animal model to study diabetic cataracts, especially for studies in females.

5.2.2 Wistar Bonn/Kobori (WBN/Kob) Rats

The WBN/Kob rat is an animal model for spontaneous diabetic syndrome and retinal degeneration (Mori et al., 1990). Cataracts are apparent at ~12 months of age in males only and appear in the lens periphery with cell swelling and disorder of lens fibers (Miyamura and Amemiya, 1998; Mori et al., 1992). In male WBN/Kob rats, total lens calcium increased at 18 months, and this was accompanied by activation of calpain 2 and 10 and proteolysis of α spectrin (Sakamoto-Mizutani et al., 2002). Although human lenses contain approximately 3% of the calpain activity found in rat lenses, calpain 2 has been suggested to be a major endopeptidase in human lenses (David et al., 1989). There is some evidence to support a role for calpain 2 in human diabetic cataract (Thampi et al., 2002a,b), suggesting that the enzyme might play a role in human diabetic cataract. The WBN/Kob model may, therefore, be useful for elucidating the roles of calpain 2 (and 10) in human cataractogenesis.

5.3 Transgenic or Knockout Mice

Transgenic and knockout mice enable researchers to study the role of a particular gene in disease. However,

diabetic mice are resistant to developing cataract and the levels of AR in the mouse lens are very low (Varma and Kinoshita, 1974). As a consequence, while mouse transgenic models have been used to study other diabetic complications, it is not a readily used model for studying diabetic cataract. However, they do offer an important role for identifying new pathogenic mechanisms brought about by genetic manipulation of the polyol pathway.

5.3.1 Aldose Reductase Transgenic (AR-Tg) Mice

The AR-Tg mice express high levels of human AR specifically in the lens. No morphological lens abnormalities were detected, indicating that overexpression of AR per se does not have any deleterious effect on the lens (Lee et al., 1995). However, when mice were induced to become galactosemic by the introduction of a 50% galactose diet, cataract developed ~1–2 days later, with the appearance of vacuoles detected at the periphery of the lens. (Lee et al., 1995). After 12–14 days, vacuoles covered the entire lens and fused together to produce a completely opaque lens by ~2–3 weeks after the initial administration of the galactose diet (Lee et al., 1995). Measurement of polyol accumulation in these lenses revealed a 20–30 fold increase in galactitol, indicating that the rapid accumulation of this polyol was the cause of the observed galactose-induced cataract (Lee et al., 1995).

AR-Tg mice injected with STZ to induce diabetes first develop cataracts at 7–14 days postinjection, which progresses to complete opacification by ~2–3 weeks (Lee et al., 1995). Lens sorbitol increased under hyperglycemic condition, but much lower than the galactitol levels under galactosemic conditions, reflecting faster accumulation of galactitol. In another study, diabetes-induced AR-Tg mice were used to study whether AR was involved in the generation of oxidative stress (Lee and Chung, 1999). The study revealed that the lenses had a significant decrease in GSH levels and a significant increase in the levels of MDA, indicative of oxidative stress (Lee and Chung, 1999), suggesting that AR is a major contributor to diabetes-induced oxidative stress. Furthermore, blocking the conversion of sorbitol to fructose by a SDH mutation, leads to higher levels of sorbitol accumulation, reduced oxidative stress, and development of cataract faster than mice with a normal SDH, indicating that SDH also contributes to oxidative stress (Lee et al., 1995).

5.3.2 Sorbitol Dehydrogenase–Deficient Mice

The SDH-deficient mouse represents a model that can simulate slow-developing cataract in diabetic patients, but is not diabetic itself (Chan et al., 2008). Cataract first developed at around 6 months of age in 5% of the mice, with ~70% of mice having cataracts at 16–17 months

(Chan et al., 2008). Cataract initially appeared as small vacuoles or clefts, followed by opacities that appeared to spread into the lens nucleus (Chan et al., 2008). Cataract development in the nondiabetic SDH deficient mice was unexpected because the mouse lens has very low AR levels and AR was thought to only be active in hyperglycemic animals due to its high K_m for glucose (Wermuth et al., 1982). While a lack of SDH did not affect lens glucose levels, the levels of sorbitol were dramatically increased in the lens (Chan et al., 2008). These findings demonstrate that the polyol pathway is active even in the nondiabetic mouse lens and that the increase in sorbitol levels most likely contributes to cataract development (Chan et al., 2008). There was no difference in GSH, MDA, or mRNA levels of antioxidant enzymes between wildtype and SDH-deficient mice, indicating that SDH deficiency did not overtly affect oxidative stress levels (Chan et al., 2008). However, introduction of a null mutation of the antioxidant enzyme glutathione peroxidase-1 (Gpx-1) into SDH-deficient mice accelerated cataract development relative to age-matched SDH-deficient mice and Gpx-1 knockout mice, indicating that oxidative stress contributes to cataract formation in SDH-deficient mice. Finally, measurement of ^{86}Rb uptake, an indicator of Na^+/K^+ ATPase activity, revealed that SDH-deficient mice had 50% lower Na^+/K^+ ATPase activity than wildtype mice, and that treatment of SDH-deficient mice with vitamin E prevented the loss of Na^+/K^+ ATPase activity (Chan et al., 2008). These findings suggest that chronic oxidative stress impairs the osmoregulatory mechanisms of the lens and may explain why diabetic patients who control their blood glucose moderately well are still susceptible to the cataract development.

6 ASSESSMENT OF DIABETIC CATARACT ANIMAL MODELS

While a number of diabetic animal models are used in diabetes research (Chatzigeorgiou et al., 2009; King, 2012), the majority of these animal models have not be used to study diabetic cataract. As such, existing models that are routinely used to study other diabetic complications could be reexamined to investigate the effects diabetes on the lenses of these animals.

While the STZ-induction appears to the model of choice for investigating type 1 diabetic cataract formation, there are also a number of animal models of spontaneous type 1 diabetes that could be explored for their use in studying diabetic cataract (Chatzigeorgiou et al., 2009). These include the diabetes-prone BB rat, which was developed from a colony of outbred Wistar rats in Canada (Nakhooda et al., 1977), the Long Evan

Tokushima Lean (LETL) rat (Kawano et al., 1991), the LEW-iddm rat (Jorns et al., 2004), and the Komeda diabetes prone (KDP) rat (Yokoi et al., 2003).

More options are available for researchers studying cataract formation in type 2 diabetes. The models in which cataracts develop slowly and thus appear in older animals are of interest. In light of this, the OLETF rat, an obese type 2 diabetic model is a promising model in which onset of cataract is first detected at 40 weeks (10 months), with bilateral cortical cataracts being formed by 60 weeks (15 months). The slow formation of cataract in the OLETF rat, the appearance of cell swelling and vacuoles in the lens cortex, and increased SDH activity relative to AR activity, bears similarities to characteristics of human diabetic lenses. Another model that would warrant further investigation is the WBN/Kob rat, a nonobese type 2 diabetic model that develops cataract at 12 months of age. Cell swelling is evident in the lens cortex and elevated calcium and calpain activation have also been demonstrated. Surprisingly, for both of these models, there is limited research on their lens physiology and biochemistry, opening up opportunities for researchers to assess the real potential of these models for studying obese and nonobese type 2 diabetic cataract formation.

7 CONCLUSIONS

Although these is much debate about the true value of using animal models in the study of diabetes and diabetic cataract, experimental models are essential tools for understanding the molecular basis, the pathogenic mechanism, and the utility of therapeutics agents in a multifactorial disease. It is unlikely that there is one animal model that entirely replicates the cataract process in humans. However, we have identified some animal models that mimic key characteristics of human diabetic cataract formation. The future use of these more relevant animal models will not only increase our understanding of human diabetic cataract formation, but will also aid our future development of anticataract therapies. The selection of an appropriate animal model(s) is, therefore, vitally important if we are to be successful in developing medical therapies to delay the onset of cataract and avoid the imminent cataract epidemic posed by our increasing diabetic population.

Animal Models for the Study of Human Disease.

1 INTRODUCTION

Retinitis pigmentosa (RP) is a well-known clinical entity that was named by German physician Franz Cornelius Donders in 1857. It is characterized by early night blindness followed by peripheral visual field alterations (tunnel vision) and eventually blindness. The incidence of RP is estimated to be 1 in 4000, which makes it one of the most common causes of severe visual impairment in humans (Hartong et al., 2006). The first type of photoreceptors to be lost is the rods, which provides black-and-white vision and functions in dark or dim light. The loss of rods initially occurs in the equatorial zone and then extends peripherally and centrally. Cones, which are responsible for color vision and function in bright light, are lost after the rods. Photoreceptor cell loss is followed by perivascular pigment deposition within the retina (Hartong et al., 2006). The fundus of an RP patient typically shows intraretinal pigmentation, referred to as bone-spicule deposits, which are created by the migration of retinal pigment epithelial (RPE) cells and their deposition around retinal vessels. RP is a heterogeneous group of retinal disorders with autosomal dominant inheritance (30%–40%), autosomal recessive inheritance (50%–60%), or X-linked inheritance (5%–15%). Although RP is primarily a genetic disease, some sporadic cases are known. RP is mostly observed in isolation (nonsyndromic) but may also occur in the following syndromes: Usher (an autosomal recessive disorder associated with deafness); Laurence-Moon-Bardet-Biedl (an autosomal recessive disease associated with obesity, hypogonadism, mental retardation, and dysmorphic extremities); Kearns-Sayre (a usually sporadic disease that is associated with progressive external ophthalmoplegia); Batten (autosomal recessive disease accompanied with neurodegenerative disease); Refsum (autosomal recessive disorder accompanied with cerebellar ataxia and chronic polyneuropathy); and Senior-Loken (autosomal recessive disease accompanied with kidney failure) (Bhatti 2006; Fleischhauer et al., 2005). RP is a noninflammatory, bilateral, progressive, degenerative pigmentary retinopathy of genetic origin. Thus, the word "retinitis" is a misnomer because retinal inflammation does not play a major role. More than 160 different mutations in genes that encode proteins with remarkably diverse functions result in rod photoreceptor degeneration (www.sph.uth.tmc.edu/retnet). Although various genes are involved in RP, the final common pathway is apoptotic cell death of the rod photoreceptors (Koenekoop, 2009). Vitamin A (Berson, 2007), vitamin A in combination with docosahexaenoic acid (DHA), an n-3 polyunsaturated fatty acid (PUFA) found in fish (Shintani and Klionsky, 2004), and lutein found in green leafy vegetables (Berson et al., 2010) can slow the progression of human. However, there is currently no cure or effective therapy for RP.

Animal models of retinal degeneration are important for a better understanding of human RP, particularly in regard to the search for treatments (Dalke and Graw, 2005; Rivas and Vecino, 2009). Mice carrying the *rd* (rodless retina or retinal degeneration) gene (now *Pde6b*), a defect in the β subunit of cyclic guanosine monophosphate phosphodiesterase (cGMP PDE), develop retinal degeneration early in life. Retinal development in *rd* mice is comparable to that in normal mice at 8 days of age; however, a reduction in the number of photoreceptor cells becomes apparent at 11 days of age, and photoreceptor cells are completely missing or reduced to a single layer of cells by 20 days of age (Nambu et al., 1996). In *rds* (retinal degeneration slow) mice carrying mutations in the *peripherin/rds* gene (now *Prph2*), photoreceptor cell loss starts at 2 weeks of age and progresses slowly with complete loss occurring 1 year after birth (Sancho-Pelluz et al., 2008). The *RCS* (Royal College of Surgeons) rat has a deletion in the gene encoding a receptor tyrosine kinase (*Mertk*) expressed in RPE cells, and the inability to phagocytize rod outer segment debris leads to photoreceptor degeneration by apoptosis (Perche et al., 2008); this degeneration begins at 20 days of age, and there are almost no detectable photoreceptors by 60 days of age. The *rd*, *rds*, and *RCS* animals are spontaneous animal models for RP that have heterogeneous genetic defects that lead to photoreceptor apoptosis, which is characterized by internucleosomal cleavage and fragmentation (Chang et al., 1993; Portera-Cailliau et al., 1994; Tso et al., 1994). Importantly, mutations in these genes have been detected in patients with RP (Perche et al., 2008; Sancho-Pelluz et al., 2008). In addition to isolated models for RP, the tubby mouse carrying a mutation in the *tub* gene (Kong et al., 2007) is an animal model for Usher syndrome, the most common syndrome associated with RP (Fleischhauer et al., 2005). In addition to spontaneous animal models, transgenic animal models of RP are available and have been used to understand the mechanisms of the disease and develop therapeutic strategies (Chader, 2002; Dalke and Graw, 2005; Rivas and Vecino, 2009). However, the establishment of additional animal models, resembling human RP, is desired for the further understanding of disease progression, the analysis of disease mechanisms, and the development of treatments.

In addition to genetic models of RP, light induces photoreceptor cell damage and death through phototoxic mechanisms (Organisciak and Vaughan 2010), and certain chemicals can artificially cause photoreceptor cell damage in animals. Mammalian eyes are highly sensitive to toxic substances, and several chemicals induce retinal degeneration in animals (Voaden, 1991). Among these chemicals, *N*-methyl-*N*-nitrosourea (MNU), an alkylating agent, exhibits its cytotoxicity by transferring its methyl group to nucleobases in nucleic acids. MNU

selectively damages photoreceptor cells and may be a good candidate for the induction of retinal degeneration. Importantly, apoptosis is the final common pathway of photoreceptor cell death in RP animal models, as well as RP patients. Thus, if MNU-induced photoreceptor cell damage is due to apoptosis, it may represent another animal model for RP.

2 TIME-COURSE PROGRESSION OF MNU-INDUCED RETINAL DEGENERATION

Herrold (1967) first described retinal degeneration in Syrian golden hamsters that received two intravenous (IV) 5-mg doses of MNU per week and were sacrificed between 4 and 7 months of age. These MNU-treated animals exhibited photoreceptor cell loss that resulted in the inner nuclear layer being in direct contact with the choroid. A single 40 mg/kg dose of MNU to F344 rats and Japanese white rabbits by an intraperitoneal (IP) and IV route, respectively, caused severe destruction of photoreceptor cells after 3 days and complete photoreceptor cell loss after 5 or more weeks (Ogino et al., 1993). A single IV 15 mg/kg dose of MNU (given together with 20 mg/kg ketamine but not MNU alone) to cats caused distinctive loss of photoreceptor cells in 7 days (Schaller et al., 1981). We tried to shorten the time-course progression of MNU-induced retinal degeneration in rats, which are frequently used for toxicological studies. The

dose of MNU needed to cause photoreceptor cell loss in 7 days was determined in albino (Sprague-Dawley) and pigmented (Brown-Norway) rats.

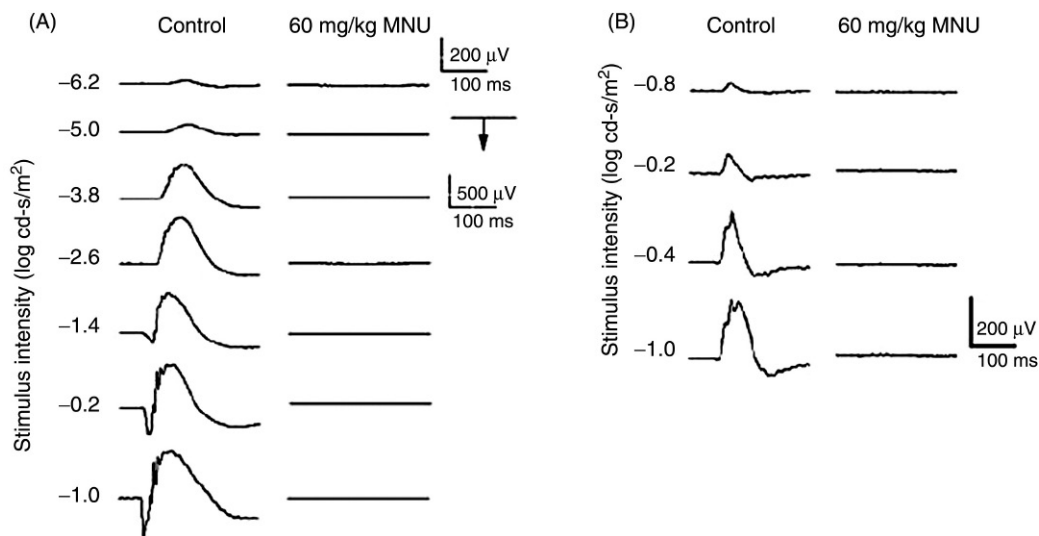
Fig. 5.1 illustrates the time-course progression of MNU-induced retinal degeneration in Brown-Norway rats. In both pigmented and albino rats, IP administration of 60 or 75 mg/kg MNU caused time-dependent retinal damage in which photoreceptor cell loss occurred over a 7-day course (Nakajima et al., 1996a,b; Yoshizawa et al., 1999, 2000). Although age-matched control (MNU-untreated) rat retina exhibited ordered retinal layers, rats treated with MNU displayed retinal photoreceptor cell loss in a characteristic pattern. Twenty-four hours after MNU administration, photoreceptor cells showed pyknosis and karyorrhexis of the nuclei, shortening of the inner segment, and disorientation of the outer segment. The destruction of photoreceptor segments can be easily recognized by the periodic acid-Schiff (PAS)-negative inner segment and PAS-positive outer segment. At this time point, the pigment deposition in the RPE cells was irregular. After 48 h, karyorrhexis of the photoreceptor cells progressed, and widespread destruction of the photoreceptor layer occurred. At 72 h, photoreceptor cell destruction had progressed to include widespread destruction of the photoreceptor segments and detachment of the RPE cells from Bruch's membrane. At this time point, cells presumed to be Müller cells with mitotic figures were present within the dying photoreceptor cells and in the inner nuclear layer. At day 7, active
FIGURE 5.1 **Time-course progression of retinal damage after a single systemic administration of 75 mg/kg N-methyl-N-nitrosourea (MNU) to 7-week-old pigmented Brown-Norway rats.** GCL, Ganglion cell layer; INL, inner nuclear layer; IPL, inner plexiform layer; ONL, outer nuclear layer; OPL, outer plexiform layer; PEL, pigment epithelial cell layer; and PRL, photoreceptor cell layer. At 48 h after MNU administration, photoreceptor cells show pyknosis and karyorrhexis and the destruction of the inner and outer segments. At 72 h, the destruction of photoreceptor cells and photoreceptor segments had progressed, the migration of the melanin-containing retinal pigment epithelial (RPE) cells began, and mitotic cells among the photoreceptor cells appeared. At day 7, active signs of photoreceptor cell destruction were indistinct because almost all of the photoreceptor cells were lost, and the inner nuclear cells were either in direct contact with choroids or separated by a few layers of cells. At day 35, vacuole formation (cystoid degeneration) was observed within the retina (hematoxylin and eosin). *Source: Reprinted with permission from Tsubura, A., et al., 2010. Histol. Histopathol. 25(7), 933–944.*


FIGURE 5.2   **Electroretinogram *(ERG)* recording 7 days after a single systemic administration of 60 mg/kg of MNU to an 8-week-old albino Sprague-Dawley rat and an age-matched MNU-untreated control.** (A) Scotopic waveforms. (B) Photopic waveforms. Both the scotopic and photopic ERG responses became undetectable in the MNU-treated rats. *Source: Reprinted with permission from Tsubura, A., et al., 2010. Histol. Histopathol. 25(7), 933–944.*

signs of photoreceptor degeneration were indistinct due to photoreceptor cell loss, and the PAS-positive outer segment was diminished. At this time point, scotopic and photopic electroretinogram (ERG) responses were undetectable, suggesting the functional loss of the retina (Fig. 5.2) (Kiuchi et al., 2003). Thus, MNU caused complete photoreceptor cell death, as observed structurally and functionally, in a 7-day course.

At 21 and 35 days, the inner nuclear layer was either in direct contact with the choroid or was separated from it by a few layers of cells. At these time points, RPE cell migration occurred within the retina, and vacuole formation (cystoid degeneration) occurred in the inner nuclear layer and inner plexiform layer. In rats, although the migration of RPE cells was observed within all layers of the retina, direct contact to intraretinal vascular cells was indistinct even 150 days after MNU administration. When a lower dose of MNU (50 mg/kg) is applied to Sprague-Dawley rats, photoreceptor cell loss requires a longer period of time (Jeong et al., 2011). In addition to these histopathological analyses, optic coherence tomography has been used to obtain cross-sectional noninvasive images to monitor the progression of MNU-induced retinal degeneration in animals (Yamauchi et al., 2011).

3 RETINAL DEGENERATION CAUSED BY MNU IN VARIOUS ANIMAL SPECIES

In Sprague-Dawley and Brown-Norway rats, photoreceptor cell loss occurred over a 7-day period after 60 or 75 mg/kg of MNU was administered to young mature animals at 7 weeks of age (Nakajima et al., 1996a,b;

Yoshizawa et al., 1999, 2000). A single systemic administration of MNU-induced retinal degeneration in both female and male mammals including the house musk shrew *Suncus murinus* (Insectivora), mice of the BALB/c, GRS/A, and C57BL strains, rats of the Sprague-Dawley, Lewis, Brown-Norway, Long-Evans, and Copenhagen strains (Emoto et al., 2016a), the Syrian golden hamster (Rodentia), cat (Carnivora), and nonhuman primates (monkey; *Macaca fuscata and Macaca fascicularis*) (Kinoshita et al., 2015; Tsubura et al., 1998). Rodent studies indicate that retinal susceptibility to MNU does not show strain differences (Emoto et al., 2016a; Tsubura et al., 1998). However, the dose of MNU necessary for the induction of retinal degeneration in a 7-day period differed among species (Table 5.1). In mice, both systemic IP administration of 60 mg/kg MNU or topical intravitreal (IVT) administration of 3 mg/kg MNU cause retinal degeneration within a week (Rösch et al., 2014). Although systemic MNU administration affects both eyes, topical administration only affects the injected eye. Moreover, although the photoreceptor cell loss required more than 7 days, MNU causes retinal degeneration in Japanese white rabbits (Lagomorpha) (Ogino et al., 1993) and Sudanian grass rats (Rodentia) (Boudard et al., 2010, 2011). Interestingly, MNU together with ketamine (but not MNU alone) was necessary for the development of photoreceptor cell damage in cats (Schaller et al., 1981). Ketamine blocks calcium channels associated with *N*-methyl-D-aspartate (NMDA) receptors, which prevents the influx of ions and subsequent photoreceptor cell death in adult rabbits (Paques et al., 2006). In contrast, ketamine enhances neuronal cell death in rats by compensatory upregulation of NMDA

TABLE 5.1   Retinal Degeneration Induced by *N*-Methyl-*N*-Nitrosourea (MNU) in Different Animal Species

Vertebrata	Species	Age or body weight	MNU (mg/kg)	Route of administration	Site of origin	Migration of retinal pigment epithelial cells	References
Mammal	Monkey	Young adult	40	IV	Equatorial zone	No migration	Tsubura et al. (1998)
	Cat	5–10 months	15[a]	IV	ND	ND	Schaller et al. (1981)
	Rabbit	2.3–2.5 kg	40[b]	IV	ND	ND	Ogino et al. (1993)
	Hamster	7 weeks	90	IP	Posterior pole	Contact with intraretinal blood vessels	Taomoto et al. (1998)
	Grass rat	2–6 months	150[c]	IP	ND	ND	Boudard et al., 2010

receptors in the developmental stage (Zou et al., 2009). In an unpublished experiment performed by our laboratory, ketamine hydrochloride diluted in physiologic saline was subcutaneously (SC) injected into 7-day-old and 12-week-old Sprague-Dawley rats. A dose of 0, 10, 20, and 40 mg/kg was administered 6 times at 2-h intervals. Rats were sacrificed 24 h after the first injection. In 7-day-old rats, dose-dependent single cell necrosis of the brain occurred, and single cell necrosis of the retinal ganglion cells (not photoreceptor cells) occurred in all groups (unpublished observation). The number of rats with single cell injury in the inner retina was 2 of 11 rats in the 0 mg/kg group; 3 of 12 rats in the 10 mg/kg group; 3 of 15 rats in the 20 mg/kg group; and 4 of 13 rats in the 40 mg/kg group. Ketamine did not cause retinal ganglion cell injury in these rats. Ketamine at a dose of 40 mg/kg was lethal in 7-day-old animals (10 of 13 animals), whereas 12-week-old animals treated with ketamine did not die or exhibit damage to the brain or retina. Thus, the effects of ketamine on photoreceptor cells may be species-specific. Insectivora are considered to be the most primitive class of primates and also considered to be related to rodents (Romer and Parson, 1978). Among the insectivora, the house musk shrew *Suncus murinus*, which belongs to the family Soricidae, is widely distributed throughout the tropical regions of Asia and the Far East, and also inhabits southern Japan. Shrews have morphological and functional phenotypes that are similar to those of primates, and some of these phenotypes may closely reflect those of humans; therefore, the shrew is a valuable experimental animal from a

phylogenetic point of view (Tsubura et al., 1995). Thus, phylogenetically, MNU-induced retinal degeneration observed from shrews to monkeys may suggest that MNU-induced retinal degeneration is a universal phenomenon in mammals. Similar to human RP, degeneration originates from the equatorial zone in monkeys, whereas degeneration originates from the central retina (posterior pole) and extends to the peripheral retina in shrews, mice, rats, and hamsters (Kinoshita et al., 2015; Tsubura et al., 1998). Rats and mice are nocturnal rod-dominant animals (98 and 96% rods, respectively) with a sparse distribution of cones across the retina. Although the total number of cones in the human retina is of the same order ($\sim$5%), many are concentrated in the central macular zone. This difference in the distribution of rods and cones among different animal species might explain the differences in the initiation site of photoreceptor cell damage. Moreover, in addition to mammals, MNU targets fish photoreceptor cells. Zebrafish incubated in fresh water containing 150 mg/kg MNU in 10 mM phosphate-buffered saline (PBS; pH 6.3) for 1 h exhibit photoreceptor cell loss over a 7-day period (Tappeiner et al., 2013). Unlike mammals, zebrafish displays persistent retinal neurogenesis throughout their life. Characteristically, within a month after photoreceptor cell degeneration, zebrafish photoreceptor cells regenerate from Müller cells. In rats, Müller cells express rodopsin and synaptophysin in response to MNU damage (Wan et al., 2008), but further study is required to determine whether these rodopsin- and synaptophysin-positive cells, which are presumed to be Müller cell-derived photoreceptor

cells, acquire functional properties. Cultured human Müller cells retain the capacity to express photoreceptor-specific markers; however, confirmation is necessary to determine whether they obtain functional properties when transplanted to athymic mouse retina (Giannelli et al., 2011). Unlike zebrafish, mammals do not exhibit persistent retinal neurogenesis throughout life.

In human RP, cone disappearance occurs secondary to rod loss. Cones can be assessed using peanut agglutinin staining. Light damage to the retina causes rod loss followed by cone loss in transgenic T17M rhodopsin mice (Krebs et al., 2009). The retinal damage in mice caused by IP injection of 60 mg/kg MNU consists of rod disappearance in parallel with the progressive disappearance of peanut agglutinin-labeled cones from the central retina to the periphery (Krishnamoorthy et al., 2008). In diurnal cone-rich Sudanian grass rats that receive an IP injection of 150 mg/kg MNU, cone loss is delayed relative to rod loss (Boudard et al., 2010). MNU-induced cone disappearance secondary to rod loss is similar to that observed in human RP. However, MNU only targets rod cells in cone-rich zebrafish (Tappeiner et al., 2013), with MNU inducing rod cell but not cone cell loss, although photoreceptor function is impaired in both rod and cone cells in monkeys (Kinoshita et al., 2015). In parallel to photoreceptor cell loss, intraretinal migration of melanin-containing RPE cells occurred in rats and hamsters (Table 5.1); however, RPE cells in contact with blood vessels were observed only in hamsters (Taomoto et al., 1998). Interestingly, RPE migration did not occur in monkeys, mice, shrews, or zebrafish (Tappeiner et al., 2013; Tsubura et al., 1998; Yuge et al., 1996).

4 AGE-RELATED PHOTORECEPTOR CELL DAMAGE AND SENSITIVITY TO MNU

In contrast to the MNU-induced photoreceptor cell loss in young mature animals, MNU administered transplacentally (Smith and Yielding, 1986) or to newborn animals (Nambu et al., 1998a,b) resulted in retinal dysplasia characterized by the progressive disorganization of neuroblasts, which led to rosette formation in the outer neuroblastic/nuclear layer (Fig. 5.3). Retinal dysplasia characterized by rosettes is a developmental anomaly present at birth (Godel et al., 1981). In C57BL mice, retinal dysplasia developed when 60 mg/kg MNU was administered to 0- or 3-day-old pups but not to pups that were 5 days old or older (Nambu et al., 1998a). In contrast, retinal degeneration occurred when MNU was given to mice that were 11 days old or older. Interestingly, no structural alteration of the retina occurred when 60 mg/kg MNU was administered to 5- and 8-day-old mice. MNU administered in the proliferative phase of retinal development led to retinal dysplasia, but MNU had no effect on the retinal developmental stage when administered after the proliferation of neuroblastic cells had ended. However, after retinal tissue had differentiated into specialized cells, photoreceptor cells became susceptible to MNU. In the mature retina of Lewis rats, photoreceptor cell loss occurred over a 7-day period when >90, >50, and ≥35 mg/kg MNU was given to 21-, 50-, and 150-day-old animals, respectively (Nambu et al., 1998b). Ontogenetically, the sensitivity of photoreceptor cells to MNU-induced retinal degeneration increased with age. This increased sensitivity in parallel to
FIGURE 5.3 **Retinal dysplasia after a single systemic administration of 60 mg/kg MNU to 0-day-old C57BL mice.** (A) Retinal rosette in the outer nuclear layer at 8 days of age (hematoxylin and eosin). (B) Electron micrograph of the retinal rosette at 20 days of age. In some areas the photoreceptor segments radiated toward the center, and in other areas the photoreceptor cell nuclei directly face the center. A single layer of pigment epithelial cells was observed above the Bruch's membrane. *Arrowheads* indicate the outer limiting membrane. Bar = 4 μm. *Source: Reprinted with permission from Nambu, H., et al., 1998. Pathol. Int. 48(3), 199–205.*

aging may be caused by the accumulation of DNA damage with age. However, regardless of the time of MNU administration to rats that are at least 21 days old (after the retina has matured), the loss of photoreceptor cells was a selective phenomenon in that no other neural cells in the retina were affected by MNU.

5 PHOTORECEPTOR CELL DEATH, CELL DEBRIS REMOVAL, AND RPE CELL MIGRATION

5.1 Photoreceptor Cell Death

Apoptosis and autophagy-associated cell death are the two fundamental types of programmed cell death (Hotchkiss et al., 2009). Apoptosis (type I programmed cell death) is characterized by condensation of the cytoplasm and nucleus, accompanied by chromatin condensation, nuclear fragmentation, and the formation of plasma membrane blebs. Autophagic cell death (type II programmed cell death) is characterized by the accumulation of autophagosomes and autolysosomes. Autophagosomes fuse with lysosomes to form autolysosomes, in which acid hydrolases catabolize the ingested material into metabolic substrates. Paradoxically, autophagy may function as an essential survival mechanism by producing energy from the breakdown of deleterious products and organelles (Mizushima, 2007). In most normal tissues and cells, autophagy occurs at basal levels (basal autophagy) and contributes to the routine turnover of cytoplasmic components. In disease conditions, autophagy contributes to cell damage but can also protect cells from injury (Shintani and Klionsky, 2004). Photoreceptor degeneration in several animal models for RP occurs through apoptosis (Chang et al., 1993; Portera-Cailliau et al., 1994; Tso et al., 1994).

An apoptotic mechanism is responsible for MNU-induced retinal degeneration in rats (Nakajima et al., 1996b) and other species (Taomoto et al., 1998; Yuge et al., 1996). Light microscopy studies of MNU-treated rat retina revealed that the dying photoreceptor cell nuclei appeared hyperchromatic after 24 h and that the degree of hyperchromatic nuclei progressed after 72 h (Fig. 5.4A). Among the dying photoreceptor cells and in the inner nuclear layer, scattered mitotic cells, presumed to be Müller cells, were observed. Dying photoreceptor cells were selectively labeled with terminal deoxynucleotidyl transferase-mediated dUTP nick-end labeling (TUNEL) 24 and 72 h after MNU (Fig. 5.4B). Electron microscopy showed photoreceptor cell nuclei to be pyknotic while Müller cell nuclei remained viable (Fig. 5.4C). In addition, internucleosomal DNA fragmentation was detected in the retina 12 and 24 h after MNU administration; the fragmentation peaked 72 h after

MNU administration and was almost negligible at day 7 (Fig. 5.4D). These findings suggest that an apoptotic mechanism is responsible for photoreceptor cell death.

In normal photoreceptor cells, besides the intermittent shedding of the disk from outer segments, autophagy functions as a degradative pathway in photoreceptor metabolism. Autophagic vacuoles are mainly encountered in the myoid portion of the inner segments of photoreceptor cells with dense material (Remé et al., 1999). In BALB/c mice, autophagosomes were detected in the myoid portion of the inner segment of the photoreceptor cells in untreated controls (Fig. 5.5). However, autophagosomes were barely detectable 72 h after the administration of 75 mg/kg MNU when the level of apoptosis peaked (Kuro et al., 2011). Decreased levels of basal autophagy concomitantly occurred during the course of apoptosis progression in photoreceptor cells of MNU-treated mice. Several animal models for RP indicate that defects in retinal genes encoding rod proteins initiate the pathogenesis of RP leading to the apoptotic rod cell death, which is followed by the loss of cones. In contrast to rods, cone loss is due to nutritional deficiencies, starvation, and autophagy (Punzo et al., 2009). The role of autophagy in photoreceptor cells appears to be complex.

5.2 Removal of Apoptotic Photoreceptor Cells

Clearance of apoptotic cells is mediated by professional phagocytes, such as macrophages and nonprofessional phagocytes, which are cells near apoptotic cells in which phagocytosis is not their principal function (Erwig and Henson, 2008). Macrophages, Müller cells, and RPE cells participate in the clearance of damaged retinal neuronal cells (Chang et al., 2006; Strauss, 2005). During the course of photoreceptor cell apoptosis caused by 75 mg/kg MNU in rats, mitotic cells appeared in the inner nuclear layer and within dying photoreceptor cells 72 h after MNU administration when apoptosis peaked (Fig. 5.4A). Cells not undergoing apoptosis contained proliferating cell nuclear antigen (PCNA) in their nucleus (Fig. 5.6A) and glial fibrillary acidic protein (GFAP) and/or vimentin in their proliferating cell processes (Fig. 5.6B); these characteristics are indicative of Müller cells. These cells appeared 48 h after MNU administration and peaked at 72 h. Proliferating Müller cell processes contained numerous phagocytic inclusions derived from apoptotic photoreceptor cells (Fig. 5.6C). The role of Müller cell proliferation and the extension of their processes within damaged areas may also participate in stabilizing and preserving the damaged retina. At days 7 and 21 after MNU administration, there was an influx of ED1-positive and ED2-negative bone marrow-derived microglia/macrophages within the retina (Fig. 5.6D) (Kaneko et al., 2008; Nakajima et al., 1996a,b). Therefore, Müller cells, macrophages, and RPE cells with
FIGURE 5.4   Apoptosis characteristics of photoreceptor cell death induced by MNU. (A) Pyknotic photoreceptor cell nuclei were observed in 75 mg/kg MNU-treated Sprague-Dawley rats 72 h after MNU treatment. Mitotic cells presumed to be Müller cells *(arrowheads)* are indicated (hematoxylin and eosin). (B) Terminal deoxynucleotidyl transferase-mediated dUTP nick-end labeling (TUNEL). TUNEL-positive signals are restricted to photoreceptor cell nuclei of Sprague-Dawley rats 72 h after administration of 75 mg/kg MNU. (C) Electron micrograph. MNU-treated rat retina showed hyperchromatic photoreceptor cell nuclei, leaving Müller cells located in the upper left corner intact. Retinal tissue was from Sprague-Dawley rats 24 h after administration of 75 mg/kg MNU. Bar = 3.5 μm. (D) DNA fragmentation in the retina of Lewis rats treated with 60 mg/kg MNU and untreated controls. DNA ladders appeared in MNU-treated retina 12 and 24 h after MNU and peaked 72 h after MNU; the ladder was negligible at day 7. *Source: Reprinted with permission from Tsubura, A., et al., 2010. Proliferation of Müller cells is indicated by: (A) Proliferating cell nuclear antigen (PCNA)-positive nuclei *(PCNA)*, (B) vimentin-positive cytoplasm (Vimentin), and (C) electron micrograph. Proliferating Müller cell processes contain numerous phagocytic inclusions. Bar = 4 μm. (D) ED-1-positive migrating macrophages *(arrowheads)* are observed within the injured outer retina (ED-1). *Source: Reprinted with permission from Nakajima, M., et al., 1996b. Am. J. Pathol. 148(2), 631–641.*

phagocytic function were involved in the removal of apoptotic photoreceptor cells, which were characterized by marked cytoplasmic and nuclear condensation and fragmentation into membrane-bound bodies. No inflammatory response was observed in these processes.

5.3 Bone Spicule Pigmentation

Fundus pictures of RP patients show a pale, waxy optic nerve head, attenuated retinal blood vessels, and characteristic bone spicule pigment in regions of photoreceptor degeneration (Li et al., 1995). The bone spicule pigment corresponds to melanin-containing RPE cells clustered around branching blood vessels in the inner retina. Translocated RPE cells in contact with retinal blood vessels are a distinctive feature of human RP. Although photoreceptor cell loss by apoptosis occurs in various vertebrate species, a phenotypically similar

model can only be reproduced in MNU-treated hamsters (Taomoto et al., 1998). When Syrian golden hamsters received a single IP injection of 90 mg/kg MNU at 7 weeks of age, photoreceptor cell apoptosis developed 24 h after the treatment and resulted in photoreceptor cell loss at day 7. On day 5, when the photoreceptor cells were almost lost, the migration of RPE cells to the photoreceptor layer started. After day 7, and during 2–20 weeks after MNU injection, RPE cells migrated and reached all layers of the retina, and some were in contact with retinal vessels (Fig. 5.7A–B). Rhodopsin knockout ($rho^{-/-}$) mice on a C57BL/6 background, a murine homolog of an autosomal recessive form of human RP, completely lack rod outer segments and functional rods. Rod photoreceptor cells are quickly lost in these mice, followed by progressive cone degeneration at approximately 3 months of age (Jaissle et al., 2010). After the loss of all photoreceptor cells, the inner retinal vessels are in direct
FIGURE 5.7　**Bone spicule pigment formation in 90 mg/kg MNU-treated Syrian golden hamster 20 weeks after MNU treatment.** (A) Note translocated Fontana-Masson-positive cells *(arrowheads)* are in contact with an intraretinal blood vessel (Fontana-Masson). (B) Translocated pigment epithelial cells are in contact with basal lamina of a retinal vessel (V). Bar = 1 μm. *Reprinted with permission from Taomoto, M., et al., 1998. Graefe's Arch. Clin. Exp. Ophthalmol. 236(9), 688–695.*

contact with migrated RPE cells. Different results were found in conventional C57BL mice treated with 60 mg/kg MNU and monitored for 21 days. The photoreceptor nuclei and rod/cone layer were destroyed, resulting in the inner nuclear layer being in direct contact with RPE cells. A single layer of RPE cells was preserved above Bruch's membrane. There was no evidence of RPE cell migration far into the retina, and the RPE cells did not contact the intraretinal vessels (Yuge et al., 1996). Thus, the rhodopsin knockout genotype may be involved in the bone-spicule phenotype in C57BL mice. Although the fate of RPE cells differs among species, photoreceptor cell loss by apoptosis is the primary event in human RP and MNU-induced retinal degeneration in animals.

6 MOLECULAR MECHANISMS IN PHOTORECEPTOR CELL DEATH CAUSED BY MNU

6.1 DNA Adduct Formation

Photoreceptor cell death is the major hallmark of RP, although the mechanisms leading to photoreceptor apoptosis remain poorly understood. MNU is an alkylating agent that interacts with DNA to yield a variety of reaction products. The predominant adduct (70%–90%) following the reaction of methylating agents with DNA is at the 7-position of guanine, which yields the 7-methyldeoxyguanosine (7-medGua) adduct (Degan et al., 1988). While 7-medGua does not appear to be directly mutagenic, it is useful for the detection of methylating agent

exposure because it is more stable than mutagenic O^6-methyldeoxyguanosine. Immunohistochemically, 7-medGua DNA adducts were selectively detected in the photoreceptor cell nuclei of F344 and Sprague-Dawley rats and C57BL mice 3, 6, 12, and 24 h after MNU exposure, with a gradual decrease at days 3 and 7 (Kiuchi et al., 2002; Ogino et al., 1993; Yoshizawa et al., 1999). Accumulated DNA adducts in the photoreceptor cell nuclei might suppress DNA synthesis, causing photoreceptor cell death. After DNA adduct accumulation, photoreceptor cell apoptosis was confirmed by DNA laddering, TUNEL signals, and ultrastructural nuclear images.

6.2 PARP Activity

Poly(ADP-ribose) polymerase (PARP) is an abundant nuclear enzyme involved in DNA repair. DNA damage induced by alkylating agents activates PARP, which repairs DNA damage by using nicotinamide adenine dinucleotide (NAD^+) as a substrate (Carson et al., 1986). PARP hyperactivation results in the depletion of cellular NAD^+ pools, leading to ATP deficiency, energy loss, and subsequent cell death. After Sprague-Dawley rats were treated with 60 mg/kg MNU, the PARP activity in retinas, as evaluated by the expression of poly(ADP-ribose) (PAR), which is the product of PARP, increased at 12 and 24 h and peaked at 72 h. PAR immunoreactivity at 24 h was restricted to degenerative photoreceptor cell nuclei (Uehara et al., 2006). PARP overactivation is also observed in photoreceptor cells of P23H and S344ter transgenic rats carrying rhodopsin mutations (Kaur et al., 2011). In retinal explant cultures derived

from PARP knockout and wild-type animals, the wild-type retina subjected to *Pde6b* inhibition to imitate the *rd* mouse condition shows massive photoreceptor cell degeneration, while cell death is reduced in the PARP knockout culture (Sahaboglu et al., 2010). PARP activation plays a pivotal role in mediating photoreceptor cell apoptosis not only in the MNU model but also in an inherited mouse model of retinal degeneration. PARP regulates transcription through its interaction with transcription factors, such as nuclear factor-κB (NF-κB) and activator protein-1 (AP-1) (Aguilar-Quesada et al., 2007; Andreone et al., 2003; Chiarugi, 2002; Skaper, 2003).

6.3 Transcription Factors

Transcription factors serve as pivotal regulators of cell survival or cell death. NF-κB is a ubiquitous transcription factor that acts as a master regulator of stress responses and plays an essential role in cell injury. NF-κB activity is regulated at multiple levels (Vermeulen et al., 2002). In its latent form in the cytoplasm, NF-κB is bound to IκB, which prevents its translocation into the nucleus. Phosphorylation of IκB at serine 32 is necessary for the release of active NF-κB. Phosphorylation of the NF-κB p65 subunit at serine 276 is necessary for NF-κB to be constitutively active in the nucleus and exert efficient transcriptional activity. The administration of 60 mg/kg MNU to Sprague-Dawley rats did not increase the phosphorylated-IκB (serine 32) protein levels. However, phosphorylated-NF-κB (serine 276) protein levels were significantly decreased 12, 24, and 72 h after MNU administration (Miki et al., 2007). NF-κB is constitutively active in cultured 661W mouse photoreceptor cells, and light exposure decreases NF-κB activity, leading to photoreceptor cell death; thus, the preservation of NF-κB activity in photoreceptor cell nuclei is necessary for photoreceptor cells survival (Krishnamoorthy et al., 1999). In contrast, the activation and nuclear translocation of NF-κB p65 occurs during the course of the retinal degeneration of *rd* mice (Zeng et al., 2008). NF-κB activation can induce both anti- and proapoptotic effects, depending upon the specific model of retinal degeneration and the pathological stimuli.

AP-1 is a dimeric complex mainly composed of c-Jun and c-Fos, and it is closely associated with intracellular signals for cell cycle, differentiation, and apoptosis. Increased AP-1 activity in the retinas of light-exposed c-fos[+/+] mice implicates the contribution of AP-1 to apoptosis induction. Retinas from c-fos[−/−] mice have unchanged AP-1 activity and are resistant to apoptosis. These results indicate that c-Fos is essential for the light-induced apoptotic pathway (Wenzel et al., 2000). A gene expression analysis of retinas from MNU-treated rats, consisting of microarray analysis and real-time RT-PCR, showed that c-Fos was upregulated by MNU (Yang

et al., 2007). However, in contrast to light exposure, MNU exposure causes photoreceptor apoptosis in both c-fos[+/+] and c-fos[−/−] mice (Wenzel et al., 2000). c-Jun and the phosphorylation of its N-terminus at serine 63 and serine 73 by c-Jun N-terminal kinase (JNK) are associated with neural apoptosis (Estus et al., 1994; Xia et al., 1995). In parallel to photoreceptor cell apoptosis induced by a single IP injection of 60 mg/kg MNU to Sprague-Dawley rats, the phosphorylation of JNK peaked at 12 h and the phosphorylation of c-Jun peaked at 24 h, followed by a gradual decrease. The induction of AP-1 (c-Jun and c-Fos) was observed at 12 h, peaked at 24 h, and then gradually decreased at 3 and 7 days. These results indicate the importance of JNK/AP-1 in the MNU-induced apoptotic pathway (Uehara et al., 2006). However, in an apparent contradiction, phosphorylated c-Jun is not required for MNU-induced photoreceptor apoptosis in mice (Grimm et al., 2001). The lack of a requirement for phosphorylated c-Jun may be due to the shorter observation period (2 h after MNU exposure) or species differences. NF-κB and JNK are closely linked, and JNK plays a key role by interacting with the Bcl-2 family of apoptosis regulator proteins (Liu and Lin, 2005; Okuno et al., 2004).

p53 is a transcription factor that plays a crucial role against genotoxic stress and is a major regulator of cell death in response to DNA damage (Donehower and Bradley, 1993). Eight-week-old p53[−/−], p53[+/−], and p53[+/+] mice generated in 129/Sv-derived embryonic stem cells backcrossed onto a C57BL background received an IP injection of 60 mg/kg MNU and were sacrificed after 7 days (Yoshizawa et al., 2009). Regardless of the p53 gene status, equivalent levels of photoreceptor cell loss were observed, indicating that MNU-induced photoreceptor cell degeneration was p53-independent. In agreement with this observation, photoreceptor cell apoptosis is p53-independent in *rd* mice (Wu et al., 2001) and *rds* mice (Ali et al., 1998), as well as following light-induced retinal damage (Marti et al., 1998).

6.4 Bcl-2 Family Proteins

The Bcl-2 family proteins are important determinants of apoptosis. Bcl-xL and Bcl-2 prevent apoptosis, whereas Bax induces apoptosis. Sprague-Dawley rats were given a single IP injection of MNU. At 40 mg/kg, MNU caused upregulation of Bax and Bcl-xL, which peaked at 24 h. The Bax/Bcl-xL ratio also increased and peaked 24 h after MNU (Yang et al., 2007). At 60 mg/kg, MNU caused upregulation of Bax, which peaked after 72 h and remained high for 7 days, while Bcl-2 expression was unchanged (Uehara et al., 2006). However, it was reported that 60 mg/kg MNU caused upregulation of Bax and downregulation of Bcl-2 after 24 h (Xu et al., 2008). After 12 h, a 75 mg/kg dose of MNU caused downregulation of Bcl-2 and upregulation of Bax, which peaked 24 h after

MNU (Yoshizawa et al., 1999). Cell destructive stimuli caused by different levels of MNU may evoke varying effects on the Bcl-2 family proteins involved in apoptosis, but the proapoptotic/antiapoptotic ratio seems to rise after MNU injection.

6.5 Caspase Activation

Caspases (cysteine aspartate-specific proteases) coordinate and execute the apoptotic process. The substrates cleaved by caspases include members of the Bcl-2 family of apoptosis regulator proteins. The caspase family plays a decisive role in the execution of retinal apoptosis in that the caspase-3/CPP32, caspase-6/Mch2, and caspase-8/FLICE protease activities peaked 72 h after 75 mg/kg MNU administration to Sprague-Dawley rats (Yoshizawa et al., 1999). Similarly, in 40 mg/kg MNU-treated Sprague-Dawley rats, caspase-3 activity significantly increased at 24 h, peaked at 72 h, and decreased at day 7 (Gao et al., 2010). However, in 45 mg/kg MNU-treated C57BL mice, caspase-3-positive staining and a change in caspase-3 mRNA values were not detected at 1, 3, and 7 days after MNU treatment (Zulliger et al., 2011). Other apoptotic pathways may be involved in MNU-damaged photoreceptor cells.

6.6 Calcium Overload and Calpain Activation

Cytotoxic stimuli result in a massive calcium (Ca^{2+}) influx into the target cells, and increased cellular Ca^{2+} concentrations cause calpain (calcium-dependent cysteine protease) activation (Goll et al., 2003). Ca^{2+} overload, calpain activation, and increased caspase-3 activity occur in the rd model of photoreceptor degeneration (Doonan et al., 2005; Sharma and Rohrer, 2004). Ca^{2+} influx, membrane depolarization, and energetic collapse caused by a depletion of ATP and NAD^+ are frequently associated with neuronal cell death (Kristián and Siesjö, 1998; Nicholls and Ward, 2000). PARP overactivation and the resulting energetic collapse trigger apoptosis-inducing factor (AIF)-mediated photoreceptor cell death in rd mice (Paquet-Durand et al., 2007). Calpain does not directly cause chromatin condensation, but an activated form of AIF participates in DNA fragmentation and photoreceptor cell death (Sanges et al., 2006). DNA damage-induced PARP activation further dysregulates Ca^{2+}, resulting in calpain activation and AIF induction, which are followed by cell death (Vosler et al., 2009). In 60 mg/kg MNU-treated Sprague-Dawley rat retina, total retinal Ca^{2+} significantly increases 24 h after MNU treatment and continuously increases over 7 days, compared with MNU-untreated rat retina (Oka et al., 2007). The 280 kDa intact form of α-spectrin is ubiquitously localized in both the inner and outer retina, and calpain activity can be detected by the presence of calpain-induced

α-spectrin proteolysis products at 150 kDa (proteolyzed by caspase-3 and calpain) and 145 kDa (proteolyzed by calpain) (Shimazawa et al., 2010). In the retinas of BALB/c mice, calpain activity was increased 24 h after 60 mg/kg MNU treatment (Kuro et al., 2011). In the retinas of 60 mg/kg MNU-treated Sprague-Dawley rats, total retinal Ca^{2+} significantly increases and calpain activity dramatically increases at 1 and 3 days after MNU administration, respectively, and these levels decrease at day 7 (Oka et al., 2007). Cyclin-dependent kinase 5 (Cdk5) is a protein serine/threonine kinase requiring the regulatory subunit p35 for activity (Lew et al., 1994; Tsai et al., 1994). Conversion of p35 to p25 by calpain and prolonged activation of Cdk5/p25 may be a possible downstream mechanism for photoreceptor cell death (Oka et al., 2007). The calpain cascade is involved in retinal degeneration after MNU treatment, as well as in rd retina.

6.7 Reactive Oxygen Species Production

Oxidative stress contributes to the pathogenesis of neurodegenerative disorders, and reactive oxygen species (ROS) production in response to oxidative stress is implicated in photoreceptor cell death, including retinal DNA damage in rd mice (Sanz et al., 2007). When 100 μg/mL MNU is added to cultured murine 661W photoreceptor-derived cells or mouse RGC-5 ganglion cell line, MNU induces radical generation (as measured by intracellular ROS levels) in 661W cells, but not in RGC-5 cells. Oxidative stress is involved in photoreceptor cell death in MNU-induced retinal degeneration in rodents (Emoto et al., 2013, 2014; Tsuruma et al., 2012). MNU treatment increases the levels of the oxidative stress markers 8-hydroxy-2-deoxyguanosine (8-OGdG) and heme oxygenase-1 (HO-1) compared with untreated controls (Emoto et al., 2013, 2016b). Thus, MNU selectively elevates ROS in photoreceptor cells and induces photoreceptor cell death in vitro and in vivo.

6.8 Autophagic Cascade

Microtubule-associated protein light chain 3 (LC3), which is the mammalian homolog of yeast Atg8, is the best-characterized autophagic marker. LC3 has two forms, LC3-I (18 kDa), which is localized to the cytosol, and its proteolytic derivative, LC3-II (16 kDa), which is localized to the autophagosome membrane (Kabeya et al., 2000). LC3-II levels have been correlated to the number of autophagosomes and autophagic activity (Kabeya et al., 2000; Mizushima, 2004). In BALB/c mice treated with 60 mg/kg MNU, caspase-3 activity gradually increased, while LC3 activity gradually decreased during 72 h after MNU administration (Fig. 5.8). In contrast to the gradual increase in apoptosis, the gradual decrease in
FIGURE 5.8 *N*-methyl-*N*-nitrosourea (MNU, 75 mg/kg) accelerates apoptosis and suppresses autophagy in BALB/c mouse retina. Over the 72 h post-MNU treatment period: (A) Caspase-3 expression is gradually increased. (B) LC3 expression is gradually decreased. *Source: Reprinted with permission from Kuro, M., et al., 2011. In Vivo, 25(4), 625–631.*

basal autophagy was noteworthy in the course of MNU-induced retinal degeneration. In normal photoreceptor cells, besides the intermittent disk shedding from the outer segments, autophagy functions as a degradative pathway in photoreceptor cell metabolism. As shown in Fig. 5.5, autophagic vacuoles are mainly encountered in the myoid region of the inner segment of the photoreceptor cells with dense material (Remé et al., 1999). The loss of autophagosomes and autolysosomes in MNU-treated mouse retinas, as determined by electron microscopy, indicates the suppression of basal autophagy (Kuro et al., 2011). The role of autophagy in cell death is controversial. However, in quiescent cells, such as neurons, the suppression of basal autophagy causes neurodegeneration in mice (Hara et al., 2006); thus, autophagy in neuronal cells plays a cell-protective role. Therefore, both increased apoptosis and decreased autophagy may accelerate the MNU-induced photoreceptor cell death in mice.

Possible death signals caused by MNU are summarized in Fig. 5.9. MNU causes DNA adduct formation restricted to photoreceptor cell nuclei, followed by increased PARP activity that leads to the inactivation of NF-κB and activation of JNK/AP-1, causing downregulation of Bcl-2, upregulation of Bax, and the activation of caspase-3, -6, and -8. Also, calpain activity is increased by Ca^{2+} dysregulation, leading to the prolonged activation of Cdk5/p25. Together, these observations indicate that the generation of ROS is involved in photoreceptor cell apoptosis. MNU also suppresses basal autophagy, which may also contribute to the acceleration of photoreceptor apoptosis. These molecular events may partially explain

MNU-induced photoreceptor cell apoptosis. Fig. 5.9 also shows possible strategies for photoreceptor rescue with therapeutic agents.

7 THERAPEUTIC TRIALS AGAINST MNU-INDUCED PHOTORECEPTOR APOPTOSIS

7.1 PARP Inhibitors

Our laboratory performed therapeutic trials in an MNU-induced animal model for RP, and the results are summarized in Table 5.2. Seven- or 3-week-old animals received 40–60 mg/kg MNU. Nicotinamide (NAM), a water-soluble B group vitamin (vitamin B3/niacin), was SC injected at a dose of 1000, 25, 10, or 0 mg/kg immediately after 60 mg/kg MNU administration, and animals were sacrificed 7 days later. NAM significantly suppressed MNU-induced photoreceptor cell loss in a dose-dependent manner (Kiuchi et al., 2002), as evaluated by the photoreceptor cell ratio [(photoreceptor cell thickness/total retinal thickness) ×100] in HE-stained sections of the central retina (Yoshizawa et al., 2000). The photoreceptor cell ratio after treatment with 1000, 25, 10, and 0 mg/kg NAM was 33, 34, 22, and 6%, respectively. The percent inhibition of the photoreceptor cell ratio, which was determined as [(NAM-treated—NAM-untreated animals)/NAM-treated animals) × 100], was 82, 82, and 73% in the 1000, 25, and 10 mg/kg NAM-treated groups. Treatment with 1000 mg/kg NAM yielded no side effects. Functionally, scotopic and photopic ERGs
FIGURE 5.9 Possible molecular signaling events occurring in response to MNU-induced photoreceptor apoptosis and therapeutic intervention. *AA*, Arachidonic acid; *3-AB*, 3-aminobenzamide; *Ac-DEVD-CHO*, caspase-3 inhibitor; *CUR*, curcumin; *DHA*, docosahexaenoic acid; *EDRV*, edaravone; *GTE*, green tea extract; *MaFGF*, mutant of acidic fibroblast growth factor; *NAM*, nicotinamide; *NGN*, nargenin; *PLE*, persimmon leaf extract; *Reishi*, Ganoderma lucidum; *SNJ-1945*, calpain inhibitor; *VPA*, valproic acid; and *XIAP*, X-linked inhibitor of apoptosis.

showed that 1000 mg/kg NAM protected both rods and cones from MNU damage (Kiuchi et al., 2003). The suppression of photoreceptor cell loss by 1000 mg/kg NAM was confirmed structurally and functionally. Moreover, NAM at a dose of 1000 mg/kg significantly suppressed photoreceptor cell loss when administered up to 6 h after MNU; however, NAM administered 12 h after MNU was ineffective (Kiuchi et al., 2002). NAM did not reduce the levels of 7-medGua DNA adducts. Therefore, NAM did not prevent DNA damage; rather, the DNA damage appeared to be repaired. NAM, a precursor of NAD$^+$, may block the depletion of NAD$^+$ or inhibit PARP activation (Purnell and Whish, 1980). When 1000 mg/kg NAM was administered at the same time as MNU, PARP activation was diminished, and the level of downstream JNK/AP-1 expression was compatible to that in untreated animals (Uehara et al., 2006). Therefore, the mechanism by which NAM suppressed MNU-induced retinal damage involved PARP inhibition through the JNK/AP-1 signaling

pathway. These results indicate that PARP inhibition can block MNU-induced photoreceptor cell apoptosis. The beneficial effect of PARP inhibition against MNU injury was confirmed by using the PARP inhibitor 3-aminobenzamide (3-AB).

3-AB suppressed 60 mg/kg MNU-induced photoreceptor apoptosis (Miki et al., 2007). An SC injection of 50 or 30 mg/kg 3-AB, administered concurrently with MNU, significantly suppressed photoreceptor cell loss. The photoreceptor cell ratio after treatment with 50, 30, and 0 mg/kg 3-AB was 48, 38, and 18%, respectively. The percent inhibition of the photoreceptor cell ratio was 63 and 53% in the 50 and 30 mg/kg 3-AB-treated groups, respectively. Retinal damage can also be expressed as the retinal damage ratio [(length of damaged retina/whole retinal length) × 100] (Yoshizawa et al., 2000). Damage to the retina was defined as the presence of less than four rows of photoreceptor nuclei in the outer nuclear layer. The retinal damage ratio was 0, 11, and 70% in animals

TABLE 5.2 Percent Inhibition of Retinal Damage After Therapeutic Trials of Different Agents Against MNU Injury in Rats and Mice

| | Animal | MNU | Test chemicals | | | Photoreceptor cell ratio (%) | | Retinal damage ratio (%) | | |

Animals received intraperitoneal injection of MNU and were sacrificed 7 days later; photoreceptor cell ratio at the central retina is calculated as (photoreceptor cell thickness/total retinal thickness) × 100; percent inhibition of photoreceptor cell ratio is calculated as the photoreceptor cell ratio as [(reagent-treated–untreated animals)/reagent-treated animals × 100]. Retinal damage ratio is calculated as [(retinal length composed of less than four rows of photoreceptor cells/total retinal length) × 100]; Percent inhibition of retinal damage ratio is calculated as the retinal damage ratio in [(untreated–reagent-treated animals)/ untreated animals × 100]. *AA*, Arachidonic acid; *3-AB*, 3-aminobenzamide; *Ac-DEVD-CHO*, caspase-3 inhibitor; *BW*, body weight; *CUR*, curcumin; *DHA*, docosahexaenoic acid; *GTE*, green tea extract; *IP*, intraperitoneal; *IVT*, intravitreal; *NAM*, nicotinamide; *PO*, peroral; *SC*, subcutaneous; *SNJ-1945*, calpain inhibitor. All values (photoreceptor cell ratio and retinal damage ratio) were statistically significant between treated and untreated groups.

that received 50, 30, and 0 mg/kg 3-AB, respectively. MNU-induced retinal damage proceeds from the central retina to the peripheral retina, indicating that 3-AB suppressed and/or delayed the progression of photoreceptor cell damage. 3-AB treatment preserved NF-κB activity and resulted in photoreceptor cell survival (Miki et al., 2007). In contrast to NAM (Kiuchi et al., 2002), 3-AB administration 4 or 6 h after MNU did not rescue photoreceptor damage (Miki et al., 2007). NAM is a PARP inhibitor, a NAD^+ precursor, and a vasodilator (Huang and Chao, 1960). Thus, in addition to PARP inhibition, the two other mechanisms may also contribute to the retinal protection provided by NAM. PARP is activated in rd retinas, and the PARP inhibitor (N-(6-oxo-5,6-dihydrophenanthridin-2-yl)-N,N-dimethylacetamide × HCl) (PJ34) has a therapeutic effect in an ex vivo model with rd retinal explants (Paquet-Durand et al., 2007). Thus, PARP inhibition can be included in RP therapy.

7.2 Caspase Inhibitors

It is theoretically possible to suppress photoreceptor cell apoptosis by inhibiting the apoptosis cascade. The apoptosis cascade converges on a family of cysteine proteinases known as caspases. X-linked inhibitor of apoptosis (XIAP) inhibits caspases 3, 7, and 9 to confer resistance to apoptosis (Liston et al., 1996). Subretinal injection of recombinant adeno-associated virus encoding XIAP 6 weeks prior to 60 mg/kg MNU administration suppresses MNU-induced photoreceptor cell apoptosis structurally and functionally when examined 24, 48, and 72 h, and 7 days after MNU administration (Petrin et al., 2003). Overall, XIAP-treated eyes show histologic protection of the outer nuclear layer in 66% (4/6) of the rats at each time point. XIAP-treated eyes in 2 of 4 animals showing morphologic protection had a diminished but recordable ERG response. XIAP gene therapy is effective against photoreceptor cell apoptosis caused by genetic mutation, as well as by MNU stress. P23H and S344ter rhodopsin transgenic rats carry rhodopsin mutations that affect the protein folding and sorting of rhodopsin, respectively. In these transgenic rats, XIAP gene therapy provides long-term neuroprotection of photoreceptor cells structurally and functionally by inhibiting the action of caspase-3, -7, and -9 (Leonard et al., 2007).

IVT administration of Z-YVAD-FMK and Z-DEVD-FMK, caspase-1/4 and 3/7 inhibitors, respectively, as well as Z-VAD-FMK, a broad spectrum caspase inhibitor, transiently suppresses photoreceptor apoptosis and preserves photoreceptor function in RCS rats (Perche et al., 2008). Z-VAD-FMK and Z-DEVD-FMK protect, while Z-YVAD-FMK shows no protective effect, against light-induced retinal degeneration in rats (Perche et al., 2007). In rd/caspase-3 double-mutant mice, although rods eventually die in the absence of caspase-3,

the lack of caspase-3 does not abolish but reduces the number of apoptotic cells (Zeiss et al., 2004). Ac-DEVD-CHO, a caspase-3 inhibitor, was IP administered at a dose of 2 mg/kg to rd mice every other day from 8 days of age (Yoshizawa et al., 2002). Photoreceptor cells were significantly preserved in Ac-DEVD-CHO-treated mice at 13 days of age, but the effect was lost at 17 days of age. Thus, the caspase-3 inhibitor transiently delayed the progression of retinal degeneration in rd mice. In Sprague-Dawley rats, two IVT injections of 4000 ng Ac-DEVD-CHO dissolved in PBS were administered 0 and 10 h after the IP administration of 60 mg/kg MNU (Yoshizawa et al., 2000). Ac-DEVD-CHO suppressed MNU-induced photoreceptor cell apoptosis as evaluated by TUNEL labeling 24 h after MNU and ameliorated retinal damage 7 days after MNU administration. The TUNEL index 24 h post-MNU was 79.5% in the peripheral retina and 83.7% in the central retina, while Ac-DEVD-CHO significantly reduced the TUNEL index to 59.7 and 71.8%, respectively. Total retinal thickness and outer retinal thickness 7 days after MNU was 38 and 2 μm in the peripheral retina and 75 and 2 μm in the central retina, respectively, while Ac-DEVD-CHO treatment increased these values to 71 and 31 μm and 77 and 9 μm, respectively. The retinal damage ratio 7 days after MNU administration was significantly decreased from 99% to 54% by Ac-DEVD-CHO treatment. Caspase inhibitors are likely to be useful for the treatment of human RP. However, apoptotic retardation in the absence of caspase-3 implies the presence of caspase-independent mechanisms (Doonan et al., 2003).

7.3 Calcium Channel Blockers

Apoptotic photoreceptor cells in rd mice have increased levels of intracellular calcium (Doonan et al., 2005). In rd mice, the calcium channel blockers D-cis-diltiazem (Frasson et al., 1999) and nilvadipine (NVP; 5-isopropyl-3-methyl 2-cyano-1,4-dihydro-6-methyl-4-(3-nitrophenyl)-3,5-pyridinedicarboxylate) (Takano et al., 2004) are able to preserve photoreceptor cells from degeneration. NVP also delays apoptotic progression of photoreceptor cells in rds mice (Takeuchi et al., 2008). In 75 mg/kg MNU-treated Lewis rats, daily IP administration of 0.05 mg/kg NVP starting 7 days before MNU until 1 or 3 days after MNU provides no retinal protection at 1 and 3 days after MNU (Maruyama et al., 2001). The ineffectiveness of NVP in the MNU model may be explained by the use of a higher dose of MNU (75 mg/kg instead of 60 mg/kg), which might have caused excessive DNA damage in photoreceptor cells that was beyond the rescue capacity. Therefore, we repeated the experiment in Sprague-Dawley rats that received daily IP administration of 0.1 or 1.0 mg/kg NVP dissolved in a mixture of ethanol:polyethylene glycol 400:distilled water (2:1:7).

The NVP treatment was started 7 days before the administration of 60 mg/kg MNU and continued until 7 days after MNU administration. Again, retinal protection was not achieved (unpublished observation).

7.4 Calpain Inhibitors

Although the calpain inhibitor *N*-acetyl-leu-leu-norleucinal (ALLN) does not protect against photoreceptor degeneration in *rd* retinal explants (Doonan et al., 2005), the calpain inhibitors ALLN and *N*-acetyl-leu-leu-methioninal (ALLM) prevent the activation of AIF and reduce apoptosis in *rd* mice photoreceptor cells in vivo. The knockdown of AIF expression completely blocks apoptosis in *rd* photoreceptor cells in vitro (Sanges et al., 2006). In *RCS* rats, the calpain inhibitors ALLN and PD150606 effectively inhibit photoreceptor apoptosis (Mizukoshi et al., 2010), while Mu-Phe-hPhe-FMK (MuhPhe) does not reduce photoreceptor apoptosis (Perche et al., 2008). The calpain inhibitor ((1S)-1-[([(1S)-1-benzyl-3-cyclopropyl-amino-2,3-di-oxopropyl]amino)carbonyl]-3-methylbutyl) carbamic acid 5-methoxy-3-oxapentyl ester (SNJ-1945) has good penetration into the retina when perorally (PO) administered (Shirasaki et al., 2006) and has a low level of side effects (Oka et al., 2006). At a dose of 100 mg/kg IP or 200 mg/kg PO 30 min before and just after light exposure, SNJ-1945 significantly protects photoreceptor cell loss in ddY mice (Imai et al., 2010). In 60 mg/kg MNU-treated BALB/c mice, 80 mg/kg SNJ-1945 was administered IP 3 h prior to MNU and thereafter once daily for 7 days (Kuro et al., 2011). The photoreceptor cell loss was significantly prevented as compared with MNU-treated mice that did not receive SNJ-1945. The photoreceptor cell ratio at the central retina (20.0± 2.1 vs. 33.7± 4.6) and the retinal damage ratio (79.3± 6.4 vs. 34.5± 12.7) revealed that the photoreceptor cell preservation caused by SNJ-1945 was significant. In MNU-treated Sprague-Dawley rats, a retinal protective effect was observed with PO administration of 200 mg/kg SNJ-1945 within 30 min after MNU, and once daily for 7 days (Oka et al., 2007). Thus, both IP and PO administration of SNJ-1945 is effective, and SNJ-1945 ameliorates MNU-induced photoreceptor cell loss in rats and mice.

7.5 Polyunsaturated Fatty Acids

Although there are no established standard treatment modalities for RP, vitamin A and DHA supplementation slows the progression of retinal degeneration in RP patients (Shintani et al., 2009). Patients with RP had mean decreased values of red blood cell DHA concentrations, and serum levels were correlated with retinal levels. Decreased amounts of DHA and arachidonic acid (AA) in plasma phospholipids are observed in Usher syndrome (Bazan et al., 1986). Photoreceptor membranes are richly endowed with DHA (22:6n-3), an n-3 PUFA, and AA (20:4n-6), an n-6 PUFA, indicating that these fatty acids play an integral role in photoreceptor cells. *rd* mice have lower levels of DHA in the retina and in photoreceptor cells (Scott et al., 1988). Seven-week-old Sprague-Dawley rats were fed an AIN-76A (basal) diet or a DHA diet, in which 5% corn oil and 5% corn starch from the AIN-76A diet were replaced by 9.5% DHA and 0.5% linoleic acid (LA), for 2 weeks. Then, the rats received 60 mg/kg MNU and continued to receive the same diet or were switched to the opposite diet for 3 or 7 days until they were sacrificed (Moriguchi et al., 2004). Three days after MNU administration, the progression of photoreceptor damage was delayed in parallel with serum DHA levels. Seven days after MNU administration, although the damage was not delayed in parallel with serum DHA levels, the retinal damage ratio was significantly lower in rats fed DHA at some point compared to rats fed the basal diet throughout the experimental period. The retinal damage ratio was 38% in rats who received the DHA diet for 14 days before MNU administration, 46% in rats who received the DHA diet 7 days after MNU administration, and 47% in rats who received the DHA diet 14 days before and 7 days after MNU administration; in contrast, the retinal damage ratio was 88% in rats who received the basal AIN-76A diet (without DHA) throughout the experimental period. Thus, the DHA diet likely delayed the onset and suppressed the progression of photoreceptor cell apoptosis. DHA interferes with pro- and antiapoptotic proteins of the Bcl-2 family and protects photoreceptor cells from apoptosis (Rotstein et al., 2003).

Seven-week-old Sprague-Dawley rats were given MNU at a dose of 50 mg/kg, which is lower than the dose needed to cause photoreceptor cell loss within 7 days in all treated animals. Thereafter, the rats received one of five diets containing the following fatty acids: 10% LA (LA diet); 9.5% palmitic acid (PA) and 0.5% LA (PA diet); 9.5% eicosapentaenoic acid (EPA) and 0.5% LA (EPA diet); 4.75% EPA, 4.75% DHA, and 0.5% LA (DHA plus EPA diet); or 9.5% DHA and 0.5% LA (DHA diet) (Moriguchi et al., 2003). The rats were observed for 20 weeks after MNU administration. The degree of retinal lesions varied significantly among the five diet groups. The incidence of retinal damage [(number of rats with retinal degeneration/total number of rats) ×100] and the retinal damage ratio for each diet was: LA diet, 88 and 61%; PA diet, 41 and 18%; EPA diet, 73 and 40%; EPA plus DHA diet, 53 and 24%; and DHA diet, 0 and 0%, respectively. Thus, the DHA diet completely suppressed retinal damage, while the EPA diet, which is rich in another n-3 PUFA, did not suppress retinal damage. The DHA plus EPA diet had a weaker retinal protective effect, whereas the lesions were accelerated in rats fed the LA diet. DHA is significantly enriched in the retinas

of diurnal Sudanian grass rats as compared to the retinas of Brown-Norway rats, resulting in a relative resistance to MNU-induced damage (Boudard et al., 2011). Thus, the role of DHA in the adult retina seems to be important. In contrast to the beneficial effects of dietary DHA, conjugated DHA, a mixture of positional and geometric isomers of DHA, did not evoke beneficial effects against MNU-induced photoreceptor damage (unpublished observation). In cultured retinal neurons, DHA supplementation decreased photoreceptor cell death, whereas PA, oleic acid, or AA was unable to decrease photoreceptor cell death (Politi et al., 2001; Rotstein et al., 1996).

DHA and AA are highly concentrated in the phospholipid bilayer of biologically active brain and retinal neural membranes, and supplementation of DHA and AA may protect infants from visual problems (Brémond-Gignac et al., 2011). Lower levels of AA have been found in the retinas of *rd* mice (Cagianut et al., 1985). When *rd* mice were fed diets containing various doses of AA (control diet, 0.008% AA; low-dose AA diet, 0.13% AA; medium-dose AA diet, 0.50% AA; and high-dose AA diet, 2.01% AA) through the last 2/3 of pregnancy and the lactation period, the retinal degeneration of the pups sacrificed at 12 or 18 days of age was not affected (unpublished observation). Sprague-Dawley rats were fed diets containing various doses of AA (same diets as listed earlier) beginning 2 weeks prior to mating and continuing through gestation (3 weeks) and the lactation period (3 weeks). Then, the 3-week-old male pups were given 50 mg/kg MNU IP, fed the same diet their mothers had received for 1 week, and subsequently sacrificed (Yoshizawa et al., 2013). AA dose-dependently ameliorated retinal injury, as shown by the photoreceptor cell ratios and retinal damage ratios in each group: control diet, $19.4 \pm 11.9\%$ and $39.5 \pm 14.4\%$; low-dose AA diet, $32.0 \pm 16.2\%$ and $21.2 \pm 17.4\%$; medium-dose AA diet, $46.7 \pm 2.8\%$ and $2.7 \pm 3.7\%$; and high-dose AA diet, $43.6 \pm 8.8\%$ and $6.1 \pm 6.7\%$, respectively. The medium- and high-dose AA groups showed significant retinal improvement compared to the control diet group. Thus, AA supplementation ($\geq 0.5\%$ in the diet) during the prenatal, perinatal, and neonatal period is effective in suppressing MNU-induced retinal degeneration. Toward optimizing human vision, it has been recommended that infants receive at least 0.3% fatty acids from DHA with at least 0.3% AA (Hoffman et al., 2009). However, these AA diets given to 10-week-old male Sprague-Dawley rats for 6 weeks did not improve retinal damage caused by 60 mg/kg MNU administered at 15 weeks of age to animals that were sacrificed at 16 weeks of age. Thus, the role of AA in the infant retina (but not the adult retina) seems to be important.

Valproic acid (VPA), a short-chain fatty acid that is a heat shock protein (HSP) 70 inducer, suppresses MNU-induced photoreceptor cell death through inhibition of apoptotic caspase signals; HSP70 may also modulate photoreceptor apoptosis through the calpain pathway (Koriyama et al., 2014).

7.6 Health Supplements

Resveratrol (3,5,4'-trihydroxystilbene), a polyphenolic phytoalexin, is a naturally occurring product found in grape skin and red wine that has various bioactivities including anticarcinogenic effects (Nakagawa et al., 2001). Light-induced photoreceptor cell damage in BALB/c mice is significantly reduced both structurally and functionally by prior treatment with resveratrol at a dose of 50 mg/kg daily for 5 days by gastric intubation (Kubota et al., 2010). The retinal protective effect of resveratrol is via inhibition of retinal AP-1 activity as measured by c-Fos levels. However, seven daily doses of 50 mg/kg resveratrol dissolved in 0.3% carboxymethyl cellulose solution (administered PO from 3 days prior to 3 days after MNU administration) could not rescue retinal damage caused by 60 mg/kg MNU in Sprague-Dawley rats that were sacrificed and examined 7 days after MNU administration (unpublished observation).

Anthocyanins are plant pigments that are widely distributed in berries, dark grapes, cabbages, and other pigmented foods, plants, and vegetables. They belong to the widespread class of phenolic compounds collectively named flavonoids. Although the mechanisms of action have not been described, when anthocyanins extracted from black soybean seed coat (50 mg/kg/day) were PO administered daily for 4 weeks (but not 1 or 2 weeks) to 50 mg/kg MNU-treated 10-week-old male Sprague-Dawley rats, retinal damage was reduced, as determined by ERG responses and retinal morphology (Paik et al., 2012).

Ganoderma lucidum, known as Reishi or Lingzhi, is a medical mushroom used for more than 4000 years in China to promote health and longevity. Sprague-Dawley rats received ganoderma spore lipid (GSL) at a dose of 0, 0.5, 1, 2, and 4 g/kg each day for 3 days via the intragastric route; then, the rats received an IP injection of 40 mg/kg MNU and were sacrificed 1, 3, 7, or 10 days later (Gao et al., 2010). GSL at a dose of 2 g/kg inhibited the decrease of a- and b-wave amplitudes and suppressed photoreceptor cell apoptosis through Bax, Bcl-xl, and caspase-3 regulation. A daily 2 g/kg dose of GSL or 2 g/kg dose of fish oil (containing 70% n-3 PUFAs, of which DHA accounted for 54% and EPA for 7%) exerted a similar potency in suppressing MNU-induced retinal damage (Gao et al., 2011).

7.7 Neurotrophic Factors

Neurotrophic factors protect neurons and initiate their growth. These factors are neuroprotective in a

range of diseases including retinal disease (Thanos and Emerich, 2005). IVT injection of 500 ng of basic fibroblast growth factor (bFGF, FGF-2) in 1 μL PBS at 23 days of age when photoreceptor cell degeneration starts in *RCS* rats results in photoreceptor cell rescue 2 months after the injection (Faktorovich et al., 1990). IVT injection of 1150 ng of bFGF in 1 μL of PBS to F344 rats 2 h prior to constant light exposure reduces the progression of photoreceptor degeneration (Faktorovich et al., 1992). IVT injection of 1 μg of bFGF in 1 μL of PBS into BALB/c mice 3 h prior to light damage affords photoreceptor protection from light-induced damage (O'Driscoll et al., 2008). Acidic FGF (aFGF, FGF-1) ameliorates ischemic injury of the rat retina (Cuevas et al., 1998), but the use of aFGF requires caution because of its mitogenic activity (Galzie et al., 1997). In this context, mutant aFGF (MaFGF), which is a nonmitogenic form of human aFGF, has been developed and applied to the MNU model (Wu et al., 2005) by IVT injections at 0 and 12 h after MNU administration (Xu et al., 2008). In 60 mg/kg MNU-treated Sprague-Dawley rats, IVT administration of MaFGF at a dose of 1.25 and 2.5 μg protects MNU-induced retinal damage in rats 7 days after MNU through upregulating Bcl-2 and downregulating Bax. The apoptotic index 24 h post-MNU was 38.1 ± 3.6% in the peripheral retina, while it was 27.5 ± 2.5% and 21.1 ± 1.9% after MaFGF treatment at a dose of 1.25 and 2.5 μg, respectively. Total retinal thickness and outer retinal thickness 7 days after MNU in the peripheral retina were 37 ± 2 and 3 ±1 μm, while 1.25 and 2.5 μg MaFGF increased these values to 44 ± 2 and 15 ± 2 μm, and 55 ± 3 and 22 ± 2 μm, respectively. The central retina was beyond the rescue capacity of MaFGF treatment. The apoptotic index 24 h post-MNU was 38.1 ± 3.6% in the peripheral retina, while it was 27.5 ± 2.5% and 21.1 ± 1.9% after MaFGF treatment at a dose of 1.25 and 2.5 μg, respectively.

7.8 Antioxidants

Edaravone (EDRV) is a potent antioxidant and free-radical scavenger. At a dose of 1 μM, EDRV reduces MNU-induced free-radical production in cultured murine 661W photoreceptor-derived cells (Tsuruma et al., 2012). After adult ddY mice were treated by IP injection of 60 mg/kg MNU, EDRV at a dose of 0, 0.3, or 1.0 mg/kg was IV injected immediately and 6 h after MNU treatment. Seven days after MNU treatment, the vertical length of the outer nuclear layer relative to the inner nuclear layer was compared, and EDRV at 1.0 mg/kg (but not 0.3 mg/kg) significantly suppressed the reduction in the outer nuclear thickness compared to mice not treated with EDRV. EDRV inhibits MNU-induced photoreceptor cell death by its ROS-scavenging activity. Many phytochemicals possess antioxidant activity and may be useful in suppressing retinal damage caused by MNU.

Prevention of MNU-induced retinal damage was observed following oral administration of persimmon leaf extract (PLE) in mice (Kim et al., 2015), and topical treatment (eye drops) with naringenin (NGN, found in citrus and grape fruit) in rats (Lin et al., 2014), both of which have antioxidant activity. Curcumin (CUR), a yellow pigment of turmeric and a constituent of curry powder, and green tea extract (GTE), which mainly contains the potent antioxidant epigallocatechin gallate (EGCG), were effective in suppressing MNU-induced retinal damage (Emoto et al., 2013, 2014). Seven-week-old rats were given daily IP injection of 200 mg/kg CUR or PO administration of 250 mg/kg GTE for 10 days, starting 3 days prior to 40 mg/kg MNU, and retinas were examined 7 days after MNU. CUR and GTE treatment suppressed MNU-induced photoreceptor apoptosis with no side effects. Significant increases in oxidative stress markers, such as nitrotyrosine and S-nitro-cysteine, occur in photoreceptor cells after mice are treated with MNU (Chen et al., 2014). CUR and GTE treatment lowered the levels of the oxidative stress marker 8-OHdG and HO-1 following MNU administration in rats (Emoto et al., 2013, 2016b). In an effort to identify potential synergistic interactions between CUR and GTE, 7-week-old rats were treated with daily IP injection of either 100 mg/kg CUR and PO administration of 125 mg/kg GTE (low dose antioxidant), or 200 mg/kg CUR and 250 mg/kg GTE (high dose antioxidant) for 10 days starting 3 days prior to 40 mg/kg MNU, and retinas were examined 7 days after MNU (unpublished observation). However, no synergistic effects were observed. In high-dose, low-dose, antioxidant-free MNU-treated rats, and untreated control rats, photoreceptor ratios were 13.2, 11.4, 11.3, and 44.5%, and retinal damage ratios were 67.5, 72.0, 71.2, and 0%, respectively. Potential synergic interactions between CUR and DHA were examined in 7-week-old rats by IP injection of 200 mg/kg CUR and PO administration of 2 mL DHA for 10 days starting 3 days prior to 40 mg/kg MNU. Retinas were examined 7 days after MNU (unpublished observation) treatment, and no synergistic effects were evident.

7.9 Autophagy Preservation

Rapamycin is a negative regulator of mammalian target of rapamycin and has been used to induce autophagy. BALB/c mice received IP injections of 10 mg/kg rapamycin during the 10-day light damage period (Kunchithapautham et al., 2011), which significantly improved photoreceptor rod survival and function and reduced apoptosis. As decreased basal autophagy in photoreceptor cells occurs along with apoptosis after MNU treatment, rapamycin was utilized in the MNU model. Daily doses of 2 mg/kg rapamycin (dissolved in 0.4% ethanol and 1.6% cremophore EL) were IP injected into

7-week-old BALB/c mice for 7 days before and 7 days after 60 mg/kg MNU administration. Seven days after MNU treatment, mice were sacrificed and examined, and photoreceptor cell survival was not promoted by this protocol (unpublished observation). In cones, autophagy suppression might be necessary for cone-cell survival because reduced cone-cell function secondary to rod-cell loss is due to autophagic cell death through stimulation of the insulin/mammalian target of rapamycin pathway (Punzo et al., 2009).

7.10 Cell Transplantation

In addition to the pharmacological approaches described earlier, degenerative photoreceptors can be repaired and retinal function rescued if the damaged photoreceptors can be replaced with healthy cells that make appropriate synaptic connections with the remaining functional circuitry within the retina. Photoreceptor cells and stem/progenitor cells can be used for cell transplantation. Photoreceptor cell loss caused by MNU can be repaired by cell transplantation. Synapses between transplanted neurons and host retina are formed, and partial functional recovery is achieved when dissociated photoreceptors are transplanted concomitantly with chondroitinase ABC, a bacterial enzyme that degrades the chondroitin sulfate proteoglycan side chain, 1 day after MNU treatment in adult C57BL mice (Suzuki et al., 2007). Chondroitinase ABC, which degrades chondroitin sulfate proteoglycans in the extracellular matrix, may help eliminate the barrier between photoreceptor transplants and host retina and may increase the neurite-extending activity. Some of the progeny of the Müller glia in adult rat retina undergo gliosis and proliferate in response to photoreceptor cell loss caused by MNU, and they express a rod-specific marker and synaptic proteins (Wan et al., 2008). Cultured Müller cells that are transplanted show a regenerative capacity by migrating into the MNU-induced damaged retina and expressing a rod-specific marker. Müller cells have progenitor/stem-cell properties and can be used for cell replacement therapy.

8 CONCLUDING REMARKS

A single systemic administration of MNU induces photoreceptor cell loss in various mammalian species, from insectivora to primates, and fish (zebrafish). Disease progression is rapid in that the active signs of photoreceptor cell apoptosis end by day 7. MNU causes DNA adduct formation in photoreceptor nuclei, followed by increased PARP activity that leads to the activation of JNK/AP-l and inactivation of NF-κB, causing the downregulation of Bcl-2, upregulation of Bax, and the activation of caspase-3, -6, and -8. In addition, increased intracellular Ca^{2+} levels activate calpain, leading to prolonged activation of Cdk5/p25. Furthermore, MNU leads to ROS production in response to oxidative stress. Collectively, these molecular events appear to cause photoreceptor cell apoptosis. In parallel to a gradual increase in photoreceptor cell apoptosis, there is a gradual decrease in basal autophagy essential for cell survival. Many novel approaches have been applied to control MNU-induced photoreceptor cell death (Fig. 5.9). MNU-induced photoreceptor apoptosis can be suppressed by the following agents: PARP inhibitors, such as NAM and 3-AB; DHA, AA, VPA, Reishi, and MaFGF, which may interfere with pro- and antiapoptotic molecules; caspase inhibitors XIAP and Ac-DEVD-CHO; calpain inhibitor SNJ-1945; and free-radical scavenger and antioxidants EDRV, CUR, GTE, NGN, and PLE. In addition to pharmacological manipulation, cell transplantation may possibly rescue MNU-induced retinal damage. MNU-induced photoreceptor cell death is a valuable animal model for human RP. Although the potency of agents that suppress MNU-induced photoreceptor cell death in animals does not guarantee that these agents will be effective in humans, it may be worthwhile to extrapolate these results to RP patients. Special techniques useful for the establishment and evaluation of MNU-induced retinal damage are described later in the chapter.

9 APPENDIX: SPECIAL TECHNIQUES

9.1 MNU Preparation and Administration

MNU (Fig. 5.10) is a direct-acting alkylating agent that does not require metabolic activation to be effective and is known to methylate DNA. MNU is sensitive to humidity and light, and storage at temperatures below −10°C is recommended. The purity of MNU obtained from the manufacturer can differ between lots. Therefore, the equivalent purity must be considered in every occasion. MNU must be stored at −20°C in the dark, and since MNU stability depends on the pH of the medium, it is dissolved in physiological saline containing 0.05% or 0.1% acetic acid immediately before use. This solution should be kept on ice and shielded from light. A 23-G needle is used for administration to rodents. The dose of MNU (per kg of body weight of animals) needed to cause complete loss of photoreceptors in 7 days depends on the animal species (Table 5.1). The half-life of MNU
FIGURE 5.10   Chemical structure of MNU.

under physiological conditions is <1 h (Weisberger and Williams, 1975), and the half-life in plasma is only 5–15 min (Smith and Yielding, 1986). Therefore, the injection solution must be freshly prepared every 15 min.

9.2 Eyeball Fixation and Processing for Light Microscopy

Immediately after sacrifice, eyes are removed, and a hole is made in the corneal edge through the anterior chamber with a 27-G needle to facilitate entry of fixative to the retina. For light microscopic examination, one eye is fixed overnight in neutral-buffered formalin, and the other eye is fixed overnight in methacarn (60% methanol, 30% chloroform, and 10% acetic acid). The fixed tissues are then embedded in paraffin and cut into sections. The sections are cut at the center of the retina, parallel to the optic axis and optic nerve. The sections are stained with hematoxylin and eosin (HE) or other special stains or are used for immunohistochemistry. Formalin-fixed but not methacarn-fixed eye specimens easily develop separation of the outer layers of the retina from the underlying retinal pigment epithelium, whereas formalin fixation can only be suitable for certain staining. Therefore, both fixatives must be used properly according to their purpose.

9.3 Electron Microscopy

After eyeballs are fixed for 1.5 h in 0.5% Karnovsky fixative, the cornea and lens of each eye are removed for better penetration of the fixative. Then, the eyes are post-fixed in 2% OsO_4 and embedded in Luveak-812. Semi-thin sections (thickness, 1 μm) stained with toluidine blue are used to locate areas to be examined by electron microscopy. Thin sections stained with uranyl acetate and lead citrate are examined by transmission electron microscopy.

9.4 Immunohistochemistry

Antibodies useful in retinal immunohistochemistry, along with their clone name and source, suitable fixative, the necessity of preincubation, and the expression site of their target protein, are listed in Table 5.3. Anti-7-methyldeoxyguanosine (7-medGua) detects the DNA adducts produced by MNU (Yoshizawa et al., 1999), and antipoly(ADP-ribose) (PAR) labels activated PARP in cells damaged by MNU (Uehara et al., 2006). Antiphosphodiesterase (PDE) 6β and antirhodopsin label photoreceptor outer segments (Emoto et al., 2014). Antivimentin and antiglial fibrillary acidic protein (GFAP) can be used to stain proliferating Müller cell processes, and antiproliferating cell nuclear antigen (PCNA)

TABLE 5.3 Antibodies Used to Detect Retinal Pathology Caused by MNU in Animals

Antibody	Clone	Source	Fixative	Preincubation	Expression site	References
7-methyldeoxyguanosine	Polyclonal	Gift from PC Wild, Univ. of Leeds, UK	Amex[a]	Yes[b]	Disrupted photoreceptor nuclei	Yoshizawa et al. (1999)
Poly(ADP-ribose)	10H	Trivingen, Gaithersberg, MD, USA	Methacarn	No	Disrupted photoreceptor nuclei	Uehara et al. (2006)
Phosphodiesterase 6β	Polyclonal	Abcam, Cambridge, UK	Formalin	Yes[c]	Photoreceptor outer segments	Emoto et al. (2014)
Rhodopsin	RET-P1	Millipore, Temecula, CA, USA	Formalin	Yes[c]	Photoreceptor outer segments	Emoto et al. (2014)
Vimentin	V9	Dako, Glostrup, Denmark	Methacarn	No	Proliferating Müller cells	Nakajima et al. (1996b)

Proliferating cell nuclear antigen	PC10	Novocastra, Newcastle upon Tyne, UK	Methacarn	No	Proliferating Müller cells	Nakajima et al. (1996b)
Rat macrophage and monocyte	ED1	Serotec, Oxford, UK	Formalin	Yes[d]	Infiltrating macrophage	Nakajima et al. (1996b)
Rat macrophage	ED2	Serotec	Formalin	Yes[d]	Resident macrophage	Nakajima et al. (1996b)

[a] Amex, Acetone methylbenzoate xylene (Sato et al., 1986).
[b] 0.05N sodium hydroxide in 40% ethanol for 5 min, 5% acetic acid in 40% ethanol for 15 s, and 1% nonfat milk in PBS-saline for 1 h.
[c] Heat treatment in 0.01M citrate buffer pH 6.0 in 115°C for 10 min.
[d] 0.1% trypsin for 15 min.

can be used to stain proliferating Müller cell nuclei (Nakajima et al., 1996b). Anti-ED-1 stains macrophages that have infiltrated the retina, while anti-ED2 stains resident macrophages (Nakajima et al., 1996b). Immunohistochemistry can be performed by using a labeled streptavidin biotin (LSAB) staining kit (Dako, Carpinteria, CA, USA), 3,3'-diaminobenzidine (DAB, Wako Pure Chemical, Osaka, Japan) for antigen visualization, and hematoxylin for counterstaining. Also, cross-reactivity data for each antibody is needed before utilization with animal tissues.

9.5 In Situ Apoptotic Cell Detection

Apoptotic cells can be identified by using the TUNEL assay and by performing formamide-induced DNA denaturation and staining with a monoclonal antibody (MoAb) against single-stranded DNA (formamide-MoAb). TUNEL detects the DNA fragmentation caused by apoptotic signaling cascades. The assay relies on the presence of nicks in the DNA that can be identified by terminal deoxynucleotidyl transferase, an enzyme that will catalyze the addition of dUTPs that are secondarily labeled with a marker. Formalin-fixed, paraffin-embedded specimens can be utilized in the TUNEL assay by using a commercially available apoptosis detection kit (ApopTag, Millipore, Billerica, MA, USA) according to the manufacturer's instructions (Nakajima et al., 1996b). The formamide-MoAb technique can be performed by using the protocol of Frankfurt and Krishan (2001). Briefly, formalin-fixed, paraffin-embedded retinas are sectioned, and the sections are deparaffinized. Each section is incubated with PBS containing 0.1 mg/kg saponin and 20 µg/mL proteinase K for 20 min, rinsed in PBS, rinsed in distilled water, and heated in 50% formamide (diluted with distilled water) at 56–60°C for 20 min. After heating, sections are transferred into ice-cold PBS, in which they are incubated with mouse monoclonal anti-single-stranded DNA antibody (clone F7-26, Chemicon, Temecula, CA, USA) diluted ×10 with Tris-buffered saline-containing Tween 20 (TBST: 0.05 M Tris-HCl (pH 7.6) buffer containing 0.1% Tween 20). The sections are then stained by using an LSAB staining kit. In both methods, DAB is used as the chromogen, and hematoxylin is used as the counterstain (Miki et al., 2007).

9.6 Internucleosomal DNA Fragmentation Assay

Eyes are excised from the sacrificed animals. The corneas and lenses are removed, and the retinal DNA is isolated by the digestion of cells with proteinase K at a concentration of 0.2 µm/µL in tissue lysis buffer solution [50 mM Tris-HCl (pH 8.0), 10 mM EDTA (pH 8.0), 0.5% SDS] at 50°C for 2 h. RNase A, at a concentration of 0.2 µg/µL, was then added to the lysate and incubated for 1 h, followed by extraction with phenol/chloroform. Ten µg of DNA are analyzed by electrophoresis in 1.5% (w/v) agarose gel and visualized under UV light after staining with ethidium bromide (Uehara et al., 2006).

9.7 Western Blot Analysis

For western blot analysis, a protein extract is prepared by homogenizing the retinas in lysis buffer solution [50 mM Tris-HCl (pH 8.0), 125 mM NaCl, 1 mM sodium fluoride, 1 mM sodium orthovanadate, 10 mM sodium pyrophosphate, and 1 mM PMSF] containing the protease inhibitors leupeptin, pepstatin, and aprotinin, each at a final concentration of 1 µg/mL. The homogenates are sonicated and then centrifuged at $110 \times g$, and the resulting pellets are discarded. Protein concentrations are measured by using the DC protein assay method (BioRad, Hercules, CA, USA). Aliquots of lysates equivalent to 80 µg of protein are electrophoresed through polyacrylamide gels and transferred to Hybond-P PVDF membranes (Amersham Biosciences, Buckinghamshire, UK). The membranes are blocked with 5% nonfat powdered milk and then incubated with the primary specific antibody. Then, the blots are washed and incubated with the appropriate secondary antibody. Antiactin antibody can be used as the loading control (Uehara et al., 2006).

9.8 Morphometric Analysis

Methacarn-fixed, paraffin-embedded, and HE-stained sections obtained from the central part of the eyeball, which is parallel to the optic axis and nerve, including the ora serrata and optic nerve, should be used for morphometric evaluation. Total retinal thickness (from the internal limiting membrane to the pigment epithelium) and outer retinal thickness (from the outer nuclear layer to the pigment epithelial layer) are measured by using NDP.view (Yoshizawa et al., 2009). The measurements are collected at the central retina (approximately 400 µm from the optic nerve) and the peripheral retina (approximately 400 µm from both sides of the ciliary bodies) (Fig. 5.11). The photoreceptor cell ratio is calculated as [(outer retinal thickness/total retinal thickness) × 100]. To determine the area of retinal damage, the entire length of the retina and the length of the damaged area (dotted space located in the central retina around the optic disk in rodents) in HE preparations are measured. A damaged retina is designated as the presence of less than four rows of photoreceptor nuclei in the outer nuclear layer, and the retinal damage ratio is calculated as [(length of damaged retina/whole retinal length) × 100] (Yoshizawa et al., 2000).
FIGURE 5.11 Morphometric analysis of photoreceptor cell ratio and retinal damage ratio. (A) The photoreceptor cell ratio is calculated as [(outer retinal thickness/(total retinal thickness) $\times$ 100]. *O*, Outer retinal thickness; *T*, total retinal thickness. (B) To determine the retinal damage ratio, the entire length of the retina and the length of the damaged area are measured. The damaged retina is designated as the presence of less than four rows of photoreceptor nuclei in the outer nuclear layer, and the retinal damage ratio is calculated as [(length of damaged retina/whole retinal length) $\times$ 100]. The *dotted* region in the scheme indicates the injured area at the central retina around the optic nerve, leaving the peripheral retina intact.

9.9 Electroretinogram Recording

ERG recording in rats is performed as follows (Kiuchi et al., 2003). First, the animals are dark-adapted for 12 h and prepared under dim red light. Next, the rats are anesthetized with an intramuscular injection of ketamine and xylazine. Then, pupils are dilated with topical tropicamide and phenylephrine HCl, and the rats are then placed on a heating pad. ERGs are recorded with a gold wire loop on the cornea by using tetracaine topical anesthesia and a drop of methylcellulose. A gold wire electrode is placed on the sclera 1 mm from the temporal limbus. The ground electrode is placed on the ear. Signals are band-pass amplified (range, 1–1000 Hz) by using a computer-assessed signal averaging system (Power Lab, AD Instruments, Castle Hill, Australia). Scotopic ERG responses are averaged with a stimulus interval of 3–60 s (depending on intensity), and 20–30 photopic responses are averaged with a stimulus interval of 1 s. Strobe flash stimuli are presented in a Ganzfeld bowl (Model GS2000, LACE Electronica sel via Marmiccilo, Pisa, Italy). The maximum luminance of the stimulus is 1.0 log cd-s/m^2 (photopic unit), and neutral density filters are used to reduce the stimulus intensity. Six stimulus levels, at equal log intervals, ranging from -6.2 to 1.0 log cd-s/m^2, are used for the scotopic ERG recording. Four stimulus levels, at equal intervals, ranging from -0.8 to 1.0 log cd-s/m^2, are used for the photopic ERG recording on a rod-desensitizing white adapting background of 1.3 log cd-s/m^2.

1 INTRODUCTION

Cardiovascular diseases are the leading cause of mortality and morbidity in the United States. Although the incidence has been declining over the past decades, the mechanisms of diseases are still incompletely understood and developments of new therapeutic approaches are required. Both of these critical activities rely heavily on basic and preclinical research in which highly relevant animal models are required for accurate translational research from novel discovery at the bench to treatment at the bedside. Currently, more than 90% of all laboratory animals are mice and rats. Obviously, there are several advantages of using rodent species. First, it is easy to maintain and also costs less compared to larger animal species. Second, mice and rats reproduce quickly and have a short lifespan. Most importantly, rodent, particularly mice, are easily amenable to genetic manipulation, either through conventional gene knockout, knock-in, transgenic expression, and/or inducible systems where genes expression can be altered at specific times. Because of this, the vast majority molecular and genomic mechanistic insight into cardiovascular development and diseases has come from genetically-engineered

mouse models. However, it has been recently noticed that many potential exciting therapeutic interventions have ultimately failed in clinical trials; thus, exposing a significant gap between preclinical research data and clinical trial results (Arrowsmith, 2011; Mullard, 2011; Prinz et al., 2011). Additionally, irreproducibility between different laboratories has increased significantly (Arrowsmith, 2011; Mullard, 2011; Prinz et al., 2011). Besides the major species difference between rodent and human as one of the answers, multiple physiological measurements from different directions are difficult to be performed and also less reproducible in the rodent species, which also contribute to the inconsistency between laboratories, as well as between these small animals and humans. Anesthesia and recent surgical trauma is another important factor to influence laboratory results. Accordingly, a suitable larger animal model, such as dogs and pigs, under conscious state with appropriate direct measurements of cardiovascular function is needed to complement early rodent studies and to serve as a better translational research tool. It should be further pointed out that contradictory results in drug discovery, as well as cardiovascular control can even be found between nonhuman primates and other larger mammals (Shen, 2010). To conduct experiments in nonhuman primates, it requires special resources, techniques, expertise, and consideration of welfare concerns; hence, medical research using nonhuman primates currently only represents <0.3% of the laboratory animals used. Nevertheless, nonhuman primates still to be considered as important translatable model, as it has unique advantage of significant physiological, metabolic, biochemical, and genetic similarity with humans (Shen, 2010; Shen et al., 2008a). Current chapter is focused on, but not exclusive to, surgically manipulated larger animal models including nonhuman primates. Equally important, several factors that influence model characteristics, as well as considerations for accurate preclinical cardiovascular measurements and correct data interpretation are also discussed. Genetically engineered and chemically or diet-induced animal models are beyond the scope of this chapter.

2 MYOCARDIAL ISCHEMIC MODELS

2.1 Brief Coronary Artery Occlusion-Induced Myocardial Stunning

Coronary artery spasm, myocardial revascularization, and coronary artery bypass grafting often produce a consequence of a brief myocardial ischemia with a reversible, but prolonged, regional myocardial dysfunction for hours to days in patients. This clinical phenomenon has been termed as "myocardial stunning." The first post-

ischemia induced myocardial dysfunction in conscious dog model was described by Heyndrickx et al. (1975). During the past three decades, myocardial stunning was extensively studied in different animal species, primarily dogs, pigs, rabbits, and nonhuman primates (Bolli and Marban, 1999; Shen and Vatner, 1996). Brief coronary artery occlusion and reperfusion can be achieved by transiently inflating and deflating a surgically-implanted hydraulic occluder around either the left circumflex or left anterior descending coronary artery. The duration of coronary artery occlusion should not be more than 15 min to avoid irreversible myocardial injury. The regional myocardial dysfunction is closely correlated with the duration of coronary artery occlusion. Thus, the confirmation of complete coronary artery occlusion and reperfusion is critical for a reproducible consistent pattern of myocardial dysfunction within and among experiments when same ischemic protocol is utilized. Ideally, a coronary blood flow probe proximal to the occluder needs to be implanted for continuously monitoring of coronary blood flow during the entire experiment. The regional myocardial function in both potential ischemic zone and contralateral nonischemic zone, which is the end point for myocardial stunning, can be measured directly using a transit time dimension gauge technique (Shen and Vatner, 1996; Shen et al., 2008a). Concomitant continuous measurements of both coronary blood flow and regional myocardial function are essential for the study of myocardial stunning. Other physiological measurements should be also considered which include arterial pressure, heart rate, as well as left ventricular (LV) pressure, and its first derivative (dP/dt). These parameters along with regional myocardial function and coronary blood flow provide a comprehensive profile for assessment of myocardial stunning. Fig. 6.1 illustrates the changes in continuous waveforms of LV pressure, LV dP/dt, wall thickness of posterior and anterior left ventricular walls, coronary blood flow, and heart rate in a chronically instrumented conscious dog during brief coronary artery occlusion.

The degree of myocardial stunning is characterized by both the level of regional myocardial dysfunction and the duration of myocardial function recovery. There are several factors to affect the degree of myocardial stunning, which can lead to increase variability or lack of reproducibility. First, incomplete coronary artery occlusion, even residual leak of coronary blood flow, can result in significantly less myocardial stunning as compared to a complete coronary artery occlusion. Usually, this can be easily detected from coronary blood flow and regional myocardial function in the ischemic zone. However, the change in regional function can also be induced by opening collateral channels, rather than incomplete coronary artery occlusion, particularly in dog species, where coronary precollateral channels are present.
FIGURE 6.1 **Effects of brief left circumflex coronary artery occlusion on systolic wall thickening in posterior ischemic and anterior nonischemic walls.** Note that wall thickening in the posterior wall was diminished during the coronary artery occlusion which was confirmed by complete loss of coronary blood flow (Shen et al., 1988).

Second, where regional myocardial function is measured within the ischemic area can produce marked variability of myocardial stunning in different animals. The closer the center of ischemic area the more severity of myocardial dysfunction is. When the location of myocardial function measured is close to boarder zone, the myocardial stunning often cannot be clearly detected. Thus, it is important to know the exact potential ischemic zone and then find the center of ischemic zone for measurement of regional myocardial function before study is performed. This can be easily achieved by a brief coronary artery occlusion, that is, less than 10 s during the surgery, to induce a temporal color change of epimyocardium to outline of the ischemic zone. The dimension gauge should be placed as close to central ischemic zone as possible. A representative regional myocardial function recording in a chronically instrumented conscious dog during control, left circumflex coronary artery occlusion, and after coronary artery reperfusion is shown in Fig. 6.2.

Noninvasive techniques, such as echocardiograph, are more limited in sensitivity. It is also relatively difficult to repeatedly measure the regional myocardial function in the exact same location over the time, a limitation not present with the direct measurement via fixed, chronically implanted ultrasonic dimension gauge. Further, when longitudinal or repeated myocardial stunning data are compared in the same animal, the slight change in location of measurement via noninvasive techniques should be carefully considered.

Although myocardial stunning in the dog model has been studied extensively, one of the major concerns for this particular species is that myocardial stunning cannot be reproduced when the same experiment is performed several days later. Our previous study demonstrated that reductions in regional myocardial function, assessed by systolic wall thickening via surgically implanted dimension gauge, were significantly less in the 2nd and 3rd myocardial stunning experiments as compared to the 1st experiment (Shen and Vatner, 1996). Interestingly, the same repeated ischemic protocol studied in pigs does not show the "preconditioning-like effects" as seen in the dog model (Shen and Vatner, 1996). The effects of three separate 10-min coronary artery occlusions, each 2 days apart, on systolic wall thickening in both ischemic and nonischemic zone in conscious dogs and pigs are shown in Figs. 6.3 and 6.4, respectively. Clearly, repeated myocardial stunning performed in dog model results in a great variability compared to that observed in pigs. Understanding the different characteristics of myocardial stunning in different species is important for choosing a right model to meet goals of different studies.

Myocardial stunning can also be performed in conscious or tranquilized nonhuman primate models, that is, monkey or baboon. The basic implanted transducers
FIGURE 6.2	**Phasic waveforms of left ventricular (LV) pressure, rate of change of LV pressure (dP/dt), and posterior and anterior wall thickness in a conscious dog subjected to 10 min of coronary artery occlusion (CAO) followed by 3 h of coronary artery reperfusion.** Note there was no major effect on systolic wall thickening in nonischemic (anterior) zone, whereas systolic wall thickening in ischemic (posterior) wall zone reversed to wall thinning during CAO and was depressed at 3 h of CAR (Shen and Vatner, 1996).
FIGURE 6.3	**Three separate 10 min of coronary artery occlusion (CAO) and reperfusion, performed 2 days apart, in conscious dogs.** Note that following coronary artery reperfusion, depression of systolic wall thickening in the ischemic zone was more severe and prolonged after 1st coronary occlusion than after 2nd and 3rd occlusions. *$P < 0.05$, 1st versus 2nd and 3rd coronary occlusions (Shen and Vatner, 1996).

and experimental protocols are similar to those used in dog or pig models. Since left ventricular wall thickness in nonhuman primates are often smaller than those seen in dogs and pigs, regional myocardial function usually is assessed using left ventricular segmental length, rather than wall thickness, via implanted ultrasonic dimension gauges in the remote, adjacent, and central risk areas. Fig. 6.5 shows a schematic illustration for instrumentation and direct measurements for cardiac global and regional myocardial segmental length in a conscious monkey subjected to a brief coronary artery occlusion. A typical experimental set up in conscious nonhuman primates is shown in Fig. 6.6.

2.2 Chronic Coronary Stenosis

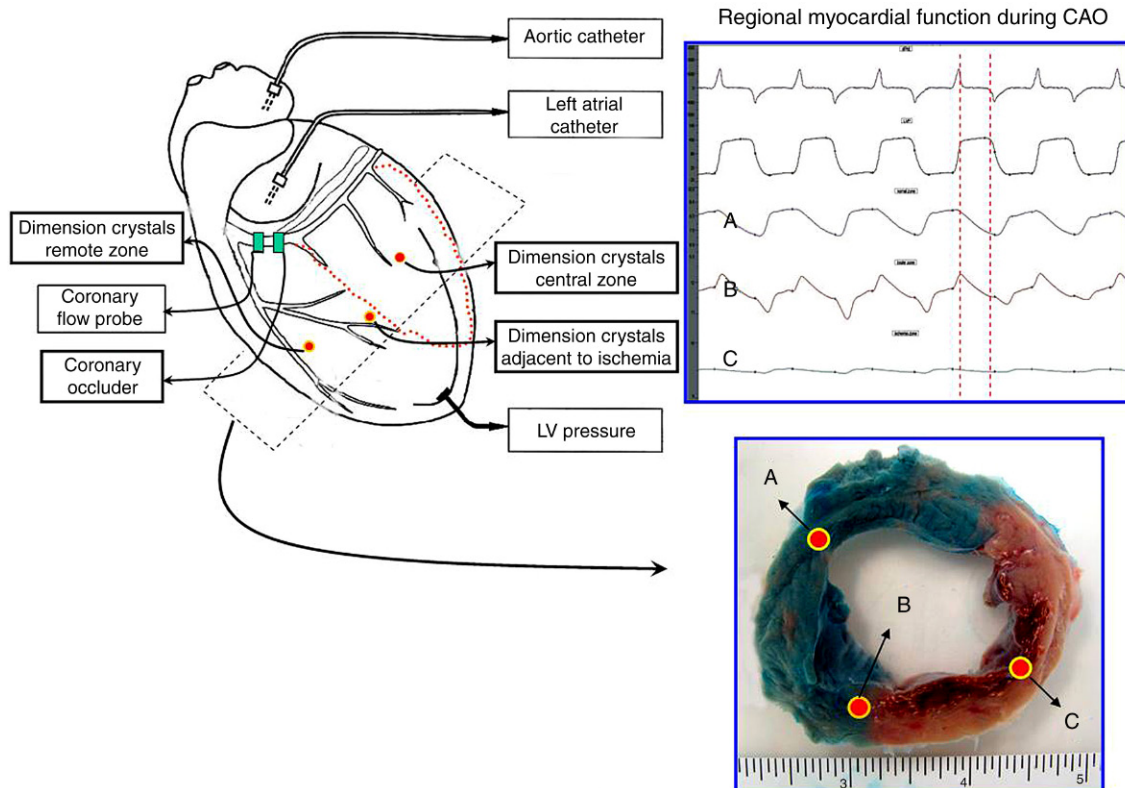
Coronary artery stenosis is one of the most common symptoms in patients with heart disease. It is usually caused by chronic atherosclerosis accumulation on the inner linings of arteries, which restricts coronary blood flow to the myocardium. Since the pathophysiological process of coronary artery stenosis has been well understood, it is relatively easy to use a highly atherogenic diet to induce a chronic arterial stenosis model in different species (Moghadasian, 2002). The limitation, however, is that the model development requires a long period of time. Recent transgenic/knockout animal models have
FIGURE 6.4 **Three separate 10 min of coronary artery occlusion (CAO) and reperfusion, performed 2 days apart, in conscious pigs.** Note that following coronary artery reperfusion, depression of systolic wall thickening in the ischemic zone was similar among three separate performed coronary artery occlusion and reperfusion. (Shen and Vatner, 1996).


FIGURE 6.5 During brief coronary artery occlusion (CAO), there was a complete loss of regional segmental length in the central ischemic zone (C) during systolic phase, while remote nonischemic zone was reduced normally (A). The function in the adjacent to ischemic zone (B) became nonsynchronous, as compared to the remote nonischemic zone (unpublished report).

the advantage to develop atherogenesis faster without special diet need, but are limited to rodent, where physiological measurements are difficult to be made as stated earlier. In the current section, two chronic coronary artery stenosis models in conscious pigs are described. It is well accepted that the pig is a better model for chronic myocardial ischemic studies, as compared to dog models which has well established, preexisting collateral channels that can significantly alter myocardial function and extent of stenosis-induced ischemia.

Ameroid constrictor, a special device for gradual reduction in coronary blood flow, has been used extensively

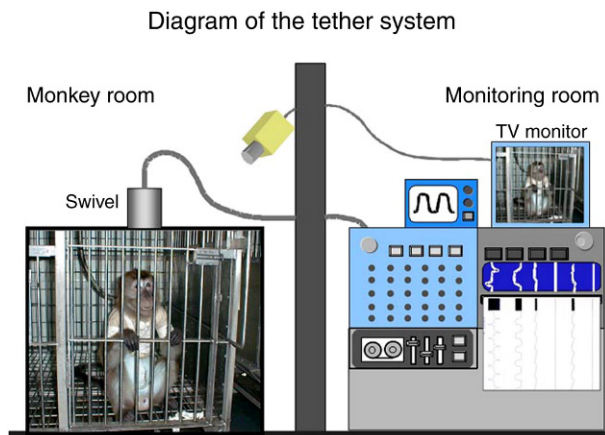
Diagram of the tether system


FIGURE 6.6 **Illustration of experiment conducted in conscious monkey via a tether system (unpublished report).**

for studies of coronary artery stenosis in pigs over past several decades. The constrictor is made by casein inside a ring of stainless steel, which swells at a predictable rate over time as it absorbs body fluid and eventually blocks the lumen of ring. The lumen diameter of constrictor is usually from 2–4 mm depending on the size of coronary artery. Because of the properties of this device, the coronary stenosis is progressively increased leading to complete or almost complete coronary artery occlusion after the device is implanted for weeks to months. The Ameroid constrictor can be implanted around either left circumflex or left anterior descending coronary arteries. In order to prevent surgically induced preconstriction, the coronary artery should be isolated longer than the width of the Ameroid constrictor. The size of Ameroid constrictor selected should be very similar to the diameter of vessel. However, the diameter of coronary artery is often significantly less, soon after it is isolated owing to the phenomenon of mechanically-induced constriction from the surgical isolation procedure in pig. Because if this, the correct diameter of coronary artery should be determined at least 10–15 min after the dissection is completed. To help the coronary artery restore to its initial condition, applying a few drops of lidocaine on the surface of coronary artery is often helpful.

The speed of gradual lumen closure from the Ameroid constrictor has been studied in vitro (Elzingz, 1969; Monnet and Rosenberg, 2005). Using a constant perfusion system to simulate in vivo coronary blood flow rate, Elzingz demonstrated that the flow through Ameroid constrictor placed in a warm saline bath was reduced to minimal level, that is, 3 ± 1 mL/min, from a baseline of 47 ± 0 mL/min after 10 days. When the Ameroid constrictor was coated with silicone, the flow reduction was significantly slower, that is, 20 ± 2, 11 ± 2, and 7 ± 2 from baseline of 46 ± 0 mL/min at 10, 20, and 40 days, respectively (Elzingz, 1969). A report by Monnet and Rosenberg showed that Ameroid constrictors incubated in saline or

plasma diluted with saline to obtain a different protein concentrations were not completely closed at 27 days and lumen diameter was 0.21 ± 0.22 mm from baseline of 3.5 mm. The experiments further indicated that the high plasma protein concentrations caused more rapid closure than the others (Monnet and Rosenberg, 2005). These in vitro data provide direct evidence for better understanding of the changes in lumen diameter in vivo. However, the real change in vivo can be different from those fixed in vitro conditions, as several factors could affect the pattern of coronary stenosis, for example, the size of Ameroid constrictor selected, level of body fluid and/or blood accumulated in the location of the Ameroid constrictor placed, etc. Ideally, a hydraulic occluder distal to the Ameroid constrictor should be implanted along with other measurements in the myocardial area perfused by the coronary artery in order to determine the degree of coronary stenosis. First, the changes in blood flow and regional function can be observed, but not precisely, in resting condition when the Ameroid constrictor progressively reduces the diameter of coronary artery. Next, when the hydraulic occluder is applied for several seconds to minutes, either blood flow or regional myocardial function should change significantly if the coronary blood flow is not altered by the Ameroid constrictor, that is, very early time postimplantation of Ameroid constrictor. When the Ameroid constrictor progressively reduces the diameter of coronary artery, the brief coronary artery occlusion induced changes in blood flow or function should be also gradually less. By using combination of hydraulic occluder with flow/function measurements, the degree of Ameroid constrictor induced coronary stenosis in conscious pigs was demonstrated in our previous study (Shen and Vatner, 1995). Examples of the effects of brief coronary artery occlusion on regional myocardial function and myocardial blood flow during progressive coronary stenosis in conscious pigs are shown in Figs. 6.7 and 6.8. At day 1 of Ameroid constrictor implanted, a time point when the constrictor should have no effect of coronary artery diameter, brief coronary artery occlusion resulted in maximal changes in both regional function (Fig. 6.7) and blood flow (Fig. 6.8). At 20 days after the Ameroid constrictor was implanted, the baseline regional function, but not blood flow, was depressed compared to day 1. Further, coronary artery occlusion did not suppress the blood flow to minimum. The regional function was also detected, indicating that partial blood flow still passed the Ameroid constrictor. The amount of blood flow detected was from contralateral myocardium via newly developed collateral circulation due to chronic coronary stenosis. At 32 days, baseline myocardial function was returned toward the level of baseline at Day 1 and brief coronary artery occlusion did not induce significant changes in both function and blood flow, indicating that collateralization has been
FIGURE 6.7 **Effects of brief coronary artery occlusion (CAO) using hydraulic occluder placed distal to Ameroid contractor on left circumflex coronary artery on systolic wall thickening (WT) at day 1, day 20, and day 32 in conscious pigs.** Note that CAO induced progressively less of a deficit in systolic WT as the stenosis gradually increased and collateral developed (Shen and Vatner, 1995).

well developed and the Ameroid contractor was almost completely closed, which cannot play any role in control regional myocardial function and blood flow.

Our prior study provides a comprehensive picture of the relationship between Ameroid constrictor and degree of coronary stenosis in conscious animal model. Since this model produces a progressive, but nonsustained, stenosis leading to almost complete coronary artery occlusion, it cannot represent a typical chronic coronary stenosis induced myocardial hibernation seen in patients (Shen and Vatner, 1995). On the other hand, this model is useful to study coronary revascularization as the collateral vessels are rapidly developed by myocardial ischemia induced by severe coronary stenosis.

Chronic coronary stenosis can also be induced in pig model using either a hydraulic occluder (Kim et al., 2003; Shen et al., 2008b; St. Louis et al., 2000) or a fixed diameter device (Fallavollita et al., 2001; Page et al., 2008). The surgical preparation is similar to those from the Ameroid constrictor induced stenosis model. Either left circumflex or left anterior descending coronary arteries can be used. The results from several laboratories have shown that the coronary blood flow can be reduced 30%–90% for hours when a hydraulic occluder was applied (Kim et al., 2003; Shen et al., 2008b; St. Louis et al., 2000). Studies from fixed diameter devices, that is, 1.5–2.0 mm, implanted on coronary artery demonstrated that both myocardial function and blood flow were reduced substantially at 2–3 months after surgery, suggesting a hibernating myocardium developed (Fallavollita et al., 2001; Page et al., 2008).

However, it should be pointed out that one important phenomenon of coronary circulation is autoregulation mechanism, a unique intrinsic ability to maintain a constant myocardial blood flow when the perfusion pressure is changed. Briefly, when the coronary artery is partially occluded, the coronary artery pressure distal to the occlusion initially reduced and myocardial blood flow in this area also falls. The blood flow then returns toward baseline within few minutes, as the coronary vasculature dilates (i.e., coronary vascular resistance decreased). In most circumstances, new established steady-state blood flow could be very close to baseline, that is, before coronary stenosis, despite the reduced perfusion pressure induced by partial occlusion. Only when the perfusion pressure is beyond the range of coronary autoregulation, blood flow decreases passively in parallel with
FIGURE 6.8 **Effects of brief coronary artery occlusion (CAO) using hydraulic occluder placed distal to Ameroid contractor on left circumflex coronary artery on regional myocardial blood flow in endo- (ENDO) and epi-(EPI) myocardium systolic wall thickening (WT) at day 1, day 20, and day 32 in conscious pigs.** Note that CAO reduced blood flow in both layers, and still decreased blood flow at 20 days, indicating that coronary artery was not occluded. However, CAO only slightly decreased ENDO but not EPI blood flow at 32 days, indicating that collateral had developed extensively (Shen and Vatner, 1995).

the reduction in perfusion pressure. Based upon this well-established concept of autoregulation, it is unlikely to keep a sustained reduction in coronary blood flow when a hydraulic occluder or fixed diameter device are used. Indeed, our prior experiments using a hydraulic occluder to maintain coronary stenosis found that coronary blood flow cannot be controlled at a fixed reduction level. In fact, the reduction in coronary blood flow during short period of time, that is, less than 15 min period, varied from 35% to 45% even with repeated and precise stenosis adjustments made (Shen et al., 2008b). This was also described in the study by St. Louis et al. (2000). Despite of the limitation of this model, partial coronary stenosis that does not significantly induce collateralization provides a model to study the hibernating myocardium. In addition, the difference between these models versus human hibernating myocardium is the absence of atherosclerotic vascular disease.

2.3 Prolonged Coronary Artery Occlusion With and Without Reperfusion-Induced Myocardial Infarction

Myocardial infarction (MI) refers to the interruption of coronary blood supply to certain myocardial area which leads to irreversible myocardial tissue death. Most commonly seen MI in patients comes from complete blockage of a coronary artery following the rupture of a vulnerable atherosclerotic plaque. The extent to which MI is developed depends upon duration and location of the

coronary artery occlusion. Animal models of MI can be achieved by direct occlusion of coronary artery using either reversible hydraulic occluder or ligation. Numerous studies from different species including, mice, rat, rabbit, dog, pig, and nonhuman primates, have been reported previously. Since the procedure to produce MI seems to be straightforward, the detailed description of the procedure in different species is not included in this section. Since myocardial infarct size can be easily influenced by several factors including assessment of infarct size, these areas are particularly emphasized in the current section.

Protocols for induction of MI vary from permanent coronary artery occlusion to coronary artery occlusion followed by reperfusion. The minimal time required for coronary artery occlusion-induced MI in most species should not be less than 20–30 min, which provides a clear and minimal size of MI. It is well known that the infarct size is closely correlated with the duration of coronary artery occlusion. However, the relationship does not appear to be linear, particularly when the time of occlusion is beyond 90 min in most species. Our previous studies in a conscious dog model showed that a 40- and 90-min of coronary artery occlusion resulted in about 16 and 32% of infarct size, respectively (Shen et al., 1996a), while 24 h of coronary artery occlusion induced about 45% of infarct size (Shen et al., 1988) as shown in Fig. 6.9. The relationship between the duration of coronary artery occlusion and infarct size in conscious pig model blunted compared to the dog model. Our previous results found that the infarct size was 46, 54, and 53% from the 40, 60,
FIGURE 6.9   **Effects of different time of coronary artery occlusion on infarct size, expressed by infarct size/area at risk, in conscious dogs.** Note that there is a nonlinear relationship between the duration of coronary occlusion and infarct size. *Source: Replotted based on data from Shen, Y-T., Fallon, J.T., Iwase, M., Vatner, S.F., 1996b. FIGURE 6.10 **Effects of 90 min of coronary artery occlusion (CAO) and reperfusion (CAR) on area at risk (AAR), infarct size (IF), and IF expressed as percentage of AAR (IF/AAR) in conscious pigs** *(open bars),* **dogs** *(hatched bars),* **and baboons** *(filled bar).* The IF/AAR was greatest in pigs and least in baboons (Shen et al., 1996a).

and 90 min of coronary artery occlusion, respectively (Chen et al., 2011; Shen et al., 1996a).

Our prior study demonstrated that there are major species differences in infarct size among conscious dogs, pigs, and nonhuman primates (Shen et al., 1996a). As shown in Fig. 6.10, a 90-min of coronary artery occlusion resulted in a significantly greater infarct size in pigs compared to dogs and baboons. It is not surprising the difference between dog and pig species, because of the difference in preexisting collateral channels. Interestingly, both baboons and pigs are characterized by similar collateral circulation, but show a significant difference in infarct size (Shen et al., 1996a). Although the mechanism of the major difference in infarct size between these two species is unclear, the difference could be partially attributed to natural protective mechanisms and/or less coronary reperfusion-induced myocardial injury in baboon, as evidenced by more blood flow in the endomyocardial layers during the time of reperfusion in baboons compared to pigs (Shen et al., 1996a). Also, it should be mentioned that the same species but different strain could also make the difference in infarct size, for example, beagle would have a greater infarct size than mongrel dogs (Uemura et al., 1989).

Several other factors are also involved in development of infarct size. The site of coronary artery occlusion or ligation is an obvious one, that is, the more proximal to the origin of coronary artery; the more infarct size would be. In larger animal species, it is not difficult to identify a similar location for coronary artery occlusion in different animals, as coronary branches can be identified easily. However, this is difficult in small animal species, such as mice and rats. More importantly, slight difference in location for coronary occlusion would result

in a great difference in infarct size as the heart is very small. Because of the importance of location for coronary artery occlusion, the infarct size in all species should be expressed as a function of area at risk (IF/AAR), rather a percentage of left ventricular mass (IF/LV), which rely on the anatomic area at risk that is decided by surgeon or possibly difference between individual animals.

Another factor that influences infarct size during the procedure of coronary artery occlusion is incomplete coronary artery occlusion, which has been also discussed in the section of myocardial stunning. The confirmation of complete occlusion before reperfusion is critical. In larger animal species, this can be accomplished by monitoring coronary blood flow and regional myocardial function in the ischemic zone, and comparing those with the same measurements at very beginning time after coronary artery occlusion. For example, the time points at about 5 and 85 min during the coronary artery occlusion is often used for a 90 min of coronary artery occlusion protocol. If the physiological measurements show difference between these two points, the experiment usually should not be considered as valid in animals that do not have preexisting collateral channels, such as pigs and nonhuman primates. In dog models, however, myocardial function could be slightly changed at the later compared to the early time points, because of collateral channels. This can particularly happen when the measurement of regional myocardial function is in the risk, but adjacent to boarder zone, which easily recruits blood from the contralateral area via the preexisting collateral channels. Accordingly, an ideal method for confirmation of coronary artery occlusion should include both regional myocardial blood flow, measured by either radioactive or colored microsphere techniques, and coronary blood flow in the species that have preexisting collateral channels. Furthermore, the infarct size in those animal species should be expressed by using the slope of transmural collateral blood flow versus IF/AAR, which helps to exclude all influences from collateral channels. Apparently, it is difficult to be performed in small animal models.

Our preliminary unpublished data found that coronary occlusion on left anterior descending coronary in pig or dog models appears to be much more vulnerable to ventricular arrhythmias leading to ventricular fibrillation compared to those from occlusion on left circumflex coronary artery. The left anterior descending coronary artery occlusion also induced a relative larger infarct size as compared to those from left circumflex coronary occlusion. Consistent with what we found, Becker et al. (1983) also reported that permanent occlusion of left anterior descending coronary in anesthetized dogs produced a significant larger infarct size (52%) than those from left circumflex coronary artery occlusion (32%) with a similar size of risk area. Using

microsphere technique to measure regional myocardial blood flow in this study, the collateral blood flow was found to be markedly lower in left anterior descending coronary artery perfused area compared to the area of left circumflex coronary artery, demonstrating that relatively lower level of collateral blood flow is the factor to be responsible for larger infarct size developed (Becker et al., 1983).

Another important factor that affects myocardial infarct size during coronary artery occlusion is the change in myocardial demand. This is important when the coronary artery occlusion is conducted in conscious animals, in which heart rate and arterial blood pressure can be changed markedly via the intact autonomic control. Several previous studies failed to show that the myocardial demand, as expressed by indirect measurement of rate pressure product, affected myocardial infarct size in anesthetized animals (Miura et al., 1987; Reimer et al., 1985), but did affect the infarct size in conscious animals (Reimer et al., 1985). Also, different anesthesia along with recent surgical trauma not only affects cardiovascular control, but also alters the biochemical system, as well as, myocardial calcium handling (Li et al., 1993; Pagel et al., 1993).

MI can be usually detected within the area at risk by gross examination with histochemical tetrazolium stains (TTC) for identifying infarcted tissue from salvaged tissue, as well as, the tissue from nonischemic area. Thus, it is important and also is the first step to identify the area at risk before any staining technique is used, as the infarct size should be expressed as a percentage of area at risk, rather than total left ventricular mass. In larger animal species, a dual perfusion system is often used (Shen et al., 1988, 1996a). In order to prevent blood clot in coronary circulation, animal needs to be first heparinized prior to euthanasia. Immediately after the whole heart is removed, the ascending aorta is cannulated (distal to the sinus of Valsalva) and perfused retrogradely with blue dye, such as Evans, Alcian blue, etc. Simultaneously, the coronary artery at the site of occlusion is cannulated and perfused with saline. The pressure for the perfusion apparatus should be maintained at 100–150 mmHg via a reservoir for both cannulas. The simultaneous perfusion should be maintained until the nonischemic area is clearly stained with blue dye. In small animal species, such as rat and mice, a similar concept, but modified procedure can be carried out in vivo. After animal is heparinized and euthanized, saline should be perfused retrogradely via aorta proximal to the heart while its distal to the heart is ligated. Once all blood is washed out, the site of coronary artery occlusion/reperfusion should be ligated again. The blue dye can be delivered via either aorta or directly slow injection through the apex of left ventricle. After completion of perfusion procedure, the heart is sectioned at the atrioventricular junction and the right ventricle can be kept or removed. Usually the ventricle can be divided into 5–8 rings for larger animal species, and 3–5 rings for small animal species. The individual ring should be carefully labeled, weighed, and then imagined using a digital camera for both sides of each ring. At this point, the coronary artery perfused territory from each ring, that is, anatomical area at risk, should clearly show native color, whereas the remainder of the areas shows the blue stain. One of example from a mouse heart subjected to 60 min of coronary artery occlusion is shown in Fig. 6.11. After TTC staining, the area at risk was no longer detected. Thus, it is extremely important to perfuse the heart using blue dye first before TTC staining in order to obtain the anatomic area at risk.

TTC is one of the most popular histochemical stains used in the quantification of infarct size; it stains viable myocardium red (TTC positive), but does not react with infarcted myocardium (TTC negative) because of lack of dehydrogenase enzymes. The concentration of the TTC is about 1% in phosphate buffer to achieve the level of pH 7.4. All rings are incubated in the TTC solution at 37–38°C for several minutes until the nonischemic myocardial tissue becomes clearly red. TTC stain can also be perfused at the same time when the heart perfusion is performed. The major advantage of this method compared to the incubated rings is that the tissue can be stained entirely, rather than the exposed surface from each ring. However, it is important that the TTC solution can be only perfused in the coronary occluded area while the nonischemic areas still need to be perfused with either saline or blue dye with equal perfusion pressure. This will prevent the tissue from nonischemic region from being stained with TTC and thus retain a clear area at risk. Due to the technical limitation, the perfusion of TTC is not possible in small animal species.

Although TTC is sensitive to differentiate the irreversible infarcted myocardium from nonischemic myocardium, several factors often result in "false positive" or "false negative" results. Downey (1990) reported that assessment of MI using TTC often has the limitation when tested agents, for example, free radical scavenger, are used. Thus, the TTC stain should not be used when any agents that may have potential effects on cardiac enzymes, which would directly react with TTC to cause "false positive." Early studies utilized conventional histological method also found other important limitations of using TTC. Vivaldi et al. (1985) demonstrated that myocardial infarction in rodent species can be identified by TTC at 30 min after coronary artery occlusion. Six hours after coronary occlusion in rodent species, however, the differentiation of reversibly from irreversibly infarcted tissue at the 1–2 mm
FIGURE 6.11 Example of slice of heart from a mouse subjected to 60 min of coronary artery occlusion before (A) and after TTC staining (B). Note that the infarct tissue can be easily detected after TTC staining. Anatomic area at risk was no longer clearly visible after TTC (unpublished data).

peripheral margin of the infarct became less sharp. At the macroscopic boundary of the infarcted tissue, myocardium not stained with TTC always had irreversibly salvaged myocytes, while the myocardial tissue stained with TTC often had a narrow zone of mixed salvaged and irreversible damaged tissue adjacent to the infarct (Vivaldi et al., 1985), indicating that the TTC is ideal for the early detection of MI.

The reason why TTC stain should not be used too long after occlusion is that myocardial remodeling has commenced. The myocardial mass in ischemic area starts to shrink within a few days following coronary artery occlusion and reperfusion. As a matter of fact, the infarcted tissue can be directly observed from the risk area without any staining methods during the time between 4 and 7 days following coronary artery occlusion/reperfusion. Fig. 6.12 shows a pig heart subjected to coronary artery occlusion for 90 min followed by 4 days of reperfusion. The irreversible infarcted tissue mixed with hemorrhage and necrosis located in endo- and midmyocardial layer can be differentiated from salvaged tissue located in epimyocardial layer in the risk area, while the nonischemic tissue was stained with blue dye. When the reperfusion time was extended to 7 days, the infarcted tissue was much clearer and sharp as compared to 5 days of reperfusion. Fig. 6.13 shows a pig heart 7 days after coronary artery reperfusion. The mixed hemorrhage and necrosis was a lot less compared to 4 days of reperfusion.

The total weight of infarcted tissue normalized by the area at risk for the infarct size (IF/AAR) from each animal can be calculated using planimetry from all sliced rings with or without TTC stain. Numerous computer-assisted planimetry techniques are now available. Both surface areas of each ring of heart should be measured and averaged. Based upon the infarct area, areas at risk and nonischemic area along with the weight from each ring, infarct size can be obtained. In chronic coronary artery occlusion and reperfusion animal models, that is, longer than 1 week, the infarct size will be difficult to be obtained using the earlier method because of myocardial remolding. Usually, the infarct size can be determined by measuring the circumferences of the left ventricle and the infarcted region, and then expressed as a percentage
FIGURE 6.12 **A slice of heart from a pig subjected to left circumflex coronary artery occlusion followed by 4 days of reperfusion.** Note that the infarct tissue can be differentiated from salvaged tissue within the area at risk without any staining procedure (Shen et al., 1996a).
FIGURE 6.13   **A slice of heart from a pig subjected to 60 min of left circumflex coronary artery occlusion followed by 7 days of reperfusion.** Comparing with 4 days of reperfusion shown in Fig. 6.12, the infarct tissue within the area at rick was much clearer and sharper while the mass of entire risk area had not been reduced (unpublished report).

FIGURE 6.14   **A slice of heart from a pig 6 weeks after left circumflex coronary artery occlusion.** Note that the infarct was clearly different from normal myocardium (unpublished report).

of the LV perimeter. Fig. 6.14 shows an example of one slice of pig heart 6 weeks after coronary artery occlusion. Clearly, the remodeling process completely changed the ratio between infarcted and salvaged tissue within the area at risk. Without knowing the exact area at risk, the infarct size could be significantly influenced by the site of coronary occlusion. Thus, when a protocol for study of a cardioprotective agent involves prolonged reperfusion, the results can be affected significantly by inconsistency in the site of coronary artery occlusion between animals.

3 HYPERTENSION AND LEFT VENTRICULAR HYPERTROPHY MODELS

3.1 Hypertension

One in every three adults in the United States has hypertension, a major risk factor for cerebral, cardiac, and renal events. More than 90% of cases are categorized as essential (primary) hypertension, which does not have a clear underlying cause, but has been known to contain a significant genetic component. Remaining 5%–10% of cases are categorized as secondary hypertension, which can be induced by several conditions, such as renal disease, adrenal gland dysfunction, pregnancy, or medication. Because of complex and unknown mechanisms of hypertension, creating an animal model to mimic clinical hypertension is difficult.

Several genetically induced hypertensive models, primarily in small animal species have been developed and characterized. One of the most notable models is the spontaneously hypertensive rat (SHR) which represents the essential hypertension. The SHR strain was produced as early as 1960s by Okamoto and Aoki (1963). Subsequently, double transgenic mice and rat models, for example, the stroke-prone spontaneously hypertensive (SHRSP) model, as well as, other genetically engineered models have been developed. In addition, mineralocorticoid deoxycorticosterone salt sensitive models have also been developed in rodent, which provides another pathway for the study hypertension (Johns et al., 1996). Due to the limitation of small animal species for comprehensive physiological measurements, a larger animal model of hypertension is required. The most direct method to mimic the pathological changes in hypertensive patients is to use surgical manipulation by either kidney wrapping or renal artery stenosis. The surgical procedure for perinephritic hypertension can be performed via a left flank incision (Kirby and Vatner, 1987; Uemura et al., 1993). After perinephric fat is removed, the kidney can be wrapped by an unbleached silk pouch. Care should be taken to avoid inadvertent stenosis of the renal artery. The procedure for renal vascular stenosis uses either suture or a metal clip to reduce diameter of renal artery by approximately 50%. Based on our prior experience, both procedures only produce a minimal to moderate level of hypertension in dog models. In conscious nonhuman primates, monkey model, however, we found renal artery stenosis produces more stable hypertension compared to the dog model. In order to achieve a sustained moderate to severe hypertension, a contralateral nephrectomy is needed which can be performed at the same time or 1–2 weeks after initial surgical procedure is completed (Kirby and Vatner, 1987; Uemura et al., 1993).

3.2 Pulmonary Hypertension

Like systemic arterial hypertension, pulmonary hypertension is also divided into primary and secondary pulmonary arterial hypertension. In contrast to systemic arterial hypertension, secondary pulmonary hypertension is much more common than primary pulmonary hypertension. The causes of pulmonary hypertension include blood clots, artery constriction, and/or heart and lung dysfunction. Several animal models have been studied. The most commonly used models in small animal species are the hypoxia or chemical-induced pulmonary hypertension (Stenmark et al., 2009). More recently, genetically manipulated mouse models have been generated which provides insight into the role of specific molecules in the pulmonary hypertensive process (Stenmark et al., 2009). We adapted both hypoxia and thromboxane induced pulmonary hypertension procedure to a larger animal, pig, model in our previous studies (Ho et al., 2012). Briefly, hypoxia is induced under anesthesia with ventilation by changing fraction of inspired O_2 to the level about 0.1% via introducing N_2 into the inspiratory limb of the ventilator. The mean pulmonary artery pressure is elevated by 5–10 mmHg from baseline level in the pig model. Chronic infusion of thromboxane-induced pulmonary hypertension resulted in a greater increase in pulmonary artery pressure compared to hypoxia induced hypertension. The major limitation of these models is that the mechanism of hypertension is very different from human pulmonary hypertension.

It is known that acute pulmonary embolism is also a major cause of pulmonary hypertension which can be mimicked by administration of air, blood clots, or synthetic microspheres in animal models (Marsboom and Janssens, 2004). We have modified the microsphere injection method and made it possible for direct and repeated administration of microspheres directly into the pulmonary circulation in a chronically instrumented conscious pig model. Under continuous monitoring of cardiac output, pulmonary, systemic arterial, right and left atrial pressure along with SPO_2, glass microspheres can be infused multiple times, several hours to days apart. The increase in mean pulmonary artery pressure and pulmonary vascular resistance can be doubled, but it returns toward the baseline level within few hours, which is the major limitation of this model. Repeated injections for 5–6 times within a 2-week period resulted in a chronic elevation of mean pulmonary artery pressure. By using a chronically implanted catheter technique, this model can be studied under fully conscious state. Preliminary results from our pilot study are shown in Figs. 6.15 and 6.16. Clearly, systemic hemodynamics were not changed significantly, while pulmonary arterial pressure, pulmonary vascular resistance, and right atrial pressure were elevated markedly compared to control, suggesting that pulmonary embolism alone selectively causes right ventricular dysfunction, while left ventricular function was still preserved.

3.3 Left Ventricular Hypertrophy

Left ventricular hypertrophy is an adapted response to physiological or pathological stress, such as hypertension, MI, neurohormonal dysfunction, and valve defection. Much progress has been recently made in the development of left ventricular hypertrophy linked with molecular and genetic basis. Most common methods for development of left ventricular hypertrophy are through MI, chronic hypertension, or aortic stenosis. As described in the section of MI, myocardial remodeling occurs following MI. Myocardial wall thickness in the ischemic region becomes thinned and also enlarged due to the tissue shrinking, while the contralateral nonischemic region gradually hypertrophies via the constantly enhanced contractile force to compensate the function loss from ischemic region. Fig. 6.17 shows a left ventricular cross section from one pig at 6 weeks after left circumflex coronary artery occlusion (Fig. 6.17B) compared to the pig with the same protocol but without coronary artery occlusion (Fig. 6.17A). The wall thickness from nonischemic region, particularly at the adjacent to ischemic region, appears to be greater as compared to the remote area of nonischemic region, as well as to control pig.

In nonhuman primates, about 2 months after left anterior descending coronary artery ligation, left ventricular mass/body weight is slightly increased. However, given the reduction in myocardial mass in the infarcted region, the degree of hypertrophy should be greater than observed (Shen et al., 2005). Hypertension is another approach to induce left ventricular hypertrophy. Using a perinephritic hypertension dog model, left ventricular mass during developing hypertension, that is, 2–4 week, was increased by more than 20% (Uemura et al., 1993). Overall, both MI and hypertension induced hypertrophy in larger animal species should be considered as a physiological response to stress which does not reach a pathological alternation in myocardium.

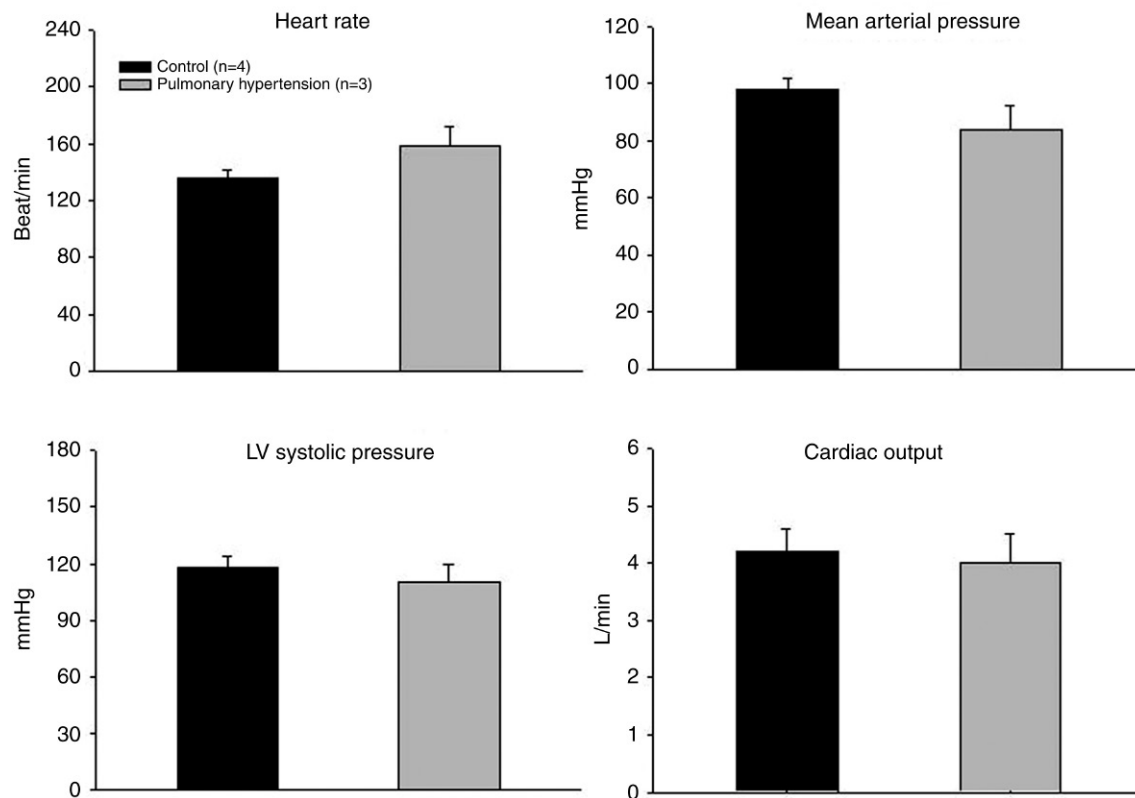
Aortic banding is an optimal approach to induce left ventricular hypertrophy which is much more severe compared to ischemia and hypertension induced models. In dogs, aortic banding often produces a moderate to severe hypertrophy, that is, more than 40% up to 80% increase in left ventricular weight/body weight (Hittinger et al., 1992, 1994). The banding procedure is performed in mongrel puppies at 8–10 weeks of age. Briefly, through a right thoracotomy at the third or fourth intercostal space, the ascending aorta 0.5–1.0 cm above the coronary


FIGURE 6.15 **Effects of pulmonary embolism on heart rate, mean arterial pressure, LV systolic pressure, and cardiac output in conscious pigs.** There was a slight change in all these indices compared to control (unpublished data).
FIGURE 6.16 **Effects of pulmonary embolism on stroke volume, right atrial pressure, mean pulmonary arterial pressure, and pulmonary vascular resistance in conscious pigs.** There was a marked increase in pulmonary artery pressure and resistance, along with increased right atrial pressure, while stroke volume was unchanged compared to control (unpublished data).
FIGURE 6.17 Representative left ventricular (LV) cross sections from two pigs with (B) and without (A) myocardial infarction. Note that the wall thickness, particularly adjacent to myocardial infarction is enlarged compared to that without myocardial infarction (Shen et al., 1999).

arteries is dissected free of surrounding tissue. A 10-mm wide Teflon cuff is placed around the aorta and tightened until a thrill could be palpated over the aortic arch. The Teflon band creates a fixed supravascular aortic lesion, which produces progressive increasing stenosis as the puppies grow. Animals are studied for about 1 year after banding (Hittinger et al., 1992, 1994). The left ventricular and aortic pressure gradient in this model could reach 100–150 mmHg. Global and regional myocardial function and coronary blood perfusion in response to stress are clearly impaired (Bishop et al., 1996; Hittinger et al., 1994). The aortic banding induced hypertrophy can be also used in adult animal, but the degree of aortic stenosis should be less than used in puppies. The degree of hypertrophy is also much less severe as compared to the chronic banding model in puppies. The left ventricular and aortic pressure gradient should be controlled to less than 100 mmHg to avoid acute decompensation (von Harsdorf et al., 1997). The aortic banding procedure can also be used in rodent species for the development of left ventricular hypertrophy. Following anesthesia and

mechanical ventilation in mouse models, a left thoracotomy can be performed via the second intercostal space. Aortic stenosis is induced by tying a 7-0 polyester braided suture ligature against an appropriately sized needle, to provide a reproducible transverse aortic constriction of 65%–70% when the needle is removed. Chronic left ventricular hypertrophy also can be induced in nonhuman primates via multiple, progressive coronary artery occlusion followed by repeated rapid ventricular pacing. Detailed experimental protocol and results is shown in the section of heart failure.

4 HEART FAILURE MODELS

Heart failure is a final pathway from different cardiovascular diseases, which is the leading cause of cardiovascular mortality and morbidity in the United States. The most common cause of heart failure in patients is the ischemic cardiomyopathy resulting from insufficient myocardial perfusion associated with complex neurohormonal activation. Heart failure generally can be characterized by a decrease in cardiac function, increase in systemic vascular tone, and sodium retention. The most extensively used heart failure animal models are the MI in all animal species (Ellis et al., 1964; Nuttall et al., 1985; Pfeffer and Pfeffer, 1988; Sabbah et al., 1991; Van der Giessen et al., 1989) and the rapid ventricular pacing (Armstrong et al., 1986; Chow et al., 1990; Hendrick et al., 1990; Wilson et al., 1987) in larger animal species. Recently, many transgenic knockout or overexpression of heart failure models in small animal models has also been developed.

4.1 Heart Failure Induced by Ischemia

Previous studies showed that ligation of coronary artery in rats induce a significant impairment of left ventricular function leading to heart failure. In those studies, the infarct size can reach to the level of 35%–50% of the left ventricle (Pfeffer and Braunwald, 1990; Pfeffer and Pfeffer, 1988; Shen et al., 1996b). However, the level of infarct size in rats is difficult to reproduce in larger animal species, because of sudden death due to uncontrolled acute cardiogenic shock or ventricular fibrillation. Although several previous studies reported that chronic heart failure can be induced in pig models a few weeks after coronary artery occlusion (Van der Giessen et al., 1989; Van Woerkens et al., 1993), there are no significant changes in left ventricular contractile function as assessed by left ventricular dP/dt in these studies. Since the infarct size can be variable, it is reasonable to characterize all animals after MI, and then divide them into different subgroups, in order to obtain the animals that meet the criteria of the diagnosis of systolic heart failure.

A prior study shows that left ventricular end diastolic pressure was only slightly increased even in the most severe group (Zhang et al., 1996); further indicating that heart failure induced by coronary artery occlusion alone in larger animal models is different from those observed in small animals.

It has been reported that unlike coronary artery occlusion produced by either occluder or ligation, multiple intravascular microembolization in dogs can induce progressive myocardial injury that leads to heart failure (Nuttall et al., 1985; Sabbah et al., 1991). However, the procedure requires intracoronary injection technique often conducted under anesthesia in a catheterization laboratory or a special catheter chronically implanted in coronary artery. Furthermore, it is difficult to find a consistent protocol for the number of injections and amount of microembolization. Thus, this model cannot be easily produced by most laboratories.

4.2 Heart Failure Induced by Rapid Ventricular Pacing

Rapid pacing produces a fast and significant decrease in cardiac function which meets the hemodynamic criteria of heart failure. Rapid pacing can be produced using pacing leads located at atrium, right or left ventricles. Most prior studies in larger animal species have used right ventricular pacing via pacing leads implanted in the free wall of right ventricle. The pacing rate, controlled by a programmable internal or external cardiac pacemaker, ranges of 200–300 bpm depending on species, for example, 220–230 bpm in pigs (Shen et al., 1998), 230–240 bpm in dogs (Shannon et al., 1993; Shen et al., 2000), 280–290 bpm in monkeys (Park et al., 2009; Shen et al., 2005, 2008a), and 320–340 bpm in rabbits (Liu et al., 2001). The duration of the pacing varies from few days to weeks. The severity of cardiac dysfunction depends on both the rate and duration of pacing. The major limitation of the pacing model is that the cardiovascular hemodynamics, as well as, biochemical alterations, progressively revert to near baseline levels after pacing is ceased (Larosa et al., 1993; Shannon et al., 1993), indicating that the mechanisms of pacing model are different from those of the irreversible failing heart seen in humans. Thus, the definition of pacing model in general should be considered as a severe, but reversible injury leading to dilated cardiomyopathy.

4.3 Myocardial Ischemia Super Imposed with Pacing

Given the limitation of the reversible nature of rapid pacing alone, we developed a pig heart failure model induced by sequential coronary artery occlusion followed by rapid ventricular pacing (Shen et al., 1999). Unlike either intervention alone, left ventricular dysfunction and abnormal systemic hemodynamics are severe and do not progressively reverse after cessation of pacing, suggesting that the underlying mechanism following combined MI and rapid ventricular pacing is different from pacing or ischemia alone-induced heart failure. It is conceivable that the nonischemic myocardium can compensate for the loss of regional function after coronary artery occlusion and maintain global left ventricular performance. In the presence of MI, rapid ventricular pacing increases the energy demand of the nonischemic myocardium possibly beyond the range of compensation. Consequently, compensatory mechanisms presumably operating particular within the border zone may be insufficient, resulting in irreversible myocardial damage. Thus, MI followed by rapid ventricular pacing should be considered as a better mimic of the process of heart failure observed in human.

Fig. 6.18 shows a schematic illustration of surgically implanted instrumentations and the protocol for induction of heart failure in this model. The progressive MI in the pig model can be performed by two left circumflex coronary artery occlusions. The first occlusion is performed using the occluder implanted distally to the origin of its first margin branch, which results in about infarct size less than 20% of left ventricle (Shen et al., 1999). The second occlusion is performed 48 h after the first occlusion by using the second occluder implanted at the proximal circumflex coronary artery, resulting in about the infarct size more than 30% of left ventricle. By using this stepwise manner, the acute mortality during the coronary artery occlusion can be minimized with maximizing the infarct size. The rapid right ventricular pacing at a rate of 220 bpm usually can be initiated 2 days after the second coronary artery occlusion.

Figs. 6.19 and 6.20 show the comparison of cardiovascular function in the rapid ventricular pacing protocol with and without sequential coronary artery occlusions induced MI. The changes in cardiac function as expressed by cardiac output, left ventricular dP/dt, and left ventricular fractional shortening are similar with pacing, which are clearly depressed. However, during the 3 weeks recovery period, that is, cessation of pacing, cardiac function returns toward control level in the pacing group without myocardial ischemia. In contrast, in the group with myocardial ischemia and pacing, the cardiac function remained depressed.

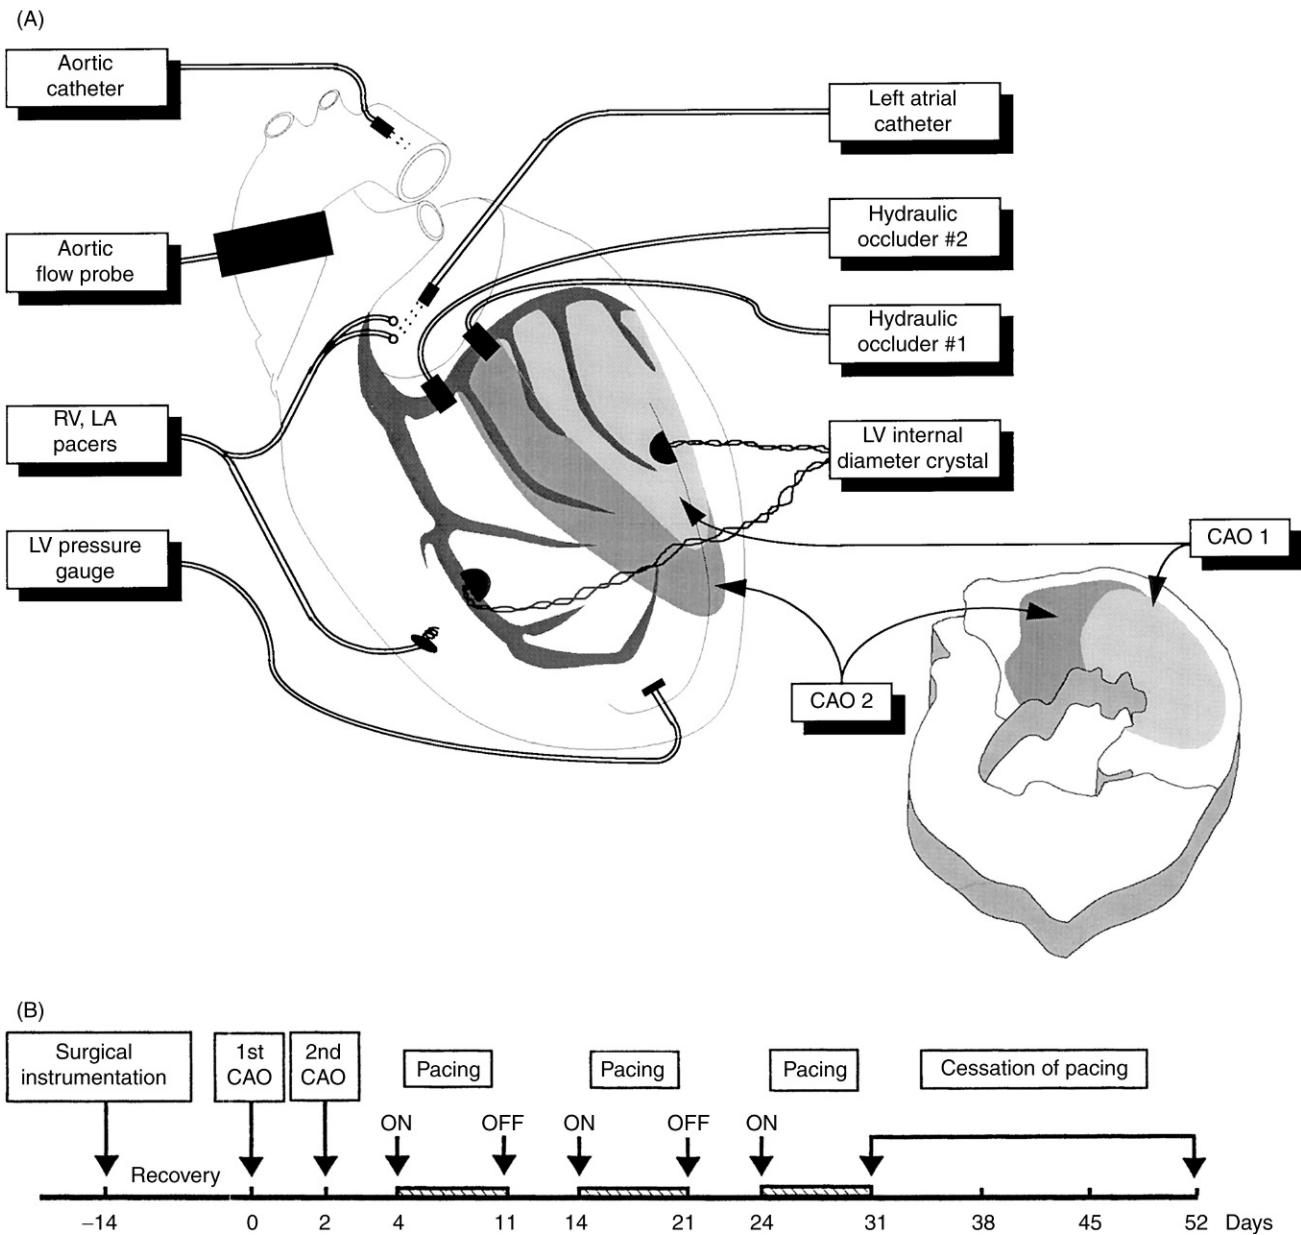
Models of heart failure induced by myocardial ischemia superimposed with rapid ventricular pacing have been studied in other larger animal species, such as dogs (Shen et al., 2010) and nonhuman primates, monkeys (Park et al., 2009; Shen, 2010). The induction of heart failure in conscious monkey model is different from that used for pigs and dogs. The detailed experimental protocol is shown in Fig. 6.21. MI is induced by permanent


FIGURE 6.18 (A) Schematic illustrations of instrumentation implanted for measurements of cardiac and systemic dynamics. ligation of the left anterior descending coronary artery at half the distance from its origin in combination with ligation of all branch vessels via thoracotomy at the fourth/fifth intercostal space. In addition to the ligation of the coronary artery, instrumentations to record hemodynamics along with pacing leads can be implanted selectively, as needed.

Approximately 2 months after coronary artery ligation surgery, rapid ventricular pacing is applied at approximately 220–290 bpm for 3–4 weeks. Our previous studies (Park et al., 2009; Shen, 2010; Shen et al., 2005)

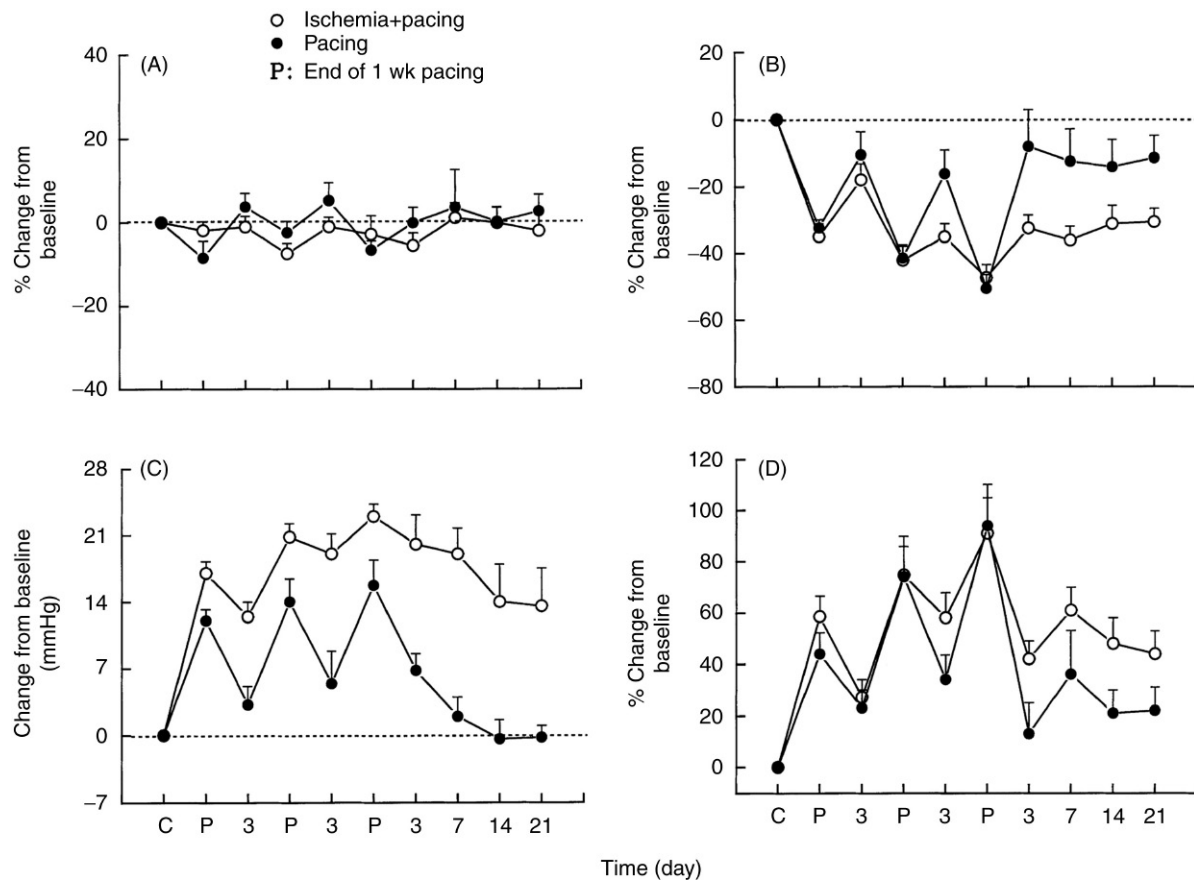
demonstrated that before rapid pacing is applied (i.e, 2 months after coronary ligation), LV dP/dt was slightly decreased compared with control, indicating that MI even after 2 months does not cause a significant reduction in left ventricular function. Following rapid ventricular pacing, LV dP/dt was significantly reduced, while left ventricular end-diastolic pressure was significantly increased. Using this model, left ventricular mass, based on the direct measurement of LV/body weight ratios, was demonstrated to be increased compared with control, indicating that left ventricular hypertrophy is also


FIGURE 6.19   Time course if changes in mean arterial pressure (A), cardiac index (B), mean left atrial pressure (C), and total peripheral resistance (D) before (C) and after three 1-week periods of pacing (P) separated by 3 days of rest and during a 21-day postpacing recovery period in conscious pigs. Note that there were differences in all indices except for mean arterial pressure during the recovery period between pacing alone and pacing combined with myocardial ischemia groups (Shen et al., 1999).

produced. Given the reduction in cardiac mass induced by scar formation, the degree of hypertrophy is likely to be greater than that suggested by the cardiac weight alone (Shen, 2010; Shen et al., 2005). Fig. 6.22 shows the results of cardiac function and LV /body weight in conscious monkey model with heart failure. Clearly, the nonhuman primate model enables the investigation of all stages of heart failure, from initial myocardial ischemia to compensated left ventricular hypertrophy leading to end-stage of decompensated heart failure. This model provides a unique opportunity for elucidation of cardiovascular disease mechanisms and also the evaluation of novel interventions.

By using the same concept, the heart failure model can also be induced by pressure overloaded, that is, banding aorta, induced left ventricular hypertrophy followed by rapid pacing (Shen et al., 2010). Table 6.1 shows that left ventricular hypertrophy (LVH), just like MI alone, does not reduce baseline cardiac function. However, when myocardial ischemia or left ventricular hypertrophy combined with pacing, significantly decreased left ventricular dP/dt and increased left ventricular end

diastolic pressure is observed. The combination of two different approaches generates a better model for study of heart failure.

4.4 Cardio-Renal Syndrome Induced by Biventricular Dysfunction

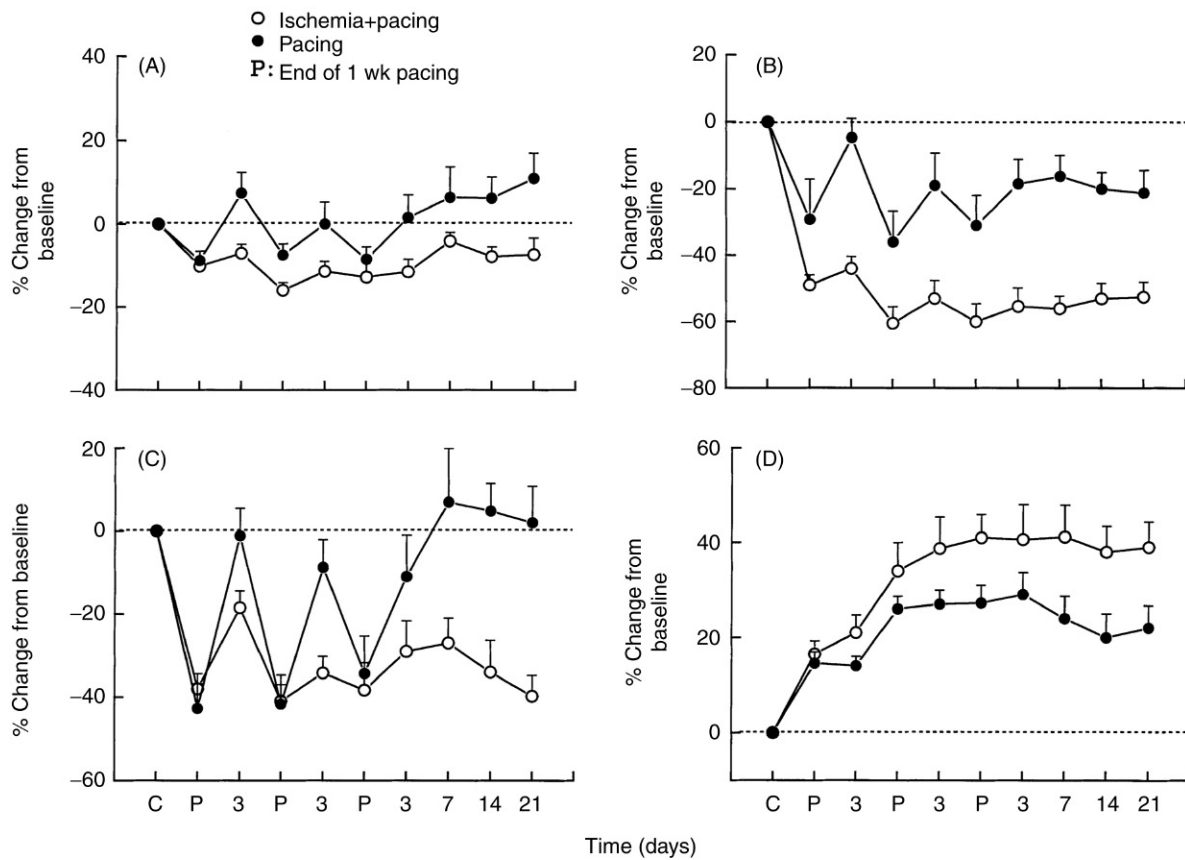
A number of interactions between heart and kidney disease have been described and are termed the cardio-renal syndrome. The interaction is bidirectional, that is, heart or kidney can induce acute or chronic dysfunction in the other organ. It has been well accepted that this cardiovascular disorder is often much worse than isolated heart or kidney dysfunction alone. Despite severe left ventricular contractile dysfunction, animal models of heart failure are often associated with preserved renal function until the terminal stages of heart failure. Clinical studies have demonstrated an association between renal dysfunction in heart failure and right, rather than left ventricular dysfunction (Damman et al., 2009; Mullens et al., 2009; Testani et al., 2010). This observation is likely explanation why animal models fail to exhibit


FIGURE 6.20 Time course if changes in left ventricular (LV) systolic pressure (A), LV fractional shortening (B), LV dP/dt (C), and LV end diastolic dimension (D) before (C) and after three 1-week period of pacing (P) separated by 3 days of rest and during a 21-day postpacing recovery period in conscious pigs. Note that all indices were stable after cessation of pacing in the pacing combined with myocardial ischemia, compared to pacing alone groups (Shen et al., 1999).

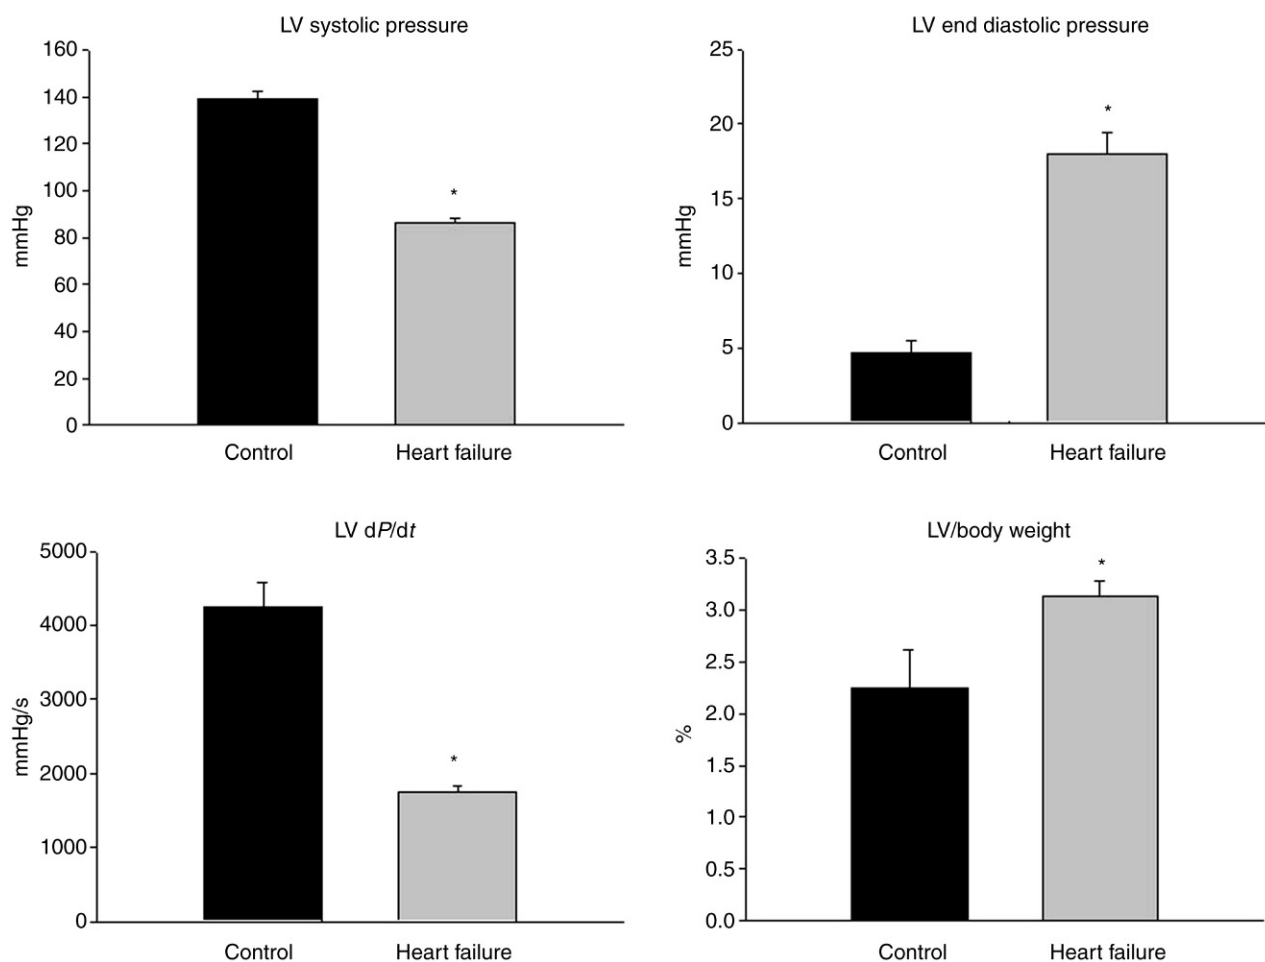
Hemodynamic and LV/body weight in control and heart failure monkeys


FIGURE 6.22 **Averaged date from monkey model of heart failure.** Note that LV function, as assessed by LV systolic pressure, LV dP/dt, and LV end diastolic pressure, were significantly altered at the end of stage of heart failure compared to control. LV/body weight was also elevated significantly (Shen et al., 2005).

TABLE 6.1 Baseline Values in Conscious Dogs Before Pacing (Normal, MI, and LVH) and in Conscious Dogs After Pacing (MI-sHF and LVH-sHF) (Shen et al., 2010)

	Before Pacing			After Pacing	
	Normal ($n = 4$)	MI ($n = 5$)	LVH ($n = 7$)	MI-sHF ($n = 6$)	LVH-sHF ($n = 5$)
Mean arterial pressure (mm Hg)	92 ± 6.6	88 ± 2	93 ± 1.8	87 ± 5.0	89 ± 5.3
Heart rate (bpm)	90 ± 7.2	116 ± 11[†]	123 ± 3.4*	143 ± 7.1*	142 ± 7.2*
Mean left atrial pressure (mm Hg)	3.4 ± 1.0	6.8 ± 1.5	4.6 ± 0.5	25 ± 0.9*[†]	22 ± 2.1*[†]
LV systolic pressure (mm Hg)	115 ± 4.7	110 ± 1.5	188 ± 6.6*	101 ± 5.2	133 ± 11
LV end-diastolic pressure (mm Hg)	7.3 ± 1.7	7.6 ± 0.7	11 ± 0.9	28 ± 2.4*	29 ± 2.5*
LV dP/dt max (mm Hg/s)	2861 ± 180	3425 ± 215	3705 ± 281	1663 ± 111*	1780 ± 93*

* $P < 0.05$ versus normal.
† There is 1 less animal in this measurement than for all others in this group.

renal dysfunction, since existing animal models manifest predominantly left ventricular dysfunction. Accordingly, we have accomplished and characterized a combined microembolization in pulmonary circulation followed by rapid ventricular pacing in pig species to induce biventricular dysfunction which mimics the cardiorenal syndrome seen in patients.

A schematic illustration of surgically-implanted instrumentations and the experimental protocol are shown in Figs. 6.23 and 6.24, respectively. After recovery from surgery, repeated infusions of glass microspheres into the pulmonary circulation via pulmonary artery catheter is performed for about a month. The rapid ventricular pacing at a rate of 220–230 bpm is initiated after the first week of glass microspheres is injected. Cardiac and renal vascular dynamics are monitored twice a week during the development of biventricular dysfunction. Fig. 6.25 shows a representative waveform record from a conscious pig subjected to microsphere injection followed by 3 weeks of rapid ventricular pacing. Both left and right ventricular functions, that is, LV dP/dt, right atrial pressure, as well as, renal blood flow were significantly changed compared to baseline. The average cardiac and renal vascular dynamic results are shown in Fig. 6.26 (A and B). These data support the notion that right ventricular dysfunction is important for interaction between heart and kidney. One of major limitations for this model development is that the amount of microspheres and number of injections are variable between the individual animal. Therefore, adjustment of the injection requires the hemodynamic monitoring continuously during the
FIGURE 6.23 Schematic illustrations of instrumentation implanted for measurements of left ventricular (LV) pressure gauge, ascending aortic and renal blood flow probes along with catheters for different pressure measurements (unpublished data).

time of each injection and then frequently monitored during the entire course of model development. To optimize the protocol and achieve a consistent and predictable result, further studies are needed.

5 MODELS WITHOUT CARDIOVASCULAR DISEASES

5.1 Vascular Stiffness in Aging and Gender

It has been recognized increased vascular stiffness with aging represents an independent cardiovascular risk factor (O'Leary et al., 1999). Although rodent species can be served as a useful model for study of aging, major limitation is the species difference between rodent and human. In addition, due to the size of vessel from rodent species, a direct physiological measurement of vascular stiffness in conscious animals, which requires both pulse pressure and vascular diameter, is not possible. A schematic illustration of surgically implanted instrumentations for study of vascular stiffness in non-human primates, specifically rhesus monkeys, is shown in Fig. 6.27. All instrumentations implanted are similar to those described in the previous section. Aortic diameter is measured with miniature piezoelectric ultrasonic dimension crystals. Experiments can be conducted in fully conscious animals using the same set up system as shown in Fig. 6.6.

Aortic strain is calculated as systolic aortic diameter—diastolic aortic diameter (Dd)/Dd. Pressure strain (Ep) is calculated as K $\times$ (systolic blood pressure − diastolic blood pressure)/aortic strain (K = 1333). Aortic stiffness (β) is computed by In(Ps/Pd)/aortic strain (Qiu et al., 2007; Zhang et al., 2016). Baseline of aortic stiffness in male young and old, female young and old monkeys are shown in Fig. 6.28. Pulse pressure was increased in

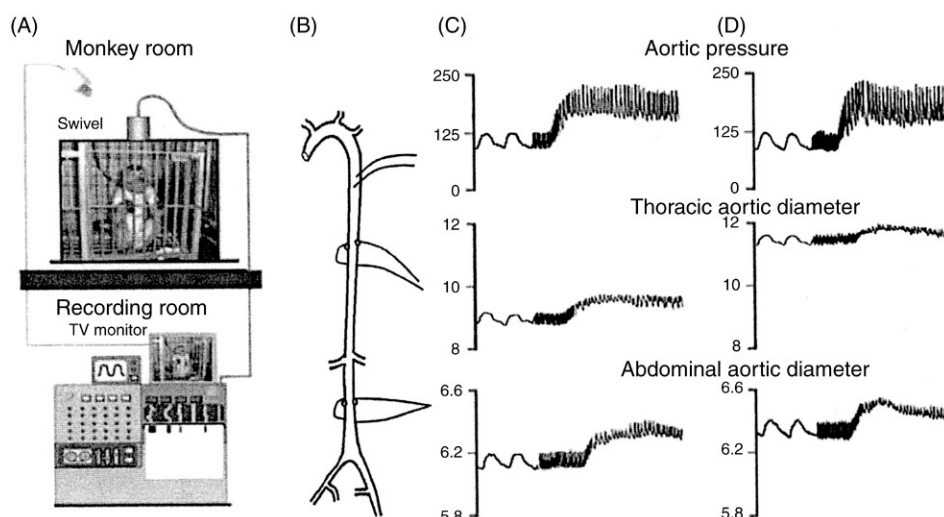
Note that both left and right ventricular function along with renal hemodynamic were impaired significantly compared to baseline (unpublished data).


FIGURE 6.27 (A) A chronically instrumented, conscious monkey was connected to a tether system; (B) the aorta was instrumented with descending thoracic aortic catheter for measurement of aortic pressure and ultrasonic dimension crystals on opposing surface of the thoracic and abdominal aorta for measurements of aortic diameters. Examples of response to acute phenylephrine-induced hypertension are shown in young monkey, (C) and in old monkey (D) (Zhang et al., 2016).
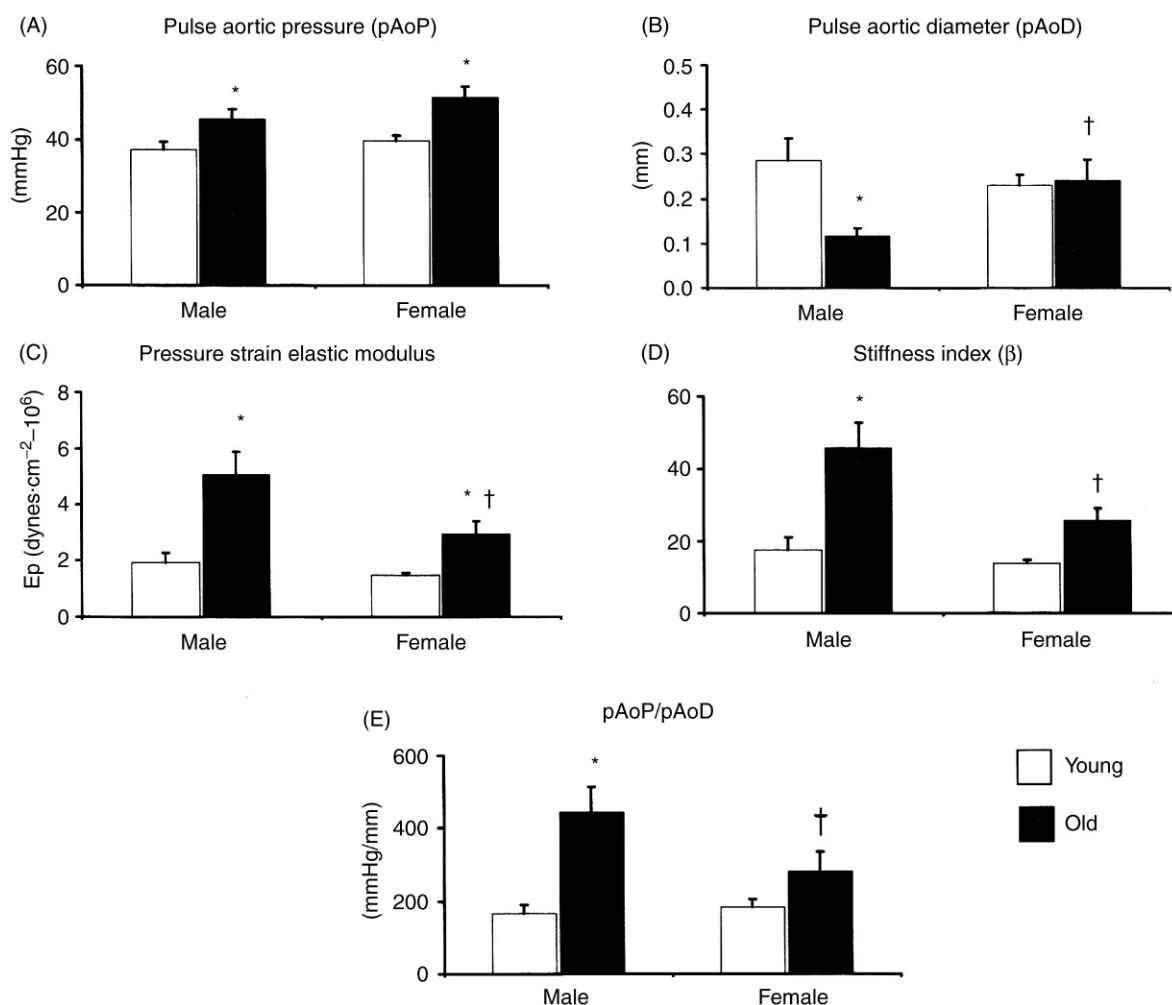

FIGURE 6.28 **Baseline aortic stiffness in young and old male, young and old female conscious monkeys.** Measurement of pulse aortic pressure (pAoP; A), pulse aortic diameter (pAoD; B), pressure strain elastic modulus (Ep; C), stiffness index (β; D), and ratio of pAoP to pAoD (E) are compared in these 4 groups. *$P < 0.05$ versus corresponding young monkeys; [†] $P < 0.05$ versus corresponding old male monkeys (Qiu et al., 2007).

both male and female old monkeys, while mean aortic pressure was similar among the four groups. Pulse diameter was greater in old females than old males. These differences in pulse diameter account for the greater increase in the pressure strain elastic modulus (Ep) and the stiffness index (β) in old male monkeys compared with old female monkeys, which reflects the increased stiffness with aging in male monkeys.

5.2 Cardiovascular Denervation

Heart transplantation is an alternative approach for patients with end stage of heart failure. It is well-known that all nerves from the original heart will be destroyed and replaced by donor heart nerves without external nerve supply. Therefore, heart transplantation has also been considered as a surgical procedure of total cardiac denervation. In patients with severe coronary artery stenosis leading to coronary artery occlusion, bypass surgery, that is, coronary artery bypass graft, has been also extensively used to restore blood supply in patients. This surgical procedure, however, also partially or completely destroys the innervation of myocardium that are perfused by the coronary artery, since majority of cardiac sympathetic nerve fibers are located subepicardially and travel along the routes of major coronary arteries. Thus, total or selective cardiac denervated animal models are required to model these clinical surgical approaches. In addition, it is important to unitize denervated animal models to understand the role and mechanism of cardiovascular control in preclinical drug research and development.

5.2.1 Selective Regional Left Ventricular Denervation

Regional ventricular denervation can be performed in either posterior or anterior left ventricular wall in larger animal species, as long as main and branch of coronary arteries can be surgically dissected and separated from myocardium. The procedure often requires a combination of surgical and chemical techniques (Kudej et al., 2006; Randall and Ardell, 1985). There are three major steps to complete the procedure, for example, posterior left ventricular denervation. First, the ventrolateral cardiac nerve at the point of the left superior pulmonary vein needs to be isolated and sectioned completely. Second, the left circumflex coronary artery from all is surrounding tissue starting at proximal to the left marginal branch and continuing to the posterior descending coronary arteries. The last procedure is to apply phenol to the atrioventricular groove above the isolated portion of the left circumflex coronary artery, all the way down the posterior groove to the apex and also down the marginal branch of the left circumflex coronary artery to the apex. The phenol can be given by using a small cotton-tripped

applicator to carefully apply to the surface of dissected areas. The procedure for anterior left ventricular wall denervation is similar to the posterior wall denervation. The confirmation of the regional denervation can be accomplished by examination of tissue norepinephrine level from the denervated area compared to innervated contralateral area. In the tissue from denervated area should be essentially depleted compared to contralateral area of tissue.

5.2.2 Left Ventricular Denervation

Left ventricular denervation can be performed by using either a combination of surgical and chemical techniques as described earlier or the surgical technique alone (Randall and Ardell, 1985; Shen et al., 1988, 1990a). Basically, the surgical procedure consists of dissection across the superior surface of the left atrium and sectioning of the ventrolateral cardiac nerves and then stripping the adventitial layers of the main pulmonary artery distal to its origin on the side facing the left atrial surface. The next step is to remove all nerves located between the aorta and pulmonary artery that project onto the surface of the left ventricle over the left main coronary artery. The phenol can be applied around the circumference of the atroventricular groove and to the triangular-shaped fat pad above the coronary sinus on the posterior wall as an optional approach. If the surgical procedure is well accomplished, the application of phenol is not necessary. Total ventricular denervation can be confirmed at the time of surgery by lack of increase in left ventricular contraction and rate during direct electrical stimulation of the left and right ansae subclaviae at a 10 Hz, 5 ms with 5–7 V, which is completely different from what is observed before the surgical denervation procedure is started. The denervation can be further confirmed using tissue norepinephrine level as described earlier.

5.2.3 Total Cardiac Denervation

Total cardiac denervation can be performed by either chronic permanent (Randall et al., 1980; Shen et al., 1990b) or acute reversible procedures (Arndt et al., 1981; Dorward et al., 1983; Shen et al., 1991). The chronic total cardiac denervation procedure is to use the intrapericardial denervation technique by surgically stripping the adventitia and nerve fibers from the main pulmonary artery, left superior pulmonary vein, and right pulmonary artery; sectioning the left ventrolateral cardiac nerve and the pericardial reflection in the transverse sinus and azygos vein. Furthermore, dissection around the pericardial reflection at the bifurcation of the right pulmonary artery needs to be completed. The completeness of the total cardiac denervation can be verified at surgery by confirming the lack of ECG response to bilateral stellate ganglion stimulation at a 10 Hz, 5 ms with 3–5 Vor bilateral vagal stimulation at a 20 Hz, 5 ms with 3–5 V. The denervation can be further

confirmed by tissue norepinephrine level from both right and left ventricles. Acute reversible total cardiac denervation is a relatively easy and fast approach for studies to compare the presence and absence of total cardiac denervation in same animals. The procedure only requires implanting a catheter in the pericardial space and acute denervation can be induced by injection of anesthetics, for example, procaine or lidocaine, into the pericardial space periodically during the experiment. The amount of anesthetics and duration between two injections depend on the size of heart and drug half-life.

The total cardiac denervation both chronic and acute models can be also examined by a pharmacological approach, that is, elimination of the reflex heart rate changes induced by either efferent or afferent stimulations. Usually, a vasodilator and vasoconstrictor, for example, phenylephrine and nitroglycerin, can be administered intravenously. Also, injection of veratridine alkaloid via the left atrium to determine reflex cardiovascular actions mediated from receptors in the myocardium (Shen et al., 1990b).

5.2.4 Sinoaortic Baroreceptor Denervation

Sinoaortic baroreceptor located in aorta and carotid arteries plays important role in regulating arterial blood pressure and blood volume. The denervation procedure needs to be performed in both areas with a combination of surgical and chemical approaches. Aortic denervation is accomplished by stripping all nerve fibers and connective tissue from the aortic root to the second intercostal artery (Shen et al., 1990b, 1991). The brachiocephalic and the subclavian arteries are also stripped from the aorta cranially to the second set of branches. After that, the carotid sinus denervation needs to be performed in both right and left common carotid arteries. Both arteries should be carefully isolated and stripped of nerve fibers and connective tissue all the way past the bifurcation of the internal and external carotid arteries. Phenol is applied to all stripped surfaces of the vessel. The confirmation of sinoaortic baroreceptor denervation can be determined by a similar pharmacological method as described earlier. The lack of reflex heart rate changes in response to alterations of arterial blood pressure can be observed when either a vasodilator or vasoconstrictor is injected intravenously. However, the response to left atrial injection of veratridine alkaloid should remain intact, indicating that the cardiac receptor is not affected by the surgical procedures (Shen et al., 1990b).

6 FUTURE DIRECTIONS

With advances in molecular and genomic research offering novel insights into the cardiovascular diseases, many transgenic mouse models have been developed and characterized. The major advantage of genetically engineered models is that a specific cellular target can be manipulated, and its role in pathogenesis established. This has led to an explosion of potential targets for therapeutic intervention. In the current chapter, we emphasize the need to validate novel targets in well-characterized, larger animal models that provide better potential for clinical translatability. Without this important translational step, many exciting research discoveries from mouse models could fail to translate into improved clinical outcomes in human studies, which has unfortunately become the norm rather than the exception. As such, it is reasonable to rethink our research strategy to include validation in clinically relevant larger animal models before proceeding to clinical trials. We have highlighted most of the existing larger animal models that can be studied in the conscious, chronically instrumented state. This unique experimental approach is vital to the accuracy and validity of experimental findings. Furthermore, advances in the development of larger animal models with multiple disorders, rather than single disorders, allow the examination of important clinical syndromes, such as cardiorenal syndrome and diabetic cardiomyopathy.

Importantly, these cardiovascular syndromes are often much worse than heart or kidney disease alone. Our preliminary and feasibility studies presented in this chapter are to call attention for future direction of translation cardiovascular medicine. Thus, while reductionist approaches are useful identifying cardiovascular targets of therapeutic interest, larger animal models of cardiovascular disease and syndromes are essential in the study of disease mechanisms, as well as target validation.

Cardiovascular Models: Heart Secondarily Affected by Disease (Diabetes Mellitus, Renal Failure, Dysfunctional Sympathetic Innervation)

Jitka Sviglerova, Jitka Kuncova, Milan Stengl

Biomedical Center, Charles University, Pilsen, Czech Republic

1 THE HEART AND DIABETES MELLITUS

Diabetes mellitus represents a serious medical problem with increasing prevalence in both developed and developing countries that has reached a global epidemic level with significant social and economic consequences. Diabetes mellitus may be classified as type 1 diabetes (insulin-dependent) or type 2 diabetes (noninsulin-dependent). Type 1 diabetes is characterized by a complete (or almost complete) lack of endogenous insulin due to destruction of β-cells in pancreatic islets of Langerhans. This chapter will be focused on animal models of type 1 diabetes mellitus and cardiovascular complications that accompany the disease. The cardiovascular diseases are the primary cause of death in diabetic patients and the prevalence of and mortality from cardiovascular

diseases are several fold higher in patients with diabetes mellitus than in the general population. One of the most important cardiovascular complications is a diabetic cardiomyopathy characterized by an early diastolic and later systolic dysfunctions, (Mahgoub and Abd-El-fattah, 1998) microangiopathy, hypertrophy of cardiac myocytes, (Gargiulo et al., 1998), and finally by heart failure (Jarret, 1989). The possible mechanisms of diabetic cardiomyopathy include metabolic disturbances, myocardial fibrosis, small vessel disease, cardiac autonomic neuropathy, and insulin resistance (Fang et al., 2004).

Various experimental models may be used for studying the type 1 diabetes mellitus and associated complications. Spontaneous hyperglycemia and ketoacidosis occur in BB rats, in which pancreatic insulitis rapidly followed by selective destruction of β-cells develops between 50 and 90 days of age (Mordes et al., 1987). Another model of spontaneous autoimmune diabetes is the nonobese diabetic (NOD) mouse (Makino et al., 1980). These mice develop insulitis at the age of 5 weeks and by 7 months 80% of female and 20% of male mice become diabetic. Beside these spontaneous models, the β-cell may be destroyed by experimental viral, surgical, or pharmacological interventions. The viral induction of diabetes was demonstrated with encephalomyocarditis virus or Kilham rat virus in rats (Jordan and Cohen, 1987; Yoon and Jun, 2006). For pharmacological induction of diabetes, usually alloxan or streptozotocin are used (Dunn et al., 1943; Rakieten et al., 1963). This chapter will further focus on streptozotocin-induced diabetes mellitus in laboratory animals with special emphasis on the rat model of streptozotocin-induced diabetes mellitus.

2 METHODOLOGICAL ASPECTS

Streptozotocin (2-deoxy-2-(3-methyl-3-nitrosoureido)-D-glukopyranose), an antibiotic with antineoplastic effects produced by *Streptomyces achromogenes* bacteria, destroys selectively the β-cells of pancreatic islets of Langerhans (Fig. 7.1) (Junod et al., 1967). Streptozotocin induces DNA strand breaks and DNA alkylation that leads to necrosis of pancreatic β-cells (Elsner et al., 2000; Yamamoto et al., 1981). Streptozotocin is transported inside the β-cell by the glucose transporter GLUT2 and expression of GLUT2 is therefore required for the toxic effect (Elsner et al., 2000; Schnedl et al., 1994). The signaling pathways of the toxic effect of streptozotocin involve activation of inducible NO-synthase, increase in NO concentration, (Flodström et al., 1999) increased H_2O_2 generation (Takasu et al., 1991).

Development of diabetes mellitus after the application of streptozotocin is very fast, especially in the rat. The sensitivity of β-cells to glucose is significantly reduced already 2 h after application of streptozotocin, the destruction and significant reduction of the number of β-cells occurs in several hours after application (West et al., 1996). This is accompanied by changes in glucose and insulin plasma levels: 2 h after application a hyperglycemia with no changes in plasma and pancreatic insulin levels develops, followed by hypoglycemia with increased plasma levels of insulin but no change in pancreatic insulin level. One day after application of streptozotocin, the rats show all characteristic symptoms of diabetes including hyperglycemia, glycosuria, polyuria, reduced plasma, and pancreatic insulin levels (Junod et al., 1969).

Streptozotocin may be applied in a single dose or in repeated manner, usually dissolved in citrate buffer (pH 4.5), by intravenous, intraperitoneal, or intraarterial injection. In our experiments, diabetes was reliably induced by a single intravenous injection of streptozotocin dissolved in citrate buffer in tail vein at dose of 65 mg/kg body weight. The dose necessary for diabetes induction in rats varies between 40 and 60 mg/kg body weight, although higher values are sometimes reported (Ganda et al., 1976). The diabetic symptoms correlate well with the dose used. In general, in doses below 40 mg/kg body weight only slight changes in glycemia, glycosuria, and insulin plasma levels are observed and
FIGURE 7.1 **Histology and immunohistochemistry of the pancreatic islets of Langerhans in control** *(left panel)* **and streptozotocin-induced diabetic** *(right panel)* **rats.** In diabetic rats, the number and size of islets was reduced and the immunoreactivity for insulin was diminished.

these slight changes tend to normalize spontaneously in up to 25% of animals (Junod et al., 1969). With a sufficient dose of streptozotocin, the induction of diabetes in rats is easy, fast, and reliable. In a majority of studies employing this rat model, however, the pathogenesis of diabetes and associated symptoms were usually studied just for several weeks or months during which diabetes is fully developed and maintained. The long-term effects of streptozotocin and possible recovery from streptozotocin-induced diabetes are explored much less. In our experiments, we followed the rats with streptozotocin-induced diabetes for one year and a recovery was observed in a significant portion of animals. All 152 rats showed fully blown diabetes for the first 6 months of experiment. In the second half of the year, two different groups could be clearly distinguished. In the diabetic group ($n = 92$) the glycemia remained high (above 18 mmol/L), the body weight did not grow, plasma levels of insulin were kept low, and histological analysis revealed reduction in number and size of pancreatic islets with a lack of insulin-secreting cells. In contrast, the recovery group ($n = 60$) showed in the second half of the year significant differences that were not present in the first 6 months of experiment: lower glycemia (below 12 mmol/L), steadily growing body weight, higher plasma levels of insulin that approached values found in control animals (Fig. 7.2). Also, the histological structure of pancreatic islets was similar to control animal with a number of well-preserved β-cells. Therefore,

after 6 months there was a significant group of animals (~40%) that showed a significant recovery with a number of parameters approaching values in control, nondiabetic animals. The only test that was able to reliably distinguish the recovery animals from nondiabetic controls was the glucose tolerance test. The glucose tolerance test was performed in the 9th and 12th month of the experiment and the curve clearly showed pathological values similar to the diabetic group and significantly different from those of control nondiabetic animals. Both streptozotocin groups responded by a decreased secretion of insulin. In conclusion, the streptozotocin-induced diabetes mellitus in rats was stable for 6 months, afterward, however, a significant recovery developed in ~40% animals. The functional insufficiency of the recovery in this period (7–12 months after streptozotocin application) may be uncovered by the glucose tolerance test. The insulin secretion in recovery animals is probably sufficient at rest, however, an increased glucose load unmasks the still impaired glucose tolerance (Fig. 7.3). In majority of animals (~60%) no recovery was observed and severe diabetes persisted throughout the period of 12 months. A spontaneous recovery from streptozotocin-induced diabetes was already described in neonatal rats, in which streptozotocin was applied at birth, (Garofano et al., 2000) or in adult animals but with low dose streptozotocin (Rakieten et al., 1976; Su et al., 2000).

Beside rat, streptozotocin is used for induction of diabetes also in other species. In mice, the type 1 diabetes

may be induced either by a single higher dose of streptozotocin or by repeated application of lower doses, both applied intraperitoneally. In case of single dose application, a reliable induction is described for doses of 200 mg/kg (Anderson et al., 1974; Guz et al., 2002). A serious disadvantage of single dose application is very high immediate lethality (up to 90% for 180 mg/kg in our hands). Repeated application of streptozotocin is usually performed with doses of 40–50 mg/kg daily applied for five consecutive days (Carlsson et al., 2000). The characteristic diabetic symptoms (hyperglycemia, glycosuria, stagnant body weight) develops after application of the last dose. The mice typically show significant intergender differences: in male mice the plasma levels of glucose after streptozotocin application were significantly higher than in female mice. Since testosterone administration is known to increase the hyperglycemic response in castrated males and females, as well as in noncastrated females, it probably contributes to the diabetogenic effects of streptozotocin (Rossini et al., 1978).

The diabetogenic effects of streptozotocin in guinea pig are controversial. According to some studies, guinea pigs are resistant to the diabetogenic effects of streptozotocin (Kushner et al., 1969). In contrast, other studies describe a reliable guinea pig model of streptozotocin-induced diabetes on basis of reduced growth rate, beta cell dysfunction, polydipsia, polyuria, and glycosuria (Schlosser et al., 1987). Differences in the experimental methods of diabetes induction, especially dosing and application, may be responsible for these discrepancies. The most recommended methods include intracardiac application of streptozotocin (200 mg/kg) preceded by insulin administration, (Aomine et al., 1990) intracardiac injection of streptozotocin (150 mg/kg) without insulin, (Schlosser et al., 1987) or intravenous application of streptozotocin (Gorray et al., 1986). Based on differences in the method of diabetes induction, also the diabetic parameters, the time course of the disease or associated lethality differ between the models. In our experimental conditions, whereas the intraperitoneal application of streptozotocin (300 mg/kg) did not induce any diabetic symptoms, the intravenous administration of streptozotocin (150 mg/kg) lead to significant glycosuria. The histological analysis of pancreas did not reveal any signs of destruction of islets regardless of the method of streptozotocin administration. Even the glycosuria observed after intravenous administration of streptozotocin may not be the diabetic symptom but rather a result of a direct nephrotoxic effect of streptozotocin that was described in patients. This hypothesis is supported by the fact that a daily administration of insulin (5 i.u./kg) did not prevent the glycosuria.

With regard to the rabbit model of diabetes, the studies using the alloxan-induced model clearly prevail. The studies with streptozotocin-induced diabetes in rabbit are rare and contradictory. There is some evidence about diabetogenic effects of streptozotocin in adult rabbits, as well as fetuses but other studies argue

against this possibility (Chaffin et al., 1995; Kedar and Chakrabarti, 1983; Kushner et al., 1969; Lazarus and Shapiro, 1972; Lazar et al., 1968).

From large mammals, streptozotocin was successfully used to induce diabetes in dog and pig. In dog the application of streptozotocin was associated with high mortality and therefore several techniques were developed to reduce the dose of streptozotocin and the associated mortality. Freyse et al. (1982) combined partial pancreatectomy and low dose (2 mg/kg) streptozotocin infusion into the superior pancreaticoduodenal artery. Other techniques include a combined intravenous administration of streptozotocin and alloxan or suprarenal intraarterial infusion of streptozotocin and alloxan after balloon occlusion of the juxtarenal abdominal aorta (Liu et al., 2000; Salis et al., 2001). Another large mammal species sensitive to the diabetogenic effects of streptozotocine is pig (and minipig). For a reliable diabetogenic effect of streptozotocin in both pig and minipig a dose of 100–150 mg/kg is needed (Gäbel et al., 1985). In minipigs a successful induction of diabetes by two low doses (40 mg/kg) was also reported (Rolandsson et al., 2002).

3 EXPERIMENTAL RESULTS IN THE RAT MODEL OF STREPTOZOTOCIN-INDUCED DIABETES

3.1 Diabetes and Cardiac Contractility

Effects of chronic (16 weeks) streptozotocin-induced diabetes on cardiac contractility were investigated using the right ventricle papillary muscles (Svíglerová et al., 2005). Streptozotocin-induced diabetes decreased the contraction force of the papillary muscles considerably. Furthermore, the dependence of the contraction force on stimulation frequency was reduced, especially at lower rates (<1 Hz). The kinetics of contraction were also influenced, diabetes prolonged significantly both the time to peak contraction and relaxation time. Next, the effects of insulin on cardiac contractility were investigated in both control and diabetic animals. Surprisingly, insulin reduced the contraction force in both control and diabetic groups (Fig. 7.4). To elucidate the negative inotropic effects of diabetes and of insulin in more detail, additional experiments aimed at various stages of excitation–contraction coupling were performed.

First, the rest potentiation of cardiac contraction was tested. In rats, the first contraction after a period of rest is increased. This phenomenon is called post-rest potentiation of contraction and it mainly reflects function of the Na^+/Ca^{2+} exchange and of the sarcoplasmic reticulum Ca^{2+} pump (Bers and Christensen, 1990; Shattock and Bers, 1989). Steady-state stimulation (1 Hz) was interrupted by a rest period of variable duration and the first postrest contraction was always increased (Fig. 7.5). In diabetic myocardium the postrest potentiation of contraction was preserved, however, the increase in postrest contraction was less pronounced (Fig. 7.5). Furthermore, the dependence of potentiation on the duration of the resting period was flatter in diabetic rats than in control rats. Insulin did not influence the postrest potentiation in control rats but it significantly enhanced the
FIGURE 7.4 **The effect of insulin on the contraction force in control and diabetic rats.** The dependence of contraction force (CF) on stimulation frequency in control (A) and diabetic rats (B). Values were normalized to the contraction force at 1 Hz in baseline solution. *Open squares*, baseline; *filled circles*, effect of insulin (80 i.u./L). * Significantly different from baseline ($P < 0.05$). FIGURE 7.5 **The postrest potentiation of contraction in control and diabetic rats.** *Open squares*, control rats; *filled circles*, STZ-diabetic rats. *, significantly different from control rats (*P* < 0.05). The upper inset: the last steady-state contraction (SS) and the first postrest contraction (postrest) of the right ventricle papillary muscle in the rat. Left, control animal; right, diabetic rat. a.u., arbitrary units.

phenomenon in diabetic rats. This strongly suggests that the negative inotropic effect of insulin is not mediated by influencing processes of sarcoplasmic reticulum Ca^{2+} loading.

To verify this further, pharmacological interventions with cyclopiazonic acid, a selective blocker of sarcoplasmic reticulum Ca^{2+} pump (SERCA2) and with nifedipine, a blocker of sarcolemmal Ca^{2+} transport through L-type Ca^{2+} channels (L-type Ca^{2+} current, ICaL), were employed. Cyclopiazonic acid (3 μmol/L) showed a negative inotropic effect, this effect being similar in both control and diabetic animals. Cyclopiazonic acid also slowed down the relaxation, especially the second half of it. Administration of insulin on top of cyclopiazonic acid further decreased the contraction, again in both control and diabetic rats. The insulin-dependent decrease of contraction in the presence of cyclopiazonic acid was similar to that in the absence of it. This again suggests that the Ca^{2+} uptake to sarcoplasmic reticulum by SERCA2 is not a major determinant of the negative inotropic effect of insulin and that different mechanisms must be involved. Nifedipine (3 μmol/L) diminished the contraction force in both experimental groups and this effect was strongly dependent on stimulation frequency as reported previously being much more pronounced at high frequencies (Schouten and ter Keurs, 1991). Administration of insulin on top of nifedipine did not affect the contraction further. This lack of effect of insulin in the presence of nifedipine was also observed at low frequencies of stimulation, in which the reduction of contraction by nifedipine was only minor. These data suggest that

insulin inhibits ICaL and the reduction of ICaL leads to the negative inotropic effect. In the presence of nifedipine, which binds to ICaL channels, this inhibitory action of insulin would be prevented. However, the effect of insulin on ICaL was investigated directly using the patch-clamp method in rat isolated ventricular myocytes (Aulbach et al., 1999). In contrast to the aforementioned hypothesis, no inhibition but stimulation of ICaL by insulin was found. If this is also the case in our experimental conditions of multicellular preparation, the impairment of triggering SR Ca^{2+} release by ICaL (decreased efficiency of this process) remains as the most likely mechanism. The central finding of the negative inotropic effect of diabetes corresponds well with other studies that indicate a vast number of cellular mechanisms contributing to this phenomenon: depression of sarcoplasmic reticulum Ca^{2+}-ATPase and its enhanced inhibition by phospholamban, (Ganguly et al., 1983; Teshima et al., 2000; Vasanji et al., 2004) defective sarcolemmal Ca^{2+}-ATPase, (Heyliger et al., 1987; Makino et al., 1987) depression of Na$^+$-Ca^{2+} exchanger, (Chattou et al., 1999; Makino et al., 1987) reduced L-type calcium current, (Chattou et al., 1999; Lee et al., 1992) decreased number of sarcoplasmic reticulum ryanodine-sensitive Ca^{2+} channels, (Teshima et al., 2000; Yu et al., 1994) and alterations of contractile proteins, such as diminished Ca^{2+} sensitivity, shifts in myosin isoenzymes (from V1 myosin with high ATPase activity to V3 myosin with low ATPase activity), (Malhotra and Sanghi, 1997) reduced cross-bridge cycle rate, (Ishikawa et al., 1999) altered myosin heavy chain isoform expression (Rundell et al., 2004).

3.2 Diabetes and Autonomic Cardiac Innervation

Cardiovascular autonomic neuropathy is one of the most common diabetes-associated complications and it contributes significantly to the increased morbidity and mortality of diabetic patients (Kuehl and Stevens, 2012). In the rat model of streptozotocin-induced diabetes the autonomic neuropathy was demonstrated by functional studies, for example, blunted chronotropic responses to both nadolol and atropine suggesting diminished vagal and sympathetic control, diminished circadian variation in the heart rate and altered baroreflex sensitivity (Chang and Lund, 1986; Hicks et al., 1998). We have investigated how diabetes affects the content, release, and uptake of norepinephrine in cardiac sympathetic nerves in early and later stages of streptozotocin-induced diabetes in female rats (Kuncová et al., 2003). In isolated atria, the diabetic state significantly affected norepinephrine concentrations. An initial significant increase (1 month after onset of diabetes) was followed by a sustained decline in tissue noepinephrine concentrations that became significantly different 7 months from the onset of disease

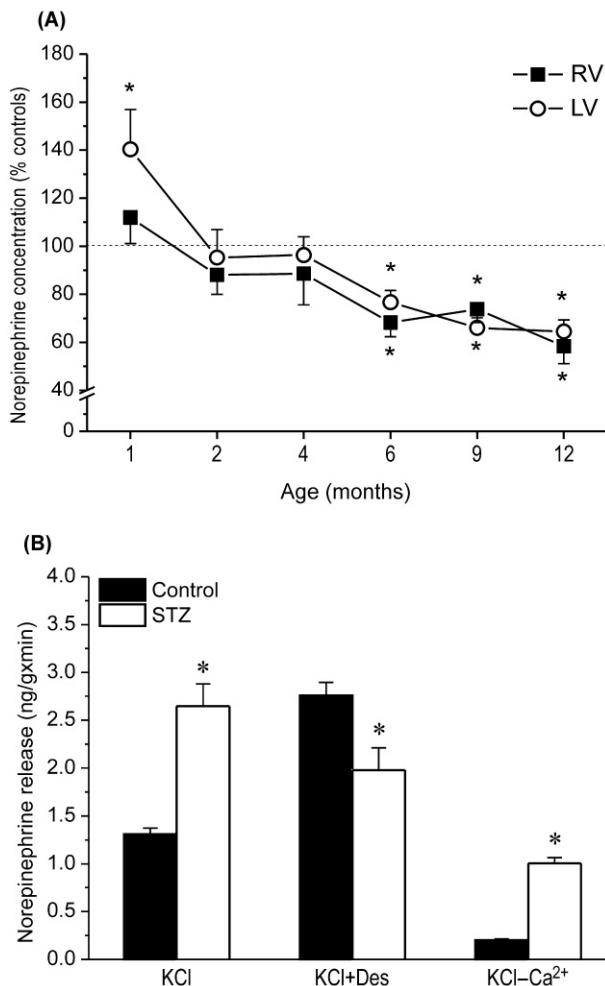
(Fig. 7.6A). Both basal and potassium-evoked releases of norepinephrine were significantly increased 4 months from the onset of disease. The neuronal uptake blocker desipramine significantly reduced both basal and potassium-evoked releases of norepinephrine 4 months from the onset of diabetes suggesting that a substantial portion of norepinephrine release was due to a calcium-independent carrier-mediated process. In experiments with calcium-free solution in the presence of desipramine the potassium-evoked release of norepinephrine was nearly abolished in control rats. In diabetic rats (4 and 7 months from the induction) the potassium-evoked release was still significantly higher than the basal one.


FIGURE 7.6 The impact of STZ-induced diabetes on norepinephrine concentrations in the free walls of the right (RV) and left ventricles (LV) expressed in percentage of the respective control values (*dashed line*) (A). Values are means ± SEM (*n* = 6). *P* < 0.05 compared to the respective control rats. Norepinephrine (NE) release from the atria of STZ-diabetic rats (B). KCl-evoked release of NE in the control atria and preparations from STZ-diabetic rats 4 months after the onset of diabetes (KCl), NE KCl-evoked release in the presence of neuronal uptake blocker desipramine (10–6 mol/L) (KCl + Des), KCl-evoked release of NE in the absence of calcium ions (KCl−Ca^{2+}). Error bars = SEM. *P* < 0.05 compared to the respective control value, *n* = 5.

Therefore, the norepinephrine-releasing mechanisms may remodel in the time course of chronic diabetes and may contribute to the decreased norepinephrine concentration in the atria of rats with streptozotocin-induced diabetes. The increased potassium-evoked release of norepinephrine from the diabetic atria might be attributed to the abnormal function of neuronal transporter (Fig. 7.6B).

Next we focused on the peptidergic innervation of the heart. The cardiac sensory nerve fibers may, in addition to conveying impulses toward the CNS, upon stimulation directly release neuropeptides from their peripheral terminal located within the heart. This mode of action has been termed the local effector function of sensory nerve terminals (Holzer, 1988). Calcitonin gene-related peptide (CGRP) is the major neuropeptide released from such nerve terminals in the heart (Franco-Cereceda and Lundberg, 1988). CGRP was described to exert a number of effects in the heart: CGRP increases heart rate and contractile force in the isolated rat atrium, (Wang and Fiscus, 1989) it is a powerful vasodilator increasing coronary artery perfusion, (Miyauchi et al., 1987; Saito et al., 1987) and it is involved in ischemic preconditioning (Källner and Franco-Cereceda, 1998). Diabetes was reported to abolish the protective effects of ischemic preconditioning and this effect may be related to the reduction in CGRP release in diabetic heart (Kersten et al., 2000; Lu et al., 2001; Tosaki et al., 1996). We therefore analyzed the quantitative changes in cardiac CGRP content and expression of its receptor during diabetes development. CGRP concentrations in diabetic ventricles increased significantly, reaching approximately twofold levels of control at 16 weeks after application of streptozotocin. Also the GRP content of both atria increased in diabetic rats, but the increase was less marked. Immunohistochemistry revealed the known distribution of CGRP immunoreactive varicose nerve fibers around the ascending aorta and coronary vessels, in the atrial myocardium, subendocardial layer including valves, papillary muscles, and within cardiac ganglia. The distribution was not visibly altered by diabetes. The expression of mRNA for the ligand-binding subunit of CGRP receptor, the calcitonin receptor-like receptor, was increased two- to threefold after 4 weeks of diabetes in the right atrium and ventricle and declined thereafter to fall below control levels 16 weeks from the onset of diabetes. The same pattern, although quantitatively less pronounced, was also observed in the left ventricle. The time pattern of the calcitonin receptor-like receptor was different in the left atrium with a decreased expression in the initial phase of diabetes (4 weeks from induction). In contrast to our findings of increased cardiac CGRP content and an unchanged innervation pattern of the heart by CGRP-immunoreactive fibers, the rat sensory dorsal root ganglion neurons were reported to respond to streptozotocin-induced

diabetes with decreased expression of the CGRP precursor (Diemel et al., 1994; Rittenhouse et al., 1996). These discrepant observations are best explained by impaired CGRP release from nerve terminals, leading to intraaxonal accumulation of the peptide despite a reduced supply from the perikaryon. The alterations of the CGRP signaling system in experimentally induced diabetic cardiomyopathy that include both the ligand and its receptor may contribute to functional impairment of cardioprotective mechanisms that involve CGRP released from sensory nerve terminals.

Another peptide that is present in cardiac innervation is neuropeptide Y (NPY). NPY is the most abundant neuropeptide in the cardiac innervation. It is produced by cleavage from a large precursor, preproNPY, and its most prominent source in the heart are the postganglionic sympathetic axons that originate from cell bodies located in the cervicothoracic sympathetic chain ganglia like the stellate ganglion (Gu et al., 1983). NPY elicits multiple effects in the heart: induction of vasoconstriction, (Pernow et al., 1987) modulation of intracellular calcium in endocardial endothelial cells, (Jacques et al., 2003) regulation of protein turnover and of constitutive gene expression in hypertrophying cardiomyocytes, (Nicholl et al., 2002) presynaptic inhibition of noradrenaline release from sympathetic axons, (Lundberg et al., 1984), and induction of angiogenesis (Zukowska-Grojec et al., 1998).

Our analysis by radioimmunoassay revealed a decrease of rat heart NPY content in long-term (6–12 months) streptozotocin-induced diabetes (Kuncová et al., 2005). NPY concentrations in the atria of diabetic rats did not differ from those in age-matched control rats 1, 2, 4, 6 months in the right atria and even 9 months after diabetes induction in the left atria. A significant decrease in NPY levels in the right and left atria was only observed 9 and 12 months after streptozotocin administration, respectively. In the ventricles, NPY concentrations were significantly decreased 6 months after the onset of diabetes. Interestingly, partial spontaneous recovery of diabetes was associated with increased NPY levels in the atria. These data suggest that the cardiac NPY signaling system is affected in diabetes mellitus, which may be of relevance for the pathogenesis of the functional and structural impairment of the heart during progression of the disease. To further test this hypothesis, we investigated the quantitative changes in ligand (preproNPY) and receptor expression within the different chambers of the heart, as well as the extrinsic ganglia that supply axons to the heart. Since neuronal mRNA expression is restricted to the area of the cell bodies, separate analysis of the stellate ganglion and of upper thoracic dorsal root ganglia allowed us to discriminate between changes in the sympathetic and the sensory nerve supply to the heart (Chottová Dvoráková et al., 2008). Ventricular, but not atrial innervation density by NPY immunoreactive

fibers was diminished, and preproNPY expression was transiently (26 weeks) reduced in left atria, but remained unchanged in sympathetic neurons and was not induced in DRG neurons. In all ganglia and heart compartments, Y1 receptor expression dominated over Y2 receptor, and Y1 receptor immunoreactivity was observed on cardiomyocytes and neuronal perikarya. Atrial, but not ventricular Y1 receptor expression was upregulated after 1 year of diabetes. Therefore, at the level of sympathetic and spinal sensory neurons, residing in the stellate ganglion and upper thoracic dorsal root ganglia, respectively, the capacity to express preproNPY and prejunctional receptors (Y1, Y2 receptors) is maintained even 1 year after onset of diabetes. Ventricular sympathetic terminals, however, appear to be affected by long-term diabetes (6 months to 1 year), as revealed by a diminished ventricular NPY content and a reduced innervation density documented by immunohistochemistry (Kuncová et al., 2005). The data indicate that the imbalance of the cardiac intrinsic and extrinsic neuronal NPY-Y1/Y2 receptor signaling system develops slowly in the course of streptozotocin-induced diabetes and that the atria and ventricles are affected differentially. This is in line with a well-known imbalance in diabetic cardiac autonomic neuropathy, in which the parasympathetic branch of the autonomic nervous system is affected more than the sympathetic one and in which the atria and the ventricles are affected differentially (Pourmoghaddas and Hekmatnia, 2003).

3.3 Conclusions and Clinical Implications

In general, the ideal animal model should mimic the human subject metabolically and pathophysiologically and should develop end-stage disease comparable to those in humans (Russell and Proctor, 2006). Obviously, with regard to the complexity of the organism and the multifactorial nature of the disease, there will always be some differences between the animal model and clinical situation and the translation from the model must be very careful. With this limitation in mind, the model of streptozotocin-induced diabetes corresponds to the human diabetes prior to the proper diagnosis and therapy. It allows obtaining important information about early changes developing in various tissues that may later result in serious impairment/failure of organ function. The model is suitable for studying diabetic cardiomyopathy in early stages after induction of the disease but less appropriate for investigating diabetic macroangiopathy (Tomlinson et al., 1992). The diabetic autonomic neuropathy in streptozotocin-induced diabetes resembles the diabetic complication in patients; however, the contribution of underlying mechanisms is probably different: the role of the polyol pathway being probably less important in patients than in diabetic rat (Nakamura et al., 2002;

Pfeifer et al., 1997). With regard to the cardiovascular system, a number of differences between man and rat exist in physiological conditions and these discrepancies may be further accentuated by the disease, for example, in contrast with human disease the diabetic rats show a low blood pressure, a pronounced bradycardia and increased baroreflex sensitivity. In conclusion, the rat model of streptozotocin-induced diabetes provides information that is relevant for the clinical situation, especially about the early stages of diabetes development. However, a number of differences in the organ physiology, as well as in the pathogenesis of the disease must be considered when translating the experimental findings to clinic.

3.4 The Heart and Renal Failure

Renal failure is the inability of the kidneys to excrete waste products and to keep water, electrolyte, and acid-base balance under basal conditions. Renal failure is divided into two types: acute failure characterized by sudden loss of kidney function which can be eventually recovered to normal and chronic failure caused by slow progressive loss of kidney function. Chronic renal failure (CRF) is the end stage of many chronic renal diseases including glomerulopathy, tubulointerstitial nephritis, polycystic kidney disease etc.

CRF is associated with higher risk of cardiovascular complications including hypertension, arteriolosclerosis, arrhythmia, impairment of the cardiac autonomic innervation, and disorder of ventricular myocardium (mainly of the left ventricle). Cardiovascular disorders like ischemic heart disease, heart failure, and sudden cardiac death resulting from aforementioned complication are the leading causes of death in CRF population and account for approximately 50% of all death (London, 2003). The incidence of cardiovascular death in patients with CRF younger than 30 years is even 150 times higher compared to general population (Johnstone et al., 1996). Since CRF has rising incidence and prevalence (the prevalence of CRF in all stages increased from 10% in 1988–94 to 13.1% in 1999–2004 in US adult population) it has become a global health problem (Castro and Coresh, 2009).

3.5 Animal Models of Chronic Renal Failure

To better understand CRF and its complications the experimental animal models were introduced into biomedical research. CRF can be induced by many methods divided into chemical nephrectomy and the remnant kidney model achieved by either vascular ligation (infarction model) or surgical nephrectomy in which approximately 1/6 of the functional renal tissue is preserved. For the chemical nephrectomy the immunological techniques or the nephrotoxic agents like doxorubicin, (Allison et al., 1974; Yoneko et al., 2007) cisplatin, (Heidemann

et al., 1990) uranyl nitrate, (Fukuda and Kopple, 1980), or aristolochic acid are used (Debelle et al., 2004). Vascular ligation model is based on the unilateral nephrectomy followed by ligation of vessel supplying the renal poles of the contralateral kidney (Purkerson et al., 1976). The most frequently used model of CRF is a surgical partial (usually five-sixth) nephrectomy consisting of the unilateral total nephrectomy followed by contralateral partial nephrectomy, by contralateral unilateral renal cortex destruction with electrocoagulation, (Boudet et al., 1978) by cryosurgery, (Kumano et al., 1986) or by contralateral papillectomy (Kroon et al., 1962). The chemical induction of CRF is relatively easy but disadvantages of this method are obvious—a lot of undesirable effect including cardiotoxicity, lower reproducibility, and lower similarity to the human disease (Chow et al., 2003). On the other hand the remnant kidney model is associated mainly with the technical difficulties—hemorrhage and higher mortality due to operative and postoperative complications in surgical nephrectomy and heterogeneity of ligation model due to anatomical variations of the renal artery and possible formation of collateral vessel that bypass the ligated vessel (Liu et al., 2003). The advantages of both the methods, that is, homogeneity in the surgical model and lower mortality of the ligation technique, are connected in the method of renal mass reduction by ligation of the renal parenchyma (Perez-Ruiz et al., 2006).

The first animal partial surgical nephrectomy was performed by Thodore Tuffier in dog at the end of 19th century but no changes in the elimination of urine or urea were found despite the loss of kidney mass (Tuffier, 1889). Since then the surgical method was refined to achieve a characteristic signs of renal failure and the technique was gradually applied in other species including mice, (Gagnon and Gallimore, 1988) rats, (Chanutin and Ferris, 1932; Liu et al., 2003; Platt et al., 1952) rabbits, (Brown et al., 1990) cats, (Adams et al., 1994) piglets, (McKenna et al., 1992) sheep, (Eschbach et al., 1980) cattle, (Vogel et al., 2011) etc. Based on many experiments the surgical partial nephrectomy performed in two steps became a standard method for induction of renal failure. In our laboratory, the surgical 5/6 nephrectomy model in rat was used to study and describe the basic features of this model and the progressive changes in cardiovascular functions.

4 EXPERIMENTAL RESULTS IN RAT MODEL OF RENAL FAILURE

4.1 Chronic Renal Failure Induced by Partial Nephrectomy

Four-months-old Wistar male rats (Velaz, Prague, Czech Republic) were randomly allocated into subtotal nephrectomy (NX) and control groups. All operations

were performed under total anesthesia by intraperitoneal injection of sodium pentobarbital (100 mg/kg, i.p., Sigma Aldrich, Czech Republic) and xylazine (10 mg/kg, i.p., Rometar, Bioveta, Czech Republic). In NX group the anaesthetized rat was placed on its abdomen with fixed limbs and the left dorsolateral incision (approximately 2–3 cm wide) was made into the skin. The exposed back muscles were moved aside and the left kidney was carefully pulled out of the retroperitoneal space. The surrounding connective tissue of the kidney was removed with special care in the upper pole to prevent damage to the adrenal gland. The renal vessels were clamped by an atraumatic microvascular clamp and both poles (2/3 of the functional kidney mass) were resected by cuts perpendicular to the longitudinal axis of the kidney (Fig. 7.7). The cut surface was cauterized and then treated by hemostat Lyostypt (B. Braun, Germany). After bleeding was stopped the microvascular clamp was removed and the renal stump was returned into the retroperitoneum. Two weeks after the partial nephrectomy the right kidney was exposed by the previously described procedure. The renal pedicle was ligated by nonabsorbable multifilament suture (PremiCron, B. Braun, Germany)

and the total right nephrectomy was done to achieve 5/6 reduction of the total renal mass. The sham operation in control rats consisted of renal evacuation, decapsulation, and returning the intact kidney into the abdominal cavity performed bilaterally in a two-week interval. In both experimental groups the strict aseptic rules were respected, the incisions were sutured in two layers by monofilament suture (Premilene, B. Braun, Germany) and covered by a liquid bandage. After each operation, rats were treated by one-time subcutaneous application of antibiotic marbofloxacinum (5 mg/kg, s.c., Marbocyl, Vétoquinol, Czech Republic) and housed individually with free access to food and water. The presented results were obtained 10 weeks after the second step of surgery if not stated otherwise.

A significant increase of creatinine and urea concentrations in serum, polyuria and a decrease in glomerular filtration rate measured by creatinine clearance indicated a severe impairment of the kidney functions (Table 7.1). Functional markers of CRF (appearing already one week after the second step of surgery and remaining almost unchanged for weeks) were associated with morphological changes in the remnant kidney. The renal stump

Renal functional parameters in serum (S) and urine (U), body weight and absolute and relative kidney weights of control (sham) and partially nephrectomized (NX) rats 10 weeks after surgery.
* Significantly different from sham-operated rats, $P < 0.05$.

had an atypical pale color, its wet weight was significantly higher than a single kidney of healthy controls (Table 7.1) and displayed typical remodeling of the renal tissue (Fig. 7.8). The capsular surface of the operated kidneys of the partialy nephrectomized rats was depressed in several areas. No necrotic areas were found, but the medullary pyramids were distorted.

In contrast to the infarction method in which declined glomerular filtration rate varies in rather wide range, surgical nephrectomy gives more reproducible values of glomerular filtration rate probably owing to precise control of renal ablation (Liu et al., 2003). Moreover, surgical nephrectomy enables to induce a standardized, stable uremia at predetermined levels—mild uremia (due to 3/4 nephrectomy), moderate uremia (5/6 nephrectomy), and severe uremia produced by 7/8 reduction of the functional renal mass (Ormrod and Miller, 1980).

Both systolic and diastolic pressures measured by tail-cuff method were significantly increased in NX rats 3 weeks after surgery and further while no difference in blood pressure between sham and nephrectomized groups was found 1 week after surgery, for example, in the acute phase of renal failure (Fig. 7.9).
FIGURE 7.8 **Microscopic changes of the kidney 10 week after partial nephrectomy.** Unlike in sham-operated rats (A), the superficial cortex of the operated kidneys (B) of the nephrectomized (NX) rats was severely disorganized. The loss of tubules resulted in a crowding together of the glomeruli, and the interstitial tissue was considerably expanded, severely fibrosed and heavily infiltrated by chronic inflammatory cells. In the deeper and juxtamedullary cortex of the NX rats (C), proximal and distal the tubules were dilated and some of them contained densely eosinophilic casts. The medullary tubules of the operated kidneys (D) seemed to be recovered. Verhoeff's hematoxylin and green trichrome stain, scale bar 100 µm (A, B, C), and 50 µm (D).

4.2 Cardiovascular Parameters of the Rat Model

The morphological and functional impairment of the myocardium resulting from CRF is called uremic cardiomyopathy characterized by the left ventricular hypertrophy associated with systolic and diastolic dysfunctions (Parfrey et al., 1991; Zoccali et al., 2004). The myocardium impairment leads to a decrease in cardiac contractility followed by a drop in cardiac output caused by the diminished left ventricular compliance (Johnstone et al., 1996). Factors contributing to the pathogenesis of the uremic cardiomyopathy are hemodynamic (pressure overload due to hypertension and arteriolosclerosis and volume overload caused by water and sodium retention, arteriovenous shunt and anemia), (London and Parfrey, 1997; Kalantar-Zadeh et al., 2009) nonhemodynamic or metabolic (activation of renin-angiotensin system, ischemia, electrolyte dysbalance, the effect of uremic toxins including parathyroid hormone, advanced glycation end products, reactive oxygen species, cytokines, asymmetric dimethylarginine etc.) (Vanholder et al., 2003).

Structural, contractile, and electrophysiological remodeling was also observed in the hearts of partially nephrectomized rats. Both absolute and relative heart weights were significantly higher in NX rats compared to sham-operated ones. Since the weights of the left ventricle including septum (LV) and LV weight to body weight ratio were significantly increased, the change in weight of the uremic heart resulted probably from the hypertrophy of LV. The apparent concentric hypertrophy of LV (Fig. 7.10) developing already 10 days after the surgery was verified by the morphometric immunohistological analysis of cardiac cells showing the increase in the cross-sectional area of cardiac myocytes in LV of NX group (Table 7.2).

TABLE 7.2   Cardiac Parameters of Control and Partially Nephrectomized Rats, 100 Weeks After Surgery

	sham	NX
Heart weight (g)	0.935 ± 0.033	1.158 ± 0.047*
Left ventricle + septum (g)	0.753 ± 0.022	0.942 ± 0.062*
Right ventricle (g)	0.182 ± 0.012	0.217 ± 0.034
Heart weight/body weight (g/kg)	1.92 ± 0.03	2.7 ± 0.17*
Left ventricle/body weight (g/kg)	1.55 ± 0.04	2.21 ± 0.19*
Right ventricle/body weight (g/kg)	0.37 ± 0.01	0.49 ± 0.07
Cross-sectional area of LV myocytes (μm^2)	431.32 ± 21.54	597.67 ± 23.56*,#
Cross-sectional area of RV myocytes (μm^2)	396.01 ± 36.91	460.89 ± 21.29

LV, left ventricle; RV, right ventricle.
* Significantly different from sham-operated rats.
# Significantly different from RV, $P < 0.05$.

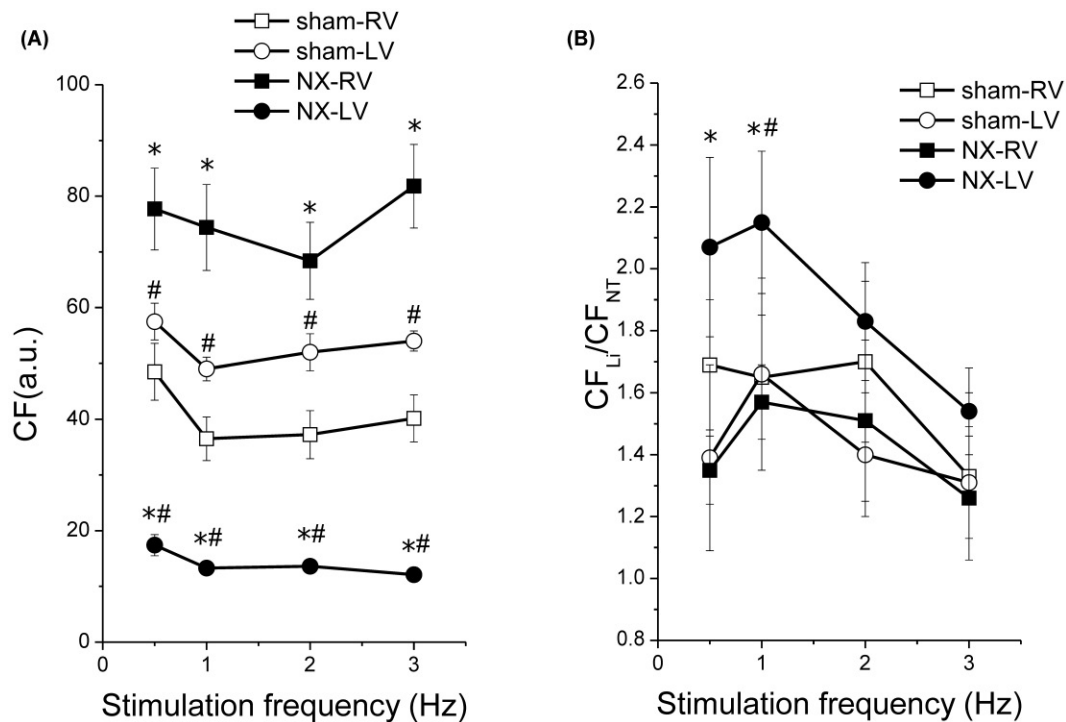
Contraction force (CF) measured on papillary muscles in control Tyrode solution was significantly higher in the left ventricle (LV) compared to the right ventricle (RV) in control animals at stimulation frequencies 0.5, 1, 2, and 3 Hz. In NX rats, the contractile remodeling was different in LV and RV—CF was significantly augmented in RV but significantly reduced in LV compared to age-matched controls at all stimulation frequencies tested (Fig. 7.11A). Fifty percent substitution of extracellular sodium with lithium (an intervention stimulating the reverse mode of sodium-calcium exchanger), had a significant positive inotropic effect only in LV of NX animals


FIGURE 7.11 **Steady-state contraction (CF) of papillary muscles in control (sham) and partially nephrectomized rats (NX).** (A) The dependence of CF on stimulation frequency in the right *(RV, squares)* and left *(LV, circles)* ventricles in control *(open symbols)* and NX *(filled symbols)* rats in control Tyrode solution. (B) The effects of lithium substitution on CF: the ratio of CF in solution with 50% Li$^+$ substitution (Li) and in control Tyrode solution (NT) in the right *(RV, squares)* and left *(LV, circles)* ventricles in control *(open symbols)* and NX *(filled symbols)* rats. a.u., arbitrary units. * Significantly different from control rats, # significantly different from RV, $P < 0.05$.

but neither in RV nor in both ventricles sham-operated rats (Fig. 7.11B).

The rest-potentiation phenomenon reflecting the function of Na$^+$/Ca^{2+} exchanger (i.e., the increase in contraction force after period of rest characteristic for rat myocardium) was more pronounced in LV than in RV. Nephrectomy further enhanced the relative rest-potentiation in LV, but suppressed it in RV (Fig. 7.12A) regardless of the duration of period of rest (10–300 s). The rest-potentiation phenomenon compensated the interventricular changes in steady-state CF described in NX group: enhanced rest-potentiation for reduced steady-state contraction in LV and reduced rest-potentiation for increased steady-state contraction in RV (Fig. 7.12B).

Time to peak of contraction (TTP) in LV and time parameters of relaxation, that is, time from peak of contraction to 50% relaxation (R50) and time from peak of contraction to 90% relaxation (R90) in both ventricles were significantly prolonged due to partial nephrectomy at all stimulation frequencies tested. Nephrectomy also led to shortening of action potential duration at 50% (APD50) and 90% (APD90) level of repolarization in both ventricles. In contrast to the contractile functions the electrophysiological remodeling and the prolongation of relaxation in NX rats was similar in both ventricles (Table 7.3).

Cardiovascular autonomic dysfunction (CAD) contributes to higher incidence of arrhythmias, blood pressure disturbances and sudden cardiac death in patients suffer from CRF (Robinson and Carr, 2002). CAD is characterized by decreased baroreceptor sensitivity, increased sympathetic tone but decreased parasympathetic one (Zoccali et al., 1982). The sympathetic hyperactivity is explained by the abnormal stimulation of sensory renal nerves innervating the affected kidney which is potentiated by cumulation of adenosine in the ischemic renal tissue. These afferent signals integrated in central nervous system together with stimulation of renin-angiotensin system, alteration of NO metabolism, and the effect of uremic toxins results in a higher sympathetic outflow (Schlaich et al., 2009). In contrast to the sympathetic nervous system, little is known about the pathogenesis of the uremic impairment of the parasympathetic cardiac innervation.

The resting heart rate values obtained from conscious animals by electrocardiography progressively increased in NX rats to be significantly different from controls 10 weeks after surgery (Fig. 7.13A). Cardiac parasympathetic tone measured by an increase in the heart rate after application of muscarinic blocker atropine to animal pretreated by beta-blocker metipranolol was significantly lower in NX rats showing the alteration of cardiac parasympathetic innervation due to CRF (Fig. 7.13B).

Time parameters of contraction-relaxation cycle and action potential duration in left (LV) and right (RV) papillary muscles of control (sham) and partially nephrectomized (NX) rats at stimulation frequency 1 Hz. TTP, time to peak of contraction, R_{50}, time from peak of contraction to 50% relaxation, R_{90}, time from peak of contraction to 90% relaxation, APD_{50}, duration of action potential at 50% level of repolarization, APD_{90}, duration of action potential at 90% level of repolarization.
*Significantly different from control rats,
#Significantly different from RV, $P < 0.05$.

In vitro experiments, the muscarinic agonist carbachol exerted a negative chronotropic effect on the isolated rat heart atria (Fig. 7.14A) and a negative inotropic effect on the papillary muscles in both rat ventricles (Fig. 7.14B) without the significant difference between control and NX groups. No differences between sham-operated and nephrectomized rats were also revealed in negative chronotropic responses to the stimulation of

vagus nerve (Fig. 7.15), the relative expression of muscarinic M2 receptors in all cardiac chambers and in the relative expression of high affinity choline transporter, vesicular acetylcholine transporter, and choline acetyltransferase in left atria.

Rat uremic myocardium showed the characteristic signs of uremic cardiomyopathy—hypertrophy and contractile dysfunction of LV. Occurrence of LV hypertrophy prior to hypertension and the absence of RV hypertrophy suggest that pressure and volume overloads are not the critical contributors to the development of LV hypertrophy in NX rats and the humoral factors should be considered. Partial recovery of contractile function of LV by rest-potentiation and by lithium substitution of extracellular sodium indicates the role Na^+/Ca^{2+} exchanger in the different interventricular cardiac remodeling of the heart in partially nephrectomized rats (Švíglerová et al., 2012). Cardioacceleration present in rats with CRF resulted probably from the decreased tone of cardiac parasympathetic innervation what corresponds with findings in a number of human studies proving that the alteration of parasympathetic division of autonomic nervous system more than sympathetic one contributes to uremic autonomic neuropathy (Giordano et al., 2001; Zoccali et al., 1982). Since the intact intrinsic cardiac cholinergic signaling system the impairment of the central parasympathetic activity partially nephrectomized rats is suspected (Kuncová et al., 2009).
FIGURE 7.13 **Heart rate in control (sham) and partially nephrectomized (NX) rats.** (A) Resting heart rate. FIGURE 7.14 **The chronotropic and inotropic effects of carbachol in control (sham) and partially nephrectomized rats (NX).** (A) The effect of carbachol on beating rate of the isolated rat heart atria. *Open squares*—sham, *filled squares*—NX. (B) The effect of carbachol (10–4 mol/L) on contraction force (CF) of papillary muscle from left *(LV, empty bars)* and *right (RV, hatched bars)* ventricles measured at stimulation frequency 1 Hz in the presence of noradrenaline (10–4 mmol/L) in control *(left panel)* and NX *(right panel)* rats. The negative inotropic effect of carbachol was more pronounced in LV of both control and NX rats. *r.u.*, relative units (values are normalized to CF in carbachol-free solution with norepinephrine. * Significantly different from RV, $P < 0.05$.

4.3 Conclusions

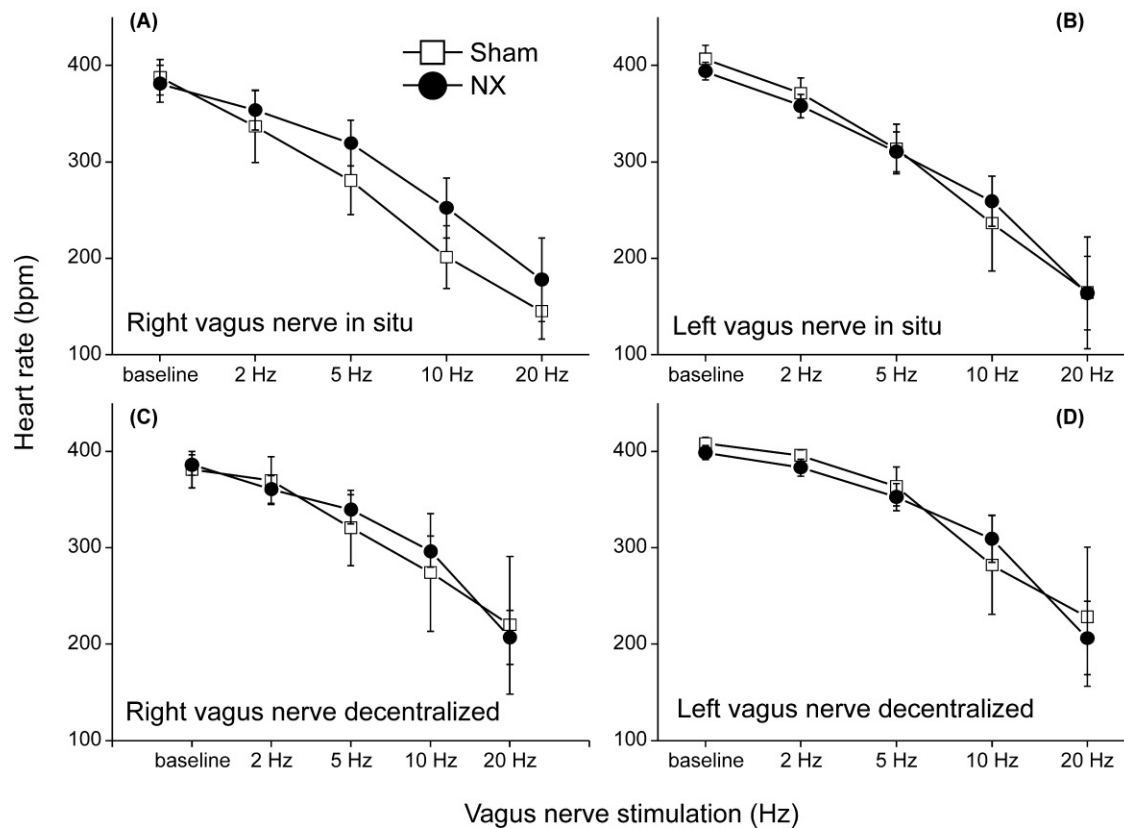
The presented model of 5/6 surgical nephrectomy in rat performed in two steps displays the typical features of uremia including reduced glomerular filtration rate, increased serum levels of urea and creatinine and arterial hypertension. The model also simulates cardiovascular complications of human CRF—hypertrophy and systolic dysfunction of the left ventricle and the impairment of


FIGURE 7.15   **Chronotropic effect of the vagus nerve stimulation.** The right (A, C) and left (B, D) vagus nerves were stimulated in situ (A, B) or after decentralization (C, D). *Sham*, control rats; *NX*, subtotally nephrectomized rats.

autonomic cardiac innervation. The advantages of this model like similarity to human diseases, homogeneity, reproducibility and stability of uremia, precise control of renal mass reduction, and minimum undesirable effects exceed disadvantages including a higher risk of mortality, rather fast onset of uremia compared to slow progression in humans and the difficulty of technique.

In the clinical application of research findings the earlier mentioned disadvantages of rat model of partial nephrectomy and presently known differences between rat and human myocardium should be considered. Under physiological conditions, shorter duration of action potential, inverted force-frequency relationship, insignificant role of Na/Ca exchanger in calcium removal from cytoplasma, faster heart rate are typical for rat heart (Grossman, 2010). Atherosclerosis characteristic for human CRF occurs only rarely in rats (Ritskes-Hoitinga and Beynen, 1988). Moreover cardiovascular diseases resulted from CRF develop slowly in human patients which are usually older, multimorbid and both gender are represented whereas animals used in research are usually young and healthy, the onset of cardiovascular complications is relatively rapid and the majority of experiments is performed on males. Taken together, the rat model of CRF induced by 5/6 surgical nephrectomy plays important role in the study of chronic renal diseases and their cardiovascular complications

nevertheless the experimental results must be implicated in human medicine with caution.

5 THE HEART AND DYSFUNCTIONAL SYMPATHETIC INNERVATION

Cardiac sympathetic innervation plays an important role in the regulation of the cardiac functions, particularly heart rate, contractility, and velocity of conduction. Removing the sympathetic nerves supplying the cardiovascular system could be important for the understanding the heart function in clinical conditions affecting the neural control of the heart. In the experimental practice, the variety of sympathectomy methods is used, including surgical ablation of the sympathetic chains, immunosympathectomy, and chemical damaging of the sympathetic neurons. Among them, chemical sympathectomy is the most suitable method for small laboratory animals, such as rat and mice (Picklo, 1997). In the classical view, the only source of norepinephrine in the mammalian heart is postganglionic sympathetic fibers. However, recent experimental evidence suggests that norepinephrine is distributed in the heart in at least three additional sources:

1. Intrinsic ganglion neurons of the cardiac nerve plexus that express tyrosine hydroxylase (TH) and

dopamine β-hydoxylase (DBH), that is, enzymes essential for norepinephrine synthesis (Slavikova et al., 2003). In the rat heart, the cell bodies of ganglion neurons are located in the atria, particularly the left one, but not in the ventricles (Batulevicius et al., 2003).

2. Intrinsic catecholaminergic (ICA) cells that are diffusely distributed throughout the heart including both atria and ventricles contribute to the total cardiac content of norepinephrine and epinephrine by 18, and 13%, respectively (Huang et al., 1996). ICA cells do not have neuronal or chromaffin cell ultrastructural morphology on electron microscopic analysis and are capable of catecholamine uptake and release (Huang et al., 2005).

3. Negligible portion of norepinephrine in the atria could be localized in two additional cell types: small intensely fluorescent (SIF) cells and glomus-like bodies (GLB) displaying moderate or week DBH immunoreactivity, respectively, suggesting the presence of norepinephrine (Kummer et al., 1986).

In addition, catecholamines dopamine and epinephrine could also contribute to the regulation of the cardiac function in a more complex way than recognized to date. Classically, epinephrine is secreted by the adrenal medulla and reaches the heart via the circulation. Epinephrine release from the heart after sympathetic nerves stimulation was concomitantly attributed to the uptake of this catecholamine by norepinephrine transporter and its subsequent release (Lameris et al., 2002). However, an expression of phenylethanolamine *N*-methyltransferase (PNMT), enzyme decisive in epinephrine synthesis was demonstrated in the heart, both in neuronal and nonneuronal elements (Huang et al., 1996; Ebert and Taylor, 2006).

Finally, dopamine regarded so far as mere norepinephrine precursor, seems to be involved in the cardiac catecholaminergic system in a more intriguing manner. Dopamine can be detected in the cardiac ganglia and SIF cells (Slavikova et al., 2003). Dopamine receptors that are distinct from α- and β-adrenoreceptors, are expressed in the heart, suggesting that dopamine could mediate cardiospecific effects (Emilien et al., 1999). Norepinephrine-independent dopamine release has been already demonstrated (Ilebekk et al., 1983).

With regard to the novel and complex view on the organization of the cardiac catecholaminergic system, we aimed to review our results of the studies dealing with two methods of chemical sympathectomy, that is, neonatal administration of guanethidine and 6-hydroxydopamine to rats and the impact of these interventions on various cardiovascular parameters.

6 METHODS OF CHEMICAL SYMPATHECTOMY

6-hydroxydopamine (6-OHDA) was the first chemical recognized to cause selective damage to the noradrenergic neurons (Thoenen and Tranzer, 1973). It enters the cells via norepinephrine transporter, undergoes a series of chemical transformations to reactive quinone compounds that stimulate free radicals production, membrane disintegration, and neuronal death. Guanethidine is also a substrate of norepinephrine transporter in the sympathetic nerve endings. It replaces norepinephrine in the synaptic vesicles, causes swelling of mitochondria and increase in protein content in the sympathetic ganglia followed by lymphocyte infiltration and concomitant retraction of the whole sympathetic postganglionic neurons (Burnstock et al., 1971).

In our studies, both chemicals were applied in doses reported to cause permanent loss of the sympathetic postganglionic neurons. After birth, rats received subcutaneously 6-OHDA (100 mg/kg) dissolved in 0.9% NaCl solution containing 0.1% ascorbic acid on postnatal days 1–7, 14, 21, and 28 or guanethidine sulfate (50 mg/kg) dissolved in 0.9% NaCl solution on postnatal days 1–21. The control group received equal volumes of solvent at the same time points. All rats were used for further experiments at the ages of 20, 40, 60, 90, and 150 postnatal days.

7 EXPERIMENTAL RESULTS IN THE RAT MODEL OF CHEMICAL SYMPATHECTOMY

7.1 Concentrations of Norepinephrine, Epinephrine, and Dopamine in the Heart

Both sympathotoxins, guanethidine and 6-OHDA enter the sympathetic nerve endings via norepinephrine transporter and cause degeneration of the whole sympathetic neurons. It is thus interesting that guanethidine sympathectomy was repeatedly reported to be more extensive than that using 6-OHDA and that not all cells expressing norepinephrine transporter display the same susceptibility to the toxins (Burnstock et al., 1971; Johnson et al., 1976). Therefore, we have determined norepinephrine, epinephrine, and dopamine levels in all heart compartments of denervated rats at the ages of 20–150 postnatal days to compare the efficacy of both regimens. Catecholamines levels were assayed in tissue extracts by radioimmunoassay using commercial kits (IBL Hamburg, FRG).

In the control animals, all catecholamines concentrations were relatively stable in the whole course of experiment (Table 7.4).

Fig. 7.16 shows the effect of chemical ablation of the cardiac sympathetic nerves on norepinephrine concentrations in the heart compartments. Guanethidine

TABLE 7.4 Norepinphrine, Epinephrine, and Dopamine Concentrations in the Heart of Control Rats

Age (days)		RA (ng/g)	LA (ng/g)	RV (ng/g)	LV (ng/g)

	DA	95 ± 7	116 ± 12	44 ± 5	29 ± 2
	EPI	62 ± 6	45 ± 5	41 ± 5	31 ± 3

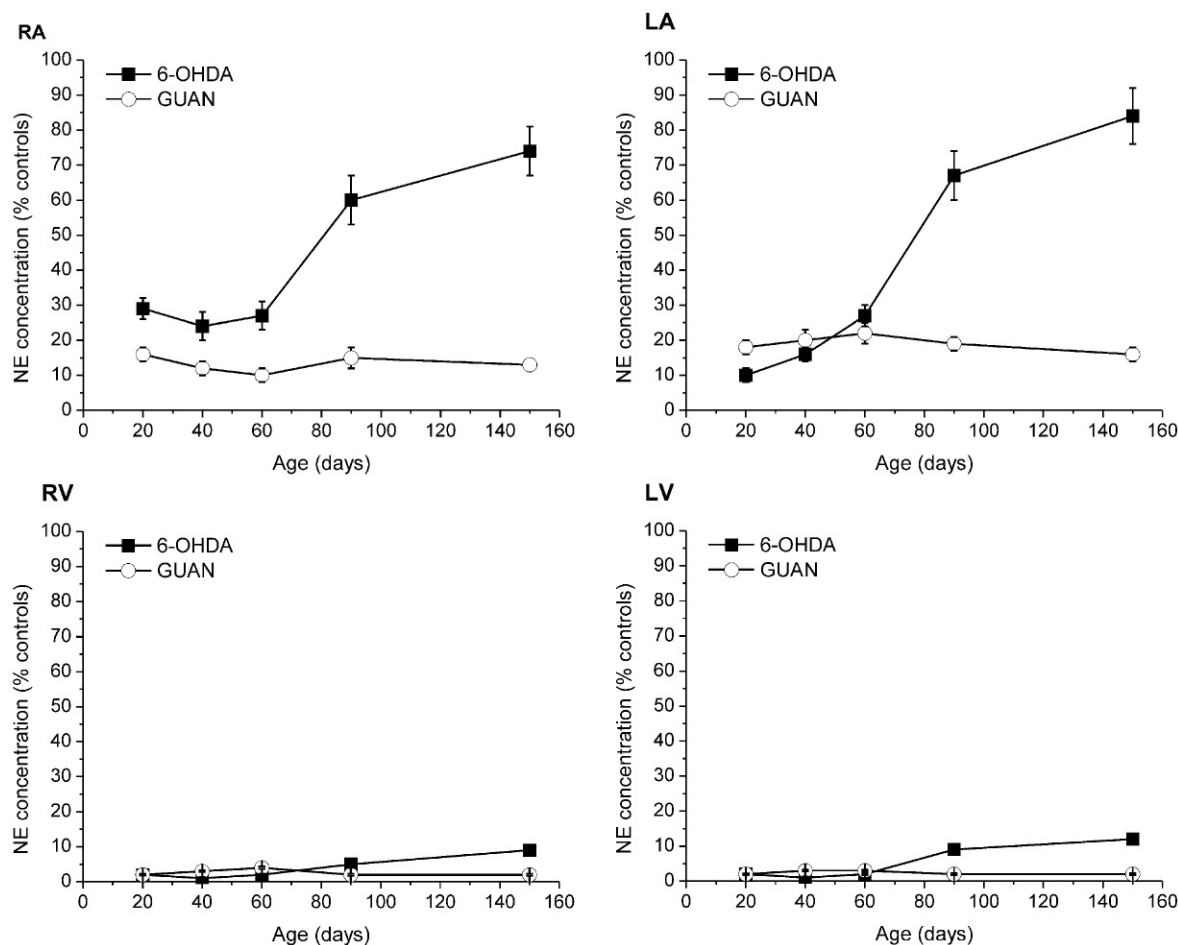
DA, dopamine; EPI, epinephrine; LA, left atrium; LV, free wall of left ventricle; NE, norepinephrine; RA, right atrium, RV, free wall of right ventricle. Control rats aged 20–150 days. Data expressed as mean ± S.E.M.; n = 5–8 per group and age category.


FIGURE 7.16 **Norepinephrine (NE) concentrations in the right and left atria (RA, LA, respectively) and free walls of the right (RV) and left (LV) ventricles of 20-, 40-, 60-, 90-, and 150-day-old rats sympathectomized by 6-hydroxydopamine (6-OHDA) or guanethidine (GUAN).** Data are expressed in percentage of the control values as mean ± S.E.M., n = 6–9 per group and age category.

sympathectomy resulted in more profound depletion of norepinephrine in the heart, although catecholamine content remained slightly higher in the atria than in the ventricles. In addition, partial recovery of norepinephrine tissue stores could be observed in rats treated by 6-OHDA in the atria, but not in the ventricles.

The effects of both treatments on dopamine concentrations in the heart are shown in Fig. 7.17. Whereas in 6-OHDA treated animals, dopamine levels completely restored to control values at the age of 90 days, in rats denervated by guanethidine, dopamine concentrations ranged around 30% throughout the whole experiment. However, relative reduction in dopamine concentration after both interventions was smaller than that of norepinephrine suggesting dopamine tissue stores not accessible by both neurotoxins.

Epinephrine concentrations in the denervated atria restored to control values after 6-OHDA treatment and remained significantly lower than in controls after guanethidine administration. In the ventricles, both compounds had similar effect—epinephrine tissue levels were significantly lower than in the age-matched controls being more extensively reduced after guanethidine (Fig. 7.18).

7.2 Neuropeptide Y and Calcitonin-Gene Related Peptide Concentrations

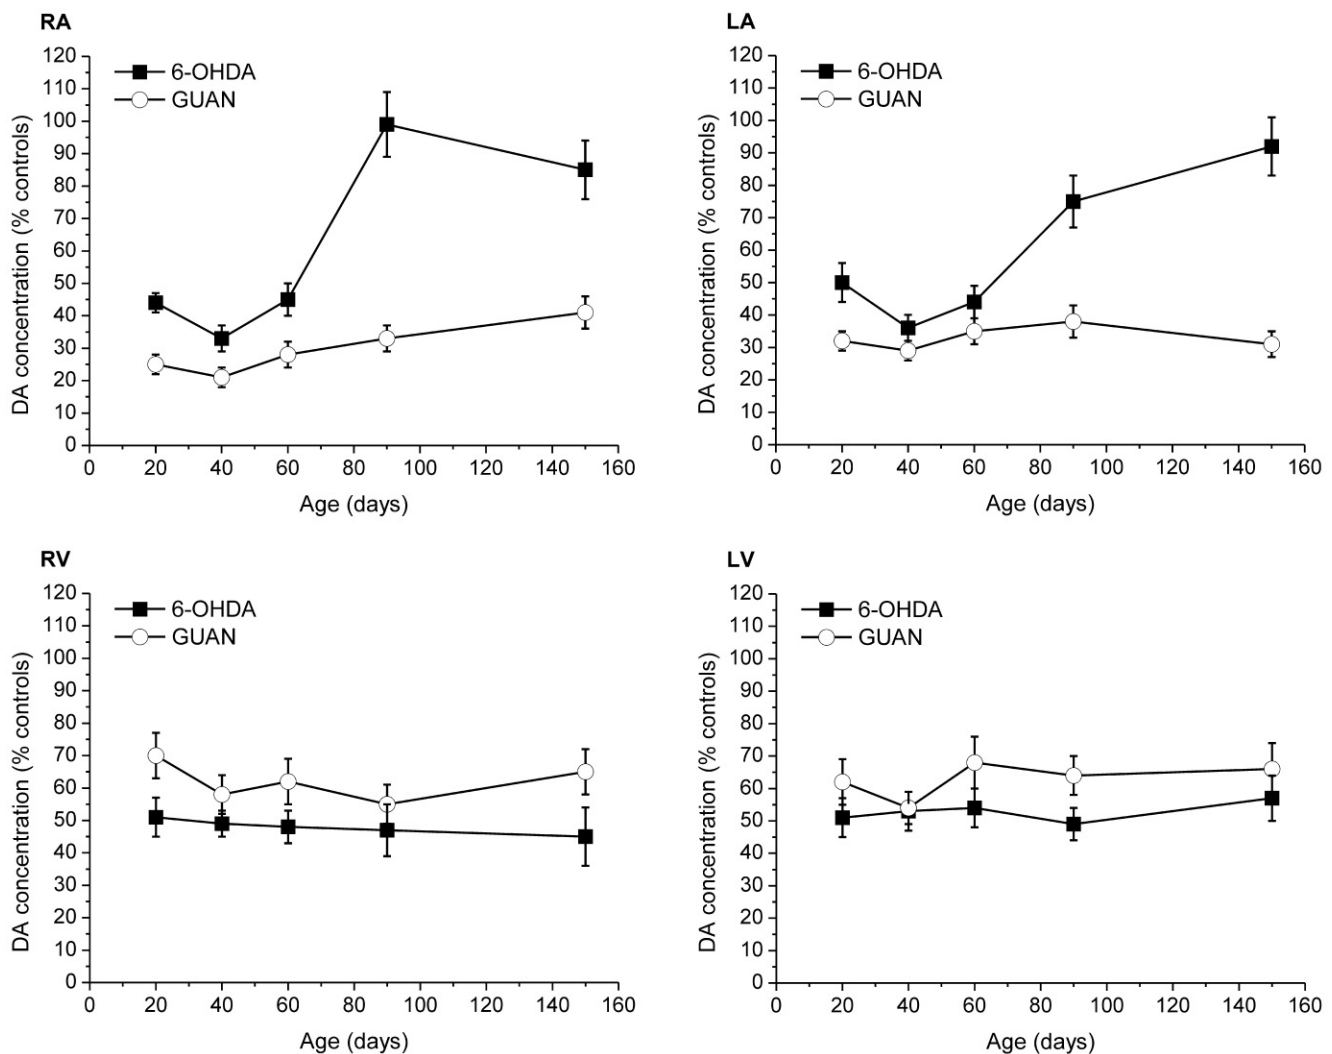
Although norepinephrine is the principal neurotransmitter of the sympathetic postganglionic nerve fibers supplying the heart, neuropeptide Y (NPY), which is costored with norepinephrine in most sympathetic nerves, also exerts multiple effects on the heart (Zukowska et al., 2003). Besides the true sympathetic neurons, NPY is localized in the intrinsic cardiac ganglia that contain nerve cell bodies both positive and negative to norepinephrine transporter


FIGURE 7.17 Dopamine (DA) concentrations in the right and left atria (RA, LA, respectively) and free walls of the right (RV) and left (LV) ventricles of 20-, 40-, 60-, 90-, and 150-day-old rats sympathectomized by 6-hydroxydopamine (6-OHDA) or guanethidine (GUAN). Data are expressed in percentage of the control values as mean ± S.E.M., n = 6–9 per group and age category.
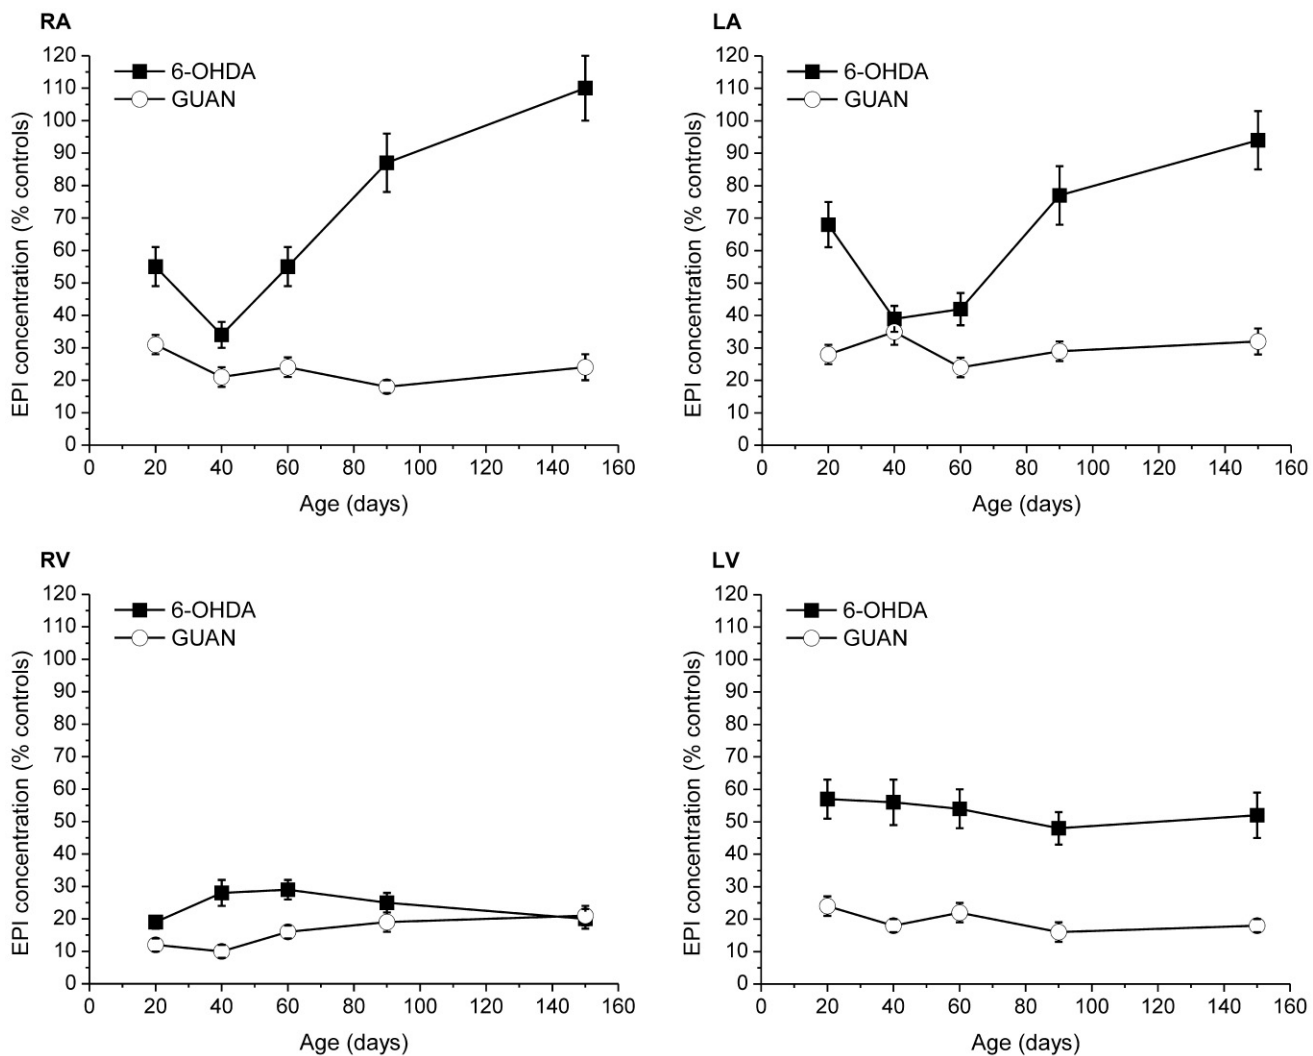

FIGURE 7.18   Epinephrine (EPI) concentrations in the right and left atria (RA, LA, respectively) and free walls of the right (RV) and left (LV) ventricles of 20-, 40-, 60-, 90-, and 150-day-old rats sympathectomized by 6-hydroxydopamine (6-OHDA) or guanethidine (GUAN). Data are expressed in percentage of the control values as mean ± S.E.M., $n = 6$–9 per group and age category.

immunoreactivity (Palomar et al., 2011). Moreover, NPY has been recently demonstrated in the endothelial and endocardial cells (Abdel-Samad et al., 2007). Contribution of the individual pools of the peptide to its total content in the heart is not precisely known. Fig. 7.19 shows the time course of NPY concentrations assayed by RIA using commercial kits (Phoenix Pharmaceuticals, CA, USA, and IBL Hamburg, FRG) after both types of sympathetic denervation. Relatively high NPY levels seem to prove NPY localization outside the sympathetic nerves. Restoration of catecholamines and NPY concentrations after 6-OHDA, but not guanethidine could be at least partly explained by the different sensitivity of the intrinsic ganglia to both toxins.

Calcitonin gene-related peptide (CGRP) is a principal neurotransmitter of the sensory neurons and it exerts multiple effects on the cardiomyocytes and coronary vasculature (Giuliani et al., 1992). It has been repeatedly

reported that neonatal sympathectomy is associated with an abrupt increase in CGRP levels in the heart (Rubino et al., 1997). Table 7.5 shows CGRP concentrations in the individual heart compartments after 6-OHDA and guanethidine treatments. Administration of both toxins led to significant increase in CGRP levels in both atria and ventricles. However, in 6-OHDA treated rats, there could be observed a trend of decreasing CGRP levels with age.

8 FUNCTIONAL PARAMETERS

8.1 Resting Heart Rate and Chronotropic Responses to Atropine and Metipranolol

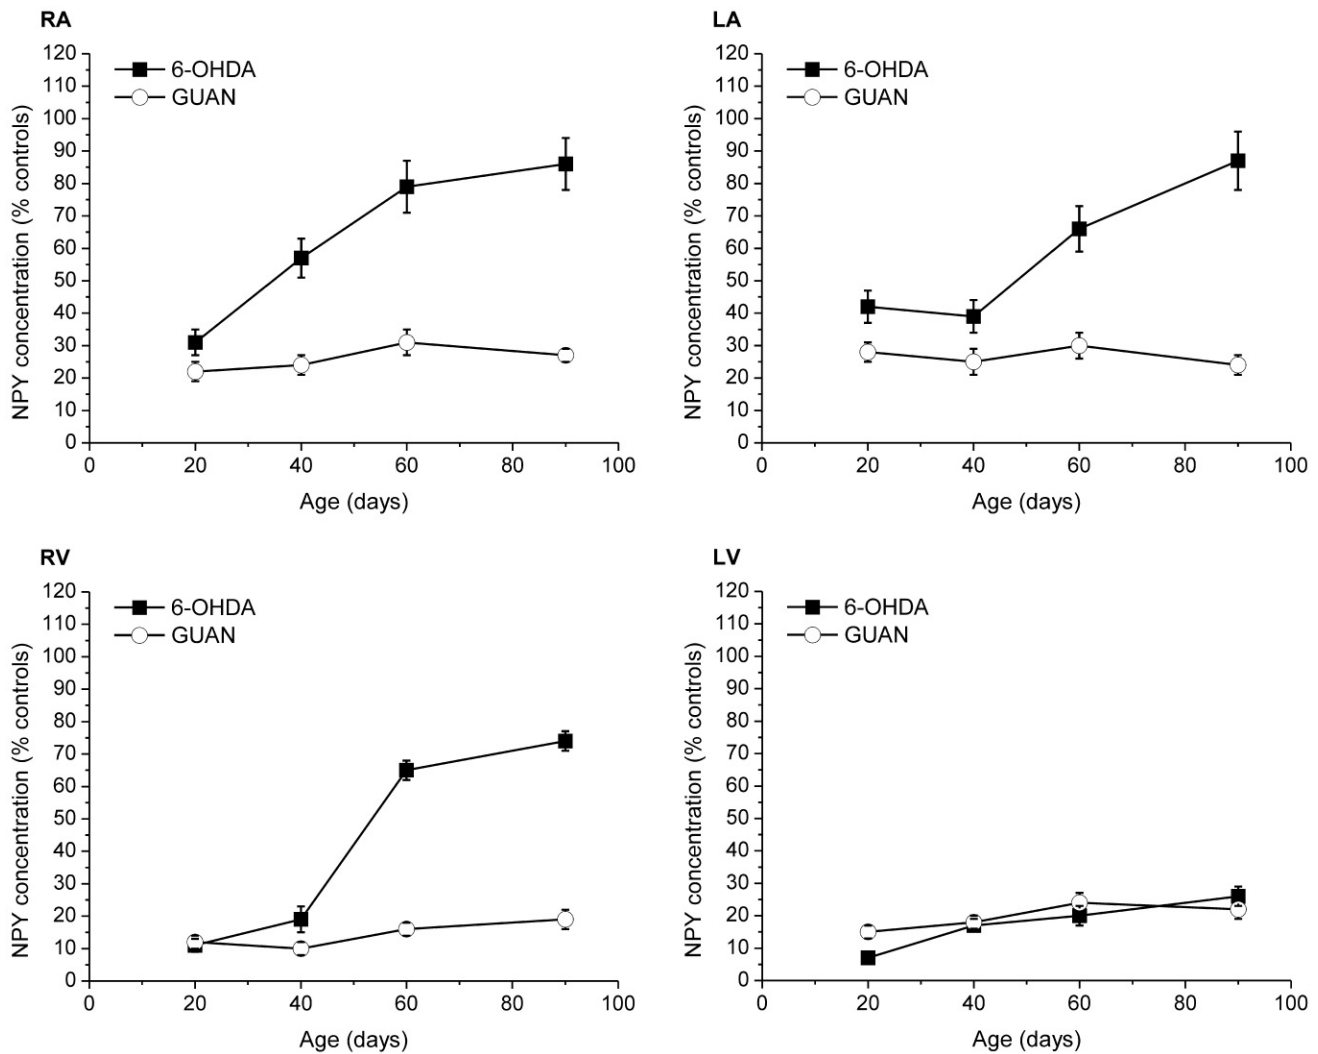
The rats were placed in a small chamber with electrodes in the floor that were connected to an electrocardiograph. (EKG Seiva Praktik, Prague, Czech Republic).


FIGURE 7.19 **Neuropeptide Y (NPY) concentrations in the right and left atria (RA, LA, respectively) and free walls of the right (RV) and left (LV) ventricles of 20-, 40-, 60-, and 90-day-old rats sympathectomized by 6-hydroxydopamine (6-OHDA) or guanethidine (GUAN).** Data are expressed in percentage of the control values as mean ± S.E.M., n = 5–8 per group and age category.

TABLE 7.5 Relative CGRP Concentrations in the Rat Heart

Age (days)		RA (% controls)	LA (% controls)	RV (% controls)	LV (% controls)

Data are expressed in percentage of the control age-matched values as mean ± S.E.M.; n = 6 per group and age category.
FIGURE 7.20   Resting heart rate in the rats sympathectomized by 6-hydroxydopamine (6-OHDA) or guanethidine (GUAN) and the age-matched controls aged 20–150 days. Data are expressed as mean ± S.E.M., n = 8–10 per group and age category, *P < 0.05, compared to the respective control value.

To estimate the tonic influence of the cardiac sympathetic innervation on the heart rate, the β-adrenergic receptor antagonist metipranolol (Hoechst-Biotika, Martin, Slovac Republic; 2 mg/kg, s.c.) was administered subcutaneously after pretreatment with the muscarinic receptor blocker atropine (atropine sulphate, Sigma Aldrich, Prague, Czech Republic; 4 mg/kg of body weight).

As shown in Fig. 7.20, the resting heart rate was significantly higher in the sympathectomized animals at the ages of 20 and 40 days and then it did not significantly differ from the age-matched controls.

The effect of metipranolol after previous administration of atropine suggested that estimated tonic effect of the sympathetic nerves on the heart rate was lower after both types of sympathectomy and that chemical ablation of the sympathetic nerves resulted in lower but not negligible tonic β-adrenergic effect (Fig. 7.21). This finding cannot be explained by an expected increase in the
FIGURE 7.21   The net effect of metipranolol (MP) after previous atropine (ATR) administration estimating the "sympathetic tone" in the control rats and animals sympathectomized by 6-hydroxydopamine (6-OHDA) or guanethidine (GUAN) aged 20–150 days. Data are expressed as mean ± S.E.M., n = 8–10 per group and age category. *P < 0.05, compared to the respective control value.

density and/or sensitivity of cardiac beta-adrenergic receptor signaling system following chemical sympathetic denervation, since denervation supersensitivity could be observed when ablation of the sympathetic nerves is performed in adult, but not neonatal animals (Slotkin et al., 1995).

8.2 Beating Rate of the Isolated Right Atria

The heart rate was further analyzed on the isolated right atria of 6-OHDA rats in the modified Tyrode solution without and with tyramine, substrate of norepinephrine transporter that replaces it in the synaptic vesicles causing its release (Sulzer et al., 2005). As shown in Fig. 7.22, tyramine had no or significantly lower effect in the sympathectomized atria of all age categories. However, at the age of 90 days, tyramine had

significant positive chronotropic effect that was blocked by β-adrenergic blocker propranolol.

8.3 Contraction Experiments

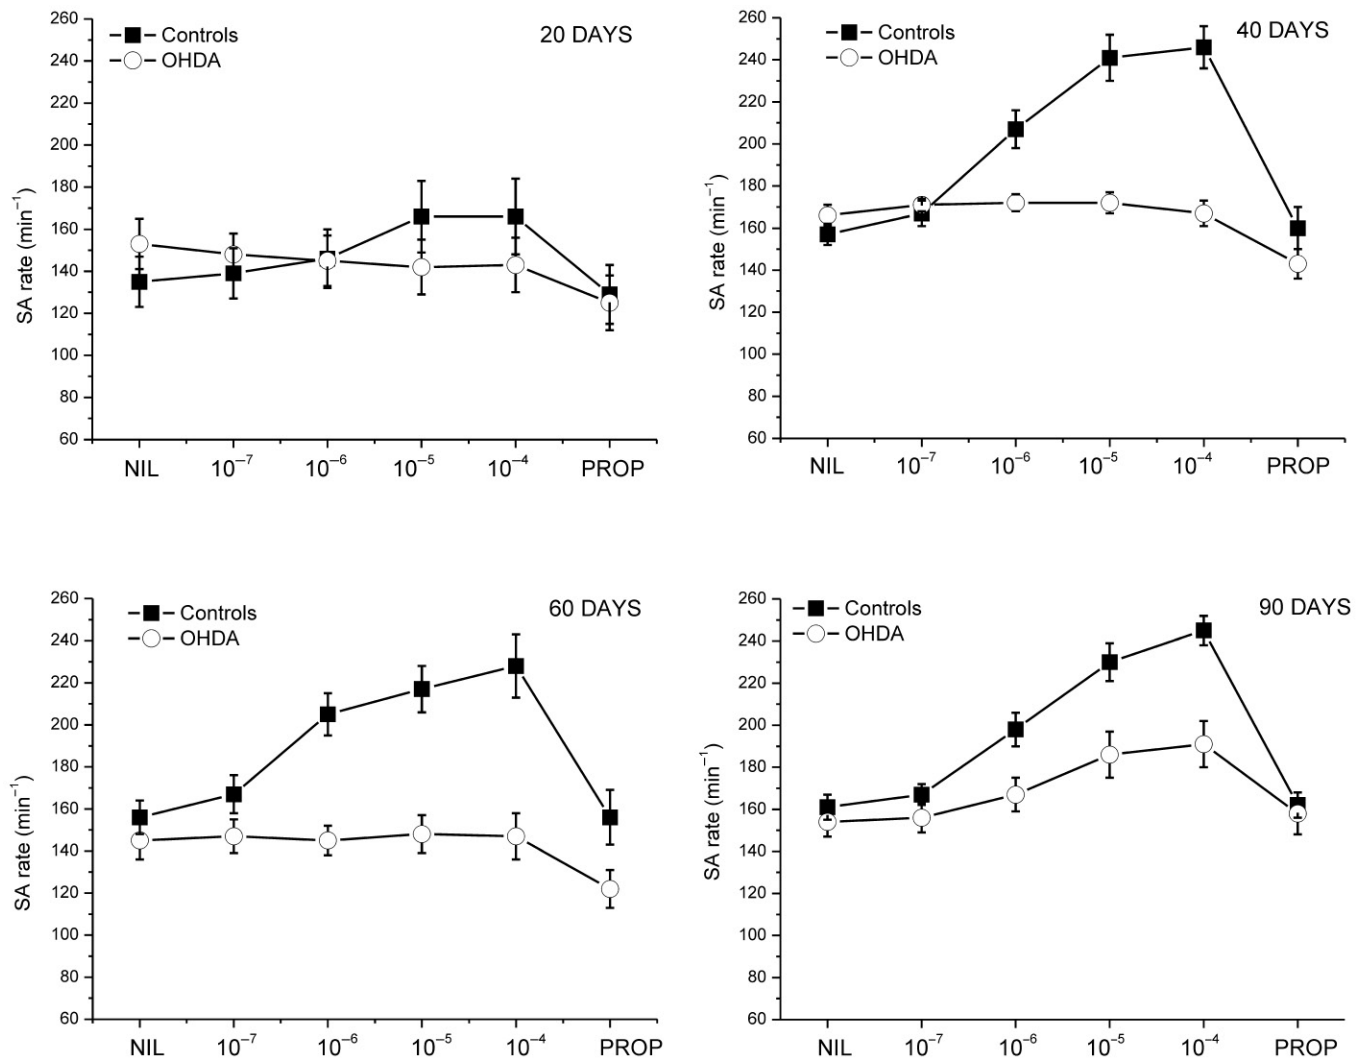
Inotropic properties of the denervated cardiac tissue were measured on the isolated papillary muscles in an experimental chamber with Tyrode solution using an isometric force transducer F30 (Hugo Sachs, Germany). The resting tension was set so that the developed twitch tension reached 90%–95% of maximum at stimulation frequency of 1 Hz. After a stabilization period, steady-state contractions at various stimulation frequencies (3, 2, 1, 0.5, 0.3, 0.2, and 0.1 Hz) were recorded. Contractions were measured in arbitrary units (a.u.). Time course of contraction was characterized using time-to-peak (time from resting tension to the peak of contraction, TTP)


FIGURE 7.22 The effect of tyramine on the beating rate of the isolated right atrium (SA rate) in the control and sympathectomized rats aged 20–90 days. Data are expressed as mean ± S.E.M., n = 8–10 per group and age category.
FIGURE 7.23 **The contraction force of the control and sympathectomized (6-OHDA) rats aged 20, 40, and 60 days.** (A) Contraction force (CF) of papillary muscles from the right ventricles (RV) in control ($n = 6$) and sympathectomized rats ($n = 5$). (B) Contraction force (CF) of papillary muscles from the (LV) ventricles in control ($n = 6$) and sympathectomized ($n = 5$) rats. Stimulation frequency was 1 Hz. a.u., arbitrary units. *$P < 0.01$, compared to the respective control value, #$P < 0.01$, compared to the respective value in the right ventricle.

and half-maximal relaxation time (R/2) parameters. The resting tension was taken as zero. Chemical sympathectomy significantly decreased the contraction force of the papillary muscle in all age categories in the left ventricle and in 20- and 40-day-old rats in the right ventricle and (Fig. 7.23). At day 60, however, this reduction disappeared and the contraction force of the right papillary muscle was comparable to control. The effect of the chemical sympathectomy on the contraction force was well expressed at all stimulation frequencies tested (0.1–3 Hz), that is, the force of contraction of papillary muscles in denervated rats was always significantly lower than in control rats except the right ventricle papillary muscles at the age of 60 days.

In both control and denervated rats, time to peak of contraction (TTP) shortened with increasing frequency of stimulation in all age groups. Neither chemical sympathectomy nor age of animals affected TTP. Similarly, half-maximal relaxation time shortened with increasing frequency of stimulation and there was no difference between the intact and sympathectomized rats at any age (data not shown).

In the control rats, administration of tyramine significantly increased the contraction force of papillary muscles from both ventricles independent of age. The values of the contraction force of the right and left ventricular papillary muscles after application of β-adrenergic blocker propranolol (10–4 mol/L) on top of tyramine (10–4 mol/L) were not significantly different from values in tyramine-free solution in any age group. In contrast, both right and left ventricle papillary muscles of sympathectomized rats were insensitive to both tyramine and propranolol in all age groups (Fig. 7.24).

8.4 Experimental and Clinical Implications

Taken together, neonatal chemical sympathectomy leads to profound, but differential changes in concentrations of catecholamines and neuropeptides in the rat heart compartments. Guanethidine-induced sympathectomy seems to have long-term effect on the norepinephrine tissue stores. However, with regard to novel findings in the organization of the catecholaminergic system in the heart, the precise cell types attacked by the compound could be better analyzed by quantitative immunohistochemical analysis. Norepinephrine and NPY tissue content was completely or partially restored in the atria of 6-OHDA treated rats and the same trend could be observed in the ventricles. In contrast, guanethidine effect on the cardiac levels of sympathetic neurotransmitters was stable and no tendency to recovery could be observed. It is thus tempting to speculate that intrinsic ganglion cells containing norepinephrine and NPY and displaying norepinephrine transporter immunoreactivity could serve as a source of these recovering tissue stores in 6-OHDA treated rats and that the stable and profound effect of guanethidine might occur due to its more complex toxic effect not only on extrinsic postganglionic neurons but also on noradrenergic and NPY-ergic nerve structures of the intrinsic ganglion plexus of the rat heart.
FIGURE 7.24 **The effect of tyramine and propranolol on contraction force of the control and sympathectomized rats.** Contraction force (CF) of papillary muscles from the right (RV) and left ventricles (LV) in control rats and rats sympathectomized by 6-hydroxydopamine (6-OHDA). Values were normalized to the CF in tyramine-free solution. Stimulation frequency was 1 Hz. D = age in days. P = administration of propranolol (concentration 10^{-4} mol/L) on top of tyramine (concentration 10^{-4} mol/L).

Neonatal chemical sympathectomy seems to be an excellent tool to analyze neurotransmitter equipment of individual cell types; it could help to study mutual trophic effects of cardiac neurons and myocardial cells. It is also a simple method to study the impact of neuronal activity on the postnatal development of chronotropic and inotropic properties of the heart. However, with regard to various clinical conditions affecting the sympathetic nerves (diabetes mellitus, amyloidosis, Parkinson disease, drug and alcohol abuse etc.), the results of these studies should be interpreted with caution, since the early postnatal degeneration of the sympathetic nerves or even some intrinsic ganglion neurons leads to an excessive growth of the sensory nerves, which is not finding typical for the previously listed diseases. Nevertheless, the ability of the heart to restore its catecholaminergic system after previous denervation and at least some functional parameters could be important in the investigation of various degenerative and hereditary autonomic neuropathies and the regulation of the heart function after the transplantation.

Animal Models of Atherosclerosis

Godfrey S. Getz, Catherine A. Reardon

Ben May Institute for Cancer Biology, University of Chicago, Chicago, IL, United States

In this chapter, we will primarily focus on models of atherosclerosis and myocardial infarction.

Atherosclerosis is a complex vascular inflammatory disease that underlies most clinical cardiovascular diseases. This includes coronary artery disease with complicating myocardial infarction, many subtypes of stroke, peripheral vascular disease, and aortic aneurysms. For coronary arterial disease, the risk factors are many; foremost of which are elevated LDL cholesterol levels, reduced HDL cholesterol levels, increased inflammation as measured by plasma levels of C-reactive protein and serum amyloid A, and leukocytosis, especially monocytosis. In some cases, it is unclear to what extent the factors are biomarkers as distinct from etiologic mediators. In what follows we pay attention to how one can modify these and other potential risk factors in the variety of animal models to determine the answer to the preceding question. Each model has advantages and disadvantages, though we recognize that no animal model can faithfully duplicate the situation in human patients. Recent development of advanced technologies can however, mitigate some but not all of the differences, especially those that are reflective of the fundamental physiological features of the model (species). Regardless, animal mod-

els are of particular value for the preclinical testing of potential therapeutic agents. Atherosclerosis is often enhanced in obese and diabetic subjects. These additional risk relationships, which may or may not operate via the traditional risk factors mentioned earlier, will not be discussed in this chapter, as they will be taken up in other chapters of this collection.

Atherosclerosis is a complex, focal, chronic inflammatory reaction of the intima of large and medium sized arteries. The features of the atherosclerotic plaque depend upon the maturation state of the lesion. The focality of lesion development is determined by the local hemodynamic pattern. Lesions preferentially develop in areas of disturbed flow, with regions of vessels experiencing laminar flow being relatively protected from lesion development. Lesion development depends on the interaction of global factors, for example, hyperlipidemia, with the focal environment in susceptible areas of vessel wall. The endothelium in the atherosclerosis prone and atherosclerosis protected regions of the vessel wall exhibits differences in barrier function and gene expression. An established risk factor that mediates the initiation of atherogenesis is high plasma levels of LDL. The near wall concentration of LDL is higher in the areas of disturbed

flow than it is in areas of laminar flow. Atherogenesis is initiated by the influx of plasma LDL into the intima at the susceptible sites where the lipoprotein is retained by interaction with intimal proteoglycans. ApoB100 on the LDL has a specific binding site for proteoglycans. The retained LDL in the intima may be modified by digestion with acid sphingomyelinase resulting in aggregation of the lipoprotein or by oxidation. Oxidized LDL initiates a number of proinflammatory processes. Its interaction with endothelial cells alters gene expression, including the upregulation of adhesion molecules resulting in the influx of monocytes that differentiate into macrophages within the intimal microenvironment. The macrophages take up the modified LDLs via their scavenger receptors or by macropinocytosis of aggregates of lipoproteins and in the process becoming lipid laden foam cells. The lipoprotein cholesterol liberated from the lipoprotein in the endosomal compartments traffics to the endoplasmic reticulum or to cell membranes where it may contribute to enhanced signaling. Most of the sterol in the endoplasmic reticulum is esterified by acyl cholesterol acyl transferase and is stored in the lipid droplets of the foam cells. There is a notable change in gene expression and protein levels in the lipid loaded cells. This includes upregulation of proteins that promote cholesterol efflux and proinflammatory cytokines and chemokines that among other things attract lymphocytes to the plaque. The result is a soup of cytokines and chemokines that are responsible for communication among the cells of the plaque microenvironment. The accumulation of free cholesterol in the endoplasmic reticulum of the macrophage foam cell can elicit the unfolded protein response and then apoptosis of these cells, which are removed by other macrophages by a process known as efferocytosis. However, with inefficient efferocytotic removal of these apoptotic cells, they undergo secondary necrosis (Tabas et al., 2015), which among other effects results in the liberation of the stored lipid droplets, creating a pool of extracellular lipid. The modified LDL may also function as a neoantigen eliciting an adaptive immune response. Macrophages in the plaque may function as antigen presenting cells, presenting modified peptides derived from the endocytosed LDL, eliciting an immune response to such potential autoantigens.

Among the consequences of macrophage signaling is the production of growth factors that promotes the proliferation of lesion macrophages. Other factors act on smooth muscle cells to promote their migration from the media into the intima where they proliferate and produce matrix and fibrous proteins that contribute to the formation of the fibrous cap over the intimal plaque. This contributes to the stable plaque phenotype. The plaque may be destabilized by the action of a variety of proteases secreted from macrophages and other inflammatory cells in the plaque. Disruption of the fibrous plaque can result in platelet aggregation and activation, which can lead to occlusion of the lumen and the interruption of the blood supply. This atherothrombosis is the critical unfavorable clinical sequelae of atherosclerosis. Prior to such an event, most of the features of the evolving atherosclerotic plaque are clinically silent. Thus most preventive approaches to dealing with atherosclerotic cardiovascular disease are directed at lowering the risk factors. Although the earlier description suggests a linear progression of lesion development, this is not necessarily the case in vivo.

It is 103 years since Anitschkov in his seminal studies first drew attention to cholesterol in eliciting arterial lesions in the rabbit (Steinberg, 2013). His studies were surprisingly thoughtful and perceptive. As it turns out the rabbit is particularly sensitive to a dietary cholesterol load. These observations could not be duplicated in rodents or dogs, which required the addition of cholate or thiouracil, respectively, to elicit both hypercholesterolemia and modest arterial lesions. With the subsequent large volume of work in animal models, our understanding of the process of atherogenesis has advanced immensely. This has involved both large animal models and murine models, especially the genetic manipulation of the mouse (Table 8.1).

1 PRIMATE MODELS

With the goal of understanding the human disease, one might expect many studies of the species that are closest in evolutionary distance, namely nonhuman primates, to have been undertaken. Indeed atherosclerosis in baboons, chimpanzees, rhesus monkeys, Cynomolgus monkeys, and African green monkeys has been studied (Getz and Reardon, 2012; Phillips et al., 2014). Nonhuman primates have a lipoprotein profile that closely resembles that of humans, with significant baseline concentrations of VLDL and LDL and heterogeneous HDL particles. Their hemodynamic profile and heart rate resembles that in humans. Upon the feeding of fat and cholesterol enriched diets, these animals develop lesions in the major arteries, including coronary arteries. Cynomolgus monkeys have been employed to explore the role of gender on the development of coronary artery atherosclerosis. As with humans, coronary artery lesions in Cynomolgus monkeys are more frequent in males than in females, but ovariectomy restores the equivalence of lesion frequency between the genders. The social behavior of these animals also allows for the analysis of social stress on coronary artery lesions. When subject to recurrent reorganization of social groups, dominant males have increased coronary lesions compared to subordinate males. However when in stable social groups, dominant males have fewer lesions, though not significantly so. On the other

TABLE 8.1   Animal Models of Atherosclerosis

Species	Advantages	Disadvantages
Nonhuman primates	Human-like lipoprotein profile	Ethical considerations of using this species, including genetic manipulations
	Human-like atherosclerotic lesions, including in coronary artery	Long time frame for lesion development
	Capable of sampling tissues/cells from vessels	Expense
Pigs	Human-like lipoprotein profile except for HDL subclasses	Currently few genetically modified models, although through the development of new techniques this limitation may be reduced
	Human-like atherosclerotic lesions, including in coronary artery	Expense
	Capable of sampling tissues/cells from vessels	
	Can be imaged noninvasively	
Rabbits—wild type		
	Cholesterol sensitive	Largely foaming lesions
	Express CETP (all rabbits)	β-VLDL is primary lipoprotein
		Hepatic lipase deficient (all rabbits)
	Can be imaged noninvasively	Currently few genetically modified models, although through the development of new techniques this limitation may be reduced
Rabbits—WHHL	Human-like lipoprotein profile	
	Spontaneously develop human-like lesions, including coronary lesions	
Mice—wild type	Multiple inbred strains with different susceptibility to atherosclerosis	Development of atherosclerosis requires a cholesterol and cholate containing diet
		Lipoprotein profile is significantly different from humans
Mice—genetically modified	More human-like lipoprotein profile in $Ldlr^{-/-}$ mice except for HDL subclasses	$Apoe^{-/-}$ mice accumulate remnant particles
	Atherosclerosis develops over a relatively short period of time	Lack of complex human-like atherosclerotic lesions
	Ease of breeding to generate transgenic/knockout/knockin or conditional knockout of specific genes on atherogenic background	Seldom observe coronary lesions except in complex models
		Limited ability to sample tissues/cells from vessel wall
		Limitations for noninvasive imaging

hand, dominant females always have fewer lesions than subordinate females (Kaplan et al., 2009).

Primates have the further advantage of their size allowing for the examination of arterial tissues and cells. However, there are several disadvantages to the use of these animals. Recently there has emerged a moral and ethical concern about whether these sentient animals should be used for experiments requiring their sacrifice as the endpoint of the study. The expense of the husbandry is substantial and few laboratories can bear this expense. Their life cycle and thus time line for development of atherosclerosis is long compared to that for other animal models and their susceptibility to genetic modulation is very limited, although modern technologies are beginning to overcome this particular barrier to experimentation (Niu et al., 2014).

2 PORCINE MODELS

A more tractable large animal model that does not pose the moral or ethical problems of the nonhuman primates is the pig, which has both similarities and modest differences from humans. Pigs have a similar cardiac

anatomy and develop atherosclerosis in a distribution similar to that seen in humans, including the coronary arteries. The pig resembles humans in having an apoB dependent lipoprotein profile. However, the pig does not express either cholesteryl ester transfer protein (CETP) or apo(a) and its HDL is homogeneous. Unstable plaques are also not characteristic of the arterial lesion in this species, perhaps related to differences in the thrombotic systems in pigs and humans (Vilahur et al., 2011). In seminal studies, Ross Gerrity (1981) followed the trajectory of monocytes into the atherosclerosis sensitive areas and their conversion to macrophage foam cells in the intima of swine using scanning electron microscopy. The ratio of monocytes to macrophage foam cells in the intima declined as the lesion matured. Atherosclerosis sensitive areas of increased permeability were defined by their ability to take up Evans blue dye.

Initial reports on the genetics of the lipoprotein system of the pig came from the laboratory of Jan Rapacz. First was the report of an apoB epitope change that led to hypercholesterolemia with elevated buoyant LDL and increased atherosclerosis in the coronary, iliac, and femoral arteries (Prescott et al., 1991). A later report concerned the finding of a point mutation in the ligand-binding domain of the LDL receptor (R84C) leading to recessive hypercholesterolemia (Hasler-Rapacz et al., 1998). The advent of recent genetic technologies involving the transplant of mutated somatic nuclei into the zygote have shown the proof of principle for the creation of new strains of Yucatan minipigs with specific genetic alterations. One of these involved the use of the Sleeping Beauty transposition system to create a somatic cell bearing a gain of function mutation in the proprotein convertase subtilisin/Kexin type 9 (PCSK9) gene that leads to reduced surface presentation of the LDL receptor in the liver and consequent reduced clearance of LDL (Al-Mashhadi et al., 2013). With high fat, high cholesterol diet, LDL levels were significantly increased and atherosclerosis formed in coronary arteries, aortic arch, and abdominal aorta in the PCSK9 mutant expressing pig, with lesion histology resembling human lesions. The atherosclerotic plaques in the pigs could be noninvasively imaged, suggesting that this transgenic pig may be useful model for preclinical testing of drugs or devices in an atherogenic environment. A second example is the use of AAV8 to reduce the expression of the LDL receptor in a somatic cell followed by nuclear transplant into zygote. The resultant minipig had elevated LDL levels and consequent atherosclerosis (Davis et al., 2014). Peter Davies has taken advantage of the size of the minipig to isolate endothelial cells from atherosclerosis sensitive aortic regions, including in the coronary artery, and atherosclerosis resistant regions within the same vessel to define the endothelial transcriptome (Civelek et al., 2011). Perhaps not surpris-

ingly, the transcriptomes differ significantly from one another.

3 RABBIT MODELS

As mentioned earlier, the feeding of cholesterol to rabbits, which are very sensitive to dietary cholesterol, has been fairly widely used for atherosclerosis research. Indeed until the description of mice deficient in apoE or the LDL receptor, rabbits, were the most frequently used animal models for atherosclerosis research (Fan et al., 2015). This includes cholesterol fed rabbits, particularly New Zealand White (NZW) rabbits and Japanese White rabbits, and the Watanabe Heritable Hyperlipidemic (WHHL) rabbits that develop atherosclerosis on a chow diet. The rabbit is a medium sized animal that is relatively inexpensive, easily bred, and housed, and shares advantages with larger animals with respect to tissue sampling and analysis of lesions. The WHHL rabbits were described in the early 1980s (Tanzawa et al., 1980). These rabbits have defective LDL receptor function due to a 12 nucleotide deletion (four amino acids) in the region of the gene encoding the cysteine rich ligand binding domain of the LDL receptor (Kita et al., 1982) and thus are defective in clearance of plasma LDL. But the receptor plays no role in the clearance of methylated LDL (Bilheimer et al., 1982). The lipoprotein profile of cholesterol fed NZW rabbits is distinct from that of the WHHL rabbits. The predominant lipoprotein in WHHL rabbit plasma is LDL, while in cholesterol fed rabbits this is β-VLDL. HDL levels are low in the WHHL rabbit. Comparing human and rabbit lipoprotein, there are similarities and differences. In both species, apoB is not edited in the liver, CETP is present in the plasma and HDL is heterogeneous, but the rabbit HDL does not contain apoA-II (Fan et al., 2015). Atherosclerotic lesions in cholesterol fed rabbits are largely foam cell lesions, although advanced lesions with calcification are also present. On the other hand, in the WHHL lesions are more like the complex lesions seen in human arteries. The advanced lesions in the aorta of the WHHL rabbit aged about 1 year have necrotic and lipid cores overlaid with a fibrous cap. While lesions develop in the coronary arteries of cholesterol fed rabbits, their distribution is not the same as in the WHHL rabbits and only in the WHHL rabbits do the coronary artery lesions advance to an obstructed artery resulting in myocardial infarction (Fan et al., 2015). The analysis of the whole genome of NZW, Japanese White, and WHHL rabbits has just been reported along with an analysis of the transcriptome in the liver and aorta of control and cholesterol fed NZW animals (Wang et al., 2016). Despite the differences in lipoproteins discussed earlier, the transcriptome of the aorta of cholesterol fed NZW and WHHL was surprisingly similar. One needs to note a caveat that this may not be found in older

animals with more advanced lesions. In the liver transcriptome, however, many more differentially expressed genes were noted in the cholesterol fed rabbits than in the WHHL rabbits, in keeping with previous reports that cholesterol was deposited in several tissues of the fed animals in contrast to the WHHL rabbits (Buja et al., 1983).

The range of plasma cholesterol levels is much narrower for the WHHL rabbits than for the cholesterol fed NZW rabbits. This makes the former rabbits very valuable for the assessment of therapeutic approaches, particularly for hypercholesterolemia. Additional genetic models have been created. At least 16 transgenic lines have been established affecting apoproteins, and enzymes influencing plasma lipoprotein metabolism, as well as a few genes affecting the vascular wall (Fan et al., 2015). This review points out the potential for creating gene knockouts in rabbits using modern targeting technologies, such as ZFN (zinc finger nucleases), TALEN (Transcription Activator Like Effector Nucleases), and CRISPR/Cas9 (Clustered Regularly Interspaced Palindrome Repeats/CRISPR Associated nucleases).

4 MOUSE MODELS AND ATHEROSCLEROSIS

4.1 Cholesterol and Lipoproteins

Unlike rabbits, rats and mice are relatively resistant to dietary cholesterol induced hypercholesterolemia, probably because of the capacity of their liver to readily convert cholesterol to bile acids, which are excreted into the bile. This process can be attenuated by the feeding of the bile acid cholate or by the administration of thiouracil. Thus, feeding rats a cholate containing cholesterol enriched diet resulted in modest lesions in rats (Wissler et al., 1954). Beverly Paigen used a similar diet in mice. The diet contains 15% fat derived either from milk fat or cocoa butter, 1%–1.25% cholesterol and 0.5% cholic acid or sodium cholate (Ishida et al., 1991; Paigen, 1995) and is often referred to as the Paigen diet. Inbred strains of mice fed the Paigen diet showed considerable variability in their susceptibility to diet induced aortic sinus atherosclerosis, which did not correlate with the plasma lipid responses to the diet. Among the strains studied, C57BL/6 was the most susceptible and this is the strain most widely employed in the experimentation on murine atherosclerosis. Indeed fully backcrossing genetically manipulated mice onto this background to evaluate its role in atherosclerosis is important, except in those instances when evaluating genetic differences across inbred strains is the goal of the study. The mouse has important advantages and disadvantages as a suitable model for atherosclerosis studies. It is small, easily bred and housed, inexpensive and highly susceptible to genetic manipulation. However, it's small size makes it difficult to sample arterial tissue for analysis. Its lipoprotein profile is also distinct from humans. In mice, HDL is their major lipoprotein and it is relatively homogeneous compared to human HDL. The atherosclerosis that develops in mice on the Paigen diet is limited and is confined to the apex of the aortic sinus. To induce robust atherosclerosis in mice, the lipoprotein profile must be substantially altered genetically to one in which there is a predominance of apoB containing lipoproteins. However, mice do not express CETP. But even in these genetically modified mice, atherosclerosis is not identical to that seen in primates. The distribution of the atherosclerotic lesions is different. Lesions are readily induced in the aortic sinuses in mice but not humans. This is probably related to the rapid heart rate in mice and the consequent flow disturbance around the aortic valves. Obstructive coronary lesions are very rarely seen except in certain complex genetic models to be discussed later. Also the lesions are relatively stable, seldom revealing the instability that is seen in advanced human lesions and that accounts for the clinical sequelae, including thrombosis that is so characteristic of human atherosclerotic heart disease.

Preclinical atherosclerosis research was greatly stimulated by the description of mice lacking either apoE or the LDL receptor in the early 1990s (Ishibashi et al., 1993; Plump et al., 1992; Zhang et al., 1992). These two models have been widely employed to gain understanding of the cells and genes/proteins that are important participants in atherogenesis (Hopkins, 2013; Tabas et al., 2015). As useful as are these two models, they nevertheless exhibit important differences especially in their lipoprotein composition and the mechanism by which the absence of the proteins promotes atherosclerosis. We have recently reviewed these differences (Getz and Reardon, 2016). Many cell types produce apoE and its absence impacts several metabolic processes. In lipoprotein metabolism, apoE is an important ligand for the uptake of lipoproteins by cell surface receptors on hepatocytes. Intestinally derived chylomicrons acquire apoE in the plasma, primarily from HDL. During the lipolysis of the triglycerides in chylomicrons in the circulation, chylomicron remnants are formed. Their clearance is mediated by apoE binding to three hepatic receptors; the LDL receptor, the LDL receptor related protein (LRP1), and heparan sulfate proteoglycans. The three receptors have some modest measure of functional redundancy. Hence, $Apoe^{-/-}$ mice are hyperlipidemic, whether on chow or high fat diets, primarily due to the accumulation of cholesteryl ester rich apoB48-containing chylomicron remnants. On the other hand, $Ldlr^{-/-}$ mice have profoundly elevated LDL levels with apoB100 as its major apoprotein that is increased on high fat diet fed animals along with an increase of triglyceride-rich VLDL.

$Apoe^{-/-}$ mice develop extensive atherosclerotic lesions even when fed chow, though of course lesion development and maturation are accelerated with the feeding of a high fat, high cholesterol Western type diet (in the absence of cholate). The more advanced lesions resemble human lesions. On the other hand, very little lesion development occurs in $Ldlr^{-/-}$ mice fed standard chow. A high cholesterol diet is required, with or without high fat, to elicit significant lesions. With added dietary fat $Ldlr^{-/-}$ mice are insulin resistant. Mice are unusual in that the apoB100 mRNA is edited in the liver to produce hepatic apoB48, which is produced only in the intestine in other species. The global removal of this activity, coupled with LDL receptor deficiency results in another model ($Ldlr^{-/-}Apobec^{-/-}$) that develops atherosclerosis while being fed a standard chow diet (Powell-Braxton et al., 1998).

It is very difficult to assess the comparability of atherogenesis in these two models because of the differences in their lipoprotein classes, size, and lipid and protein composition. In order to assess the relative atherogenicity of these particles, Stephen Young and coworkers created animals that express only apoB100 in both the $Apoe^{-/-}$ and the $Ldlr^{-/-}$ backgrounds (Veniant et al., 2008). Fortuitously, female animals of each of these genotypes had very similar total plasma cholesterol levels. In the apoE deficient background the cholesterol was carried in a smaller number of cholesterol rich large particles, while in the LDL receptor deficient background, the cholesterol was transported in a larger number of smaller particles, each of which carries a lower load of sterol. When fed a standard chow diet the $Ldlr^{-/-}apoB^{100/100}$ animals had more atherosclerosis. Increased permeability of these smaller lipoproteins across the vascular endothelium may be the mechanism.

4.2 Endothelial Cells

The major cell types that have been implicated in the atherogenic process are endothelial cells, monocyte/ macrophages and their subsets, and a variety of lymphocytes. The endothelial cells represent the cellular barrier to the influx of macromolecules and cells into the subendothelial space in the arterial wall. Endothelial cells are activated by hyperlipidemia and exhibit distinct gene expression profiles depending upon their flow exposure patterns. As pointed out earlier, atherogenesis localizes to sites of blood flow disturbance in the macrovascular arteries. The atherosclerosis resistant areas express important flow dependent genes, such as endothelial nitric oxide synthase (eNOS) with the production of high levels of nitric oxide and flow dependent activation of the transcription factors KLF4 and KLF2 that integrate antiinflammatory and antithrombotic gene expression in the endothelium at these sites. Thus the knockout of

these molecules in atherogenic mouse models results in an increment in atherosclerosis (Tabas et al., 2015). The atherosclerosis sensitive areas are distinct from their atherosclerosis resistant counterparts in that they express adhesion molecules that participate in the temporary sequestration of the cells in the blood, for example, monocytes on the surface of the endothelial cells. Such molecules include vascular cell adhesion molecule (VCAM) and platelet endothelial cell adhesion molecule (PECAM), although the role of this latter molecule in atherosclerosis is complex (Getz and Reardon, 2016).

4.3 The Monocyte/Macrophage

The macrophage is the core cell of the atherosclerotic plaque. Crossing of $Apoe^{-/-}$ mice with the $Mcsf1^{-/-}$ mice reinforced this. M-CSF1 (op) is the prime growth factor for monocytes and macrophages and the double knockout mice have a lower blood monocyte level and significantly lower atherosclerosis, especially in female mice, despite markedly elevated plasma cholesterol levels (Smith et al., 1995). Bone marrow transplantation has been employed to elucidate the contribution of bone marrow derived cells, especially monocyte/ macrophages, to atherogenesis. Transplantation of wild type bone marrow (expressing apoE) into apoE deficient hosts repairs the hyperlipidemia and atherosclerosis phenotype of $Apoe^{-/-}$ mice (Boisvert et al., 1995; Linton et al., 1995). Macrophage derived apoE is not unique in its ability to reduce the atherosclerosis phenotype. This is accomplished with transgenic expression of apoE at low levels in the adrenals, even with little effect on the hyperlipidemia (Thorngate et al., 2000). However, comparable plasma levels of apoE derived from adipose tissue is ineffective in repairing either the hyperlipidemia or the atherosclerosis (Huang et al., 2013). In contrast to the results with apoE expressing bone marrow, the transplantation of wild type bone marrow (expressing the LDL receptor) into $Ldlr^{-/-}$ recipients has virtually no effect on the atherosclerosis or the hyperlipidemia (Herijgers et al., 1997).

The adherent cells are attracted into the underlying intima by chemotactic gradients, the most important of which is that between CCL2 (MCP-1) and CCR2, a receptor highly expressed on major subsets of monocytes, notably the Ly6c^{hi} or inflammatory monocytes, which are the major monocyte subset involved in atherogenesis. The monocytes sequestered in the intima differentiate into macrophages, which participates in both the oxidative modification of the retained lipoproteins and their uptake by the scavenger receptors of the cells, forming foam cells. The loading of macrophages with cholesterol results in a variety of responses. These include the activation of cells to produce a variety of cytokines and chemokines that regulate the activation of endothelial cells and smooth muscle cells in the vessel wall. The chemokines

include CCL2 that attracts further monocytes from the blood, growth factors that promote the proliferation of macrophages, and others that stimulate the migration of smooth muscle cells into the intima. With the loading with cholesterol, some of this sterol may crystallize, and these crystals have been shown to activate the inflammasomes, which promotes the activation of caspase 1 and the production of IL-1β (Duewell et al., 2010).

Cholesterol loading results in changes in the expression of a network of proteins designated in the macrophage cholesterol responsive network (Becker et al., 2010). This network was identified by mass spectrometry using peritoneal macrophages from $Ldlr^{-/-}$ mice fed a Western type diet or standard chow. The proteins in this network belonged to several functional groups, including immune function, proteases, and complement proteins. The nuclear receptor liver X receptor (LXR) is also activated in cholesterol-loaded cells. Among the LXR stimulated proteins are several involved in reverse cholesterol transport, for example, ABCA1 and ABCG1, which may contribute to the limitation of cholesterol overload. It is evident that the cholesterol homeostasis in macrophages is complex, in which feedback mechanisms play an important regulatory role. One aspect of this regulation is the balance between incoming total cholesterol and the extent of its reesterification. Some free cholesterol is transported to the plasma membrane of the cell, where it can promote lipid raft formation, a microdomain important for signal transduction. Enrichment of the endoplasmic reticulum with free cholesterol in cholesterol-loaded macrophages can activate the unfolded protein response and subsequent apoptosis (Tabas et al., 2015). In the early stages of atherosclerosis, the apoptotic cells are removed by the efferocytotic activity of neighboring macrophages. The phagocytosed apoptotic cells contribute to the cholesterol load of the phagocytosing macrophage, so setting in motion a complex feed forward mechanism. If and when efferocytosis is no longer effective, for example, when Mertk, the apoptotic receptor on the cell surface of the efferocyte, is cleaved by the macrophage secreted proteases, the apoptotic cells may undergo secondary necrosis, forming the necrotic core of the more advanced plaques.

The enrichment of lipid rafts results in the concentration within these membrane microdomains of many enzymes and signaling molecules, including growth factor receptors and Toll Like Receptors (TLR), especially TLR2 and 4. The latter can serve as a receptor for minimally modified LDL, that is, LDL with modest extents of oxidative modification. The polyunsaturated fatty acids in minimally modified LDL are oxidized by the macrophage lipoxygenase. It's binding to TLR4 signals to the cell to produce inflammatory cytokines and to refashion the actin cytoskeleton, resulting in the macropinocytosis of the LDL products in the microenvironment (Miller et al., 2011). TLR4 signaling may also stimulate the production of reactive oxygen species. Growth factor receptor enrichment facilitates the proliferation of macrophages within the plaque.

Recent work has highlighted the importance of monocytosis and neutrophilia as positive risk factors for the development of atherosclerotic heart disease (Tall and Yvan-Charvet, 2015). One of the major influences on the production of these white blood cells is cholesterol homeostasis in their progenitor cells. The enrichment of cholesterol in these progenitor cells leads to increased expression of the common β subunit of IL-3/GM-CSF receptor and increased levels of these growth factor receptors and M-CSF receptor in lipid rafts. This results in the proliferation of the hematopoietic stem progenitor cells (HSPC) in response to IL-3, GM-CSF, and M-CSF giving rise to GMP and CMP cells, precursors of monocytes and granulocytes, respectively (Murphy et al., 2014). Monocytosis is more profound in $Apoe^{-/-}$ mice than in $Ldlr^{-/-}$ mice, probably due to apoE functioning in a cell autonomous fashion to promote cholesterol efflux in the HSPCs by its binding to cell surface heparan sulfate proteoglycans (Murphy et al., 2011). In this location, apoE serves as an acceptor for the efflux cholesterol.

4.4 Smooth Muscle Cells

As atherosclerotic plaques progress, smooth muscle cells migrate from the media into the intima, where they are responsible for the production of matrix proteins and the formation of the fibrous cap that provides a barrier against the activation of platelet by interaction with matrix proteins. One of the disadvantages of the $Apoe^{-/-}$ and $Ldlr^{-/-}$ models of atherosclerosis is that it is rare to observe unstable lesions with accompanying thrombosis as a result of the disruption of the fibrous cap that is seen in humans and several larger animal models. The basis for the lesion stability is not clear. These are the general views of the role of smooth muscle cells in atherogenesis. However, recent work with $Apoe^{-/-}$ animals has cast some ambiguity about this description (Tabas et al., 2015). This is because of the apparent ability of both smooth muscle cells and possibly macrophages to undergo phenotypic switching, so that the origin of the foam cells and smooth muscle like cells in the intima is uncertain. Thus smooth muscle cells that migrate into the intima may lose some of their characteristic markers and acquire macrophage markers and may become lipid-loaded. In addition, some apparent smooth muscle cells seem to be derived from the bone marrow. The ambiguity of these identifications awaits more definitive work.

4.5 Lymphocytes

The earlier discussion relates to the participation of the innate immune system in atherogenesis. The striking

increased incidence of cardiovascular diseases in patients with autoimmune diseases, such as systemic lupus erythematosus and rheumatoid arthritis suggests a strong involvement of the adaptive immune system as well (Witztum and Lichtman, 2014). The adaptive immune system is composed of a variety of T cell and B cell subsets. Some T cell subsets are found in atherosclerotic plaques. Th1 cells are proinflammatory, produce IFNγ and may provide help for antibody production. The inflammatory contribution of Th2 and Th17 cells is less clear. The action of the proinflammatory cells is countered by the antiinflammatory regulatory T cells (Tregs), which produce IL-10 and/or TGFβ. There is an extensive literature on the complex participation of T and B cells in atherogenesis, which we cannot detail here (Witztum and Lichtman, 2014). The atherosclerotic effect of the elimination of these adaptive immune cells depends upon the balance between the proinflammatory cells and their antiinflammatory counterparts, so that the outcome may not be predictable and straightforward. Both $Apoe^{-/-}$ mice and $Ldlr^{-/-}$ mice have been crossed with $Rag^{-/-}$ (recombination activating gene) mice that lack T and B cells. Both $Apoe^{-/-}Rag^{-/-}$ and $Ldlr^{-/-}Rag^{-/-}$ mice have reduced plasma cholesterol and reduced aortic root atherosclerosis but not innominate artery atherosclerosis (Reardon et al., 2001, 2003). The latter findings suggest that the balance between pro- and antiinflammatory immune cells may differ in different arterial beds. The specific removal of FOXP3+ Tregs in the $Ldlr^{-/-}$ background (Getz and Reardon, 2014; Klingenberg et al., 2013) leads to an increment in plasma cholesterol, mainly in the VLDL fraction, and also an increase in aortic sinus atherosclerosis. A model of autoimmune disease is seen in $Ldlr^{-/-} Apoa1^{-/-}$ mice that manifests as skin inflammation, lymphadenopathy, and a relative depletion of Tregs (Wilhelm et al., 2010; Zabalawi et al., 2007). This may contribute to the enhanced atherosclerosis observed in these mice.

A minor subset of T cells are natural killer T (NKT) cells, which bridge the innate and adaptive immune system, but are relevant because of they respond to lipid antigens. There are two classes of NKT cells. The major subset has relatively invariant T cell receptors, which in mice are Vα14Jα18 and a restricted set of β-chains. These are designated invariant NKT cells (iNKT). A second less frequent subset have a more diverse set of T cell receptor chains. The iNKT cells recognize glycosyl sphingolipid antigens presented by CD1d, a MHC class 1-like molecules, that is expressed on dendritic dells and macrophages and even on epithelial cells. The activating antigen may be endogenous or be derived from microorganisms, including those in the gut microbiome, though the precise nature of the endogenous antigen is not clear. These cells are readily activated without the necessity for prior education. Upon activation, they secrete IL-4 and IFNγ.

The liver and adipose tissue are enriched in iNKT cells. In the liver, iNKT cells make up as much as 40%–50% of the total T cells under "normal" conditions but the level of iNKT may vary quite widely depending upon the physiological circumstances. The adoptive transfer of splenocytes from Vα14 transgenic mice that are enriched in iNKT cells into immune deficient recipients ($Ldlr^{-/-}Rag^{-/-}$ mice) shows these cells to be proatherogenic (VanderLaan et al., 2007). This observation is consistent with findings using CD1d or Jα18 deficient mice crossed with either $Ldlr^{-/-}$ or $Apoe^{-/-}$ mice (Getz et al., 2011). Vα14tg/$Ldlr^{-/-}$ mice fed a high fat, high sucrose, cholesterol containing diet develop increased obesity, and atherosclerosis (Subramanian et al., 2013). A recent study indicates that the atherogenic activity of NKT cells is dependent on the cytotoxicity of the perforin and granzyme B secreted by the NKT cells (Li et al., 2015). IL-4 and IFNγ are not required for this effect. The perforin/granzyme B induces apoptosis in the lesional cells resulting in increased secondary necrosis in the lesion.

Like T cells, there are multiple subclasses of B cells. B2 cells are conventional antibody producing B cells that are probably proatherogenic, though their role is not without controversy (Tsiantoulas et al., 2014). Perhaps their precise activity depends on whether they are marginal zone or follicular B2 cell subsets. B1a cells produce germ line encoded natural antibodies of the IgM subtype and are found in the peritoneal cavity and spleen. A major set of B1a cells recognizes phosphocholine of bacterial cell wall and the phosphocholine head group of oxidized phosphatidylcholine. This antibody, designated T15/EO6, is found at high levels in $Apoe^{-/-}$ mice. These natural antibodies are thought to be atheroprotective, as exemplified by the increased atherosclerosis in $Ldlr^{-/-}$ mice that have cell surface IgM that is not secreted (i.e. soluble IgM deficient)(Lewis et al., 2009). It is noteworthy that these mice have an otherwise intact immune system. This may be relevant since the adoptive transfer of B1 cells producing "normal " levels of IgM to immune deficient $Ldlr^{-/-} Rag^{-/-}$ mice has no effect on atherosclerosis (Reardon CA, unpublished). Another minor subset of B cells is the B regulatory cells whose impact on atherosclerosis is unexplored.

4.6 Murine Models of Atherosclerosis Based on Expression of ApoE Variants

There are three common allelic variants of human apoE with the three protein isoforms designated as apoE2, apoE3, and apoE4. The isoforms differ by the amino acids at residues 112 and 158. Cysteine is present in both these positions in apoE2, while arginine occupies both positions in apoE4. ApoE3, the most frequent, "normal" isoform, has cysteine at position at 112 and arginine at 158. These amino acid variations result

in different protein conformations, which contributes to their functional differences. This has been reviewed by Mahley et al. (2009). In humans, some individuals homozygous for *APOE2* exhibit type III hyperlipoproteinemia and atherosclerosis, as well as xanthomatosis. This phenotype is thought to be attributable to the poor interaction of apoE2 with the LDL receptor and the consequent accumulation of VLDL remnants in the plasma. The reason why all *APOE2* homozygotes do not manifest this phenotype is not clear and is thought to require some additional genetic or environmental factor or factors. In human plasma, apoE3 preferentially associates with HDL, while apoE4 preferentially associates with VLDL. The differential lipoprotein association is primarily due to the interaction between residues 255 (glutamic acid) and 61(arginine) in apoE4, an interaction that is permitted by the presence of arginine at position 112. ApoE4 has a higher affinity for the LDL receptor than does apoE3. As a result, cholesterol-rich lipoproteins are more readily taken up by hepatocytes leading to the downregulation of the synthesis of the LDL receptor. Thus *APOE4* homozygotes tends to be hypercholesterolemic and more susceptible to atherosclerosis than *APOE3* homozygotes. In order to further explore the function of the isoforms, Maeda and coworkers created isoform replacement mice (Pendse et al., 2009), that is, mice expressing each of the human apoE isoforms in place of endogenous murine apoE. The *APOE2* replacement mice manifest a phenotype very similar to that seen in human subjects with type III hyperlipoproteinemia, including increased atherosclerosis. The *APOE4* replacement mice have a complex phenotype that also manifests an increased tendency to develop atherosclerosis. Thus, these replacement mice offer further opportunities for the exploration of the functions of the isoforms in a tractable experimental context.

Mouse apoE has an amino acid sequence similar to human apoE4 with respect to the amino acid at positions 112 and 158, but unlike the latter it has threonine at position 61 rather than arginine. Weisgraber and Raffai attempted to humanize mouse apoE by converting Thr61 to Arg61 (Raffai et al., 2001). In the course of this mutation they inserted a neomycin gene between two loxP sites in intron 3 of the apoE gene. This construct resulted in low expression of apoE (2%–5% of normal levels), so the resultant mice were designated "hypomorphic." Hypomorphic apoE mice fed chow exhibited a normal lipoprotein profile, but they were particularly sensitive to diet induced (containing cholate) hyperlipidemia and atherosclerosis (Raffai and Weisgraber, 2002). When the neomycin gene was excised by inducing Cre-mediated recombination, the mice had normal lipoproteins even on the atherogenic diet. *Apoe*$^{-/-}$ mice and hypomorphic apoE mice were crossed with *Ldlr*$^{-/-}$ mice. The resulting strains of mice were equally hypercholesterolemic on

chow diet and developed atherosclerosis, but the small amount of apoE in the hypomorphic cross was sufficient to reduce atherosclerosis (Gaudreault et al., 2012).

An additional atherogenic model based on a variant of apoE is the APOE*3 Leiden transgenic mouse (Lutgens et al., 1999; van Vlijmen et al., 1994). ApoE*3 Leiden has low affinity for the LDL receptor. The mice are less hyperlipidemic than *Apoe*$^{-/-}$ mice but develop atherosclerosis when fed an atherogenic diet.

4.7 Gene Identification by Strain Crosses

As mentioned earlier in this chapter, inbred strains of mice vary greatly in their susceptibility to develop atherosclerosis. In attempts to identify genes that might regulate atherosclerosis, *Apoe*$^{-/-}$ or *Ldlr*$^{-/-}$ mice in a sensitive genetic background (e.g., C57BL/6) have been crossed with *Apoe*$^{-/-}$ or *Ldlr*$^{-/-}$ mice in a resistant background (e.g., FVB). Several quantitative trait loci (QTL) were found from such crosses (Stylianou et al., 2012). However, after many studies, a single risk gene has been positively identified, *Raetle*, a major histocompatibility gene (Rodriguez et al., 2013). Given the advance in recent genetic technologies, it is not clear that this is the most cost effective approach. That said, a few crosses have been informative. Comparing C57BL/6 *Apoe*$^{-/-}$ with 129 *Apoe*$^{-/-}$ *mice*, aortic root lesions develop much more rapidly in the C57BL/6 strain, while aortic arch lesions develop more quickly in the 129 *Apoe*$^{-/-}$ strain. An intercross between these two strains identified a QTL that is associated with the increased aortic arch lesions that is also associated with the angle of the aortic arch bend in the 129 strain, likely producing different hemodynamic profiles at this aortic site in the two strains (Maeda et al., 2007; Tomita et al., 2010). An intercross of DBA *Apoe*$^{-/-}$ and 129 *Apoe*$^{-/-}$ revealed different QTLs for aortic root and aortic arch lesion development (Kayashima et al., 2014, 2015).

4.8 Experimental Myocardial Infarction in Mice

The most clinically important outcome of unstable atherosclerosis is coronary artery thrombosis and myocardial infarction. The most straightforward method to experimentally induce myocardial infarction is by the ligation of the left coronary artery, which is easily accomplished in the mouse because of its distinct coronary anatomy (Kumar et al., 2005). Myocardial infarction has been studied in *Apoe*$^{-/-}$ mice, in which it was shown that the healing of the infarct takes place in two stages. The first stage involves the influx of inflammatory monocytes (Ly6c^{hi}), followed by a predominance of healing monocytes (Ly6c^{lo}) at the infarct site. However, this switch may not be by influx of Ly6c^{lo} monocytes, but rather by the conversion of Ly6c^{hi}cells to Ly6c^{lo} cells in

situ (Dutta and Nahrendorf, 2015). The use of $Apoe^{-/-}$ mice for these experiments enabled the investigators to assess the effect of myocardial infarction on ongoing atherosclerosis. They showed that the cardiac injury indeed increased atherosclerosis, perhaps by the promotion of monocytosis, a known risk factor for atherosclerosis (Dutta et al., 2012). The increment in blood monocytes probably derives from the bone marrow under the influence of the stimulation of the sympathetic nervous system signaling (Dutta et al., 2012) and also the spleen, where extramedullary hematopoiesis is promoted (Robbins et al., 2012; Swirski et al., 2009). It is noteworthy that unlike the monocytosis induced by cholesterol loading of hematopoietic stem cells in the bone marrow (see earlier) when there was an accompanying neutrophilia, the response to myocardial infarction only involved the monocytes.

One of the striking features of the two models of murine atherosclerosis ($Apoe^{-/-}$ and $Ldlr^{-/-}$) is that they do not develop significant lesions in the main coronary arteries. However, more complex genetic models based on these two backgrounds do in fact develop these lesions (Table 8.2). This was first seen dramatically in mice deficient in both apoE and the B type scavenger receptor, SR-BI (Braun et al., 2002). These double knockout mice, even when fed standard chow, survived only to about 8 weeks of age. They had occlusive coronary artery lesions, evidence of platelet activity, myocardial fibrosis, and left ventricular cardiac dysfunction. SR-BI promotes the selective uptake of cholesteryl ester from HDL. It is widely expressed including on HSPC and this expression is required for the regulation of monocytosis and leukocytosis by apoA-I and HDL (Gao et al., 2014). The biogenesis of platelets is influenced by hypercholesterolemia, in part by promoting the conversion of megakaryocyte progenitors to mature platelets and by activating platelets (Wang and Tall, 2016). The ABC transporter ABCG4 is involved in the regulation of platelet production. In its absence, cholesterol accumulates in the

platelet and the thrombopoietin receptor is more highly expressed on the surface of megakaryocytes (Murphy et al., 2013). Elevated HDL reduces platelet biogenesis by promoting cholesterol efflux via ABCG4. SR-BI mediates the increase in eNOS activity in endothelial cells induced by HDL. SR-BI deficiency also leads to a change in the ratio of free to ester cholesterol in HDL and may not be as efficient in promoting cholesterol efflux. It is not possible to be certain which of the actions of SR-BI is most important in determining the phenotype seen in the $Apoe^{-/-}Srb1^{-/-}$ double knockout mice.

Variations on the SR-BI double knockout approach have also been associated with coronary artery occlusion and myocardial infarction. The binding of HDL to SR-BI initiates the activation of the downstream signaling: the adaptor protein PDZK1 (PDZ domain containing protein), Akt1 (Protein kinase B serine threonine kinase), and eNOS are activated. In fact when any of these proteins is eliminated in association with apoE deficiency, a very similar cardiac phenotype is observed as in the $Apoe^{-/-}Srb1^{-/-}$ mice, but only when an atherogenic diet is fed (Trigatti and Fuller, 2015). SR-BI deficiency has also been coupled with the hypomorphic apoE model. Such double mutant mice are normal when fed chow, but develop the coronary artery and cardiac phenotype when fed an atherogenic diet containing cholate (Zhang et al., 2005). In this model, transplantation of bone marrow expressing SR-BI rescues the coronary artery atherosclerosis, fibrosis, and cardiomegaly but not the lipoprotein dyslipidemia, underlying the importance of the receptor on some of the bone marrow derived cells (Pei et al., 2013). $Srb1^{-/-}Ldlr^{-/-}$ mice also develop occlusive coronary artery atherosclerosis and myocardial infarction (Fuller et al., 2014). This model is sensitive to the diet composition, being most obvious with diets enriched in cholesterol. The frequency of platelet markers in the occluding lesion was highest in mice fed the Paigen diet that contains cholate. There is little correlation between the atherosclerotic lesions in the coronary arteries and the aortic root.

$Apoe^{-/-}$ $Ldlr^{-/-}$ mice also exhibit coronary artery atherosclerosis and myocardial infarct when fed a Western type diet (Caligiuri et al., 1999). The overexpression of urokinase in macrophages on an $Apoe^{-/-}$ background leads to coronary artery lesions and myocardial infarction (Cozen et al., 2004). Thus, it is possible to generate murine models of coronary artery atherosclerosis and its consequent myocardial infarction by a variety of complex pathways based on either the $Apoe^{-/-}$ or the $Ldlr^{-/-}$ models. Both the ligation approach and genetic approach to coronary artery atherosclerosis and myocardial infarction provide models for preclinical testing of various therapies, though the latter has the virtue of working in the context of ongoing atherosclerosis which both contributes to and results from the therapeutic strategy.

TABLE 8.2   Mouse Models that Develop Coronary Artery Atherosclerosis and Myocardial Infarct

Genetic mouse model	Comments
$Apoe^{-/-}Srb1^{-/-}$	Survive only until 8 weeks of age
$Apoe^{-/-}Pdzk1^{-/-}$	Requires atherogenic diet
$Apoe^{-/-}Akt1^{-/-}$	Requires atherogenic diet
$Apoe^{-/-}Enos^{-/-}$	Requires atherogenic diet
$Ldlr^{-/-}Srb1^{-/-}$	Requires diets enriched in cholesterol
$Apoe^{-/-}Ldlr^{-/-}$	Requires atherogenic diet
Hypomorphic apoE, $Srb1^{-/-}$	Requires atherogenic diet with cholate

5 CONCLUDING COMMENTS

In this chapter, we have described a variety of large and small animal models that are used for the study of atherosclerosis. Each of these models has its unique advantages and limitations, not the least of which relates to husbandry issues. None of them fully duplicates the human condition and no doubt investigators appreciate this. The development of the new genetic technologies briefly referred to in this narrative will in the near future greatly expand our capacities to fashion new models based on what has been learned from analyses of disease related variations in the human genome of patients with cardiovascular disease. The limitations notwithstanding, the mouse models in particular have been of great value in uncovering potential mechanisms of atherogenesis, a very complex inflammatory disease that changes substantially over time. In the earlier narrative, we have tended to emphasize aspects of the cell biology of atherogenesis rather than the detailed biochemical interactions between cells and lipoproteins and their respective cross talk. Details of the latter can be found in excellent reviews (Hopkins, 2013; Tabas et al., 2015).

Animal Models of Metabolic Syndrome

Jessica P. Wayhart, Heather A. Lawson

Washington University School of Medicine, St. Louis, MO, United States

1 INTRODUCTION AND OVERVIEW

The metabolic syndrome (MetS) is a suite of metabolic complications including central obesity, hypertension, insulin resistance, impaired fasting glucose, dyslipidemia, and inflammation that, in some combination, increases an individual's risk of developing type-2 diabetes (T2D) and/or cardiovascular disease (CVD). Each of these metabolic complications is rising worldwide due to factors such as increasing population size, population aging, urbanization, excess caloric intake, and decreased physical activity. Prevalence of MetS currently exceeds 20% in the United States (for a review, see Eckel et al., 2005 and references within). While aspects of most expert definitions of MetS overlap, there is no single internationally accepted clinical definition because diagnostic criteria used to identify individual risk factors vary among populations, Table 9.1 (Einhorn et al., 2003; Grundy et al., 2005; International Diabetes Federation (IDF), 2006; Parikh and Mohan, 2012; The European Group for the study of Insulin Resistance (EGIR), 2002; World Health Organization (WHO), 1999). For example, intraabdominal fat deposits can lead to severe insulin resistance and T2D in some South Asian populations at body mass indexes that are not considered obese in Western populations (Spiegel and Hawkins, 2012). Variations in diagnostic criteria make it difficult to compare results of studies across populations, and worldwide prevalence of MetS per se is not well quantified. The lack of a single accepted definition has led some investigators to favor keeping individual metabolic complications separate for clinical management. However, others believe that identifying individuals with an aggregation of metabolic complications provides information that

TABLE 9.1　Multiple Expert Definitions of the Metabolic Syndrome (MetS)

Group	Diagnostic criteria
American Association of Clinical Endocrinologists (AACE)	Based on clinical judgment, some combination of the following: • Central obesity • High blood pressure • Hypertriglyceridemia • Impaired glucose tolerance • Inflammation • Low HDL-C
American Heart Association/National Cholesterol Education Program Adult Treatment Panel III (AHA/NCEP ATP III)	Three or more of the following: • Central obesity • High blood pressure • High fasting glucose • Hypertriglyceridemia • Low HDL-C
European Group for the Study of Insulin Resistance (EGIR)	Elevated plasma insulin plus two or more of the following: • Central obesity • High blood pressure • High fasting glucose • Hypertriglyceridemia
International Diabetes Federation (IDF)	Central obesity plus two or more of the following: • High blood pressure • High fasting glucose • Hypertriglyceridemia • Low HDL-C
World Health Organization (WHO)	Glucose intolerance, impaired glucose tolerance or diabetes and/or insulin resistance plus two or more of the following: • Central obesity • High blood pressure • Hypertriglyceridemia • Microalbuminuria

should guide clinical management (Eckel et al., 2005; Grundy, 2008; Kahn et al., 2005; Simmons et al., 2010).

Although clinical definitions of MetS are disputed, the frequent clustering of certain metabolic complications has been a recognized phenomenon since the 1920s (Kylin, 1923). Over time, this clustering has been referred as *syndrome X*, *the deadly quartet*, and the *insulin resistance syndrome* and represents a premorbid condition that is a substantial biomedical and public health challenge. Knowing how and why multiple metabolic complications cluster in some individuals and not in others will greatly improve clinical prevention, management and therapy of TD2 and CVD. To this end, research using animal models has provided key insights into MetS etiology and pathophysiology with the goal of uncovering potential therapeutic targets.

Animal models provide complex biological systems that can be controlled, manipulated, sampled, and studied under conditions and at scales that are not ethical or practical for human studies. While some physiological features of MetS components vary among species, the units of research translation are the underlying genes, biological processes, and/or physiological pathways that can alter normal metabolic phenotypes (Kraja et al., 2008). MetS is complex, involving nonlinear interactions among multiple organs such as adipose tissue, brain, gut, liver, pancreas, and skeletal muscle. Animal models provide an opportunity to examine interorgan cross talk in a whole organism and to directly sample relevant tissues. Even when an animal model does not faithfully mimic the human disorder, novel biological insights can be gained from an in vivo approach. For example, the mouse- and rat-based characterizations of the genes encoding the hormone leptin, *Lep*, and the leptin receptor, *Lepr*, identified mutations affecting lipid metabolism that result in extreme obesity in rodents (Chung et al., 1998; Cool et al., 2006; Kurtz et al., 1989; Varga et al., 2009). In humans, mutations in the orthologous genes LEP and LEPR represent extremely rare cases of obesity (Bergman et al., 2006; Gesta et al., 2007). Yet this animal-based research was essential to further research characterizing leptin metabolism and to identify the hypothalamic pathways controlling signals of satiety and the neural pathways in the brain's striatal region that control perceptions of reward associated with food intake (Belgardt et al., 2009; Elmquist et al., 1999; Konner et al., 2009).

This chapter provides an overview of animal models of MetS that are used to understand etiology and pathophysiology to inform potential therapies. Research aimed at understanding MetS etiology can identify and protect at risk individuals. Research aimed at understanding pathophysiology can shed light on how the clustering of different MetS components increases an individual's risk of developing T2D and CVD. It is important to note that these two broad categories —etiology and pathophysiology—are not mutually exclusive. Rather each informs the other and each is used to develop further research efforts aimed at testing therapeutic strategies to guide appropriate clinical interventions. Animal models of MetS tend to focus on specific metabolic components although, as is seen in humans diagnosed with MetS, individual metabolic complications will often cluster in any given model. For example, obesity and insulin resistance generally coincide in most rodent models, and increased adiposity is associated with dyslipidemia and insulin resistance in both nonhuman primate and porcine models.

2 CHOOSING AN ANIMAL MODEL OF MetS

Rodents, especially mice, are the most commonly used animal model for studying MetS, particularly for genetic studies, because they are relatively easy to

breed and maintain, have highly standardized phenotyping protocols, and high-coverage whole-genome sequences are available for the most commonly studied inbred strains. Table 9.2 lists the most frequently used mouse metabolic phenotyping tests and the data collected for each test. When studying MetS, multiple tests are performed on the same animal to study correlations among different phenotypes that mimic the clustering of metabolic complications in humans. An exciting new technology for assaying multiple measurements simultaneously in rodents is the PhenoMaster system (TSE Systems, Germany). The system uses intrahome-cage technology, and is capable of indirect calorimetry, as well as measurement of food consumption, fluid intake, and activity.

TABLE 9.2 Common Mouse Phenotyping Tests for MetS

Phenotyping test	Data collected
Euglycemic-hyperinsulinemic clamp	Insulin action and glucose metabolism
Intraperitoneal insulin sensitivity test (IPIST)	Insulin resistance, glucose tolerance, glucose disposal
Intraperitoneal glucose tolerance test (IPGTT)	Insulin secretion, glucose tolerance, glucose disposal
Oral glucose tolerance test (OGTT)	Insulin secretion, glucose tolerance, glucose disposal
Fasted bleed (4–6 h)	Glucose, insulin, blood biochemistry, other hormones (e.g., leptin, glucagon, peptide-YY)
Metabolic caging	Food intake, water intake, urine and feces production, urine biochemistry and glucose
Noninvasive intestinal fat absorption	Fecal fat absorption
Echocardiography	Myocardial performance
Cardiac telemetry	Blood pressure, heart rate, pulse pressure, activity
Indirect calorimetry	Metabolic rate (oxygen consumption, carbon dioxide production, respiratory quotient)
Meal pattern analysis	Food intake
Lipid profiles	Triglycerides, total cholesterol, phospholipids, free fatty acids
Fast protein liquid chromatography	Lipoproteins, lipids, apolipoproteins
Quantitative magnetic resonance	Fat mass, lean mass, water content
Tail cuff	Blood pressure
Running wheels	Energy expenditure, circadian activity
Measuring animal	Body weight, body length, fatpad and organ weights (at necropsy)

Several obese, diabetic, and hypertensive mouse strains are well characterized and have been used for decades of biomedical research. Further, transgenic and knockout mouse resources are commercially available (these are discussed in Section 4.1). Other species, including nonhuman primates and larger mammals, such as dogs, pigs, and sheep have also made important contributions to understanding MetS. In some cases these other species may be more appropriate animal models than rodents (Varga et al., 2009). For example, rodent fat depots are not directly translatable to humans (Pond and Mattacks, 1987). Thus the most common measurements used in human anthropometric studies (e.g., waist circumference) are not equivalent in mouse studies of obesity and adiposity. Additionally, there are important biochemical distinctions in adipose tissue between humans and mice. For example, levels of the adipokine adipsin are low in obese mice, but high in obese humans. High levels of the adipokine resistin impairs glucose tolerance in mice, but does not appear to do so in humans (Arner, 2005). Further, mouse lipoprotein profiles are composed mainly of high-density lipoprotein (HDL), which is atheroprotective, whereas humans carry mostly low-density lipoprotein (LDL). Pigs have similar LDL levels to humans, develop atherosclerotic plaques at the same sites as humans (in the aorta and carotid artery), and have similar hemodynamic parameters (Kalt et al., 2008; Turk and Laughlin, 2004). Pigs are frequently used to model CVD and atherosclerosis because their cardiovascular system is morphologically and functionally similar to humans (Litten-Brown et al., 2010). Certain breeds of pigs (namely the Ossabaw minipigs and domestic Piebalds) develop obesity, hypertension, and insulin resistance that fit some definitions of MetS in humans (Spurlock and Gabler, 2008).

Precise criteria to diagnose T2D in mice are not established, however, many aspects of blood glucose control are similar between mice and humans, so mice are frequently used to model glucose homeostasis and regulation of glucose metabolism. Notably, nonhuman primates develop T2D with similar pathological features as humans, including increased plasma triglyceride levels and total cholesterol concentrations (Wagner et al., 2006). Increased levels of adiposity in both baboons and rhesus macaques is associated with insulin resistance and dyslipidemia, similar to humans diagnosed with MetS (Comuzzie et al., 2003). Further, obesity and its associated metabolic complications have been extensively studied in dogs, since domestic dogs have experienced their own obesity "epidemic." There exists a wealth of pathological data available for many different breeds, and dogs exhibit variation in metabolic traits similar to that seen among human populations. Thus dog represents a potentially fruitful large animal model for testing biomedical hypotheses because of the

abundant physiological information available through veterinary data (Edney and Smith, 1986). Additionally, canine models provide a resource for longitudinal data collection that is not possible in smaller animal models (Ionut et al., 2010; Zheng et al., 2010).

Larger mammals may represent more physiologically faithful models of the individual metabolic complications comprising MetS. However, the expense, housing requirements, longer lifespan, relatively less standardized phenotyping protocols, and species-specific ethical considerations, particularly with nonhuman primates, make large scale studies using these animal models impractical. Thus when choosing an animal model of MetS, one must consider its relevant strengths and, when possible, integrate multiple lines of evidence. For example, results identified through discovery research using a rodent model can inform, be integrated with, and ideally validated by, small-scale follow-up studies using a larger mammalian system, which can then be a bridge toward designing relevant human studies.

3 ANIMAL MODELS OF MetS ETIOLOGY

Understanding MetS etiology is important for implementing prevention strategies, as well as for prescribing appropriate therapeutic interventions. The rising prevalence of metabolic complications among human populations is environmental in origin yet there is clearly an important genetic component reflected in variations in prevalence between the sexes and among ethnic groups (Eckel et al., 2005). Given the same environment, some individuals will develop metabolic complications while others will not, indicating that standing genetic variation modifies the effects of the environment on phenotype. In some cases, but not others, metabolic complications will cluster resulting in MetS. For example, common complications that cluster with obesity (and in some combinations define MetS, as discussed earlier) include insulin resistance, dyslipidemia, and increased blood pressure. Data from 1994 to 2004 of National Health and Nutrition Examination Survey (NHANES) found that approximately 32% of obese adults were "metabolically healthy" based on measures of blood pressure, homeostasis model assessment of insulin resistance (HOMA-IR), and plasma triglycerides and HDL-cholesterol concentrations (Wildman et al., 2008). Heritability estimates for individual MetS components are up to 70% for body mass index (BMI), 50%–90% for T2D, 22%–62% for systolic blood pressure, 20%–66% for diastolic blood pressure, 8%–72% for total cholesterol, and 19%–72% for total triglycerides (Bogardus, 2009; Clee and Attie, 2007; Elder et al., 2009; Permutt et al., 2005; Song et al., 2006; Walley et al., 2009). Clearly much phenotypic variability in these metabolic parameters can be attributed to

heritable genetic variation, and animal models are fundamental in discovering the genetic underpinnings of these parameters and of their relationships to each other. Animal models of MetS etiology allow both genetic and environmental factors to be controlled for, manipulated, and monitored in study populations of known origin (Lawson and Cheverud, 2010). This facilitates the discovery of genetic mechanisms, the testing of environmental influences, and the investigation of how these two factors—genetics and environment—sometimes interact and result in MetS.

4 GENETIC FACTORS

4.1 Common Rodent Genetic Models

Genetic studies using classic rodent models of obesity, such as the ob/ob and db/db mice and the Zucker fa/fa rats have identified single genes, namely leptin, *Lep* (ob/ob and Zucker fa/fa rats), and the leptin receptor, *Lepr* (db/db), with major variants leading to extreme obesity and other metabolic complications. Leptin is an adipose tissue derived protein hormone that binds to, and decreases the activity of, neuropeptide Y neurons. This signals satiety, and mutated forms of leptin results in an inability to feel sated leading to hyperphagia and obesity (for a comprehensive review of leptin biology, see Havel, 2004). In addition to extreme obesity, each of these animals to some degree are hyperinsulinemic, insulin resistant, and exhibit defective thermogenesis (Chung et al., 1998; Cool et al., 2006; Kurtz et al., 1989). The leptin-deficient mouse model, $Lep^{ob/ob}$, arose from a spontaneous mutation at the Jackson Laboratory (Ingalls et al., 1950). These mice are obese by 4 weeks of age, and can weigh up to 4 times that of their littermate controls on a standard chow diet. In addition to hyperphagia, reduced energy expenditure and extreme obesity, $Lep^{ob/ob}$ mice have elevated serum cholesterol levels. However, this elevation is in HDL-rather than in LDL-cholesterol, so they are actually protected from developing diet-induced atherosclerosis (Nishina et al., 1994). An additional metabolic abnormality in $Lep^{ob/ob}$ mice involves disregulation of the hypothalamic-pituitary-adrenal axis, of which leptin is an important regulating hormone (Malendowicz et al., 2007). A complication with this model is that $Lep^{ob/ob}$ are infertile, which impedes collecting appropriate samples sizes (Kennedy et al., 2010). Leptin receptor-deficient mice, $LepR^{db/db}$, have nearly identical metabolic profiles and hypothalamic-pituitary-adrenal axis and reproduction problems as $Lep^{ob/ob}$ mice. The significant difference between the two models is that $LepR^{db/db}$ mice have pronounced concentrations of circulating leptin while the $Lep^{ob/ob}$ mice have none at all. Thus the $LepR^{db/db}$ model is frequently used to study

how leptin concentrations affect different cell types in metabolic studies (Surmi et al., 2008). Finally, the leptin receptor-deficient obese Zucker fa/fa rat model is significantly hyperphagic compared to its lean littermates by as early as 17-days old (Kava et al., 1990). These rats are hyperlipidemic and hyperinsulinemic, but are relatively normoglycemic. They are frequently used to study adipose tissue in obesity and the physiological effects of disregulation of leptin signaling (Miranville et al., 2012; Pico et al., 2002).

The Agouti lethal yellow mouse model, $A^{y/a}$, has several spontaneous mutations affecting expression of the agouti protein, transcribed by the agouti gene, A. The agouti protein acts as an antagonist of the melanocortin-signaling pathway, which mediates leptin action. These mice display variation in coat colors and develop adult onset obesity and insulin resistance due to hyperphagia and hypoactivity. Obese $A^{y/a}$ mice are hypertensive but they do not form atherosclerotic lesions on high fat diets (Burgueno et al., 2007). It is easier to obtain offspring and appropriate sample sizes from $A^{y/a}$ than from either $Lep^{ob/ob}$ or $LepR^{db/db}$ because $A^{y/a}$ remain fertile until approximately 4 months of age (Kennedy et al., 2010). Other commonly used single-gene rodent models of obesity and insulin resistance include the fat/fat (variants responsible for the phenotype have been characterized in carboxypeptidase E, Cpe) and tub/tub (variants responsible for the phenotype have been characterized in the tubby candidate gene, Tub) mice (Carroll et al., 2004; Coleman and Eicher, 1990; Naggert et al., 1995).

The low-density lipoprotein receptor-deficient mouse, $LdlR^{-/-}$, is a model of hyperlipidemia that has elevated atherogenic LDL lipoprotein levels similar to that seen in humans with hypercholesterolemia (Ishibashi et al., 1993). These mice will become obese and develop insulin resistance in response to high fat diets (Wu et al., 2006). The apolipoprotein E-deficient mouse, $apoE^{-/-}$, is another frequently used model that develops severe hyperlipidemia, but generally does not become obese and insulin resistant, even on a high fat diet (Hofmann et al., 2008). APOE is a lipoprotein ligand that is recognized by multiple receptors in the liver. Mutant forms of APOE result in elevated very low-density lipoprotein (VLDL). To better approximate the clustering of metabolic complications of MetS, $A^{y/a}$, $Lep^{ob/ob}$, and $LepR^{db/db}$ mice can be crossed with $LdlR^{-/-}$ or $apoE^{-/-}$ mice (Hasty et al., 2001).

When designing an experiment using these classic monogenic models it is important to consider strain background (Coleman and Hummel, 1973). Each strain has a unique combination of alleles and therefore of disease susceptible loci. Different mouse strains vary for different phenotypic traits and when considering complex, polygenic traits, such as those comprising MetS, genetic background—that is, strain effects—can

confound results. This is because of epistatic and/or compensatory interactions among loci. For example, when the Lep^{ob} mutation is bred into a BTBR (black and tan, brachyuric strain) background, the $Lep^{ob/ob}$ mice develop severe diabetes (Clee et al., 2005). However, in the C57BL/6J (the most widely used of all inbred strains and the $Mus\ musculus$ reference genome strain) background, $Lep^{ob/ob}$ mice present as mildly hyperglycemic between 8 and 12 weeks of age, but then glucose levels return to near normal (Coleman and Hummel, 1973). In contrast to other strains, BALB $Lep^{ob/ob}$ mice are fertile (Clee and Attie, 2007). FVB (friend virus B strain) $LepR^{db/db}$ mice have more severe hyperinsulinemia and hyperglycemia than C57BL/6J $LepR^{db/db}$ mice (Chua et al., 2002). $A^{y/a}$ mice are generally studied on C57BL/6J or KK (originally generated from wild-derived ddY mice in Japan) backgrounds, and the MetS phenotype is more extreme in the KK strain, with KK $A^{y/a}$ animals exhibiting age-onset obesity, hypertension, insulin resistance, and diabetic nephropathy (Okazaki et al., 2002).

The models described previously represent some of the most commonly used monogenic rodent models of metabolic complications. However, single-gene mutations account for a very small percentage of the overall heritable variation of any MetS component, and account for a negligible percentage of MetS cases in human populations (Bogardus, 2009). Polygenic rodent models have also been developed that include, but are not limited to, the NZO, TallyHo, and KK inbred mouse strains and the OM, WOKW, and SHR rats (Bielschowsky and Goodall, 1970; Clee and Attie, 2007; Dulin and Wyse, 1970; Fisler et al., 1993; Kloting et al., 2006; Noda et al., 2010; Song et al., 2006). Each of these models is frequently used to study the genetic inheritance of individual MetS components and how these components correlate. NZO, the New Zealand obese strain, is a spontaneous model of polygenic obesity and insulin resistance. It is frequently used as a model of MetS because in addition to being obese, animals are hyperinsulinemic, show reduced insulin-stimulated glucose uptake in muscle and adipose tissues, have high serum triglyceride levels, and present with elevated blood pressure. TallyHo is a naturally occurring model of obesity and diabetes that also displays hyperlipidemia. KK mice (of which there are many substrains) are obese, hyperleptinemic, severely hyperinsulinemic, and animals display insulin resistance in both adipose and muscle tissues. OM, the Osborne–Mendel rat, is susceptible to dietary obesity and develops cardiac hypertrophy and hyperinsulinemia (Fitzgerald et al., 2001). WOKW, the Wistar Ottawa Karlsburg W rat, is obese and exhibits decreased insulin sensitivity and insulin-stimulated glucose uptake in adipose tissue. WOKW animals also display dislipidemia and hyperleptinemia and are frequently crossed with disease-resistant rat strains for studying

MetS (Kovacs et al., 2000). SHR, the spontaneously hypertensive rat, is the most frequently used animal model of blood pressure and hypertension, but it is commonly used to study MetS because these animals also display insulin resistance, hypertriglyceridemia, and obesity (van den Brandt et al., 2000). Recently, a new rat model of MetS, the UCD-T2DM, was generated by researchers at the University of California-Davis by crossing the obese Sprague-Dawly rat with lean Zucker diabetic fatty rats. The UCD-T2DM rat develops polygenic obesity with insulin resistance, impaired glucose tolerance and beta-cell decomposition (Cummings et al., 2008).

Polygenic models may be better suited than monogenic models for studying the genetic underpinnings of MetS etiology, because most of the metabolic complications comprising the individual MetS components are the result of many interacting genes of individually small effects. The Jackson Labs provides a comprehensive catalog of mouse models of MetS components including both monogenic and polygenic models for CVD, T2D, and obesity (http://www.jax.org). Their catalog provides information on strain history, phenotypes, health and husbandry, as well as their susceptibility to diseases. Further, the Jackson Labs provides an online version of the book "Biology of the Laboratory Mouse," which provides information on mouse biology, as well as husbandry (http://www.informatics.jax.org/greenbook/). Additionally, the Mouse Phenome Database provides phenotypic information across mouse strains. The Rat Genome Database (http://rgd.mcw.edu/) provides genotypic and phenotypic information on rat models, and provides multiple tools for researchers to mine rat-generated genomic and phenotypic data. These resources include valuable information for designing and executing rodent model studies, which are not only aimed at understanding MetS etiology, using the aforementioned described monogenic or polygenic models, but also aimed at identifying the genetic underpinnings of MetS components through targeted candidate gene approaches or through genetic mapping studies that identify quantitative trait loci (QTL) and novel genes associated with variation in metabolic parameters.

Recently, the number of whole genome sequences for individual mouse strains has expanded immensely. The Wellcome Trust's Mouse Genomes Project has made the complete genomes of 36 inbred strains available for the scientific community's use (http://www.sanger.ac.uk/science/data/mouse-genomes-project). Their database includes raw sequence data in addition to characterized polymorphisms, such as SNPs, indels, and structural variants. Additionally, whole genome sequences for the FVB/NJ (Wong et al., 2012), LG/J, and SM/J (Nikolskiy et al., 2015) inbred strains are available, including strain specific variants relative to the reference C57BL/6J strain. Further, the Mouse Diversity Array measures

~600,000 genotypes and has been applied to several hundred laboratory strains (Yang et al., 2009). These data significantly improve researchers' ability to relate genotype to phenotype and elucidate underlying molecular mechanisms (Keane et al., 2011).

4.2 Candidate Gene Approaches: Testing Biological Hypotheses

Candidate gene approaches can be used to test hypotheses about the genetic basis of a trait, based on a priori knowledge of that trait and some biological evidence that a focal gene of interest affects phenotype. Candidate genes are usually studied in animal models by targeted manipulation using genetic engineering technologies in embryonic stem cells to knockout (to remove or disrupt transcription of the gene of interest) or to knock-in (to mutate or to insert a variant of the gene of interest), and then to monitor any phenotypic consequences in mice heterozygous and/or homozygous for the targeted gene. Knockout (KO) models can provide key insights into target gene actions, and knock-in (KI) mice are useful for assessing subtle effects of mutations on protein structure or function. KO and KI mice are produced by incorporating the modified embryonic stem cells into the germ line, and then by interbreeding animals that develop with one copy of the targeted gene in their cells to generate animals that are homozygous for the manipulated gene. A key problem with genetic manipulation approaches is that manipulation of the targeted gene may result in embryonic death, preventing study of its effects on offspring or adult phenotype. Another problem is that genetic manipulations can induce compensatory changes, where other mechanisms take over the targeted gene's action and the targeted gene appears to have little phenotypic effect, even if it is important. Still, targeted manipulation of candidate genes is a powerful way to test biological hypotheses because mutations can be selectively targeted to specific tissues, cells, and/or particular developmental stages allowing physiological, developmental and/or behavioral complications to be studied. Manipulation of the mouse genome has been possible for over 20 years, and there are many resources available for planning and executing such experiments (Capecchi, 1989a,b; Nadeau et al., 2001). For example, The International Mouse Phenotyping Consortium (http://www.mousephenotype.org/) is working to mutate every protein-coding gene in the mouse, and Mouse Genome Informatics (http://www.informatics.jax.org/) provides a collection of phenotypes and mutagenesis community resources (Collins et al., 2007).

Recently, CRISPR/Cas9 technology has allowed for generation of null, conditional, precisely mutated, reporter, or tagged alleles in mice (Jinek et al., 2012; Singh et al., 2015). This gene-editing technique is being used

to generate new KO mice, via a CRISPR (clustered regularly interspersed short palindromic repeats) mediated nonhomologous end joining approach. This approach utilizes single guide RNAs, which are directly injected into embryos along with Cas9 mRNA. This results in mice bearing frame-shifting mutations (insertion/deletions) that disrupt target genes. KI mice use CRISPR mediated homology directed repair. This approach utilizes a single-stranded oligonucleotide or a plasmid template, which is coinjected with single stranded RNAs and Cas9 mRNA. Generation of Cre-recombinase-dependent Cas9 allows tissue-specific or conditional gene editing (Yang et al., 2013). The Jackson Labs has generated close to 200 CRISPR/Cas9 mediated mouse models on multiple genetic backgrounds (www.jax.org/mouse-search).

4.3 Thrifty Genes

One hypothesis proposed to explain the genetic underpinnings of MetS, and which has motivated many candidate gene studies, is the "thrifty genotype hypothesis". The thrifty genotype hypothesis proposes that for most of evolutionary history, high-caloric foods were rare relative to the energy that was required to acquire them (Neel, 1962). Genetic variation that was efficient at stowing away excess calories in adipose tissue may have led to survival and fertility advantages that were advanced by natural selection over time. This hypothesis assumes that these "thrifty" genetic variants predispose an individual to metabolic complications in an environment where high-caloric foods are easily obtained. Candidate gene approaches testing the thrifty genotype hypothesis focus on genes involved in physiological processes necessary for energy balance, storage, and nutrition partitioning.

For example, the peroxisome proliferator-activated receptors (PPARs) are lipid-activated nuclear receptors that are necessary for multiple physiological processes important for energy balance (Lodhi and Semenkovich, 2014; Wang, 2010). These include fatty-acid catabolism (PPARα), thermoregulation and insulin homeostasis (PPARδ), and lipid metabolism and glucose homeostasis (PPARγ) (Barbier et al., 2002; Grimaldi, 2005; Wahli et al., 1995). $Ppar\alpha^{-/-}$ mice have decreased expression of fatty-acid oxidation genes and have a fatty liver phenotype indicating that $Ppar\alpha$ regulates hepatic lipid catabolism (Akiyama et al., 2001; Aoyama et al., 1998; Sugden et al., 2002). $Ppar\delta$ adipose-specific knockout mice have compromised thermoregulation. Analysis of $Ppar\delta$ deficient brown fat cells generated from mice containing floxed [a method of conditional targeting wherein one or more of a candidate gene's exons are flanked by lox P sites, allowing the gene to be manipulated by Cre recombinase action (reviewed in Brault et al., 2007)] $Ppar\delta$ alleles show downregulated expression of fat-burning

genes, indicating that $Ppar\delta$ is important in brown fat metabolism (Pan et al., 2009). Additionally, $Ppar\delta$ skeletal muscle-specific knockout mice have increased weight and insulin resistance relative to controls (Schuler et al., 2006). $Ppar\gamma$ adipose-specific knockout mice show lipodystrophy, high serum free-fatty acids and triglyceride levels, and decreased leptin and adiponectin levels (He et al., 2003). $Ppar\gamma$ muscle-specific knockout mice show increased adiposity and insulin resistance (Hevener et al., 2003; Norris et al., 2003). These studies have demonstrated that the PPARs play a substantial role in energy balance and metabolism, and that disruption of normal PPAR transcription can contribute to multiple metabolic complications clustering as MetS. These genes have been implicated in human association studies for both obesity and T2D (Kunej et al., 2012). However, more research is required to understand the detailed molecular mechanisms by which the PPARs interact with each other and with other genes in their transcriptional pathways.

Another candidate gene studied to test the thrifty gene hypothesis is the melanocortin-4 receptor, MC4R. The central melanocortin system mediates leptin action and plays an important role in energy homeostasis (Cone, 2005). Variations in MC4R cause obesity in humans (Marti et al., 2003; Willer et al., 2009). $Mc4\text{-}R^{-/-}$ mice develop the obese, hyperglycemic, and hyperinsulinemic phenotypes that are typical of MetS; however, their triglycerides appear to be normal and they tend to be hypotensive (Tallam et al., 2005). The obesity in these mice is behavioral, resulting from hyperphagia, but the hyperinsulinemia is only partially due to obesity as young $Mc4\text{-}R^{-/-}$ animals have elevated circulating insulin levels prior to becoming obese (Fan et al., 2000). A final example of this candidate gene approach tested the thrombosponin receptor, CD36. CD36 first identified as associated with insulin sensitivity and hypertension in SHR rats discussed earlier (Aitman et al., 1999; Pravenec et al., 2001). Insulin sensitivity affects the body's ability to use stored fat for energy and reduced insulin sensitivity or insulin resistance is a precursor for T2D. Further studies in $Cd36$ knockout mice revealed that this gene plays an important role in lipid processing, in insulin action, and atherogenesis (Drover et al., 2005; Goudriaan et al., 2005; Varga et al., 2009). Follow-up studies in human populations confirm that mutations affecting CD36 expression play a role in MetS risk (Griffin et al., 2001; Ma et al., 2004; Miyaoka et al., 2001).

Mouse models focused on testing biological hypotheses about candidate genes have advanced the study of MetS etiology by identifying a large number of physiologically plausible genes and pathways. However, as discussed earlier, strain background is important for assessing phenotypic consequences of candidate gene effects. For example, 85% of C57BL/6J mice heterozygous

for the insulin receptor knockout ($InsR^{+/-}$) and heterozygous for the insulin receptor substrate-1 ($Irs-1^{+/-}$) develop apparent diabetes by 6 months of age. However, only 64% of DBA mice and only 2% of 129Sv mice with the same mutations do (Kulkarni et al., 2003). Thus strain background must be considered along with the use of appropriate controls when designing candidate gene experiments.

4.4 Candidate Gene Approaches: Translating Human GWAS Results

Related to the candidate gene approach to test specific hypotheses about thrifty genes is the use of mouse models to directly test hypotheses about variants that were identified in human genome-wide association studies (GWAS). The idea is to translate variants that are significantly associated with common diseases in human studies to an animal model, with the goal of identifying the disease-causing gene within a GWAS linkage block. Variants identified in GWAS are part of linkage blocks, or sequences that are nonrandomly inherited together, and the disease-associated variant is usually not obvious and can often be found in noncoding sequence far from annotated genes (Wellcome Trust Case Control Consortium, 2007). An example of this candidate gene approach used mouse models to test the fat mass and obesity associated FTO locus. Multiple GWAS identified FTO as associated with T2D (although the association with T2D was lost once body mass index was controlled for) (Cox and Church, 2011; Dina et al., 2007; Frayling et al., 2007; Scuteri et al., 2007). *Fto* knockout mice showed a lean phenotype, reduced adipose tissue, and increased energy expenditure, despite being hyperphagic relative to controls. These animals also exhibited increased postnatal lethality and growth retardation (Fischer et al., 2009). An experiment that incorporated a missense mutation into the gene, causing loss of *fto* demethylase function, resulted in mice with reduced adipose tissue but without the additional phenotypic complications of the knockout (Church et al., 2009). Finally, over expression of the *fto* gene in mice resulted in extreme obesity due to hyperphagia (Church et al., 2010). Targeted manipulation of *fto* in these mouse models suggests FTO plays a role in energy homeostasis. This supports the GWAS results indicating that certain variants in human populations put an individual at risk for developing obesity and other obesity-related metabolic complications of MetS.

Another focused candidate approach targeted a linkage peak (containing multiple genes) on human chromosome 3 that is associated with a combined obesity-insulin factor in multiple human studies (Kraja et al., 2012). The researchers integrated the human linkage results with results from a mouse genetic mapping study that identified a significant association with serum insulin and glucose levels in the syntenic region of mouse chromosome 6. The researchers then performed a targeted association analysis in the focal human chromosome 3 region. By using the mouse results to "protect" the focal region in the human data from the extreme burden of multiple tests correction (essentially using the mouse results as an a priori hypothesis), novel genetic associations with multiple MetS components were identified.

The National Center of Biotechnology Information (NCBI) provides a database of genotypes and phenotypes (dbGaP) that both archives and distributes results of GWAS and other human genotype to phenotype studies, including many studies focused on metabolic complications (http://www.ncbi.nlm.nih.gov/sites/entrez?db=gap). As discussed in Section 1, the exact same variant is unlikely to affect humans and other species in the exact same way, but the units of research translation are the underlying genes, biological processes, and/or physiological pathways the genes interact in that can alter normal metabolic phenotypes. An assumption of this candidate approach is that these units of research translation have a similar function in humans and other species with respect to the disease process. Developing animal models that target variants underlying GWAS loci represents a powerful translational tool for identifying potential causal genes and elucidating how they function in disease and/or disease risk. Additionally, because human/mouse homology is well defined, using mouse results to protect homologous regions in these archived human data for correlated phenotypes will increase statistical power and identify new variants in candidate regions associated with disease and/or disease risk. Incorporating the candidate gene approach with GWAS results is a powerful method of identifying potentially relevant variants associated with MetS and rodent, especially mouse, models have proven invaluable tools for characterizing function and deconstructing molecular mechanisms (Fig. 9.1). Other genetic studies using animal models aim to identify novel MetS associated variants through hypothesis-free genetic mapping studies.

4.5 Identifying Quantitative Trait Loci and Novel Genes

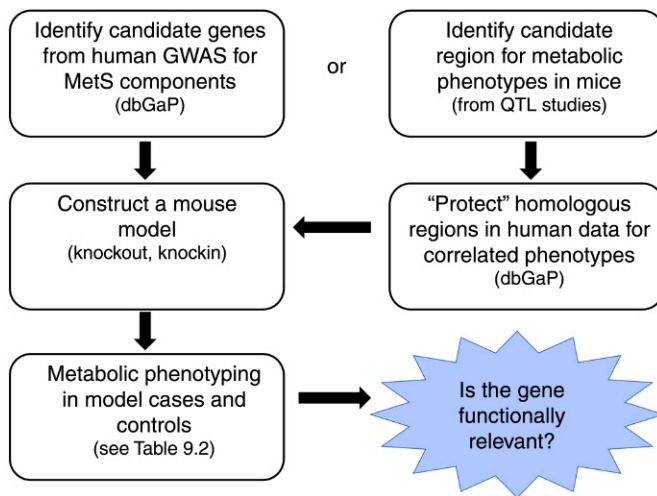
Genetic mapping studies in animal models allow large numbers of offspring to be generated from relatively few founders of known genomic background. When the founders crossed differ in the trait of interest, for example, in levels of adiposity, phenotypic variation in the offspring can be correlated with genotypic variation in markers scored in the same individuals to identify QTL. Common markers used in QTL mapping are single-nucleotide polymorphisms, SNPs, but other


FIGURE 9.1 **A candidate gene approach for translating human GWAS results.** Associations identified in human studies can be directly tested in a mouse model to determine if the candidate gene affects the phenotype. Alternatively, mouse QTL regions can be used to mine GWAS results for correlated phenotypes and protect human syntenic regions from strict genome-wide multiple tests corrections. Candidate genes that are significant in the protected region (but that may have only been suggestive at the genome-wide level) can then be tested for functional relevance by going back to the mouse.

FIGURE 9.2 **An example QTL.** LOD scores (limit of detection, *y*-axis) are plotted along a chromosome (illustrated here in centiMorgans, *x*-axis) and represent the strength of a genomic association with phenotypic variance in a population. A higher LOD score indicates a lower probability that the association is by chance. A significance threshold is determined based on the number of genomic markers tested. The highest LOD score indicates the peak of the QTL and a support interval is defined (generally a 1-LOD drop from the peak position) to identify a physical region of the genome that can be interrogated for candidate genes. Note the cartoon chromosome refers to a generic mouse chromosome. All mouse chromosomes are acrocentric.

markers that vary within the experimental population, for example, microsatellites, can be used. In QTL studies, smaller sample sizes are required to find associations that can explain more than 50% of the heritable variation of a trait. In humans, thousands of individuals are required and findings typically explain a very small portion of the heritable variance. QTL represent physical locations on a chromosome in which genetic variants associate with phenotypic variation that was measured in the experimental population, illustrated in Fig. 9.2. As with candidate gene approaches, most QTL associated with MetS components have been identified and characterized in rodent, especially mouse, models (reviewed in: Lawson and Cheverud, 2010).

For rodent QTL mapping studies, the general experimental design is to first cross two inbred strains that are phenotypically distinct for the trait of interest (appropriately distinct strains can be identified using the Mouse Phenome Database and the Jackson Labs catalog as discussed earlier). The F_1 offspring are then either bred to each other to generate an F_2 intercross population, or bred back to one or both parental strains to generate a backcross population. An intercross between two genetically identical F_1 animals will result in F_2 animals with recombination on both transmitted chromosomes. An F_2 intercross, by having all possible combinations of genotypes represented at each locus, can provide information on both additive and dominance genetic effects. One-half of the chromosomes in

backcross offspring will be recombinants from the F_1 parents. Backcross offspring are either heterozygote or homozygote for one parental allele at each locus, and can therefore provide information on alleles acting in a dominant fashion. In addition to using backcross or intercross experimental populations, QTL are commonly mapped in recombinant inbred (RI) strains, chromosome substitution strains or outbred stocks (for detailed discussion on these types of mice, refer to the Jackson Labs' "Biology of the Laboratory Mouse" online reference: http://www.informatics.jax.org/greenbook/). In a QTL study, mapping resolution (the power to localize an association) is a function of the number of recombination events that occur between genotyped markers. For example, an F_{16} Advanced Intercross population has 8 times the recombination of an F_2 intercross and QTL support intervals will be much smaller, containing 10s rather than 100s of genes to interrogate, as illustrated in Fig. 9.3 (Lawson and Cheverud, 2010).

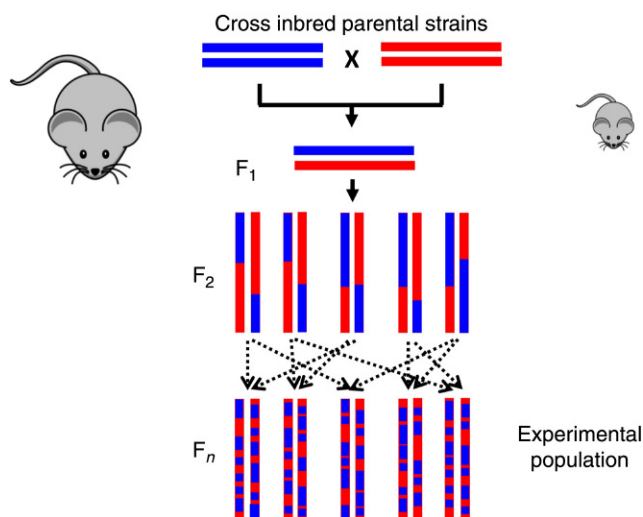
Mouse Genome Informatics (http://www.informatics.jax.org/) archives and maintains a database of mouse QTL under their Genes and Markers Query form. This resource can be used to determine if intervals identified in a QTL mapping study replicate (have been identified in mapping studies using other strains of mice), lending higher confidence to the region. There are currently 326 QTL associated with obesity, 212 with T2D, 340 with serum lipid traits, and 33 with hypertension listed in the database (Lawson and Cheverud, 2010). For studying


FIGURE 9.3 **Recombination increases the power to identify candidate genes.** When designing a QTL mapping study, the F1 offspring will be genetically identical. Brother-sister mating in the F1 will result in recombination and QTL can be identified in an F2 population. However, support intervals can be enormous, composed of hundreds of genes. Further interbreeding will increase recombination in every subsequent generation, which will narrow QTL support intervals and reduce the number of candidate genes to interrogate.

MetS, the most relevant QTL will be those associated with variation in multiple metabolic components.

For practical reasons the mouse is the animal model of choice for QTL mapping, but other studies have identified QTL associated with MetS components using pedigreed populations of baboons and pigs. The Southwest National Primate Research Center (SNPRC) at the Texas Biomedical Research Institute (San Antonio, TX) houses a large captive, pedigreed and genotyped baboon population (http://txbiomed.org/primate-research-center/). Baboons are used extensively in biomedical research and there are many physiological and genetic similarities between old-world monkeys and humans that make baboons an ideal model for MetS. SNPRC collects multiple metabolic data on their pedigreed colony (which is a mixture of yellow, *Papio hamadrayas cynocephalus*, and olive, *Papio hamadrayas anubis*, baboons) including measures of body composition (e.g., fat mass, fat-free mass, and waist circumference) and blood serum parameters. Approximately 10% of these animals become obese despite the population's uniform environment. Studies have found that increased adiposity in these baboons is significantly associated with dyslipidemia and insulin resistance, indicating this population is a good model for MetS (Comuzzie et al., 2003). Similar clustering of metabolic complications is also observed in studies of the rhesus macaque, another old-world primate frequently used in biomedical research (Bodkin et al., 1993). The SNPRC baboons have been used

to quantify heritabilities of multiple metabolic traits (Cai et al., 2004; Cole et al., 2003; Comuzzie et al., 2003). Research integrating the rich phenotype and genotype data collected in this pedigreed population have identified QTL associated with metabolic traits, such as HDL cholesterol (Cox et al., 2007), LDL cholesterol (Kammerer et al., 2002), adipocyte volume (Bose et al., 2010), and cholecytokinin, a major satiety signaling protein (Voruganti et al., 2007).

Pigs have been studied for fat and meat production in agriculture for decades, and pigs are becoming more frequently used animal models in biomedical research. The Ossabaw minipig and the Pietrain domestic pig are particularly promising porcine models for MetS research because obesity, insulin resistance and hypertension cluster in these two breeds. Combining metabolic phenotypes with genotyped markers in pig mapping studies has identified QTL for lipid metabolism in a Duroc x Pietrain intercross (Uddin et al., 2011), for obesity in a Meishan x Large White intercross (Bidanel et al., 2001), and for serum glucose and lipid levels in a White Duroc x Erhualian intercross (Chen et al., 2009). The Animal QTLdb (http://www.animalgenome.org/QTLdb/app) has a searchable pig QTL database that stores published pig QTL results and phenotypic parameters for different breeds, including phenotypes that are biomedically relevant to MetS (fat and adipose traits are listed as "meat quality traits") (Hu et al., 2005).

QTL mapping is powerful in that it requires no a priori knowledge of genes that may be involved in the trait. This is important for multifactorial conditions, such as MetS, which have complex etiologies and likely result from interactions of many genes of individually small effects. QTL mapping can thus lead to discovery of novel genes and genetic variants associating with phenotypic variation that can subsequently become targets of focused candidate gene studies. The UCSC Genome Browser has multiple mammalian genomes available to query, including low-coverage assemblies, such as the pig (*Sus scrofa*). Genes located in a QTL interval submitted to the browser can be identified (http://genome.ucsc.edu/index.html) and interrogated. The human genomic position homologous to the QTL region identified in an animal model study can be evaluated using NCBI Homology tools (http://www.ncbi.nlm.nih.gov/guide/homology/). Once a QTL is identified in an animal model mapping study, genes within the support interval can be interrogated using public databases, such as the National Center For Biotechnology Information: Entrez Gene (http://www.ncbi.nlm.nih.gov/gene) and PubMed (http://www.ncbi.nlm.nih.gov/pubmed) to identify and rank order the most plausible candidate quantitative trait genes for further interrogation of function (using methods discussed in Sections 4.2 and 4.4).

4.6 GWAS in Model Organisms

GWAS in model organisms can deconstruct the genetic underpinnings of metabolic disorders with improved power of detection and resolution over QTL mapping. GWAS are now feasible in mice given the breadth of variants characterized across phenotypically diverse strains as discussed earlier in Section 4.1. New strains, such as those generated by the collaborative cross, as well as commercially available outbred strains, such as the diversity outbred mice, provide gene-level resolution for mapping complex traits (Churchill et al., 2004; Svenson et al., 2012). GWAS in mice have identified loci involved in MetS components including lipids and blood pressure (Bennett et al., 2010; Zhang et al., 2012). Incorporation of additional phenotypic information, for example, of metabolites, has allowed researchers to place GWAS associated genes into specific metabolic pathways and identify correlations among metabolic parameters. For example, researchers were able to establish that insulin resistance and plasma arginine levels are related in mice (Parks et al., 2015). Identifying such correlations could help establish biomarkers for the complex relationships among MetS components.

A proposed approach for using GWAS in dogs is to identify loci associated with obese and lean dogs within breeds prone to obesity, followed by crossbreed comparison of variants (Switonski and Mankowska, 2013). In swine, there is a spectrum of fatness and body size phenotypes bred for agriculture. Selective genotyping of animals at the far ends of the phenotypic spectrum allows a reduction of sample size and an increase in cost efficiency (Fowler et al., 2013). As dogs and pigs are both appreciated models for human disease, any advancement in our understanding of their genetic susceptibility to MetS is beneficial to medical research.

4.7 Identifying Epigenetic Signatures Associated with MetS Components

Imprinting is defined as the unequal expression of an allele depending on its parent-of-origin. Over 80 imprinted genes have been identified in humans, and ≈30% of these genes overlap with genes demonstrated to be imprinted in mice (Herrera et al., 2011). Bioinformatic studies predict that several hundred more genes are likely to be imprinted in both species (Luedi et al., 2005, 2007). Most direct observations of imprinting have been carried out through analysis of monoallelic expression in reciprocal matings of inbred mouse strains. Imprinted genes are known to be involved in metabolic functions (Rampersaud et al., 2008), and failures in imprinting can result in metabolic complications by altering expression of growth and cellular differentiation factors. Genomic imprinting failures have been associated with

rare genetic syndromes having extreme forms of obesity (e.g., Prader–Willi syndrome) and mapping studies have identified imprinted genes (e.g., *GNAS*) affecting metabolic complications, such as obesity and insulin resistance in both humans and mice (Butler, 2009; Dong et al., 2005). QTL mapping studies in mice have identified loci having parent-of-origin effects on multiple MetS components, and some of these loci may be imprinted (Cheverud et al., 2011; Lawson et al., 2011a,b; Lawson et al., 2010). A striking result from these murine mapping studies is that parent-of-origin effects on metabolic traits is complex: in addition to the better characterized paternal and maternal patterns, polar and bi-polar dominance patterns were frequently observed. Polar dominance occurs when there are no additive genetic effects, so the two homozygote trait values are the same, yet there is a difference in the trait values between the two heterozygotes such that one class of heterozygote is in line with the homozygotes and the other is not, depending on parent of origin. In bi-polar dominance, again there is no significant difference between the two reciprocal homozygotes, but a pronounced difference occurs between the two reciprocal heterozygotes such that one class of heterozygote has the highest trait value of any other genotype class and the other class of heterozygote has the lowest trait value of any other genotype class as illustrated in Fig. 9.4 (for a detailed explanation of complex parent-of-origin patterns, including mathematical derivation, see Wolf et al., 2008). This complex pattern is rarely documented in human studies due to lack of sufficient genotypic information or statistical power, but
FIGURE 9.4 **An example of a bi-polar dominance parent-of-origin effect** In this example, trait value is the *y*-axis (trait value can be weight, cholesterol level, etc.) and the genotype classes are depicted on the *x*-axis. Parent-of-origin of alleles is known with *red* indicating a maternally derived allele and *blue* indicating a paternally derived allele. At this locus, there are no additive genetic effects (no difference in trait value between individuals belonging to the two homozygote classes), but there is a difference between the two reciprocal heterozygotes such that one class has the lowest trait value of any other genotypic class and the other has the highest trait value. Thus the same allele can be both protective and a potential risk factor depending upon parent-of-origin.

it does occur. For example, a study using the Icelandic genealogy database showed that the same genetic variant increases T2D risk when paternally inherited but decreases T2D risk when maternally inherited (Kong et al., 2009). This is consistent with a bipolar dominance parent-of-origin effect.

Epigenetic modifications, cell-specific changes in DNA chemistry that do not alter the DNA sequence itself, can affect gene expression and may underlie some of the parent-of-origin effects associated with MetS components found in mouse mapping studies. Commonly studied molecular epigenetic signatures include DNA methylation, histone modification, and small noncoding RNA interference. Tissue and T2D disease-stage specific altered methylation patterns were found in the Zucker diabetic fatty rat model relative to controls (Williams and Schalinske, 2012). A genome-wide methylation analysis in pig adipose and muscle tissues identified methylation patterns that segregated by breed (the researchers compared methylomes among three breeds: Landrace, Rongchang, and Tibetian), by sex, by tissue, and by fat depot (Li et al., 2012a). This work also identified regions that were "differentially methylated," meaning one allele is methylated while the other allele is not. This pattern is suggestive of parent-of-origin methylation, which may affect expression of genes in a parent-of-origin manner, and is a signature of imprinting (Harris et al., 2010). An exciting direction for future research is to combine results identified in animal QTL mapping studies with whole-genome epigenetic profiling.

4.8 Mouse ENCODE

The Mouse ENCODE Consortium was developed as a counterpart to the human Encyclopedia of DNA Elements (ENCODE). Using similar technologies and pipelines, Mouse ENCODE maps functional elements of the mouse genome, such as transcription, transcription factor binding, chromatin modifications, and replication domains. These data were mapped in a wide range of mouse tissues and cell types, mostly generated from C57BL/6J and are available to the research community at www.mouseencode.org.

The public availability of these data sets has significantly impacted comparative studies of mouse and human genomes. Studies have revealed conservation of some basic regulatory systems between humans and mice, as well as high levels of divergence in gene expression and regulation (Yue et al., 2014). Washington University in St. Louis houses an epigenome browser with which researchers can explore these existing datasets, or upload their own data to visualize a candidate region's genomic context (http://vizhub.wustl.edu/). Identification of patterns of epigenetic effects in animal models can be translated to human studies and will provide a framework for clarifying the relationship between DNA sequence variation and metabolic complications. This is a step toward development of better therapeutic strategies for MetS.

5 ENVIRONMENTAL FACTORS

5.1 Fetal Programming

Maternal developmental environment has been shown to affect not only fetal and early postnatal growth, but also adult susceptibility to MetS (Barker, 2007). Compromised nutrition during fetal and early postnatal life increases susceptibility to metabolic complications later in life because of "fetal programming" during critical periods of development and a mismatch between early and adult nutritional environments. The precise mechanism(s) through which this phenomenon occurs is unknown, but recent work suggests that epigenetic modifications of DNA affect many molecular processes related to intrauterine growth and development (Aagaard-Tillery et al., 2008; Heerwagen et al., 2010). Research in guinea pigs found that mothers fed moderately restricted diets throughout their pregnancies (70% of ad libitum intake/kg body wt.) gave birth to small pups and their adult male offspring were hyperinsulinemic (Kind et al., 2003). A similar study in guinea pigs found that mildly restricting maternal diet (85% of ad libitum) increased both total cholesterol and LDL cholesterol levels in male offspring (Kind et al., 1999). Maternal undernutrition is associated with increased arterial blood pressure in offspring that persists into adulthood in both sheep and rat models (McMillen and Robinson, 2005). Offspring of rat mothers fed restricted protein diets (50% less protein than standard chow-fed controls) had poor pancreatic beta-cell proliferative capacity at birth. When the low protein diet was maintained, weanlings, pancreatic islet morphology, and insulin content was found to be reduced (Bertram and Hanson, 2001). Recent rodent models have shown that maternal high fat diet, or overnutrition, also increases offspring susceptibility to developing adult metabolic complications (Liang et al., 2009; Morris and Chen, 2009; Odaka et al., 2010). When mothers consume a high fat diet their offspring tend toward obesity as adults, regardless of offspring diets. However, other research suggests that it is maternal adiposity and not dietary fat consumed that affects offspring susceptibility to adult metabolic complications (White et al., 2009). In sheep, maternal obesity and overnutrition results in metabolic complications in adult offspring (Long et al., 2011). Further, ovine models suggest that overnutrition affects adult offspring risk in two stages: first during the periconceptional period and second in late pregnancy (George et al., 2010). Studies

in nonhuman primates support findings from rodents and sheep. In baboons, preweaning overnutrition resulted in permanently increased adiposity in females (Lewis et al., 1986). In macaques, maternal high fat diet predisposed adult offspring to adult nonalcoholic fatty liver disease, which is highly correlated with MetS (McCurdy et al., 2009). Additionally in macaques, maternal overnutrition before and during pregnancy resulted in increased postnatal adiposity in offspring (Grayson et al., 2010). Thus the pattern of susceptibility to adult metabolic disease resulting from fetal programming is U-shaped, with both maternal undernutrition and overnutrition affecting offspring MetS risk (Taylor and Poston, 2007). Work in the rhesus macaque also showed that offspring of high fat fed mothers had increased proopiomelanocortin mRNA expression and decreased agouti-related protein mRNA expression, suggesting that maternal overnutrition during pregnancy may activate proinflammatory cytokines that could alter melanocortin activity (Grayson et al., 2010). Evidence in rodent models suggest molecular epigenetic mechanisms, such as those discussed in Section 4.7, underlie at least some of these effects (Lillycrop et al., 2005; Vickers et al., 2005). Identifying variation in epigenetic marks that associate with variation in maternal effects on fetal programming is a fruitful avenue for further research.

Maternal effects on fetal programming are generally considered environmental because they are not a function of the offspring's genome. Rather they result from the maternally produced developmental environment. Nearly all studies in mouse model systems have focused exclusively on maternal environmental effects using genetically uniform C57BL/6J mothers and offspring. But maternal genetic variations are also responsible for substantial variability in the fetal and neonatal developmental environment (although the effect is environmental with respect to the offspring). Murine maternal effect QTL associated with early offspring growth in a cross-fostered F_3 generation of a LG/J x SM/J intercross showed that variation in maternal genotype accounted for >30% of among litter offspring variation (Wolf et al., 2002). Another mouse study measured maternal genetic effects on multiple MetS components and found that variation in maternal genotype accounted for up to 10% of adult offspring phenotypic variation (Jarvis et al., 2005).

5.2 Nutrition

Animal models are ideal for studying the effects of nutrition on MetS etiology because commercial diets are readily available, allowing dietary composition to be precisely monitored. Further, specialized high fat and high sucrose diets have been developed that mimic the human "Western" diet hypothesized to underlie the past 30 years' rising rates of metabolic disease. In mouse, strains have been characterized by whether they become obese on a Western diet [referred to as diet-induced obesity (DIO) strains] or not (referred to as dietary-resistant strains). Variation in high fat dietary response has been quantified in 43 inbred strains for 10 phenotypic traits, including metabolic parameters in blood serum levels and adiposity (Svenson et al., 2007). Another study quantified variation in macronutrient diet self-selection across different inbred mouse strains (Smith et al., 2000). This study is interesting in that it shows that individual preference for certain macronutrients vary according to genetic background. Consistent with rodent results, dietary studies in nonhuman primates show that some species become obese and/or develop other metabolic complications while other species do not. For example, squirrel monkeys fed high fat, high sucrose diets became obese, while cebus monkeys fed the same diet did not (Ausman et al., 1981). This supports results from rodent models indicating that genetic background is an important factor of dietary risk. A recent study in rhesus macaques provided with a 500 mL/day 15% fructose-sweetened beverage showed that animals developed multiple MetS components including central obesity, dyslipidemia, inflammation, and insulin resistance. A subset of these animals developed overt T2D (Bremer et al., 2011), indicating that rhesus macaque is a good model for studying variation in dietary response and MetS. Further, the rhesus macaque genome has been sequenced at relatively high coverage, providing an opportunity to study gene by dietary–environment interactions in a nonhuman primate model of MetS (Gibbs et al., 2007). An exciting avenue of research uses animal models to study dietary influences on gut microbiota and the metabolic consequences of upsetting gut microbial diversity. Studies in rodents indicate that dietary environment can lead to bacterial disruptions that influence energy extraction from food, fat storage, serum lipid levels, and insulin resistance. This suggests that the gut microbiome is an important link between dietary environment and MetS (for a review, see Tilg and Kaser, 2011 and references within). However, much of this research has been conducted in rodent knockout or germ-free models, so the translational application to human subjects remains to be explored.

5.3 Gene by Dietary Environment Interactions

As discussed previously, standing genetic variation can modify the effects of the environment on expression of phenotype. Characterizing gene by environment, particularly gene by dietary environment, interactions are essential to understand MetS etiology and for identifying potential risk factors in the context of personalized medicine. These interactions are challenging to parse

from human studies where environmental factors can be difficult to accurately measure or, in the case of GWAS, can be computationally prohibitive to analyze. However, some studies have successfully characterized gene by diet interactions in human populations and there is an effort to archive these results as they pertain to metabolic traits (Lee et al., 2011). Animal models can dissect gene by environment interactions and the most frequently studied model is the mouse, using the targeted or discovery methods discussed earlier in Sections 4.2 and 4.4, but with an added dietary parameter in the model (Lawson and Cheverud, 2010). As discussed earlier, genetic background (strain or species) needs to be taken into account when designing such studies.

For example, a targeted knockout approach demonstrated that high fat fed $Ppar\alpha^{-/-}$ mice accumulated significantly higher lipid concentrations in their livers relative to wild-type controls. Interestingly, $Ppar\alpha^{-/-}$ mice that were fasted for 24 h developed additional metabolic complications including hypoketonemia, hypoglycemia, impaired thermoregulation, and increased serum free fatty acid (FFA) levels. This result indicates that $Ppar\alpha$ plays a role in regulating the fatty acid oxidation response to fasting (Kersten et al., 1999; Leone et al., 1999). QTL have been identified in crosses between inbred mouse strains fed with high fat diets (e.g., Taylor et al., 2001; West et al., 1995; York et al., 1996). However, generally these studies do not map variation in metabolic traits in high fat versus low fat diets, which is necessary to characterize the gene by diet interaction. Recently, gene by diet interactions (high fat vs. low fat isocaloric diets) were characterized for multiple MetS components in studies of an F_{16} generation of an Advanced Intercross between the LG/J and SM/J inbred mouse strains (Cheverud et al., 2011; Lawson et al., 2010, 2011a,b). A major finding from these studies was that interactions are not consistent between the sexes or among the traits studied: for adiposity and serum lipid levels, high fat fed females were the most affected cohort and for diabetes-related traits, high fat fed males were the most affected cohort. These studies also demonstrated that if context was not taken into account in the mapping model (context referring to the sex and/or dietary environment), genetic associations are missed. For example, if a genetic effect is found only in high fat fed females, the lack of genetic effects in the other sex by diet cohorts will wash the association out if the entire population is pooled together in the analysis. Additionally, if the additive genetic effects between two cohorts in a population are of opposite directions (the homozygote genotypes change ranks in different environments), the association will be washed out if the two cohorts are pooled (Fig. 9.5). This result has important implications for human studies.

Gene-by-dietary-environment interactions that are identified in rodent models have potential to inform
FIGURE 9.5 **An example of a gene-by-diet interaction with homozygote genotypes changing rank order in different dietary environments.** This figure illustrates that genetic associations can be missed if environment is not taken into account. In this example, trait value is the *y*-axis and homozygote genotypes are depicted on the *x*-axis. On a high fat diet, individuals with the AA genotype at the marker locus have a higher trait value than individuals with the aa genotype. The opposite is true for individuals on a low fat diet. If individuals of both diets are pooled together in an analysis, the opposite genetic effects of the two cohorts will wash each other out, despite a clear genetic association with the trait and gene by diet interaction. This result has been found in mouse models of MetS (Lawson et al., 2011a) and has implications for human studies.

human studies and potentially increase their power to identify patterns of interactions in populations of human subjects (using methods described in Sections 4.2 and 4.4). The idea is to identify biomarkers with dietary effects on metabolic parameters that may be context-dependent and that are relevant to the clinical reality of MetS in a nutritional genomics context. The promise of nutritional genomics is that it can provide personalized dietary recommendations based on an individual's genetic make-up at loci found to interact with diet. Personalized dietary recommendations aimed at prevention and therapy represent a practical clinical translation of animal model research to public health, particularly for MetS components, such as dyslipidemia or insulin resistance that could be delayed or even prevented through dietary modifications (Bouchard and Ordovas, 2012).

6 ANIMAL MODELS OF MetS PATHOPHYSIOLOGY

Understanding MetS pathophysiology in animal models can shed light on why some obese individuals develop metabolic complications while others do not. Further, animal models may also shed light on why some lean individuals develop multiple MetS components in the absence of obesity. Most animal models focused on pathophysiology attempt to understand the link between obesity and insulin resistance, which is an important risk factor for developing T2D and CVD. Physiological studies generally focus on the roles of adipose tissue, endocrine function, and fatty acid metabolism in metabolic complications, although each of these

factors is interrelated. Recently, the role of autophagy in obesity has been garnering attention. This is important because some fat depots (visceral adipose tissue) are correlated with increased risk of developing insulin resistance whereas others (subcutaneous adipose tissue) are actually correlated with decreased risk (reviewed in: Hardy et al., 2012), yet the mechanisms underlying these correlations are unknown. Animal models that test mechanistic hypotheses are the first step toward gaining new biological insight into MetS. Physiological studies inform genetic studies (and are also informed by genetic studies), and candidate gene studies can be designed based on physiological results with the idea that identifying molecular mechanisms underlying metabolic complications can lead to the discovery of novel biomarkers and the development of better therapeutic strategies for MetS.

6.1 Adipose Tissue: Hormones, Remodeling and Inflammation

The role of leptin in MetS is discussed earlier in Section 4.1. Adiponectin is another adipose tissue derived protein hormone that was discovered shortly after leptin was characterized in a mouse model (Havel and Bremer, 2010). Adiponectin has been shown to be a key factor linking visceral adipose tissue to MetS. It is the most abundant protein secreted by adipocytes, and high circulating levels of adiponectin is correlated with increased insulin sensitivity and resistance to metabolic complications (Scherer, 2006). Low circulating adiponectin levels is correlated with insulin resistance in rhesus monkeys (Hotta et al., 2001) and in rodent models (Cummings et al., 2008; Nawrocki et al., 2006). A recent study used RNA-sequencing to profile genes expressed in liver in both adiponectin knockout and wild-type mice (Liu et al., 2012). This study found differential expression in genes involved in several glucose and lipid pathways that are fruitful targets for focused candidate gene studies aimed at identifying functional pathways regulated by adiponectin.

Adipose tissue remodeling and inflammation is likely involved in the pathogenesis of MetS. The accumulation of large adipocytes is associated with increasing rates of adipocyte death, inflammation, and insulin resistance. Macrophages localize to the dead adipocytes and form crown-like structures that envelope and ingest the adipocyte and its lipid droplet (Cinti et al., 2005). This clearance of dead adipocytes by macrophages is an initial remodeling event that promotes proinflammatory activation of macrophages, and results in a bimodal distribution of both large and small adipocytes. DIO mice show marked increases in adipocyte size, death, and macrophage content (Strissel et al., 2007). This is positively correlated with insulin resistance, dylipidemia, and non-

alcoholic fatty liver disease (Ferrante, 2007). Mice with loss of function mutations in monocyte chemoattractant protein-1 (*Mcp1*) and its receptor (*Ccr2*) have decreased adipose macrophage content and appear to be protected from high fat diet induced insulin resistance (Kanda et al., 2006; Weisberg et al., 2006). Further, mice overexpressing *Mcp1* have increased levels of adipose tissue macrophages and increased insulin resistance. At baseline, mouse adipose tissue macrophages show low expression of macrophage differentiation markers. Overnutrition results in a macrophage population "shift," with increasing levels of monocytes being recruited from circulation into the adipose tissue (Lumeng et al., 2007), indicating that DIO results in adipose tissue remodeling and remodeling-associated inflammatory response. Expression studies in rodent models are illuminating some of the genes involved in the intercellular communication among adipose tissue cell types, including TNF, SFRP5, and WNT5a (among others). A promising avenue of research using animal models is aimed at inhibiting the infiltration of monocytes into adipose tissue and potentially ameliorating the inflammatory response and preventing insulin resistance (Ouchi et al., 2011; Suganami and Ogawa, 2010 for a review of macrophages in adipose tissue remodeling and inflammation). It is worth noting that adiponectin is considered an antiinflammatory adipokine, and circulating levels decrease as inflammation increases. Recent pharmaceutical based research in mice has found that inhibiting *Mcp1* expression both reduces inflammation and increases adiponectin levels in adipose tissue (Vinolo et al., 2012).

6.2 Free Fatty Acid Metabolism

Altered FFA metabolism is an important factor in the pathogenesis of insulin resistant glucose metabolism, dyslipidemia, and possibly inflammation associated with obesity in MetS (Boden, 2006; Shulman, 2000). Excess plasma FFA concentration impairs the ability of insulin to stimulate muscle glucose uptake and suppresses hepatic glucose production (Ferrannini et al., 1983). Increased FFA delivery to the liver increases hepatic VLDL-triglyceride production and plasma triglyceride concentrations (Lewis et al., 1995). This increases the transfer of triglycerides from VLDL to HDL, which leads to increased HDL clearance and results in decreased plasma HDL concentrations (Hopkins and Barter, 1986). Visceral adiposity is associated with lipid accumulation in the liver and insulin resistance. It has been hypothesized that FFAs released during lipolysis of visceral adipose tissue causes insulin resistance because these fatty acids enter the portal vein and are directly delivered to the liver, leading to hepatic insulin resistance, triglyceride accumulation and increased secretion of atherogenic lipoproteins (Despres and Lemieux, 2006).

This so-called "Portal Theory" of MetS has been tested in canine models at both molecular and physiological levels. Dog intraabdominal fat depots are easily measured using magnetic resonance imaging, and invasive procedures, such as portal vein cannulation and omentectomy (surgical removal of the greater omentum and its constituent visceral adipose tissue) are easier to perform in larger mammals than in rodents, although recently a rat model has been developed with a chronically implanted portal vein catheter to quantify pulsatile insulin secretion (Matveyenko et al., 2008). As is observed in human populations, dogs naturally exhibit wide variance in fat deposition and increased levels of visceral adiposity is highly correlated with insulin resistance in dogs (Bergman et al., 2006, 2007; Kim et al., 2003). Differential expression of several important genes involved in FFA metabolism (LPL, HSL, and PPARγ) in both visceral fat and liver tissue was observed between high fat fed dogs and controls. Liver insulin receptor binding was decreased by 50% in the high fat fed dogs, providing circumstantial molecular evidence supporting the portal theory (Kabir et al., 2005). Omentectomy in a dog model has been demonstrated to improve insulin sensitivity, supporting the association between visceral fat and insulin resistance, however, the FFA-portal vein link between visceral fat and insulin resistance was not supported in this model (Lottati et al., 2009). Further, isotope tracer data from human subjects suggests that only 20% of FFAs delivered to the liver derive from visceral fat, indicating that it is unlikely that the delivery of fatty acids via the portal vein underlies the strong correlation between visceral fat and insulin resistance (Nielsen et al., 2004). Thus more research is required to test the FFAs hypothesis in the context of visceral fat and insulin resistance, and animal models will be integral to understanding this connection in the context of MetS pathophysiology.

6.3 Gastrointestinal Hormones

Hormones produced by the gastrointestinal tract are essential to glucose and lipid metabolism. These hormones are involved in short-term regulation of satiety and potentially in long-term regulation of adiposity and energy homeostasis (for a comprehensive review of endocrine regulation of energy balance, see Havel and Bremer, 2010; Suzuki et al., 2011). Animal models have been critical to understanding the roles of hormone action in MetS, and to characterizing receptor, and signaling pathways that can be manipulated for therapeutic intervention. Ghrelin is a peptide hormone produced by, and secreted from, endocrine cells of the stomach and proximal small intestine. It increases hunger and potentially stimulates food intake, although high circulating ghrelin concentrations are negatively correlated with body weight (Tschop et al., 2001). Nevertheless, direct administration of ghrelin has been found to increase food intake resulting in weight gain in a rat model (Tschop et al., 2000). Glucose-dependent insulinotropic polypeptide (GIP) is a hormone secreted by K-cells in the duodenum and proximal jejunum in response to carbohydrate ingestion. GIP receptors are located in pancreatic islets, brain, adrenal, and adipose tissues. GIP augments glucose-stimulated insulin secretion (D'Alessio et al., 2001). Ablating GIP producing K-cells in a mouse model appears to protect animals from dietary obesity, and administering a GIP receptor antagonist in high fat fed mice has been reported to reverse obesity and insulin resistance (Althage et al., 2008; McClean et al., 2007). Glucagon-like peptide-1 (GLP-1) is produced by L-cells in the ileum. Administering GLP-1 receptor antagonist has been shown to improve glucose tolerance in a baboon model (D'Alessio et al., 1996). GLP-1 is also produced in neurons in the hypothalamus. Administering GLP-1 directly into the brains of rats has been shown to inhibit feeding and result in weight loss (Tang-Christensen et al., 1996). Oxyntomodulin (OXM) is cosecreted with GLP-1 from L-cells in the ileum. Administration of OXM inhibits food intake in rats, likely by increasing energy expenditure (Dakin et al., 2002). Peptide-YY (PYY) is produced by L-cells in the ileum and colon. PYY concentrations rise after feeding, peak after 1–2 h, and remain elevated for several hours longer. Higher levels of PYY are secreted after fat ingestion than after either carbohydrate or protein ingestion (Suzuki et al., 2011). It has been observed in a mouse model that PYY administration inhibits food intake, promoting weight loss and fat oxidation (Adams et al., 2006), although this result has not been observed in other mouse studies (Tschop et al., 2004). These gastrointestinal hormones all converge on major signaling pathways in the brain, namely the arcuate nucleus of the hypothalamus and the dorsal motor nucleus of the vagus nerve in the brainstem. Each represents promising therapeutic targets for appetite regulation in the context of MetS. The fundamental knowledge derived from animal models of endocrine regulation can set the stage for planning appropriate and safe therapeutic manipulations of these signaling pathways in human subjects.

6.4 Autophagy

Autophagy is an intracellular process wherein cell cytoplasm constituents and structures are isolated by a phagophore, segregated from the cytoplasm into an autophagosome, which then fuses with a lysosome to form an autolysosome whose contents are degraded and recycled for use in the cell. Autophagy is a response to stress but it also plays a role in normal cell remodeling (Mizushima and Klionsky, 2007). Autophagy is inhibited by mTOR activation in the presence of insulin-like and

other growth factors (Jung et al., 2010). It is induced by a reduction in mTOR signaling, activating a protein serine/threonine kinase complex. Autophagy has recently been associated with metabolic function, including regulation of lipid metabolism (Singh et al., 2009) and obesity (Goldman et al., 2010; Zhang et al., 2009). Inhibiting autophagy leads to an increase in circulating triglyceride levels and a decrease in triglyceride breakdown, suggesting that accumulating lipids decreases autophagy, potentially leading to a deleterious positive feedback loop in the cell's physiology (Singh et al., 2009). Key genes involved in this process include: ATG1, ATG7, BCN1, LC3, and class III P13K among others. Recently, an adipose tissue specific *Atg7* knockout mouse model found that adipose-specific *Atg7*$^{-/-}$ animals weigh less and have reduced reproductive fat depots relative to wild-type controls (Zhang et al., 2009). The knockouts consumed food at the same rate as wild-type mice regardless of diet, yet they failed to develop obesity when on a high fat diet. Additionally, they were more active than wild-type controls. *Atg7*$^{-/-}$ animals exhibited lower serum triglyceride, cholesterol, FFA, and leptin levels, but normal adiponectin and glucose levels with decreased serum insulin levels and increased insulin sensitivity. At the cellular level, adipogenesis was less efficient in *Atg7*$^{-/-}$ primary mouse embryonic fibroblasts than in wild-type controls. Histological analysis showed that *Atg7*$^{-/-}$ adipocytes were smaller and often contained multiple small lipid droplets rather than the single large droplet found in wild-type cells. A recent study in an Ossabaw pig model found that inhibited myocardial autophagy was associated with development of MetS (Li et al., 2012b). Better understanding the pathophysiology and the molecular underpinnings of autophagy in metabolic traits in animal models could facilitate the exploration of this cellular process in human obese subjects with the idea that exploitation of this pathway has therapeutic potential for MetS.

7 CONCLUSIONS

To prescribe the right therapies for MetS, one needs to be able to predict phenotype from genotype to some degree. Animal models have advanced our understanding of the genotype-metabolic function relationship through testing hypotheses about genetic underpinnings and molecular pathophysiologies that lead to the clustering of metabolic complications putting an individual at risk of developing T2D and/or CVD. Bioinformatic tools and archived genomic and phenotypic data for different animal model systems make it possible to design and execute focused studies using the species or strains that most appropriately mimic the clinical reality of MetS. Exciting advances in genomics make it possible to explore both

genetic and epigenetic modes of gene regulation and to understand how genes modify environmental effects on phenotypic variation. Characterization of molecular physiological pathways in animal models—especially direct characterizations in disease-relevant tissues—can illuminate potential therapeutic targets. Patterns identified in animal models can be translated to studies of human subjects for the improvement of human health.

Animal Models of Type 1 and Type 2 Diabetes Mellitus

Aileen King, Amazon Austin

King's College London, London, United Kingdom

1 INTRODUCTION

Diabetes mellitus is a metabolic disease characterized by hyperglycemia due to a relative or complete deficiency of the hormone insulin. This hormone, which is secreted from the beta cells in the pancreatic islets of Langerhans, is essential in the control of blood glucose concentrations by facilitating glucose uptake and metabolism in peripheral tissues, such as the liver, muscle, and adipose tissue. There are two main classifications of diabetes: Type 1 diabetes and Type 2 diabetes. Type 1 diabetes is caused by the autoimmune destruction of the beta cells, leading to insulin deficiency whereas Type 2 diabetes is characterized by insulin resistance and an inability of the beta cells to adequately compensate with

increased insulin secretion. Acute symptoms of the disease include fatigue, polydipsia, and polyuria. Due to a severe insulin deficiency, Type 1 diabetes patients can present with acute weight loss and in some severe cases ketoacidosis and coma. Chronic hyperglycemia can lead to a variety of complications, such as neuropathy, nephropathy, and retinopathy. Animal models are routinely used in diabetes research as blood glucose homeostasis is well preserved across different species. Rodents are most commonly used for ethical and practical reasons (Renner et al., 2016) although larger animals, such as pigs, cats, dogs, and primates are used for specific studies. Although the symptom of hyperglycemia connects different types of diabetes, the etiology and patient characteristics of each is diverse. The animal model

chosen will depend on whether a model of Type 1 or Type 2 diabetes is required. In addition, the choice will be influenced by the study design, for example, whether the aim is to understand more about the pathogenesis, prevent disease onset or to treat the disease (King and Bowe, 2016).

2 TYPE 1 DIABETES

Type 1 diabetes is most commonly diagnosed in children and young adults. At the time of diagnosis, patients have very little endogenous insulin production and thus require life-long insulin therapy. Both genetic and environmental factors play a role in the disease, evidenced by identical twin concordance of around 27% (Hyttinen et al., 2003). Disease susceptibility has been linked with various major histocompatibility complex (MHC) genes in which genetic variations can either protect or increase risk of disease (Erlich et al., 2008; Pociot et al., 2016). Environmental triggers of the disease are not well understood but viruses have been implicated in some cases (Rewers and Ludvigsson, 2016). The disease is mainly characterized by severe hyperglycemia due to a substantial reduction in insulin production due to autoimmune destruction of the pancreatic beta cells (Wilcox et al., 2016). Therefore animal models of Type 1 diabetes should ideally have a large reduction in beta cell mass by either replicating the autoimmune process or by other means. Some of the most commonly used rodent models of Type 1 diabetes are outlined in Table 10.1.

2.1 Spontaneous Models of Autoimmune Type 1 Diabetes

A key histopathological characteristic of Type 1 diabetes is insulitis, which is the immune cell infiltration of the pancreatic islets, ultimately leading to beta cell death (Campbell-Thompson et al., 2016). Another distinctive feature of Type 1 diabetes is the presence of autoantibodies, such as islet antigen 2 (IA2), glutamic acid decarboxylase, and zinc transporter 8 (ZnT8) (Knip et al., 2016). Spontaneous autoimmune diabetes has been discovered in several rodent strains, which have been further inbred to provide strains in which diabetes develops at a relatively high incidence (Mathews, 2005). Although these rodent models have some differences from the human condition, they have been very useful in understanding some key aspects of the disease, such as the pathogenesis of insulitis, as human pancreas samples are difficult to obtain.

2.1.1 Nonobese Diabetic Mouse

One of the most commonly used autoimmune models of Type 1 diabetes is the nonobese diabetic (NOD) mouse. This strain was originally developed from inbreeding a colony of cataract-prone outbred Jcl:ICR mice to create a model of spontaneous autoimmune Type 1 diabetes. These mice develop severe insulitis within 2–4 weeks in females and 5–7 weeks in males leading to beta cell destruction and hyperglycemia by 30 weeks in up to 80% of females and 30% of males (Makino et al., 1980). The progression of the disease within NOD mice is a complex interaction of immune cell responses with involvement from macrophages, dendritic cells, NK cells, B lymphocytes, and T lymphocytes (Jorns et al., 2014; Lee et al., 1988; Welzen-Coppens et al., 2013). By the time insulitis is fully established at around 12–14 weeks, T lymphocytes are the predominate cell infiltrating the islets (Magnuson et al., 2015) causing beta cell destruction and leading to overt diabetes (Jayasimhan et al., 2014).

It should be noted that the extent of insulitis differs from humans, with NOD mice showing severe insulitis in nearly all islets whereas in the human diabetic islets the insulitis is less pronounced and not all islets are not affected (Driver et al., 2011; In't Veld, 2014). One disadvantage of using the NOD mouse is the uncertainness of when overt diabetes will develop as it can range from 18

TABLE 10.1   Main Characteristics of Most Commonly Used Rodent Models of Type 1 Diabetes

Model of Type 1 diabetes	Onset	Age/time of induction	Immune cell involvement?	Useful to understand pathogenesis?	Useful in prevention studies?
Nonobese diabetic (NOD) mice	Spontaneous	12–30 weeks	Yes	Yes	Yes
Biobreeding (BB) rats	Spontaneous	8–16 weeks	Yes	Yes	Yes
Lew.1AR1-iddm rats	Spontaneous	~8 weeks	Yes	Yes	Yes
Komeda diabetic-prone (KDP) rats	Spontaneous	~8 weeks	Yes	Yes	Yes
Akita mice	Spontaneous	~4 weeks	No	Some aspects	No
Low dose streptozotocin	Induced	Within days	Yes	Some aspects	Some aspects
High dose streptozotocin	Induced	Within days	No	No	No
Alloxan	Induced	Within days	No	No	No

to 30 weeks. Several tools exist to induce a rapid-onset model. One is the injection of cyclophosphamide, in which one or two intraperitoneal injections can induce overt diabetes rapidly in prediabetic male and female NOD mice (Harada and Makino, 1984; Yasunami and Bach, 1988). Alternatively, if islets are transplanted from a young NOD mouse to an overtly diabetic mouse, the newly transplanted islets rapidly succumb to insulitis and thus can be studied in a more controlled time frame (Wang et al., 1992). Finally, adoptive transfer models can be used to induce a diabetic phenotype rapidly into another mouse (Christianson et al., 1993; Wicker et al., 1986).

The NOD mouse has been an important tool in understanding the genetic risk factors associated with the development of Type 1 diabetes. Several genetic loci have been shown to have contributing or protective effects on the development of diabetes in NOD mice (Driver et al., 2012; Pearson et al., 2016). One example of this is the MHC, which is highly important in both NOD mouse and human diabetes development (Nerup et al., 1974; Prochazka et al., 1987). Indeed in humans, it is the most robust genetic predictor of Type 1 diabetes susceptibility (Pociot et al., 2016). Other genetic predictors present in both NOD mice and humans include cytotoxic T-lymphocyte-associated protein 4 (CTLA-4) (Ueda et al., 2003). However, it should be noted that many susceptibility loci identified in NOD mice turned out not to have an effect on the development of Type 1 diabetes in humans (Driver et al., 2011). Due to the common immunogenic progression of diabetes between NOD mice and humans, these mice provide a valuable tool for assessing therapies that target the immune components of the disease, mostly aimed at either modulating immune cell communication or suppressing T cell activation (Atkinson and Leiter, 1999). However, despite NOD mice being a vital model for studying the disease, many factors strongly influence the NOD mouse's susceptibility to respond to intervention treatment. Diabetes development is prevented in NOD mice if they are not kept in a specific pathogen-free environment (Leiter, 1993), which has been attributed to the influence of gut microbiota in different environmental conditions (Alam et al., 2011; King and Sarvetnick, 2011). Therefore diabetes incidence can be affected by different husbandry practices. Another source of variation is the age of the mouse at the time of treatment as it has been suggested that young diabetic NOD mice are more likely to respond to treatment than older mice (Roep, 2007). It has thus become clear that different conditions play a part in the efficacy of treatments within NOD mice and may be the reason for a few therapies being effectively translated to human trials (Jayasimhan et al., 2014; Reed and Herold, 2015). In the example of the anti-CD3 and IL-1 combination therapy, a multicenter trial was conducted based on some previous work showing the benefit of this treatment in

NOD mice (Ablamunits et al., 2012); however, human trials were not able to completely replicate the results seen in NOD mice (Daifotis et al., 2013), which was attributed to dosing, choice of endpoints and the fact that some patients may not be "responders" to that specific treatment (Herold et al., 2013; Reed and Herold, 2015). Indeed it is worth noting that the underlying pathology of the disease may differ between different patients and it is possible that the NOD mouse model only represents one subset of Type 1 diabetes patients.

New experimental models using NOD mice have now been developed including humanized and genetically altered NOD mice (Pearson et al., 2016; Serreze et al., 2016). These advances have shown promising results, however, important differences still remain between Type 1 diabetes in the NOD mouse and humans which should be taken into consideration when designing studies (Pearson et al., 2016; Reed and Herold, 2015; Roep, 2007; Simpfendorfer et al., 2015). Nonetheless, NOD mice are still widely used and are an asset to investigating the complex mechanisms of Type 1 diabetes.

2.1.2 BB Rat

Biobreeder (BB) rats were created from a Wistar colony in which spontaneous autoimmune diabetes had occurred (Mathews, 2005). Two separate diabetes-prone strains were derived: the inbred BBDP/Wor and the outbred BBdp, as well as a diabetes resistant BB strain known as BBDR (Mordes et al., 2004). In the diabetes-prone BB rats, hyperglycemia develops between 8 and 16 weeks of age with 90% developing diabetes within the first 3 months (Mathews, 2005). In contrast to NOD mice, there is no bias toward either sex. However, incidence of diabetes varies depending on housing conditions, much like the NOD, with up to 50% becoming diabetic in normal conditions (Nakhooda et al., 1978) and up to 90% in viral antibody-free conditions (Like et al., 1991). The pathogenesis of diabetes in these rats involves B cells, dendritic cells, macrophages, NK cells, and T cells infiltrating the islets directly and leading to insulitis 2–3 weeks before overt diabetes is established (Hanenberg et al., 1989). The resulting diabetes can be quite severe and therefore the rats often need to be maintained on insulin to prevent ketoacidosis (Bortell and Yang, 2012). In contrast to NOD mice, the insulitis in BB rats is not preceded by periinsulitis and thus may be a better alternative for insulitis studies, as this pattern more closely resembles the pathology seen in humans (Mordes et al., 2004). As with NOD mice and humans, BB rat susceptibility to diabetes has been linked with MHC class II gene loci (Jacob et al., 1992). However, BB rats are lymphopenic with a substantial reduction in CD4+ T cells and very few CD8+ T cells (Jorns et al., 2014) and from this perspective differ from the human disease. This lymphopenia is caused by a frameshift mutation

in Gimap5 causing T cell apoptosis and is necessary for the development of Type 1 diabetes in the BB rats (MacMurray et al., 2002). BB rats have a reasonably predictable onset of diabetes so have been a useful model in which to dissect the serum factors linked to early stages of diabetes progression (Kaldunski et al., 2010). They have also proved useful in investigating novel therapies targeting disease progression (Gotfredsen et al., 1985; Like et al., 1984; Scott et al., 1997).

2.1.3 Lew.1AR1-iddm

The Lew.1AR1-iddm rat was derived from a colony of congenic Lewis rats in Hannover, Germany, in which a spontaneous mutation in Lew.1AR1 rats lead to a Type 1 diabetic phenotype (Lenzen et al., 2001). The original incidence of diabetes in these rats was 20% but subsequent inbreeding increased the incidence up to 80% (Jorns et al., 2005). Overt diabetes develops around 8–9 weeks of age in both genders and is preceded by insulitis in the pancreas only around a week before diabetes onset (Jorns et al., 2005). Cells identified in the insulitis include CD4+ and CD8+ lymphocytes, macrophages, NK cells, and B cells (Lenzen et al., 2001; Mathews, 2005). In contrast to NOD mice and BB rats, the Lew.1AR1-iddm rat does not show signs of other autoimmune diseases and unlike BB rats they are not lymphopenic. This model has been used to understand the mechanisms involved in development of Type 1 diabetes from both a genetic point of view (Weiss et al., 2008) and the pathogenesis of the insulitis (Jorns et al., 2004). In addition, intervention studies have been carried out on this rat model (Jorns et al., 2010, 2015).

2.1.4 Komeda Diabetes-Prone Rat

The Komeda diabetes-prone (KDP) rats were derived from the Long-Evans Tokushima Lean strain, which were selectively bred to create diabetes prone (Kawano et al., 1991) and diabetes free substrain (Komeda et al., 1998). These rats develop typical signs of Type 1 diabetes including polyuria, hyperglycemia, and weight loss at around 60 days (Komeda et al., 1998). In similarity to the other rodent autoimmune models of Type 1 diabetes, beta cell loss is due to insulitis, but in KDP rats the cytokine profile differs where interferon-γ and tumor necrosis factor-α rather than interleukin-1β predominates (Jorns et al., 2014). Although these animals are not lymphopenic like BB rats, they do show signs of autoimmunity to the salivary and lacrimal glands (Mordes et al., 2004). These rats have not been extensively studied outside of Japan, but they been used to understand genetic susceptibilities to Type 1 diabetes. As with other rodent models and humans, MHC class II has been shown to be important in the development of the disease (Yokoi et al., 2012). In addition, a non-MHC susceptibility gene was identified (Casitas B-lineage lymphoma b)

in which polymorphisms were subsequently identified in the human disease (Yokoi et al., 2002). Although the most common variants do not seem to be linked to Type 1 diabetes in humans, some rarer missense mutations have been identified in human Type 1 diabetes patients (Yokoi et al., 2008).

2.2 Spontaneous Models of Nonautoimmune Diabetes

2.2.1 Akita Mouse

Mice differ from humans as they have two genes for insulin: *Ins1* and *Ins2*. The Akita mouse, also known as the Ins2 mouse or MODY4 mouse, was derived from a C57Bl/6 colony in which a spontaneous mutation of the *Ins2* gene resulted in early onset diabetes (Yoshioka et al., 1997). The mutation is an autosomal dominant missense mutation which stops one of the crucial disulphide bonds forming between the A and B chains of insulin 2, leading to misfolding of the proinsulin-2 protein (Wang et al., 1999). Electron microscopy has shown that this misfolded protein appears to aggregate in enlarged endoplasmic reticulum (ER). These aggregates are C-peptide positive but are around twice the size of expected proinsulin and have been shown to be linked to chaperone proteins, such as binding immunoglobulin protein (BiP). As these proteins are not fit for secretion, the ER unfolded protein response is triggered to degrade the aggregates. With limited degradation capacity within the ER, this accumulation ultimately leads to ER stress and beta cell destruction by apoptosis, specifically by a proapoptotic factor Chop (Oyadomari et al., 2002). These mice develop hyperglycemia, insulinopenia, polydipsia, and polyuria within 4 weeks of age and so provide a solid model of Type 1 diabetes (Izumi et al., 2003). Male mice in particular develop severe hyperglycemia and may require insulin administration to survive. However, females show a much less pronounced hyperglycemia (Oyadomari et al., 2002), which may be due to the protective effect of estrogen (Le May et al., 2006). Therefore, these mice have been used in both Type 1 diabetes research and Type 2 diabetes research as the severe deficiency of functional insulin in males gives a Type 1 diabetes phenotype, whereas the role of beta cell ER stress in the pathogenesis is of interest in studies of Type 2 diabetes.

In Type 1 diabetes research, the inability of the Akita mouse beta cells to regenerate have made this model a useful tool in investigating the impact of islet transplantation therapies (Mathews et al., 2002).

2.3 Chemical Induction of Diabetes

Several compounds have been tested and have been shown to induce diabetes in animal models, however, the two most studied and routinely used are streptozotocin

(STZ) and alloxan, both of which are glucose analogs. STZ and alloxan both work through the glucose transporter GLUT2 found in beta cells (Elsner et al., 2002; Schnedl et al., 1994). They do, however, have differing downstream mechanisms but ultimately both lead to almost complete ablation of beta cells within the islets causing a severe deficiency in insulin production leading to hyperglycemia and weight loss and thus reproducing the main symptoms of Type 1 diabetes. These compounds have been used for many years in animals for several reasons including their predictable symptom onset and relative low-cost compared to breeding spontaneously diabetic animals. These compounds provide stable hyperglycemia in small animals within a week (Deeds et al., 2011) and provide an ideal platform to study ways to decrease hyperglycemia which are not beta cell dependent, for example, in new insulin therapies or when investigating the efficacy of islet transplantation. The kidney and liver also contain the GLUT2 transporter but have better protection against the effects of these toxins, nonetheless care should be taken to avoid overdose as it will cause toxic effects in these organs (Elsner et al., 2002; Schnedl et al., 1994). Due to their analogy to glucose, alloxan and STZ compete with glucose for uptake via GLUT2, which is why some investigators suggest fasting prior to administration. Although beta cell regeneration does not routinely occur after alloxan or STZ administration, it has been reported for both these compounds (De Haro-Hernandez et al., 2004; Yin et al., 2006) and therefore measures to control for this should be taken.

2.3.1 Alloxan

Alloxan [2,4,5,6-tetraoxypyrimidine; 5,6-dioxyuracil] is a pyrimidine derivative of uric acid, first discovered in 1818 by Brugnaletti and then again in 1838 by Wohler. This compound was first noted to have diabetogenic effects in 1943 when central islet necrosis was found in alloxan-treated rabbits (Dunn et al., 1943). From then on, it has been used to model Type 1 diabetes in animal experimentation. Doses vary between studies; however, it is suggested that single doses ranging from 50 to 150 mg/kg produce chronic hyperglycemia in rodents depending on administration route and strain (Leiter and Schile, 2013; Szkudelski, 2001). Alloxan has been shown to begin exerting its effects within 2 min (Szkudelski et al., 1998) as plasma insulin levels are seen to rise consequently giving a period of hypoglycemia preceding long-term hyperglycemia. This hyperglycemia has been shown to be chronic but has been occasionally shown to ameliorate over time with blood glucose concentrations normalizing and body weight returning or surpassing original levels (De Haro-Hernandez et al., 2004). This has been proposed to be due to superior beta cell regeneration with alloxan treated-compared to STZ-treated animals as was demonstrated in guinea pigs (Gorray

et al., 1986), although it should be noted that the islets from different animal species show different susceptibilities to this toxin (Tyrberg et al., 2001).

Alloxan's mechanism of action has been compiled over the years from in vitro and in vivo studies and it is now well established. The uptake of alloxan through GLUT2 transporters on the beta cells leads to rapid cell destruction. As alloxan enters the beta cell, reactive oxygen species reduce the alloxan to dialuric acid, which can then go on to reoxidize to alloxan and generate free radicals, such as superoxide. Superoxide can form hydrogen peroxidase, as well as reduce Fe^{3+} ions leading to hydroxyl radicals, both of which damage the DNA of the beta cells leading to fragmentation and ultimate cell death. The hydrogen peroxidase has also been suggested to be involved in causing a surge of intracellular calcium leading to the high initial peak in insulin levels following alloxan administration (Szkudelski, 2001) which can in itself cause damage to the beta cells. This cyclical destruction may account for the ongoing action of alloxan long after its clearance from the body with a half-life of only 1.5 min at 37°C (Lenzen and Munday, 1991). Alloxan also has a second mode of impact on the insulin secretion of the beta cells as it has high affinity for —SH containing groups most notably found on glucokinase, the glucose-sensing molecule within the beta cells. Binding of alloxan to glucokinase inactivates it and ultimately hinders glucose-stimulated insulin secretion (Lenzen et al., 1987).

2.3.2 Streptozotocin

Streptozotocin [2-Deoxy-2-({[methyl(nitroso)amino] carbonyl}amino)-β-D-glucopyranose] (STZ) is an antibiotic made by the fungus *Streptomycetes achromogenes* and can be used both in a single high dose or multiple low doses to provide chronic diabetes. STZ also works through the GLUT2 transporter and accumulates intracellularly forming the alkylating product diazomethane resulting in beta cell death through alkylation of the DNA within these cells. The destruction of the beta cells by STZ is multifactorial. STZ itself is a nitric oxide donor and this can directly impact the DNA and cause damage. In addition, STZ causes production of free radicals like superoxide, much like alloxan, which ultimately leads to hydrogen peroxidase and hydroxyl-induced DNA damage through disruption of ATP production in the mitochondria. This DNA damage causes activation of poly ADP-ribosylation reducing intracellular NAD^+ and further decreasing the available ATP in the mitochondria. This overall reduction in ATP leads to less insulin synthesis and secretion from the beta cells. The subsequent glucose overload then activates the PKC pathways and results in downstream glycation products resulting in further oxidative stress and cell apoptosis, necrosis and DNA damage (Goyal et al., 2016). STZ

also has the ability to both directly and indirectly activate NFκB, which in turn leads to cytokine production and mitochondrial dysregulation, contributing to beta cell disruption.

STZ has a half-life of 15 min and it is therefore recommended that it must be administered as a fresh preparation each time, dissolved in a pH 4.5-citrate buffer for maximum effect. There are many differences in the doses between species and strains with doses ranging from 100 to 300 mg/kg for single high dose and 30–80 mg/kg for multiple low dose injections (Deeds et al., 2011). In fact, other factors, such as age and sex also play a large role as younger rodents have been shown to be more susceptible to STZ than older animals (Leiter, 1982) and females have partial resistance to STZ due to estrogens which appear to attenuate STZ-induced hyperglycemia as shown in rats (Riazi et al., 2006). STZ seems to have a slightly better toxicity profile than alloxan with fewer deleterious effects, for example, in the liver (El-Hawari and Plaa, 1983), as well as having a large therapeutic window making it now a more favorable option for the induction of diabetes. It should also be noted that STZ can induce lymphopenia, which could affect the interpretation of islet transplantation studies in which immune tolerance could be involved (Muller et al., 2011).

2.3.2.1 SINGLE HIGH DOSE STZ

A single high dose of STZ in rodents ranges from 35 to 65 mg/kg for rats and between 100 and 300 mg/kg for mice depending on the strain and sex. There is an initial hyperglycemia phase within the first few hours followed by up to 8 h of hypoglycemia preceding the slow increase of blood glucose levels to the usually in the range of 400–600 mg/dL (22–33 mM) over the consecutive 3–5 days (Deeds et al., 2011; Goyal et al., 2016). The reports of hypoglycemia have given rise to some protocols recommending the administration of glucose within the early period following injection. However, recent data by King et al. (2016) using continuous glucose monitoring in rats has shown that STZ-induced diabetes within hours with no signs of hypoglycemia.

2.3.2.2 MULTIPLE LOW DOSE STREPTOZOTOCIN

Multiple low dose STZ treatment is used to model insulitis, as well as produce hyperglycemia in rats and mice. Multiple doses of STZ between 20 and 40 mg/kg are administered over 3–5 consecutive days leading to depletion of around 85% of beta cells. This type of dosing induces an inflammatory response leading to macrophage infiltration of the islets that ultimately leads to beta cell death by cytokine mediated damage (Lukic et al., 1991; Sandberg et al., 1994; Yang et al., 2003). It is likely that this occurs through an NFκB-dependent pathway as blocking this pathway genetically leads to fewer animals becoming diabetic (Mabley et al., 2002).

A dramatic loss of beta cell mass and secretory function occurs within 1 day followed by the maximum macrophage infiltration which is seen later at around day 3 (Bonnevie-Nielsen et al., 1981). Unlike in human Type 1 diabetes, the beta cell destruction occurs in the absence of T lymphocyte involvement and thus investigators should interpret results in this model cautiously and preferably use it together with a spontaneous autoimmune model of beta cell destruction.

2.4 Virus-Induced Models of Diabetes

Viruses have been implicated to be involved in the pathogenesis of some cases of Type 1 diabetes (van der Werf et al., 2007). Animal models have therefore been developed to recapitulate viral infection leading to beta cell destruction, which can occur either directly or indirectly (Jun and Yoon, 2003). A variety of viruses have been used in animal models including Coxsackie B virus (Kang et al., 1994), Encephalomyocarditis virus (Craighead and McLane, 1968), and Kilham rat virus (Guberski et al., 1991). The models are complicated by the results depending on timing and efficiency of the viral infection. Indeed, depending on the conditions, some viruses have been shown to protect rather that cause Type 1 diabetes (von Herrath et al., 2011). Nonetheless, these models show an important proof of principle that viruses can induce a Type 1 diabetes phenotype and have increased our knowledge of this process.

2.5 Large Animal Models of Type 1 Diabetes

In some studies of Type 1 diabetes, it is desirable to use a large animal model. Spontaneous diabetes in larger animal models is relatively uncommon and the onset is unpredictable making spontaneous models rather unpractical. Therefore beta cell ablation is usually used. This can be achieved by pancreatectomy or by chemically ablating the beta cells using STZ.

2.5.1 Pancreatectomy

Whereas it is not practical or ethical to use pancreatectomy in rodents with the sole aim of inducing hyperglycemia, it is more widely used in larger animals. When carried out by a skilled surgeon, pancreatectomy is a reliable method to induce hyperglycemia in pigs (Morel et al., 1991), dogs (Fisher et al., 2001), and primates (He et al., 2011). However, the ethical implications should be carefully considered, as this is an invasive procedure that can lead to a variety of side effects. One potential use is in islet transplantation studies where autotransplantation can be carried out in a pig (Emamaullee et al., 2009b) or primate model (Rajab et al., 2008) as these animals have a similar islet: portal vein size as humans.

2.5.2 Chemical Ablation of Beta Cells in Large Animals

STZ can be used in large animals to deplete beta cells and has primarily been used in pigs (Hara et al., 2008) and primates (Koulmanda et al., 2003). Although it is very effective in primates, pigs show a reduced response to STZ due to a low GLUT2 expression (Dufrane et al., 2006). Increasing the STZ dose can lead to renal and hepatic toxicity and thus in pigs a narrow therapeutic window makes effective beta cell ablation difficult to achieve. Some studies have reported a correcting of hyperglycemia within 4 weeks of the STZ injection into pigs and thus careful attention is required to make sure spontaneous recovery is not affecting the study outcome (Dufrane et al., 2006). Some investigators have combined a partial pancreatectomy with a reduced STZ dose in pigs (Wise et al., 1985). Multiple low dose STZ has been used on primates to try and come closer to modeling human pathogenesis in Type 1 diabetes. One study showed that rhesus monkeys administered low dose STZ showed both hyperglycemia and autoantibodies to insulin, which is a valuable tool for preclinical testing (Wei et al., 2011). However, it is worthy to note that it has been shown that cynomolgus monkeys administered STZ-developed lymphopenia, which could interfere with interpretation of transplantation studies (Nagaraju et al., 2014).

2.6 Choosing an Animal Model for Type 1 Diabetes

If the study aims to understand the pathogenesis of Type 1 diabetes, an autoimmune model should be used. The NOD mouse, BB rat, Lew.1AR.1-iddm rat, and KDP rat have all contributed to understanding more about the genetic susceptibility of the disease and, in varying degrees, the effector mechanisms in beta cell destruction. Likewise, one of these models would ideally be used in prevention studies that involve manipulation of the immune attack on the beta cells. The low dose STZ model could also be used in addition to prevent immune mediated attack on the beta cells, but should ideally be combined with a spontaneous model.

In investigations that aim to study new insulin formulations or beta cell replacement therapies, the beta cell ablation models of STZ or alloxan could be used as the lack of beta cells is a more important characteristic of the model than the process that led to it. In addition the male Akita mouse is an ideal model in that scenario, as beta cell regeneration does not occur.

2.7 Endpoints in a Type 1 Diabetes Study

2.7.1 Blood Glucose Concentrations and Weight

In prevention and curative studies, the most obvious endpoint is blood glucose concentrations. However, it is important that bodyweight is also monitored as blood glucose concentrations will fall if the animal is not eating properly which could give the false impression that the animal is curing when in fact they are sicker. To truly be convinced that blood glucose homeostasis is improved, weight gain should be seen in conjunction with a reduction in blood glucose concentrations. Normal blood glucose concentrations are not well defined in rodents, although it should be noted that mice tend to have higher blood glucose concentrations than rats and humans. In rodent studies of Type 1 diabetes, blood glucose concentrations greater than 300 mg/dL (16.7 mM) is often defined as diabetic, although 400 mg/dL (22.2 mM) or higher is also used. Defining when the animal has cured is more difficult. The most conservative studies define less than 200 mg/dL (11.1 mM) as cured, although other studies use below 300 mg/dL (16.7 mM). In reality one can regard mice with blood glucose concentrations between 200 and 300 mg/dL (11.1 and 16.7 mM) as neither fully diabetic nor fully cured. It is usual to confirm "diabetes" or "cure" with blood glucose measurements taken over the course of several days to avoid a single fluctuation giving a false result. It should be noted that blood glucose concentrations vary between strains (Leiter, 2009) and also depend on the time of day that blood glucose is measured. The timing of blood glucose concentration measurement is particularly relevant if using rats or mice as these nocturnal animals feed at night. Therefore blood glucose concentrations during the day are lower than at night and this variation is considerably magnified in models of Type 1 diabetes (King et al., 2016). In general, blood glucose concentrations should be measured as early in the morning as possible and at the same time point each day. Continuous blood glucose monitoring by telemetry is a way to circumvent this problem, but is rather expensive and invasive for everyday use. However, it could be a useful tool to use in optimized models to really show improvements in minute-to-minute blood glucose variations (King et al., 2016).

2.7.2 Insulitis Scoring

In therapies designed to prevent the autoimmune attack on the islets, scoring of insulitis in histological sections of the pancreas at the end of the study can provide evidence of successful manipulation of the immune response. Typically, islets are scored from 0 to 3 depending on extent of the immune infiltration (Yoon et al., 1999). It is important that scoring occurs blinded to prevent bias and ideally should be carried out by two independent researchers scoring each sample. A more refined method is fluorescence-activated cell sorting to analyze the phenotype of the infiltrating cells (Magnuson et al., 2015).

2.7.3 Immune Cell Phenotyping and Autoantibody Response

To characterize the immune response during the autoimmune attack, cells of the peripheral blood, spleen, or lymph nodes can be analyzed by fluorescence-activated cell sorting (Pontesilli et al., 1987). In addition, autoantibodies in the serum can be measured by ELISA, radiobinding assays (Lampasona et al., 2008), or electrochemiluminescence-based assays (Lo et al., 2011). Immune cell secretory products, such as cytokines can be measured by enzyme-linked immunospot (ELISpot) (Emamaullee et al., 2009a).

2.7.4 Ruling Out Regeneration of Endogenous Beta Cells

In chemically induced beta cell ablation models, regeneration of endogenous beta cells could confound results and should be therefore ruled out. This can be done by insulin staining of the pancreas or measuring insulin content of the pancreas at the end of the study. In studies where islets have been transplanted under the kidney capsule, nephrectomy can be used to remove the graft at the end of the study with a reversion to hyperglycemia expected to show the graft was responsible for normoglycemia (Rackham et al., 2011).

3 TYPE 2 DIABETES

Type 2 diabetes is caused by an inability of the beta cell to fully compensate to insulin resistance, leading to a relative deficiency in insulin and hyperglycemia (Weir and Bonner-Weir, 2004). The disease has a strong genetic link but it is clear that, environmental factors play an important role in disease development (Franks and Pare, 2016). Indeed, the incidence of Type 2 diabetes has increased rapidly with the global epidemic in obesity, which is one of the major risk factors to the disease (Kahn and Flier, 2000). Impaired glucose tolerance is usually caused by decreased insulin sensitivity and is an important stage in the development of Type 2 diabetes (Weir and Bonner-Weir, 2004). At this stage of the disease, some beta cell compensation is usually apparent and thus it is an ideal stage, during which the development of overt Type 2 diabetes can be prevented by intervention (Eriksson et al., 1999). Many preclinical studies, therefore use animal models of impaired glucose tolerance and thus these models will also be discussed as they form an important part of Type 2 diabetes research. Overt diabetes occurs in both human and animal models when beta cell function and/or mass are impaired to the extent that insulin production is no longer sufficient to compensate for insulin resistance (Masiello, 2006; Weir and Bonner-Weir, 2004). Some of the most commonly used rodent models in Type 2 diabetes are outlined in Table 10.2.

3.1 Obese Models

As obesity-induced insulin resistance is a major contributor to the pathogenesis of Type 2 diabetes, many animal models are either genetically obese or obesity is induced by manipulation of the diet. Although most of these obese models are characterized by insulin resistance, not all will necessarily develop overt diabetes and many model a prediabetic state of impaired glucose tolerance.

Many genetically obese mouse strains are monogenic, that is, obesity is caused by the mutation or manipulation of a single gene. Although monogenic mutations are a rare cause of human obesity, in rodent models they are often used to replicate the insulin resistant and glucose intolerant state that embodies some of the main characteristics of Type 2 diabetes. The two most commonly used monogenic mouse models (Lep$^{ob/ob}$ and Lep$^{db/db}$ mice) have an aberrant leptin signaling pathway, leading to hyperphagia and subsequent obesity (Wang et al., 2014). A disrupted leptin signaling pathway is also a key characteristic of the Zucker fatty rat and Zucker fatty diabetic rat. Other mouse and rat models display polygenic obesity (Joost and Schurmann, 2014). Although this more accurately reflects the human condition, it raises other problems including the lack of a genetically similar lean control. Obesity can also be induced in mice and rats by feeding them a high-fat or high-fat/high-sugar diet (Hariri and Thibault, 2010), which may reflect the pathogenesis of the human disease.

3.1.1 Monogenic Models of Obesity

3.1.1.1 LEP$^{OB/OB}$ MICE

A single autosomal recessive mutation on the gene encoding leptin causes the obese phenotype in Lep$^{ob/ob}$ mice (Zhang et al., 1994). The nonsense mutation leads to a lack of functional leptin and thus the satiety pathway in these mice is disrupted leading to extensive hyperphagia. Lep$^{ob/ob}$ mice gain weight rapidly from an early age and by 2–4 weeks of age the obese phenotype starts to become apparent (Lindstrom, 2007). This is coupled with hyperinsulinemia and glucose intolerance. There is no beta cell dysfunction and although beta cell mass increases to compensate for insulin resistance (Tomita et al., 1992); these animals can still become hyperglycemic. However, the diabetic phenotype is usually relatively mild and it is transient in nature with a peak in blood glucose concentrations at 3–5 months after which they fall (Lindstrom, 2007). In addition, these mice have a variety of comorbidities including hyperlipidemia and infertility. It should also be noted that they have reduced energy expenditure and reduced physical activity. As with other animal models of Type 2 diabetes, the background strain of the Lep$^{ob/ob}$ mice determines the severity of the diabetic phenotype and on the C57BLKS/J background a more severe phenotype is evident (Coleman and Eicher, 1990; Hummel et al., 1972).

TABLE 10.2 Key Characteristics of Rodent Models of Type 2 Diabetes

Type of model	Examples	Obese?	Islet phenotype
Monogenic obesity	Lep$^{ob/ob}$ mice	√	Background dependent—C57Bl/6: compensation, C57Bl/KS: inadequate compensation
	Lep$^{db/db}$ mice	√	Initial compensation then reduction in beta cell mass. Severity background dependent as for Lep$^{ob/ob}$ mice.
	Zucker diabetic fatty rats	√	Inadequate beta cell compensation
Polygenic obesity	KK-Ay mice	√	Some beta cell compensation
	OLETF rats	√	Progressive beta cell degeneration
	New Zealand obese mice	√	Reduced beta cell mass
	TallyHo/Jng mice	√	Some beta cell compensation
Diet manipulation	High-fat feeding	√	Some beta cell compensation
	High-fat/high sucrose feeding	√	Some beta cell compensation
	Psammomys obesus	√	Progressive beta cell degeneration
Planned strain development	Goto-Kakizaki rats	x	Beta cell mass or function compromised.
	NoncNZO10/Ltj mice	√	Initial compensation then reduction in beta cell mass
	Zucker diabetic Sprague Dawley rats	√	Initial compensation then reduction in beta cell function
	UC Davis Type 2 diabetes mellitus rat	√	Initial compensation then reduction in beta cell function
	Human islet amyloid polypeptide rat	x	Amyloid deposits leading to beta cell degeneration
	Human islet amyloid polypeptide mouse	x	Amyloid deposits leading to beta cell degeneration
Induced models of beta cell insufficiencies	Neonatal streptozotocin rat	x	Depletion then mass regeneration
	Pancreas injury models	x	Depletion then mass regeneration
	High-fat diet + streptozotocin	√	Initial compensation then reduction in beta cell mass

3.1.1.2 LEP$^{DB/DB}$ MICE

The cause of the obese phenotype in Lep$^{db/db}$ mice is a nonfunctional leptin receptor due to a single autosomal recessive mutation resulting in abnormal mRNA splicing (Chen et al., 1996). In similarity to Lep$^{ob/ob}$ mice, this leads to hyperphagia and obesity from early in life (Hummel et al., 1966). Animals are hyperinsulinemic (Coleman and Hummel, 1974) and this coupled with beta cell dysfunction (Berglund et al., 1978) leads to severe hyperglycemia depending on the background strain (Coleman, 1978). In similarity to the Lep$^{ob/ob}$ mice, the background strain of the Lep$^{db/db}$ mice can determine the severity of the diabetic phenotype with C57BL/KS mice becoming more severely diabetic to the extent that they can develop ketosis (Hummel et al., 1972). This may be due to the poor ability of this strain to compensate with increased beta cell replication (Swenne and Andersson, 1984).

3.1.1.3 ZUCKER FATTY RATS AND ZUCKER DIABETIC FATTY RATS

Zucker fatty rats have a mutated leptin receptor (Phillips et al., 1996) leading to hyperphagia (Kowalski et al., 1998) with obesity apparent from around 4 weeks of age (Wang et al., 2014). They are hyperinsulinemic (Trimble et al., 1986) and have poor glucose tolerance (Triscari et al., 1979) although are not overtly diabetic. The Zucker diabetic fatty (ZDF) rat is a substrain of the Zucker fatty rat, which was derived from hyperglycemic Zucker fatty rats to gain a model with diabetic features (Peterson et al., 1990). It is severely insulin resistant and males become overtly diabetic at 8–10 weeks, which is due to an inability of beta cells to compensate for insulin resistance, which is associated with changes in islet morphology (Tokuyama et al., 1995). Females do not tend to develop overt diabetes but diabetes can be induced by feeding a high-fat diet (Corsetti et al., 2000).

3.1.2 Polygenic Models of Obesity

There are several different rodent models of impaired glucose tolerance and diabetes that are induced by a polygenic obese phenotype. It could be argued that this more closely reflects obesity in humans that monogenic strains. Models, such as these have been used to identify genes involved in the development of obesity-induced diabetes in humans (Joost and Schurmann, 2014).

3.1.2.1 KK AND KK-AY MICE

KK mice are hyperleptinemic, mildly obese mice that develop impaired glucose tolerance characterized by severe insulin resistance and hyperinsulinemia (Clee and Attie, 2007). There are signs of beta cell compensation with increased pancreatic insulin content and islet hypertrophy (Nakamura and Yamada, 1967). The introduction of the *Ay* gene led to KK-Ay substrain, which is more severely hyperinsulinemic and is overtly diabetic (Suto et al., 1998).

3.1.2.2 OTSUKA LONG-EVANS TOKUSIMA (OLETF) RATS

This strain derives from a spontaneously diabetic rat discovered in a colony of Long-Evans rats (Kawano et al., 1994). Selective breeding leads to the OLETF strain, which is characterized by mild obesity, hyperinsulinemia, and late-onset hyperglycemia, which occurs after the age of 18 weeks (Moran, 2008). Males are prone to develop diabetes, which occurs after progressive degeneration of the islets. Initially, there is a period of islet hyperplasia up to the age of 40 weeks after which the islets become fibrotic, apoptosis is detected and beta cell mass is reduced (Hong et al., 2002).

3.1.2.3 NEW ZEALAND OBESE MICE

New Zealand Obese (NZO) mice are obese due to hyperphagia (Leiter and Reifsnyder, 2004). The cause of this is most likely a defect in leptin transport across the blood brain barrier as these mice are hyperleptinemic and resistant to peripherally administered leptin but respond to centrally administered leptin (Halaas et al., 1997). They are hyperinsulinemic as a result of insulin resistance and have increased hepatic glucose production (Andrikopoulos et al., 1993; Veroni et al., 1991). Impaired glucose tolerance worsens with age and approximately half of males develop overt diabetes (Haskell et al., 2002). In male mice that have overt diabetes, a reduced beta cell mass is evident (Lange et al., 2006). The NZO strain has been used in a carbohydrate intervention diet model, in which carbohydrates are initially restricted from weaning and then fed from 18 weeks leading to rapid beta cell loss and induction of hyperglycemia in the space of 16 days (Kluth et al., 2011).

3.1.2.4 TALLYHO/JNG MICE

This strain of mice was derived from selective breeding of hyperglycemic mice discovered in an outbred colony of Theiler original mice (Kim et al., 2001). These obese mice have characteristics often seen in obese patients including increased plasma triglycerides, cholesterol and free fatty acids (Kim and Saxton, 2012). Male mice develop hyperglycemia at around 10–14 weeks whereas females do not become overtly diabetic (Kim and Saxton, 2012). Hyperinsulinemia is evident with

resulting hypertrophied and degranulated beta cells (Leiter et al., 2013).

3.1.3 Diet-Induced Models of Obesity and Diabetes

Manipulation of the diet by feeding rodents a high-fat, high-energy diet is another means of inducing obesity in rodents. This model is relevant given it reflects the mechanism of obesity-induced diabetes in humans. It is especially a useful tool in knock-out and transgenic mice in an attempt to establish whether the gene of interest affects the ability of islet function to adapt to the obesogenic environment. In addition, diet manipulation during pregnancy can be used as it can lead to aberrations in blood glucose homeostasis in the offspring.

3.1.3.1 HIGH-FAT FEEDING IN MICE AND RATS

Obesity can be induced by feeding mice a high-fat diet. This entails increasing the fat content of their chow from about 11% fat to around 58% fat (Surwit et al., 1998). It was first described in C57Bl/6 mice in 1988 and since then has been used in numerous studies (Surwit et al., 1988). Although overt diabetes does not usually occur, insulin resistance leading to glucose intolerance is a characteristic of this model (Winzell and Ahren, 2004). It therefore models an obesity-induced prediabetic state. Although increased weight gain can be detected within a week of high-fat feeding (Winzell and Ahren, 2004), it is typically administered over a longer time period (8–12 weeks) (Muhlhausler, 2009). It should be noted that the susceptibility to diet-induced obesity varies between different rat and mouse strains and thus the strain should be chosen carefully before commencing a study (Almind and Kahn, 2004; Surwit et al., 1998). It has also been shown that there is a variation in the response to high-fat feeding within inbred strains and thus it is not only genetic factors determining the outcome (Burcelin et al., 2002). The C57Bl/6 mouse strain has been shown to be susceptible to obesity and mild hyperglycemia when fed a high-fat diet and thus is a popular strain to use (Winzell and Ahren, 2004). In rats, the Sprague Dawley and Wistar strains are often used although it has been reported that the Wistar rat is more susceptible to the metabolic phenotypes (Marques et al., 2016).

3.1.3.2 HIGH-FAT HIGH SUCROSE FEEDING IN MICE AND RATS

High-fat high sucrose diets are also used to induce aberrant blood glucose homeostasis in rodents (Fernandes-Santos et al., 2009; Sampath and Karundevi, 2014). For example, a diet with addition of lard and sucrose can induce differences in weight in Sprague Dawley rats by day 30 (Nakajima et al., 2015). By day 56, increased adiposity, insulin resistance and hyperglycemia were evident. It should be noted that although the overall calorie intake is increased in this diet overall food consumption

is reduced due to the high calorific value. This can lead to a protein deficiency and should be carefully controlled for. This combination of a high-fat and high-sugar diet is thought to most closely resemble the diet that has dramatically increased obesity levels in humans over the past few decades.

3.1.3.3 DIET-INDUCED OBESITY IN THE SAND RAT (*PSAMMOMYS OBESUS*)

The sand rat is lean in its natural desert habitat where it feeds on low calorie vegetation, but in a laboratory setting becomes obese, hyperinsulinemic, and ultimately hyperglycemic when fed a standard chow diet (Shafrir et al., 2006). This is due to its poor adaptation to excess nutrition and thus it serves as a model of the "thrifty gene effect" where it is hypothesized, that rapid evolution from scarcity to nutritional abundance in some developing countries has led to a diabetes epidemic (Joffe and Zimmet, 1998). The progression from normal blood glucose metabolism to diabetes in the sand rat has been described in four different stages. Stage A is normoglycemic and normoinsulinemic, stage B is normoglycemic and hyperinsulinemic, stage C is hyperglycemic and hyperinsulinemic, and finally stage D is hyperglycemic and insulinopenic. Progression from stage A to C can be prevented by restricting the diet but stage D is characterized by beta cell attrition and is nonrecoverable (Shafrir et al., 2006). These pathophysiological changes reflect the progress of the disease in some patients and reflect a model of over nutrition and subsequent failure of beta cell adaptation.

3.1.3.4 PRENATAL DIET MANIPULATIONS

Developmental origins of metabolic diseases have been demonstrated in humans. For example, studies of children born just after the Dutch Winter Famine showed that in adulthood there were increased incidences of impaired glucose tolerance (de Rooij et al., 2006). In addition, an inappropriately high nutrient supply in utero has also been shown to lead to increased incidence of Type 2 diabetes later in life (Pettitt and Knowler, 1998). It is therefore clear that nutrient supply in utero is important and either restriction or oversupply of nutrients can lead to disturbed glucose homeostasis in adulthood.

3.1.3.4.1 MATERNAL LOW-PROTEIN MODEL IN RATS Pregnant dams fed a low protein diet (8% rather than 20%) give birth to growth-restricted offspring with a low body weight, which develop symptoms of Type 2 diabetes later in life (Muhlhausler, 2009). After birth, there is a period of rapid postnatal growth (Ozanne, 2001) and this has also been implicated as an important component of the model. Insulin sensitivity is initially enhanced but in adulthood insulin resistance develops leading on to a Type 2 phenotype (Ozanne et al., 2005).

Indeed, protein restriction during pregnancy has been shown to affect the offspring's islets, as well as insulin sensitive tissues, such as liver, fat, and muscle (Ozanne et al., 2005; Thompson et al., 2007). Islets in neonates are smaller than control animals and have higher levels of apoptosis (Petrik et al., 1999). A postnatal high-fat diet exacerbates the phenotype and in these animals (Claycombe et al., 2013).

3.1.3.4.2 MATERNAL OVER NUTRITION IN RATS High-fat feeding of pregnant dams has been associated with increased obesity and impaired blood glucose homeostasis in adulthood in the offspring (Srinivasan et al., 2006). The consequent obesity in the offspring may directly affect blood glucose homeostasis, although it has been suggested that abnormal development of the beta cells may also contribute to the phenotype (Cerf et al., 2007). Indeed offspring have hyperinsulinemia and impaired glucose tolerance (Srinivasan et al., 2006), as well as impaired beta cell function (Cerf et al., 2007; Taylor et al., 2005).

3.2 Planned Strain Development

Although many models of diabetes have been discovered through inbreeding of spontaneously diabetic rodents, some newer models have been created through planned breeding or genetic engineering to obtain a strain with Type 2 diabetes features.

3.2.1 Goto-Kakizaki Rats

Goto-Kakizaki (GK) rats were established by repeated breeding of glucose intolerant Wistar rats (Goto et al., 1976), which led to a nonobese rat model of Type 2 diabetes. In contrast to obese models, insulin resistance is not the main initiator of hyperglycemia in GK rats; the aberrant blood glucose homeostasis is largely due to an insufficient insulin response (Ostenson and Efendic, 2007; Portha et al., 2001). The cause of this varies between colonies, with the Stockholm and Dallas colonies presenting with defects in insulin secretion whereas in the Paris colony the rats have a 60% reduced beta cell mass (Portha et al., 2009). In addition, the islets in the Paris colony of GK rats show signs of inflammation and fibrosis and therefore have some features of islets in Type 2 diabetes patients (Homo-Delarche et al., 2006).

3.2.2 NoncNZO10/Ltj Mice

The NoncNZO10/Ltj mouse strain was specifically developed at the Jackson Laboratory by combining independent diabetes risk-conferring quantitative trait loci from two different NZO strains with a nonobese nondiabetic mouse strain (NON/Lt) which had a propensity for high nonfasting blood glucose concentrations (Leiter et al., 2013). The model is characterized by severe insulin

resistance in the liver and skeletal muscle which is evident from 8 weeks and hyperglycemia develops from around 12 weeks of age (Cho et al., 2007). Although islet mass initially increases to compensate for the insulin resistance, beta cell loss then occurs leading to overt diabetes (Leiter et al., 2013).

3.2.3 UC Davis Type 2 Diabetes Mellitus Rat

The UC Davis Type 2 diabetes mellitus rat (UCD-T2DM rat) was developed by breeding insulin-resistant obese Sprague Dawley rats with ZDF lean rats. The outcome of this breeding strategy was the creation of a strain that was characterized by adult-onset obesity, insulin resistance, and impaired glucose tolerance ultimately leading to diabetes due to beta cell loss (Cummings et al., 2008). It has been suggested that this closely mimics the disease progression in Type 2 diabetes. Diabetes develops in both males and females, although females develop the disease approximately 3–4 months after males with males developing overt diabetes at around 26 weeks and females at 40 weeks.

3.2.4 Zucker Diabetic Sprague Dawley Rats

Zucker diabetic Sprague Dawley (ZDSD) rat strain was developed by crossing ZDF rats with a substrain of Sprague Dawley rat, which was selectively bred for its susceptibility to obesity induced by high-fat feeding (Peterson et al., 2015). In contrast to the ZDF rat, this strain has a functional leptin pathway (Choy et al., 2016). However, when fed a specific diet (Purina 5008 chow), rats gain weight, which is coupled with a decrease in insulin sensitivity (Choy et al., 2016). There is an initial compensation in beta cell function but the disease progresses resulting in overt diabetes. In this model, onset of overt diabetes is variable between individual rats but at least half are overtly diabetic by 21 weeks (Reinwald et al., 2009). Due to the similar background of the rats, it is likely that ZDSD and UCD-T2DM rats have similar characteristics, but as far as we are aware, have not been directly compared.

3.2.5 Models of Amyloid Deposition

A characteristic of Type 2 diabetes is the deposition of amyloid with the islets, leading to altered structure and function (Clark, 1989). Amyloid is derived from islet amyloid polypeptide (IAPP); however, IAPP in rodents is not amyloidogenic and thus does not aggregate to form the histopathological fibrils (Hoppener et al., 1994). Therefore rodent models have been created to express human IAPP in order to recapitulate the human pathogenesis of islet amyloid deposition. The human islet amyloid polypeptide (HIP) rat develops islet amyloid and diabetes presents at between 5 and 10 months of age (Butler et al., 2004). The beta cell mass of the rats is reduced by 60%, primarily due to increased rates of apoptosis (Matveyenko and Butler, 2006a). In mice, human IAPP (hIAPP) expressed under the insulin promoter leads to deposition of human amyloid within the islets causing toxicity (Janson et al., 1996). The mice initially have impaired glucose-induced insulin secretion and a reduction in beta cell mass follows, resulting in hyperglycemia (Matveyenko and Butler, 2006b).

3.3 Induced Models of Beta Cell Insufficiencies

The role of the beta cell in the development of Type 2 diabetes has become increasingly apparent (Weir and Bonner-Weir, 2004). Even in states of severe insulin resistance, diabetes will not develop if the beta cell is able to compensate. Although an inability of the beta cell to compensate for insulin resistance is a feature of many of the Type 2 diabetes strains already discussed, it is sometimes of value to focus on the function and mass of beta cells in an induced model, which allows studies to be carried out in a more specific time frame.

3.3.1 Neonatal Streptozotocin Administration

STZ administration to neonatal rats (2 days old) induces hyperglycemia within 2 days (Portha et al., 1974). This is followed by regeneration of the beta cells and a return to normoglycemia is reached within 10 days. However, the regeneration process is not sufficient to meet the metabolic demands of the growing rat and by 6 weeks the rats revert to hyperglycemia (Bonner-Weir et al., 1981). The insulin inadequacy is thought be caused by a combination of beta cell dysfunction (Trent et al., 1984) and reduced beta cell mass (Trent et al., 1984) although insulin resistance has also been described in this model (Takada et al., 2007).

3.3.2 Pancreas Injury Models

Injury models, such as duct ligation and pancreatectomy lead to substantial and rapid beta cell regeneration. These models are therefore useful to understand beta cell proliferation and neogenesis. In rats, a 60% pancreatectomy does not lead to an increase in blood glucose concentration and regeneration is mild (Leahy et al., 1988). However, a 90% pancreatectomy leads to hyperglycemia and extensive beta cell regeneration (Bonner-Weir et al., 1983). Within a period of 4 weeks, the endocrine portion of the pancreas has increased by eightfold. In mice, 60% pancreatectomies are more commonly used due to technical difficulties of carrying out this procedure on such a small animal (Li et al., 2016). This leads to compensatory beta cell proliferation in a normoglycemic state, which is a useful tool to study beta cell mass regulation.

In rats, ligation of the tail portion of the pancreas, which accounts for 50%–60% of the pancreatic mass, leads to massive degeneration of this portion of the

pancreas (Wang et al., 1995). It is replaced by ductal structures by day 3 and by day 5 it consists of ductal structures interspersed with small islets in connective tissue. During the 1st week, the beta cell mass in the tail portion nearly doubles making it an ideal model in which to study beta cell regeneration. Hyperglycemia does not occur in this model, indeed blood glucose concentrations decreases, which may reflect the invasiveness of this procedure. However, in the mouse model of ductal ligation, no overall change in pancreatic mass occurs (Rankin et al., 2013) which indicates important species differences in mechanisms of beta cell regeneration.

3.3.3 *High-Fat Diet and Streptozotocin*

The high-fat fed and STZ rat model was originally described in 2000 by Reed et al. (2000). This model aims to combine inducing insulin resistance through diet with reducing beta cell mass to mimic the natural history and metabolic characteristics of Type 2 diabetes. In the original model, 7-week-old Sprague Dawley rats were high-fat fed for 2 weeks. At this stage glucose tolerance was normal compared to control fed rats, but insulin resistance was indicated by hyperinsulinemia in response to a glucose load. A single dose of 50 mg/kg STZ was administered to fasted rats, which leads to an induction of hyperglycemia. This model was then modified to use low dose STZ (Srinivasan et al., 2005; Zhang et al., 2008). This model has now been used in many studies, primarily using Sprague Dawley or Wistar rats. The age of initiation of high-fat feeding, length of high-fat feeding, and doses of STZ have varied somewhat, which could lead to different metabolic profiles of the model between different studies (Skovso, 2014). One potential controversy with this model is to what extent beta cell mass should be reduced to model Type 2 diabetes as, if the beta cell mass reduction is too severe, one could argue it more closely resembles an obese Type 1 diabetes model. Therefore the STZ dosing and frequency is an important component of the model, with low doses of STZ preferable. Overall a variety of factors affect the metabolic outcome of the rats with some studies modeling an early and others a late stage of Type 2 diabetes (Skovso, 2014).

3.4 Large Animal Models of Type 2 Diabetes

Some larger animals spontaneously develop Type 2 diabetes, making them ideal to study with regard to understanding the human condition. Others are suitable models for over nutrition and obesity. Cats develop diabetes in middle age, which is associated with obesity and insulin resistance (O'Brien, 2002). However, the most striking similarity is the deposition of amyloid in the islets as it is one of the few species other than old world monkeys that develop this feature of Type 2 diabetes (Henson and O'Brien, 2006; Hoenig, 2012). Indeed,

in similarity to humans, this leads to a loss of beta cell mass. Unlike cats, dogs do not spontaneously develop Type 2 diabetes (Rand et al., 2004) and thus diabetes has to be experimentally induced. High-fat feeding combined with STZ has been used in dogs to induce a Type 2 diabetes phenotype (Ionut et al., 2010). Feeding a highly palatable diet, which is high in fat and carbohydrate, induces obesity. Beta cell function compensates for the insulin resistance and therefore a second intervention is required where beta cell mass is reduced by administering STZ. Pigs have been used in Type 2 diabetes research for a variety of reasons. One is that they have anatomical and metabolic similarities to humans. Another major reason is their susceptibility to atherosclerosis, which makes it a suitable model in which to study cardiovascular complications of Type 2 diabetes (Bellinger et al., 2006). A wide variety of different pig strains have been used in studies. Differing degrees of aberrations in blood glucose homeostasis have been induced by high-fat feeding or a combination of high-fat feeding and chemically induced reductions in beta cell (Bellinger et al., 2006; Koopmans and Schuurman, 2015; Koopmans et al., 2006). Old-world nonhuman primates spontaneously develop Type 2 diabetes, which has many similarities to the human disease, including obesity-induced insulin resistance and islet amyloid deposition, which leads to impaired beta cell function and mass (Wagner et al., 2006). These primates have therefore provided a useful model in which to study the pathogenesis of Type 2 diabetes and pharmacological interventions.

3.5 Choosing an Appropriate Model for Type 2 Diabetes Research

Type 2 diabetes is a disease in which several different genetic and environmental factors contribute to the pathogenesis. Therefore one single animal model does not recapitulate the human disease, although many models have characteristics of Type 2 diabetes in humans. The choice of animal model will therefore depend whether the researcher is trying to understand the pathogenesis or whether trying to prevent or treat a specific aspect of the disease. It is appropriate in many studies to use an obese model, although this often models insulin resistance and a prediabetic state rather than overt diabetes. Insulin resistance is a key component of many obese models and often precedes overt diabetes and therefore may reflect an early stage of the disease. There are a variety of obese models to choose from including monogenic and polygenic models, as well as induction of obesity through dietary manipulation. In humans, loss of beta cell mass in Type 2 diabetes is an important factor in disease progression. Therefore animal models of beta cell insufficiencies are vital if this aspect of the disease is being investigated.

3.6 End Points in a Type 2 Diabetes Study

3.6.1 Glucose Tolerance Tests

In both humans and animal models of Type 2 diabetes, random blood glucose concentrations are often close to normal or only slightly elevated. Subsequently, glucose tolerance tests are often used to study blood glucose homeostasis under stimulated conditions. Animals are usually fasted prior to being administered the glucose load, to determine basal blood glucose concentration. In many studies, mice or rats are fasted overnight, although it has been suggested that this is inappropriate as these nocturnal animals feed overnight and thus rather than a fast it represents starvation (McGuinness et al., 2009). It has therefore been suggested that 6 h is a more appropriate time to fast rodents. Glucose can be administered intraperitoneally, intravenously, or orally by gavage and typically a dose of 1–2 g/kg is used. In normal nondiabetic mice, the blood glucose usually peaks at 15–30 min and reverts to basal levels by 120 min (Bowe et al., 2014). The definition of impaired glucose tolerance and diabetes is not clear in animal models. Impaired glucose tolerance is an inability to clear a bolus of glucose (often around 2 g/kg) from the blood supply in a defined time period (often 2 h). Many researchers regard glucose tolerance as "impaired" if it is significantly worse than in the control. Others regard it as abnormal if glucose concentrations have not returned to basal levels within the 2-h period.

3.6.2 Serum Insulin Concentrations

Measuring the concentrations of insulin in the blood can help determine whether beta cell function is impaired. Often glucose is injected into fasted animals to stimulate the beta cells and insulin is measured in serum removed prior to injection and at early (within the first 5 min) and later time points (around 30 min). Sensitive assays should be used, such as ELISA, which can measure accurate insulin concentrations in small blood volumes that can be ethically extracted from living mice. It should be noted that insulin concentrations per se cannot fully determine the cause of hyperglycemia in the animals.

3.6.3 Measuring Insulin Resistance

An approximate measure of insulin resistance can be obtained through carrying out insulin tolerance tests. Animals are often fasted for 6 h and insulin is injected and blood glucose measured over the next 60–90 min to determine how responsive the animal is to insulin. A more elegant measure of insulin sensitivity is the hyperinsulinemic-euglycemic clamp (DeFronzo et al., 1979) but this is less well used as the technique is invasive, technically demanding and usually requires the animals to be anaesthetized.

3.6.4 Ex Vivo Analysis

3.6.4.1 PANCREAS HISTOLOGY

It is often appropriate to study islet histology after the study ends. Islet and/or beta cell size and number can be investigated (Xu et al., 1999), as well as islet morphology (Arrojo e Drigo et al., 2015). In early stages of Type 2 diabetes, islets may appear larger than control animals whereas in late stages beta cell mass can be decreased. Beta cell proliferation rates can be determined by administering BrdU to the animals prior to the end of the study (Cordoba-Chacon et al., 2014) or using a proliferation marker, such as Ki67 (Jorns et al., 2014). In HIP rats and hIAPP transgenic mice islet morphology with regard to amyloid deposition can be studied using Congo Red to stain amyloid fibrils (Hoppener et al., 2008).

3.6.4.2 FUNCTION OF ISOLATED ISLETS

At the end of the study, islets from the pancreas can be isolated using a collagenase digestion technique. They can be used to study glucose-induced insulin secretion in either static or perifusion studies. Other parameters, such as glucose oxidation rates and insulin biosynthesis can also be measured. Such investigations allow beta cell function to be studied in detail in standardized conditions.

4 DIABETIC COMPLICATIONS

Diabetic complications, such as neuropathy, nephropathy, retinopathy, and cardiovascular disease arise in both Type 1 and Type 2 diabetes. In humans, these complications develop after chronic hyperglycemia and thus many rodent models do not develop complications due to the relatively short periods of hyperglycemia. STZ is often used in diabetes induction when studying complications, but the possibility of direct effects of the STZ on the specific organ should be considered. An example of this is in the study of neuropathies, where it has been shown that STZ directly stimulates the TRPA1 channels, which could complicate the interpretation of results (Andersson et al., 2015). The Akita mouse is an STZ-free alternative that has been used to study diabetic neuropathy (Islam, 2013), although many of the Type 2 models are also suitable for this purpose.

Models of retinopathy include STZ-induced models of hyperglycemia, as well as spontaneous Type 1 and Type 2 models, such as Akita mice, NOD mice, and Lep$^{db/db}$ mice (Lai and Lo, 2013). The pathogenesis of retinopathy can also be investigated by using normoglycemic models of proliferative retinopathy, such as oxygen-induced retinopathy.

A variety of different animal strains have been used to model nephropathy including OLETF rats, Lep$^{ob/b}$ mice, Lep$^{db/db}$ mice, Zucker fatty rats (Betz and Conway, 2016). STZ-induced diabetes has also been used, but possible

direct effects of STZ on the kidneys should be controlled for. Akita mice have also been used but the disease progression is limited so may not be the best model for late stage experiments (Alpers and Hudkins, 2011). It should be noted that susceptibility to diabetic nephropathy is strain dependent with the C57Bl/6 relatively resistant (Betz and Conway, 2016).

5 GENDER, STRAIN, AND AGE EFFECTS IN ANIMAL MODELS OF DIABETES

Many rodent models of diabetes show a gender bias in the severity and/or incidence of diabetes. In NOD mice, females have a higher incidence of diabetes than male mice, whereas in Akita mice, the male mice show a more severe phenotype, which is insulin dependent. Many Type 2 diabetes models also show a gender effect, with examples in which males are more insulin resistant and prone to diabetes. This is particularly noticeable in polygenic obese models and may be due to increased obesity leading to more severe insulin resistance. In addition, estrogen has been shown to have protective effects to beta cell damage (Le May et al., 2006). In addition, strain effects can be very prominent in metabolic research (Fontaine and Davis, 2016). This ranges from susceptibility to STZ (Wolf et al., 1984) to susceptibility to high-fat feeding (Almind and Kahn, 2004). In addition, there are strain differences in the ability of beta cells to compensate to insulin resistance (Hummel et al., 1972). Age should also be considered when carrying out an investigation in animal models of diabetes. In autoimmune models, it has been suggested that interventions at earlier ages are more successful than interventions in older mice (Roep, 2007). In obese animals, insulin resistance may progress with increasing age. However, beta cell compensation can also occur in older mice, meaning that the diabetic phenotype can lessen with increasing age. Ideally, several strains and both genders should be used to confidently demonstrate a given treatment has effect. The age of the animal at the time of the study should also be carefully considered. It is therefore of utmost importance that the strain, gender, and age of the rodent model is carefully chosen when embarking on a study within metabolic research.

6 CONCLUSIONS

There are numerous animal models available in which to study Type 1 and Type 2 diabetes. No single animal model accurately reflects the pathogenesis of either disease and thus the choice of animal model will depend on which aspect of the disease is relevant to the study. Ideally, more than one animal model should be used to convincingly demonstrate the effect of a potential therapy. Strain and gender effects should also be carefully considered during experimental design. Nonetheless, animal models of diabetes have clearly been of huge benefit in understanding the pathogenesis and treatment of this complicated disease.

Model Nematodes in Obesity Research

Yu Nie, Stephen R. Stürzenbaum

King's College London, London, United Kingdom

1 OBESITY IS A GLOBAL CRISIS

The incidence of obesity is rising at an alarming rate, and presently affects a large proportion of the global population, in particular developed countries, such as the United States (the obesity rate is 35% among adults and 17% among children) and the United Kingdom (the adult obesity rate is about 20%). Besides, more than 40 million children under the age of five are overweight, which may lead to an increased chance of obesity (Wang et al., 2008a).

Abnormal or excessive fat accumulation occurs when energy intake is higher than the expenditure. Obesity is a complex trait caused by the interaction of genetic factors, an imbalanced dietary lifestyle, and other individual indispositions. Genetic susceptibility is the key contributing factor to the phenotypic variations in obesity. Indeed, animal mutants bearing defective metabolism pathways display various fat or skinny phenotypes.

The body mass index (BMI) is a basic predictor defining overweight (25–29.9 kg/m^2) and obesity (>30 kg/m^2). It is calculated by the following formula:

$$BMI = \frac{Weight\,(kg)}{\left[Height\,(m)\right]^2}$$

This is a simple measure that correlates well with densitometry measurements of fat mass. To distinguish

between fat mass and lean mass better, bioelectrical impedance quantifies the electrolyte solution resistance across the extremities. The waist-to-hip ratio (WHR) is an alternative approach that assesses the distribution of body fat. Skinfold thickness measures the size of the subcutaneous fat deposit.

The prevalence of obesity is accompanied with incalculable economic costs and social impacts. The healthcare cost linked to overweight and obesity has more than doubled every decade, and now accounts for one-sixth of the total health budget and a considerable consequential percentage loss of GDP (e.g., > 1% in United States and > 3.6% in China) (Popkin et al., 2006). Indeed, obesity facilitates the development of type 2 diabetes mellitus, hypertension, cardiovascular diseases, musculoskeletal disorders, respiratory problems, neurological damages, and cancers to name a few. Evidence suggests a "J-shaped" association between BMI and mortality (Berrington de Gonzalez et al., 2010). The notion that obesity can result in a lethal disease is unfortunately ignored by a large proportion of the population.

2 OBESITY: AN UNSOLVED MEDICAL PROBLEM

Timely, effective development and implementation of corrective therapies are needed, given that obesity remains a largely unsolved medical problem. Overweight and obesity can be managed by lifestyle changes or through the introduction of bariatric means; however, the success rate has been modest due to the low compliance with such regimes and limited availability. This has led to the development of effective pharmacological therapies that target weight loss.

The US Food and Drug Administration (FDA) requires that a suitable weight-loss drug demonstrate a minimum efficacy, namely to induce a loss of at least 5% of initial body weight over a 12-month period (Cooke and Bloom, 2006). Given the prevalence of obesity and the resulting financial potential, it is perhaps surprising that the pharmaceutical industries have not flooded the market. In the 1990s, the antiobesity drugs fenfluramine (Pondimin) and dexfenfluramine (Redux) were withdrawn from the market due to severe side effects linked to heart valve damage (Connolly et al., 1997), and similarly mazindol (Sanorex) was retracted in 2000 (Glazer, 2001). In 2008, rimonabant (Acomplia) was withdrawn due to its adverse effects on mental health, and 2 years later, sibutramine (Reductil) was withdrawn because of the associated severe contraindications, including tachycardia and hypertension (Williams, 2010). The only remaining FDA-approved antiobesity medications are phentermine (Adipex-p), phendimetrazine (Bontril), diethylpropion (Tenuate), and orlistat (Xenical). The first three appetite-

suppressants involve the short-term management of exogenous obesity (typically less than 12 weeks), but are characterized by restrictions due to the side effect profiles on the cardiovascular and neurological systems. Orlistat, a gastrointestinal tract and pancreatic lipase inhibitor, is the only remaining drug approved for long-term (>6 months) treatment. It is the saturated derivative of lipstatin, a potent natural inhibitor of pancreatic lipases isolated from the bacterium *Streptomyces toxytricini* (Barbier and Schneider, 1987). However, Orlistat's efficacy is moderate, leading to a 3%–4% reduction in body weight over a 2-year period, but is compounded by severe gastrointestinal side effects, such as steatorrhea and incontinence (Rucker et al., 2007).

In 2012, new drug applications of lorcaserin HCL (Belviq) (not approved in 2010 due to concerns over carcinogenicity observed in animals) and a combination of phentermine with the antiepileptic agent topiramate (Qnexa) (not approved in 2010 due to concerns over teratogenic potential) were resubmitted, and subsequently the FDA advisory committee supported its potential use for weight-management purposes (Kang and Park, 2012), notably some 13 years after the last weight-loss drug was approved. Although the benefits may outweigh the risks of a long-term application, the full approval is still pending, suggesting that regulatory committees are now more reluctant to approve novel treatments in the absence of long-term safety data.

3 MODEL ORGANISMS USED FOR BIOMEDICAL RESEARCH

"The Principles of Human Experimental Techniques" published in 1959 promoted the humane treatment of experimental animals, thereby defining the foundation of the replacement, reduction, and refinement (3R's) (Russell and Burch, 1959). In response to ethical concerns in the application of vertebrate animals, invertebrate models emerged. Examples include airborne insects (e.g., the fly *Drosophila*), terrestrial animals (e.g., the nematode *Caenorhabditis elegans*) and freshwater/marine life (e.g., planarians, crustaceans, and molluscs) (Wilson-Sanders, 2011) (Table 11.1).

Obesity is a challenging research topic, as homeostatic regulation of energy balance involves multiple tissues and molecular pathways, and is complicated by the complex interplay between the development/reproduction and lipid-storage capacity. One powerful model organism is the nematode *C. elegans* that can provide an insight into the feeding and defecating behavior, neuroendocrine signaling, mobilization, and a characterization of the genetic basis of lipid metabolism, and can, thereby, help tease apart the fundamental regulation of energy balance.

TABLE 11.1 Common Models Used to Study Fundamental Aspects of Diseases and Drug Discovery

Organism type	Species
Virus	T4 phage
	Phi X 174
Prokaryotes	*Escherichia coli*
	Bacillus subtilis
Eukaryotes	
Protists	*Chlamydomonas reinhardtii*
	Tetrahymena thermophila
Fungi	*Saccharomyces cerevisiae*
	Schizosaccharomyces pombe
Plants	*Arabidopsis thaliana*
	Lemna gibba
Animals	
Invertebrates	Nematode (*Caenorhabditis elegans*)
	Fruit fly (*Drosophila melanogaster*)
Vertebrates	Guinea pigs (*Cavia porcellus*)
	Zebrafish (*Danio rerio*)
	Chicken (*Gallus gallus domesticus*)
	Mouse (*Mus musculus*)
	Rat (*Rattus norvegicus*)
	Non-human primates (*Pan troglodytes*)
FIGURE 11.1 **A microscopic view of *C. elegans*.** (A) A population of mixed age on nematode growth media (NGM) agar. (B) A close-up of a single adult wild type worm, which has laid four eggs. (C) A high-resolution view of the head region of a hermaphrodite adult.

4 THE NEMATODE *CAENORHABDITIS ELEGANS*: SMALL IS BEAUTIFUL

C. elegans is a member of the phylum Nematoda and inhabits a wide range of habitats. The wild type strain (N2) originally isolated from Bristol (United Kingdom) and mutants can be maintained (using standardized protocols) in the laboratory on nematode growth media (NGM) plates supplemented with *Escherichia coli* (the food source) (Fig. 11.1). One of the key advantages of *C. elegans* is its short reproductive cycle (about 3 days) and life span (about 21 days) (Fig. 11.2).

C. elegans is, in many ways, an in vivo test tube. It is one of the simplest metazoan animals, only one millimeter in length, yet facilitating large-scale cultivation of thousands of staged animals. *C. elegans* is unsegmented, has a bilaterally symmetrical body tapering at both ends, and is transparent. The self-fertilizing hermaphrodite adult is made up of 959 somatic cells and produces homozygous progenies, which are genetically identical (bar spontaneous mutations). The male, which has a higher number of cells, one gonad and a tail with nine sensory palps to anchor the vulva, arises through a spontaneous nondisjunction in the hermaphrodite germ line, which is rare (typically less than 0.1% of a standard population) and can only copulate with its hermaphrodic counterpart. This feature represents an ideal tool for genetic crossing of two genotypes (Fig. 11.2).

The *C. elegans* genome is small and compact; it contains more than 20,000 protein-encoding genes assembled over 100 million base pairs. Although approximately only 1/30th the size of the human genome, many genes and core metabolic pathways are evolutionary conserved between the nematode and mammals (Hillier et al., 2005). *C. elegans* is thus primitive, and yet shares many of the most essential biological characteristics that are central to human biology (Table 11.2).

In 1963, Sydney Brenner introduced *C. elegans* as a model organism for developmental biology and neurobiology. Since then, the worm system has been applied to many fields, including genetics, cell biology, neuroscience, aging, stroke, muscle-associated disorders, metabolic diseases, cancer, embryogenesis, sex determination, and larval development (Markaki and Tavernarakis, 2010). Besides, the genome was fully sequenced in 1998 and the cell lineage of every single cell division, producing 959 somatic cells, was mapped in the 1980s. In addition, an RNA interference (RNAi) bacterial library containing 86% of the worm open reading frames has been constructed. Although injecting RNA into the body cavity of the animal induces gene silencing in most species, only *C. elegans* and a few other distantly related nematodes can take up RNAi molecules via the diet (Félix, 2008). Moreover, owing to its viability postfreezing, thousands of *C. elegans* strains are readily available (Table 11.3).
FIGURE 11.2 **The life cycle of *C. elegans* cultured at 25°C.** Under optimal growth conditions, the entire life cycle of hermaphrodite is completed within 3 days from the first larval stage (L1) to adulthood. Males arise from the fusion of nullo-X gametes (gametes that lack an X chromosome) and normal X-bearing gametes, at a rare frequency of less than 0.1%. When exposed to undesirable conditions (stress, crowding, or lack of food) the L1 enters "dauer," a stage that allows the worm to survive up to 4 months. Once conditions improve, the dauer animal develops to an L4 stage and oogenesis commences.

TABLE 11.2   A Comparison of the Genome and Proteome of Model Organisms

Species	Genome size (Mb)	% Of human genome	Protein count	% Of human protein
Homo sapiens **(human)**	**2,996.4**	**100**	**71,340**	**100**
Mus musculus (mouse)	2,671.8	89	39,412	55
Danio rerio (zebrafish)	1,391.7	46	47,861	67
Gallus gallus (chicken)	1,230.3	41	46,393	65
Drosophila melanogaster (fruit fly)	148.5	5	30,443	43
Caenorhabditis elegans **(nematode)**	**100.7**	**3**	**28,026**	**39**
Rattus norvegicus (Norway rat)	48.7	1.6	38,722	54
Saccharomyces cerevisiae (yeast)	12.3	0.4	5,404	8
Escherichia coli (bacterium)	5.2	0.2	4,931	7

Bold entries highlight the genome and proteome of human and *C. elegans* individually.

GFP, Green fluorescent protein; RNAi, RNA interference.

A comprehensive knowledge infrastructure has emerged over the past years, notably the strain and genome databases, such as those offered by the Caenorhabditis Genetics Center (http://cbs.umn.edu/cgc) or WormBase (http://wormbase.org). The abundance and open-access nature of resources have empowered worm researchers not only to focus on central biological issues, for example, aging, neurobiology, development, and evolution, but also other emerging fields, such as the biology of fat metabolism (Table 11.4).

5 THE BASIC BIOLOGY OF OBESITY: FROM A WORM'S PERSPECTIVE

Decades of genetic and physiological studies have focused primarily on murine lipid metabolism, which has contributed significantly to our knowledge of human energy homeostasis. *C. elegans* has been used to a lesser extent, nevertheless research has identified critical pathways, defined molecular mechanisms, uncovered new leads linked in particular to insulin signaling, the influence of serotonin on obesity, and the response to dietary glucose, feeding, and satiety (Zheng and Greenway, 2012). *C. elegans* lacks multifunctional adipocytes and certain fat-regulatory mechanisms, such as the leptin secretion from the white adipose tissue observed in mammals. It is also a cholesterol auxotroph, but is able to manufacture essential fatty acids (C18:2*n*6 and C18:3*n*3) endogenously and independent of dietary uptake (Mullaney and Ashrafi, 2009) (Fig. 11.3).

Setting aside the aforementioned physiological differences, many of the evolutionary conserved pathways governing energy metabolism have been identified in worms. The nuclear hormone receptor NHR-49 (the homolog of the human peroxisome proliferator–activated receptor-α, PPARα), for example, acts as a crucial regulator of metabolic gene transcription in worms (Chawla et al., 2001); social feeding is a sophisticated behavior, which depends on the worm homolog of the neuropeptide Y receptor NPY (a major regulator of mammalian feeding behavior) (De Bono and Bargmann, 1998); fat storage in *C. elegans* is also dependent on the AMP-activated protein and target of rapamycin (TOR) kinases, sterol regulatory element–binding protein (SREBP), and CCAAT/enhancer-binding protein (C/EBP) transcription factors (McKay et al., 2003); and a conserved set of lipases in worms have mammalian orthologs involved in the balancing of energy input and output via the liberation of triglycerides (Wang et al., 2008b). Other examples include the existence of fatty acid transporter homologs (CeFATPa and CeFATPb), to transport fatty acids between tissues (Grant and Hirsh, 1999) and lipid-binding proteins (Hirsch et al., 1998).

6 KEY FEATURES OF FAT METABOLISM IN *CAENORHABDITIS ELEGANS*

6.1 Dietary Uptake of Fatty Acids

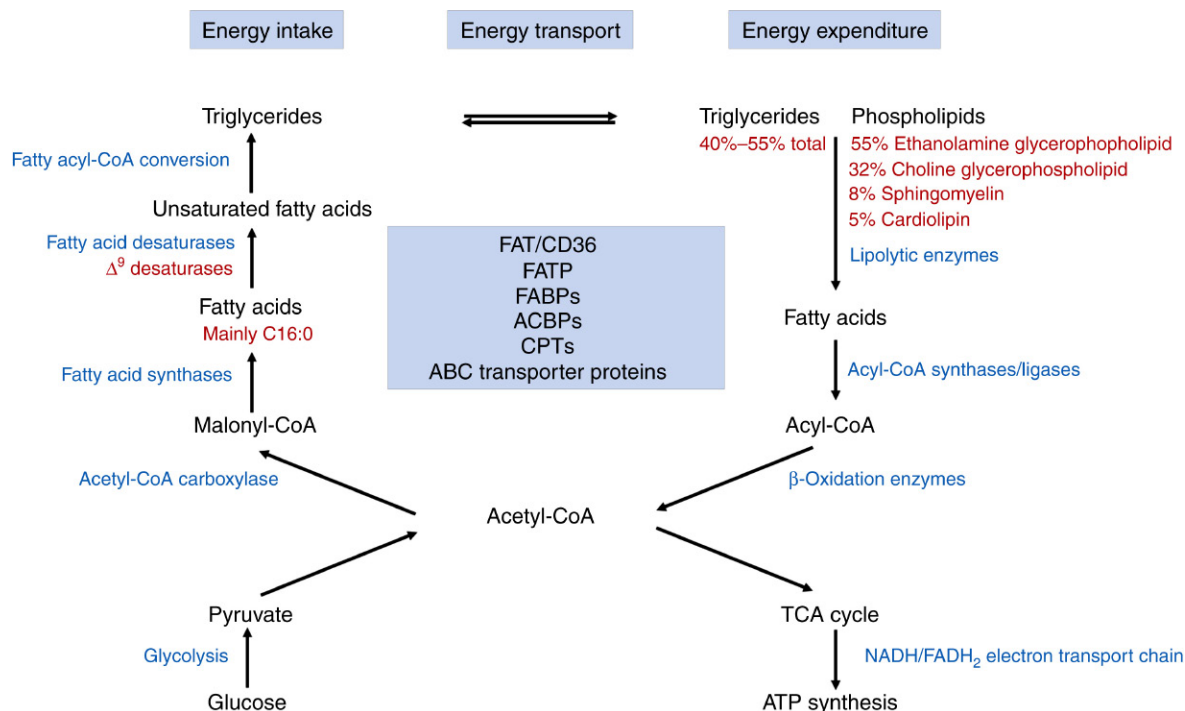
The protein-coupled peptide transporter, PETP-1, increases intestinal proton influx, fatty acid absorption, and thus fat content. The sodium–proton exchanger, NHX-2, plays an essential role in the intestinal pH regulation and fatty acid transport, with the *nhx-2* mutant displaying a


FIGURE 11.3 **Overview of the coordination of energy in** *C. elegans*, **involving the synthesis and breakdown pathways of mainly fat and sugar.** *ABC*, ATP-binding cassette; *ACBP*, acyl-CoA–binding proteins; *ATP*, adenosine triphosphate; *CPT*, carnitine–palmitoyl transferases; *FABP*, fatty acid–binding protein; *FADH₂*, flavin adenine dinucleotide; *FAT/CD36*, fatty acid translocase; *FATP*, fatty acid transport protein; *NADH*, nicotinamide adenine dinucleotide; *TCA*, tricarboxylic acid cycle.

low-fat profile. The import and activation of exogenous fatty acids is modulated by fatty acid transport proteins (FATPs) (i.e., ACS-20 and ACS-22, which are homologs of human FATP4). Acquired fatty acids and acyl-CoA are transported further by intracellular binding proteins, including LBP-1 to -9, FAR-1 to -8, and ACBP-1 to -7 for the degradation (Elle et al., 2010).

6.2 Synthesis of Fatty Acids

High levels of fatty acids originate from diet digestion, but some fatty acids, such as 7% of palmitic acid, 5% of palmitoleic acid and vaccenic acid, and 20% of oleic acid and polyunsaturated fatty acids are synthesized de novo in *C. elegans*, assisted by acetyl-CoA carboxylase (encoded by *pod-2*) and fatty acid synthase (encoded by *fasn-1* or *phi-46*) (Perez and Van Gilst, 2008). The monomethyl branched-chain fatty acids, in contrast, are mostly produced endogenously by worms. Monounsaturated fatty acids are converted by Δ^9 desaturases, which in worms are FAT-5, FAT-6, and FAT-7. FAT-2 and FAT-3 can desaturate monounsaturated fatty acids to polyunsaturated fatty acids (Brock and Watts, 2006).

6.3 Storage of Macronutrients

By binding to an insulin-link ligand, the nematode insulin receptor, DAF-2, activates the phospohinositide-3-kinase AGE-1 and the phosphorylation cascade via PIP3, ultimately leading to the phosphorylation of DAF-16 [Forkhead box O (FOXO) homolog] and its relocation. A loss of functional DAF-2 causes fat accumulation, as well as an altered life span, dauer formation, and stress responses (Mukhopadhyay and Tissenbaum, 2007). In comparison, the insulin receptor in mammals selectively increases fat deposits in adipocytes, while decreases fat content in muscles and neurons (Biddinger and Kahn, 2006). DAF-7 is a TGF-β–like ligand which, under nutrient deprivation, binds to the TGF-β receptor complex homologs: DAF-1 and DAF-4, thereby inhibiting the receptor-associated co-SMAD, DAF-3, subsequently regulating the feeding rate, fatty acid synthase activity, and lipid content. Under nutritional conditions, the expression of DAF-2 is downregulated, resulting in feeding rate changes and related dauer arrest along with lipid accumulation (Greer et al., 2008). Serotonin, a key neurotransmitter, is essential in maintaining the feeding rate in *C. elegans* via G-protein coupled receptors: SER-1 and -7. It also regulates the level of lipid storage via a β-oxidation relevant pathway, and depends on SER-6 and the serotonin-gated chloride channel, MOD-1. The synthesis of serotonin in neurons is activated by tryptophan hydroxylase TPH-1, and an impaired TPH-1 expression is linked to high-fat phenotypes (Srinivasan et al., 2008). Eukaryotic rapamycin (TOR) kinase targets protein complexes: TORC-1 and -2, and regulates the metabolic balance. RICT-1, a component of TORC-2, plays an important role in lipid regulation. An impaired function

TABLE 11.5 A Selection of Transcription Factors Involved in the Lipid Metabolism of *C. elegans*

Transcription factors	Mammalian homologs	Functional annotations
NHR-49	By sequence closely related to the mammalian HNF4α, while functionally similar to the PPARα	NHR-49 relocates to the nucleus and binds to promoter sequences containing hormone-response elements to regulate the transcription of target genes linked to lipid mobilization in *C. elegans*. A deletion of *nhr-49* induces profound changes in lipid synthesis, fatty acid β-oxidation, lipid saturation, glycolysis, and gluconeogenesis.
SBP-1	SREBP	SBP-1 is the only SREBP homolog in *C. elegans* and by homology, most closely related to mammalian SREBP-1c. The function of SBP-1 in lipogenesis of *C. elegans* is, however, yet to be delineated at a molecular level.
LPD-2	C/EBP	LPD-2 regulates the expression of lipogenic enzymes and plays a role in the development of *C. elegans*. The *lpd-2*–deficient worm mutant arrests at the larvae stage.
KLF-1/-2/-3	KLF-1 and -3 are homologs of human KLF-1; KLF-2 is the homolog of human KLF-7	The expression of KLFs regulates developmental functions, reproduction and lipid storage in *C. elegans*. KLF-3 in particular plays a role in fatty acid synthesis and degradation.
MDT-15	ARC105 as a subunit of the mediator complex	MDT-15 integrates several transcriptional regulatory pathways to monitor the availability and the nature of ingested materials in *C. elegans*.

ARC, Activator-recruited cofactor; C/EBP, CCAAT/enhancer binding protein; HNF4α, hepatocyte nuclear factor 4α; KLF, Krüppel-like factor; LPD, lipid depleted; MDT, mediator; NHR-49, nuclear hormone receptor 49; PPARα, peroxisome proliferator activated receptor α; SBP-1, sterol regulatory element–binding protein 1; SREBP, sterol regulatory element–binding protein.

of TORC-2, as a result of the depletion of RICT-1, induces lipid accumulation in worms (Jones et al., 2009).

6.4 Fat Catabolism

C. elegans stores fat, as mammals, mainly as triglycerides that are hydrolyzed into glycerol and fatty acid by a range of lipases to release energy. In dauer-stage animals, lipolysis is suppressed, which can be attributed to the downregulation of the *C. elegans* ortholog of the mammalian adipocyte triglyceride lipase. Another example is K04A8.5, a lipase whose intestinal expression significantly reduces lipid accumulation in vivo (Wang et al., 2008b). Likewise, worms on a restricted diet exhibit elevated levels of intestinal lipase, FIL-1 and -2, and thus a greater degree of triglyceride degradation (Jo et al., 2009).

Many mammalian transcription factors involved in energy homeostasis have functional counterparts in *C. elegans*, which are summarized in Table 11.5.

7 TECHNICAL ADVANCES DRIVING LIPID RESEARCH IN NEMATODES

One of the first methods to assess fat content utilized the lipophilic dye Sudan black, which allows the post-fix staining of worms (Kimura et al., 1997). Later, fluorescent dyes, such as LipidTOX, were used in place of Sudan black by a similar fixation protocol for easier visualization of the neutral lipids. Fat storage of worms was shown to take place mainly in the droplets/granules of intestinal and hypodermal cells (Wood, 1987).

Vital dye staining of fat in intact living animals was introduced to physically track the endogenous uptake and transport of lipids in a high-throughput manner. The most commonly used dyes are Nile red and fatty acid–conjugated BODIPY, both complement the microscopy-based methods of fat visualization (Greenspan et al., 1985).

However, fluorescent properties, though extremely sensitive, may not accurately reflect the endogenous fat levels. These limitations can be circumvented by means of biophysical techniques, such as coherent anti-Stokes Raman spectroscopy (CARS) and stimulated Raman scattering (SRS) (Hellerer et al., 2007).

Individual lipid species and parameters can also be defined by biochemical techniques (Watts, 2002), such as high performance liquid chromatography (HPLC), thin layer chromatography (TLC), gas chromatography (GC), and gas chromatography–mass spectrometry (GC-MS) analysis or via an enzymatic determination. Metabolic labeling strategies have helped to define individual contributions of de novo fat synthesis and dietary absorption to overall fat metabolism (Perez and Van Gilst, 2008).

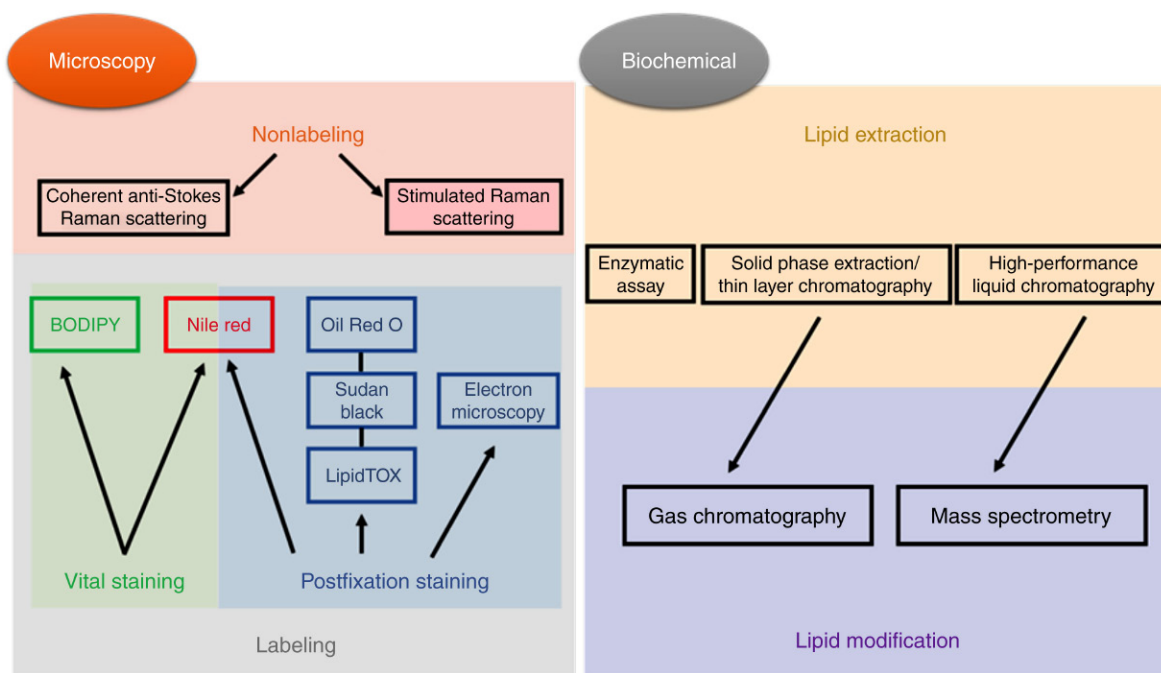
Genetic screens have elucidated gene targets involved in fat-regulatory pathways. In addition, expression profiling and epistasis analysis have pinpointed specific components and pathways that are involved in β-oxidation, fatty acid synthesis, and acyl-CoA synthesis (Srinivasan et al., 2008). Owing to the power of the worm model, it is now possible to move beyond the study of overall fat content and examine the specific


FIGURE 11.4   Overview of research techniques applied to track lipid storage and mobilization in *C. elegans*.

genetic targets that contribute to lipid homeostasis. Indeed, past experiments have included the mapping of obesity-related genes, targeted gene deletions, mutagenesis, and genome-scale RNAi screens, which in concert have uncovered over 400 genes that are involved in body fat regulation (Ashrafi et al., 2003) (Fig. 11.4).

8 THE INTESTINE: A DRIVER OF LIPID METABOLISM

In the absence of a dedicated liver and adipose tissue, the nematode's intestine has been suggested to act as a multifunctional organ. The entire intestine in an adult hermaphrodite is composed of merely 20 cells, with every 2 or 4 cells arranged in rings that enclose the lumen cavity spanning almost the entire length of the worm's body. Each of these intestinal cells is derived from a single embryonic blastomere (E) and the intestinal organogenesis is complete before the worm hatches.

The *C. elegans* intestine constitutes roughly one-third of the total somatic mass of the worm body. The digestive potential of worms is impressive: each cycle of defecation (a dynamic process that occurs in 45–50 s intervals) ejects up to half of the gut content. It is estimated that worms consume several million bacteria each day, while the average duration of a bacteria within the intestine is less than 2 min. Genes that are highly enriched in the intestine have helped to define the biology of digestion in *C. elegans*, for example, genes coding lysozymes and pore-forming proteins that ease the physical ingestion of

the bacterial diet, ATPases that acidify the intestinal lumen, and proteases/peptidases that catalyze the protein digestion.

Although the development of the intestine is programmed in a precise manner, its shape and function can be extremely flexible. The intestinal cytoplasm of long-lived dauer larvae is, for example, packed with electron-dense "cytosomes." The intestinal lumen constricts as part of an energy-restriction mechanism. These changes are reversed in worms that emerge from the dauer status.

C. elegans obtains fatty acids from its diet or by de novo synthesis to yield acetyl-CoA. The catabolism is realized through β-oxidation that takes place in two main sites: the mitochondria and peroxisome. Most peroxisomes are, therefore, found in the intestinal cells. Moreover, the nematode stores fat predominantly in intestinal lipid droplet (LD) organelles and lysosome-related organelles (LROs), the so-called "gut granules," which are involved in the intestinal differentiation and lipid metabolism. Serving as the primary triglyceride depot, the structural and biophysical characteristics of LDs or LROs are yet to be defined in detail.

9 THE LIPID DROPLETS ARE THE MAIN SITE OF TRIGLYCERIDE ACCUMULATION

LDs are characterized by the phospholipid monolayer membrane, which encases the lipid core. LDs are not inert fat particles, but rather dynamic organelles that function

in both energy storage and catabolism. They store neutral lipid triglycerides and polar lipids, including phospholipids and sterol esters, which help buffer cells from the toxic effects caused by excessive lipids. A disturbance of the lipid composition can result in larger LDs or they may break up into smaller units, facilitating the further digestion by lipases (Guo et al., 2008). Moreover, various enzymes required for the synthesis of triglyceride have been detected in isolated LDs, demonstrating their role in lipid anabolism (Fujimoto et al., 2007).

In mammals, LDs occupy adipocytes; however, the exact mechanisms that govern the distribution and mobilization of lipids in worms at the subcellular level are not clear. Lipophilic staining and physical approaches have identified that the intestine as the primary site and the hypodermis as the secondary site of energy storage, with additional deposits observed in maturing oocytes of the germ line, fertilized embryos, and in rare cases, muscle tissue. Accordingly, various classes of lipids are stored in distinct vesicular compartments, which can be differentiated by their electron densities (Chen et al., 2006; Hermann et al., 2005; Leung et al., 1999).

The LDs of nematode intestinal cells are typically large in size (spherical diameter > 10 μm), which is comparable to LDs in mammalian adipocytes. Excessive triglyceride in LDs are catabolized through β-oxidation in the mitochondria and peroxisome. A genetic defect in the peroxisomal β-oxidation pathway (e.g., in the *daf-22* lacking the terminal enzyme in peroxisomal fatty acid β-oxidation) results in a high-fat phenotype, namely an increase in the size of LDs (Zhang et al., 2010a). Transgenic DAF-22::GFP, which is expressed in the intestine, the hypodermis, and the body wall muscle of worms, is suppressed in *acs-22* and *dgat-2* mutants that lack fatty acyl-CoA synthetase and a diglyceride acyl transferase, respectively (Xu et al., 2012). This suggests that the mechanisms underlying the formation of LDs are conserved between worms and mammals. However, the mechanisms that govern the dynamic change in shape, size, or density of LDs are not yet fully understood.

10 THE NILE RED VITAL STAINING CONUNDRUM

Nile red was initially defined as a highly specific vital stain, allowing the detection of intracellular LDs in cultured aortic smooth muscle cells and peritoneal macrophages, as it selectively dissolves in the lipids and fluoresces with no local interaction with the tissue constituent (Greenspan et al., 1985). Ashrafi et al. (2003) reported how the Nile red assay could be applied to *C. elegans* to analyze fat storage and mobilization within a whole genome RNAi screen. As Nile red does not influence the growth rate, brood size, feeding, or lifespan of worms, it has since become a widely applied lipid proxy in nematodes. The accuracy of the methodology was, however, subsequently questioned as worms accumulated Nile red in lysosomal compartments rather than the major fat stores (Brooks et al., 2009; O'Rourke et al., 2009; Schroeder et al., 2007). A comprehensive comparison of fat-soluble vital dyes (BODIPY and Nile red), CARS, and standard biochemical triglyceride quantification found that CARS and the biochemical quantifications differed from the vital dyes that were limited to staining acidic organelles of lysosomal origin (Yen et al., 2010). An alternative to the vital dye staining method is staining in a postfixative manner. Fixation allows the direct penetration of the lipophilic dye to the hydrophobic targets.

The application of the vital Nile red staining is, in comparison to the fixative Oil Red O dye, more conducive, time efficient, and especially more suitable for high-throughput drug screening. Indeed, from a biophysical and biochemical perspective, Nile red–stained LROs were recently recognized to be the main location of cholesterol storage and a reduction of Nile red staining was noted to correlate with the bulk ratio of triglyceride to protein in nematodes (Zhang et al., 2010b). Likewise, lipid accumulation in endolysosomal compartments under pathophysiological conditions was observed (Schmitz and Grandl, 2009). The precise mechanisms of the uptake, transport, and turnover of these dyes are still not fully understood and further investigations are needed to provide a comprehensive understanding of the local interactions between exotic dyes and lipids/organelles in vivo. Any result derived from Nile red staining should, therefore, be validated by an alternative independent approach.

11 LYSOSOME-RELATED ORGANELLES PARTICIPATE IN LIPID MOBILIZATION

LROs can be stained by Nile red and are acidic, autofluorescent, birefringent, and express PGP-2, GLO-3, and FUS-1 as important functional proteins (Hermann et al., 2005). LROs may not be the main location of fat storage in *C. elegans*; however, this does not rule out that the LRO compartments play a role in the metabolism of lipid or physiologically relevant fats. Indeed, worms utilize energy reserves upon food deprivation via the recycling of LRO-mediated nutrients (Finn and Dice, 2006).

The Niemann–Pick type C disease in mammals underline the important role lysosomes play in the metabolism of cholesterol and sphingolipid (Futerman and Van Meer, 2004). Unlike mammalian cells, nematodes store cholesterol exclusively in LROs rather than LDs (Lee et al., 2015). Worms with a lysosomal storage disorder (*ncr* mutants) show diverse phenotypes, including a disturbed cholesterol trafficking and a hypersensitivity toward cholesterol derivation (De Voer et al., 2008).

Nematodes contain an essential gene that is a homolog of *Drosophila* SREBP. It is similar to those proteins regulating cholesterol levels in mammals and was reported to regulate enzymes for the synthesis of saturated fatty acids and phosphatidylethanolamine (Seegmiller et al., 2002).

Numerous studies in other organisms have highlighted the complex interaction(s) between LROs and LDs. Lipolysis and autophagy, for example, are both involved in nutrient deprivation–induced responses, namely lipids stored as triglycerides in LDs are hydrolyzed into fatty acids, and intracellular proteins and organelles sequestered in autophagosomes are transported to lysosomes as energy sources. This observation leads to the notion that LDs and LROs may be associated during starvation. Furthermore, an abnormal increase in intracellular lipid impairs the autophagic clearance, which traps cells in a harmful cycle with additional lipid retention. The therapeutic strategies to increase autophagic function have thus formed the basis of a new approach proposed to treat metabolic syndromes (Singh et al., 2009).

LRO can be observed in worms by means of specific acidic markers, including acridine orange and LysoTracker. The colocalization of Nile red and LysoTracker suggests that an interlinked mechanism underlies the LRO-regulated lipid metabolism. Following the death of a worm, LROs rupture and in turn result in a burst of strong autofluorescence, which greatly interferes with lipid visualization (De Duve, 1963).

12 INTESTINAL AUTOFLUORESCENCE: FRIEND OR FOE?

The majority of autofluorescence in worms is observed in granules of the intestinal cells. Histochemical staining of the autofluorescent granules suggested that they contain acid phosphatase, a lysosomal enzyme. Further, the autofluorescent granules accumulate exogenous material and concentrate a lysosomotropic weak base and are thus thought to act as secondary lysosomes (Clokey and Jacobson, 1986). The acidic intestinal compartments of the 1.5-fold stage embryo can be stained with acridine orange, which colocalize with birefringent gut granules; similarly, the autofluorescent and acidic LysoTracker Red–stained compartments colocalize with gut granules in newly hatched L1-stage larvae, confirming the birefringent, autofluorescent, and lysosomal identity (Hermann et al., 2005). Indeed, autofluorescence and lysosomal metabolism are interlinked. For example, progressive neurodegeneration and the accumulation of autofluorescent material are caused by mutations in lysosomal hydrolase genes (Futerman and Van Meer, 2004). In worms, defects in the expression of eight *glo* genes, namely *apt-6*, *apt-7*, *vps-16*, *vps-41*, *glo-1*, *glo-2*, *glo-3*, and *glo-4*, are responsible for the mislocalization of birefringent material into the intestinal lumen during embryogenesis, with the first four genes encoding proteins that are homologous to components of the AP-3–mediated Golgi-to-vacuole trafficking pathway (Odorizzi et al., 1998), while the latter are homologous to *Drosophila* eye pigmentation genes regulating the biogenesis of LROs (Dell'Angelica, 2004). LROs in *C. elegans* may, therefore, share some functional characteristics with the pigment granules in *Drosophila* and mammalian melanosomes (Hermann et al., 2005). Currently there are two main hypotheses regarding the chemical identity of the LRO fluorophore, namely that is lipofuscin like or anthranilic acid (AA) like.

12.1 Theory 1: Lipofuscin-Like Autofluorescence

The solubility of autofluorescent pigments closely resembles "lipofuscin" pigments (Clokey and Jacobson, 1986). They both accumulate during oxidative stress, and are marked by an extreme emission and diffusion in aged individuals (Katz and Robison, 2002). The spectra of both autofluorescence and lipofuscin overlap with most commonly used fluorophores (Kalyuzhny and Wessendorf, 1998). This broad excitation and emission characteristic suggests that lipofuscin-like pigments might be composed of a mixture of different, although related, fluorescent molecules (Steiner and Kirby, 1969).

12.2 Theory 2: Anthranilic Acid–Like Autofluorescence

According to a recent chemical analysis, the blue fluorescence observed within nematode intestinal cells is AA glucosyl ester, a product of the kynurenine pathway (Coburn et al., 2013). Altered intestinal fluorescence (*flu*) phenotypes can arise from mutations affecting the kynurenine pathway enzyme, such as *flu-1* and *flu-2*. The kynurenine pathway is known to be implicated in neurodegeneration and immunity (Munn et al., 1998; Sasaki et al., 2012). In *Drosophila*, kynurenines were hypothesized to contribute to aging; however, very little is known about the biology of kynurenines in nematodes. AA may harbor antibiotic properties to protect nematodes from a pathogen attack or may act as a photon protectant (Gems and Coburn, 2013).

Given the evolutionarily conserved role of electronlucent LDs and electron-opaque LROs in energy homeostasis, they are considered to be central in maintaining the energy balance. *C. elegans* offers unique opportunities to visualize fluorescence at a single-cell resolution in live animals, and combined with the plethora of genetic tools and biochemical assays, this model organism promises to advance our understanding of lipid metabolism in vivo.

13 A WHOLE GENOME APPROACH

C. elegans is amenable to high-throughput, genome-wide, and whole organism–association screens. For example, a genome-wide RNAi knockdown screen has identified around 400 genes that are linked to fat disturbance in worms. In addition, hundreds of genes are pleiotropic, causing multiple biological effects ranging from fat disorder, sterility, growth arrest, to lethality (Ashrafi et al., 2003). Extending this effort, a microscopic analysis of more than 300 RNAi-treated worms pinpointed evolutionary conserved genes that are associated with embryonic lipids (Schmökel et al., 2016).

A high-throughput phenotypic assay may lead to the discovery of genes not previously associated with metabolic process. Indeed, Oil Red O staining in tandem with high-volume image–based phenotyping allowed the efficient, rapid, and robust sample preparation and analysis of genetic/chemical perturbations in whole animals (Wählby et al., 2014).

A recent high-throughput study suggested that miR-NAs play a role in the lipid mobilization in worms. L4 larvae were subjected to a 12-h starvation period and 13 miRNAs were shown to be downregulated; however; the miR-35 family was upregulated 6–20 fold (Garcia-Segura et al., 2015).

A proteome analysis of lipid droplets isolated from wild type N2 and *daf-2* mutants identified 354 proteins that belong to various functional classes, including lipid metabolism, trafficking, transport, and signal transduction, to name a few. The top 100 most abundant LD proteins were studied further via RNAi knockdown and ACS-4 was characterized as a LD-associated protein (Vrablik et al., 2015). These recent studies carried out at the DNA, RNA, and protein level highlight the powerful quantitative phenotyping approaches that are possible with the invertebrate worm model.

14 NEW AVENUES OF LABEL-FREE METHODS

The challenges surrounding the inconsistencies of vial dye staining in nematodes have led to the development of new approaches for identifying the ubiquitous fat distribution and revealing lipid phenotypes stored in intestinal cells, gonads, germ line, and hypodermis. One exciting progress has been the application of biophysical tools, such as CARS microscopy, which demonstrated the advantages of a label-free method in comparison to standard fluorescence microscopy (Hellerer et al., 2007).

CARS allows the visualization of LDs by analyzing signals derived from the specific vibration of intrinsic carbon–hydrogen stretching. CARS imaging provides an accurate estimation of the size and number of LDs, as well as the dynamic monitoring of lipid molecules.

The order of polymethylene chains can be estimated by CARS by recording the asymmetric and symmetric CH_2 vibrations and their ratio: a higher ratio represents a gel phase of highly ordered methyl chains, while a lower ratio is linked to the liquid phase of less-ordered chains (Wurpel et al., 2002). Further subtraction of the background resonance improves the CARS spectra and allows a more accurate measurement of the lipid signal (Hagmar et al., 2008). By applying the spectral information from pointwise confocal Raman microspectroscopy, analysis of the fingerprint region of the CARS spectrum enables the detection of lipid-chain unsaturation and thus detailed phenotypes of worms from different genetic backgrounds. Subgroups of lipid-storage compartments can also be identified in the presence or absence of autofluorescence. Additionally, the differences in the amount of autofluorescent granules can be observed and quantified in worm strains (Le et al., 2010). The spectral interferometric polarization CARS (SIPCARS) allows the hyperspectral analysis of lipid phenotypes, as well as the quantification of lipid enrichment (Littleton et al., 2013).

SRS is another vibrational imaging technique typically employed for *C. elegans*. Signals can be recorded in nanosecond resolution and thus offer a high volume of pixel information and an exceptional optical sectioning capability. Moreover, the SRS signal exhibits a linear dependence on the underlying resonant bonds (as opposed to CARS, which typically returns a nonlinear output), thereby simplifying the extraction of quantitative features. An RNAi screen combined with quantitative imaging of lipids by means of single-frequency SRS yielded eight new genetic regulators of fat storage in worms (Wang et al., 2011). Likewise, a combination of hyperspectral SRS and multivariate analysis in the fingerprint vibration region resulted in the quantitative mapping of fat distribution, as well as the degree of lipid saturation, oxidation, and cholesterol enrichment in vivo in a whole worm. This approach confirmed that LROs are the main sites for storage of cholesterol in worms (Wang et al., 2014). SRS was further used in metabolic fingerprinting to probe the spatial–temporal dynamics of metabolites at the subcellular level, which revealed a lack of interaction between saturated and unsaturated fatty acids (Fu et al., 2014). One caveat of SRS is the difficulty to scale up to multiple channels, and, therefore, it is challenging to acquire the full spectral details of novel biological samples.

15 TRENDS AND CHALLENGES

To gain deeper insights into fat regulation, investigations from multiple aspects are called for, spanning signaling, transcription, neuronal circuits, development, behavior, and others. In addition to the LD–LRO interaction, further crosstalk between LDs and other subcellular

organelles, lipid species, nutrient factors, and additional bioactive molecules in various tissues, such as hypodermis and gonads, should be explored. The well-defined nervous system of worms offers unique avenues to decipher neural circuits that govern metabolism, feeding behaviors, and nutrient perception. Moreover, the nematode can provide an insight into physiological pathways and external factors, such as environmental perturbations.

Given the central role of the intestine in the uptake and storage of lipids, studies have mostly focused on gut cells to quantify and phenotype lipid molecules. It has been argued that the nematode intestine shares many features of the mammalian intestine and liver, while its hypodermal cells function as mammalian adipocytes (Lemieux and Ashrafi, 2015). One concern is that biochemically extracted lipids from hermaphrodites may comprise a considerable amount of intestinal yolk or embryonic lipid rather than genuine fat reserves that are needed for somatic structures. Therefore a detailed assessment of the dynamics of fat metabolism in different tissues is needed, as this will facilitate the quantitative phenotypic analysis of energy homeostasis in single worms and populations.

In summary, *C. elegans* is uniquely positioned, as it allows in vivo animal research at a single-cell resolution via a versatile experimental tool set. By acknowledging both its strengths and limitations, the nematode holds promise for the improvement and optimization of our knowledge base pertaining to lipid metabolism. Having said that, no single species can ever serve as a universal model. To advance of our knowledge of evolutionary conserved mechanisms of life, we should gather data from two or more organisms (Bolker, 2012).

Animal Models for Manipulation of Thermogenesis

John-Paul Fuller-Jackson, Iain J. Clarke, Belinda A. Henry

Monash Biomedical Discovery Institute, Monash University, Clayton, VIC, Australia

1 INTRODUCTION

Metabolic function is a highly regulated process and, as for all physiological systems, it is governed by feedforward and feedback signals that maintain homeostatic balance. This metabolic balance is controlled by neuronal systems in the brain that regulate food intake and energy expenditure. Feedforward signals are provided by upregulation of orexigenic factors and downregulation of anorexigenic factors, to increase food intake and decrease energy expenditure. In response to starvation or reduced food intake, the activity of the orexigenic neurons, neuropeptide Y (NPY), and agouti-related protein (AgRP) increase and the activity of the anorexigenic proopiomelanocortin (POMC) neurons decrease. Peripherally derived feedback factors influence these central systems, examples being ghrelin, glucagon-like peptide 1 (GLP1) (from the gastrointestinal tract), and leptin (from adipose tissue). Ghrelin stimulates food intake, whereas leptin and GLP-1 are inhibitory. Ghrelin

levels are increased in low body weight conditions and leptin levels are reduced, allowing for homeostatic correction via stimulation of hunger and a reduction in energy expenditure.

Whereas there is significant knowledge of the systems that regulate food intake, relatively less is known about the control of energy expenditure. The rate of energy expenditure is substantially driven by sympathetic outflow from the brain to the peripheral organs/tissues, such as brown fat and skeletal muscle. Dogma stipulates that factors which increase food intake concurrently reduce energy expenditure and vice versa. Thus, elevation of NPY activity in the brain and reduction in melanocortin activity leads to increased food intake and reduced energy expenditure. A number of studies over recent years have targeted regulation of the systems controlling food intake, as a means of combating the global escalation in the incidence of obesity and Type II diabetes. Historically, these have not been successful for various reasons. In some instances, pharmacological agents have been used,

but virtually all of these act within the brain and have been withdrawn because of side effects. A new generation of pharmaceuticals, such as Contrave, Liraglutide, and Qsymia, have, however, produced some promising weight-loss effects. Lifestyle diet and exercise programs have not been successful because individuals who lose weight eventually drift back to their prior body weight/adiposity. This is because of the inherent "set-point" of individuals that is genetically determined. According to this theory, predisposition to obesity is genetically programmed and is typically unmasked by a poor-quality diet (high fat and/or high sugar) or sedentary behavior. Examples of predisposition to an obese phenotype can be readily observed when rodents are placed on a "junk food" diet, so some animals become obese (diet-induced obesity, DIO) and others do not (diet resistant, DR). This is also shown in the classical studies of Bouchard et al. (1990), whereby overfeeding by 1000 cal/day for 100 days resulted in highly variable weight gain across sets of twins, whereas there was a strong correlation between twins. This demonstrates that genetic factors not only determine the set-point body weight but that this is at least partly mediated via innate differences in energy expenditure.

With systematic failure to control obesity by controlling food intake, an important question is whether energy expenditure targets are more fruitful. The latter has various components, which will be discussed later, but one potential target that could yield significant results is thermogenesis. It has been generally accepted that thermogenesis occurs primarily in brown adipose tissue (BAT), because the brown adipocytes are rich in mitochondria and express uncoupling protein 1 (UCP1) (Cannon and Nedergaard, 2004; Lowell and Spiegelman, 2000). Furthermore, BAT is highly vascularized and receives profuse innervation from the sympathetic nervous system (SNS) (Cannon and Nedergaard, 2004; Lowell and Spiegelman, 2000). Activation of UCP1 via an increase in sympathetic activity results in the dissipation of energy through heat production (Cannon and Nedergaard, 2004; Lowell and Spiegelman, 2000). It was originally thought that BAT was exclusively found in neonates, and levels diminished in early life reaching negligible levels in adults, but we now know that this is not the case. Landmark imaging studies in humans revealed the presence of BAT in the clavicular, neck, and sternal regions of the body (Cypess et al., 2009; van Marken Lichtenbelt et al., 2009; Virtanen et al., 2009) and, as a result, this has become a more prominent therapeutic target. Recent studies have shown that BAT mass can be regulated by environmental factors, such as cold temperature. In addition, a long list of regulators of mitochondria and UCP1 function in BAT have been assembled. While the targeting of BAT might be a realistic way of controlling obesity, another approach could be to determine whether thermogenesis occurs in other tissues, through means other than BAT/UCP1. This would open up the possibility of manipulating thermogenesis and expenditure of energy through heat on a much larger scale than by the specific focus on BAT. Recent studies have indicated three very significant advances in this regard. Firstly, BAT is not confined to very small and focal depots within the body and can be found interspersed in white adipose tissue (WAT) (Cypess et al., 2009; Henry et al., 2010; Symonds et al., 2012; van Marken Lichtenbelt et al., 2009; Virtanen et al., 2009). Secondly, brown adipocytes can be "created" via the "browning" of WAT (Barbatelli et al., 2010; Petrovic et al., 2010). Furthermore, thermogenesis occurs in muscle, which may provide another fruitful target for manipulation of energy expenditure.

In this chapter, we examine animal models which have utility for the study of energy expenditure, particularly thermogenesis, and we indicate means of manipulation of energy expenditure.

2 THERMOGENESIS—A SIGNIFICANT DETERMINANT OF ENERGY EXPENDITURE

2.1 Brown Fat

As detailed earlier, BAT is frequently regarded as the primary thermogenic organ (Cannon and Nedergaard, 2004, 2010). Brown adipocytes are thermogenic due to their mitochondrial rich nature and specialized expression of UCP1. Activation of BAT occurs via the SNS whereby increased sympathetic activity increases noradrenaline (NA) release at brown adipocytes, activating cAMP, and leading to the intracellular mobilization of free fatty acids (Fig. 12.1). It is the mobilization of free fatty acids that activates UCP1 and initiates thermogenesis (Fig. 12.1). In order to support this thermogenic function, BAT is profusely innervated by the SNS and is highly vascularized (Cannon and Nedergaard, 2004; Lowell and Spiegelman, 2000). Within the mitochondria, the electron transport chain creates a proton gradient that is required for ATP synthesis. When activated, UCP1 creates proton leakage across the inner-mitochondrial membrane, "stealing" protons from ATP synthase, which ultimately reduces ATP synthesis but increases energy expenditure through the production of heat. This basic theory underlying the process of thermogenesis has been widely studied.

2.1.1 Derivation of BAT

A number of studies have sought to define the embryonic lineage of BAT. This is based on the premise that increasing levels of BAT could be beneficial for the
FIGURE 12.1 **The mechanism of brown fat activation and thermogenesis.** Dietary and cold stimuli are sensed by first-order neurons in the preoptic area and the hypothalamus. These stimuli are then relayed via the brainstem, causing activation of the sympathetic nervous system *(SNS)*. Activation of the SNS results in increased noradrenaline release within brown adipose tissue *(BAT)*, acting on β-adrenoceptors *(β-AdR)* located on brown adipocytes and activation of uncoupling protein 1 *(UCP1)*. The increase in UCP1 creates a proton leak across the mitochondrial membrane, uncoupling oxidative phosphorylation and leading to the dissipation of energy through thermogenesis.

development of novel antiobesity agents. Brown adipocytes are derived from a mesenchymal lineage similar to white adipocytes and myocytes (Kajimura et al., 2009; Seale et al., 2008). WAT and BAT are considered to be morphologically and functionally distinct tissues, but this requires revision as outlined later in the chapter. White adipocytes are unilocular, containing a single fat droplet and have few mitochondria, whereas the brown adipocyte is multilocular (containing many smaller lipid droplets) and contains numerous mitochondria. The primary function of white adipocytes is to store energy in the form of triglycerides, whereas brown adipocytes consume energy through the process of thermogenesis. In line with these differing functions, brown adipocytes are more closely related to myocytes than to white adipocytes. A "true" brown adipocyte is derived from a Myf-5 myocyte precursor, whereby the transcription factor PR-(PRD1-BF-1-RIZ1 homologous) domain containing protein 16 (PRDM-16) has been shown to inhibit myocyte development and enforce the development of brown adipocytes (Seale et al., 2008). Deletion of the gene that encodes PRDM-16 abolishes BAT development and results in skeletal muscle formation (Seale et al., 2008). A number of other factors also stimulate the expansion of BAT formation, including bone morphogenic protein 7 (BMP7), fibroblast growth factor 21 (FGF21), PPARγ and PGC1α agonists (Ahfeldt et al., 2012; Kajimura et al., 2009; Ohno et al., 2012; Schulz et al., 2011). PPARγ and PRDM16 exert synergistic effects via the CCAAT/enhancer-binding proteins (CEBPs) to promote BAT development (Lefterova et al., 2008). Overexpression of PRDM-16 in white subcutaneous fat results in the "browning" of WAT and the production of brown-like

adipocytes (see later). Although many studies have focused on increasing the *levels* of BAT to combat obesity, *activation* of BAT is also fundamentally important to this objective.

2.1.2 Neural Control of BAT

The SNS is integral to the activation of thermogenesis, whereby both cold and dietary stimuli increase thermogenesis via the localized release and action of NA. This effect is mediated via the β-adrenergic receptors (β-AdR) expressed by brown adipocytes. Indeed, all three isoforms of β-AdR are coexpressed in brown adipocytes and there is a general redundancy with regard to the control of thermogenesis (Collins et al., 2010). For example, gene deletion of all three β-AdR in the β-AdR-less mice causes obesity in the absence of hyperphagia and the obese phenotype is driven by a reduction in UCP1 and obliteration of thermogenesis (Bachman et al., 2002). The β-AdR-less mice show significant atrophy of BAT and an infiltration of white fat (Bachman et al., 2002). It has recently been shown, however, that under thermoneutral conditions chronic stress can increase BAT activity in the β-AdR-less mice (Razzoli et al., 2016). This stimulatory effect is independent of NA and is thought to be mediated via a purinergic SNS pathway (Razzoli et al., 2016). The neural network that governs the SNS and controls thermogenesis is complex. Injection of pseudorabies virus, a polysynaptic retrograde tracer, into the interscapular BAT of rats demonstrates that neurons arising from the preoptic area (POA), hypothalamus, and the brainstem all converge in an integrated network that projects to BAT (Oldfield et al., 2002). Neurons within the POA are essential to thermoregulation, receiving

information regarding ambient temperature upon skin cooling, and in turn exert effects on thermogenesis via a neuronal network involving the hypothalamus and brainstem. Overall, neurons within the POA activate BAT thermogenesis (Morrison and Nakamura, 2011). Earlier work identified a subset of cold-inhibited and warm-activated gamma-aminobutyric acid (GABA)-containing neurons in this region of the brain that mediate cold-induced activation of thermogenesis (Morrison et al., 2014; Nakamura and Morrison, 2008). These GABA-ergic neurons regulate BAT activity via projections to the dorsomedial hypothalamus (DMH) and the raphe pallidus (Cao and Morrison, 2006; Cao et al., 2004; Morrison et al., 2014; Nakamura et al., 2005). More recent work, using Designer Receptor Exclusivity Activated by Designer Drugs (DREADD) technology, however, shows that activation of GABA neurons in the POA had little effect on body temperature or energy expenditure (Yu et al., 2016). Indeed, the latter study provides strong evidence to suggest that leptin receptor-expressing neurons in the POA are central to the metabolic (food intake and energy expenditure) adaptations that occur in response to changes in ambient temperature (Yu et al., 2016). In addition to the POA, neural networks within the hypothalamus are known to be important in the dual control of food intake and energy expenditure.

Typically, neuropeptides that stimulate food intake also inhibit thermogenesis and vice versa (Verty et al., 2010). In this regard, the arcuate nucleus of the hypothalamus (ARC) is considered a primary center in the control of energy homeostasis. Within the ARC, two distinct neuronal populations regulate food intake and energy expenditure:

- The appetite-inhibiting cells, the POMC neurons, which produce melanocortins.
- The appetite-stimulating cells that contain NPY and agouti-related protein (AgRP).

NPY and AgRP inhibit thermogenesis (Billington et al., 1991; Small et al., 2003) and the melanocortins (α-, β-, and γ-melanocyte stimulating hormone encoded by the POMC gene) stimulate thermogenesis (Voss-Andreae et al., 2007). At least a subset of these neurons are located outside the blood brain barrier and therefore receive peripheral signals regarding nutritional state (Morita and Miyata, 2012); this includes endocrine signals, such as leptin, insulin, GLP-1, and ghrelin, as well as metabolic signals, such as glucose (Cone et al., 2001; Parton et al., 2007). The neurons of the ARC project to other hypothalamic regions, such as the lateral hypothalamus (LH), ventromedial hypothalamus (VMH), DMH, and the paraventricular nucleus (PVN), allowing for second order signaling (Gautron and Elmquist, 2011). In addition, signals, such as leptin can also cross the blood brain barrier and act

directly on neurons in hypothalamic nuclei beyond the ARC (Dhillon et al., 2006; Qi et al., 2010). In mice, leptin acts at the DMH to stimulate sympathetic output and increase BAT thermogenesis (Enriori et al., 2011; Simonds et al., 2014). Physiological studies and neural tracing studies have shown that neurons in the ARC and the LH (orexin—ORX and melanin-concentrating hormone—MCH neurons) are important in regulating not only food intake but also energy expenditure, especially thermogenesis (Pissios, 2009; Szekely et al., 2010). It is important to note that there are two ORX peptides (A and B), with approximately 50% sequence identity, produced by posttranslational processing of a single precursor protein. In a broad sense, ORX-A is thought to be more relevant to the control of energy homeostasis than ORX-B (Ferguson and Samson, 2003).

In rodents, intracerebroventricular (i.c.v.) infusion of ARC-derived peptides alters BAT thermogenesis. In particular, infusion of either NPY or AgRP stimulates food intake and inhibits thermogenesis in BAT, whereas infusion of the melanocortin, α-melanocyte stimulating hormone (α-MSH), inhibits food intake and stimulates thermogenesis in BAT (Voss-Andreae et al., 2007). Melanocortin action at both hypothalamic and nonhypothalamic sites (preganglionic cholinergic neurons of the SNS and parasympathetic nervous system) increases BAT thermogenesis (Berglund et al., 2014; Song et al., 2008). Furthermore, a recent study in male rats, showed that MC4R activation in the VMH with melanotan II (a nonspecific melanocortin receptor agonist) increased NA turnover and heat dissipation in skeletal muscle (Gavini et al., 2016), demonstrating that the melanocortin system regulates both BAT and muscle thermogenesis (discussed later). Retrograde labeling of neurons in the brain with pseudorabies virus tracers, which are transported across synapses, show that both NPY and POMC neurons project widely throughout the brain, especially the hypothalamus. Thus, BAT is under the control of hypothalamic neurons, through a polysynaptic network of neurons in the brain and ultimately through sympathetic outflow. NPY neurons project to a network in the hindbrain that controls sympathetic innervation to blood vessels within BAT, whereas POMC cells project directly to a neural network that innervates brown adipocytes (Oldfield et al., 2002). Studies in rodents have clearly elucidated a role for the melanocortins in the control of BAT thermogenesis and around 40% of POMC cells in the ARC coexpress virus when the polysynaptic retrograde tracer pseudorabies is injected into BAT (Oldfield et al., 2002). In rodents, central infusion of melanotan II increases BAT temperature (Song et al., 2008) and the melanocortin 4 receptor (MC4R) is expressed in numerous brain regions that constitute parts of a neuronal pathway that extend to BAT; these include the forebrain, hypothalamus, midbrain, and brainstem (Song et al., 2008). Thus, the central

melanocortin system is integral in the control of thermogenesis and this is exemplified in knockout mouse models for both POMC and MC4R (Butler and Cone, 2002; Butler et al., 2001); where impaired energy expenditure and thermogenesis is an important component leading to the obese phenotype.

As indicated earlier, neurons in the LH that produce ORX and MCH are also known to regulate thermogenesis. Both of these neuropeptides stimulate food intake, but exert differential effects in terms of the regulation of thermogenesis. Dichotomous findings have been obtained in studies of the effects of ORX on thermogenesis, which may be because ORX also regulates physical activity, and mutations in the ORX system (either the gene that encodes prepro-ORX or the ORX receptors) result in narcolepsy (Chemelli et al., 1999). Orexin also acts centrally to regulate food intake and energy expenditure, but these effects are thought to be secondary to those which regulate arousal and activity (Willie et al., 2001). Nevertheless, ORX neurons project into the brainstem and spinal cord and appear to be important in the regulation of thermogenesis (Marcus and Elmquist, 2005). In rats, around 30% of ORX-B and 50% of MCH neurons provide neural connections to the SNS innervating BAT (Adler et al., 2012). One study showed that blockade of the ORX-A receptor by i.c.v. infusion of the antagonist, SB-334867-A, increased BAT temperature in male rats, indicative of an endogenous effect of ORX to inhibit thermogenesis (Verty et al., 2010). This observation is, however, contradicted by a number of other studies, whereby i.c.v. infusion of ORX or direct injection into the rostral raphe pallidus increases BAT thermogenesis (Tupone et al., 2011). More recent work has also shown that deletion of orexin results in obesity and this is primarily caused by a deficit in thermogenesis due to diminished differentiation of brown adipocytes from preadipocytes (Mohammed et al., 2014; Sellayah et al., 2011). This clearly demonstrates that brain-derived ORX is important not only in the control of thermogenesis in adult animals but also in the embryonic development of BAT. It is clearly apparent that there is a complex neural network located within the hypothalamus that ultimately regulates sympathetic outflow and BAT function.

2.1.3 UCP1 Knockout Models—Alternative Pathways for Thermogenesis

Genetic models in mice have been used widely to characterize the cellular pathways that underpin thermogenesis in BAT, especially with respect to UCP1 function. As indicated earlier, cold and dietary stimuli act at the brain to activate the SNS, leading to an increase in the release of NA at BAT. Activated β-AdR on brown adipocytes, stimulates an increase in cAMP and the mobilization of intracellular free fatty acids. In turn, this activates UCP1 and adaptive thermogenesis (Cannon and Nedergaard, 2004; Lowell and Spiegelman, 2000). Rodent studies clearly support the notion that the level of activation of UCP1 is an important index of metabolic state and energy expenditure. Thus, physiological challenges that induce a state of negative energy balance, such as fasting and lactation inhibit UCP1 in BAT (Rothwell et al., 1984; Trayhurn and Jennings, 1988; Xiao et al., 2004). This is considered to be a part of the metabolic adaptation response, whereby UCP1 is reduced to inhibit energy expenditure and to restore energy balance. Accordingly, activation of UCP1 is an integral component of adaptive thermogenesis in rodents.

On this basis, it is hardly surprising that genetic deletion of UCP1 results in impaired tolerance to cold. On the other hand, it is surprising that some UCP1 knockout mice are not obese (Enerback et al., 1997). Neither do some UCP1-deficient mice display increased susceptibility to obesity when fed a high-fat diet (Enerback et al., 1997). One explanation for these observations is that UCP1 knockout mice have a compensatory increase in mitochondrial proton leakage within skeletal muscle, which prevents the development of an obese phenotype (Monemdjou et al., 2000). There is, however, no underpinning mechanism that may account for this altered muscle function, although, potential regulators of skeletal muscle thermogenesis have been identified (see later). More recent work in UCP1 knockout mice clearly demonstrates that ambient temperature is a predominant factor in the manifestation of an obese phenotype in this animal model (Feldmann et al., 2009). Previous studies (Enerback et al., 1997) housed animals below thermoneutral conditions and it is thought that increased energy expenditure, to maintain core body temperature, concealed the effects of UCP1 gene deletion on body weight. Recent work in animals housed at thermoneutrality show, however, that deletion of the UCP1 gene causes obesity in animals fed both chow and high-fat diet (Feldmann et al., 2009).

Ablation of BAT in mice has been achieved with the UCP-diphtheria toxin A chain (UCP-DTA) transgene, whereby a BAT-specific promoter was used to drive expression of DTA and reduce BAT levels; this causes marked effects on body weight and adiposity. UCP-DTA mice display reduced oxygen consumption at baseline and in response to stimulation with a β3-AdR-ligand (Klaus et al., 1998; Lowell et al., 1993). Thus, ablation of BAT by these means may have a greater effect on thermogenesis, body weight, and adiposity than seen in animals with global UCP1 KO. This suggests that mechanisms other than UCP1 in BAT may be operative in the retention of thermogenic function in UCP1 knockout animals. One possibility may be the activation of uncoupling protein-3 (UCP3), a factor that has more widespread distribution than its analog, UCP1. Indeed, allelic variation in intron 1 of the gene that encodes

UCP3 can impact on thermogenesis, cold tolerance, and the propensity to obesity. Thus, work in hamsters demonstrated an allelic variation in intron 1 that impacts on UCP3 expression in BAT and not in skeletal muscle. Impaired UCP3 expression in BAT reduces cold tolerance (Nau et al., 2008), and results in increased body weight in both males and females (Fromme et al., 2009). This suggests that, although UCP1 in BAT of rodents is integral to the control of body weight, it may not be the sole mediator of BAT function and other proteins, such as UCP3 may also be important, at least in hamsters.

2.1.4 BAT and Thermogenesis in Humans

As early as 1981, studies demonstrated the presence of multilocular adipose tissue and increased expression of mitochondrial markers within adipose tissue of the interscapular region of Scandinavian outdoor workers, in comparison to indoor workers (Huttunen et al., 1981), suggesting the presence of BAT in the former. The evolution of techniques using positron-electron tomography (PET)-scanning to measure fluorodeoxyglucose (FDG) uptake enabled the collection of the unequivocal evidence for functional and active BAT in at least some adult humans. PET-scanning has shown pockets or islands of adipose tissue that display high metabolic activity via increased FDG uptake, consistent with the presence of brown adipocytes (Cypess et al., 2009; Nedergaard et al., 2007; van Marken Lichtenbelt et al., 2009; Virtanen et al., 2009). These regions of metabolically active adipose tissue are located around the neck, clavicular, sternal, and paraspinal regions (Fig. 12.2), as verified by UCP1 expression in biopsies. The incidence of active BAT under warm conditions is unsurprisingly low, being less than 10% (Au-Yong et al., 2009; Cypess et al., 2009) but in protocols using mild cold exposure, the presence of functional BAT is found in up to 95% of subjects (Saito et al., 2009; van Marken Lichtenbelt et al., 2009). Nonetheless, biopsies of the fat tissue taken from the neck region in subjects who are not positive for BAT on PET-scanning still show higher expression of UCP1 and β3-Adr when compared to subcutaneous fat (Lee et al., 2011b). Thus, the incidence of functional BAT is likely to be underestimated by PET scanning. Even in the absence of demonstrable UCP1 expression, it has been shown in vitro that adipose samples from the neck region contain precursor cells for BAT and that brown adipocyte formation can be induced under tissue culture conditions (Lee et al., 2011a). Thus, it is now indisputable that BAT exists in adult humans and is likely to play a role in energy expenditure.

Various factors alter BAT thermogenesis including cold, age, adiposity, and a variety of metabolic hormones. Whereas BAT activity increases in response to cold exposure, the incidence of functional BAT is inversely related to levels of adiposity, BMI, and age
FIGURE 12.2　Distribution of BAT in humans, sheep, and rodents. Humans and sheep have brown adipocytes interspersed among white adipose tissue. In humans, brown adipocytes are primarily found in the neck, supraclavicular, and paraspinal regions. In sheep, UCP1 expression is abundant in sternal and retroperitoneal adipose tissue, which indicates that these fat depots are enriched in brown adipocytes. In contrast, rodents contain a defined brown fat depot, which is located in the interscapular region.

(Cypess et al., 2012, 2009; van Marken Lichtenbelt et al., 2009). In lean subjects (BMI <25); moderate cold exposure at 16°C activates BAT in virtually all subjects (97%), but with increasing age and adiposity the ability for cold to activate BAT is reduced (Orava et al., 2011; Ouellet et al., 2012; Saito et al., 2009; Virtanen et al., 2009; Yoneshiro et al., 2011b). Indeed, weight loss in morbidly obese subjects can increase the incidence of active BAT, although this is a moderate effect (Vijgen et al., 2012). Thus, variation in the levels of functional BAT may

determine the susceptibility of an individual to become obese and may influence the rate of weight gain associated with aging.

The amount of BAT is higher in neonates and declines across childhood, but may increase again across the pubertal transition (Gilsanz et al., 2012). This is, however, sex-dependent, being greater in males than in females. This sexual dimorphism relates to changes in muscle mass, so that males gain greater muscle and BAT mass across puberty (Gilsanz et al., 2012; Hu and Gilsanz, 2011). This observation is consistent with the derivation of BAT and the observation that myocytes and brown adipocytes share a common embryonic precursor (see earlier). In spite of the greater increase in BAT levels in males across puberty, female adults have greater BAT mass than males (Hu and Gilsanz, 2011). Accordingly, it has been hypothesized that gender differences in BAT activity are determined by sex differences in the levels of androgens, estrogens, and progesterone. Indeed, there is a reduction in BAT activity associated with the decline in estrogen levels in women that occurs at menopause (Quarta et al., 2012). In rodents, androgens induce weight gain and obesity (Clegg et al., 2006; Mauvais-Jarvis, 2011; McInnes et al., 2006; Moverare-Skrtic et al., 2006) whereas estrogen protects against this (Clegg et al., 2006; Mauvais-Jarvis, 2011). This may be partly mediated by the effects of sex steroids on thermogenesis (Clarke et al., 2012a; Quarta et al., 2012). Specifically, 17β-estradiol acts at estrogen receptor (ER) α expressing neurons within the VMH to increase BAT thermogenesis (Martinez de Morentin et al., 2014; Xu et al., 2011). In sheep, testosterone reduces thermogenesis in males but not females (Clarke et al., 2012a), clearly exemplifying sexual dimorphism in energy expenditure. The endocrine control of thermogenesis in humans is relatively unexplored, but insulin and thyroid hormone are known to increase glucose uptake in BAT (Orava et al., 2011). Other recent studies in humans have suggested that BAT may be an important buffering tissue to control glycaemia (Lee et al., 2016; Poher et al., 2015). Indeed, DIO causes insulin resistance in BAT of mice (Roberts-Toler et al., 2015). Additional endocrine factors that regulates BAT activity in humans are thought to include irisin, FGF21, and bone morphogenic proteins (BMPs) (Celi et al., 2015; Sidossis and Kajimura, 2015). In order to exploit BAT thermogenesis in the development of antiobesity therapies, it will be imperative to understand the endocrine control of this specialized tissue.

2.2 BAT and Thermogenesis in White Adipose Tissue

Whereas mice and rats maintain circumscribed brown fat depots that endure into adulthood, the majority of mammalian species exhibit brown adipocytes interspersed within white adipose beds (Nedergaard et al., 2010; Symonds et al., 2012) (Fig. 12.2). As indicated earlier, at least a proportion of humans display adipose tissue beds within the neck, clavicular, and paraspinal regions that are abundant in brown adipocytes and BAT-precursor cells (Cypess et al., 2009; van Marken Lichtenbelt et al., 2009; Virtanen et al., 2009). Similarly, sheep do not have a defined brown fat depot, but have regions of adipose tissue that are rich in UCP1, indicating the presence of brown adipocytes within these sites (Fig. 12.2). In lambs, UCP1 is highly expressed in the sternal, clavicular, pericardial, and retroperitoneal adipose depots. Temperature profiling in adipose depots of adult sheep indicates site-specific thermogenic differences, such that retroperitoneal fat exhibits greater thermogenic potential than subcutaneous gluteal fat (Henry et al., 2008). Typically basal temperature and UCP1 mRNA levels are lower in gluteal fat than in retroperitoneal fat (Henry et al., 2008, 2010). Furthermore, central administration of leptin or peripheral administration of estrogen increases heat production in peripheral tissues, indicative of thermogenesis (Clarke et al., 2013; Henry et al., 2008), and these stimulatory effects are greater in retroperitoneal fat than subcutaneous gluteal fat (Clarke et al., 2013; Henry et al., 2008). This suggests that diffuse adipose beds are thermogenic, most likely due to brown adipocytes interspersed among WAT. White adipocytes express UCP2 (a homolog of UCP1) and although initial reports suggested that this homolog could uncouple oxidative phosphorylation in mitochondria in vitro, this has not been replicated in vivo (Fleury et al., 1997). Indeed, rectal temperature is not altered in UCP2-deficient mice, consistent with a lack of effect on thermogenesis (Abdelhamid et al., 2014). WAT only displays thermogenic properties when UCP1 is overexpressed in adipocytes (Kopecky et al., 1995) or through the recruitment of brown-like adipocytes (described later in the chapter).

2.3 "Browning" of White Adipose Tissue

The recent description of beige or brite (brown in white) cells (Barbatelli et al., 2010; Petrovic et al., 2010) casts further complexity on the role of fat cells in thermogenesis. Beige cells are distinct from true brown fat cells, since they are not derived from the myf-5 lineage. In fact, beige cells are brown-like adipocytes that can be recruited in typically white fat depots and are most prevalent in subcutaneous fat (Barbatelli et al., 2010; Petrovic et al., 2010; Seale et al., 2011). Beige cells express essential thermogenic machinery, including UCP1 and PGC1α. Overexpression of PRDM-16 increases beige recruitment in subcutaneous fat of mice, leading to increased energy expenditure and relative protection against DIO (Seale et al., 2011). In addition to genetic manipulations, a number of physiological processes including β-adrenergic

stimulation and cold exposure, increase recruitment of beige cells within WAT. In rodents, exercise induces the recruitment of beige adipocytes, but data are lacking on the occurrence of this particular process in humans (Bostrom et al., 2012; Norheim et al., 2014; Stanford et al., 2015; Sutherland et al., 2009; Trevellin et al., 2014). The beige cell is morphologically distinct to both white and brown adipocytes and displays an intermediate phenotype, containing more mitochondria than white fat cells and being paucilocular, in that they do not contain a single fat droplet, but rather multiple droplets. Beige cells express PRDM-16, PGC1α, and UCP1, and recent studies have also identified short stature homeobox2 (Shox2), homeobox C9 (Hoxc9), Tmem26, Tbx1, and Cited1 as beige-specific markers (Lidell et al., 2013; Petrovic et al., 2010; Sharp et al., 2012; Walden et al., 2012; Wu et al., 2012). Although beige cells are derived from a different lineage to brown adipocytes, both are capable of utilizing energy, so that increasing the recruitment of beige cells has become a popular means of weight-loss therapy (Ishibashi and Seale, 2010). Importantly, beige cells are derived from bipotential precursors in that the precursors can develop into beige cells in response to cold or SNS stimulation (Jia et al., 2016; Lee et al., 2014b), or alternatively can become white adipocytes in response to a high-fat diet (Lee et al., 2012). To date, the majority of work investigating beige cells has been carried out in rodents and there are relatively few translational studies. In humans, beige cells have been identified in WAT depots (Jespersen et al., 2013; Sidossis et al., 2015) and adipose tissue of the neck and supraclavicular regions contain white, brown, and beige adipocytes (Jespersen et al., 2013).

It has long been thought that the beneficial effects of exercise are greater than the immediate energy spent during a bout of physical activity. In response to exercise the skeletal muscle of mice secretes irisin, a myokine that acts to increase beige cell recruitment in subcutaneous adipose tissue (Bostrom et al., 2012). Furthermore, in vivo treatment with irisin increases energy expenditure without any associated effect on food intake or physical activity (Bostrom et al., 2012). Irisin also improves glucose kinetics in DIO mice (Bostrom et al., 2012). Within adipocytes, irisin acts via the ERK and MAPK pathways to induce expression of the key thermogenic regular, PGC-1α (Zhang et al., 2014), but the cognate receptor for irisin has not been identified (Xie et al., 2015). Initial work produced contradictory findings in humans as irisin levels were not changed by exercise (Raschke et al., 2013). More recently, the use of tandem mass spectrometry has shown that irisin is indeed secreted by human skeletal muscle in response to exercise (Jedrychowski et al., 2015). In addition to irisin, in mice, meteorin-like hormone (metrnl) is increased in muscle in response to exercise and in adipose tissue

in response to cold-exposure (Rao et al., 2014). Metrnl acts via an eosinophil-dependent increase in interleukin 4, which promotes browning of WAT (Rao et al., 2014). There are no equivalent data in larger mammals on the effects of metrnl on thermogenesis. To date, studies in humans have failed to demonstrate any effect of exercise to induce "browning" or to recruit beige cells in white adipose depots (Hew-Butler et al., 2015; Scharhag-Rosenberger et al., 2014; Vosselman et al., 2015). Indeed, the physiological and pharmacological factors that may contribute to the recruitment of beige cells in humans remains largely unknown.

FGF21 is secreted from the liver and is upregulated in response to starvation. FGF21 induces the expression of thermogenic genes in WAT in mice (Fisher et al., 2012). The mechanistic link between FGF21 and BAT appears to be twofold, through the FGF receptor 1 and its coreceptor β-klotho (Yie et al., 2009), and via the SNS (Douris et al., 2015). At the cellular level, this leads to increased UCP1 expression and oxidative metabolism, as well as a systemic decrease in serum glucose and lipids, the latter being partially attributed to FGF21's induction of adiponectin secretion (Fisher et al., 2012; Holland et al., 2013; Kolumam et al., 2015; Lin et al., 2013). In humans, irisin and FGF21 are considered to be important in cold-induced activation of BAT thermogenesis (Lee et al., 2014a). Pharmacological administration of FGF21 causes weight loss and reverses insulin resistance, dyslipidaemia, and hepatic steatosis in rodent models of obesity (Xu et al., 2009; Zhang et al., 2013). In nonhuman primates, higher levels of endogenous FGF21 expression were associated with resistance to HFD (Nygaard et al., 2014). Initially this weight loss was thought to be primarily mediated via browning of WAT and the activation of BAT (Lee et al., 2015), since treatment with a long-acting FGF21 analog increased UCP1 in BAT and increased beige cell recruitment in inguinal fat (Talukdar et al., 2016), without accompanying changes in food intake. Nonetheless, FGF21 treatment causes equivalent weight loss in UCP1 knockout mice (Samms et al., 2015; Veniant et al., 2015), so the mechanisms of FGF21-induced weight loss remain unknown. Nonetheless, browning of WAT has clear beneficial metabolic effects via increasing energy expenditure and modulating glucose metabolism (Lee and Greenfield, 2015). It now becomes important to identify physiological and pharmacological means to either activate BAT or to induce functional beige cell formation in humans.

2.4 Skeletal Muscle

The notion that skeletal muscle is thermogenic has been contentious, largely due to the conflicting data across species. The brain provides a metabolic link to skeletal muscle via the SNS (Braun and Marks, 2011)

and this is likely to control thermogenic output (Henry et al., 2008). Mammalian skeletal muscle expresses both UCP2 and UCP3, with the latter being most abundant (10-fold higher than UCP2) (Clarke et al., 2012a; Henry et al., 2011). In addition, avian species do not possess UCP1 but retain an avian UCP (aUCP), which is expressed in skeletal muscle and shows greatest homology with mammalian UCP3 (Argyropoulos and Harper, 2002). Initial in vitro studies clearly demonstrate that UCP3 can uncouple oxidative phosphorylation in isolated mitochondria (Gong et al., 1997). Along with mitochondrial uncoupling, cellular pathways, such as futile calcium cycling and myosin-ATP turnover have also been suggested to underpin thermogenesis in skeletal muscle (Tseng et al., 2010). Here we review evidence for skeletal muscle thermogenesis in rodents, sheep, and humans.

2.4.1 Rodents

Studies investigating thermogenesis in skeletal muscle of rodents have produced conflicting data and it is generally considered that BAT is the primary or "sole" tissue capable of thermogenesis in such species (Cannon and Nedergaard, 2004, 2010). This consensus is challenged by consideration of the role of UCP3 in skeletal muscle. In mice, 3,4-methylenedioxymethamphetamine (MDMA or ecstasy)-induced hyperthermia is associated with an increase in UCP3 levels in skeletal muscle (Mills et al., 2003), indicative of a role for UCP3 in the control of thermogenesis and the regulation of body temperature. Initial gene knockout studies reported that ablation of the gene that encodes UCP3 attenuates cold tolerance but animals do not display a metabolic phenotype; these animals do not gain weight when fed a normal chow diet (Gong et al., 2000). Further studies implicated UCP3 in the maintenance of body weight in animals fed a high-fat diet as transgenic mice with overexpression of UCP3 in skeletal muscle were resistant to DIO (Tiraby et al., 2007). Ablation of UCP3 increases the propensity to weight gain when mice are fed a high-fat diet (Costford et al., 2008). Thus, a role for UCP3 in mediating thermogenesis and energy expenditure is unmasked when mice are exposed to an obesogenic diet.

In spite of the genetic studies, physiological studies have produced conflicting data. In vivo studies indicate that UCP3 levels typically reflect peripheral fatty acids and not the state of uncoupling or changes in energy expenditure. A good example of this is the effect of fasting on UCP3 expression. The catabolic state induced by fasting is associated with an increase in free fatty acids and also an increase in UCP3, which does not reflect the drive to conserve energy in states of negative energy balance (Cadenas et al., 1999). This contrasts with the demonstration that fasting reduces UCP1 expression in BAT consistent with the effort to conserve energy. The discordance between negative energy balance and UCP3 expression/function is not, however, always apparent. Lactation induces a catabolic state and this occurs in association with reduced UCP3 levels in skeletal muscle (Xiao et al., 2004). To further add complexity, changes in UCP3 levels in rodents often do not correlate to altered mitochondrial function (Cadenas et al., 1999). Deletion of the UCP1 gene increases UCP3 expression in skeletal muscle in cold-adapted animals, which suggests that a compensatory increase in the latter may improve cold tolerance in UCP1 knockout mice (Shabalina et al., 2010). In spite of this, the increase in UCP3 is not associated with an increase in uncoupled respiration in the skeletal muscle of UCP1 knockout animals (Shabalina et al., 2010). Furthermore, it has been suggested that any thermogenic potential of skeletal muscle in mice is derived from brown adipocytes interspersed among the muscle fibers (Almind et al., 2007). Indeed, stripping muscle tissue of these interspersed brown adipocytes is thought to abolish any thermogenic potential of muscle tissue (Almind et al., 2007). Although, more recent work has shown that isolated muscle fibers retain the ability to produce heat, but this occurs via calcium cycling (see later in the chapter) (Barclay, 2012). Thus in rodents, UCP3 may not be an important determinant in driving skeletal muscle thermogenesis. However, this may not be the case in larger mammals, such as sheep or humans and role for UCP3 in muscle thermogenesis will be discussed in detail later.

In general thermogenesis is thought to be due to altered mitochondrial function, whereby there is a switch that results in an increase in uncoupled or state 4 respiration. In skeletal muscle, however, additional metabolic and cellular pathways have been linked to heat production and energy expenditure (Kusminski and Scherer, 2012).

2.4.1.1 AMP-ACTIVATED PROTEIN KINASE

AMP-activated protein kinase (AMPK) is a metabolic fuel sensory kinase. Its primary function is the determination of the relative degree of glucose utilization and fatty acid oxidation; activation of AMPK in the skeletal muscle increases glucose utilization, fatty acid oxidation, and mitochondrial biogenesis (Kusminski and Scherer, 2012). Apart from this, phosphorylation of AMPK has been linked to an increase in muscle thermogenesis in rodents. Thus, administration of 3,5-diiodo-L-thyronine (T2) stimulates thermogenesis, associated with the activation of AMPK in skeletal muscle (Lombardi et al., 2008). Similarly, the A/J strain of mice, which is relatively resistant to DIO, displays associated elevated levels of AMPK activity and an increase in muscle thermogenesis (Kus et al., 2008). Other studies have linked the phosphorylation of AMPK to the thermogenic effect of leptin. Thus, leptin acts directly on mouse skeletal muscle to activate AMPK and to increase oxygen

consumption in vitro (Solinas et al., 2004). Other in vivo studies in mice show that peripheral and central administration of leptin activates AMPK (Minokoshi et al., 2002). In rats, the effect of direct application of leptin to phosphorylate AMPK in isolated muscle fibers is dependent on the fiber type, with activation occurring in white but not red fibers (Janovska et al., 2008). Thus, in rodents, various endocrine factors activate AMPK and this has been linked to skeletal muscle thermogenesis. This contrasts to the work in sheep, showing that a central infusion of leptin does not phosphorylate AMPK (Laker et al., 2011), but increases skeletal muscle thermogenesis (Henry and Clarke, 2008; Henry et al., 2008, 2011). Furthermore, direct infusion of AICAR into the femoral artery of ovariectomized ewes phosphorylates AMPK in skeletal muscle, but does not alter heat production (Henry et al., 2011). Hence, although the activation of AMPK has been linked to skeletal muscle thermogenesis in rodents, the same does not appear to be true for larger mammals, such as sheep.

2.4.1.2 FUTILE CALCIUM CYCLING

Calcium cycling occurs across the sarcoplasmic reticulum (SR) membrane in skeletal muscle and involves the ryanodine type 1 receptor (RyR1) and the sarco/endoplasmic reticulum calcium-dependent ATPases (SERCA). Skeletal muscle expresses SERCA1 and SERCA2a subtypes. The RyR1 pumps calcium from within the SR into the cytosol of the myocyte and activating mutations of RyR1 cause malignant hyperthermia (Lanner, 2012). Increasing the cytosolic calcium concentration either through release from the SR or across the cell membrane (i.e., through neurotransmitter stimulated opening of sodium channels) leads to activation of SERCA (Arruda et al., 2007; de Meis et al., 2005). In order to maintain intracellular calcium homeostasis SERCA is activated to pump calcium back across the SR membrane, which is dependent on the hydrolysis of ATP; this drives heat production (thermogenesis). Central administration of leptin increases SERCA2a levels in the skeletal muscle of rodents (Ukropec et al., 2006), which would increase in thermogenesis driven by futile calcium cycling. In rodents, the endogenous regulator of SERCA, sarcolipin, has been clearly linked to thermogenesis, energy expenditure, and the regulation of body weight. Sarcolipin binds to SERCA, which uncouples calcium transport from the hydrolysis of ATP, leading to an increase in the futile cycling of calcium and heat production. In the absence of BAT (surgical removal) or UCP1 (genetic deletion), sarcolipin increases muscle thermogenesis and is essential for cold-adaptation (Bal et al., 2012; Rowland et al., 2016). In mice, overexpression of sarcolipin in skeletal muscle increases oxygen consumption and fatty acid oxidation, which is associated with a relative resistance to weight gain in animals fed a high-fat diet (Maurya et al., 2015). Current work is investigating futile calcium cycling as a mode of thermogenesis in skeletal muscle in larger mammals and it is clear that postprandial elevation in muscle temperature is associated with upregulation of both RyR1 and SERCA2a (Clarke et al., 2012b).

2.4.2 Sheep

Sheep are a useful and novel model for the investigation of thermogenesis in skeletal muscle for various reasons. Being a larger species, it is possible to implant temperature recording devices in multiple tissues and to obtain serial blood samples to analyze circulating hormones and metabolic factors concomitantly. In addition, photoperiod has a profound effect on energy balance and this is a useful experimental model. In contrast to rodents, BAT depots are relatively low in adult sheep, so any thermogenic output of this tissue may be due to mechanisms other than the activation of UCP1 (Henry et al., 2011; Symonds et al., 2012). Alternatively, a series of studies show that heat production in skeletal muscle can be programmed by meal feeding, as well as various endocrine factors including leptin and the sex steroids.

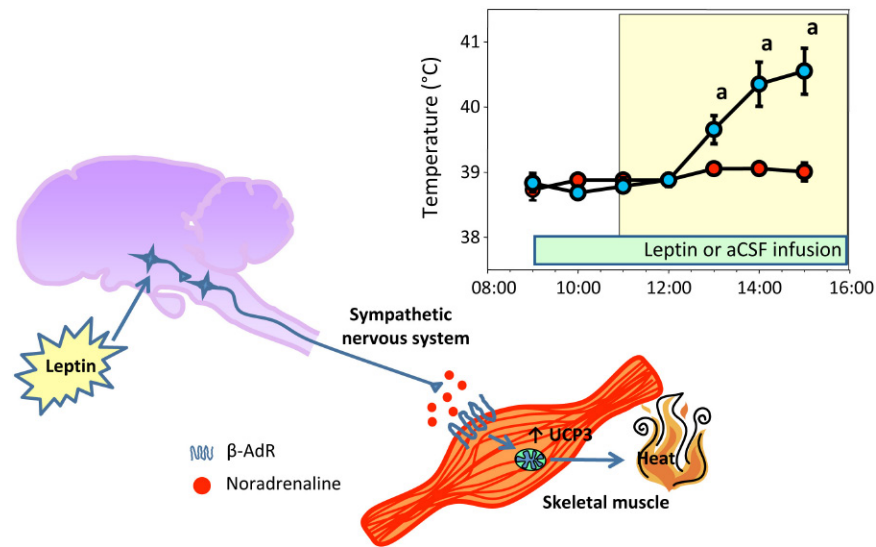
Sheep are grazing species and eat continuously so they do not typically display meal-associated rhythms that are evident in humans. Placing sheep on a meal-feeding regime, however, where they are subjected to temporal food restriction, entrains a meal-associated rhythm. A good example of this is the preprandial rise in ghrelin levels, which is an orexigenic hormone secreted from the abomasum. Meal feeding in sheep can entrain a preprandial elevation of circulating levels of ghrelin in sheep, as is seen in humans (Solomon et al., 2008; Sugino et al., 2002). Similarly, meal-feeding in sheep entrains a postprandial elevation in heat production in peripheral tissues including adipose tissue and skeletal muscle (Henry et al., 2008). The heat production elicited in skeletal muscle is driven by intracellular mechanisms. Simultaneous measurement of femoral artery blood flow and skeletal muscle temperature demonstrates that feeding-associated rise in temperature occurs without an associated change in tissue perfusion (Clarke et al., 2012b). The postprandial response appears to be elicited by mitochondrial uncoupling and futile calcium cycling pathways. In isolated mitochondria, feeding increases uncoupled respiration, but this occurrs in the absence of any major shift in the expression of UCP3 (Clarke et al., 2012b). On the other hand, feeding increased the level of expression of RyR1 (mRNA), as well as SERCA2a protein levels (Clarke et al., 2012b). This clearly demonstrates that feeding activates futile calcium cycling and this may be a primary mechanism for the dissipation of excess calories at the time of feeding. Further study is required to investigate the role of sarcolipin controlling SERCA function and muscle thermogenesis in sheep.


FIGURE 12.3 **Leptin acts at the brain to increase postprandial thermogenesis in skeletal muscle.** Intracerebroventricular infusion of lepton (*blue* symbols) increases heat production in skeletal muscle compared to control animals receiving artificial cerebrospinal fluid (*aCSF*: *red* symbols). Leptin-induced thermogenesis is associated with an increase in the expression of uncoupling protein 3 *(UCP3)* mRNA and protein in muscle. Thus, leptin acts win. The brain to increase sympathetic output resulting in increased noradrenaline release within muscle. Noradrenaline acts via the β-adrenergic system to increase UCP3 and activate thermogenesis. Feeding window is depicted by the *yellow* box. *β-AdR*, β-adrenoceptors. *Source: Adapted with permission from Henry, B.A., Dunshea, F.R., Gould, M., Clarke, I.J., 2008. Profiling postprandial thermogenesis in muscle and fat of sheep and the central effect of leptin administration. Endocrinology 149(4), 2019–2026.*

Central administration of leptin markedly enhances postprandial thermogenesis in skeletal muscle in sheep (Henry and Clarke, 2008; Henry et al., 2008, 2011) and this has been linked to altered mitochondrial function (Fig. 12.3). Indeed, the increase in skeletal muscle temperature in response to i.c.v. leptin treatment precedes any change in core body temperature, suggesting that the former drives the latter (Henry et al., 2008). Leptin-induced heat production is associated with an increase in UCP3 expression in skeletal muscle, without a coincident effect on UCP1 expression. Accordingly, postprandial heat production in muscle is unlikely to be due to increased thermogenesis within brown adipocytes interspersed among the muscle tissue. On the other hand, the increase in UCP3 levels supports the notion that myocytes are capable of thermogenesis via mitochondrial uncoupling. Indeed, uncoupled respiration is increased in mitochondria isolated from skeletal muscle of leptin-treated animals, in accordance with the biochemical hallmarks of thermogenesis. Thus, leptin acts at the brain to increase thermogenesis in skeletal muscle and this is associated with an increase in UCP3 expression and a switch toward uncoupled respiration.

In addition to leptin, thermogenesis in the skeletal muscle of sheep is regulated by sex steroids. Sexually dimorphic effects are seen, such that continuous testosterone treatment of castrated male sheep reduces skeletal muscle heat production (Clarke et al., 2012a), but does not do so in ovariectomized ewes. Importantly, testosterone did not alter the postprandial thermogenic response but acts to cause an overall downregulation of basal body temperature (Clarke et al., 2012a). It is possible, however, that the effect of testosterone on metabolism and energy balance are primarily effected via aromatization and are therefore due to actions of estrogen and not direct effects at the androgen receptor (Mauvais-Jarvis, 2011). In contrast, however, to the effects of testosterone, estrogen acts to increase skeletal muscle thermogenesis in females (Clarke et al., 2013). Thus, the effect of testosterone to inhibit muscle thermogenesis is via androgenic actions and most importantly is sexually dimorphic (Clarke et al., 2012a). Although testosterone and estrogen can modulate skeletal muscle temperature neither steroid impacts on the expression of UCP3, suggesting that effects of steroids on thermogenesis are mediated by alternative cellular systems, such as futile calcium cycling.

Overall, consistent data have been obtained in sheep, indicating that skeletal muscle is thermogenic and two distinct cellular pathways are important arbitrators of this response—mitochondrial uncoupling and futile calcium cycling across the SR membrane.

2.4.3 Humans

Prior to the recent reaffirmation that functional and active BAT is retained into adulthood in humans, it was thought that skeletal muscle may be the primary thermogenic tissue. Early work by Astrup (1986) demonstrated that skeletal muscle could account for up to 50% of ephedrine-induced thermogenesis, whereas adipose tissue accounts for approximately 5%. Although this original

paper did not characterize adipose depots that are now known to be rich in brown adipocytes, a recent paper substantiates this earlier work. Cypess et al. (2012) recently demonstrated that low dose ephedrine (1.5 mg/kg bodyweight) had no effect on BAT activity, but others have shown that high doses (2.5 mg/kg) could activate BAT (Carey et al., 2013). Despite this, chronic administration of low dose ephedrine reduces glucose uptake and BAT activity in humans (Carey et al., 2015). Glucagon can increase energy expenditure without an effect on BAT, further suggesting that alternative tissues are important in terms of adaptive thermogenesis and energy expenditure in humans (Salem et al., 2016). Because humans and other large mammals have relatively little BAT mass compared to rodent species, it has therefore been hypothesized that skeletal muscle thermogenesis is of considerable significance (Rowland et al., 2015). Variation in basal proton leakage within human skeletal muscle accounts for around 20%–50% of the variation in basal metabolic rate (Rolfe and Brown, 1997). As detailed later in the chapter, differences in UCP3 expression in skeletal muscle of obese females alters proton leakage and impairs weight loss (Harper et al., 2002). Thus, skeletal muscle, particularly the activity of UCP3 therein appears to be integral to adaptive thermogenesis and energy expenditure in humans. In spite of the earlier, the means by which thermogenesis in skeletal muscle mediates cold-adaption in humans is unclear. There is no doubt that exposure to cold activates UCP1-mediated BAT thermogenesis (van Marken Lichtenbelt et al., 2009; Vijgen et al., 2011; Wijers et al., 2010; Yoneshiro et al., 2011a), but an equivalent function in muscle is yet to be fully elucidated. Although the uptake of glucose by BAT is increased in response to cold exposure, skeletal muscle accounts for the vast majority of glucose utilization during this adaptive period (Blondin et al., 2015), but there is no associated change in UCP3 protein levels (Wijers et al., 2008). The cold-induced increase in energy expenditure is correlated with an increase in state 4 or uncoupled respiration in permeabilized muscle fibers, in spite of this (Wijers et al., 2008). This observation is similar to that displayed during the postprandial increase in muscle thermogenesis in sheep, whereby feeding increases uncoupled respiration without an effect of UCP3 gene or protein levels. To date, in humans (Blondin et al., 2015; Wijers et al., 2008) or in sheep (Clarke et al., 2012a), there have not been direct measurements of UCP3 activity and it remains possible that differences in mitochondrial uncoupling are not driven by changes in the level of gene expression but increased activity of UCP3. Whatever the mechanism, skeletal muscle represents 40% of body mass, which means that small increments in thermogenesis within this tissue would have significant effects on total energy expenditure. Given the paucity of evidence for skeletal muscle thermogenesis as a major contributor

of energy expenditure in rodents, other animals models, such as the sheep (and in humans) highlight the importance of this tissue and such species are ideal for studies to further delineate possible pathways and mechanisms that can be exploited for the development of antiobesity agents.

2.5 Models of Obesity

In humans, monogenetic forms of obesity are extremely rare, although a number of them have been reported. Mutations in the *obese (ob)* gene that encodes for the hormone leptin, result in profound obesity in humans and rodent species. Type II diabetes, immune dysfunction, and infertility are also displayed in individuals bearing such mutations (Farooqi, 2008; Farooqi and O'Rahilly, 2008). Nonetheless, *ob* mutations are rare in humans and the most common monogenic causes of obesity in humans are within the melanocortin system (Krude et al., 1998). Mutations in the melanocortin 4 receptor can account for as many as 6% of individuals with severe childhood obesity (Farooqi et al., 2003). Genetic models have been extensively studied in rodents (Boersma et al., 2012) and although this will not be considered here, thermogenesis is consistently reduced in these cases. For example, mutations in the leptin system (either the obese gene or in the signaling form of the leptin receptor) abolishes thermogenesis. Thus, the obese phenotype is driven not only by hyperphagia but also a concomitant reduction in thermogenesis and energy expenditure. Indeed, as early as 1977, both *ob/ob* mice and *fa/fa* rats were shown to be intolerant to cold exposure due to an inability to activate thermogenic pathways (Trayhurn et al., 1977). Furthermore, *ob/ob* mice develop obesity even when pair-fed with normal mice, demonstrating that a reduction in energy expenditure is a primary factor in the obese phenotype. Nevertheless, because human obesity is rarely caused by a monogenetic mutation, it is imperative that we characterize thermogenesis in polygenetic models. The application of quantitative genetics, to select for the polygenic condition of obesity or the reverse is well exemplified in the selection of mice for high heat loss (and consequent leanness) (Moody et al., 1999).

2.6 Diet-Induced Obesity and Thermogenesis

Long-term changes in adiposity impact on the neuroendocrine and neural networks that regulate energy homeostasis. Typically these changes reflect compensatory responses, in an effort to return body weight and levels of adiposity to normal. In sheep, low levels of adiposity increase the levels of appetite-stimulating peptides including NPY and MCH in an effort to drive food intake and reduce energy expenditure, ultimately increasing body weight (Barker-Gibb and Clarke, 1996;

Henry et al., 2000). With respect to the melanocortin system, long-term changes in adiposity also elicit compensatory effects to correct body weight toward normal. Low levels of adiposity will either decrease (Backholer et al., 2010) or have no effect on the levels of POMC mRNA; although there is minimal effect on POMC gene expression, low levels of adiposity alter POMC processing (Backholer et al., 2010). Chronic undernutrition and reduced adiposity inhibits the production of melanocortins and stimulates the synthesis of β-endorphin, thus there is an inhibition of the POMC-derived factors that inhibit food intake and an upregulation of those that stimulate food intake (Backholer et al., 2010). Ultimately, these changes in neuropeptide gene expression drive a correction in food intake through appetite drive but also impact on thermogenesis by means of a homeostatic mechanism, returning body weight back to the "set-point" of the individual.

It is generally held that increased rates of thermogenesis may be protective against weight gain. In humans and rodents, obesity is associated with an increase in sympathetic output, which would theoretically alter thermogenic output. A key component of obesity in mice is the development of leptin resistance, whereby exogenous leptin no longer inhibits food intake (Enriori et al., 2007; Munzberg et al., 2004; Myers et al., 2008), but the ability of leptin to activate the SNS and induce BAT thermogenesis is maintained; this is effected by direct action of leptin on the DMH (Enriori et al., 2011), although the target cells are not yet defined. Consistent with this, the majority of studies in rodents demonstrate that high fat feeding increases the expression of UCP1 in BAT, but there has been some discrepant data showing either no effect or a reduction in UCP1 expression in response to high fat feeding (Fromme and Klingenspor, 2011). This contrasts with data in humans, in whom BAT activity falls with increasing BMI and adiposity (van Marken Lichtenbelt et al., 2009); this is likely to confound weight loss and exacerbate the obese state. On the other hand, DIO has no effect on heat production in either adipose tissue or skeletal muscle in sheep (Henry and Clarke, unpublished data). In summary, animal models have not provided conclusive data demonstrating changes to thermogenesis that are representative of the condition of obesity in humans.

Innate differences in thermogenesis are seen to underlie the propensity to become obese and may also abrogate the ability of some individuals to lose weight. DIO rats have reduced BAT thermogenesis compared to their DR counterparts (Lockie et al., 2013). In women, lower UCP3 expression in skeletal muscle is associated with reduced mitochondrial uncoupling and an inability to lose weight (Harper et al., 2002). In addition, differences in weight loss compared to predicted weight loss in dieting humans have been ascribed to variations in diet-induced

thermogenesis (Goele et al., 2009). It is possible that reduced thermogenic potential may impact on the ability of individuals to maintain weight loss, but some individuals maintain a reduction in thermogenesis for up to 1 year after weight loss (Rosenbaum et al., 2008). In addition, DR strains of mice and rats display differential expression of UCP1 in response to high fat feeding compared to those that are susceptible to weight gain. DR strains of mice (AyJ and C57BLyKsJ) exhibit higher UCP1 expression in BAT during high fat feeding than DIO-prone strains (C57BLy6J) (Surwit et al., 1998). In addition to BAT, however, DR mice and rats increase ectopic expression of UCP1 in both skeletal muscle and WAT, particularly within subcutaneous WAT (Almind et al., 2007; Veyrat-Durebex et al., 2011). Indeed, in DIO animals, high fat feeding actually reduces UCP1 levels in subcutaneous fat and thus the ability to increase ectopic UCP1 may be a primary factor in determining susceptibility to obesity. Further work is required to measure ectopic expression of UCP1 in adipose tissue and skeletal muscle of larger mammals, such as sheep.

2.7 Photoperiod and Seasonality as Models of Metabolic Function

Domesticated and wild animals display marked seasonality in reproductive function, that is controlled by day length (Robinson, 1959), but also display seasonality in a number of other physiological processes. Animals are either long-day breeders or short-day breeders, such that the reproductive axis is activated by increasing day length or decreasing day length, respectively. Sheep are short-day breeders and hamsters are long-day breeders. With respect to "seasonality" of reproduction, it is firmly established that this is due to changing day length, "measured" by the perception of light through the eye, transmitting a signal to the suprachiasmatic nucleus (SCN). The signal is then relayed to the pineal gland, which secretes melatonin during the hours of darkness [reviewed in Boden and Kennaway (2006) and Kennaway (2005)]. CLOCK gene expression within the SCN is a fundamental driver of seasonality, being well characterized in numerous species including hamsters (Reiter, 1980) and sheep (Karsch et al., 1984; Lincoln et al., 2003). While seasonality of reproduction has been studied extensively, the impact of photoperiod and temperature on metabolic balance is less clearly deciphered. Seasonal changes in body weight and adiposity are displayed by many species including woodchucks (Young et al., 1982), squirrels (Zucker et al., 1983), hamsters (Wade and Bartness, 1984b), deer (Gaspar-Lopez et al., 2009), and sheep (Clarke et al., 2000), among other species. Although somewhat dampened, seasonality with respect to energy balance is also apparent in humans, with photoperiodic regulation of the occurrence

of BAT (Au-Yong et al., 2009). Interestingly, although both Syrian and Siberian hamsters breed during long-day photoperiod (LD), the former gain weight on short day photoperiod (SD) and the latter lose weight (vide infra). Importantly, however, studies in both species of hamsters have conclusively demonstrated a role for melatonin as a controller of metabolic function.

In Syrian hamsters, animals held on SD show a greater gain in weight than those held on LD, but the difference is greater in females than in males (Bartness and Wade, 1984). It was further demonstrated that in animals held on LD, afternoon injections of melatonin displayed an increase in body weight. SD and melatonin treatment of animals on LD increased BAT mass but there was an indication that norepinephrine-stimulated oxygen consumption (an index of thermogenesis) was lower in animals on SD. The curious lack of indication of statistical significance of the results in this paper render the data difficult to interpret, but there is a suggestion that the ability to gain weight on SD is due to reduced energy expenditure, as well as increased food intake as indicated by the increased amount of energy stored in the carcass. Similar data were presented in another paper on photoperiodic change and melatonin effect on body weight and fat accumulation in Syrian hamsters (Wade and Bartness, 1984b), emphasizing that the "seasonal obesity" is associated with a reduction in energy expenditure. It would be interesting to determine the effects of photoperiod on energy expenditure in this species with more sophisticated measures of energy expenditure.

In Siberian hamsters (Wade and Bartness, 1984a), SD reduces body weight in gonad-intact males, castrated males, and in gonad-intact females. The lack of effect in ovariectomized females led to the suggestion that the gonadal steroids are important for the response to photoperiod in this sex, but the same is not true for males. The reduction in body weight in response to SD, as well as melatonin injections in the afternoon on LD, were accompanied by a reduction in food intake by 4 weeks, but reduction in body weight preceded this by 2 weeks, suggesting that the photoperiod-induced change was due to alteration in energy expenditure. Consistent with this, both SD and melatonin treatment reduced the mass of interscapular BAT. These results with Siberian hamsters are at odds with two earlier communications on the same species (Heldmaier and Hoffmann, 1974; Heldmaier et al., 1981), which showed that SD or melatonin treatment *increases* BAT weight. Similar to this, a recent study in lean and obese Zucker diabetic rats, showed that melatonin could induce "browning" of the subcutaneous fat depot, irrespective of body weight (Jiménez-Aranda et al., 2013). Indeed, melatonin-induced browning coincided with increased heat production in inguinal fat and increased expression of UCP1 and PGC1α (Jiménez-Aranda et al., 2013), which supports the notion that the

effects of melatonin on body weight are due at least in part, to an upregulation of thermogenesis.

Photoperiod has been shown to regulate the expression of a number of clock genes in the SCN and the pars tuberalis of the Siberian hamster (Johnston et al., 2005), but this was not related to any changes in the expression of genes involved in appetite/energy expenditure control. More recent studies, however, suggest a role for CLOCK genes in both the brain and adipose tissue in the control of BAT activity in mice. Global deletion of *Bmal1* in mice increases BAT mass, increases UCP1 expression, and improves cold tolerance (Nam et al., 2015). Interestingly, specific deletion of *Bmal1* in WAT, mimics the phenotype of the global knockout (Nam et al., 2015). Similarly, targeted-ablation of *Bmal1* in SF-1 neurons on the VMH results in an increase in energy expenditure and enhanced thermogenic capacity of BAT in mice (Orozco-Solis et al., 2016). In this case, it was proposed that increased BAT thermogenesis is driven by enhanced SNS activity in the *Bmal1* mutant mice (Orozco-Solis et al., 2016). It is important to note that global deletion of any CLOCK gene would affect all cells in the body (all cells express CLOCK genes), leading to potential effects on SNS, free fatty acid and glucose production, production of transcription factors. This would be expected to have widespread ramifications on whole body metabolism and energy homeostasis. It is also likely that different CLOCK genes act in concert to control energy expenditure since global deletion of the Period2 (*Per2*) gene leads to the opposite phenotype to the *Bmal1* knockout animal. Mice that lack *Per2* are cold-intolerant and have lower body temperature at either 21 or 4°C compared to wild-type controls (Chappuis et al., 2013).

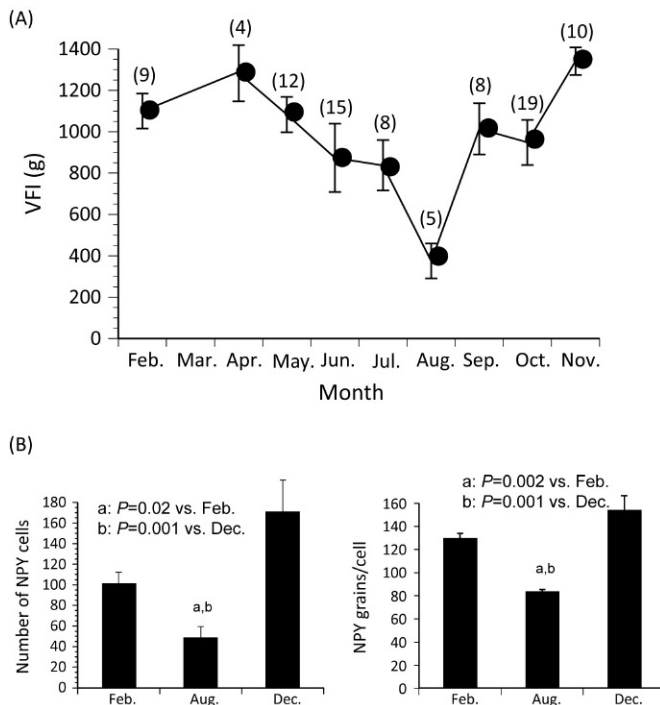
In sheep, a distinct seasonal cycle in appetite is apparent, as displayed in ovariectomized ewes (Clarke et al., 2000), which indicates that the effect of photoperiod is independent of changing levels of gonadal steroids between breeding to nonbreeding season. The nadir of food intake is seen in the Winter–Spring, which is consistent with an effect of SD to reduce appetite and body weight in gonad-intact Soay rams (Lincoln et al., 2001). The change in appetite in ovariectomized ewes was tightly correlated to changes in the expression of the gene for the orexigenic peptide, NPY in the ARC (Clarke et al., 2000), but not the level of expression of the POMC gene (Fig. 12.4). Another study of Soay rams recapitulated the effect of SD to reduce food intake (Fig. 12.5), also showing reciprocal changes in expression of the NPY and POMC, such that the former was reduced and the latter increased under SD (Fig. 12.6). Interestingly, the gonad-intact animals of this study became refractory to the SD and began to increase food intake after 16 weeks—this was directly related to changes in NPY and POMC gene expression that was not seen in the


FIGURE 12.4 Changes in (A) voluntary food intake *(VFI)* and (B) expression of the neuropeptide Y *(NPY)* gene in the accurate nucleus of ovariectomized ewes across an annual cycle. Food intake declines on short-day photoperiod (Southern Hemisphere) and this is directly related to the level of expression of NPY. *Source: Adapted with permission from Clarke, I.J., Scott, C.J., Rao, A., Pompolo, S., Barker-Gibb, M.L., 2000. Seasonal changes in the expression of neuropeptide Y and pro-opiomelanocortin mRNA in the arcuate nucleus of the ovariectomized ewe: relationship to the seasonal appetite and breeding cycles. J. Neuroendocrinol. 12(11), 1105–1111.*

castrated rams. Another intriguing facet of these data is that, although castrated animals maintained a reduced level of food intake on SD, they gained adiposity. In other words, they became fat while food intake was minimal. Similar results were obtained in ovariectomized ewes, which were subject to normal seasonal cycles of photoperiod (adiposity increased at a time when food intake was reduced) (Anukulkitch et al., 2009). In both cases, the most likely explanation for this is a reduction in energy expenditure on SD. The only data which are available to support this notion were provided by one study which indicated changes in metabolic rate across seasons in Soay rams (Argo et al., 1999). Since this model shows such major changes with changing photoperiod, it may be instructive to interrogate the mechanisms underlying changes in energy expenditure.

Other studies in Siberian hamsters and in sheep, both of which display reduced food intake and body weight on SD, have yielded a wealth of information on expression of appetite-regulating genes in the hypothalamus. After exposure to SD, the following changes occur relative to LD:

- Plasma leptin levels and brain leptin receptor expression are lower in Siberian hamsters and Soay rams (Clarke et al., 2003; Marie et al., 2001; Mercer et al., 2000; Rousseau et al., 2003; Tups et al., 2004).
- POMC expression is lower in the arcuate nucleus of the hamster (Mercer et al., 2000; Reddy et al., 1999; Rousseau et al., 2003), but higher in the Soay ram (Clarke et al., 2003).
- NPY expression is lower in the ARC of Soay rams (Clarke et al., 2003) and ovariectomized ewes (Clarke et al., 2000), but no significant changes were seen in Siberian hamsters (Mercer et al., 2000; Reddy et al., 1999; Rousseau et al., 2003).
- Expression of AgRP is lower in Soay rams (Clarke et al., 2003), but in Siberian hamsters, expression is either elevated (Mercer et al., 2000) or unchanged (Rousseau et al., 2003).
- Melanin-concentrating hormone gene expression is higher in the perifornical area and the dorsomedial hypothalamic nucleus of Soay rams (Clarke et al., 2003), but there is no effect of photoperiod in the hamster (Mercer et al., 2000).
- The expression of cocaine and amphetamine-related transcript (CART) is higher in SD than LD in Siberian hamsters (Adam et al., 2000).

Expression of ORX and MCH genes are higher (in early summer/autumn) and reach a nadir, when voluntary food intake falls in late winter/early spring (Anukulkitch et al., 2009). Given that relative adiposity increases at the latter time point, when food intake is minimal, there is an obvious role of seasonal change in energy expenditure (thermogenesis?) that has not been detailed—the changes in expression of ORX and MCH may be salient to the potential change in energy expenditure at this time, for reasons indicated previously.

In summary, these studies show inconsistencies in the effects of photoperiod on expression of genes for appetite-regulating peptides in different species, but the data from sheep show changes more consistent with the observed changes in food intake. Information on the extent to which changes in energy expenditure are caused by photoperiod is rudimentary and some systematic studies with state-of-the-art equipment could yield interesting data on mechanisms.

2.7.1 Effect of Sex, Season, and Leptin Resistance

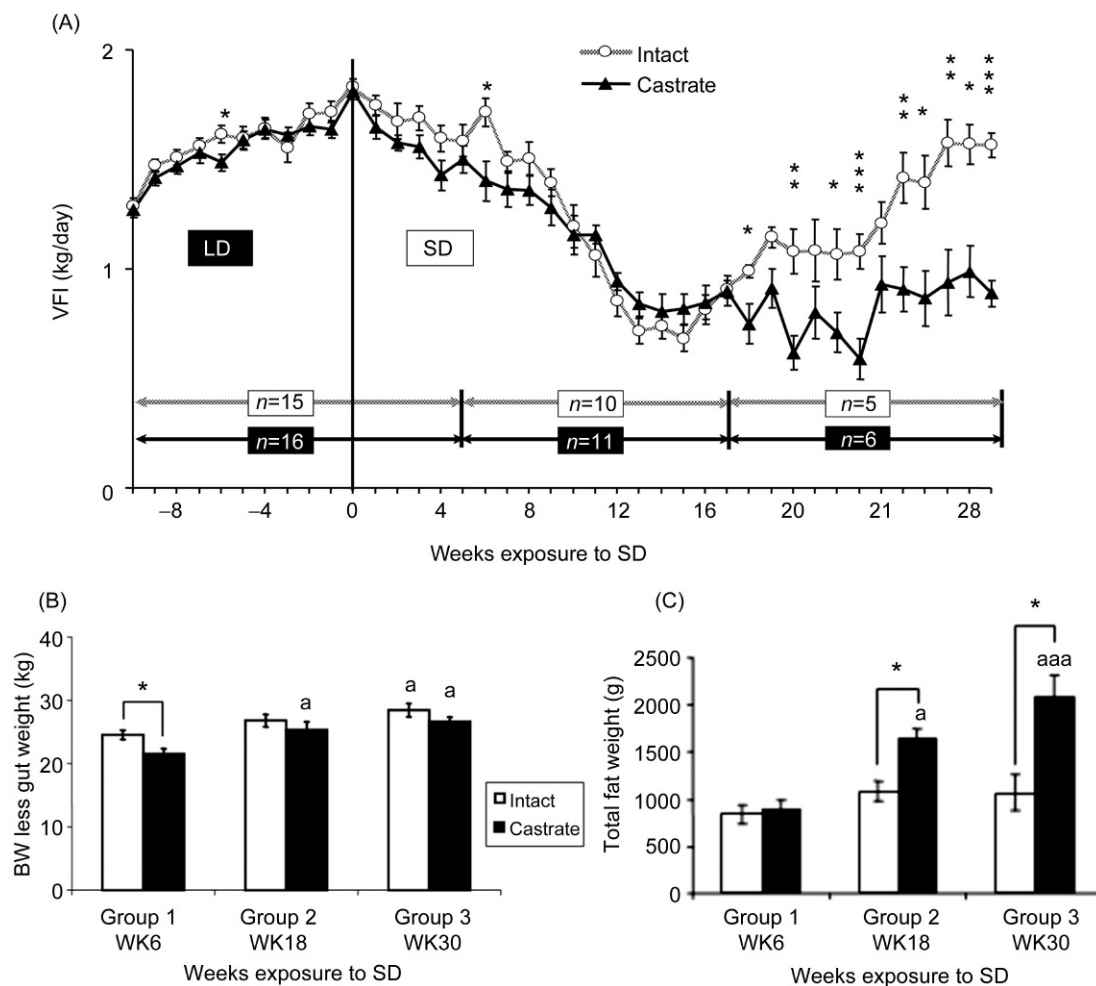
As indicated earlier, the effects of photoperiod on body weight differ in male and female hamsters, in accordance with gonadal status. In sheep and rodents, the satiety effect of leptin is greater in females than males (Clarke, 2001; Clegg et al., 2003, 2006). In addition, in sheep, the anorectic effect of leptin is greater in the


FIGURE 12.5 Effect of photoperiod on food intake, body weight, and adiposity in gonad-intact and castrated Soay rams. (A) Voluntary food intake (mean ± standard error) is reduced by short-day photoperiod *(SD)* dater transition from long-day photoperiod *(LD)*. This occurs in both gonad-intact animals and castrated animals, but the former eventually becomes photorefractory and food intake rises again, in spite of the SD. The numbers in each stage of the study were reduced because animals were taken to measure gene expression in the brain. (B) There are minimal changes in overall body weight *(BW)* less rumen weight (to account for differences in gut fill). (C) There are, however, significant photoperiod-dependent changes in adiposity. Note that castrated animals gain weight, while eating less food. *$P < 0.05$, **$P < 0.01$ for difference between groups indicated. [a]$P < 0.05$, [aa]$P < 0.01$, [aaa]$P < 0.001$ compared with week 6; and [b]$P < 0.05$, [bbb]$P < 0.001$ compared to week 18 within groups of the same gonadal status. *Source: Adapted with permission from Clarke, I.J., Rao, A., Chilliard, Y., Delavaud, C., Lincoln, G.A., 2003. Photoperiod effects on gene expression for hypothalamic appetite-regulating peptides and food intake in the ram. Am. J. Physiol. Regul. Integr. Comp. Physiol. 284(1), R101–R115.*

spring than the autumn (Clarke et al., 2001) (Fig. 12.7). Furthermore, the expression of the leptin receptor fluctuates across the year. Curiously, when the expression of leptin receptor is maximal food intake is greatest (at least 6 weeks after the summer solstice) (Anukulkitch et al., 2009). To add to the perplexity, transition from LD to SD also causes a reduction in leptin transport into the brain within 5 weeks (Adam et al., 2006) (Fig. 12.8). This may not have a great impact on the ability of leptin to regulate NPY and POMC neurons in the arcuate nucleus, which shows porosity to blood borne leptin (Faouzi et al., 2007), so transport to this level of the brain at least, may have only minimal impact on the ability of leptin to act on appetite-regulating systems.

As to whether altered leptin sensitivity or functionality leads to changes in energy expenditure in the sheep remains unknown.

2.7.2 The Role of Thyroid Hormone Action Within the Hypothalamus

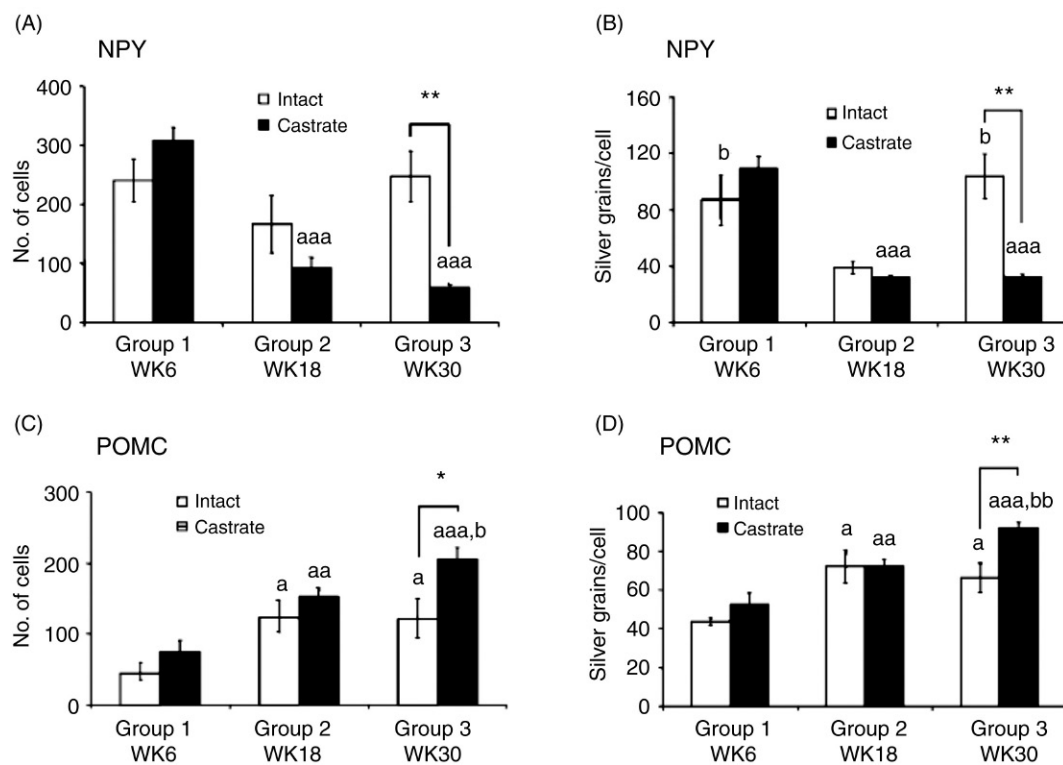
One mechanism that may be highly relevant to metabolic change with photoperiod is metabolism of thyroid hormones in the hypothalamus. Type 2 iodothyronine deiodinase (Dio2) is an enzyme that converts T4 to the active form, T3, and is found in the hypothalamus. Original work in birds identified this enzyme as being regulated by photoperiod and being relevant to control of reproductive function (Yoshimura et al., 2003). This


FIGURE 12.6 **Expression of the *NPY* and *POMC* genes in the arcuate nucleus for which data are shown in Fig. 12.5.** Note the close relationship between the expression of the gene for the orexigenic peptide (NPY) and the gene for the anorectic melanocortins (POMC) and the food intake of the animals displayed in Fig. 12.5. *Source: Adapted with permission from Clarke, I.J., Rao, A., Chilliard, Y., Delavaud, C., Lincoln, G.A., 2003. finding was then replicated in mammals (Watanabe et al., 2004). In particular, the enzyme is found in the ependymal cell layer and the "cell-clear" zone overlying the tuberoinfundibular sulcus (Revel et al., 2006; Watanabe et al., 2004). In the Siberian hamsters, Dio2 is inhibited by SD or melatonin treatment (Watanabe et al., 2004). Similar results have been obtained in Syrian hamsters, but not in Wistar rats that are not photoperiodic (Revel et al., 2006). These studies also showed that the SD reduction in the expression of the enzyme is not affected by castration, but is upregulated by pinealectomy. Emphasizing that the enzyme is regulated by photoperiod, Yasuo et al. (2007) showed a response to photoperiod in Fischer 344 rats (photoperiodically regulated reproduction), but no similar response in Wistar rats. Saanen goats are SD breeders and, consistent with the notion that the activity of the enzyme relates to reproduction, Dio2 is inhibited by LD (Yasuo et al., 2006). In sheep, the notion that the expression of Dio2 is regulated by thyroid-stimulating hormone (TSH) has been investigated. TSH production is increased by LD (nonbreeding condition) and

TSH increases expression of Dio2 (Hanon et al., 2008). Again, this has been related to seasonal breeding but the question as to whether it relates to seasonal appetite/energy expenditure cycles is not known. Since Dio2 expression is affected in the same way by photoperiod in both Syrian and Siberian hamsters, whereas body weight responses to photoperiod are clearly different in the two species, it seems most likely that it relates more to reproductive function than metabolic control. This has, however, not been rigorously examined by, for example, administration of the inhibitor of Dio2, iopanoic acid. Differences between Syrian and Siberian hamsters extend to control of the seasonality of reproductive function (Bartness et al., 1993) as well, which may, at least in part, be due to the differences in the sites of action of melatonin. Thus, in Siberian hamsters, the SCN lesion prevents the inhibitory effect of exogenous melatonin infusions (Bartness et al., 1991), but this is not the case in Syrian hamsters (Bittman et al., 1989). As to how this extends to control of metabolic function, particularly thermogenesis, is not known.

2.7.3 Vitamin D and Photoperiod

In humans, low vitamin D is often associated with the obese state and insulin resistance (Soares et al., 2012), but little is known as to whether this is a cause or effect relationship. In humans, however, consumption of a breakfast high in vitamin D leads to increased fat oxidation and increased thermogenesis during the postprandial period (Ping-Delfos and Soares, 2011). This suggests that vitamin D may be important in modulating or increasing energy expenditure via activation of thermogenic pathways, at least in humans.

There are few data on the effect of vitamin D on energy expenditure or thermogenesis in animal models, but there is some suggestion of an inhibitory effect in rodents, in contrast to findings in humans. For example, mice that lack vitamin D or the vitamin D receptor exhibit a lean DR phenotype (Narvaez et al., 2009). Interestingly, food intake is slightly increased in the vitamin D receptor knockout animals and the lean phenotype appears to be at least partly driven by an increase in UCP1 in WAT (Narvaez et al., 2009). This is substantiated by targeted overexpression of the vitamin D receptor in the adipocytes of transgenic mice, which reduces UCP1 expression in BAT, reducing energy expenditure and leading to an obese phenotype (Wong et al., 2011).

As the vitamin D receptor is a nuclear receptor, it can act directly to alter expression of target genes, with specific findings pertaining to the repression of ELOVL3 in WAT (Ji et al., 2016). ELOVL3 is a BAT-specific marker, so reduced expression indicates that vitamin D is an inhibitor of BAT development and/or function in rodents. Interestingly, the central actions of vitamin D are completely opposite, causing reduced food intake and body weight in mice through the activation of POMC neurons within the ARC (Sisley et al., 2016). Such findings support the hypothesis that vitamin D deficiency is associated with obesity, but there are clearly disparate effects centrally and peripherally. There clearly appears to be a relationship between vitamin D, the control of body weight, and energy expenditure, but further investigation is required to try to address the apparent species differences, as well as the possible differences between central and peripheral effects on energy homeostasis.

2.8 Fetal Growth Retardation and Subsequent Effect on Metabolic Balance

Undernutrition during gestation is known to reduce birthweight and have long-term impact on body weight, body composition, and metabolic health. In humans, effects of maternal undernutrition on long-term weight regulation in progeny is dependent on the timing of undernutrition and the availability of food in the early postnatal period. Exposure to famine during the early stages of gestation increases the body weight of the offspring (Painter et al., 2005; Zeltser, 2015). Similar observations have been observed in sheep, where undernutrition during the first 3 months of gestation leads to increased adiposity and resultant obesity during adulthood (Gnanalingham et al., 2005). The similarities between sheep and humans are not surprising given that both are precocial newborns and thus the formation of neural circuits that regulate food intake and energy expenditure are largely formed prior to birth (Symonds, 2013).

The "Barker Hypothesis" (Barker and Osmond, 1986; Barker et al., 1989, 1993) states that early life events, especially prior to birth, have detrimental effects that are manifested in later life. In particular, this hypothesis focussed on the predisposition to heart disease, but it is now clear that early life events can lead to a number of adverse health issues, including cancer. This is reviewed in de Boo and Harding (2006), detailing the implications of fetal programming on disease in later life, as shown in Fig. 12.9. Animal models of the human disease have been developed, one being that of placental restriction (Robinson et al., 1979). This model, developed in sheep, involves the surgical removal of "caruncles" in the uterus that are the placental structures. Removal of caruncles leads to reduction in the growth of the fetus and a reduction in birthweight. As a consequence, the offspring have insulin resistance when young and glucose tolerance is compromised in the adults (De Blasio et al., 2007a,b, 2010, 2012; Gatford et al., 2008; Owens et al., 2007). In this model, insulin resistance appears to be due to reduced expression of genes related to insulin signaling and metabolic function in skeletal muscle, but not liver (De Blasio et al., 2012). It would be interesting to determine whether such fetal programming affects thermogenic function and alters energy expenditure in this way.

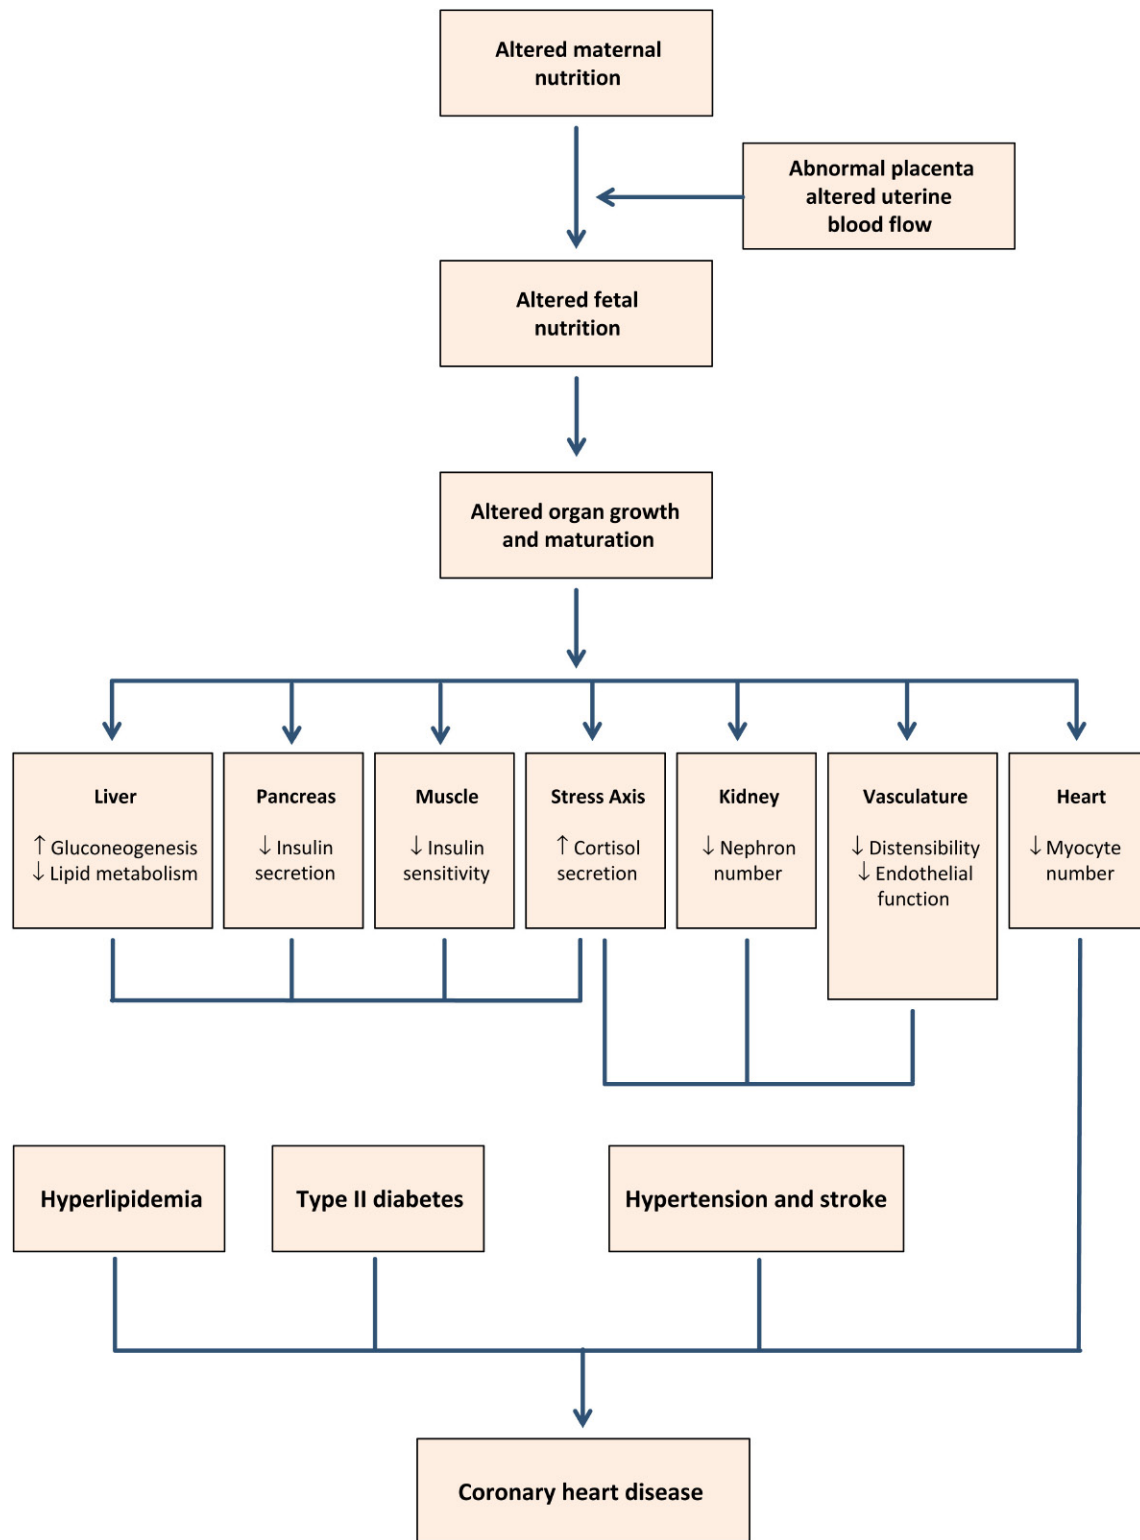
In rodents, the state of maternal nutrition clearly impacts on the developing neural circuitry that govern energy homeostasis (Zeltser, 2015). In rodents, which are altricial as newborns, the hypothalamic connections are primarily established during the postnatal period (Bouret, 2012). A primary driver of nutritional programming of hypothalamic circuitry appears to be circulating leptin levels. The neural projections extending from the ARC are disrupted in ob/ob mice (Bouret et al., 2004). Furthermore, this can only be reversed by leptin treatment during the neonatal period and not in adulthood; leptin replacement during postnatal days 4–12 restored AgRP- and αMSH-positive fiber density in the PVN (Bouret et al., 2004). The long-term consequences of altered synaptic development in the absence of postnatal leptin is unknown since ob/ob mice exhibit satiety in response to leptin treatment. It has also been hypothesized, that postnatal leptin levels are important for the development


FIGURE 12.9 **Impact of early life programming on the prevalence of disease later in life.** *Source: Adapted with permission from de Boo, H.A., Harding, J.E., 2006. The developmental origins of adult disease (Barker) hypothesis. Aust. N Z J. Obstet. Gynaecol. 46(1), 4–14.*

of BAT (Zeltser, 2015). Interestingly, at postnatal day 10 the primary endogenous source of leptin is BAT and not WAT (Zhang et al., 2001). The effects of leptin on BAT development, however, are complex. In normal control or wild-type mice, neonatal leptin treatment inhibits BAT thermogenesis and increases the propensity to become obese (Vickers et al., 2008; Yura et al., 2005). In contrast, in states of leptin deficiency (ob/ob mice) or IUGR, neonatal leptin treatment improves BAT function (Bouyer and Simerly, 2013; Vickers et al., 2005). There is a lack of data on the effects of maternal programming on thermogenesis in tissues other than BAT. It would be most interesting to characterize the differential effects of maternal programming on thermogenesis in brown or beige adipocytes, as well as in skeletal muscle.

2.9 Transgenerational Effects of Obesity

In rats, female offspring, whose fathers had been rendered obese due to high-fat diet showed impaired insulin secretion and glucose tolerance, associated with altered gene profiles, particularly in the pancreatic islets (Ng et al., 2010). Hypermethylation of genes suggests epigenetic programming in these animals. Interestingly, the daughters did not have altered body weight, growth rate, energy intake, or energy efficiency, implying the unlikelihood of an impact on thermogenesis or overall energy expenditure. A study of mice born to obese fathers showed significant genetic perturbation in gametes of offspring and impaired fertility (Fullston et al., 2012). Increased body weight in F2 female offspring suggests that metabolic perturbations were transgenerational. Transcriptome analysis of pancreatic islet genes in female offspring of HFD fathers revealed alterations in the expression of 642 genes including those involved in ATP binding, the cytoskeleton and intracellular transport (Ng et al., 2010). Phenotypically this resulted in impaired glucose homeostasis possibly due to a decreased β-cell mass within the Islets of Langerhans. Another study based on the impact of paternal HFD on female offspring investigated transcriptional changes within retroperitoneal fat, as well as pancreatic cells, with 5108 genes having altered expression. Broadly speaking these changes were within pathways involved in responses to stress, cell survival, growth, and proliferation, which were hypothesized to be consistent with gene signatures characteristic of premature aging and degenerative disorders (Ng et al., 2014). What is exciting is that in the same model of transgenerational paternal metabolic influences, a short-term diet/exercise intervention can ameliorate insulin sensitivity and adiposity in female offspring. These changes are reflected at the molecular level. In HFD fathers, the expression of four X-chromosome-linked microRNAs (miRNAs) were reduced, however, with diet and/or exercise the expression profiles were restored comparable to that of controls (McPherson et al., 2015). These miRNAs are associated with early embryonic development and due to their link to the X chromosome any adverse effects as a result of altered miRNAs are more profound in females due effectively to the "double dose." These studies clearly demonstrate that maternal and paternal body weight and metabolic health are likely to have detrimental effects on progeny across a number of generations.

2.10 Polygenic Models of Obesity

Whereas single gene defects might lead to an obesity phenotype in humans and in animals, these do not account for the majority of cases in which body conformation is inherited. A large number of genes have been associated with obesity. In spite of this, it is seen that individual genes have a small influence on the obese phenotype as a whole. In a review of this topic (Walley et al., 2009), it was concluded that, in the search for single genes and gene linkage, "…our current methods are only identifying minor contributors to the genetic effect in obesity." This is most likely due to the fact that genetic determination of body conformation and propensity to become obese in an obesiogenic environment is polygenic in nature (Kunej et al., 2013). Accordingly, the application of quantitative genetics to selection of animals for obesity genotypes has provided useful animal models of the human condition. In this section we will discuss two ovine models that (1) have been selected for differences in adiposity or (2) the application of cortisol responsiveness as a marker for altered propensity to gain weight.

2.10.1 Models of Genetic Obesity

Polygenic models of obesity have been developed in chickens (Lilburn et al., 1982; Simon and Leclercq, 1982), pigs (Hetzer and Harvey, 1967; Hetzer and Miller, 1972, 1973) and sheep (McEwan et al., 2001; Morris et al., 1997; Suttie et al., 1991). Perhaps the most well-examined model is that in the sheep, which was based on the selection of animals with greater or lesser back-fat thickness and backcrossing of the animals of the two extremes; the lean and fat lines show a significant difference in adiposity, despite similar body weights and voluntary food intake (Alfonso and Thompson, 1996; Morris et al., 1997). Whereas the animals have a phenotype in the growth hormone axis (Francis et al., 1997, 1998a,b; French et al., 2006; Suttie et al., 1991), this may be only one factor contributing to the different phenotype. It is possible that the animals have different metabolic "set-point" and this might be exemplified in the steady-state level of gene expression for "appetite regulating peptides" in the hypothalamus. On a normal diet and at steady state, the level of gene expression for NPY in the arcuate nucleus is similar in
FIGURE 12.10 **Expression of genes for orexin *(ORX)* and melanin-concentrating hormone *(MCH)* in the hypothalamus of ewes selected for lean or fat phenotype.** Controls are animals from the same flock that were not selected. The animals were sampled on a normal diet, with no difference in food intake or body weight. The data are an index of expression which is obtained by the product of cell number and expression/cell. *Source: Adapted with permission from Anukulkitch, C., Rao, A., Dunshea, F.R., Clarke, I.J., 2009. A test of the lipostat theory in a seasonal (ovine) model under natural conditions reveals close relationship between adiposity and melanin concentrating hormone expression. Domest. Anim. Endocrinol. 36, 138–151.*

lean and obese animals (Anukulkitch et al., 2010), which contrasts the effects of diet-induced alterations in body weight where NPY expression is increased in normal (unselected) animals made lean by food restriction (Barker-Gibb and Clarke, 1996). This is not surprising, since the obese animals do not display leptin resistance; the reduction in food intake caused by central infusion of leptin is equivalent in genetically lean and obese animals (Henry et al., 2015). On the other hand, the expression of both ORX and MCH genes was altered. Thus, in the DMH, ORX gene expression was higher than control in lean animals and lower than control in fat animals (Fig. 12.10). A similar trend was seen for MCH gene expression in the lateral hypothalamus (Fig. 12.10). Since there is no difference in food intake in these lean and fat animals, the differences in steady-state gene expression may relate to differences in energy expenditure. Indeed, contemporaneous temperature recordings demonstrate that postprandial thermogenesis is attenuated in retroperitoneal adipose tissue of genetically obese sheep compared to their lean counterparts (Henry et al., 2015). The reduction in heat output in obese sheep is confined to adipose tissue (not skeletal muscle) and is associated with reduced UCP1 expression, supporting the notion that thermogenesis is reduced in the obese group (Henry et al., 2015). As mentioned before, MCH reduces energy

expenditure, whereas ORX increases the same (Astrand et al., 2004; Ito et al., 2003; Messina and Overton, 2007; Teske et al., 2008) and ablation of the ORX gene leads to obesity in mice (Hara et al., 2001), due to impaired development of BAT and reduced BAT thermogenesis (Sellayah et al., 2011). As to why there is a similar trend in the expression of MCH, being high in lean animals, is not known, since knockout of this gene in mice leads to accelerated weight loss (Willie et al., 2008). We propose that the altered expression of orexin may be important in determining altered thermogenesis and thus different body compositions in the genetically lean and obese sheep, but this requires further investigation.

2.10.2 Cortisol Responsiveness Marks Inherent Differences the Predisposition to Obesity

Glucocorticoids are well known to exert a broad range of metabolic effects on food intake, energy partitioning, and energy expenditure, but space does not allow these direct glucocorticoid effects to be described herein. Recent work, however, has suggested that the effects of glucocorticoids on thermogenesis differ between species. In humans, dexamethasone stimulates the differentiation and development of brown preadipocytes in adipose tissue samples from the clavicular region (Barclay et al., 2015). Furthermore, 3 days of prednisolone treatment enhanced cold-induced activation of BAT in healthy male volunteers (Ramage et al., 2016). This contrasts that seen in rodents, wherein glucocorticoids act, at least in the acute phase, to inhibit BAT function (Ramage et al., 2016). Further work is required to study the direct effects of glucocorticoids on thermogenesis in other tissues, such as skeletal muscle, and also in other large mammal models, such as pigs and sheep.

In humans, the secretion of cortisol is known to be altered in obese states, particularly in the case of abdominal or visceral obesity where cortisol levels are elevated (Duclos et al., 1999; Pasquali et al., 1993). Similarly, in sheep, DIO leads to increased secretion of cortisol in response to isolation restraint stress in comparison to their lean flockmates (Tilbrook et al., 2008). This initial work suggested that the obese state leads to dysfunction of the hypothalamo-pituitary-adrenal (HPA) axis. More recent work, however, suggests that inherent differences in cortisol responsiveness can be used to predict altered propensity to weight gain (Fig. 12.11). Initial studies identified rams as having either high or low cortisol responses to adrenocorticotropin (ACTH) with a greater response being correlated with lower feed-conversion efficiency (Knott et al., 2008, 2010). Marked differences in thermogenesis were revealed while using a similar protocol to identify high (HR) and low (LR) cortisol responders in female sheep. At baseline, in a steady nonstressed state, LR and HR eat similar amounts and have similar body composition, but HR accumulate more adipose tissue

High cortisol responsiveness
Increased CRF and AVP and decreased oxytocin
Increased POMC in anterior pituitary
Attenuated catabolic response to stress
Decreased thermogenesis in skeletal muscle
Impaired melanocortin signaling
Reactive behavioral coping strategy
= propensity to become obese

Low cortisol responsiveness
Decreased CRF and AVP and increased oxytocin
Decreased POMC in anterior pituitary
Elevated catabolic response to stress
Increased thermogenesis in skeletal muscle
Proactive behavioural coping strategy
Increased physical activity
Reduced fearfulness
= relative resistance to obesity

FIGURE 12.11 **Summary of the neuroendocrine, behavioral, and metabolic differences between animals selected for either low or high cortisol responsiveness.** Animals selected for high cortisol responsiveness exhibit increased food intake and reduced energy expenditure, which is associated with increased susceptibility to becoming obese. This figure summarizes the specific differences in neuroendocrine markers, the control of food intake, energy expenditure, and behavioral phenotypes in high or low cortisol responders. *AVP*, Arginine vasopressin; *CRF*, corticotrophin-releasing factor; and *POMC*, proopiomelanocortin. *Source: Adapted with permission from Hewagalamulage, S.D., Lee, T.K., Clarke, I.J., Henry, B.A., 2016b. Stress, cortisol, and obesity: a role for cortisol responsiveness in identifying individuals prone to obesity. Domest. Anim. Endocrinol. 56 Suppl., S112–S120.*

on a high-energy diet (Lee et al., 2014c). Furthermore, in the nonstressed basal state, LR and HR animals exhibit differences in the set-point of the HPA axis, with HR animals having increased expression of corticotrophin-releasing factor and arginine vasopressin, but reduced oxytocin levels in the PVN, as well as increased POMC mRNA in the anterior pituitary gland (Hewagalamulage et al., 2016a). Collectively these data demonstrate that high cortisol responsiveness can be used as a marker for increased susceptibility to obesity (Hewagalamulage et al., 2016b; Lee et al., 2014c,d).

Altered susceptibility to obesity in LR and HR is underpinned by a number of metabolic, neuroendocrine, and behavioral traits that ultimately lead to increased food intake (in response to stress) and reduced energy expenditure (Lee et al., 2014d). A key feature of increased propensity to weight gain in the HR animals is reduced postprandial thermogenesis in skeletal muscle (Lee et al., 2014c). HR animals also show an attenuated catabolic state in response to stress (Lee et al., 2014d). The reduction in food intake caused by psychosocial or immune stress is greater in LR than HR (Lee et al., 2014d). Furthermore, in response to lipopolysaccharide treatment the increase in muscle heat production is greater in LR, which suggests that energy expenditure is lower in HR animals (Lee et al., 2014d). Similar observations have been made in LR and HR women, where women characterized as HR tend to eat more and show greater

preference toward foods high in fat and sugar in response to stress than LR women (Adam and Epel, 2007; Epel et al., 2001; Tomiyama et al., 2011). These metabolic differences may be underpinned by altered melanocortin signaling in the PVN of the hypothalamus. Animals selected for HR, are resistant to the satiety effect of α-MSH and have reduced expression of the MC3R and MC4R in the PVN (Hewagalamulage et al., 2015). Indeed, previous work in sheep has shown the MC4R to be central to the reduction in food intake caused by immune challenge (Sartin et al., 2008). Thus selection for cortisol responsiveness, at least in sheep, identifies animals with innate differences in the melanocortin system.

In addition to the metabolic sequelae, LR and HR animals exhibit inherent behavioral differences. Animals characterized as LR display a proactive coping style in response to stress, which is exemplified by increased physical activity and reduced fearfulness (Lee et al., 2014d). This contrasts the HR animals that exhibit increased freezing, active avoidance behaviors, and increased fear, which are characteristic of a reactive coping style (Hewagalamulage et al., 2016b; Lee et al., 2014d). It has been hypothesized that proactive coping strategies are associated with increased physical activity and thus is another means by which LR animals may expend more energy than HR (Koolhaas et al., 1999, 2010).

In summary, selection for cortisol responsiveness identifies individuals with increased susceptibility to

become obese. This increased propensity to gain weight is underpinned by a suite of metabolic, behavioral, and neuroendocrine factors that ultimately lead to reduced energy expenditure and increased food intake (under certain conditions).

3 CONCLUDING REMARKS

The energy balance equation, in which energy intake and energy expenditure are factored is a crucial consideration for means of control of obesity. This chapter has sought to highlight the relevance of the latter and to examine models that might be useful in its interrogation. Thermogenesis is defined as the dissipation of energy through the specialized production of heat; this process occurs in brown and beige adipocytes, as well as skeletal muscle. To date, there has been a prominent focus on the role of BAT thermogenesis in the maintenance of energy balance and the control of body weight. The recent identification of beige adipocytes has sparked a great deal of interest. The ability to transform or recruit beige adipocytes within typical WAT depots is likely to have beneficial effects not only on body weight, but also on metabolic health (e.g., improved glucose metabolism). In order to advance this area of research it is imperative to not only understand how we might expand BAT or beige adipocytes, but how these tissues are effectively activated.

Larger animal models, such as the sheep have been useful in elucidating the role of skeletal muscle thermogenesis. This process primarily occurs via two distinct mechanisms, that is, mitochondrial uncoupling through UCP3 and futile calcium cycling. In sheep, feeding is associated with activation of both pathways and a concomitant increase in muscle heat production. Given the relative abundance of skeletal muscle in comparison to BAT in humans, agents that target muscle thermogenesis may have broader application in the development of antiobesity therapies.

It is clear from genetic models (genetically lean and obese sheep and selection for cortisol responsiveness) and other natural models (such as photoperiodic change) that thermogenesis can play a significant role in the determination of adiposity and that this is a potential target for manipulation. Furthermore, large animal models have allowed dissection of the differential contribution of BAT and skeletal muscle to total thermogenic capacity and the control of body weight. For example, genetic obesity in sheep coincides with impaired BAT thermogenesis in retroperitoneal fat, whereas reduced skeletal muscle thermogenesis is a key component of the increased propensity to become obese in animals characterized as high cortisol responders. Given that efforts to regulate energy intake have been unsuccessful, it is suggested that models of thermogenesis offer a realistic alternative.

Animal Models of Liver Diseases

Yoshihisa Takahashi, Toshio Fukusato

Teikyo University School of Medicine, Tokyo, Japan

1 INTRODUCTION

Animal models are indispensable for the elucidation of pathogenesis mechanisms, the identification of potential therapeutic targets, and the development of novel therapies for various liver diseases. Although large animals (rabbits, dogs, chimpanzees, etc.) have occasionally been used, rodents (especially mice and rats) are used most frequently. Rodents (especially mice) have the following advantages: (1) maintenance and breeding are easy because their bodies are small, and their life spans and gestation periods are short; (2) they are genetically close to humans and genetic manipulation is easy; and (3) ethical restrictions are less stringent compared with those for primates. In 2010, a gold standard publication checklist (GSPC) for animal studies was presented to facilitate future systematic reviews and metaanalyses of animal studies, to allow others to replicate and build on work previously published, to diminish the number of animals needed in animal experimentation, to improve animal welfare, and to improve the quality of

scientific papers on animal experimentation (Hooijmans et al., 2010). Those who perform animal experiments in the future should consider GSPC for planning animal studies.

When using animal models, researchers need to understand their advantages and limitations. Compared with clinical studies, animal models have the following advantages: (1) an adequate number of specimens can be taken at various time points, (2) diseases develop in a shorter time, (3) a group with a homogenous genetic background can be examined, and (4) the roles of specific genes or signaling pathways can be analyzed by using genetically modified animals. Furthermore, compared with in vitro studies, studies using animal models have the following advantages: (1) functions of the liver as a complete organ can be examined, enabling analyses of cell–cell and cell–matrix interactions; and (2) immunologic, metabolic, and endocrinologic interactions between the liver and other organs can be analyzed. However, animal experiments have limitations. Experimental animals occasionally react differently to

noxious agents than humans do. For example, the hepatitis C virus does not infect rodent hepatocytes in the natural state (Mailly et al., 2013). Furthermore, it is difficult to induce alcoholic liver disease (ALD) in rodents because they have an aversion to alcohol (Mathews et al., 2014). Common bile duct ligation (CBDL) results in secondary biliary cirrhosis after only a few weeks in rodents, whereas month-long impairment of bile flow is needed to cause severe liver fibrosis in humans (Delire et al., 2015). As currently used animal models represent the characteristics of human diseases only partially, it is important to select an animal model that is suitable for the objective of the study. In this chapter, we present a systematic review of currently used animal models of various liver diseases, along with their advantages and disadvantages.

2 CLASSICAL MODELS OF LIVER FIBROSIS (TABLE 13.1)

Liver fibrosis and liver cirrhosis are the end-stage states of most chronic liver diseases. The cellular and molecular mechanisms of liver fibrogenesis have been extensively investigated using a wide variety of animal models. Most liver fibrosis models were first developed in rats and later adapted to mice, enabling genetic manipulation. In general, mice are more resistant to liver fibrosis than rats. However, susceptibility to fibrosis is highly variable among mouse strains; severe fibrosis can be induced in several strains by optimizing experimental procedures (Bissell, 2011; Hillebrandt et al., 2002).

2.1 Liver Fibrosis Models Created Using Hepatotoxic Chemicals

Repetitive administration of hepatotoxic agents is a classical method of inducing liver fibrosis. Carbon tetrachloride (CCl_4), thioacetamide (TAA), and diethyl or dimethyl nitrosamine (DEN or DMN) are the most commonly used hepatotoxic agents. It is relatively easy to create robust models using such agents. If all animals are given a similar effective dose of an inducing agent, the reproducibility is high.

2.1.1 Carbon Tetrachloride

CCl_4 is one of the most commonly used hepatotoxic agents for the induction of liver injuries in experimental animals. It directly impairs hepatocytes by altering the permeability of the plasma, lysosomal, and mitochondrial membranes (Liu et al., 2013; Starkel and Leclercq, 2011; Wu and Norton, 1996). CCl_4 is metabolized to the noxious trichloromethyl radical (CCl_3^-) by cytochrome P4502E1 (CYP2E1) in hepatocytes, and CCl_3^- causes lipid peroxidation and membrane damage leading to severe centrilobular liver necrosis. Acute and centrilobular hepatocyte necrosis occurs following a single dose of CCl_4; however, the liver subsequently recovers. When CCl_4 is administered repeatedly, liver fibrosis occurs in the centrilobular region, and subsequently progresses to bridging fibrosis, cirrhosis, and hepatocellular carcinoma (HCC) (Constandinou et al., 2005; Domenicali et al., 2009; Frezza et al., 1994). Significant fibrosis occurs after 2–4 weeks, severe bridging fibrosis after 5–7 weeks, and cirrhosis after 8–9 weeks of administration. After 10–20 weeks, micronodular cirrhosis, portal hypertension, and ascites progressively appear (Constandinou et al., 2005;

TABLE 13.1   Classical Animal Models of Liver Fibrosis

Animal models	Main features
CCl_4	Liver fibrosis occurs in the centrilobular region
	Liver injury can be induced by various administration methods
	Liver fibrosis is resolved after withdrawal of the agent
TAA	Damage in zone 1 is conspicuous
	Liver fibrosis persists for a long period even after withdrawal of TAA
	A relatively long period is required to induce significant fibrosis
DEN and DMN	Liver damage and necrosis occur in both centrilobular and periportal areas
	Liver fibrosis and cirrhosis progress even after cessation of these drugs
	Long-term administration of DEN causes HCC
CBDL	Biliary fibrosis develops within weeks
	Liver fibrosis can be resolved by biliodigestive anastomosis
	Surgical complications (e.g., bile leakage) may occur

CBDL, Common bile duct ligation; CCl_4, carbon tetrachloride; DEN, diethyl nitrosamine; DMN, dimethyl nitrosamine; HCC, hepatocellular carcinoma; TAA, thioacetoamide.

Domenicali et al., 2009; Starkel and Leclercq, 2011). However, the timing and severity of the lesions depend on the amount, route, frequency of CCl_4 administration, and on the species and strain of the animal. Liver injury can be induced by various administration methods, such as intraperitoneal injection, subcutaneous injection, oral gavage, and inhalation. When CCl_4 is administered by intraperitoneal injection, inflammation and necrosis may occur at the site of injection, which can impede the experiment. Although it requires special equipment and training, inhalation is an effective method when a noninvasive procedure is indispensable. Phenobarbitone, phospholipase D, and acetone potentiate liver injury by CCl_4 and promote liver fibrosis (Charbonneau et al., 1986; McLean et al., 1969; Ozeki et al., 1985). Liver fibrosis caused by CCl_4 is resolved after withdrawal of the agent (Iredale et al., 1998). Therefore, CCl_4 administration can be used both as a model of liver fibrosis and as a model of recovery from liver fibrosis.

2.1.2 Thioacetoamide

TAA itself is not toxic to the liver, but its metabolic intermediates (in particular TAA-S-oxide, a reactive oxygen species) covalently bind to hepatic macromolecules, leading to cellular damage and hepatocyte necrosis (Liu et al., 2013). Although TAA damages the hepatocytes of both zones 1 and 3, damage in zone 1 is more pronounced compared with that caused by other hepatotoxic agents. When low-dose TAA is administered for a long period, portal–portal or portal–central bridging fibrosis occurs and progresses to liver cirrhosis (Muller et al., 1988; Starkel and Leclercq, 2011; Zimmermann et al., 1987). Even after withdrawal of TAA, liver fibrosis persists for a long period (Muller et al., 1988). TAA administration over a long period also induces cholangiocarcinoma (CC) and HCC (Newell et al., 2008; Yang et al., 1998; Yeh et al., 2004). In addition to injection, TAA can be administered in drinking water. A drawback of this model is that a relatively long period is required to induce significant fibrosis. Several months are necessary to induce severe fibrosis/cirrhosis in mice or rats by administration of TAA (Muller et al., 1988; Reif et al., 2004; Salguero Palacios et al., 2008).

2.1.3 Diethyl Nitrosamine and Dimethyl Nitrosamine

DEN and DMN are hydroxylated by CYP2E1 in liver cells, yielding diazonium ions as the bioactive intermediates (Liu et al., 2013). These metabolites cause alkylating damage to nuclear acids, leading to hepatocyte necrosis and liver carcinogenesis. Liver damage and necrosis occur in both the centrilobular and periportal areas with subsequent formation of fibrotic septa (Liu et al., 2013). Liver fibrosis and cirrhosis progress even after the administration of DEN and DMN has ceased

(Jenkins et al., 1985; Tsukamoto et al., 1990). Furthermore, the long-term administration of DEN causes HCC (Newell et al., 2008; Poirier, 1975). Therefore, this model is suitable for the study of the progression from liver fibrosis/cirrhosis to HCC, although it is rarely used as a model of pure fibrosis.

2.2 Common Bile Duct Ligation

CBDL is a classical experimental model of secondary biliary fibrosis. Through bile acid toxicity, CBDL causes proliferation of biliary epithelial cells and oval cells, leading to the proliferation of bile ductules, portal inflammation, fibrosis, and eventually liver cirrhosis and liver failure (Geerts et al., 2008; Kountouras et al., 1984; Popov et al., 2010). Biliary fibrosis develops within weeks. Portal hypertension, hyperdynamic circulation, portosystemic shunting, and ascites develop in rats after 6–8 weeks (Geerts et al., 2008; Popov et al., 2010; Starkel and Leclercq, 2011; Tsukamoto et al., 1990). Liver fibrosis caused by CBDL can be resolved by biliodigestive anastomosis (Abdel-Aziz et al., 1990; Issa et al., 2001; Zimmermann et al., 1997). Therefore, CBDL can also be used as an experimental model of fibrosis reversibility. The main drawback of the CBDL model is the occurrence of surgical complications (e.g., bile leakage, rupture of a biliary cyst or gallbladder). This may occur more frequently in mice than in rats because of the more pronounced fragility of some mouse strains, especially transgenic mice, and the inevitable dilatation of the gallbladder (not present in rats) (Geerts et al., 2008). Therefore, CBDL is more commonly performed for rats, but it is occasionally adapted to mice.

3 ANIMAL MODELS OF SPECIFIC LIVER DISEASES

3.1 Animal Models of Primary Sclerosing Cholangitis (Table 13.2)

Primary sclerosing cholangitis (PSC) is a rare disease that predominantly affects males; it is characterized by chronic inflammation, fibrous thickening, and stricture of intrahepatic and extrahepatic bile ducts (Fallatah and Akbar, 2011). When it progresses, it develops into biliary cirrhosis due to chronic cholestasis, resulting in liver failure. Autoimmunity has been suggested as a possible mechanism, and PSC is associated with perinuclear antineutrophil cytoplasmic antibody (pANCA) in up to 90% of patients (Vierling, 2001). Ulcerative colitis (UC) is a complication in many cases. Pathologically, fibrous thickening and inflammatory cell infiltration, mainly due to lymphocytes and plasma cells, are observed in the walls of the extrahepatic and intrahepatic bile ducts.

TABLE 13.2 Animal Models of Primary Sclerosing Cholangitis (PSC)

Animal models	Main features
DDC diet	DDC-fed mice develop pericholangitis, periductal fibrosis, ductular reaction, and consequently portal–portal bridging fibrosis and segmental bile duct obstruction
$Abcb4^{-/-}$ mice	This model reflects the histopathological characteristics of human PSC well
	This model is not complicated with either UC or CC
	This model is complicated with hepatocellular neoplasia
$Cftr^{-/-}$ mice	$Cftr^{-/-}$ mice show progressive liver disease, with hepatosteatosis, focal cholangitis, inspissated secretion, and bile duct proliferation
	There is progression to focal biliary cirrhosis after 1 year of age

CC, Cholangiocarcinoma; DDC, 3,5-diethoxycarbonyl-1,4-dihydrocollidine; UC, ulcerative colitis.

When the disease progresses, fibrosis around the bile duct walls (onion skin–type fibrosis) becomes advanced, and the obstruction and destruction of bile ducts occur, eventually resulting in scar formation. CC may arise in ~15% of patients (Liu et al., 2013).

A perfect animal model that reflects all the characteristics of PSC has not yet been developed, but models that reflect some of the characteristics have (Fickert et al., 2014; Pollheimer and Fickert, 2015). Animal models for (primary) sclerosing cholangitis have been classified into six different groups: models of cholangitis induced chemically [e.g., by 2,4,6-trinitrobenzenesulfonic acid, α-naphthylisothiocyanate, or 3,5-diethoxycarbonyl-1,4-dihydrocollidine (DDC)]; knockout (KO) mouse models [e.g., using $Abcb4^{-/-}$ or cystic fibrosis transmembrane conductance regulator ($Cftr^{-/-}$) mice]; models of cholangitis induced by infectious agents (e.g., *Helicobacter hepaticus* or *Cryptosporidium parvum*); models of experimental biliary obstruction; models involving enteric bacterial cell wall components or colitis; and models of primary biliary epithelial and endothelial cell injury (Pollheimer and Fickert, 2015; Pollheimer et al., 2011). The $Abcb4^{-/-}$ KO mouse model is most appropriate for studying fibrosis (Delire et al., 2015).

3.1.1 The 3,5-Diethoxycarbonyl-1,4-Dihydrocollidine Diet Model

DDC is known to induce Mallory–Denk bodies, which are associated with cholestasis, ALD, and non-alcoholic steatohepatitis (NASH), in the hepatocytes of experimental animals (Fickert et al., 2002). DDC administration has also been proposed as a model of sclerosing cholangitis (Fickert et al., 2007). DDC-fed mice develop pericholangitis, periductal fibrosis, ductular reaction, and consequently portal–portal bridging fibrosis and segmental bile duct obstruction.

3.1.2 Abcb4$^{-/-}$ Mice

The *Abcb4* gene encodes phospholipid transporter multidrug resistant protein 2 (MDR2). $Abcb4^{-/-}$ mice

spontaneously develop cholangitis, ductular proliferation, onion skin–type periductal fibrosis, and portal inflammation and fibrosis (Fickert et al., 2004; Mauad et al., 1994; Pollheimer and Fickert, 2015). These features are most likely linked to the lack of biliary phospholipid secretion and consequently increased concentration of free nonmicellar-bound bile acids, which subsequently cause damage to bile duct epithelial cells (Halilbasic et al., 2009; Pollheimer and Fickert, 2015). This model reflects the histopathological characteristics of human PSC as well. However, it has the drawback that it is not complicated with UC or CC, but is complicated with hepatocellular neoplasia, which is rare in PSC patients (Pollheimer and Fickert, 2015).

3.1.3 Cftr$^{-/-}$ Mice

The histological features of the livers of PSC patients are similar to those observed in cystic fibrosis (Henckaerts et al., 2009). Durie et al. (2004) evaluated multiple organs of congenic C57BL/6J $Cftr^{-/-}$ mice and found that all the $Cftr^{-/-}$ animals showed progressive liver disease with hepatosteatosis, focal cholangitis, inspissated secretions, and bile duct proliferation; mice older than 1 year showed progression to focal biliary cirrhosis. In addition, a genetic analysis of PSC patients suggested that the CFTR gene might be implicated in the pathogenesis of PSC (Henckaerts et al., 2009).

3.2 Animal Models of Primary Biliary Cholangitis (Table 13.3)

Primary biliary cholangitis (PBC) is an autoimmune disease that is characterized by chronic nonsuppurative destructive cholangitis (CNSDC). It mainly occurs in middle-aged women, who are in their 40s or 50s. In PBC, interlobular bile ducts of less than 100 µm diameter gradually collapse and vanish; eventually, fibrosis around the portal tracts progresses, resulting in liver cirrhosis. Histologically, inflammatory cell infiltration, mainly by lymphocytes and plasma cells, is observed in

TABLE 13.3 Animal Models of Primary Biliary Cholangitis (PBC)

Animal models	Main features
NOD.c3c4 mice	NOD.c3c4 mice develop antibodies to PDC-E2 and histology like human PBC
	Extrahepatic biliary ducts are also affected unlike human PBC
	NOD.c3c4 mice develop biliary cysts that are not known in human PBC
dnTGF-βRII mice	These mice develop spontaneous production of AMAs
	Severe immunological abnormalities occur in multiple organs
	These mice have a relatively short life span
IL-2Rα$^{-/-}$ mice	These mice develop portal inflammation, biliary ductular damage, and AMAs
	These mice develop UC that are often seen in PSC, but not in PBC
	The life span is short
Ae2a,b$^{-/-}$ mice	Most *Ae2a,b$^{-/-}$* mice test positively for AMA
	The rate of mice showing histological features of PBC is low
	This mouse strain seems to be very difficult to breed
Scurfy mice	100% of scurfy mice exhibit high-titer serum AMA of all isotypes
	These mice have lymphocytic infiltrates surrounding portal areas
	These mice die as early as 16–25 days after birth
MRL/lpr mice	These mice have been used as a model for the study of SLE
	The target antigens of AMA are not PDC
	The rate of mice showing PBC-like pathology is rather low
2OA-immunized mice	High levels of AMAs are detected, and cholangitis and granulomas are observed
	Fibrosis occurs when these mice are exposed to α-GalCer
	Peritonitis occasionally occurs in association with intraperitoneal injection

AE2, Anion exchanger 2; AMA, antimitochondrial antigen; dnTGF-βRII, dominant-negative form of transforming growth factor beta receptor type II; α-GalCer, α-galactosylceramide; IL-2Rα, interleukin-2 receptor alpha; MRL/lpr, Murphy Roths large/lymphoproliferation; NOD, nonobese diabetic; 2OA, 2-octynoic acid; PDC, pyruvate dehydrogenase complex; PSC, primary sclerosing cholangitis; SLE, systemic lupus erythematosus; UC, ulcerative colitis.

portal tracts, and CNSDC and bile duct disappearance are observed to various degrees, often accompanied by epithelioid cell granulomas. The disease is classified into four stages: the florid duct lesion stage, the ductular proliferation stage, the precirrhosis stage, and the cirrhosis stage. Antimitochondrial antibodies (AMAs) that react with the pyruvate dehydrogenase complex (PDC), targeting the inner lipoyl domain of the E2 subunit (anti-PDC-E2), appear in the serum of almost all PBC patients (Liu et al., 2013).

Previously reported PDC-immunized mice, neonatally thymectomized mice, peripheral blood mononuclear cell administration, Murphy Roths large/lymphoproliferation (MRL/lpr) mice, and graft-versus-host-disease models are currently seldom used because they do not reflect the characteristics of human PBC sufficiently, or they require special technical skills. Newly introduced animal models of PBC can be roughly classified into spontaneous models and xenobiotic-immunized mice.

3.2.1 Spontaneous Mouse Models

3.2.1.1 NOD.c3c4 MICE

The NOD.c3c4 mouse, the first spontaneous mouse model of PBC, was generated by introgression of B6- and B10-derived insulin-dependent diabetes regions (idd loci) into a nonobese diabetic (NOD) mouse (Irie et al., 2006). NOD.c3c4 mice develop antibodies to PDC-E2 at 9–10 weeks. Histologically, lymphocytic and eosinophilic infiltration of portal tracts, destructive cholangitis, and granuloma formation are observed, as in human PBC patients. However, unlike in human PBC patients, in this model, extrahepatic biliary ducts are also affected. Furthermore, NOD.c3c4 mice develop biliary cysts, which are not known in human PBC (Moritoki et al., 2011; Nakagome et al., 2007).

3.2.1.2 dnTGF-βRII MICE

dnTGF-βRII mice are transgenic for directed expression of a dominant-negative form of transforming

growth factor (TGF)-β receptor type II under the direction of the CD4 promoter (Oertelt et al., 2006). These mice spontaneously produce AMAs, and histologically, lymphocytic liver infiltration with periportal inflammation is observed. Additionally, the serum cytokine profile of these mice mimics that found in human PBC. The main drawbacks of this model are that severe immunological abnormalities occur in multiple organs because of a defect in TGF-β signaling in T lymphocytes, and the mice have a relatively short life span (Tsuneyama et al., 2012). Colitis, which is not a characteristic feature of PBC but is a feature of PSC, occurs in these mice (Pollheimer and Fickert, 2015).

3.2.1.3 *IL-2R$\alpha$$^{-/-}$* MICE

Interleukin (IL)-2 is critical for the development and peripheral expansion of CD4(+)CD25(+) regulatory T cells, which promote self-tolerance by suppressing T-cell responses in vivo (Nelson, 2004). IL-2 receptor alpha (*IL-2Rα*)$^{-/-}$ mice develop portal inflammation (predominantly due to T cells) and biliary ductular damage similar to that found in human patients with PBC (Wakabayashi et al., 2006). Furthermore, *IL-2Rα*$^{-/-}$ mice develop AMAs with specificity for PDC-E2. The main drawbacks of this model are that the mice develop UC, which is often seen in PSC but not in PBC patients, and that their life span is short (Liu et al., 2013).

3.2.1.4 *Ae2a,b*$^{-/-}$ MICE

Cl^{-}/HCO$_3^{-}$ anion exchanger 2 (AE2) is involved in intracellular pH [pH(i)] regulation and transepithelial acid–base transport, including secretin-stimulated biliary bicarbonate excretion. *AE2* gene expression is reduced in liver biopsy specimens and blood mononuclear cells from patients with PBC (Medina et al., 1997; Melero et al., 2002; Pollheimer and Fickert, 2015). Accordingly, the suitability of *Ae2a,b*$^{-/-}$ mice as an animal model of PBC was determined (Salas et al., 2008). Most *Ae2a,b*$^{-/-}$ mice tested positive for AMA, and about one-third of the *Ae2a,b*$^{-/-}$ mice had extensive portal inflammation, with CD8+ and CD4+ T lymphocytes surrounding damaged bile ducts. Although the *Ae2a,b*$^{-/-}$ mouse model is considered useful for studying PBC, it has the drawback that the number of mice displaying the histological features of PBC is low. Moreover, this mouse strain seems to be very difficult to breed (Pollheimer and Fickert, 2015).

3.2.1.5 SCURFY MICE

Scurfy mice are those that have a mutation in the gene encoding the forkhead box 3 (Foxp3) transcription factor that results in a complete abolition of Foxp3(+) T regulatory cells. At 3–4 weeks of age, all scurfy mice exhibit high-titer serum AMA of all isotypes (Zhang et al., 2009). Furthermore, mice have moderate-to-severe lymphocytic infiltrates surrounding portal areas, with evidence of biliary duct damage, and dramatic elevation of cytokines in serum and messenger RNAs, which encode cytokines in liver tissue, including tumor necrosis factor (TNF)-α, interferon (IFN)-γ, IL-6, IL-12, and IL-23. Although the scurfy mouse model of PBC is interesting, it has the drawback that the mice die as early as 16–25 days after birth (Brunkow et al., 2001).

3.2.1.6 MRL/lpr MICE

MRL/lpr mice spontaneously develop lymphadenopathy, hypergammaglobulinemia, serum autoantibodies, and a generalized autoimmune disease, such as glomerulonephritis and arthritis, and have been used as a model for the study of systemic lupus erythematosus. Ohba et al. (2002) examined the suitability of MRL/lpr mice as an experimental autoimmune-mediated cholangitis model for PBC. They found that histopathologically, 24 of 47 (51%) older MRL/lpr mice showed evidence of cholangitis, compared with 2 of 20 (10%) younger MRL/lpr mice. In particular, epithelioid granuloma and/or bile duct loss were seen in 11 out of 47 (23%) older MRL/lpr mice, whereas such findings were seen in only 1 of 20 (5%) younger MRL/lpr mice. The target antigens of AMA were not the PDC, but the 2-oxoglutarate dehydrogenase complex and/or the branched-chain oxoacid dehydrogenase complex, as confirmed by immunoblotting. Currently, the MRL/lpr mouse model is seldom used to study PBC, mainly because the number of mice showing PBC-like pathology is rather low.

3.2.2 Chemical Xenobiotics–Immunized Mice

There is increasing evidence that environmental factors, such as bacterial infection and exposure to xenobiotics, are important in the pathogenesis of PBC. Wakabayashi et al. (2008, 2009) reported that C57BL/6 mice and NOD congenic strain 1101 (NOD.1101) mice that had been immunized with 2-octynoic acid (2OA) coupled to bovine serum albumin (BSA) showed pathological characteristics, similar to those found in human PBC. 2OA is a putative xenobiotic that is used as an additive for food and cosmetics. High levels of AMAs were detected in the animal models, and portal infiltrates enriched in CD8+ T lymphocytes, cholangitis, and liver granulomas were observed. Thereafter, it was reported that when the 2OA–BSA immunized mice were exposed to α-galactosylceramide (α-GalCer), an invariant natural killer T-cell activator, autoimmune cholangitis was exacerbated and fibrosis occurred (Wu et al., 2011). These models require simple techniques (intraperitoneal injection) and develop PBC-like pathological conditions with high reproducibility. However, it may be necessary to improve the method of administration because peritonitis occasionally occurs in association with intraperitoneal injection.

TABLE 13.4 Animal Models of Autoimmune Hepatitis (AIH)

Animal models	Main features
Con A hepatitis	Liver injury depends on the activation of T lymphocytes by macrophages
	Circulating autoantibodies are lacking
	Rapid hepatocyte damage occurs after a single-dose Con A injection
$TGF\text{-}\beta 1^{-/-}$ mice on BALB/c background	These mice develop a lethal necroinflammatory hepatitis
	Hepatitis is dependent on IFN-γ
	The mice usually die within a few weeks
NTx-$PD\text{-}1^{-/-}$ mice	These mice produce antinuclear antibodies and develop fatal hepatitis
	The hepatitis is characterized by CD4+ and CD8+ T-cell infiltration
	These mice usually die approximately 3 weeks after birth
Alb-HA/CL4-TCR mice	These mice spontaneously develop chronic autoimmune-mediated hepatitis
	Necroinflammatory lesions and hepatic fibrosis develop
	Hepatitis occurs only in males
Ad-2D6–infected mice	These mice develop persistent autoimmune liver disease
	Cellular infiltration, hepatic fibrosis, fused liver lobules, and necrosis are seen
	These mice generate type 1 liver kidney microsomal-like antibodies

Ad-2D6, Adenovirus expressing human CYP2D6; Alb-HA/CL4-TCR, albumin- hemagglutinin/CL4 T-cell receptor; Con A, concanavalin A; IFN, interferon; NTx-PD-1, neonatal thymectomy-programmed cell death 1; TGF-β1, transforming growth factor beta 1.

3.3 Animal Models of Autoimmune Hepatitis (Table 13.4)

Autoimmune hepatitis (AIH) is a chronic, active form of hepatitis that is associated with autoimmune mechanisms. Clinically, it occurs more commonly in women and is characterized by HLA-DR4, hypergammaglobulinemia, antinuclear antibody, antismooth muscle antibody, and the symptoms of chronic hepatitis. Histopathologically, it is characterized by lymphocyte and plasma cell infiltration of the portal tracts, interface hepatitis, and hepatocyte rosette formation in periportal areas. The difficulty in generating animal models of AIH exists in abolishing immune tolerance and maintaining the long-term immune alterations that are necessary for inducing chronic hepatitis.

3.3.1 Concanavalin A Hepatitis

Concanavalin A (Con A) is a plant lectin that is purified from jack beans. Con A binds to the mannose residues of various glycoproteins and activates lymphocytes. When Con A is administered to mice, liver injury that depends on the activation of T lymphocytes by macrophages occurs (Tiegs et al., 1992). Therefore, the model might allow the study of the pathophysiology of immunologically mediated hepatic disorders, such as AIH. TNF-α and IFN-γ play important roles in Con A–induced liver injury (Gantner et al., 1995; Kusters et al., 1996) and IL-10 prevents liver injury in this model (Di Marco et al., 1999; Louis et al., 1997). Blood levels of

IL-2, IL-4, and IFN-γ dramatically increase after administration of Con A (Wang et al., 2012). Major drawbacks of this model include the lack of circulating autoantibodies and rapid hepatocyte damage following a single-dose Con A injection, which is not a typical feature of chronic AIH (Liu et al., 2013).

3.3.2 BALB/c Strain TGF-β1$^{-/-}$ Mice

TGF-β1 exhibits various antiinflammatory activities and contributes to immune homeostasis and inhibition of autoimmunity. $TGF\text{-}\beta 1^{-/-}$ mice develop an excessive inflammatory response with massive infiltration of lymphocytes and macrophages into many organs (but primarily the heart and lungs), and they die when they are 3–4 weeks old (Kulkarni et al., 1993; Shull et al., 1992). BALB/c strain $TGF\text{-}\beta 1^{-/-}$ mice develop a lethal necroinflammatory hepatitis that is not observed in $TGF\text{-}\beta 1^{-/-}$ mice with a different genetic background (Gorham et al., 2001). This hepatitis is dependent on IFN-γ and epitomizes important aspects of AIH. The drawback of this model is that the mice usually die within a few weeks.

3.3.3 NTx-PD-1$^{-/-}$ Mice

Regulatory T cells regulate immunological tolerance. They play an important role in inhibiting excessive immunological response and maintaining immunological homeostasis. Kido et al. (2008) examined the regulatory roles of naturally arising regulatory T cells and programmed cell death 1 (PD-1)–mediated signaling

in the development of AIH. They subjected *PD-1*$^{-/-}$ mice to neonatal thymectomy (NTx), which severely reduces the number of regulatory T cells. As a result, the NTx-*PD-1*$^{-/-}$ mice produced antinuclear antibodies and developed fatal hepatitis characterized by CD4+ and CD8+ T-cell infiltration of the parenchyma with massive lobular necrosis. They concluded that the NTx-*PD-1*$^{-/-}$ mice could be used as the first model of spontaneous fatal AIH. However, these mice cannot be used in long-term experiments because they usually die of fulminant hepatic failure approximately 3 weeks after birth.

3.3.4 Alb-HA/CL4-TCR Mice

Zierden et al. (2010) generated transgenic mice expressing the influenza virus hemagglutinin (HA) autoantigen under the control of mouse albumin regulatory elements and α-fetoprotein enhancers (Alb) specifically in the liver (Alb-HA mice); the mice were crossed with mice that express a specific T-cell receptor (TCR) (CL4-TCR). As a result, the double-transgenic mice (Alb-HA/CL4-TCR) spontaneously developed chronic, autoimmune-mediated hepatitis characterized by necroinflammatory lesions, hepatic fibrosis, and increased levels of aminotransferase; these features resembled those of AIH. However, this model has the disadvantage that hepatitis occurs only in males.

3.3.5 Ad-2D6–Infected Mice

Cytochrome P450 2D6 (CYP2D6) is the major human autoantigen in type 2 AIH. Holdener et al. (2008) infected mice with adenovirus Ad5 expressing human CYP2D6 (Ad-2D6). As a result, Ad-2D6–infected mice

developed persistent autoimmune liver disease characterized by cellular infiltration, hepatic fibrosis, fused liver lobules, and necrosis. As with type 2 AIH patients, Ad-2D6–infected mice generated type 1 liver kidney microsomal-like antibodies that recognized the immunodominant epitope of CYP2D6. Interestingly, Ad-2D6–infected, wild-type FVB/N mice displayed exacerbated liver damage compared with transgenic mice expressing the identical human CYP2D6 protein in the liver, indicating the presence of a stronger immunological tolerance in CYP2D6 mice.

3.4 Animal Models of Alcoholic Liver Disease (Table 13.5)

ALD is a pathological condition of the liver that is caused by long-term (usually more than 5 years) and excessive alcohol consumption. Its symptoms, such as swelling of the liver and increased serum levels of aminotransferases and γ-glutamyl transpeptidase, are improved or normalized by abstinence from drinking. ALD is classified into alcoholic fatty liver, alcoholic hepatitis, alcoholic liver fibrosis, and alcoholic liver cirrhosis. To date, no animal model has been created that reflects all the features of ALD (Brandon-Warner et al., 2012; Mathews et al., 2014). In rodents, natural aversion to alcohol, absence of addictive behavior, spontaneous reduction in alcohol intake when acetaldehyde blood levels increase, a high rate of alcohol catabolism, and a high basal metabolic rate impair the ability to attain and maintain high blood alcohol levels over time; these factors explain the lack of hepatic damage (Brandon-Warner et al., 2012; Delire et al., 2015).

TABLE 13.5   Animal Models of Alcoholic Liver Disease (ALD)

Animal models	Main features
Acute binge ethanol–feeding model	The most commonly used dosage is 4–6 g/kg body weight
	This model affects hepatic mitochondrial function and oxidative stress
	This model induces only a mild elevation of serum AST and ALT levels
Liquid diet model	Animals are fed ethanol as part of a completely liquid diet
	This model is easy to use and causes fatty liver
	Severe inflammation, necrosis, and fibrosis of the liver do not develop
Intragastric ethanol infusion model	Severe and progressive fatty infiltration is observed in the liver
	Serum AST and ALT levels become markedly elevated
	This model requires advanced skills in catheter implantation
Chronic + binge ethanol–feeding model	This model induces liver injury, inflammation, and fatty liver
	This model reflects well a history of alcohol consumption in ALD patients
	This model is less time consuming compared to other models

ALT, Alanine aminotransferase; AST, aspartate aminotransferase.

3.4.1 Acute Binge Ethanol–Feeding Model

An acute binge of one or multiple doses of ethanol has been used by many laboratories to study the pathogenesis of alcoholic liver injury (Mathews et al., 2014; Shukla et al., 2013). The most commonly used dosage is 4–6 g ethanol/kg body weight, and acute feeding of ethanol has been shown to affect hepatic mitochondrial function, oxidative stress, and inflammatory responses. However, the acute binge ethanol–feeding model has not been used widely as an animal model of ALD, partly because it induces only mild elevation of serum aspartate aminotransferase (AST) and alanine aminotransferase (ALT) levels.

3.4.2 Liquid Diet Model

Ad libitum administration of alcohol in drinking water is the best and easiest way to emulate human behavior in experimental animals. However, rodents show a strong aversion to the taste and smell of ethanol. Due to this, in this method, the animals do not consume enough alcohol to produce significant liver pathology, even when using alcohol-preferring rodent strains (Liu et al., 2013). To overcome this, Lieber and DeCarli (1982, 1986) developed the technique of feeding ethanol as part of a totally liquid diet. This technique resulted in much higher ethanol intake than with conventional procedures, and it caused fatty liver. Moreover, the technique is simple. However, in this method, severe inflammation, necrosis, and fibrosis of the liver do not develop unless second hits of, for example, vitamin A are added (Leo and Lieber, 1983). Therefore, although this model may be appropriate for studying early-stage ALD, it is not useful for investigating the advanced disease.

3.4.3 Intragastric Ethanol Infusion Model (Tsukamoto–French Model)

As oral administration of alcohol does not induce liver injury that is more severe than fatty liver, Tsukamoto et al. (1985) developed an intragastric ethanol infusion model. In this model, a catheter was inserted into the stomach of each rat, and ethanol and a nutritionally defined low-fat liquid diet were infused continuously. As a result, blood alcohol levels were maintained at high levels, and severe and progressive fatty infiltration was observed in the liver. In addition, following 30 days of intoxication, one-third of the animals showed focal necrosis with mononuclear cell infiltration in the centrilobular areas of the livers. This was correlated with markedly elevated levels of serum AST and ALT in these animals. Dietary iron supplementation to the intragastric ethanol infusion exacerbated hepatocyte damage, promoted liver fibrogenesis, and produced evident cirrhosis in some rats (Tsukamoto et al., 1995). A high-fat (HF) diet in combination with this model also caused liver fibrosis (French et al., 1986). Later, Kono et al. (2000) adapted a long-term intragastric rat protocol to mice so that KO technology could be used to study the mechanisms of ALD. The main drawbacks of this model are that it requires constant monitoring and advanced skills in catheter insertion. However, it has the advantage that nutritional intake can be controlled accurately.

3.4.4 Chronic + Binge Ethanol–Feeding Model

Bertola et al. (2013a) developed a mouse model of alcoholic liver injury by chronic ethanol feeding (10-day ad libitum oral feeding with the Lieber–DeCarli ethanol liquid diet) plus single-binge ethanol feeding. This chronic plus single-binge ethanol–feeding protocol induces liver injury, inflammation, and fatty liver synergistically, which mimics acute-on-chronic alcohol liver injury in patients. This feeding protocol can also be extended to chronic feeding for longer periods (up to 8 weeks) plus single or multiple binges. The procedure upregulates the hepatic expression of IL-1β and TNF-α, and induces neutrophil accumulation in the liver (Bertola et al., 2013b). As ALD is often caused by recent heavy drinking on top of a chronic drinking habit, this model effectively reflects a history of alcohol consumption in ALD patients. Moreover, it is less time consuming compared with other conventional models.

3.5 Animal Models of Nonalcoholic Fatty Liver Disease (Table 13.6)

Like ALD, nonalcoholic fatty liver disease (NAFLD) is characterized by fatty liver, steatohepatitis, liver fibrosis, or liver cirrhosis, but it occurs in people who do not consume excessive quantities of alcohol. Obesity, diabetes, and dyslipidemia are important risk factors of the disease, and the resulting insulin resistance, fatty degeneration of the liver, and oxidative stress are thought to be involved in its pathogenesis. NAFLD is histopathologically classified into simple steatosis, which is just fat accumulation in the liver, and NASH, which comprises a necroinflammatory reaction and ballooning degeneration of hepatocytes, as well as steatosis. NASH is usually accompanied by fibrosis. The fibrosis usually begins as perisinusoidal fibrosis characterized by a chicken-wire pattern in zone 3, and portal fibrosis gradually develops, leading to portal–portal or portal–central bridging fibrosis (Takahashi and Fukusato, 2014). Long-standing NASH may progress to liver cirrhosis and HCC (Cohen et al., 2011; Harrison et al., 2003; Powell et al., 1990). NAFLD/NASH is currently the most common chronic liver disease in developed countries. Animal models of NAFLD/NASH are classified into genetic models, dietary models, and models combining genetic and nutritional factors.

TABLE 13.6   Animal Models of Nonalcoholic Fatty Liver Disease (NAFLD)

Animal models	Main features
Genetic models	
Ob/ob mice, db/db mice, and fa/fa rats	These animals have a mutation in the leptin or a leptin receptor gene
	The metabolic status of these animals reflects human NAFLD
	Neither hepatic inflammation nor hepatocellular damage occurs spontaneously
KK-A^y mice	These mice carry a heterozygous mutation of the agouti gene
	The metabolic status is similar to that of NAFLD patients
	Significant steatohepatitis does not occur spontaneously
PPARα$^{-/-}$ mice	Many genes encoding enzymes involved in β-oxidation are regulated by PPARα
	Fat does not accumulate in the liver of these mice under normal feeding condition
	Severe fat deposition occurs in the liver under fasting conditions
PTEN null mice	These mice show massive hepatomegaly and steatohepatitis
	These mice develop liver tumors (hepatocellular adenomas and carcinomas)
	These mice show insulin sensitivity
nSREBP-1c transgenic mice	Liver histology resembles human NASH
	These mice show disordered differentiation of adipose tissue
	The liver lesion might model steatohepatitis associated with lipodystrophy
AOX$^{-/-}$ mice	AOX is the first enzyme in the peroxisomal β-oxidation system
	Microvesicular fatty change in liver cells is evident at 7 days
	AOX$^{-/-}$ mice develop hepatocellular adenomas and carcinomas by 15 months of age
MAT1A null mice	These mice develop macrovesicular steatosis and mononuclear cell infiltration
	HCC develops
	Although these mice are hyperglycemic, their insulin levels are normal
TSOD mice	This model is regarded as a polygenic model of metabolic syndrome
	Liver tumors occur spontaneously
	The severity of steatosis and inflammation is mild
Dietary models	
MCD diet	MCD diet is easy to obtain and use
	This model induces more severe histopathology of NASH than other dietary models
	The metabolic profile is opposite to that in human NASH
HF diet	HF diet induces a metabolic profile that corresponds to NASH
	NAFLD/NASH induced by HF diet may be relatively mild and highly variable
	Administration of HF diet via an implanted gastrostomy tube effectively induces NASH
Atherogenic diet	Atherogenic diet containing cholesterol and cholate induces steatohepatitis
	The addition of a HF component accelerates the pathology of steatohepatitis
	Animals fed the atherogenic diet remain remarkably insulin sensitive
Fructose	Fructose consumption is a well-known risk factor for NAFLD
	A high-fructose diet induces macrovesicular steatosis and lobular inflammation
	Steatosis is mainly distributed in zone 1
Fast food diet	A fast food diet contains high levels of saturated fats, cholesterol, and fructose
	This model induces obesity and insulin resistance
	Histologically, steatohepatitis with ballooning and progressive fibrosis is observed

AOX, Acyl-CoA oxidase; HCC, hepatocellular carcinoma; HF, high fat; MAT1A, methionine adenosyltransferase-1A; MCD, methionine and choline deficient; NASH, nonalcoholic steatohepatitis; nSREBP-1c, nuclear sterol regulatory element–binding protein-1c; PPAR, peroxisome proliferator–activated receptor; PTEN, phosphatase and tensin homolog deleted on chromosome 10; TSOD, Tsumura–Suzuki obese diabetes.

3.5.1 Genetic Models

3.5.1.1 ob/ob MICE AND db/db MICE (OR fa/fa RATS)

Leptin is a satiety hormone synthesized by white adipose tissue; it regulates energy intake and expenditure. Ob/ob mice have a mutation in the gene that encodes leptin, and db/db mice and fa/fa rats have a mutation in the gene that encodes a leptin receptor (Ob-Rb) (Anstee and Goldin, 2006; Carmiel-Haggai et al., 2005; Lindstrom, 2007). Such animals are obese, hyperphagic, inactive, insulin resistant, and spontaneously develop hepatic steatosis and type 2 diabetes. Although the metabolic status of these animals reflects that found in human NAFLD, they do not spontaneously develop either hepatic inflammation or hepatocellular damage. One of the interesting features of ob/ob mice is that they are resistant to liver fibrosis even when CCl_4 or TAA is administered (Honda et al., 2002; Leclercq et al., 2002). This finding suggests that leptin is essential for hepatic fibrogenesis.

3.5.1.2 KK-A^y MICE

KK-A^y mice are a cross between diabetic KK and lethal yellow (A^y) mice, and carry a heterozygous mutation of the agouti gene (Liu et al., 2013). KK-A^y mice show altered adipokine expression, obesity, dyslipidemia, and insulin resistance; thus, their metabolic status is similar to that of NAFLD patients. Although KK-A^y mice develop mild hepatic steatosis, significant steatohepatitis does not occur spontaneously (Takahashi et al., 2012). KK-A^y mice exhibit increased susceptibility to methionine- and choline-deficient (MCD) diet–induced steatohepatitis, where hypoadiponectinemia probably plays a key role in the exacerbation of both inflammatory and profibrogenic responses (Ikejima et al., 2007; Okumura et al., 2006).

3.5.1.3 PPARα$^{-/-}$ MICE

Many genes encoding enzymes involved in the mitochondrial and peroxisomal fatty acid β-oxidation pathways in the liver are regulated by peroxisome proliferator–activated receptor α (PPARα) (Liu et al., 2013). Although fat does not accumulate in the livers of PPARα$^{-/-}$ mice under normal feeding conditions, under fasting conditions severe fat deposition occurs in the liver in association with dramatic inhibition of fatty acid uptake and oxidation (Kersten et al., 1999; Reddy, 2001).

3.5.1.4 PTEN NULL MICE

Phosphatase and tensin homolog deleted on chromosome 10 (PTEN) is a multifunctional phosphatase and tumor suppressor that serves as a negative regulator of several signaling pathways, including PI3K/Akt (Liu et al., 2013). Mice with a hepatocyte-specific null mutation of PTEN [AlbCrePten(flox/flox) mice] show massive hepatomegaly and steatohepatitis with triglyceride accumulation, a phenotype similar to that found in human

NASH (Horie et al., 2004). In one study, steatosis developed at 10 weeks of age, and steatohepatitis and fibrosis were present at 40 weeks of age. Importantly, the PTEN null mice developed liver tumors. By 44 weeks of age, 47% of the PTEN null mice had developed hepatocellular adenomas, and by 74–78 weeks of age, 100% of the PTEN null mice had hepatocellular adenomas and 66% had HCCs (Horie et al., 2004). Therefore, this model is considered suitable for studies on carcinogenesis associated with NASH. The main drawback of this model is that the mice retain insulin sensitivity, and therefore, their metabolic status is different from that of NAFLD patients.

3.5.1.5 nSREBP-1c TRANSGENIC MICE

Overexpression of the nuclear sterol regulatory element–binding protein-1c (nSREBP-1c) in cultured preadipocytes promotes adipocyte differentiation (Shimomura et al., 1998). nSREBP-1c transgenic mice develop marked fatty liver accompanied by hyperglycemia, hypoleptinemia, and hypoadiponectinemia (Nakayama et al., 2007). The liver histology in such mice is similar to that found in NASH, that is, steatosis, mononuclear cell infiltration, pericellular fibrosis, ballooning degeneration, and Mallory–Denk body formation are seen in the livers of these transgenic mice at 20 weeks or older. However, the mice show disordered differentiation of adipose tissue, marked insulin resistance, and diabetes mellitus; thus, the liver lesion might model steatohepatitis associated with lipodystrophy rather than normal NASH.

3.5.1.6 AOX$^{-/-}$ MICE

Acyl-CoA oxidase (AOX) is the first enzyme that is involved in the peroxisomal β-oxidation system. Mice deficient in fatty AOX (AOX$^{-/-}$ mice) develop specific morphological and molecular changes in the liver characterized by microvesicular fatty change, increased mitosis, spontaneous peroxisome proliferation, increased mRNA and protein levels of genes regulated by PPARα, and HCC (Cook et al., 2001). In AOX$^{-/-}$ mice, microvesicular fatty change in liver cells is evident at 7 days. At 2 months of age, livers show extensive steatosis and the presence in the periportal areas of clusters of hepatocytes with abundant granular eosinophilic cytoplasm rich in peroxisomes. However, a compensating increase in fatty acid oxidation is observed by 6–7 months of age, and hepatic steatosis recovers by the regeneration of hepatocytes. AOX$^{-/-}$ mice develop hepatocellular adenomas and HCCs by 15 months of age (London and George, 2007; Takahashi et al., 2012).

3.5.1.7 MAT1A NULL MICE

Methionine adenosyltransferase (MAT) 1A is a liver-specific enzyme that catalyzes the formation of S-adenosylmethionine, the principal biological methyl donor.

MAT1A KO mice are susceptible to choline-deficient diet–induced fatty liver at 3 months. At 8 months, *MAT1A* KO mice develop spontaneous macrovesicular steatosis and predominantly periportal mononuclear cell infiltration (Lu et al., 2001). HCC develops in more than half of the KO mice by 18 months of age (Martinez-Chantar et al., 2002). Although *MAT1A* KO mice are hyperglycemic, their insulin levels are normal and they do not appear to develop the other features of metabolic syndrome (Martinez-Chantar et al., 2002; Takahashi et al., 2012).

3.5.1.8 TSUMURA–SUZUKI OBESE DIABETES MICE

Tsumura–Suzuki obese diabetes (TSOD) male mice spontaneously develop diabetes mellitus, obesity, glucosuria, hyperglycemia, and hyperinsulinemia without any special treatments, such as gene manipulation. Therefore, TSOD is regarded as a polygenic model of metabolic syndrome. As NAFLD/NASH is associated with metabolic syndrome, Nishida et al. (2013) determined whether these mice develop NAFLD/NASH. They observed microvesicular steatosis, hepatocellular ballooning, and Mallory–Denk bodies in the livers of 4-month-old mice, with increasing severity over time. Interestingly, small liver nodules with high cellularity and the absence of portal tracts were frequently observed after 12 months. Most of the nodules showed nuclear and structural atypia, and mimicked human HCC. Recently, it has been suggested that splenic iron accumulation is involved in the development of NASH in TSOD mice (Murotomi et al., 2016). Although TSOD mice provide a natural model of NAFLD, the mice take a long time to develop the disorder, and the severity of steatosis and inflammation is mild.

3.5.2 Dietary Models

3.5.2.1 METHIONINE- AND CHOLINE-DEFICIENT DIET

MCD diet is a classical dietary model of NASH. Although the diet comprises high sucrose (40%) and fat (10%), it lacks methionine and choline, which are indispensable for hepatic mitochondrial β-oxidation and very low-density lipoprotein (VLDL) synthesis (Anstee and Goldin, 2006). As a result, an MCD diet induces hepatic steatosis. Furthermore, oxidative stress and changes in cytokines and adipocytokines occur, contributing to liver injury (Chowdhry et al., 2010; Larter et al., 2008; Leclercq et al., 2000; Takahashi et al., 2012). When animals are fed an MCD diet, they rapidly develop steatohepatitis; this is accompanied by pericellular fibrosis that appears as a chicken-wire pattern distributed mainly in zone 3, resembling that in human NASH (Fig. 13.1). In general, the MCD diet is easy to obtain and use, and it induces a more severe histopathology of NASH than other dietary models. The degree of liver injury induced by an MCD diet depends on the species, strain, and sex of the
FIGURE 13.1　**Histological appearance of the liver of a mouse that was fed an MCD diet.** Pericellular fibrosis can be seen in intralobular zone 3 *(arrow)* (Sirius red stain, ×400).

animal. Kirsch et al. (2003) examined the responses of male and female Wistar, Long-Evans, and Sprague Dawley rats and C57BL6 mice to an MCD diet. The Wistar strain and male sex were associated with the greatest degree of steatosis in rats. Of the groups studied, male C57BL6 mice developed the most inflammation and necrosis, lipid peroxidation, and ultrastructural injury, and most closely approximated the histological features of NASH. The main drawback of the MCD diet model is that its metabolic profile is opposite to that found in human NASH. Rats or mice that are fed an MCD diet show significant weight loss and decreased serum triglyceride and cholesterol levels. Serum levels of insulin, leptin, and glucose are also decreased; serum adiponectin remains unchanged or even increases; and the animals are peripherally insulin sensitive, although they exhibit hepatic insulin resistance (Leclercq et al., 2007; Liu et al., 2013; Rinella and Green, 2004). Therefore, caution is required when interpreting the results of experiments using this animal model.

3.5.2.2 HIGH-FAT DIET

A HF diet is widely used to induce NAFLD/NASH in various experimental animals. Lieber et al. (2004) fed a HF liquid diet (71% of energy from fat, 11% from carbohydrates, and 18% from protein) to Sprague Dawley rats and examined the effects. The rats fed the HF diet ad libitum for 3 weeks developed panlobular steatosis. The diet caused abnormal mitochondria and mononuclear inflammation. Plasma insulin was elevated, which reflected insulin resistance, a pathogenic characteristic of NASH. It has subsequently been reported that the HF diet induced a metabolic profile (obesity and insulin resistance), serum data (abnormal aminotransferase activity, hyperglycemia, hyperinsulinemia, hypercholesterolemia,

and hypertriglyceridemia), and histopathology (hepatic steatosis, necroinflammation, mitochondrial lesions, hepatocyte apoptosis, and pericentral fibrosis) that corresponded to NASH in experimental animals (Ito et al., 2007; Svegliati-Baroni et al., 2006; Zou et al., 2006). However, other authors have reported that a HF diet did not induce hepatic steatosis or NASH in experimental animals (Romestaing et al., 2007). NAFLD/NASH induced by a HF diet may be relatively mild and highly variable, and may be affected by the composition and duration of the HF diet and by the species, strain, sex, and age of the animals. In a comparison of the effects of a HF diet between mouse strains, BALB/c male mice accumulated more hepatic lipid than C57BL/6J male mice, and middle-aged C57BL/6J mice increased the ratio of fat to body weight and hepatic lipid accumulation more than young mice (Nishikawa et al., 2007). To induce NASH more certainly using the HF diet, Deng et al. (2005) fed a HF diet to mice via an implanted gastrostomy tube for 9 weeks and increased the intake by up to 85% of the standard amount. As a result, overfed C57BL/6 mice progressed to obesity, with 71% larger final body weights. They had increased visceral white adipose tissue, hyperglycemia, hyperinsulinemia, hyperleptinemia, glucose intolerance, and insulin resistance. Of these mice, 46% developed steatohepatitis with increased plasma ALT, neutrophilic infiltration, and sinusoidal and pericellular fibrosis. Although this method seems to be the most certain way to induce NASH using the HF diet, it has the disadvantage that it requires specific equipment and special techniques.

Recently, various modified methods using the HF diet have been tried. The products of lipid peroxidation from oxidized low-density lipoprotein (OxLDL) are known to initiate intracellular oxidative stress (Maziere et al., 2000). It has been reported that OxLDL administration to HF diet–fed mice not only aggravates hepatic steatosis, fibrosis, and lipid metabolism, but also results in intense inflammation, including severe hepatic injury and inflammatory cell infiltration, which are the typical histological features of NASH (Yimin et al., 2012).

Ogasawara et al. (2011) determined whether mice treated with gold thioglucose—known to induce lesions in the ventromedial hypothalamus, leading to hyperphagia and obesity—and fed a HF diet had a comprehensive histological and dysmetabolic phenotype resembling human NASH. They found that gold thioglucose + HF induced dysmetabolism, with hyperphagia; obesity with increased abdominal adiposity; insulin resistance and consequent steatohepatitis with hepatocyte ballooning; Mallory–Denk bodies; and perivenular and pericellular fibrosis, as seen in adult NASH.

Fujii et al. (2013) established a reproducible NASH-HCC model in mice by combining a HF diet and the administration of streptozotocin, a naturally occurring chemical that is toxic to the insulin-producing β-cells of the mammalian pancreas. Neonatal male mice exposed to low-dose streptozotocin developed liver steatosis with diabetes after 1 week on a HF diet. A continuous HF diet decreased hepatic fat deposits but increased lobular inflammation with foam cell–like macrophages, which resembled NASH pathology. In parallel with the decreased phagocytosis of macrophages, fibroblasts accumulated to form chicken-wire pattern fibrosis. All the mice developed multiple HCC at approximately 20 weeks of age. Although this is an unnatural model, it has the advantage that HCC associated with NASH develops rather quickly.

3.5.2.3 ATHEROGENIC DIET (CHOLESTEROL AND CHOLATE)

An increase in the level of serum triglycerides and cholesterol is a risk factor for NAFLD/NASH and cardiovascular diseases. An atherogenic diet containing cholesterol and cholate induces steatohepatitis in experimental animals. Such a diet increases blood levels of AST, ALT, lactate dehydrogenase, and total cholesterol, and from a histopathological perspective, steatosis, macrophage infiltration, cellular ballooning, hepatic necrosis, myofibroblast proliferation, and hepatic fibrosis are also induced (Jeong et al., 2005; Matsuzawa et al., 2007). In one study, the addition of a HF component to the atherogenic diet caused hepatic insulin resistance and further accelerated steatohepatitis (Matsuzawa et al., 2007). Interestingly, the cholesterol and cholate components of the atherogenic diet were shown to induce distinct stages of hepatic inflammatory gene expression (Vergnes et al., 2003). The drawback of this model is that animals given the atherogenic diet remain remarkably insulin sensitive, reflecting a different metabolic status than that found in human NASH (Delire et al., 2015; Matsuzawa et al., 2007).

3.5.2.4 FRUCTOSE

Fructose consumption is a well-known risk factor for NAFLD (Ouyang et al., 2008). We showed that a high-fructose (70%) diet induced macrovesicular steatosis and lobular inflammation in rat livers (Kawasaki et al., 2009). However in this model, steatosis was mainly distributed in zone 1, a different pattern from that found in adult NAFLD patients (Fig. 13.2). Spruss et al. (2009) examined the effects of fructose on *toll-like receptor (TLR)-4* mutant mice and wild-type mice, and suggested that the onset of fructose-induced NAFLD was associated with intestinal bacterial overgrowth and increased intestinal permeability, subsequently leading to an endotoxin-dependent activation of hepatic Kupffer cells. Combining risk factors for metabolic syndrome by feeding mice trans fats and high-fructose corn syrup induced a metabolic profile and histological features similar to those found in NASH
FIGURE 13.2　**NAFLD model of a mouse that was fed a high-fructose diet.** Steatosis, mainly distributed in zone 1 of hepatic lobules, was observed (×100). *C*, Central vein; *P*, portal tract.

patients (Tetri et al., 2008). Kohli et al. (2010) demonstrated that mice maintained on a HF, high-carbohydrate diet and water with 55% fructose and 45% sucrose (wt./vol.) became obese and experienced increased levels of hepatic reactive oxygen species and a NASH-like phenotype with significant fibrosis.

3.5.2.5 FAST FOOD DIET

Fast foods have high energy densities and glycemic loads, and are often served in excessively large portions; this may be one of the reasons for the increase in the number of overweight and obese people (Rosenheck, 2008). Charlton et al. (2011) examined the metabolic and histological effects of a fast food diet (high in saturated fats, cholesterol, and fructose). Mice that were fed fast food [40% energy as fat (12% saturated fatty acids and 2% cholesterol), supplemented with high levels of fructose] became obese and insulin resistant. Steatohepatitis with pronounced ballooning and progressive fibrosis (stage 2) was also observed in the mice. Therefore, it was suggested that a diet based on high levels of cholesterol, saturated fat, and fructose induces the features of metabolic syndrome and NASH with progressive fibrosis.

3.5.3 Combination Models (Genetic Modification Plus Dietary Manipulation)

Separate genetic and dietary models of NASH do not completely reflect all its pathological characteristics in humans. Therefore, numerous combination models, created by genetic and dietary manipulation, have been developed to more closely approximate the pathophysiology of human NASH. In general, these models show more severe histopathological changes and closer pathophysiology to human NASH than individual genetic or

dietary models. Some of the representative combination models are described here.

3.5.3.1 $LDLR^{-/-}$ MICE FED A HF DIET

The low-density lipoprotein receptor deficiency ($LDLR^{-/-}$) mouse is a widely used hypercholesterolemic atherosclerosis model. Gupte et al. (2010) showed that middle-aged male $LDLR^{-/-}$ mice fed a HF diet developed NASH associated with four of five metabolic syndrome components. As observed in humans, liver steatosis and oxidative stress promoted NASH development in these mice. Aging exacerbated the HF diet–induced NASH such that liver steatosis, inflammation, fibrosis, oxidative stress, and liver injury markers were greatly enhanced in middle-aged versus young $LDLR^{-/-}$ mice.

3.5.3.2 fa/fa RATS AND db/db MICE FED A HF DIET

Carmiel-Haggai et al. (2005) determined whether a HF diet can act as a second hit and cause progression to liver injury in obese fa/fa rats. Hyperglycemia and steatohepatitis occurred in the fa/fa rats fed the HF diet (60% calories as lard). This was accompanied by liver injury as assessed by ALT, hematoxylin and eosin staining, increased TNF-α and stellate cell–derived TGF-β, collagen deposition (periportal fibrosis), and upregulation of α-smooth muscle actin. Oxidative stress occurred in the fa/fa rats fed the HF diet because lipid peroxidation and protein carbonyl levels were elevated, whereas levels of glutathione and antioxidant enzymes were very low. We recently showed that db/db mice fed a HF diet develop the histopathology of NASH (Fig. 13.3) that is associated with increased serum levels of AST and ALT, although the metabolic status did not completely reflect that of human NASH (Takahashi et al., 2014).
FIGURE 13.3　**Liver histology of a db/db mouse that was fed an HF diet.** Marked steatosis and scattered foci of lobular inflammation *(arrows)* and ballooned hepatocytes were observed (×200).

3.5.3.3 Foz/foz MICE FED A HF DIET

Foz/foz mice have a mutation in the *Alms1* gene that plays a role in intracellular trafficking, and they exhibit obesity, hyperinsulinemia, and diabetes (Arsov et al., 2006b). Foz/foz mice fed a HF diet develop serum ALT elevation and severe steatohepatitis with hepatocyte ballooning, inflammation, and fibrosis (Arsov et al., 2006a).

3.5.3.4 db/db OR *PPARα*$^{-/-}$ MICE FED AN MCD DIET

Sahai et al. (2004) fed db/db, ob/ob, and control mice an MCD diet and found that the MCD diet–fed db/db mice exhibited significantly greater histological inflammation and higher serum ALT levels than the ob/ob and control mice. Trichrome staining showed marked pericellular fibrosis in the MCD diet–fed db/db mice but no significant fibrosis in the ob/ob or control mice. Moreover, it has been reported that MCD diet–fed *PPARα*$^{-/-}$ mice developed more severe steatohepatitis associated with significantly higher serum AST levels compared with MCD diet–fed wild-type mice (Ip et al., 2003; Kashireddy and Rao, 2004).

3.6 Animal Models of Hepatitis C (Table 13.7)

HCV is an RNA virus that belongs to the Flaviviridae family and infects humans via blood transfusion or injection using an unsterilized needle. The virus encodes one long open reading frame that generates a single polyprotein precursor, which is subsequently processed into 10 individual gene products, including structural (C, E1, E2, and p7) and nonstructural (NS2, NS3, NS4A, NS4B, NS5A, and NS5B) protein subunits (Liu et al., 2013; Moradpour et al., 2007). Unlike hepatitis A or hepatitis B, hepatitis C frequently develops from acute to chronic hepatitis, and furthermore, progresses to liver cirrhosis and HCC. Chimpanzees are one of the few animals that tolerate natural HCV infection. Therefore, the chimpanzee has provided a valuable model for the study of HCV–host interactions and vaccine candidates, but its use is severely hampered by financial and ethical constraints (Vercauteren et al., 2014). As mice are naturally resistant to HCV infection, development of mouse models of hepatitis C has been challenging. However, to date, various mouse models of hepatitis C have been developed using molecular or immunological techniques.

3.6.1 Inducible-HCV Transgenic Mice

To study in vivo interactions between viral proteins and host cells, various transgenic mice models that overexpress HCV proteins have been generated. Several kinds of transgenic mice expressing HCV proteins have not provided evidence of liver pathology (Frelin

TABLE 13.7   Animal Models of Hepatitis C

Animal models	Main features
Inducible-HCV transgenic mice	Transgenic mice carrying the HCV core gene develop hepatic steatosis and HCC
	These mice are immunotolerant of HCV proteins
	Immunotolerance can be overcome using the Cre/loxP system
Immunotolerized rat model	Fetal rats are tolerized in utero with hepatocytes
	The rats support HCV gene expression and viral replication, and develop hepatitis
	A genuine adaptive immune response toward HCV cannot be expected
Human liver chimeric Alb-uPA/SCID mice	Human hepatocytes repopulate the mouse liver in a very organized fashion
	These mice show immunodeficiency
	Breeding efficacy is low and the time window for transplantation is narrow
FRG mice	These mice can be highly engrafted with human hepatocytes
	Mutant breeders of FRG mice are fully viable
	Hepatocyte repopulation can be achieved at any stage
Immunocompetent HCV-permissive mouse models	Human hematopoietic stem cells and hepatocyte progenitors are cotransfected
	These mice become infected with HCV and generate an immune response
	Viral RNA detection is low and hepatocyte repopulation is relatively poor
Genetically humanized mouse models	Human occludin and CD81 genes are expressed in these mice
	HCV infection is allowed in fully immunocompetent inbred mice
	Innate and adaptive immune responses restrict HCV infection in vivo

FRG, *Fah*$^{-/-}$/*Rag2*$^{-/-}$/*Il2rg*$^{-/-}$; HCC, hepatocellular carcinoma; HCV, hepatitis C virus; SCID, severe combined immunodeficiency; uPA, urokinase-type plasminogen activator.

et al., 2006; Kawamura et al., 1997; Koike et al., 1995; Pasquinelli et al., 1997). However, transgenic mice carrying the HCV core gene developed hepatic steatosis and HCC (Moriya et al., 1997, 1998), and HCV core–E1-E2 transgenic mice were predisposed to liver tumors (Kamegaya et al., 2005).

Transgenic mice with constitutive expression of HCV proteins have several drawbacks, such as a random transgene integration site, its artificial expression, and the potential influence of the mouse genetic background. However, one of the largest problems is that such mice are immunotolerant of HCV proteins, and therefore do not develop an immune response to them. To overcome this limitation, Wakita et al. (1998) developed efficient conditional transgene activation of HCV cDNA (nucleotides 294–3435) in transgenic mice using the Cre/loxP system. Efficient recombination was observed in transgenic mouse livers upon intravenous administration of an adenovirus that expresses Cre DNA recombinase. The findings in these mice suggested that the HCV proteins were not directly cytopathic and that the host immune response played a pivotal role in HCV infection. Thus, this HCV cDNA transgenic mouse model provides a powerful tool for the investigation of the immune responses and pathogenesis of HCV infection. Using these mice, the same group revealed that HCV proteins suppressed Fas-mediated apoptotic cell death, suggesting that HCV may cause persistent infection as a result of suppression of Fas-mediated cell death (Machida et al., 2001). Thereafter, the same group established HCV transgenic mice that expressed the full HCV genome in B cells (RzCD19Cre mice) and observed a 25.0% incidence of diffuse large B-cell non-Hodgkin lymphomas (22.2% in males and 29.6% in females) within 600 days of birth (Kasama et al., 2010). In the original method, the expression of HCV proteins was regulated by the Cre/loxP system and an adenovirus vector that expressed Cre DNA recombinase (Cre) controlled by the CAG promoter (AxCANCre). However, it was demonstrated that AxCANCre injection alone resulted in severe liver injury by the induction of the adenovirus protein IX gene. As a result, HCV protein expression in transgenic mice livers was only short term. To overcome this problem, the same group developed a Cre-expressing adenovirus vector that bore the EF1α promoter (AxEFCre) to express HCV protein in the transgenic mouse livers, and indicated that use of AxEFCre efficiently promoted Cre-mediated DNA recombination in vivo without a severe hepatitis response to the adenovirus vector (Chiyo et al., 2011).

3.6.2 Xenograft Models

3.6.2.1 IMMUNOTOLERIZED RAT MODEL

This model is based on the fact that the rat immune system does not develop until 15–17 days after gestation.

If human hepatocytes are transplanted into a rat during this period, tolerization of an immunocompetent rat can facilitate the transplantation and survival of functional human hepatocytes (Ouyang et al., 2001). Applying this principle, Wu et al. (2005) established an immunocompetent rat model of HCV infection and hepatitis. Fetal rats were tolerized in utero with 10^5 Huh 7 cells (hepatoma cell line). One day after birth, the rats received 5×10^6 Huh 7 cells, and 1 week later they were inoculated with HCV genotype 1. As a result, the HCV-inoculated immunocompetent rats supported HCV gene expression and viral replication, and provided biochemical and histologic evidence of hepatitis. However, a genuine adaptive immune response toward HCV cannot be expected in this model because of a mismatch between the rat immune system and the human major histocompatibility complex on the transplanted Huh 7 cells. Therefore, this model is only useful for studying some details of HCV infection, such as the involvement of receptors and intracellular host factors (Liu et al., 2013; Wu et al., 2005).

3.6.2.2 HUMAN LIVER CHIMERIC Alb-uPA/SCID MICE

Effective replacement of the mouse liver by human hepatocytes has become possible owing to the development of transgenic mice that overexpress hepatotoxic urokinase-type plasminogen activator (uPA) (Sandgren et al., 1991). To allow transplanted human hepatocytes to proliferate effectively in the mouse liver, mouse hepatocytes need to be destroyed. uPA is a type of protease. When the uPA gene is integrated under the control of the albumin promoter, it is exclusively expressed in the liver of the mouse and causes liver injury. uPA/severe combined immunodeficiency (SCID) mice are generated by crossing uPA transgenic mice with immunodeficient SCID mice. In these mice, transplanted human hepatocytes are not rejected; they proliferate and replace mouse hepatocytes.

Applying this technique, Mercer et al. (2001) generated mice with chimeric human livers by transplanting normal human hepatocytes into SCID mice carrying a plasminogen activator transgene (Alb-uPA). Homozygosity of Alb-uPA was associated with significantly higher levels of human hepatocyte engraftment, and these mice developed prolonged HCV infections with high viral titers after inoculation with infected human serum. Human hepatocytes repopulate the mouse liver in a very organized fashion with preservation of normal cell function in Alb-uPA/SCID mice (Meuleman et al., 2005). Once human hepatocytes are stably transplanted to Alb-uPA/SCID mice, the livers of the mice can be infected by HCV, HBV, and other viruses that infect the human liver. This model has been very useful for the study of the basic aspects of HCV pathogenesis, the evaluation of passive immunization strategies, and the assessment of novel antiviral

therapies (Akazawa et al., 2013; Meuleman et al., 2008; Singaravelu et al., 2014). However, Alb-uPA/SCID mice show immunodeficiency. As liver injury from hepatitis C is mainly caused by the host's immune response to the infection, sufficient chronic liver injury does not occur in Alb-uPA/SCID mice. Therefore, this model is not suitable for studying immune responses to HCV and related chronic liver injury. Moreover, the breeding efficacy of the mice is low, the time window for transplantation is narrow because of preweaning mortality, and the efficacy of human hepatocyte engraftment can be highly variable (Liu et al., 2013; Tateno et al., 2004; Turrini et al., 2006; Vercauteren et al., 2014).

3.6.2.3 $Fah^{-/-}/Rag2^{-/-}/il2rg^{-/-}$ MICE

Fumarylacetoacetate (Fah) is a metabolic enzyme that catalyzes the last step of tyrosine catabolism. Fah-deficient mice exhibit hypoglycemia and liver dysfunction owing to the accumulation of metabolites that are toxic to the liver (Grompe et al., 1993). The recombination-activating gene 2 KO ($rag2^{-/-}$) mouse is depleted of mature B and T lymphocytes. The IL-2 receptor, common γ-chain KO ($il2rg^{-/-}$) mouse has impaired B- and T-cell development and a complete absence of natural killer (NK) cell development. A triple KO ($Fah^{-/-}/Rag2^{-/-}/Il2rg^{-/-}$ or FRG) mouse model was created and examined to determine whether it is a superior repopulation model (Azuma et al., 2007; Bissig et al., 2007). The mice could be highly engrafted (up to 90%) with human hepatocytes from multiple sources, including liver biopsies. FRG mice have higher rates of liver chimerism than Alb-uPA/SCID mice, and propagate both HBV and HCV (Bissig et al., 2010). In contrast to Alb-uPA/SCID mice, FRG mutant breeders are fully viable, and hepatocyte repopulation can be carried out at any stage (Liu et al., 2013). More recently, other humanized chimeric mouse models of HCV (e.g., MUP-uPA SCID/Bg mice and TK-NOG mice) have been developed (Kosaka et al., 2013; Tesfaye et al., 2013).

3.6.2.4 IMMUNOCOMPETENT HCV-PERMISSIVE MOUSE MODELS

One of the major drawbacks of the human liver chimeric mouse models mentioned earlier is that they have to be immune deficient to prevent rejection of the engrafted human hepatocytes. The development of immunocompetent animal models is indispensable for the study of hepatitis C immunopathology. Washburn et al. (2011) developed humanized mice with a human immune system and liver tissues. To promote engraftment of human hepatocytes, they expressed a fusion protein of the FK506-binding protein and caspase 8 under the control of the albumin promoter (AFC8); this fusion protein induces liver cell death in BALB/c Rag2$^{-/-}$ γC-null mice. Cotransfection of human CD34+ human hematopoietic stem cells (HSC) and hepatocyte progenitors into the transgenic mice led to the efficient engraftment of human leukocytes and hepatocytes. The researchers then infected those humanized mice (AFC8-hu HSC/Hep) with primary HCV isolates and studied HCV-induced immune responses and liver diseases. They reported that the mice became infected with HCV, generated a specific immune response against the virus, and developed liver diseases that included hepatitis and fibrosis. Although this animal model of hepatitis C that includes the human immune system is promising, it has several drawbacks: a limited ability to detect viral RNA, relatively poor hepatocyte repopulation, and the lack of an efficient antibody response due to incomplete B-cell function (Liu et al., 2013).

3.6.3 Genetically Humanized Mouse Models

Human occludin and CD81 are entry factors that are necessary for HCV infection of murine cells (Ploss et al., 2009). Dorner et al. (2011) showed that the expression of the human genes that encode those two protein was sufficient to allow HCV infection of fully immunocompetent inbred mice. Later, the same group demonstrated that transgenic mice stably expressing human CD81 and occludin supported HCV entry, but innate and adaptive immune responses restricted HCV infection in vivo (Dorner et al., 2013). Blunting antiviral immunity in genetically humanized mice infected with HCV resulted in measurable viremia over several weeks. More recently, Chen et al. (2014) reported that HCV accomplished its replication cycle, leading to sustained viremia and infectivity for more than 12 months postinfection, with the expected fibrotic and cirrhotic progression in transgenic ICR strain mice that harbored both human CD81 and occludin genes.

3.7 Animal Models of Hepatitis B (Table 13.8)

HBV is a DNA virus that belongs to the Hepadnaviridae family and infects humans via body fluids, such as blood, semen, and saliva. HBV comprises 42 nm–sized round particles called Dane particles that possess a hepatitis B surface antigen (HBsAg), which corresponds to the viral envelope. Two kinds of antigens [hepatitis B core antigen (HBcAg) and hepatitis B e antigen (HBeAg)] exist in the core part. When HBeAg is positive, infective capacity is strong. A characteristic infection route of HBV is infection of the infant from the mother via the placenta or the birth canal, whereby the infant becomes a HBV carrier. Some HBV carriers do not develop hepatitis (healthy carriers), but others develop chronic hepatitis. Acute hepatitis B rarely progresses to chronic hepatitis. Although the prophylaxis of hepatitis B has become possible owing to the development of vaccines, hepatitis B remains one of the main causes of liver cirrhosis and HCC.

TABLE 13.8　Animal Models of Hepatitis B

Animal models	Main features
Animals that permit HBV infection and HBV-associated viruses that infect animals	Chimpanzees and tree shrews permit HBV infection
	WHV infects *Marmota monax* and DHBV infects ducks
	These models are not homologous to HBV infection in humans
HBV transgenic mice	
Transgenic mice that express a part of HBV genes	The influence of specific regions of HBV genes can be studied
	HBV does not replicate
	HBV cccDNA is not produced
Transgenic mice in which HBV replicates	These mice express all HBV proteins
	HBV reinfection is not observed
	HBV cccDNA is not expressed
Mice with transferred HBV genes	A recombinant adenovirus vector or hydrodynamic injection is used
	Adenovirus vector itself causes liver injury and immune response
	HBV virions that are released to the blood do not infect other hepatocytes
Human hepatocyte chimera mice	
Trimera mice	Human blood cells or tissues are implanted in irradiated mice or rats
	Viremia peaks between days 18 and 25
	This model enables the short-term evaluation of antiviral effects of drugs
Models in which human hepatocytes are transplanted to immunodeficient mice	Immortalized hepatocytes transfected with a HBV genome are used
	Engrafted cells secrete HBV virions, and HBsAg is detected in plasma
	Production of immortalized hepatocytes is difficult and time consuming
uPA/SCID mice	High-level and long-standing viremia is observed
	The mice are immunodeficient
	Mice are expensive and maintenance costs are high

cccDNA, Covalently closed circular DNA; DHBV, duck hepatitis B virus; HBsAg, hepatitis B surface antigen; HBV, hepatitis B virus; SCID, severe combined immunodeficiency; uPA, urokinase-type plasminogen activator; WHV, woodchuck hepatitis virus.

HBV is an enveloped virus. The HBV genome comprises of a partially double-stranded DNA of ~3.2 kb that is organized into four open reading frames (Liu et al., 2013). The covalently closed circular DNA (cccDNA) serves as the template for both viral transcription and replication. Infection and replication of HBV is possible in chimpanzees, but their use has become impossible for ethical reasons. Small animal models, especially mice, are preferred because they are easy to manage. To date, various animal models of HBV have been developed.

3.7.1 Animals That Permit HBV Infection and HBV-Associated Viruses That Infect Animals

Animals that permit HBV infection are very limited, and the chimpanzee is the only complete animal model. However, the chimpanzee has been classified as an endangered species, and its use in experiments on infectious diseases has been prohibited for ethical reasons.

The tree shrew (*Tupaia belangeri*) also permits HBV infection (Baumert et al., 2005). It is closely related to monkeys and has been used in experiments on HBV and HCV infection. However, the infectious efficacy of HBV in tree shrews is not high, and only temporary and low-titer infection occurs. Moreover, persistent infection does not occur. Although they can be kept in animal experiment institutions, tree shrews are difficult to breed, and wild tree shrews are usually used in experiments.

Woodchuck HBV (woodchuck hepatitis virus: WHV), which infects *M. monax*, and duck HBV (duck hepatitis B virus: DHBV), which infects ducks, have been investigated because they are similar to HBV; they have been used for viral infection experiments, the elucidation of viral life cycles, and the development of antiviral drugs (Korba et al., 2004). In woodchucks, vertical transmission of WHV causes chronic infection with high frequency, and after several years of persistent infection, almost all animals develop liver cancer. Therefore, the WHV

model has been regarded similar to the persistent infection and viral carcinogenesis caused by HBV. However, these models are not homologous to HBV infection in humans, so animal experiments using HBV are required.

3.7.2 HBV Transgenic Mice

HBV does not infect mice. However, transgenic mice in which a part of the HBV genome or the whole of the 1.3-fold long HBV genome is incorporated are useful for studying the association between HBV genes and HBV replication or carcinogenicity. HBV transgenic mice do not develop liver injury owing to immunotolerance arising from the expression of HBV proteins from the time of birth. Adenovirus vectors or hydrodynamic injection is used to introduce HBV genes to mice after birth.

3.7.2.1 TRANSGENIC MICE THAT EXPRESS A PART OF THE HBV GENOME

Transgenic mice in which a part of HBV genome is incorporated have been developed to study the influences of specific regions of HBV genes on persistent infection, immunological modification, or carcinogenicity. Chisari et al. (1987) developed transgenic mice containing the entire HBV envelope-coding region and showed that they developed ground glass hepatocytes, focal hepatocellular degeneration and necrosis, lobular macrophagic inflammation, and increased serum aminotransferase activity. Thereafter, Koike et al. (1994) studied the development of liver tumors in male HBx gene transgenic mice, and suggested that the continued expression of the HBx gene might initiate a complex progression to HCC by inducing DNA synthesis and subjecting large numbers of hepatocytes to secondary transformation events.

3.7.2.2 TRANSGENIC MICE IN WHICH HBV REPLICATES

Araki et al. (1989) produced transgenic mice that expressed and replicated the hepatitis B virus genome, and Guidotti et al. (1995) produced HBV transgenic mice whose hepatocytes replicated the virus at levels comparable to those in the infected livers of patients with chronic hepatitis. HBV possesses incomplete double-stranded circular DNA. The more than 1.3-fold long HBV genome was incorporated into the transgenic mice; therefore, they express all HBV proteins. They do not have a special promoter to express the incorporated genes, thus the expression of HBV genes is characteristically high in the liver and kidney. These mice have been used to examine the effects of antiviral drugs (e.g., nucleoside/nucleotide analogs, IFNs) or new antiviral therapies (Dang et al., 2009). These transgenic mice are suitable for studying the mechanisms of HBV replication and its relationship with host immunity in the in vivo system. However, HBV reinfection is not observed in these mice, so intracellular entry and diffusion of HBV cannot be studied. Furthermore, HBV cccDNA, which is a template for HBV replication, is not expressed. Therefore, studies on the complete elimination or the half-life of HBV are impossible.

3.7.2.3 MICE WITH TRANSFERRED HBV GENES

To overcome the limitations of the transgenic mice mentioned earlier, several researchers have transferred HBV genes to uninfected mice. Representative methods of gene transfer include the use of a recombinant adenovirus vector and the use of hydrodynamic injection of a HBV plasmid.

3.7.2.3.1 TRANSFER OF HBV GENES USING A RECOMBINANT ADENOVIRUS VECTOR Sprinzl et al. (2001) showed that adenovirus-mediated genome transfer initiates efficient HBV replication in cultured liver cells and in the experimental animals from an extrachromosomal template. To transfer hepadnavirus genomes across the species barrier, they developed adenovirus vectors in which 1.3-fold overlength human and duck HBV genomes were inserted. The adenovirus-mediated genome transfer efficiently initiated hepadnavirus replication from an extrachromosomal template in established cell lines, in primary hepatocytes from various species, and in mouse livers. Following the transfer, HBV proteins, genomic RNA, and all replicative DNA intermediates were detected. In addition, infectious virions were secreted into the sera of mice.

In contrast to transgenic mice, HBV DNA is not incorporated into the host genome in this model. Therefore, immune system–mediated viral clearance or antiviral treatment can be studied using the model. In addition, the replication of various HBV mutants can be investigated. However, long-term persistence of infection is difficult to achieve by the method using an adenovirus vector. In addition, liver histopathology is modified by the vector because the adenovirus vector itself causes liver injury and immune response. Improvements to the vector and technique are required.

3.7.2.3.2 TRANSFER OF HBV GENES BY HYDRODYNAMIC INJECTION OF HBV DNA Hydrodynamic injection is used as a method of transferring HBV genes to mouse hepatocytes without using virus vectors and without causing immune responses. In this method, plasmid DNA in which the target gene is incorporated is injected rapidly and massively to the mouse via the caudal vein; the method was established for HBV by Yang et al. (2002). After transfection of hepatocytes in vivo with a replication-competent, overlength, linear HBV genome, viral antigens and replicative intermediates were synthesized and the virus was secreted into the blood. Viral antigens disappeared from the blood as early as 7 days after transfection, coincident with the appearance of antiviral antibodies. HBV transcripts and replicative intermediates

disappeared from the liver by day 15, after the appearance of antiviral CD8+ T cells. In contrast, the virus persisted for at least 81 days after transfection of NOD/SCID mice, which lack functional T cells, B cells, and NK cells.

Although the expression of HBV genes is transient, immunomodulation by a vector is not present; thus, this model is useful for the verification of antiviral drugs and antiviral therapies. Verification of HBV elimination by treatment is also possible. Moreover, mutant HBV virions can be observed. However, in gene transfer by a vector or a plasmid, HBV virions that are released to the blood do not infect other hepatocytes, although HBV replication occurs. Therefore, the effects of antiviral drugs may be overestimated. In these methods, HBV cccDNA is produced in mouse hepatocytes; however, its significance in HBV replication requires confirmation.

3.7.3 *Human Hepatocyte Chimera Mice*

Even though HBV genes are incorporated, reinfection by HBV does not occur as long as the hepatocytes originate from the mouse. As long as hepatocytes of mice are used, it is difficult to elucidate the life cycle of HBV. To develop antiviral drugs, the diminution rate of the virus and the frequency of the occurrence of mutant strains need to be determined; the HBV replication system in mouse hepatocytes is not suitable for this purpose. Human hepatocytes are needed to carry out experiments in which HBV replicates and virions are released to infect other hepatocytes. Chimera mice that carry transplanted human hepatocytes have been generated to establish an experimental system with human hepatocytes.

3.7.3.1 TRIMERA MICE

Trimera mice (or rats) are created by the implantation of human blood cells or tissues into lethally irradiated mice (or rats), radioprotected with SCID mouse bone marrow cells. Ilan et al. (1999) first developed a mouse trimera model for human HBV infection. In this model, viremia is induced by transplantation of ex vivo, HBV-infected human liver fragments. Engraftment of the human liver fragments, evaluated by hematoxylin and eosin staining and human serum albumin mRNA expression, is observed in 85% of the transplanted animals 1-month postimplantation. HBV DNA in the serum is first detected 8 days after liver transplantation. Viremia peaks between days 18 and 25 when HBV infection is observed in 85% of the transplanted animals. This model enables the short-term evaluation of the antiviral effects of drugs. A trimera model for HCV infection has also been developed (Ilan et al., 2002).

3.7.3.2 MODELS IN WHICH HUMAN HEPATOCYTES ARE TRANSPLANTED TO IMMUNODEFICIENT MICE

To develop a murine model for HBV production, Brown et al. (2000) established an immortalized, cloned liver cell line by transferring the Simian Virus 40 large T antigen into primary human hepatocytes. These cells were stably transfected with a full-length HBV genome to generate a clone that expresses HBV genes and replicates HBV. The HBV-producing cells were transplanted into the livers of mice with combined immunodeficiency (Rag2 deficient) by intrasplenic injection. As a result, determination of plasma HBV DNA levels indicated that engrafted cells secreted 3×10^7 to 3×10^8 virions/mL into the blood, and HBsAg was detected in the plasma.

However, the production of immortalized hepatocytes is difficult and time consuming. In some cases, HBV genes are incorporated into the genome of the mouse as in transgenic mice. HBV replication is restricted, although persistent infection is achieved. Furthermore, sufficient substitution by human hepatocytes is difficult to achieve because proliferation of transplanted human hepatocytes is restricted.

3.7.3.3 uPA/SCID MICE

The uPA/SCID mouse is a useful model for HCV and HBV infection. Using this mouse model, Tsuge et al. (2005) performed transmission experiments on HBV. Human serum containing HBV and the virus produced in HepG2 cell lines that have been transiently or stably transfected with 1.4 genome length HBV DNA were inoculated. As a result, a high-level viremia (approximately 10^{10} copies/mL) was observed in mice inoculated with HBV-positive human serum samples. High-level and long-standing viremia was also observed in mice injected with the in vitro–generated HBV. The viremia continued for up to 22 weeks until death or killing. Passage experiments showed that the serum of these mice contained infectious HBV.

This experimental system may be used to accurately evaluate the direct therapeutic effects of antiviral drugs because HBV replication and diffusion are achieved. This model is useful for developing antiviral drugs that directly act on HBV, such as nucleoside/nucleotide analogs. However, analyses of immunological conditions are difficult because the mice are immunodeficient. The death rate of transgenic mice with homozygous uPA is high. Moreover, a supply of human hepatocytes is difficult to obtain and the passage of mice is difficult. Therefore, chimera mice with human hepatocytes are expensive. The cost of equipment and maintenance is also high because aseptic manipulation is necessary when handling mice, the administration of complement inhibitors is necessary for the prevention of renal impairment, and the supplementation of vitamin C, which human hepatocytes cannot produce, is necessary. The chimera mouse is an animal model in which HBV reinfection occurs effectively and with which the life cycle of HBV may be elucidated. The adoption of this model will require reductions in the cost of equipment and management.

3.8 Animal Models of Other Infectious Diseases

Hepatitis D virus (HDV), also called hepatitis delta virus, is an RNA virus that only infects hosts infected with HBV, and causes exacerbation of hepatitis. The surface of HDV is covered by HBsAg. Hepatitis D is mainly seen in the Mediterranean region. Transgenic mice, mice with humanized livers, and gene-delivery vectors have been developed for HDV, as for HBV or HCV (Aldabe et al., 2015). Various animal models for hepatitis A and E have also been developed (Krawczynski et al., 2011; Purcell and Emerson, 2001; Yugo et al., 2014). Schistosomiasis is a parasite-transmitted disease that may cause liver cirrhosis and portal hypertension. Mice infected with *Schistosoma mansoni* or *Schistosoma japonicum* develop egg-related granulomas and liver fibrosis, and can serve as a model of hepatic fibrosis (Bartley et al., 2006; Dunn et al., 1977).

4 CONCLUSIONS

In this chapter, we reviewed animal models of various liver diseases with an emphasis on their advantages and drawbacks. Many animal models for various liver diseases have been developed by genetic manipulation or exposure to external substances. No animal model completely emulates the human disease. However, animal models are very useful for elucidating certain aspects of liver diseases, such as their pathogenesis and pathophysiology, and they enable the development of novel prophylaxis or treatments. Each animal model has advantages and drawbacks; therefore, it is important to choose the most suitable model for the purpose of the study.

Animal Models of Skin Regeneration

Barbara Gawronska-Kozak, Joanna Bukowska

Institute of Animal Reproduction and Food Research, Polish Academy of Sciences, Olsztyn, Poland

1 INTRODUCTION

Damaged, lost, or injured animal organs can be reconciled through regeneration or repair. While regeneration results in the original architecture and functionality, repair leads to fibrotic tissue accumulation that forms a scar. Although scar tissues allow for the recovery of the integrity of injured tissues, the postinjured organ never regains its full functionality. Regeneration, a phenomenon common for invertebrates, is limited to lower vertebrate classes, such as fish and amphibians. It seems that vertebrate regenerative capacity has decreased during phylogenetic development and is almost lost in birds and mammals.

Regeneration mechanisms in animals fall into two categories: morphallaxis and epimorphosis. Morphallaxis, characteristic for invertebrates (i.e., hydra) is considered to be dependent on the presence of a neoblast, the group of totipotent stem cells persisting in adult tissues that replace lost organs (Ogawa et al., 2002). Epimorphosis, characteristic for vertebrates, relies on the proliferative capacity of reprogrammed/dedifferentiated cells in the place of injury that form the blastema structure.

During the regeneration process, blastema cells differentiate into cells that restore missing tissues to fully recover lost or amputated organs (Kragl et al., 2009). The blastema structure has been examined during zebrafish fin regeneration (Poss et al., 2003), axolotl limb regeneration (Endo et al., 2004; Kragl et al., 2009), and even sporadically in mammals (Clark et al., 1998; Goss and Grimes, 1975; Seifert et al., 2012a). Through-and-through punch wounds made in the ears of rabbits (Goss and Grimes, 1975) and MRL/MpJ (Clark et al., 1998), nude (Gawronska-Kozak, 2004), and spiny mice (Seifert et al., 2012a) regenerate with the presence of blastema structures. Similarly, their presence has been analyzed during amputated digit tip regeneration in mice (Fernando et al., 2011).

There is another form of epimorphic regeneration that is blastemal-independent, which includes vertebrate skin regeneration (Seifert and Maden, 2014).

Skin is the largest organ and fulfills multiple key functions, acting as an environmental protection barrier, an immunological response system, and a neuroendocrine organ (Slominski et al., 2012). Mammalian skin is composed of two layers: the epidermis and dermis, which

are separated by a basement membrane. Stratified epidermis, the superficial part of the skin, is mainly composed from keratinocytes and forms basal, spinous, granular, and stratum corneum layers (Visscher and Narendran, 2014). Cellular components of the dermal part of the skin consist mainly of dermal fibroblasts, macrophages, and mast cells. Dermal fibroblasts are the predominant cells responsible for extracellular matrix (ECM) composition through the synthesis of collagen, elastin, glycoproteins, proteoglycans, and enzymes, such as matrix metalloproteinases (MMPs), which participate in its turnover during skin homeostasis and wound healing (Clark, 1996).

As the most outer barrier, skin is the organ most frequently exposed to external insults. During physiological maintenance, the epithelial layer undergoes continuous renovation in the process of regeneration similar to other mammalian tissues including cells in the gut epithelium, blood cells, and the annual replacement of antlers. Pathological events (i.e., injury) evoke a wound healing process that can take two directions: reparative (scar-forming) and regenerative (scar-free). In the skin, the spectrum of scar formation depends of trauma severity. Whereas injury that affects the epidermal layer of the skin heals in a scar-free way, full-thickness excisional wounds comprising the epidermis, dermis, and hypodermis heal with scarring. However, this is only true when epidermal injury is not associated with underlying metabolic disorders, such as diabetes.

Reparative skin wound healing consists of overlapping phases: inflammation, proliferation, and remodeling (Clark, 1996; Werner and Grose, 2003). Inflammation, preceded by hemostasis achieved through provisional matrix formation in the form of fibrin cloth, is characterized by the attraction of inflammatory cells, such as neutrophils and monocytes that subsequently differentiate into macrophages to the wound. Inflammatory cells fulfill their function through bacteria elimination (neutrophils) and phagocytosis of necrotic tissues and neutrophils (macrophages). Macrophages release cytokines [e.g., transforming growth factor β (TGFβ) and platelet-derived growth factor (PDGF)] that stimulate epithelial cell and fibroblast movement into the wound area beginning the next stage of the wound healing process (Table 14.1) (Bryan et al., 2005; Couper et al., 2008; Cowin et al., 1998; Hubner et al., 1996; Liechty et al., 2000; Satish and Kathju, 2010). Proliferation begins as migration and proliferation followed by differentiation of epidermal cells to reepithelialize the wound area to restore skin barrier function. Attracted dermal fibroblasts migrate to the wounded dermis, and together with invading through the process of angiogenesis the network of blood capillaries generates granulation tissues to reestablish dermal integrity (Clark, 1996). Initially, dermal fibroblasts synthesize and release the components of so-called

"embryonic" extracellular matrix, such as collagen III and extra-domain A (EDA) fibronectin followed by collagen type I, which is characteristic of adult skin (Bielefeld et al., 2013). A sufficient amount of ECM deposition, replacement of collagen III by collagen type I, and the presence of myofibroblasts in the postwounded bed initiate the remodeling phase (Table 14.1) (Cass et al., 1997; Hinz, 2007). Dermal fibroblasts acquire a myofibroblast phenotype to contract the wound bed, which is followed by scar formation. ECM remodeling is controlled by MMPs that degrade wound collagen (Table 14.1) (Madlener et al., 1998; Soo et al., 2000). The product of wound repair is a mature scar; however, the repaired tissues lack epidermal appendages, such as hair follicles and sweat and sebaceous glands, meaning they never regain the functional properties of uninjured tissues. Scar tissues are considered to block the regeneration process; therefore recognizing molecular signals and pathways that direct scarring versus regeneration is a prerequisite for understanding organ regeneration. Animal models for skin regeneration are an essential foundation for research in this area.

With the enormous increase in the understanding of stem cells, regenerative medicine is currently focused on the benefits from embryonic, adult, and induced pluripotent stem cell (iPS) usage (Takagi et al., 2016). In vitro and in vivo data indicate that there is a reciprocal bond/relationship between stem cells and the niches in which they exist. To fulfill the regenerative task, both the niche and stem cells have to cooperate. Since the regenerative phenomenon undoubtedly involving stem cells and their niche has been solved in nature, study of the naturally existing and genetically modified examples of regeneration will shed light on the molecular and cellular mechanisms that control the process (Hu et al., 2014b).

Here we will focus on animal models to study skin regeneration, with an emphasis on vertebrates.

2 SKIN HEALING IN LOWER VERTEBRATE (ANAMNIOTES) MODEL ORGANISMS

2.1 Fish

Cutaneous diseases and wounding are relatively more frequent among fish compared to terrestrial vertebrates due to their intimate contact with an aquatic environment (Groff, 2001). Both aquatic and terrestrial vertebrates share a similar pattern of the basic cellular organization of full-thickness skin. Striking differences between fish and mammalian skin include (1) greater average thickness of epidermis, (2) a lack of stratum corneum, (Guerra et al., 2006), and (3) reduced dermal layer in fish. Furthermore, mucus secretion is a specific

TABLE 14.1 Comparative Summary of the Differences in Skin Wound Healing Process Between Reparative (Scar-Forming) and Regenerative (Scar-Free) Mammalian Models

Skin wound healing stages	Skin wound healing in mammals			
	Reparative (scar forming)	Regenerative (scar-free)		
			Adults	
	Adults	Fetuses	*Acomys*	Nude
Inflammation	Massive inflammation; cytokines excess (Bryan et al., 2005; Cowin et al., 1998; Hubner et al., 1996), increased number of monocytes and macrophages, overexpression of IL-1 and IL-8, decrease of IL-10 (Couper et al., 2008; Liechty et al., 2000; Satish and Kathju, 2010)	Minimal inflammation, reduced cytokines response, low levels of PDGF, TGFβ1, TGFβ2, high levels of TGFβ3 (Barrientos et al., 2008; Hsu et al., 2001; Olutoye et al., 1996), reduced levels of neutrophils and macrophages (Adzick and Lorenz, 1994; Cowin et al., 1998), downregulation of IL-1 and IL-8, overexpression of IL-10 (Couper et al., 2008; Satish and Kathju, 2010)	Lack of F4/80 macrophages, reduced cytokines levels, neutropenic, high amount of mast cells (Brant et al., 2016)	Lack of T lymphocytes, low levels of PDGF and TGFβ1 (Gawronska-Kozak et al., 2006)
	Rapid overexpression of MMP-1, -2, -3, -8, -9, -10, -12, -13, -14, and TIMP-1, -2 at the initial phase of healing and then their gradual downregulation (Madlener et al., 1998; Soo et al., 2000)	Higher levels of MMPs and reduced expression of their inhibitors (TIMPs) (Dang et al., 2003a)	High levels of MMP-2 and MMP-9 and low of TIMP-1 (Brant et al., 2015, 2016)	Bimodal pattern of MMP-9 and MMP-13 high expression detected at inflammatory and remodeling phases of healing (Gawronska-Kozak, 2011; Gawronska-Kozak et al., 2006)
Proliferation	Reepithelialization of 4 mm wounds extended to 5–7 days after injury (Soo et al., 2000)	Accelerated reepithelialization of 2 mm excisional wounds completed 72 h after injury (Dang et al., 2003a)	Rapid reepithelialization of 4 mm wounds within 3 days postinjury (Hubner et al., 1996)	Complete wound closure observed between days 1 and 3 (Gawronska-Kozak, 2011)
	High levels of collagen I; densely arranged, parallel collagen fibers, oriented perpendicular to the wound surface; lower ratio of collagen type III to type I (Lo et al., 2012); delayed collagen deposition and fibroblasts migration at the wound site (Larson et al., 2010); granulation tissue formation starts at days 4–7 (Clark, 1996; Gawronska-Kozak, 2011)	High levels of collagen III; fine, well-organized reticular collagen bundles; higher ratio of collagen type III to type I (Lo et al., 2012); faster migration of fibroblasts, synchronous fibroblasts proliferation and collagen production (Larson et al., 2010)	Slow ECM deposition, domination of type III collagen, low levels of collagen type I, extended cell proliferation in the wound bed (Brant et al., 2016; Seifert et al., 2012a)	Granulation tissue formation starts at day 3; rapid collagen turnover (Gawronska-Kozak, 2011)
	Low levels of hyaluronic acid (HA) (Longaker et al., 1991)	Abundance of HA, rapid HA deposition and its maintenance during healing (Larson et al., 2010)	High levels of fibronectin and tenascin C (Seifert et al., 2012a)	High levels of HA in wound bed (Gawronska-Kozak et al., 2006)
	Increasement in decorin levels (Beanes et al., 2001); low synthesis of fibromodulin (Soo et al., 2000)	Decorin downregulation (Beanes et al., 2001), fibromodulin increment (Soo et al., 2000)		
	Slow synthesis of cell adhesion molecules after injury (Whitby and Ferguson, 1991)	Early expression of cell adhesion molecules (fibronectin, tenascin C) after injury (Whitby and Ferguson, 1991)		
	Presence of myofibroblasts (Clark, 1996; Hinz, 2007)	Controversial presence of myofibroblasts in the wound bed (Cass et al., 1997)	Lack of myofibroblasts (detected as αSMA positive cells) (Seifert et al., 2012a)	

E. SKIN

(Continued)

TABLE 14.1   Comparative Summary of the Differences in Skin Wound Healing Process Between Reparative (Scar-Forming) and Regenerative (Scar-Free) Mammalian Models (*cont.*)

	Skin wound healing in mammals			
Skin wound healing stages	Reparative (scar forming)	Regenerative (scar-free)		
			Adults	
	Adults	Fetuses	*Acomys*	Nude
Remodeling	Slow collagen deposition; collagen content in postinjured skin at day 36 does not regain levels observed in noninjured tissue (Gawronska-Kozak, 2011)	Reticular pattern of deposited collagen, indistinguishable from the surrounding uninjured tissue (Cuttle et al., 2005)	Collagen's porous architecture (Seifert et al., 2012a)	Accelerated stabilization of collagen content (day 21 after injury) (Gawronska-Kozak, 2011)
				Second wave of upregulated MMP-9 and MMP-13 expression localized to dermis (Gawronska-Kozak, 2011)

feature of fish skin. Among many different functions, epidermal mucus plays a protective role in the initial stage of wound healing, possibly favoring regeneration and acting as an antibacterial agent because of its hydrolytic activity.

Skin wound healing in both scaled and nonscaled fish occurs rapidly, and the skin is dynamically covered by mucus along with a reepithelialization process initiated from the wound margin within a few hours after injury (Quilhac and Sire, 1999). In scaled fishes, skin lesions are covered several hours after the injury by a thin layer of epithelial cells that overlie the dermis. In the scaleless carp *Cyprinus carpio* L. and African catfish *Clarias gariepinus*, complete wound closing occurs within 24 h (Guerra et al., 2008). Healing of African catfish skin first involves hemostatic and inflammatory responses that are activated shortly after injury (Guerra et al., 2008). In this species hemorrhagic clots are observed 3 h of skin excision, but the numbers of clots gradually decrease within 12 h. Next, sliding of the epidermal layer over the wound is observed, and regenerated epidermis is formed within 24 h. Thickness of the newly established epidermis on the third day is equal to that observed in normal skin. During healing, fusion of the migratory fronts is accompanied by inflammation that remains until day 3 of injury. Finally, the original wound borders are undetectable and perfectly mimic intact skin. Within a few weeks, a new scale with the size and characteristics of a mature scale is completely regrown (Ohira et al., 2007).

Zebrafish (*Danio rerio*) have been established as a central model organism for studying regeneration due to their ability to regenerate various organs (e.g., fin, jaw, heart) and the wide availability of molecular genetics tools. Only a few years ago, Richardson et al. (2013) demonstrated that skin wound healing in zebrafish involves regeneration rather than repair with absent or minimal scar forming. Laser-induced full-thickness skin wounds made on the flank of adult zebrafish healed without scars. Major steps of cutaneous wound healing are conserved between adult zebrafish and adult mammals (Richardson et al., 2013). Apart from external fibrin clot formation, all crucial steps of wound healing in mammalian skin also occur in adult zebrafish. In contrast to mammalian systems, zebrafish wound repair involves minimal or a lack of scarring for both superficial and deep partial-thickness wounds, indicating regeneration (Richardson et al., 2013). In contrast to mammals, reepithelialization precedes inflammation in zebrafish despite a massive inflammatory response. This sequence of events suggests that reepithelialization is independent of chemotactic signals released by macrophages. However, similarly to mammals, macrophages and neutrophils are present in the healing wound, so inflammation occurs earlier than granulation tissue formation and vascularization (Richardson et al., 2013).

Skin wound healing depends on several internal (i.e., blood and nerve supply) and external (i.e., environment temperature and contamination) factors. Based on studies carried out on scaleless fishes (*Rita rita*), there is relationship between skin thickness and wound reepithelialization, indicating that thinner skin regenerates slower (Mittal and Munshi, 1974). Scale regeneration in the goldfish *Carassius auratus* L. occurs most rapidly during the first 5 days after injury, then new tissue formation gradually decreases, and continuous linear growth occurs over 5–28 days (Ohira et al., 2007). Another relevant factor influencing wound healing in fish is water temperature. In *C. gariepinus*, rapid and effective wound healing is associated with high water temperature (30°C) that is close to its natural environment (35°C) (Guerra

et al., 2008). In contrast, an Antarctic fish, *Notothenia coriceps*, maintained at 0°C delays reepithelization process over the period of 7–14 days. The wound is completely closed after 23–30 days, but wounding scale formation is not observed even after 90 days and, intriguingly, scars composed of fibroblasts and collagen fibers are observed suggesting that low temperature discourages skin regeneration (Cunha da Silva et al., 2005). Studies by Vieira et al. (2011) on the sea bream *Sparus auratus* indicated the effect of food deprivation on scale regeneration. Microarray data revealed that in fasted animals, scale removal resulted in upregulation of genes involved in cell division/mitosis, cell growth, and metabolism (e.g., interleukin enhancer binding factor, phosphoserine aminotransferase, D-3-phosphoglycerate dehydrogenase), cell proliferation (e.g., macrophage-stimulating 1, hepatocyte growth factor-like), and cell signaling (e.g., inositol monophosphatase). Upregulation of GINS complex subunit 1 (PSF1 homolog) was observed both 3 and 7 days after scale removal (Vieira et al., 2011). This complex is involved in hematopoietic stem cell proliferation during bone regeneration in mammals (Ueno et al., 2009). The upregulation of its transcripts might indicate that in teleosts, the GINS complex regulates the process of skin regeneration by activating cell proliferation.

2.2 Amphibians

2.2.1 Urodele Amphibians: Ambystomatidae (Mole Salamanders) Axolotls

Axolotls are pioneering and exemplary animal to study limb regeneration (Kragl et al., 2009). After limb amputation, keratinocytes surrounding the wound migrate to cover wounded tissues during the first 24 h. Later on, the neoepidermis forms an apical epidermal cap (AEC); disrupting or preventing AEC formation abrogates limb regeneration (McCusker and Gardiner, 2011). This observation brought attention to the neoepidermis as a source of factors that direct cascade of followed events and turn attention into scar-free skin wound healing/regeneration study.

Detailed studies on amphibian skin response to wounding showed that excisional (1.5-mm diameter) wounds made on the tail skin of axolotl (*Ambystoma mexicanum*) reepithelialized over 8 h. Interestingly, the partial basement membrane regeneration was detected as late as 12–18 days postinjury, with full development at day 90 (Levesque et al., 2010). Completely regenerated skin tissues at day 90 were undistinguishable from normal, unwounded skin. The skin regeneration process in axolotl was accompanied by a low inflammatory response measured as the number of neutrophils in wounded skin and a small number of cells expressing α-smooth muscle actin (SMA) as a myofibroblast indicator. Low levels of αSMA-expressing cells were associated with low and transient

(days 1–4) expression of the profibrotic cytokine TGFβ1. However, the study showed that axolotls are capable of making fibrous tissues in both uninjured and injured skin after bleomycin injection. This indicates that axolotl tissues possess all of the factors required for the fibrous response. Nonetheless, the regenerative, nonfibrous pathway of skin injury resolution was activated (Levesque et al., 2010).

Other studies have examined skin wound healing in both aquatic (paedomorphs) and metamorphose-induced terrestrial axolotls (Seifert et al., 2012b). Although both forms of axolotls were able to regenerate skin wounds, a significant delay in the process was observed for metamorphs. Skin wounds (4-mm diameter) completely reepithelialized during 24 and 72 h for paedomorphs and metamorphs, respectively. Injury caused blood flow into the area, but scabs never formed. The relatively long delay in new extracellular matrix production/remodeling was detected with low levels of fibronectin and high levels of tenascin-C, indicating the formation of an antiscarring matrix. Analysis of MMP expression patterns (MMP3/10a, MMP3/10b, MMP9, MMP19, MMP28) showed strong upregulation during the first postwounded days; however, the surge of expression was higher for metamorphs. The authors suggest that sustained MMP activity during skin regeneration may control the timing of ECM deposition (Seifert et al., 2012b).

2.2.2 Anura Amphibians: Xenopus laevis

Unlike urodele amphibians, anurans' regenerative capacity depends on the life stage. To study the adult skin wound healing process, postmetamorphosed (8- and 15-month-old) *X. laevis* were selected (Bertolotti et al., 2013). Incisional wounds were made on the dorsal skin of the hind legs. Histological examination demonstrated typical overlapping phases for wound healing: inflammation, new tissue formation, and remodeling. The skin wound healing process in postmetamorphosed *X. laevis* revealed the occurrence of two healing processes: regeneration of the epidermis and repair of the dermis. The healed epidermis in both 8- and 15-month-old animals showed morphological appearances similar to the unwounded surroundings. Moreover, epidermal regeneration was associated with the restoration of exocrine glands (Bertolotti et al., 2013). However, differences were detected in the timing of wound closure (reepithelialization). A single layer of epithelial cells covered the wound at 1 and 3 days for younger (8-month-old) and older (15-month-old) animals, respectively. Dermis reparative healing involved granulation tissue formation characterized by intense angiogenesis and the presence of inflammatory cells (neutrophils, macrophages, lymphocytes), fibroblasts, and myofibroblasts. Granulation tissues were eventually replaced by dense, fibrous tissues forming scar-like tissues that were distinguishable from the surrounding uninjured dermis even after

several months (Bertolotti et al., 2013). On the contrary, excisional skin wounds in *Xenopus* froglets (very young adults) healed without scars (Yokoyama et al., 2011). Neoepidermis covered the postwounded area at 24 h, and the presence of exocrine glands within newly formed epidermis was detected at day 10.

Collectively these data indicate that skin regenerative capacity in anuran amphibians depends on the stage of development. It occurs before metamorphosis and in young adults (froglets), while older animals (8–15 months) only regenerate the epidermis (Bertolotti et al., 2013; Yokoyama et al., 2011).

3 SKIN HEALING IN HIGHER VERTEBRATE (AMNIOTES) MODEL ORGANISMS

3.1 Reptiles

The higher vertebrates reptiles, birds, and mammals share structural skin characteristics that enable their success in a terrestrial environment. Moreover, shelled eggs protected by amniotic membranes allow them to develop outside an aquatic environment. Unlike amphibians, they do not have an aquatic larval stage. Among amniotes, the most remarkable regenerative features are displayed by some lizards followed by autotomy or amputation of the tail (Delorme et al., 2012). Tail regeneration is preceded by scar-free skin healing, which seems to be essential for regeneration (Delorme et al., 2012). Lizard skin/integument consists of the epidermis, dermis, and hypodermis. The epidermis is divided into horizontal layers of stratum basale, stratum spinosum, stratum granulosum, and the outermost stratum corneum (Delorme et al., 2012). Immunohistochemical analysis of postamputated tail tissues revealed increased expression of PCNA (proliferating cell nuclear antigen) and WE6 (wound keratin marker) in proliferating wound epithelium, more MMP9-positive cells and fibroblasts in the blastema structure, and the presence of TGFβ3 in fibroblasts and chondrocytes (Delorme et al., 2012). Skin wound healing studies in reptiles (lizards) showed regionally different responses to injury (Wu et al., 2014). Complete skin restoration was detected at the amputated/regenerated tail as a process preceding tail regeneration but not at the wounded tail or trunk skin. Molecular data suggest that β-catenin and tenascin-C are involved in epidermal differentiation and regeneration, respectively (Wu et al., 2014).

3.2 Mammals

Generally, mammals heal skin injuries in a reparative (scar-forming) manner. There are only two natural and unique models of true postinjured skin regeneration among mammals: mammalian fetuses and *Acomys* (spiny mice).

3.2.1 Mammalian Fetuses

Mammalian fetal skin integrity after injury is restored through a process that preserves the architecture and function of injured skin and is characterized by an absence of scar formation as seen in adult wounds. This regenerative capacity seems to be limited to fetal skin since other organs, such as the fetal stomach and intestines heal with scarring. The phenomenon of postinjured skin regeneration in mammalian fetuses occurs up to the third trimester of gestation in sheep (Longaker et al., 1990), monkey (Lorenz et al., 1993), mouse (Whitby and Ferguson, 1991), rat (Ihara et al., 1990), rabbit (Somasundaram and Prathap, 1970), and human (Lorenz et al., 1992). Thereafter, skin incisions cause scar formation. The transition from scarless fetal-type repair to adult-type repair with scar occurs between days 16.5 and 18.5 of gestation for rats (Ihara et al., 1990), 100–120 days for sheep (Longaker et al., 1990), 100–107 days for Rhesus monkeys (Lorenz et al., 1993), and 24 weeks for humans (Lorenz et al., 1992). Initially regenerative skin healing in fetuses was attributed to the womb environment, but experiments showed that it is an intrinsic feature of fetal skin rather than the uterine environment. Injuries made in adult sheepskin that had been grafted onto fetal lambs and perfused with fetal blood healed with scars. Conversely, fetal marsupials that developed outside the uterine environment heal wounds scarlessly (Armstrong and Ferguson, 1995).

Postinjured fetal skin ECM composition differs significantly from that of adult skin ECM (Colwell et al., 2005). Fetal skin regenerative healing shows rapid and greater collagen accumulation compared to newborns and adults (Table 14.1) (Adzick et al., 1985). Although hypoxia generally leads to decreased hydroxyproline accumulation and fetuses are hypoxemic during normal development, more rapid collagen deposition has been observed during fetal skin wound healing (Larson et al., 2010; Lo et al., 2012; Longaker et al., 1990). Furthermore, the ratio between collagen III and I deposition are higher for fetuses than postinjured adult tissues. Moreover, collagen fiber deposition in postinjured fetal skin are formed in a reticular patter characteristic for uninjured tissues (Table 14.1) (Colwell et al., 2005; Cuttle et al., 2005). The ECM of fetal wounds is rich in hyaluronic acid (HA), which sustains longer than in adult wounds. MMPs and their tissue inhibitors (TIMPs) modulate the ECM during skin wound repair. The higher ratio of MMP to TIMP expression in regenerating mammalian fetus skin suggests rapid collagen degradation over collagen accumulation processes to prevent scar formation (Dang et al., 2003a). Specifically, increased expression of MMP9, the marker of limb regeneration in amphibians, has been detected during fetal skin regeneration (Table 14.1) (Peled et al., 2002).

The regenerative ability of fetal skin has been attributed to differences in the expression of growth factors (e.g., TGFβ, PDGF, VEGF, FGF) (Table 14.1). Among them, the TGFβ family shows substantial differences

in expression between fetal and adult skin (Walraven et al., 2014). Embryonic wounds are characterized by high levels of TGFβ3 (antiscarring) and low levels of TGFβ1 and TGFβ2 (proscarring) (Table 14.1) (Ferguson and O'Kane, 2004; Ferguson et al., 2009).

There are convincing data that the capacity for skin regeneration is probably inherent to fetal skin. Comparisons between uninjured adult and fetal skin revealed several differences (Table 14.1) (Beanes et al., 2001; Coolen et al., 2010). The expression profiles of keratin 17 (K17), involucrin, dermal Ki-67, fibronectin, and chondroitin sulfate were higher in human fetal than adult skin (Coolen et al., 2010). Microarray analysis of gene profile expression in cultured keratinocytes and dermal fibroblasts collected before and after scarless/scarring transition revealed 546 differently expressed genes (Hu et al., 2014a). Among 60 signaling pathways that are differently regulated, β-catenin-dependent Wnt pathways appear to be key regulators of embryonic wound healing (Hu et al., 2014a).

Although, the mechanisms that underline the scarless skin repair in fetuses are unknown, the phenomenon has been linked to the low or absent inflammatory response (Table 14.1) (Adzick and Lorenz, 1994; Barrientos et al., 2008; Hsu et al., 2001; Olutoye et al., 1996). For example, the introduction of inflammation into normally scarless wounds produces scars (Dang et al., 2003b). On the phylogenetic ladder, immune system complexity appears to relate reciprocally to the regenerative capacities in vertebrate species (Harty et al., 2003). High regenerative capacities in fish and amphibians are reduced in reptiles and nearly absent in birds and mammals (Brockes et al., 2001). This relationship seems to be repeated in mammalian ontogeny according to the recapitulation rule that ontogeny is a shortened version of phylogeny. Mammalian fetuses can regenerate/scarlessly heal skin incisions up to the third trimester of gestation, the time when mature, single-positive T lymphocytes appear. For example, in rats, CD4-/CD8+ and CD4+/CD8- cells are observed on fetal days 18–19 and 20–21, respectively (Vicente et al., 1998). Additionally, it has been demonstrated that diminished inflammation is a key feature of the privileged repair of oral mucosa (scarless) (Szpaderska et al., 2003).

Since fetal regenerative ability is common for all mammals, the spectrum for experimental choices seems great. However, short gestation periods, together with very short postoperative/experimental time for small animals and technically challenging surgical manipulation, impose some limitations. Large animals, such as pigs or sheep with longer intrauterine periods, are more approachable; however, fewer molecular tools and higher housing cost are limitations of these species. Besides fetal skin changes dramatically with development, making it is difficult to distinguish between ongoing developmental changes and skin wound healing processes.

3.2.2 Acomys

Although adult mammalian skin generally possesses very limited regenerative ability, some representatives of this class are not completely without regenerative talents. African spiny mice (Acomys) represent a unique example of skin regeneration in large full-thickness wounds and demonstrate a unique ability for skin autotomy in the class Mammalia (Seifert et al., 2012a).

Acomys species belong to the subfamily Deomynae, not Murinae, and while there are many phenotypic similarities between them and Mus musculus, phylogenetically this genus is more related to gerbils (Gerbillinae) than true mice (Chevret et al., 1993). The genus Acomys includes at least eight species of small rodents found exclusively in Africa (Chevret et al., 1993). Two recently intensively studied species Acomys percivali and Acomys kempi (Seifert et al., 2012a), are reported to be capable of skin autotomy due to weak skin that easily tears from the body, which is presumably an antipredator behavior.

Recent studies carried out by Seifert et al. (2012a) revealed that African spiny mouse skin is 20 times weaker than the skin of lab mice, and 77 times less energy is required to break it. Interestingly, cellular features of Acomys skin is anatomically comparable to that observed in other rodents and there is no sign of evidence of a fracture plane attributed to skin autotomy in some lizards (Bauer and Lamb, 2005; Sanggaard et al., 2012). Moreover, the abundance of elastin fibers responsible for skin elasticity is reported to be similar among M. musculus, A. percivali, and A. kempi. Apparently, the main difference in skin morphology between these rodents concerns the size of hair follicles, which is greater in spiny mice (55.61 ± 4.28%) compared to lab mice (43.65 ± 4.62%). Large hair follicles in Acomys reduce the total content of connective tissue, probably contributing to lower skin flexibility and reduced resistance to mechanical tension.

The regenerative responses of spiny mouse to 4-mm, 15-mm (Seifert et al., 2012a), and 8-mm (Brant et al., 2016) full-thickness skin wounds significantly differs from that of scarring M. musculus. In wounds of all investigated sizes made for spiny mice, scab formation and shedding was rapid and completed several days before lab mice. Large (15-mm) wounds reduced the area by 64 ± 3.1% within 24 h after injury, whereas small ones (4-mm) reepithelialized completely by day 3 after wounding, at a rate not observed in M. musculus. By day 10, Acomys wounds had looser vasculature networks and far fewer cells with the matrix (Brant et al., 2016). Moreover, the ECM was dominated by collagen type III, whereas collagen type I was more abundant in M. musculus. Collagen fibers were also less densely packed and contained more porous structures in Acomys (Table 14.1) (Seifert et al., 2012a), a finding that could explain the regenerative fashion of healing in this genus. Interestingly, newly regenerated hair follicles were observed in uncontracted areas of the wound bed (Seifert et al., 2012a; Brant et al., 2016), and

they expressed embryonic cytokeratins, Wnt, and BMP signaling pathway elements (Seifert et al., 2012a). By the end of third week, the wound beds in *Acomys* were deeply penetrated with new hair follicles and developing sebaceous glands (Brant et al., 2016). In addition, unlike *M. musculus*, the third spiny mice species *Acomys cahrinus* also demonstrated a remarkable capacity to repair full-thickness 4-mm circular punches in the ear; Santos et al. (2016) reported that these were completely closed within 2 months. Ear tissue regeneration involved, not only skin (epidermis, dermis) but also cartilage, adipose tissue, hair follicles, and sebaceous glands. Histological studies of dorsal skin and ear pinna regeneration in *Acomys* revealed similar features with blastemal formation, suggesting that enormous regenerative ability of skin might be associated with blastemal-like tissue formation (Seifert et al., 2012a).

Brant et al. (2016) reported that several fundamental immune differences distinguish wound healing of African spiny mice from *M. musculus*. First, *Acomys* are neutropenic, and there is vast decrease in the number of neutrophils (6.7%) in the blood compared to lab mice (32%). Second, in normal (unwounded) *Acomys* skin there was a 3.5-fold increase in mast cells per unit area compared to *Mus* skin (Table 14.1). Similar up regulation of mast cells was reported following wounding in spiny mice. Third, mature macrophages (detected by F4/80 antibody) were not detected in *Acomys* wounds, whereas in *Mus* they were present at all stages of healing. However, MOMA-2, another marker of monocytes/macrophages, exhibited similar distributions in both *Acomys* and *Mus*. The lack of macrophages in the wound bed reflects reduced levels (or even absence) of many cytokines typically present in skin wounds. As many as 18 cytokines present in *Mus* were undetectable in *Acomys* (e.g., GM-CSF, G-CSF, CXCL10-11, IL-2, -4, -6, TIMP), 5 were present at similar levels in both rodents (e.g., IL-1α, -1β), and only 1 chemokine (C–C motif) ligand 5 (RANTES) (Table 14.1) was upregulated in spiny mice (Brant et al., 2016). Both the immunodeficiency of selected cell types and the absence of proinflammatory factors favor regeneration over fibrosis, improve wound healing, and guide this process toward the regenerative route. Proteomic data (Brant et al., 2015) and microarray analysis (Brant et al., 2015) carried out on *Acomys* and *Mus* skin 3, 5, 7, and 14 days after wounding indicated a moderated immune response in spiny mice, low cytokine (e.g., IL-1β, IL-4) and chemokine gene expression, and significant upregulation of collagen types III and V (COL3a1, COL5a1, COL5a2) (Table 14.1) (Brant et al., 2015). Similar to fetal wounds, spiny mice had significantly higher levels of MMP2 and MMP9 and lower expression of TIMP1 compared to *Mus* (Table 14.1) (Brant et al., 2015). These data indicate that a low immune reaction together with peculiar ECM composition underlie scarless wound healing in *Acomys*, and there are many similarities to the process in mammal fetuses.

4 GENETIC MOUSE MODELS FOR REGENERATIVE SKIN WOUND HEALING (TRANSCRIPTION FACTORS IN SKIN DEVELOPMENT AND REGENERATION)

A growing number of studies based on genome-wide analysis of gene expression aims to disseminate group of transcription factors that are crucial in regulating/redirecting reparative versus regenerative skin healing. Followed studies conducted on genetically modified mice systematically uncover the signaling pathways that are differentially regulated during scarless and scar-forming skin healing. Particularly transcription factors that belong to the large families of *Fox* (forkhead box), *Hox* (homeobox), and *Ovol* genes appear to be involved in regenerative versus reparative skin healing regulation.

4.1 Fox (Forkhead Box) Transcription Factor Family

4.1.1 Foxn1-Deficient (Nude) Mice

The unusual ability of skin healing in nude mice, described as a "plastic surgeon's dream" was observed by Barbul et al. (1989) during their study of the role of T lymphocytes in wound healing. Nude mice owe their name due to a lack of visible hair. They are immunodeficient as a result of thymus and T-cell deficiencies. Nehls et al. (1994) showed that this pleiotropic phenotype is the result of a point mutation in the transcription factor Foxn1, which is expressed in epithelial cells both in the thymus and skin. The initial evidence that nude mice exhibit a unique regenerative capacity was determined based on their ability to display scarless healing following ear hole—punches injuries (Gawronska-Kozak, 2004). Subsequent studies showed that skin wound healing in nude mice display characteristic features of regeneration, namely a lack of scar tissue formation, significantly different from control mice (Gawronska-Kozak et al., 2006). The skin wound healing process is also accelerated in nude mice. Rapid reepithelialization in nude postinjured skin is followed by faster granulation tissue formation/resolution compared with control mice (Gawronska-Kozak, 2011). The collagen content in nude mouse skin at postinjured day 21 had recovered to levels measured before injury, whereas control mice did not regain collagen content until day 36 (Fig. 14.1; Table 14.1; Gawronska-Kozak, 2011). The hypothesis that collagen turnover is accelerated in nude mice was further supported by the unusual expression patterns of MMPs, particularly MMP-9 and MMP-13, and their tissue inhibitor, TIMP1
FIGURE 14.1 **Comparison of the magnitude and time span of wound healing phases between wild-type (scar-forming) and nude (scar-free) mice.** *ECM, Extracellular matrix. Source: Redrawn from Gawronska-Kozak, B., Grabowska, A., Kopcewicz, M., Kur, A., 2014. Animal models of skin regeneration. Reproduct. Biol. 14 (1), 61–67.*

(Gawronska-Kozak, 2011; Manuel and Gawronska-Kozak, 2006). The bimodal pattern of MMP-9 and MMP-13 in nude mice detected in the early and late (remodeling) healing phases was accompanied by low TIMP1 levels during the remodeling phase (Fig. 14.1, Table 14.1). Interestingly, MMP-9 expression during the first stage of wound healing is localized to the epidermis, whereas it was detected in dermal layer, particularly dermal fibroblasts, during the remodeling stage. A similar, bimodal array of MMPs expression was detected during limb regeneration in amphibians, and the authors associated it with antiscarring functionality (Vinarsky et al., 2005). The ECM of nude postinjured skin showed similarities with postinjured mammalian fetus skin with respect to high levels of HA and low levels of proscarring cytokines (TGFβ1 and PDGF), further supporting the regenerative ability of nude skin (Fig. 14.1, Table 14.1). Subsequent in vitro studies backed up in vivo data showing high expression of MMP-9 and MMP-13, as well as collagen types I and III, in nude mouse dermal fibroblasts, but not in controls fibroblasts (Gawronska-Kozak and Kirk-Ballard, 2013). Moreover, flow cytometric analysis of freshly isolated dermal fibroblasts showed that nude dermal fibroblasts express the stem cell markers CD117 and Oct3/4 (Gawronska-Kozak and Kirk-Ballard, 2013). To determine whether the regeneration phenotype of nude mice was associated with T-cell deficiency and/or lack of thymus, experiments were performed on several murine models of immunodeficiency: thymectomized young and adult mice, mice that lack T and B lymphocytes (SCID and Rag), and immunosuppressant-treated

mice (Gawronska-Kozak et al., 2006). The analysis of postinjured skin tissues showed an absence of scar tissue exclusively in nude mice. The study revealed that neither lack of the thymus nor T lymphocytes explains the regenerative phenotype in nude mice; although they do not exclude that an inflammatory response modulates skin wound healing. The nude phenotype in mice, rats, and humans is the consequence of Foxn1 inactivity. In the skin, Foxn1 expression was detected in the hair follicles and interfollicular epidermal cells where it localized to the first layer of supra-basal cells and to a few basal cells in the epidermis (Lee et al., 1999). In uninjured skin, Foxn1 appears to govern the balance between proliferation and differentiation, promoting keratinocyte differentiation; it stimulates signal transduction between melanocytes and keratinocytes and participates in hair follicle development (Lee et al., 1999; Weiner et al., 2014). Recent data showed that Foxn1-bearing cells participate in the wound healing process through engagement in reepithelialization and possible involvement in scar formation due to Foxn1 activity during the epithelial-to-mesenchymal transition (EMT) (Gawronska-Kozak et al., 2016). Collectively, the data point to Foxn1 as a regulator of the skin's regenerative capacity.

Next-generation high-throughput DNA sequencing analysis showed similarities in skin gene signatures between mice fetuses and adult Foxn1-deficient mice (unpublished data). Moreover, the data revealed that Foxn1-deficient skin shows changes in the expression of other transcription factors associated with skin wound healing including the Hox family, Foxo, and Ovol.

4.1.2 FOXO Transcription Factor Subfamily

The mammalian forkhead box O (FOXO) subfamily belongs to a large family of transcription factors characterized by a conserved DNA binding domain and consists of FOXO1, FOXO3A, FOXO4, and FOXO6 (Huang and Tindall, 2007). These proteins can regulate a huge variety of cellular processes (Accili and Arden, 2004; Barthel et al., 2005) including tissue repair (Lara-Pezzi et al., 2007; Snijders et al., 2009) and skin homeostasis (Roupe et al., 2010; Ponugoti et al., 2013; Mori et al., 2014; Zhang et al., 2015). Mori et al. (2014) indicated that in mice skin, both *Foxo1* and *Foxo3*a genes were up regulated days 3–7 after wounding, which is in agreement with a study carried out in a diabetic mice model (Siqueira et al., 2010). Moreover, Foxo1$^{+/-}$ mice exhibited many morphological and functional features indicating improving healing, including accelerated wound closure with enhanced keratinocyte migration, decreased granulation tissue formation, reduced densities of collagen types I and III, and reduced inflammatory responses at wound sites (Mori et al., 2014). In contrast, there are some reports that deletion of FOXO1 in keratinocytes significantly reduces the wound-healing rate (Ponugoti et al., 2013). Similarly, Zhang et al. (2015) demonstrated that normoglycemic transgenic mice with keratinocyte-specific Foxo1 deletion delays wound healing, whereas diabetic littermates exhibit improved skin repair. An in vitro study revealed reduced reepithelialization of "scratch" wounds under low glucose conditions in FOXO1-silenced cells, indicating that metabolic status is one of multiple factors contributing to wound healing. One of the primary mechanisms through which FOXO1 could enhance healing is upregulation of TGFβ1 and protection of keratinocytes from oxidative stress by regulating the expression of antioxidant genes and DNA repair enzymes (Ponugoti et al., 2013). In contrast, TNFα activates FOXO1 to impair the healing process in diabetic mice (Siqueira et al., 2010).

4.2 Homeobox Genes

Candidates for skin regenerative capacity include the homeobox genes, which can be divided into two large Hox and non-Hox families (Krumlauf, 1994). Homeodomain proteins are transcription factors that regulate tissue growth and development; they are involved in pattern formation during embryonic morphogenesis and organogenesis (Kessel and Gruss, 1990; Krumlauf, 1994) including skin development (Detmer et al., 1993; Stelnicki et al., 1997, 1998b). The various expression patterns of homeobox gene families define the regional identity of the skin (Yamaguchi et al., 2005).

4.2.1 Hox Gene Family

The *Hox* genes are arrayed in four genomic loci (A, B, C, D) and a variety of transcripts from each cluster have been reported in the epidermis of fetal (Detmer et al., 1993) and adult mouse (Bieberich et al., 1991) and human (Svingen and Tonissen, 2003) skin. Interestingly, higher Hox gene expression was observed in fetal versus adult skin and tended to be restricted to keratinocytes rather than dermal fibroblasts where they participate in both cell proliferation (Komuves et al., 2002) and differentiation (Tkatchenko et al., 2001). In human fetal skin downregulation of HoxB13 may affect scarless wound healing (Potter et al., 2011). This observation was supported by the HoxB13 KO mice wound model that exhibited several cellular (e.g., faster closure) and biochemical (e.g., higher HA levels) features of early gestational wounds (Mack et al., 2003). Different genetic approaches have documented that Hoxd3 (Uyeno et al., 2001) and Hoxd8 (Jain et al., 2008) are able to modulate cellular behavior during wound healing. Recent data revealed that Hoxc13-null mice and Foxn1 (nude)-deficient mice have similar defects of skin appendages. Furthermore, downregulation of *Foxn1* in the skin of Hoxc13-null mice accompanied by reduced keratin gene levels suggests the existence of a Hoxc13 regulatory network of hair shaft differentiation (Potter et al., 2011).

4.2.2 Non-Hox Gene Family

Studies carried out on adult human skin revealed that non-Hox genes (MSX-1, MSX-2, MOX-1) are dominant regulators of dermal layer functional features (Stelnicki et al., 1997). Similarly to Hox genes, such as Hox b13, the non-Hox representative Prx2 was shown to be highly expressed in fetal dermal fibroblasts and were further induced during fetal wounding, whereas this response was not observed in adult skin (Stelnicki et al., 1998a). Cultured fibroblasts derived from Prx2$^{-/-}$ mice revealed substantial changes in pro-MMP2 expression, increased HA production, and ECM reorganization in three-dimensional collagen discs (White et al., 2003).

The non-Hox genes Msx1 and Msx2 play key roles in the development of both skin (Stelnicki et al., 1997) and hair shafts (Cai et al., 2009; Ma et al., 2003) and are suggested to be strong regulators of tissue capacity to heal wounds (Carlson et al., 1998) and regenerate digit tips in mice (Han et al., 2003; Muneoka et al., 2008). A study by Yeh et al. (2009) of genetically modified mice revealed several features indicating that Msx2 regulates cellular competence during wound repair. Msx2 null mice exhibited faster reepithelialization and wound closure, earlier appearance of cell differentiation-related keratins (K10, K14), and increased expression of αSMA and tenascin-T in granulation tissue. Additionally, in vitro studies revealed faster migratory ability and enhanced collagen matrix contraction by Msx2 null keratinocytes compared to wild-type controls. Furthermore Msx2 mutation reduced the expression of Foxn1 and its target gene acidic

keratin mHa3 (Ma et al., 2003), and both transcription factors are required to maintain Notch1 expression in the hair follicle matrix (Cai et al., 2009).

4.3 Ovol Transcription Factor Family

The Ovol family constitutes evolutionarily conserved zinc-finger transcription factors among which two members Ovol1 and Ovol2 are reported to act downstream of key developmental pathways, such as Wnt, EGF, and BMP (Dai et al., 1998). Both factors are expressed in multiple somatic epithelial tissues, including skin and hair follicles. Ovol2 mRNA level increased from embryonic day E13.5 to 16.5 in mice (Lee et al., 2014). Ovol1- and Ovol2-null mouse models exhibit epithelial abnormalities, such as hyperproliferative epidermis, expansion of K1-positive cells (Nair et al., 2006), and death during midgestation (E10.5) (Mackay et al., 2006). Interestingly, genetic approaches revealed that Ovol2 provides a compensatory function for the loss of Ovol1 (Teng et al., 2007; Lee et al., 2014). Ovol1/Ovol2 epidermal-deficient mice lack proper cytoskeletal reestablishment, resulting in and defective terminal differentiation and alterations indicating EMT (Lee et al., 2014). Furthermore, the same study revealed that Ovol2 overexpression in the epidermal basal layer and outer root sheath reduces stem/progenitor cells in mice embryo skin.

5 CONCLUSIONS

This chapter provides an overview on vertebrate models for skin regeneration, showing that among all classes, there are wild-type examples of regenerative skin healing. For more than 30 years, only mammalian fetuses were thought to be capable of regenerative skin healing. Detailed studies yielded a great amount of knowledge of fetal wound repair/regeneration involving growth factors, cytokines, ECM, and other factors. Recent discoveries that *Acomys* and Foxn1-deficient mice are capable of skin scar-free healing indicate that adult mammals also possess the molecular machinery for regeneration. The skin scar-free healing characteristic of wild-living *Acomys* permits the study of naturally occurring regenerative susceptibilities. Foxn1, Ovol, and Foxo transgenic mice have focused attention onto transcription factors that may be modulated to redirect repair into regeneration. The comparison of global gene expression between reparative and regenerative models consistently shows that the greater number of down- versus upregulated genes in regenerative skin tissues supports the concept proposed by Mercer and coworkers; that is, the large number of downregulated genes suggests that the loss of their activity is involved in regeneration induction

and maintenance (Mercer et al., 2012). Moreover, comparison of the genetic profile of skin between mouse fetuses at the scar-free healing period to Foxn1 deficient mice showed similarities in transcriptional factor genes expression. Potentially, these transcription factors may be involved in directional skin wound healing resolution (Gawronska-Kozak, unpublished data). Determining whether fetal skin immaturity has an absence of particular transcriptional factors expression as observed for Foxn1- (Gawronska-Kozak, 2004, 2011; Gawronska-Kozak et al., 2006), Ovol1- (Teng et al., 2007), Msx2- (Yeh et al., 2009), and Foxo- (Mori et al., 2014) deficient mice is one of the road maps for creating an environment suitable for regeneration.

Animal Models of Skin Disorders

Jennifer Y. Zhang

Duke University Medical Center, Durham, NC, United States

1 INTRODUCTION

Skin covers an area of 1.5–2 m² and approximately 15% of body weight. It functions as an environmental sensor and the largest biological barrier that protects from dehydration and mechanical injury, excludes toxins and microbes, and participates in immune responses. The skin epidermis and its appendages, including hair and sebaceous and sweat glands, develop from a single layer of multipotent progenitor keratinocytes (Fuchs, 2007). The normal epidermis is comprised of multilayered and stratified epithelial cells that are organized in a polarized fashion through an integrated network of cytoskeletal elements and cellular junctions (Simpson et al., 2011). Yet, the epidermis ranks among the body's most dynamic tissues, undergoing life-long self-renewal through a tightly regulated balance of cell proliferation and terminal differentiation. Disruption of this balance, along with barrier defects, represents a central process of a myriad of skin diseases.

The outer most cornified layer of the epidermis is comprised of terminally differentiated keratinocytes also known as corneocytes, which lack a plasma membrane and are encased in a cornified envelope (CE) (Rice and Green, 1977). CE consists of keratins and a mixture of insoluble proteins, such as filaggrin (*fil*ament *aggre*gating prote*in)* and involucrin that are cross-linked by transglutaminases and surrounded by a lipid envelope. The lipid envelope, along with the natural moisturizing factors (NMFs) derived mostly from degradation products of filaggrin, is responsible for water retention by the skin (Imokawa et al., 1989; Rawlings and Harding, 2004). Defects in the cornification processes compromise the mechanical integrity and skin barrier function, and lead to increased sensitivity to environmental toxins and inflammation.

Human and animal skins exhibit substantial species-specific differences in tissue architect, spatial distribution of appendages and frequency of hair cycling, as well as immune responses and percutaneous drug penetration (Bartek et al., 1972; Porter, 2003). Relative to human skin, mouse skin has a dense distribution of hair follicles, thin epidermis, and an underlying cutaneous
FIGURE 15.1 **Histology of human and mouse skin sections.** (A) Adult human abdominal skin. (B) Three-month-old mouse back skin. The epidermis *(E)* is comprised of stratified epithelial cells, namely keratinocytes. The skin pigment cells (melanocytes) are located in the epidermis and hair follicle of human and mouse skins, respectively. The dermis *(D)* houses hair follicles *(H)*, blood vessels, nerve fibers, and various immune cells. Human body skin is populated with sweat glands, whereas mouse body skin is devoid of sweat glands and enriched with hair follicles. Human and mouse skin tissues are obtained in accordance to institutionally approved IRB and IACUC protocols, respectively.

muscle layer that is generally absent in humans (Fig. 15.1). Thus, it is important to keep in mind that no animal model can completely recapitulate all aspects of human dermatological diseases. Nonetheless, those that can partially recap varying aspects of human diseases are instrumental for mechanistic understanding and drug development. In recent years, there has been an exponential increase of a wide range of animal models reported in the literature spanning from mice, rats, rabbits, dogs, monkeys, and fishes (Avci et al., 2013). Murine models are by far the most commonly reported model system owing to a multitude of favorable properties, such as facile husbandry requirements, rapid breeding (19 days of gestation) and inbred capability. These traits together with the modern gene targeting tools enable the generation of strains with inheritable, spatially and temporally inducible gene mutations (Paigen, 2003). With the whole genome data available for mouse and human (Consortium, 2012; Yue et al., 2014),

the similarities and the differences between the two species are ever more clear, and should be carefully considered during data interpretation.

Environmental insults and genetic defects are the primary root causes of skin diseases. As such, animal models of human skin diseases generally involve one or more of the following techniques: (1) induction with environmental allergens, (2) epidermal tissue-targeted genetic engineering, which includes transgene expression driven by gene promoters specifically expressed in the skin, such as cytokeratin promoters (K5, K14, or K15), and Cre-loxP-mediated gene deletion or mutation facilitated by Cre or Cre-ER transgenes expressed under epidermal cytokeratin promoters (Vasioukhin et al., 1999), and (3) xenografting, including subcutaneous tumor inoculation and de novo skin regeneration with genetically modified human keratinocytes on immunodeficient mice. This chapter covers a few examples of numerous animal models that have been reported to

show a remarkable resemblance to human inflammatory skin diseases, genetic diseases, and cancer. Not surprisingly, some of these models show partial resemblance to multiple skin diseases.

2 INFLAMMATORY SKIN DISEASE ANIMAL MODELS

Atopic dermatitis (AD) and psoriasis are the two most common inflammatory skin diseases. Both AD and psoriasis are characterized with keratinocyte hyperproliferation and elevated infiltration of various immune cells. While there is no doubt that immune cells play critical roles during disease progression and culmination, keratinocytes, the forefront barrier cells, can function as potent disease instigators. As the chicken-or-egg debate unfolds, evidence from an increasing number of animal models supports unequivocal roles of both immune cells and keratinocytes in the pathogenesis.

2.1 Atopic Dermatitis

Atopic dermatitis (AD, OMIM 603165) is a chronic or relapsing inflammatory skin disease that affects 15%–30% of children and 2%–10% adults worldwide with a strong correlation with industrialization (Bieber, 2008). The typical features of AD include chronic inflammation, pruritic allergy, disruption of epidermal barrier function, increased immunoglobulin E (IgE) levels, and a dysregulated Th2-biased peripheral immune response (Akdis et al., 2003; Bieber, 2008; Boguniewicz and Leung, 2011; Hamid et al., 1996). The etiology of AD is rather complex involving environmental and genetic factors (Bieber, 2008). Accordingly, AD animal models frequently involve sensitization with environmental allergens, microorganisms, and targeted gene mutations.

2.1.1 Epicutaneous Sensitization and Elicitation With Allergens

Allergens exist in the environment and food in many different forms including chemicals and peptides. Allergen entry through a defective skin barrier is the basis of AD-mouse models induced by epicutaneous (EC) sensitization and elicitation. Some of the frequently used experimental allergens are 2,4-dinitrochlorobenzene (DNCB), ovalbumin (OVA), and house dust mite (HDM) extracts.

2.1.1.1 2,4-DINITROCHLOROBENZENE

DNCB is an organic compound with the formula $(O_2N)_2C_6H_3Cl$. It is an important intermediate for many other industrial products. Exposure to DNCB was initially found to induce AD-like symptoms in humans in the 1980s (White et al., 1986). It has since been reported in over 1000 articles for the induction of AD-like responses in animals for drug development and phenotypic analyses of genetic animal models. For AD-focused pharmacological studies, Nc/Nga mice are particularly favored as they are prone to the development spontaneous of AD-like lesions upon aging and exposure to environmental factors when compared to other strains, such as Balb/c (Suto et al., 1999). To do this, mice are treated with topical doses of 0.1%–1% DNCB on the ear, footpads, the shaved abdominal or back skins (Garrigue et al., 1994). Tape stripping is sometimes applied to the shaved skin to enhance local skin barrier defects. Pharmacological compounds may be delivered topically, systemically via injection or oral consumption before or during DNCB treatment. The principal readouts include: (1) clinical signs of dermatitis, including severity of edema, erosion, dryness, hemorrhage, and alopecia; (2) serum IgE titers; (3) ear or footpad thickness measurements; (4) histological analysis of the challenged skin samples; (5) profiling of immune cells isolated from the lymph nodes or skin samples; and (6) epidermal barrier function analyses, such as measurement of transepidermal water loss (TEWL). These data are often collected at 12, 24, 36, 48, and 72-h time-points after sensitization. Results may be compared between drug treated versus untreated animals or wild-type versus mutant mice.

2.1.1.2 HOUSE DUST MITES

HDM refers to a large number of dust dwelling mites including the American HDM, *Dermatophagoides farinae* Hughes, and the European HDM, *Dermatophagoides pteronyssinus*. HDM is a common household aeroallergen known to cause asthma, allergic rhinitis and AD. The indoor level of HDM is associated with the severity of skin lesions (Kim et al., 2013). The bioreactive molecules of HDM consist of proteins and endotoxins derived from the body and feces. Various HDM extracts have been used for diagnostic tests, immunotherapy, and the induction of AD-like lesions in mice (Thomas, 2012). Recently, several recombinant proteins including Derp 11, a protein highly homologous to paramyosins of mites, ticks, and other invertebrates, have been tested for the sensitization of AD-lesions. Interestingly, Derp 11 is characterized as a major allergen for AD patients, but a minor one for those suffering from respiratory forms of HDM allergy (Banerjee et al., 2015). To induce murine AD-like skin lesions, HDM whole body extracts (in mg ranges) or a recombinant protein solution (e.g., Derp 11, in microgram ranges) may be topically applied to the ears and upper back skins twice a week for several weeks. AD lesions are analyzed at the macroscopic, microscopic, and molecular levels using the same sets of readouts as described for DNCB (Moniaga et al., 2010).

2.1.1.3 OVALBUMIN

OVA is a chicken protein allergen mainly found in egg white. It is commonly used to sensitize immune reactions. Prolonged EC exposure to OVA leads to the development of an AD-like dermatitis characterized by markedly increased expressions of total and OVA-specific serum IgE levels and infiltration of CD3(+) T-cells, eosinophils and neutrophils, as well as increased mRNA levels of interleukin (IL)-4, IL-5, and IFNγ (Spergel et al., 1998). This treatment generally consists of up to 3 courses of 1-week-long bandage of an OVA-soaked gauze (100 μg in 100 μL saline) to the back skins of mice. Each course is followed by 2-week-long breaks. Alternatively, mice may be sensitized via systemic administration of OVA (1 μg in 1 μL saline plus 1 μL adjuvant Imject Alum) prior to local challenges with EC OVA, which is shown to augment local sensitization of Balb/c mice to an acute Th2-polarized AD-like phenotype (Yoo et al., 2014).

2.1.1.4 *Staphylococcus aureus*

Human skin is colonized by vast numbers of bacterial communities that are distributed over the entire body with spatial and temporal specificities (Grice et al., 2009). Temporal microbial shifts (or dysbiosis) are associated with human diseases. Specifically, AD skin is disproportionally colonized with *S. aureus* (Leyden et al., 1974), and such a reduction of microbial diversity correlates with AD severity (Kong et al., 2012). Inhibition of *S. aureus* growth with antibiotics and sodium hypochlorite (bleach) baths improves eczema severity (Huang et al., 2009), implicating a contributing role of *S. aureus in disease progression.* Dysbiosis is also detected in mice that develop spontaneous AD-like lesions, as recently reported in an animal model generated to model ADAM metallopeptidase domain 17 (ADAM17)-deficiency in human, namely *Adam17(fl/fl).Sox9-Cre* mice (Kobayashi et al., 2015). ADAM17, also called TACE [tumor necrosis factor-α (TNFα)-converting enzyme], is induced by *S. aureus* protein A, and is important for the activation of TNFα and EGFR family ligands (Gomez et al., 2007). During the onset of on eczematous dermatitis, different strains of bacteria, including *Corynebacterium mastitides, S. aureus, and Corynebacterium bovis*, sequentially dominated the skin of *Adam17(fl/fl).Sox9-Cre* mice. Administration of antibiotics specific for these bacterial species reversed dysbiosis and eliminated skin inflammation. Further analysis showed that, while *S. aureus* prominently drove eczema formation, *C. bovis* induced robust T-helper 2 cell responses, indicating that dysbiotic flora have differential contributions to eczema formation (Kobayashi et al., 2015).

While the debate as to whether dysbiosis is a cause or a consequence of AD in patients unfolds; a causal effect is further supported by the evidence that *S. aureus* can enter epidermis of human skin equivalents and mice skin.

Bacteria entry past the epidermis is markedly increased in mice with epidermal barrier defects (e.g., *Cathelicidin* knockout and OVA-sensitized *filaggrin* mutant mice), and triggers increased expression of IL-4, IL-13, IL-22, thymic stromal lymphopoietin (TSLP), and other cytokines associated with AD (Nakatsuji et al., 2016). Taken together, *S. aureus*-induced AD-like lesions have clinical relevance in both human and mice. To induce AD-like lesions on mice with *S. aureus*, the dorsal skins of mice are typically shaved and disinfected with alcohol swaps. An agar disk (6 mm) containing *S. aureus* (ATCC35556 or MRSA USA300 LAC strains, 1×10^6 CFU) is then applied on the shaved area and kept in place with wound dressing film for 20 h.

2.1.2 *Genetic AD Animal Models*

Genetic linkage and protein expression studies have implicated over 100 genes with AD association (Boguniewicz and Leung, 2011). About 20% of them have been verified to show AD association by independent studies (Barnes, 2010). These genes encode proteins involved in (1) skin barrier function, (2) cell death and inflammatory responses, (3) lipid metabolism, and (4) innate and adaptive immune responses. As such, genetic AD mouse models reported so far generally involve epidermis-targeted loss-of-function mutation of genes important for skin barrier function or skin-specific keratin 5 or 14 promoter (K5 or K14)-driven transgene expression of inflammatory molecules.

2.1.2.1 FLAKY TAIL MICE

Filaggrin (*FLG)* encodes a filament-aggregating protein that promotes condensation of the keratin cytoskeleton and consequently the cell compaction process essential for squame biogenesis and epidermal barrier formation (Sandilands et al., 2009). It is by far the most well-characterized and prevalent AD susceptibility gene whose loss-of-function mutations are carried by up to 10% of the population worldwide (Palmer et al., 2006; Sandilands et al., 2007; Smith et al., 2006). These mutations represent a strong genetic predisposing factor for AD, asthma and allergies, as well as ichthyosis vulgaris, a common skin condition characterized by dry, scaly skin (Sandilands et al., 2007). The spontaneous flaky tail mouse contains a homozygous frameshift mutation in the murine *Flg* gene, resulting in expression of a truncated filaggrin protein (Fallon et al., 2009; Presland et al., 2000). These mutant mice exhibit a dry and flaky skin with annular tail and paw constrictions in the neonatal period. Topical application of the allergen OVA to the shaved abdominal skin of the flaky mice results in increased TEWL, cutaneous inflammatory infiltrates, and the development of allergen-specific IgG and IgE responses that resemble human AD.

2.1.2.2 INVOLUCRIN, ENVOPLAKIN, AND PERIPLAKIN KNOCKOUT MICE

Involucrin, a terminal differentiation marker, along with the plakin family desmosomal protein envoplakin and periplakin (Jefferson et al., 2004), forms the protein scaffold on which the CE assembles. Remarkably, mice with single or double knockouts (KO) of these genes are viable and fertile with no overt phenotypic abnormalities (Aho et al., 2004; Djian et al., 2000; Maatta et al., 2001; Sevilla et al., 2007). However, the triple KO mice develop a striking phenotype of dry and flaky skin over the entire body surface by a few days after birth. Their skins show delayed embryonic barrier formation and postnatal hyperkeratosis (abnormal accumulation of cornified cells) resulting from impaired desquamation. Their CEs are ultrastructurally abnormal, with reduced lipid content and defective filaggrin processing and degradation of desmoglein 1 and corneodesmosin. There is an elevated infiltration of CD4+ T-cells and a reduction in resident γδ+T-cells, reminiscent of AD. Thus, combined loss of the CE proteins impairs the epidermal barrier, and induces AD-like lesions (Sevilla et al., 2007).

2.1.2.3 CLAUDIN-1 MUTANT MICE

Claudins are adhesion molecules critical for the formation of tight junctions (TJ) and the barrier function of both simple and stratified epithelia. Claudin-1 (CLDN1) is commonly reduced in AD skin. Claudin-1-null ($Cldn1^{-/-}$) mice displayed postnatal lethality with wrinkled skin accompanied by excessive TEWL (Furuse et al., 2002). The lethality problem was eliminated in mice engineered to express varying levels of Claudin-1, which was achieved via insertion of a Neomycin selection maker in front of exon 1 (Δ) and crossbreeding of ($Cldn1^{Δ/+}$) mice with $Cldn1^{+/-}$ mice. The $Cldn1^{Δ/-}$ mice have a normal life expectancy, but exhibit morphological features of AD and an innate immune response characterized by neutrophil and macrophage recruitment to the skin (Tokumasu et al., 2016). These phenotypes were especially apparent in the infant stages. Adult mice showed an enhanced phenotype to DNCB-induced contact hypersensitivity response compared with WT mice. These results demonstrate that insufficient Claudin-1 expression not only compromises epidermal barrier defects, but also promotes AD pathogenesis and disease progression (Tokumasu et al., 2016).

2.1.2.4 CASPASE MUTANT MICE

Caspases are evolutionarily conserved family of cysteinyl aspartate-specific proteinases. Mammalian caspases play diverse functions in regulating programmed cell death (PCD), inflammation, immunity, and tissue morphogenesis (Man and Kanneganti, 2016). Dysregulation of caspases can contribute to skin inflammation through distinct mechanisms.

2.1.2.5 CASPASE-8

PCD is a key process underlying the terminal differentiation of keratinocytes and the formation of the stratum corneum (Candi et al., 2005). As a proximal caspase, activated by TNF/NGF family receptors, caspase-8 represents a major regulator of epidermal PCD. Humans with an inherited inactive caspase-8 (Arg248Trp) mutation display immunodeficiency due to pleiotropic defects that involve the functions of T-cells, natural killer cells, and B-cells (Chun et al., 2002). These patients suffer from a number of clinical symptoms including failure to thrive, lymphadenopathy, splenomegaly reactive airway disease, HSV labialis, and skin eczema. $aspase-8C^{-/-}$ mice are lethal. In contrast, K14-Cre-medaited deletion of $caspase-8$ in the mouse epidermis (C8cKO) elicits many clinical hallmarks of AD: epidermal thickening (acanthosis), scaling, elevated serum immunoglobulins, a biphasic T-helper cell response, mast cell infiltration, and spongiosis (Kovalenko et al., 2009; Lee et al., 2009; Li et al., 2010). These inflammatory skin lesions are associated with increased signaling of IL-1α (Lee et al., 2009), _matrix metalloproteinase-2-mediated cleavage of the cell–cell adhesion molecule E-cadherin (Li et al., 2010), and increased activities of interferon regulatory factor 3 and TANK-binding kinase (Kovalenko et al., 2009). Results from these animal model studies reveal that epidermal loss of $caspase 8$ not only affects PCD, but also alters the local microenvironment and elicits processes common to wound repair and skin inflammation.

2.1.2.6 CASPASE-1

Caspase-1, originally designated as IL-1β-converting enzyme (Keller et al., 2008), along with NLRP3 and the adaptor protein ASC, constitutes the inflammasome protein complex that plays a critical role in mounting an inflammatory response against a harmful stimulus. In an inflammatory microenvironment, such as the C8cKO skin, caspase-1 is induced by NF-κB, and stimulates proliferation of cutaneous epithelial stem cells (Lee et al., 2015). Transgenic mice generated with K14-driven expression of human Pro-Caspase-1 spontaneously developed recalcitrant dermatitis and skin ulcers, characterized by the presence of massive keratinocyte apoptosis (Yamanaka et al., 2000). The skin of these mice expressed increased levels of human caspase-1 and caspase-activated DNase, an effector endonuclease responsible for DNA fragmentation. In addition, their skin and sera showed elevated levels of mature IL-18 and IL-1β, but not of IFNγ. The plasma from these animals induced IFNγ production by IL-18-responsive NK cells. Administration of heat-killed *Propionibacterium acnes*, a potent in vivo type 1 T-cell inducer, caused IFNγ-mediated lethal liver injury in the transgenic mice, which was completely inhibited by treatment with neutralizing anti-IL-18 antibody. These results indicated that in vivo

overexpression of human caspase-1 caused spontaneous apoptotic tissue injury and rendered mice highly susceptible to exogenous type 1 T-cell-inducing condition in collaboration with endogenously accumulated proinflammatory cytokines.

2.1.2.7 CASPASE-14

Unlike most other caspases that are ubiquitously expressed, caspase-14 is selectively expressed and activated in the differentiating and cornifying layers of the epidermis and the hair follicles. It plays a crucial role in epidermal barrier formation, though not through direct regulation of the apoptotic process. Instead, caspase-14 is required for the proteolytic processing of filaggrin into the natural moisturizing factors (NMFs), such as urocanic acid and pyrrolidone carboxylic acid (Hoste et al., 2011). It is induced in epidermal keratinocytes by green tea polyphenol via MAPK pathways, and correlates with reductions of inflammatory skin lesions in the flaky tail mouse model (Hsu et al., 2007). In addition, elevated levels of caspase-14 were shown to protect skin from UVB irradiation (Bergeron et al., 2012). Conversely, caspase-14$^{-/-}$ mice display reduced epidermal barrier function and increased sensitivity to UVB radiation. In these mice, filaggrin is normally processed from precursor profilaggrin proteins, but fail to undergo terminal degradation, resulting in substantial reduction in the amount of NMFs and incomplete cornification (Hoste et al., 2011). In addition, caspase-14$^{-/-}$ mice are prone to the development of parakeratotic plaques following challenges of epidermal permeability barrier function by repetitive acetone treatment or induction of psoriasis-like dermatitis by imiquimod treatment (Hoste et al., 2013). Moreover, when challenged with bacteria, caspase-14$^{-/-}$ mice show an enhanced antibacterial response compared to wild-type mice and an imbalance of the skin-resident bacterial communities (Kubica et al., 2014).

2.1.2.8 K5-THYMIC STROMAL LYMPHOPOIETIN

TSLP, an IL-7 like cytokine, is highly expressed by keratinocytes of AD and correlated with Langerhans cell activation in AD lesional skin. TSLP can directly activate human CD11+ dendritic cells (DC) and DC-mediated Th2 response in cell culture (Soumelis et al., 2002). The role of keratinocyte-derived TSLP in skin inflammation was nicely demonstrated in K5-TSLP transgenic mice generated by crossing tetO-TSLP mice with K5-rtTA mice, which contains K5-driven expression of the reverse tetracycline transactivator. Two weeks after TSLP transgene induction via dietary doxycycline, K5-TSLP mice developed a spontaneous AD-like phenotype, with the development of eczematous lesions containing inflammatory dermal cellular infiltrates, including a dramatic increase of Th2 CD4+ T-cells and elevated serum levels of IgE (Yoo et al., 2005). In addition, these animals showed an influx of immature B-cells into the periphery cells with population expansion of follicular mature B-cells and a near-complete loss of marginal zone and marginal zone precursor B-cells. Thus, keratinocyte-derived TSLP modulates systemic B- cell development and promote humoral autoimmunity (Astrakhan et al., 2007). Similarly, keratinocyte-derived TSLP levels are correlated with skin sensitization strength and asthma severity, as demonstrated in mice in which TSLP expression was induced by topical application of MC903 (a vitamin D3 analog) (Leyva-Castillo et al., 2013). Conversely, TSLP oblation in epidermal keratinocytes reduces skin inflammation, and blocked the so-called atopic march, the progression from AD to asthma in animals with keratinocyte-specific deletion of RBP-j (the DNA-binding partner of Notch) (Demehri et al., 2009). Together, these evidence indicate that TSLP is a systemic driver of AD and atopic march, and that selective inhibition of systemic TSLP may block the development of asthma, a common allergic lung disease frequently affecting individuals with a prior history of eczema/AD (Demehri et al., 2009).

2.1.2.9 APOLIPOPROTEIN C1 (APOC1)

APOC1, along with several other plasma lipid transport genes [APOC2, APOCE, glucose-6-phosphate isomerase, the low-density lipoprotein receptor, complement component 3 (C3), and peptidase D], is mapped on human chromosome 19 (Lusis et al., 1986). APOC1 is linked to metabolic syndrome and skin inflammation. Consistently, transgenic mice engineered to overexpression APOC1 in liver and skin suffer from hyperlipidemia with strongly elevated serum levels of cholesterol, triglycerides, and FFA mainly to an accumulation of VLDL particles in the circulation (Jong et al., 1998). In addition, these mice spontaneously develop both gross and histologic features of human AD, including hyperkeratosis and parakeratosis, scaling, lichenification, dermal infiltration of inflammatory cells, and pruritus. These symptoms are accompanied with severe atrophy of sebaceous glands, the meibomian glands and subcutaneous fat tissues, and colitis. The AD symptoms of this model respond to topical treatment with corticosteroids. Moreover, oral treatment with probiotic Lactobacillus plantarum NCIMB8826 not only ameliorated colitis, but also improved skin barrier integrity and reduced epidermal thickening and inflammation (Mariman et al., 2016), which indicate that modulation of intestinal immune homeostasis may contribute to AD suppression. In this regard, AD is often linked to other atopic disorders, such as asthma, allergic rhinitis and food allergies (Bieber, 2008), and skin exposure to allergens is associated with food allergies later in life (Tordesillas et al., 2014). It is still unclear whether APOC1 is involved in these disease complications.

APOC1 displays genetic linkage to multiple other human diseases, including metabolic syndrome (Avery et al., 2011), cognitive disorder, memory impairment, and Alzheimer's disease (AD) (Ki et al., 2002; Zhou et al., 2014a,b), as well as cancer (Ko et al., 2014). These human data, along with the results of the APOC1 transgenic model, imply that regulators of lipid metabolism and lipid barrier formation of the epidermis represent a unique class of susceptibility genes that link multiple different diseases.

There are many more animal models that have been reported to show spontaneous or inducible AD-like lesions. These models are clearly instrumental for understanding molecular mechanisms underlying AD pathogenesis, the development of new AD therapeutics, and possibly elucidating other related disorders, such as asthma and metabolic syndromes.

2.2 Psoriasis

Psoriasis (OMIM 177900) is an ancient and universal inflammatory disease, initially described at the beginning of medicine in the *Corpus Hippocraticum* (460–377 BCE) as *psora*, meaning "to itch." Psoriasis affects 0.5%– 4.6% of the population with a highest prevalence among Caucasians (Lebwohl, 2003). Like AD, psoriasis involves a combination of genetic and environmental factors, and is frequently inherited, but not following a classical autosomal Mendelian profile (Lowes et al., 2007). The disease complexity and severity are heterogeneous and variable longitudinally. Genetic linkage studies performed during the past decade have identified a number of psoriatic susceptible loci, including PSORS1 (chromosome 6p21), PSORS2 (17q25), PSORS3 (4q), PSORS4 (1q21, S100A8, and S100A9), PSORS5 (3q21), PSORS6 (19p13), PSORS7 (1p), PSORS9 (4q31-34), and PSORAS1 (16q12) (Bowcock, 2004, 2005; Bowcock and Krueger, 2005; Krueger and Bowcock, 2005; Lebwohl, 2003). Nevertheless, definitive linkage of a single gene to psoriasis is made possible by recent RNA-sequencing technology which, for example, has identified association of TNFα promoter polymorphisms with psoriasis vulgaris and psoriatic arthritis (Mossner et al., 2005).

An ideal animal model for psoriasis would recapitulate all aspects of the clinical features of the disease. These include a marked hyperproliferation, thickening and altered differentiation of the epidermis, an increased T-cell infiltration and an altered vascularity, as well as a responsiveness to current antipsoriatic therapies. To date, hundreds of psoriasis mouse models have been reported with each recapitulating partial features of the human disease (Danilenko, 2008; Gudjonsson et al., 2007). Despite such limitations, data obtained from these animal models have shed light to specific aspects of disease pathophysiology, elucidating

dominant roles for both keratinocytes and T-cells (Danilenko, 2008; Gudjonsson et al., 2007; Nickoloff and Nestle, 2004). Due to the complexity of the disease etiology and manifestation, it is challenging to establish standardized validation criteria for psoriasis mouse models. However, with the technical versatility in obtaining and analyzing vast amount of genomic and gene expression data, quantitative parameters have emerged and become standardized. One such example is a recent study focused on the comparison of whole-genome transcriptional profiles of human psoriatic skin lesions with those of five different psoriasis mouse models (Imiquimod, K5-Tie2 (Wolfram et al., 2009), K14-AREG (Cook et al., 1997), K5-Stat3C (Sano et al., 2005) and K5-TGFβ1 (Fitch et al., 2009). These models show both similarities with respect to expression of genes involved in epidermal development and keratinization and variations in immune and inflammation-associated genes, as compared to the human disease (Swindell et al., 2011). Likewise, comparisons among psoriatic lesions from different anatomical sites reveal that scalp and skin psoriasis show strong similarities in immune responses. However, the scalp lesions show markedly higher magnitude of dysregulation and enrichment of the psoriatic genomic fingerprint than those of skin lesions. In addition, skin lesions are mainly associated with activation of TNFα/IL-17/IL-22-induced keratinocyte response, whereas the scalp lesions show increased modulation of IFNγ (Ruano et al., 2016).

The imiquimod-induced psoriasis model is most frequently utilized for drug development and gene function analysis in genetic animal models. Spontaneous development of psoriasis-like lesions is observed in many genetically altered animal models encompassing K5- or K14-promter-deriven epidermis-targeted transgene expression and less frequently epidermis-targeted gene knockout.

2.2.1 Imiquimod Induction of Psoriasis

Imiquimod (IMQ) is a nucleoside analog of the imidazoquinoline family, and is a potent agonist for the toll-like receptors (TLR)-7 and TLR-8. As a potent immune modulator, IMQ is initially used for topical treatment of genital and perianal warts caused by human papilloma virus, and later expanded for other skin abnormalities, such as actinic keratosis and superficial basal cell carcinomas (BCC) (Burns and Brown, 2005; Zitelli, 2005). At least two distinct mechanisms contribute to IMQ's antitumor effect. First, it activates TLR-7 and TLR-8 on DC and consequently NF-κB-dependent secretion of a multitude of proinflammatory cytokines and chemokines, leading to activation of antigen-presenting cells and other components of innate immunity and, eventually, the mounting of a profound T-helper 1 (Th1)-mediated antitumor immune response. Second, IMQ interferes with

adenosine receptor signaling pathways independent of TLR-7 and TLR-8, leading to augmentation of the pro-inflammatory activity (Schon and Schon, 2007). It was inadvertently discovered that, during topical treatment of actinic keratoses and BCC, patients with a well-controlled psoriasis developed exacerbated psoriatic lesions well beyond the treated area (Fanti et al., 2006; Gilliet et al., 2004; Patel et al., 2011; Wu et al., 2004). These lesions were marked by the infiltration of plasmacytoid DC and type I interferon activity (Gilliet et al., 2004).

Application of IMQ to mice induces inflamed scaly skin lesions that show hallmarks of plaque type psoriasis, including increased epidermal proliferation, abnormal differentiation and accumulation of neutrophils in microabesses, neoangiogenesis, and lymphocyte infiltrates consisting of CD4(+) T-cells, CD11c(+), and plasmacytoid DC (Palamara et al., 2004; van der Fits et al., 2009). Such lesions are apparent after 5–6 consecutive days of daily topical dose of 62.5 mg of IMQ cream on the shaved back and the right ear of mice. The IMQ-induced psoriasis model has been widely used to assess effects of nutrients, such as resveratrol and curcumin on disease initiation and progression (Kjaer et al., 2015; Sun et al., 2013). It has also been applied to genetically modified animal models to determine the role of specific genes, such as IL-23R and IL-17R, CXCR3, and Traf3ip2 (an NF-κB activator and an obligate adaptor for IL-17 receptor signaling), in the elicitation of skin inflammation (Ha et al., 2014; Morimura et al., 2016; van der Fits et al., 2009).

2.2.2 Psoriasis Models With Keratinocyte-Targeted Gene Alteration

2.2.2.1 TNFα AND TNFα-CONVERTING ENZYMES

Aberrant expression of TNFα and other cytokines, such as IL-1, IL-17, IL-22, IL-23, IL-36, and IFNγ, is a central element underlying the pathogenesis of psoriasis. These molecules induce both distinct and synergistic/additive effects on gene expression and development of psoriasis (Chiricozzi et al., 2011; Nakajima et al., 2011). In particular, TNFα is by far the most commonly utilized biomarker for assessment of inflammation, and TNF inhibition represents a gold standard for the treatment of psoriasis.

At low levels, TNFα orchestrates an important protective role in stimulating chemotaxis and antimicrobial activity of neutrophils, macrophages, and eosinophils. At high levels, it induces inflammation, cachexia, hemorrhage, necrosis and, ultimately, death. In skin, TNFα is produced by keratinocytes and skin resident CD11c(+)-DC (Cheng et al., 1992; Lowes et al., 2005). The detrimental effects of TNFα are revealed in transgenic mice with K14-driven expression of TNFα. These mice often die within 1 week after birth, and those survive after 1 week exhibit retarded growth with profoundly reduced adipose production, epidermal necrosis, and other features characteristic of cachexia (Cheng et al., 1992). In psoriasis, aberrant TNFα activity has been linked to genetic polymorphisms of the cis-regulatory domain or molecules involved in TNFα regulation, such as the TACE (also known as ADAM17), a member of the ADAM (a disintegrin and metalloprotease) family membrane-anchored metalloproteases.

ADAM17 processes and sheds the ectodomains of membrane-bound pro-TNFα and other membrane-anchored growth factors [e.g., heparin-binding EGF-like growth factor (HB-EGF), amphiregulin and transforming growth factor TGFα], cytokines, and receptors (Black et al., 1997; Blobel, 2005). $ADAM17^{-/-}$ mice die at birth with heart defects (Peschon et al., 1998). Mice with K14-Cre-mediated epidermal deletion of ADAM17 ($A17^{ΔKC}$) have normal skin architecture at birth, but develop pronounced defects in epidermal barrier integrity 2 days after birth (P2) followed by a spectrum of other skin defects (Franzke et al., 2012). These include curly whiskers, delayed hair outgrowth, shortened and disorganized hair follicles, dry scaly skin, and finally chronic dermatitis in adults. EGFR activation is significantly reduced in $A17^{ΔKC}$ skin, and topical treatment of these mice with recombinant TGFα significantly improved epidermal barrier function and decreased skin inflammation. Interestingly, $A17^{ΔKC}$ mice skin phenotypes are similar to those of mice lacking EGFR in keratinocytes ($Egfr^{ΔKC}$), and also overlap with those of mice with $TGFα$ deletion or mutation (such as waved 1) (Singh and Coffey, 2014). The ADAM17 substrates, including TNFα, amphiregulin, HB-EGF, and TGFα, are significantly upregulated in the TPA-induced psoriasis-like lesions in K5.Stat3C transgenic mice. Treatment of K5.Stat3C mice with TNFα or EGFR inhibitors attenuated the skin lesions (Sato et al., 2014). Overall, ADAM17 contributes to the development of psoriatic lesions through releasing of TNFα and EGFR ligands.

2.2.2.2 JUNB$^{EPI-/-}$ MICE

NF-κB and AP-1 family transcription factors are evolutionally conserved and functionally important for a wide range of cellular processes, including cell proliferation, cell survival, tissue homeostasis, and inflammation (Angel et al., 2001; Baldwin, 1996; Dixit and Mak, 2002; Eferl and Wagner, 2003; Hess et al., 2004; Jochum et al., 2001). These gene regulators play distinct functions in the skin. NF-κB controls epidermal cell proliferation and prevents premature cell death during differentiation (Seitz et al., 2000; Zhang et al., 2004). NF-κB plays key roles in inflammatory responses (Baker et al., 2011; Wullaert et al., 2011). Likewise, AP-1 proteins including JunB and c-Jun are dominant regulators of epidermal homeostasis and abnormalities (Angel et al., 2001; Eckert et al., 1997; Eferl and Wagner, 2003; Jochum et al., 2001). In human, JunB is encoded by a

gene previously mapped to human *PSOR6* (ch19p13), though the functional relevance of JunB to this locus is unclear. In addition, JunB mRNA level is increased (Park et al., 2010; Zenz et al., 2005), while its protein level is significantly reduced in the epidermal cells of psoriatic lesions as compared to uninvolved or healthy skin (Haider et al., 2006; Johansen et al., 2004; Kulski et al., 2005).

A pathogenic effect of JunB loss-of-function is validated in mice with epidermis-targeted deletion of *JunB* (*JunB^{Epi−/−}*) alone or together with *c-Jun. JunB^{Epi−/−}* mice develop joint and skin inflammation with histological and molecular hallmarks of psoriasis and psoriatic arthritis (Meixner et al., 2008; Zenz et al., 2005). These inflammatory skin lesions are further attributed to the decreased expression of the tissue inhibitor of metalloproteinase-3 (TIMP-3), an inhibitor of the TACE, and consequently uncontrolled TNFα shedding in the epidermis (Guinea-Viniegra et al., 2009). TNFR1-deletion or epidermal reexpression of TIMP-3 alleviates skin inflammation and TNFα-induced cachectic-like phenotype (Guinea-Viniegra et al., 2009). Using this *JunB^{Epi−/−}* mouse model, further studies show that systemic anti-VEGF treatment markedly reduces skin inflammation (Schonthaler et al., 2009), nicely supporting a major role of angiogenesis in psoriasis and the potential of VEGF-targeted therapies for this disease.

Consistent with these mice data, JunB-interference through siRNA-mediated gene silencing or expression of a dominant negative mutant in human keratinocytes leads to an increased cell proliferation and a decreased barrier function (Zhang et al., 2015), as well as promotion to Ras-driven tumorigenesis (Jin et al., 2011). Further ChIP-seq and RNA-seq analyses reveal that JunB regulates expression of an array of psoriasis-relevant proinflammatory molecules, such as TNFα, CXCL10, and CXCL11, through NF-κB.

2.2.2.3 IKK2^{EPI−/−} MICE

The IκB kinase (IKK) complex consists of two catalytic subunits (IKK1 and IKK2) and a regulatory subunit (IKKγ, also known as NEMO). Upon phosphorylation by the IKK complex, IκB proteins undergo proteosomal degradation, allowing the release and activation of activation of NF-κB family transcription factors (Israel, 2000; Karin and Ben-Neriah, 2000). IKK proteins play essential roles in embryonic development and tissue morphogenesis. IKK1 controls epidermal differentiation through RelB/p52, a noncanonical NF-κB signaling axis (Hu et al., 1999, 2001; Li et al., 1999a; Takeda et al., 1999). Deficiency in the X-linked NEMO gene causes incontinentia pigmenti (IP) (OMIM 308300) in both mice and human. IP is an inherited neurocutaneous disorder characterized by strips of hypopigmented skin and abnormalities of the teeth, skeletal system, eyes, and central nervous system (Makris et al., 2000; Schmidt-Supprian

et al., 2000). Germline deletion of IKK2 results in embryonic lethality with liver degeneration (Li et al., 1999b; Tanaka et al., 1999). Mice with K14-Cre-mediated epidermis-specific deletion of IKK2 (*IKK2^{epi−/−}*) develop a severe inflammatory skin disease which is attenuated by deletion of the TNFα receptor 1 (*TNFR1*) or elimination of skin macrophages by subcutaneous injection of clodronate liposomes (Pasparakis et al., 2002). However, this skin phenotype is irresponsive to deletion of CD18 (granulocytes) or T-cell antigen receptor (*TCRα*, αβT-cells) and the receptor for IFNγ (Pasparakis et al., 2002; Stratis et al., 2006). Thus, *IKK2*-deletion initiates IFNγ-independent psoriasis-like skin disease whose development requires macrophages but not granulocytes or αβT-lymphocytes.

Taken together, studies of various animal models demonstrate that keratinocyte-targeted gene alteration can initiate psoriasis and even arthritis-like lesions. Presumably, each relevant gene controls specific aspects of the disease.

2.2.3 Psoriasis Models Induced by Intradermal Injection of Cytokines

Psoriatic lesions are enriched with polarized subsets of T-cells, including T-helper 1 (Th1; CD4+), T-cytotoxic (TC1; CD8+), and T-helper 17 (Th17; CD4+) cells, as well as effector cells of innate immunity, such as neutrophils, plasmacytoid DCs, and CD11c+ DCs (Lowes et al., 2007). These immune cells are recruited and activated by different cytokines through a chain reaction.

As expected, different cytokines elicit varying aspect of the disease. Intradermal injection of IL-23, a cytokine responsible for the induction of IL-17 production by γδT-cells (Cai et al., 2011), induces skin inflammation that shares many characteristics with human psoriasis, including erythematosus, hyperplasia of the epidermis (acanthosis), parakeratosis, and leukocyte infiltration (Chan et al., 2006). The development of these lesions are dependent on TNF, IL-20R2, and IL-17 signaling (Chan et al., 2006).

IL-17 drives psoriatic inflammation via distinct and target cell-specific mechanisms. IL-17/Trafip2 signaling in keratinocytes is essential for neutrophilic microabscess formation and keratinocyte hyperproliferation. IL-17/Trafip2 signaling in dermal fibroblasts promotes cellular infiltration and accumulation of IL-17-producing γδT-cells cells in skin, forming a positive feed-forward mechanism (Ha et al., 2014). Interestingly, IL-17 is subject to regulation by adiponectin, a metabolic mediator of insulin sensitivity (Shibata et al., 2015). Adiponectin suppresses IL-17 synthesis via direct binding to AdipoR1 on γδ-T cells. Mice with adiponectin deficiency show severe psoriasiform skin inflammation with enhanced infiltration of IL-17-producing dermal γδ-T cells. Adiponectin is decreased in serum, skin, and fat tissues of psoriasis

patients. Thus, adiponectin deficiency may provide a mechanism underlying the relationship between psoriasis and metabolic disorders.

Treatment of antibiotics in adult mice ameliorates imiquimod-induced psoriasiform dermatitis, with decreasing numbers of IL-17 and IL-22 producing T-cells. Surprisingly, animals treated with antibiotics at neonatal stage show markedly exacerbated inflammatory responses when challenged with topical imiquimod and intradermal injection of recombinant IL-23 during adulthood. Using 16S rRNA gene compositional analysis, it is found that neonatal antibiotic treatment can lead to a dysregulation of gut and skin microbiota later in life and potentially an increased susceptibility to psoriasis during adulthood (Zanvit et al., 2015).

In summary, each of these animal models addresses specific aspects of human psoriasis. In spite of the enormous heterogeneity of human psoriasis, data obtained from animal model studies provide mechanistic insights, and are instrumental for drug development. At present, systemic therapies with TNF inhibitors, including adalimumab, etanercept, and infliximab, represent the mainstream treatment options for psoriasis. These agents are currently approved by the US Food and Drug Administration for the treatment of moderate to severe psoriasis (Kerdel, 2015). Nevertheless, systemic biological agents are inevitably associated risks of immune reactions and infection. Thus, local and keratinocyte-targeted therapies are highly desired, and maybe developed based on the findings obtained with animal models that address the role of keratinocytes in disease pathogenesis.

3 GENETIC SKIN DISEASE ANIMAL MODELS

3.1 Ichthyosis Vulgaris

Ichthyosis vulgaris (OMIM#146700) is characterized by dry, scaly skin, and propensity to the development of AD (eczema) and allergic responses, such as asthma. It is caused by loss-of-function mutations in the gene encoding filaggrin (Sandilands et al., 2007, 2009; Smith et al., 2006), and mainly treated with moisturizing agents (Hoppe et al., 2015).

The flaky tail mice which carry a spontaneous mutation in the filaggrin gene nicely recapitulate the human skin phenotype. This mutation resulted in the expression of a lower molecular weight form of profilaggrin (220 kDa instead of 500 kDa) that is resistant to proteolytic processing into filaggrin intermediates necessary for the production of moisturizing factors. Thus, the flaky tail mice are useful for both AD and ichthyosis vulgaris studies.

3.2 Netherton Syndrome

Netherton syndrome (NS) (OMIM 256500) is a rare and severe autosomal recessive congenital ichthyosiform dermatosis characterized by extensive skin desquamation, inflammation, multiple allergies, atopic manifestations, and hair shaft defects. Currently, there is no satisfactory treatment for NS, which can be life-threatening in infants, and palliative treatments are applied for management of skin infections, itching, and pain. NS is caused by truncated loss-of-function mutations of the serine protease inhibitor Kazal-type 5 (*SPINK5*), a gene that encodes LEKTI (lymphoepithelial Kazal-type inhibitor). Specifically, LETKI is an inhibitor specific for KLK serine protease family members (KLK5, KLK7, and KLK14) (Chavanas et al., 2000). KLK5 is characterized as an initiator upstream of KLK7 and elastase-2 (ELA2). The current state-of-hypothesis is that Pro-KLKs are synthesized and activated by matriptase in the *stratum granulosum*, but rapidly inactivated by LEKTI, thus preventing premature degradation of desmosomes. The acidic microenvironment of *stratum corneum* causes the release of active KLKs from LEKTI, and subsequent cleavage of corneodesmosomal proteins in the most superficial layers of the *stratum corneum*, ensuring finely balanced regulation of the desquamation process (Ovaere et al., 2009). LEKTI loss-of-function results in unopposed protease activities and over digestion of epidermal structural and barrier proteins.

As expected, $Spink5^{-/-}$ mice recapitulate cutaneous and inflammatory aspects of the NS disease including neonatal lethality (Descargues et al., 2005; Yang et al., 2004), which is associated abnormal degradation of the desmosomal cadherins, such as Desmoglein 1 (Dsg1) and Desmocollin-1 (Dsc1) desmoglein 1, due to unopposed KLK5 and KLK7 protease activities (Descargues et al., 2005). The uncontrolled KLK5 activity in NS epidermis appears to trigger AD-like lesions through PAR2-mediated TSLP expression, independently of the environment and the adaptive immune system (Briot et al., 2009).

Like $Spink5^{-/-}$ mice, transgenic mice engineered to overexpress human KLK5 in the granular layer of the epidermis via involucrin promoter display increased proteolytic activity of KLK5 and its downstream KLK7, KLK14, and ELA2. Similar to $Spink5^{-/-}$, KLK5 transgenic mice develop an exfoliative erythroderma with scaling, growth delay, and hair abnormalities, as well as cutaneous and systemic hallmarks of severe inflammation and allergy with pruritus. The skin shows increased expressions of inflammatory cytokines and chemokines, infiltrations of immune cells, and markers of Th2/Th17/Th22 T-cell responses along with elevated levels of IgE and TSLP in serum (Furio et al., 2014).

Conversely, deletion of *Klk5* rescues the neonatal lethality of in *Spink5*$^{-/-}$ newborn mice, and reverses cutaneous hallmarks of NS, including skin barrier defect, disordered epidermal structure, and skin inflammation (Furio et al., 2015). Notably, Klk5 loss results in reduced epidermal proteolytic activity, particularly KLK7, KLK14 and ELA2, and restoration of structural integrity of desmosomes and corneodesmosomes and normal epidermal differentiation as well as normalized expressions of Il-1β, Il17A, and TSLP.

Further supporting a role of KLK5 in NS, ablation of matriptase, a protease involved in processing of Pro-KLKs to active KLK, dampened inflammation, prevents detachment of the stratum corneum, and improves the barrier function of the epidermis of *Spink5*$^{-/-}$ mice (Sales et al., 2010). Results of this study indicate a crucial role of matriptase in NS pathogenesis and imply a role of the matriptase-pro-KLK pathway in other human skin and inflammatory diseases.

In addition to animal models, the epidermal defects is observed in organotypic 3D cultures generated with normal human keratinocytes transfected with SPINK5-targeted small interfering RNA (siRNA) and fibroblast-populated collagen gels (Wang et al., 2014). Gene silencing of KLK5 or KLK7 markedly ameliorates the epidermal architecture compromised by reduced SPINK5 expression. Together, these studies confirm a major role of KLK5 and its upstream and downstream regulators in NS.

4 ANIMAL MODELS OF SKIN CANCER

Skin cancer is by far the most common type of cancer of human body (Eisemann et al., 2014), accounting for more cases than the combined incidences of breast, prostate, lung, and colon cancers (American Cancer Society, 2016). BCC and squamous cell carcinoma (SCC) constitute the majority of nonmelanoma skin cancers, accounting for an annual incidence of approximately 4 and 1 million new cases, respectively, in the United States alone. These cancers, especially BCC, rarely spread to other parts of the body, and most of them can be effectively treated by surgery. Among the rare types of nonmelanoma skin tumors are cylindorma, tricoepithelioma, and sebaceous adenoma. These adnexal tumors are often observed as a mixed population in Brook-spiegler syndrome, an autosomal recessive disorder. Although mostly benign, they are difficult to treat due to the high multiplicity and the frequent recurrence after surgical removal. Melanoma incidence accounts for nearly 85% of skin cancer death.

The primary risk factor for skin cancer is UV radiation which induces DNA mutations through cyclobutane pyrimidine dimers and pyrimidine [6-4] pyrimidone photoproducts ([6-4]PPs) (de Gruijl, 1999; Freeman et al., 1989; Pleasance et al., 2010). Among the most well-characterized driver mutations are (1) gain-of-functions of oncogenes, such as those of the Ras-MAPK pathway (HRas, KRas, NRas, BRAF, and MEK) and cell cycle regulators (CDK4 and cyclinD1), and (2) loss-of-function mutations of tumor suppressors, such as p53, PTEN and PTCH, and cell cycle inhibitors, such as p16. The prevalence of a specific gene mutation differs among different skin tumors.

4.1 DMBA/TPA Two-Stage Chemical Carcinogenesis

4.1.1 Nonmelanoma Skin Cancer Induced by Chemicals

The two-stage chemical carcinogenesis protocol is initially developed based on anecdotal findings made in the 1920s that wounding of mouse skin that had previously been treated with carcinogenic tar were prone to skin tumor development. This protocol has since been optimized and widely used to study skin carcinogenesis of mice with different genetic backgrounds or targeted gene engineering (Abel et al., 2009; Neagu et al., 2016). In essence, it requires two stages (Fig. 15.2). In the initiation stage, one dose of a chemical carcinogen most frequently 7,12-dimethylbenz[*a*]anthracene (DMBA), a polycyclic aromatic hydrocarbon, is applied topically to the shaved or hairless skin. DMBA is metabolized by epidermal Langerhans cells to DMBA-*trans*-3,4-diol, an intermediate inductive of DNA mutations (Modi et al., 2012). *HRas is* a primary target gene of DMBA in most cases with a few exceptions, such as *Pten*$^{+/-}$ mice, in which *HRas* mutation appear to be exclusive of *Pten* loss (Mao et al., 2004). Activating *HRas* mutation, typically A to T (182) transversion in codon 61, is detectable 3–4 weeks after DMBA-treatment, and is characterized as critical event in skin carcinogenesis. In agreement with this, transgenic mice that express a constitutively active HRas^{V12} mutant under the control of the zeta-globin develop tumors without the requirement of DMBA initiation (Spalding et al., 1993). Similarity, mice with K14 promoter-driven expression of a 4-hydroxytamoxifen (4OHT)-regulated HRas-ER fusion develop papillomas following induction with 4OHT (Ortiz-Urda et al., 2005).

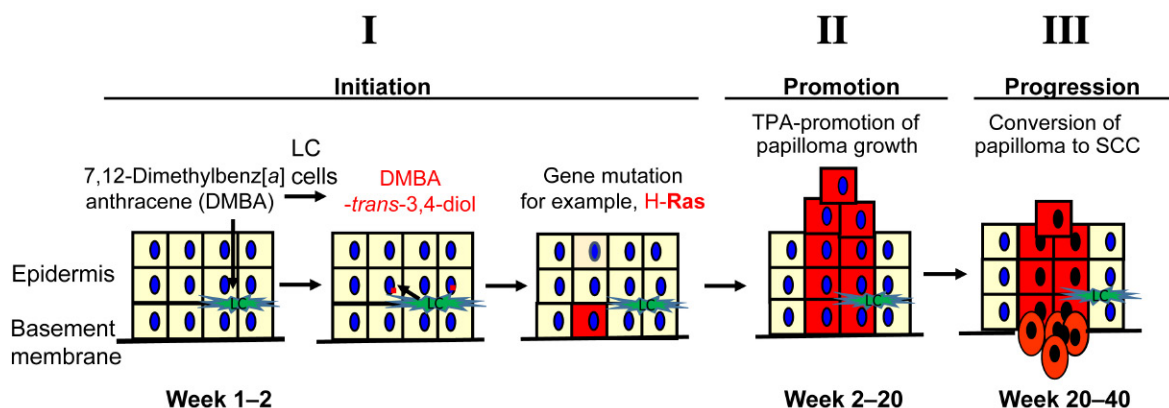
By the 6–10th weeks after TPA promotion, elevated growth of begin papillomas is readily visible. Papillomas may then progress to invasive SCC as early as 20 weeks after treatment with the promoting agent. Further progression can lead to formation of spindle cell carcinomas and even metastasis to lymph nodes, as observed in the


FIGURE 15.2   DMBA/TPA two-stage carcinogenesis. For initiation, one subcarcinogenic dose of 7,12-dimethylbenz[*a*] anthracene *(DMBA)* is applied to neonatal (50 μg in 50 μL acetone) or shaved adult skin (ranging from 2.5 to 100 μg in 200 μL acetone). DMBA is metabolized by skin resident Langerhans cells *(LC)* into DMBA-*trans*-3,4-diol which then induces gene mutations in keratinocytes. Two weeks after initiation, a promoting agent, such as 12-O-tetradecanoylphorbol-13-acetate *(TPA)* is applied (2–4 μg in 200 μL) biweekly and continues for the duration of the study, typically for 20 weeks. During promotion stage, TPA stimulates cell signaling, increases production of growth factors, and generates oxidative stress and tissue inflammation, which together create an environment that favors clonal expansion of cells with certain gene mutations, such as Ras (DiGiovanni, 1992).

transgenic mice with K14-driven expression of a catalytically deficient mutant of CYLD tumor suppressor (Miliani de Marval et al., 2011).

The rate and multiplicity of papilloma development and the frequency of malignant conversion are dependent on genetic background and the dosage of carcinogen and promotion agents used. In general, FVB and SENCAR mice are more sensitive to tumor induction than BALB/c mice. In order to minimize genetic background-dependent variations, multigeneration backcrossing is highly recommended when comparing tumorigenesis between WT and transgenic or knockout mice.

4.1.2 Melanoma Induced by Chemical Carcinogenesis

The DMBA/TPA protocol has been recently modified to induce melanocytic nevi and melanoma (Nasti et al., 2016). For this, the shaved back skin of C3H/HeN mice was painted with 50–100 μg of DMBA in 200 μL of acetone, and then treated twice weekly with topical doses of 6.25–12.5 μg TPA for 20 weeks. Dysplastic pigmented skin lesions appear with 100% penetrance around 7–9 weeks after TPA. It is believed that the low dose TPA results in the development of fewer and delayed appearance of epithelial papillomas (14–15 weeks after TPA). In addition, withdraw of TPA leads to regression of papillomas without affecting the development of pigmented lesions. By the 25th week, nests of melanocytic cells are detected in a subset of skin draining lymph nodes. Approximately 50% of the derived melanoma cell lines contain *HRas* mutations and *p16^{Ink4a}* loss. While the feasibility of this melanoma model is yet to be tested in other mouse strains, it might be useful for screening

therapeutics and identifying novel pathways associated with nevus formation (Nasti et al., 2016).

4.2 Modeling Skin Cancer With Genetically Engineered Animal Models

Numerous genetically engineered animal models have been used to study various skin cancers, including BCC, SCC, and melanoma (Gober et al., 2013), as well as other less common adnexal skin tumors, such as cylindroma (Jin et al., 2016).

4.2.1 BCC

BCC is primarily caused by the activation of the *Sonic hedgehog* (SHH) signaling pathway, most frequently, due to loss-of-function mutation of the tumor suppressor Patched 1 gene (*PTCH1*), and, less frequently, activating mutations of Smoothened (SMO) and the downstream Gli1 and Gli2 transcript factors (Hahn et al., 1996; Johnson et al., 1996). Recapitulating human BCC, *Ptch^{+/−}* mice and transgenic mice with K14- or K5-driven overexpression of SHH, an active SMO-mutant (SMO-M2), Gli1 or Gli2 all develop spontaneous BCC (Aszterbaum et al., 1999; Grachtchouk et al., 2000; Nilsson et al., 2000; Oro et al., 1997; Xie et al., 1998). Further studies with K15-driven expression of SMO-M2 in hair follicle bulge stem cells demonstrate that hair follicle stem cells can be mobilized by wounding to the interfollicular epithelium where they are capable of triggering BCC tumor formation (Wong and Reiter, 2011).

4.2.2 SCC

The Ras/MEK/MAPK signaling pathway is frequently activated in human cutaneous SCC, with *HRas* mutation

detected in about 20% of human SCC samples (Bamford et al., 2004; Pierceall et al., 1991). Transgenic mice with K14-driven expression of a tamoxifen-inducible mutant Ras (H-Ras^{V12}) or activated MEK1 develop skin tumors with features consistent with SCC (Pierceall et al., 1991; Scholl et al., 2004). p53 loss, frequently induced by UV-irradiation (Brash et al., 1991), represents another common feature of SCC. p53 is a potent tumor suppressor required for maintenance of genomic stability and cell cycle control (Hoeijmakers, 2001). $p53^{-/-}$ mice are sensitive to UV-induced skin carcinogenesis (Jiang et al., 1999). In addition to direct gene mutation, Ras/MAPK activation and p53 loss-of-function also function as important SCC-drivers in several other mouse models including transgenic mice with K14-driven expression of a constitutively active Fyn (K14-Fyn Y528F) (Zhao et al., 2009).

Nucleotide excision repair is a key process for the maintenance of DNA integrity. Patients with Xeroderma pigmentosum (XP), a rare autosomal recessive disease caused by XP loss of-function mutation, is in part characterized by extreme skin sensitivity to sunlight and by 1000-fold increased risk of developing cancer at sun-exposed areas of the skin. Consistently, $Xpa^{-/-}$ mice develop skin tumors at high frequency when exposed to UV light, and $Xpa/p53^{+/-}$ double KO mice develop tumors earlier and with higher incidences upon exposure to carcinogens as compared to their single knockout counterparts (van Steeg et al., 2001).

4.2.3 Melanoma

Mutational activation of BRAF is the earliest and most common genetic alteration in human melanoma. However, BRAF mutation is not sufficient to induce melanoma progression. In line with this, mice engineered with melanocyte-targeted Braf^{V600E} mutation via *tyrosinase* promoter-driven expression of the tamoxifen-regulated Cre-ER (*Tyr-CreER*) develop benign melanocytic hyperplasias that undergo senescence and fail to progress to melanoma (Dhomen et al., 2009). By contrast, expression of BRaf^{V600E} combined with *Pten* gene deletion in melanocytes elicits aggressive melanoma growth with 100% penetrance, short latency, and metastases to lymph nodes and lungs (Dankort et al., 2009). The *Tyr-CreER.Braf^{V600E}.Pten$^{-/-}$* mice have been extensively used to characterized mechanisms of chemoresistance (Holderfield et al., 2014; Shtivelman et al., 2014). It is also used to demonstrate that copper is required for Braf-driven melanoma tumorigenesis (Brady et al., 2014).

4.3 Modeling Skin Cancer With Human Cells

4.3.1 De Novo Human Skin Regeneration on Immunodeficient Mice

A key aspect of skin research is to utilize skin tissue models that have a human specific tissue architecture, an intact epidermal permeability barrier and physiologic connections to the systemic circulation. For this purpose, the de novo human skin regeneration technique has been proven very useful. It involves isolation of primary human keratinocytes, melanocytes, and dermal fibroblasts, multiplex gene transduction and subsequent seeding of the primary skin cells onto devitalized or synthetic human dermis, followed by skin grafting on mice with severe combined immunodeficiency (*SCID*) (Fig. 15.3A). A few weeks after grafting, the regenerated tissues develop a multilayered skin architecture that is indistinguishable from normal human skin or various skin tumors. For example, grafts regenerated with human keratinocytes transduced to express Ras and active c-Jun develop histological features of human SCC including an apparent dermal invasion and a high rate of cell proliferation as indicated by abundance of Ki-67-positive cells (Fig. 15.3B–C). In contrast, grafts expressing Ras and JunB display near normal clinical and histological appearances as manifested by the clear tissue boundaries between epidermis and dermis, and the basal cell restricted cell proliferation (Jin et al., 2011). This model has been successfully used to demonstrate that exogenous expression of CDK4, IκBα mutant (the super repressor of NF-κB), and the active mutants of MKK7 and JNK2 each is sufficient to couple with oncogenic Ras to transform normal keratinocytes into SCC (Dajee et al., 2002; Ke et al., 2010; Lazarov et al., 2002).

Consistent with SHH signaling pathway being a primary driver of BCC, skin grafts generated with keratinocytes transduced to express SHH develop into BCC within 1 month after the surgery (Fan et al., 1997). The regenerated skin tissue model has also been used to study melanoma development. This involves gene transduction of primary human melanocytes for expression of melanoma relevant genes, such as NRas, hTERT, CDK4, and dominant negative p53 mutant (p53^{DN}). The gene-transduced melanocytes are then mixed with human keratinocytes at 1:10 ratio for skin grafting. Pigmented lesions emerge and quickly develop into malignant melanoma within a few weeks after grafting on SCID mice (Chudnovsky et al., 2005).

4.3.2 Three-Dimensional Organotypic Human Skin Culture

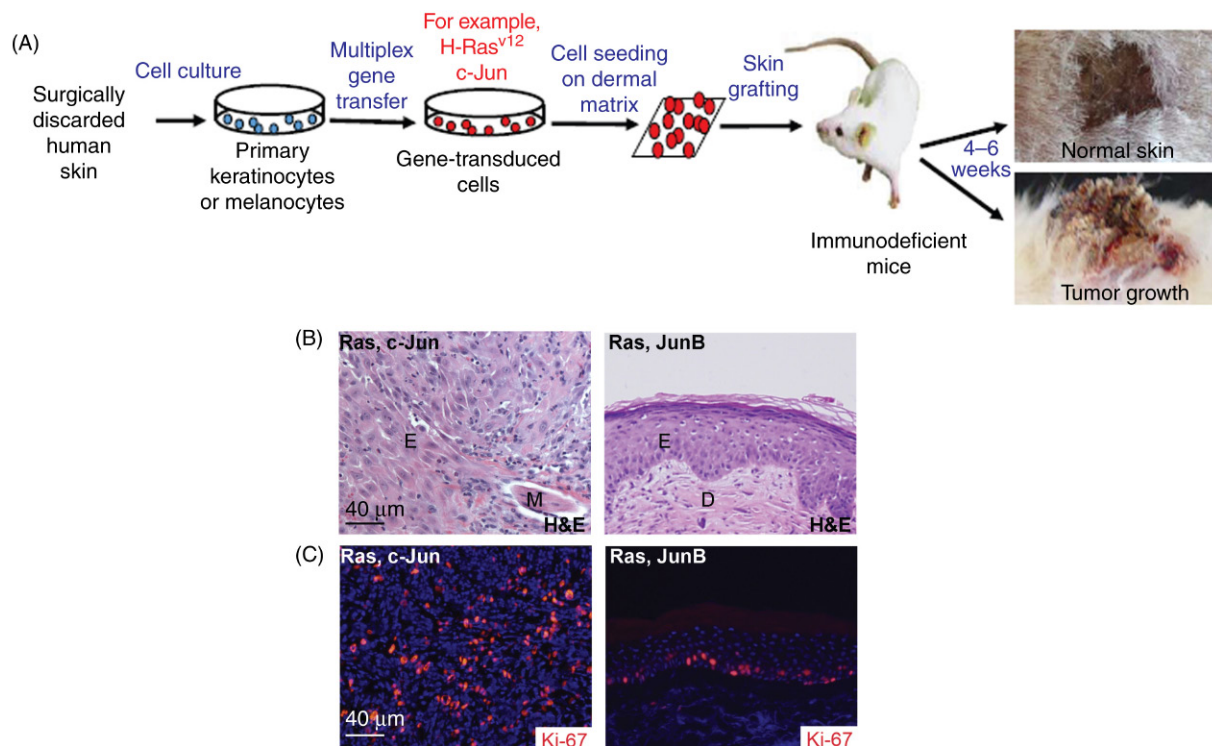
The 3D organotypic skin culture system has been proven valuable in understanding the epidermal-cell intrinsic effects and the epidermal–dermal crosstalk, as well as genetic and pharmacological impacts on epidermal growth, differentiation, barrier formation, and carcinogenesis (El Ghalbzouri et al., 2002; Maas-Szabowski et al., 2001; Margulis et al., 2005a; Szabowski et al., 2000). As depicted in Fig. 15.4A, a basic 3D skin culture system is composed of an upper chamber and lower chamber that are separated by collagen gel or dermal matrices, such as split thickness human dermis


FIGURE 15.3 **De novo regeneration of human skin tissues with defined genetic changes.** (A) Diagram of de novo human skin regeneration. (B) Histological appearance of 6-week-old skin grafts generated on immunodeficient SCID mice with primary human keratinocytes transduced to express Ras and c-Jun or JunB. E, Epidermal tissue; D,dermis; M,muscle. Grafts (n = 3–5) displayed 100% phenotypic penetrance. (C) Immunoflorescent staining for Ki-67, nuclei (*blue*, Hoechst 3342), magnification. *Source: Part B and C: Reprinted from Jin, J.Y., Ke, H., Hall, R.P., Zhang, J.Y., 2011. c-Jun promotes whereas JunB inhibits epidermal neoplasia. J. Invest. Dermatol. 131 (5), 1149–1158.*

derived from cadaver or surgically discarded skin. Human keratinocytes are seeded on the top of the dermal matrices placed in the top chamber. Dermal fibroblasts and other dermal cells are seeded in the bottom chamber either as monolayer culture or with collagen gel. For gene function studies, cells may be infected with retro or lentiviruses for targeted gene expression or silencing. Once cells are settled in their respective compartment, the media on the top chamber is removed, creating an air–liquid interface which is critical for epidermal stratification. The bottom chamber will be replenished with fresh media every 2–3 days. Skin rafts may be maintained in culture for up to 1 month, and collected at various time-points for histological analyses(Margulis et al., 2005a,b). Depending on the project needs, melanocytes or melanoma cells may be seeded together with keratinocytes. Skin grafts may be subject to pharmacological treatments during the incubation. By using this 3D culture system, we have found that tissues generated with cells transduced for expression of JunB display epidermal hypoplasia as indicated by the reduced epidermal thickness and number of Ki-67(+) cells as compared to the control tissues (Fig. 15.4B). A similar 3D setting was used to demonstrate that p63, ZNF750

and methyltransferase 1 (DNMT1) are critical for the maintenance of progenitor cells in the epidermis (Sen et al., 2010, 2012; Truong et al., 2006).

The 3D skin raft system is also nicely used to identify a key role for the extracellular matrix interaction network facilitated by the β1-integrin in cancer progression (Reuter et al., 2009). Moreover, this model can be extended to epithelial cells from other tissues, such as oropharynx, esophagus, and cervix, and investigate how genetic changes affect cancer transformation and tissue invasion (Ridky et al., 2010).

5 CONCLUSIONS

Animal models are instrumental in understanding various dermatological diseases. They will continue to be utilized for future studies with the incorporation of cutting edge technologies, such as CRISPR or lentivirus-mediated gene targeting of embryonic skin (Beronja et al., 2010; Yang et al., 2013). Meantime, the 3D organotypic tissue culture systems are expected to emerge and to be optimized for more frequent use as animal free skin equivalents.

Animal Models of Kidney Disease

Zahraa Mohammed-Ali, Rachel E. Carlisle, Samera Nademi,
Jeffrey G. Dickhout

McMaster University and St. Joseph's Healthcare Hamilton, Hamilton, ON, Canada

1 INTRODUCTION

In this chapter, we detail numerous popular models of kidney disease. To organize the work, we have divided kidney disease into its acute and chronic manifestation and detail models of either form of kidney disease separately. The need for reliable models of both acute and chronic kidney disease is apparent from the increasing prevalence of these diseases in the population and the lack of effective therapies of these disease states to prevent progression to renal failure. Animal models allow the analysis of these complex disease states in terms of pathophysiology and the testing of new therapeutics to determine if they may interfere with disease progression and prevent renal failure. These preclinical studies of novel therapeutics can only be as accurate as the disease model systems they use to represent human disease. In recognition of this fact, models are discussed in terms of their similarities to human disease and shortcomings are indicated. It is our hope that this work will guide researchers in their choice of preclinical models and increase our collective ability to find solutions to progressive kidney disease.

2 ACUTE KIDNEY DISEASE

Acute kidney injury (AKI) is a form of acute kidney disease. AKI is defined by the Acute Kidney Injury Network (AKIN) as a sudden loss of renal function indicated by an increase in serum creatinine of 26.4 µmol/L (0.3 mg/dL) or more; a 50% increase in serum creatinine from baseline; or a reduction in urine output, oliguria (<0.5 mL/kg hourly for >6 h) (Farooqi and Dickhout, 2016). AKI is of critical importance in disease outcome, as its occurrence results in increased length of hospital stay and mortality (Silver et al., 2015). It also imparts a persistent increased risk of chronic kidney disease (CKD): 10-fold, end stage renal disease (ESRD): 3-fold, and premature death: 2-fold (Silver et al., 2015). Therapy for AKI is mainly supportive, with initiation of dialysis upon acute renal failure. As such, AKI represents a class of renal disease where exploration into effective therapies may take place. As AKI is difficult to diagnosis until after renal injury has occurred and serum creatinine is a trailing biomarker of AKI, animal models of AKI offer hope of developing effective interventions into AKI. These interventions then may be tested in a

human population at high risk of AKI, prophylactically. AKI can be classified by cause into three categories, prerenal, intrinsic, and postrenal AKI.

2.1 Prerenal Acute Kidney Injury

Prerenal AKI is caused by hypoperfusion of the kidney, either absent blood flow [renal ischemia/reperfusion injury (IRI)] or reduced blood flow (renal artery stenosis). In humans, prerenal AKI is typically caused by constriction or obstruction of the blood vessels supplying the kidney (Devarajan, 2006). Animal models mimic this effect by surgically clamping or clipping renal arteries to prevent/reduce renal blood flow (Al-Suraih and Grande, 2014; Wei and Dong, 2012) or inserting a copper stent to induce stenosis (Lerman et al., 1999). These animal models of prerenal AKI develop reduced renal function, as well as increased endoplasmic reticulum (ER) stress, apoptosis, inflammation, and fibrosis.

2.1.1 Renal Ischemia/Reperfusion

Renal IRI is caused by hypoperfusion of the kidney due to decreased cardiac output or constriction or obstruction of the blood vessels supplying the kidney (Devarajan, 2006). Risk factors for renal ischemia in humans include being over 50 years old, smoking, hypertension, diabetes, hypercholesterolemia, having a family history of coronary artery disease, bilateral renal artery stenosis, having only one kidney, and having one damaged kidney. The damage seen in animal models of renal ischemia is typically worse than human kidneys that have undergone ischemia.

This animal model of renal IRI restricts blood flow to the kidney, preventing oxygen from reaching the cells. However, this does not happen uniformly throughout the kidney, and blood flow is mainly reduced in the outer medulla (Devarajan, 2006; Venkatachalam et al., 1978). The medullary thick ascending limb and the S3 segment of the proximal tubules require high oxygen consumption; therefore, ischemia tends to result in damage primarily occurring in the corticomedullary region of the kidney (Venkatachalam et al., 1978), outer medulla (OM) (Fig. 16.1). However, with an increased ischemic time, the damage extends to the inner medulla (IM) (Fig. 16.1). Under ischemic conditions, glomerular filtration rate (GFR) is reduced and solute transport to the thick ascending limb is decreased to maintain oxygen levels. This increases production of reactive oxygen species (ROS), which work to further reduce GFR and increase activity, and therefore oxygen consumption, of the thick ascending limb (Venkatachalam et al., 1978). Renal ischemia increases serum creatinine levels and blood urea nitrogen levels.

Renal ischemia/reperfusion surgery is performed in an anaesthetized animal by clamping off the renal artery (or arteries) with an atraumatic microvascular clamp for a predetermined amount of time. The clamps are then removed, and the kidneys reperfuse (Wei and Dong, 2012). There are three methods of performing renal ischemia/reperfusion surgery: (1) bilateral renal ischemia, where both renal arteries are clamped and both kidneys undergo ischemia and subsequent reperfusion (Wei and Dong, 2012) (Fig. 16.1); (2) unilateral renal ischemia, where only one renal artery is clamped and one kidney undergoes ischemia and reperfusion (Le Clef et al., 2016); and (3) uninephrectomy (UNX) with unilateral renal ischemia, where one kidney is removed from the animal and the remaining kidney undergoes ischemia/reperfusion via renal artery clamping (Skrypnyk et al., 2013). After removal of the artery clamp(s), the animal is allowed to recover and is sacrificed at a time point determined by experimental end point. Earlier time points (hours to days) allow analysis of ER stress, inflammation, and apoptosis. Longer time points (days to weeks) allow examination of the fibrotic response. Renal injury in this model tends to be correlated to nephron mass. That is, in the UNX/unilateral IRI model, the animals develop significantly more chronic damage than the bilateral or unilateral IRI models, as they have reduced nephron mass caused by UNX (Cau et al., 2009).

Bilateral IRI is the model most similar to human renal ischemic injury, where both kidneys receive reduced blood supply. Renal function and functional recovery can be measured in this model (via serum creatinine analysis), unlike in the unilateral renal ischemia model. Serum creatinine levels should be elevated by 24 h, and depending on the severity of the model, will decrease or continue to increase until sacrifice/death (Wei and Dong, 2012). Unilateral renal IRI (without UNX) does not allow for measurement of renal function, as the remaining nonischemic kidney will compensate for reduced function of the injured kidney. Interestingly, the unilateral renal ischemia model develops more severe fibrosis than the bilateral model. As such, it is often used as a model of post-AKI fibrosis. UNX with unilateral renal ischemia reduces variability in results, when compared with bilateral renal ischemia (Skrypnyk et al., 2013). It also reduces surgery times, as it takes less ischemic time to cause similar levels of damage, when one kidney has been removed. However, fewer animals actually develop renal insufficiency in this model (Skrypnyk et al., 2013). Typically mice are used for IRI studies due to the availability of numerous transgenic strains; however, mice tend to demonstrate inconsistent results with regards to injury severity. Alternatively, rats, rabbits, and dogs have also been used to study renal IRI. While the molecular and cellular responses to IRI are complicated and not fully understood, it is known that this model causes ER stress, apoptosis, inflammation, and fibrosis.

AKI: Prerenal, IR
FIGURE 16.1 **Bilateral ischemia/reperfusion (IR)–induced acute kidney injury (AKI) in cortex (Cx), outer medulla (OM), and inner medulla (*IM*) compared to sham.** To induce ischemia, the right and left renal arteries of C57BL/6 male mice were clamped for 55 min. Blood flow was then allowed to recover for 48 h before sacrificing the animals. Periodic acid-Schiff staining shows IR-induced nephropathy depicted in the figure by cellular casts *(arrows)* in Cx, OM, and IM; loss of brush borders in proximal tubular cells *(arrow head)* in Cx; tubular dilation *(asterisk)* in Cx. Images were taken with an Olympus BX41 microscope using 10× (scale bar: 500 μm) and 40× (scale bar: 200 μm) objectives.

Protein folding in the ER is inhibited by prolonged lack of oxygen, ischemia, resulting in ER stress and activation of the unfolded protein response (UPR). It has been suggested that UPR activation is actually upregulated via the reperfusion stage of IRI, not ischemia (Montie et al., 2005). The UPR is activated within minutes of reperfusion, with increased expression of the molecular chaperone, GRP78; the proapoptotic protein, CHOP; and phospho-eIF2α (Montie et al., 2005; Yang et al., 2014). As with structural damage, the primary location for ER stress marker expression is the corticomedullary junction (Montie et al., 2005). Within 24 h of reperfusion, ER stress marker expression is typically decreased (Yang et al., 2014). Preventing ER stress by enhancing protein folding with a small molecular chemical chaperone prevents tubular injury, tubular necrosis, and tubular apoptosis (Gao et al., 2012). Further, knockout of CHOP protects the kidney from decreased renal function, structural damage, and apoptosis (Noh et al., 2015). Induction of ER stress and activation of the UPR can lead to various forms of cell death, such as necrosis, apoptosis, and pyroptosis (inflammatory apoptosis) (Yang et al., 2014).

Pyroptosis is characterized by activation of caspase-1. Caspase-1 activates proinflammatory cytokines, such as IL-1β and IL-18 (Yang et al., 2014). Preventing ER stress, specifically the upregulation of CHOP, can prevent the initiation of pyroptosis, indicating this inflammatory cell death is induced by ER stress. However, bone marrow transplants between wild-type and CHOP knockout mice demonstrate that the lack of CHOP in inflammatory cells is not protective against IRI (Yang et al., 2014).

ER stress and apoptosis are intertwined in renal ischemic injury. ER stress activates signaling pathways that lead to increased expression or activation of proapoptotic proteins (Yang et al., 2014). The proapoptotic family of caspases plays a significant role in IRI-mediated apoptosis, though the roles and pathways of each individual protein are still being determined. Caspase-11 activation is induced by CHOP, as is activation of its effector, caspase-1 (Yang et al., 2014), while GSK3β upregulates Bax expression, causing caspase-3 activation (Wang et al., 2010). Interestingly, melatonin inhibits caspase-3 activation in IRI, preventing apoptosis (Kunduzova et al., 2003). NGAL has also been shown to inhibit caspase-3 activation, as well as Bax expression (Zang et al., 2014). Using IGF-1 and a caspase inactivator, researchers were able to demonstrate that inhibiting apoptosis can prevent IRI-induced inflammation. Administering the apoptosis inhibitors prior to the onset of apoptosis prevented inflammation, while administration after the onset of apoptosis did not (Daemen et al., 1999).

The inflammatory response initiated by IRI is caused by endothelial and tubular cell dysfunction. Tubular atrophy and decreased cellular adhesion occurs with renal ischemic injury. β1-Integrin is a transmembrane protein found on the basal surface of renal tubular

epithelial cells. It acts as a cellular receptor for extracellular matrix (ECM) proteins, such as type IV collagen, and works to protect cell adhesion and epithelium integrity (Molina et al., 2005). Activated β1-integrin promotes adhesion, while decreased levels of β1-integrin contribute to renal tubular epithelial cell detachment into the tubule lumen. Mice treated with HUTS-21, which promotes activation of β1-integrin, prevented IRI, TNF-α activation, macrophage and T-lymphocyte infiltration, and intratubular protein cast formation caused by epithelial cell detachment (Molina et al., 2005). Directly inhibiting TNF-α activation protects renal function and prevents tubular necrosis, cell loss, intratubular debris, fibrosis, and tubular atrophy. Further, it prevents infiltration of CD3+ cells, as well as activation of p38 and MAPK (Cau et al., 2009). Toll-like receptors (TLR) activate the innate immune response, with TLR4 playing a key role in ischemia-induced IL-6 production. TLR4 knockout mice are protected from renal ischemic injury, as well as leukocyte infiltration into renal tissue (Chen et al., 2011). TLR2 is also increased in renal tubular epithelial cells after ischemia. Further, inactivation of TLR2 protected mice from IRI-mediated structural injury, as well as reduced neutrophil infiltration and expression of monocyte chemoattractant protein (MCP)-1, TNF-α, IL-6, and IL-1 (Leemans et al., 2005).

IRI-induced inflammation involves many types of inflammatory cells, such as neutrophils, macrophages, natural killer (NK) cells, and T cells (Akcay et al., 2009). The role of neutrophils in the IRI-induced inflammatory response is controversial. They are the first cells to infiltrate the reperfused kidney, but they do not appear to have much clinical significance (Patschan et al., 2012). Inhibiting macrophage production protects the kidney from IRI; similarly, a lack of T cells, as exemplified in nu/nu-mice and Rag-1 knockout mice, also protects from ischemic damage (Burne et al., 2001; Mombaerts et al., 1992). However, it has been suggested that CD4+ T cells can be protective or injurious, depending on the balance of IFN-γ and IL-4 production (Patschan et al., 2012). NK cells are essential in the innate immune response, as they are responsible for mediating neutrophil infiltration and IFN-γ production; recruitment of NK cells from the spleen can protect the kidney from ischemic injury (Zhang et al., 2014). Rapamycin, an immunosuppressant that increases NK cell infiltration in the kidney, was found to be renoprotective shortly after ischemic injury, preventing increased serum creatinine and blood urea nitrogen levels; however, rapamycin proved to aggravate renal injury long term (7 days after reperfusion) (Zhang et al., 2014).

As mentioned, fibrosis is an irreversible chronic result of IRI, and is aggravated by reduced nephron mass. IRI induces production of fibronectin and deposition of collagen, as well as increases renal expression of TGF-β1 (Chuang et al., 2014). Fibrosis occurs at a late stage, as it is caused by aberrant repair of the injured kidney. Activated macrophages remain present as the kidney is repaired; however, these macrophages produce profibrotic cytokines, increasing the rate and severity of fibrosis (Bonventre and Yang, 2011). Further, renal tubular epithelial cells undergo changes in proliferation, resulting in a secretory phenotype that increases production of profibrotic growth factors, such as TGF-β1 (Bonventre and Yang, 2011). TGF-β1 is responsible for activating supplementary profibrotic mechanisms through the induction of profibrotic gene expression. After binding with TGF-β1, the TGF-β1 receptor interacts with Smad2/3, which enters the nucleus to regulate transcription of target profibrotic genes (Chuang et al., 2014).

Ischemic preconditioning is a mechanism used to protect against further ischemia or nephrotoxic insults. IRI preconditioning has been shown to protect the kidney from further ischemic damage from 15 min to 8 days after the initial ischemic injury (Joo et al., 2006; Park et al., 2001). Typically, the preconditioning insult causes the normal response seen with renal ischemia. However, the secondary ischemic insult is protected from decreased renal function and renal structural injury, including tubular dilation, tubular swelling and necrosis, medullary luminal congestion, and hemorrhage (Joo et al., 2006; Park et al., 2001). Inflammatory markers, such as activated JNK, p38, and MAPK, are reduced (Park et al., 2001), as are ER stress markers, such as GRP78, phospho-PERK, ATF4, and sXBP-1 (Joo et al., 2006), and apoptotic markers, caspase-12 and cytochrome-c (Wu et al., 2009). While ischemic preconditioning proves to be renoprotective in rodents, its clinical significance is still being studied.

2.1.2 Renal Artery Stenosis

Renal artery stenosis is the narrowing of arteries transporting blood to the kidney(s). It is primarily caused by atherosclerosis in humans, and increases risk of developing hypertension, CKD, as well as cardiac morbidity and mortality (Al-Suraih and Grande, 2014). Much of the tissue injury caused by renal artery stenosis is due to ischemia, as the narrow arteries cause renal hypoperfusion. Risk factors for developing renal artery stenosis include age; being female; having hypertension or other vascular diseases, CKD, or diabetes; smoking; and high cholesterol. Animal models of renal artery stenosis develop characteristics found in human renal artery stenosis, such as renovascular hypertension, decreases in cortical and whole kidney volume, decreases in cortical and whole kidney blood flow, and impaired renal function. The decreases in renal volume and blood flow correlate to the severity of the stenosis, similar to human disease (Lerman et al., 1999). Unilateral renal artery stenosis produces a significant difference between the sizes of the kidneys; however, reduced renal size is not necessarily found in bilateral renal artery stenosis (Lerman

et al., 1999). Animals with atherosclerosis, as well as renal artery stenosis, develop more severe disease. They have reduced intrarenal microvascular density, as well as increased fibrosis, tubular damage, ROS, and renal microvascular media-to-lumen ratio (Sun et al., 2016). Histologically, animal models also develop vacuolization of tubular epithelial cells, crescent-shaped structures (mainly composed of podocytes) in the glomeruli, and additional podocytic injury; further, small renal arteries develop concentric intimal hyperplasia.

Porcine models of renal artery stenosis are commonly used due to comparable renal anatomy and physiology between pigs and humans. Due to this, the pathophysiology resulting from artificially induced renal artery stenosis is similar to naturally occurring renal artery stenosis in humans. For example, the intravascular copper stent model includes development of a vascular lesion (Lerman et al., 1999). This model is also noninvasive, which puts less stress on the animals involved. It involves percutaneously using a balloon to embed a copper wire in the renal artery, which causes stenosis. Invasive models of renal artery stenosis include the two-kidney/two-clip model, the two-kidney/one-clip model, and the one-kidney/one-clip model, and can be performed in mice, rats, dogs, and pigs (Al-Suraih and Grande, 2014). These models are comparable to the IRI models (bilateral, unilateral, and unilateral with UNX), though with reduced renal blood flow instead of absent renal blood flow. These models are sensitive to antagonists of the renin–angiotensin (Ang) system, as well as changes in sodium intake (Grossman, 2010). Animals are typically sacrificed 4–12 weeks after initiation of the model.

Limited research has been conducted examining the mechanisms and roles of ER stress, apoptosis, and inflammation in renal artery stenosis. As much of the damage in renal artery stenosis models is caused by reduced, but not absent, blood flow to the kidney(s), it is likely that much of the damage found is caused by similar mechanisms as those found in IRI models. ER stress is upregulated in this model, and therefore it is likely to play a role in the development of renal damage, as well as induction of apoptosis and inflammation (Yang et al., 2014). ER stress markers, such as CHOP and GRP94, have been found to be upregulated in endothelial and proximal tubular cells of kidneys that undergo this model, but not in distal tubular cells (Zhu et al., 2013).

As mentioned, little research has been conducted to examine apoptosis in depth; researchers tend to simply note the presence or absence of apoptosis (TUNEL staining) (Chade et al., 2003; Favreau et al., 2010; Zhu et al., 2013), but not examine the mechanism(s) from which it develops. Increased levels of the proapoptotic protein, CHOP, may play a role in the increased apoptosis found in this renal artery stenosis model (Zhu et al., 2013); however, it has also been suggested that

apoptosis is induced by ROS (Lerman et al., 2009). Apoptotic markers, such as increased cleaved caspase-3 and reduced Bcl-2, are found in the kidney of this model. Interestingly, mesenchymal stem cells, which have vascular repair qualities, reduce both ER stress and apoptosis in this model (Zhu et al., 2013).

In the copper stent model, inflammatory cell infiltration occurs in the renal artery near the location of the stent; this is primarily comprised of neutrophils, which are bordered by lymphocytes and macrophages. Occasional mononuclear cells can be found in the interstitium of the kidney of this model (Lerman et al., 1999). Inflammatory markers TNF-α and IL-1β are also increased in a model of unilateral renal artery stenosis; their expression was reduced by infusion of mesenchymal stem cells (Zhu et al., 2013). NF-κB, which is involved in a proinflammatory signaling pathway as well as a fibrotic pathway, was found to be significantly increased in a model of atherosclerotic renal artery stenosis, but not in a model without atherosclerosis (Sun et al., 2016). As mentioned, inhibiting apoptosis can prevent inflammation in IRI kidneys (Daemen et al., 1999). While this mechanism has not been studied in renal artery stenosis, it is possible that a similar system exists, whereby apoptosis leads to inflammation.

Renal artery stenosis causes renal fibrosis, which is worsened with atherosclerosis (Sun et al., 2016) or hypercholesterolemia (Chade et al., 2003), an atherosclerotic simulator. As mentioned, NF-κB, which activates profibrotic cytokines, is increased in tubular, interstitial, and glomerular cells. TGF-β is also increased in the renal tubules and glomeruli. Hypercholesterolemia increased levels of fibrosis, NF-κB, but not TGF-β in this model (Chade et al., 2003). When Smad3, which is downstream of TGF-β, is genetically knocked out of a mouse, the animal is almost entirely protected from renal artery stenosis. The kidneys developed less tubular atrophy, interstitial inflammation, and interstitial fibrosis (Warner et al., 2012).

2.2 Intrinsic Acute Kidney Injury

Intrinsic AKI is caused by structural damage to the kidney, specifically the glomeruli, renal tubules, and interstitium. Damage to these structures results in acute tubular necrosis, typically caused by nephrotoxic sources or ischemia. Damage is primarily found in the proximal tubules, though severe cases can also damage the distal tubules. Causes of intrinsic AKI include toxins and drugs, damage to the striated muscle, and sepsis.

2.2.1 Antibiotics

2.2.1.1 AMINOGLYCOSIDES

The effect of aminoglycosides on the kidney is most commonly studied using gentamicin. Gentamicin is frequently used to combat severe infections caused by

Gram-negative bacteria (Singh et al., 2012). It induces AKI by binding to phospholipids on the brush border, then translocating to the transmembrane protein, megalin. It is then endocytosed into the cell, where it binds to phospholipids in the lipid bilayer, reducing phospholipase activity and phospholipid metabolite production (Singh et al., 2012). Gentamicin alters other factors that may play a role in nephrotoxicity as well, such as superoxide anion and hydroxyl radical generation, antioxidant defense systems, and the renin–Ang system (Singh et al., 2012). Gentamicin accumulates in proximal tubular cells, altering the function of organelles. This results in tubular necrosis, proximal tubular cell vacuolization, mesangial hypercellularity, glomerular endothelial cell proliferation, cortical interstitial edema, and dilation and congestion of intertubular capillaries.

Typically, AKI is induced in animal models via intraperitoneal injection at a dose of 100 mg/kg for 5 days (Erdem et al., 2000), though other doses and end points have been used as well (40–200 mg/kg twice a day, for up to 14 days) (Bledsoe et al., 2008; Ortega et al., 2005; Volpini et al., 2006). While subcutaneous (Bledsoe et al., 2008) and intramuscular (Volpini et al., 2006) injections are also used, the intraperitoneal injection is the most similar to aminoglycoside-induced AKI in a clinical setting. The gentamicin model of AKI is typically performed on rats, as they are most similar to human gentamicin-induced nephrotoxicity (Suzuki et al., 1995), but other species are also used, such as mice (Whiting et al., 1981), dogs (Kai et al., 2013), and minipigs (Cui et al., 2015).

Gentamicin, once endocytosed, is reallocated into organelles via retrograde endosomal trafficking, including the ER and lysosomes (Sandoval et al., 2000). This absorption into the ER may be what initiates ER stress, which is exemplified by increased GRP78 and GRP94 expression and XBP1 splicing. Additionally, gentamicin treatment slightly increases renal expression of caspase-12 (Peyrou et al., 2007), as well as other apoptotic markers, such as caspase-3 (Bledsoe et al., 2008; Cui et al., 2015), cytochrome-c, and Bax (Suh et al., 2013). In vitro work demonstrates that apoptosis is dependent on the amount of drug accumulation in the cells (El Mouedden et al., 2000), though gentamicin-mediated lysosomal rupture also contributes to activation of proapoptotic pathways via protease release (Schnellmann and Williams, 1998). Further, it has been suggested that storage of gentamicin in lysosomes and other organelles is protective; however, gentamicin damages the lysosomal membrane (Servais et al., 2005), resulting in its release from the lysosome into the cytosol (Servais et al., 2006). Once in the cytosol, it activates the mitochondrial apoptosis pathway, induces oxidative stress, and decreases ATP stores (Morales et al., 2010; Simmons et al., 1980). Gentamicin induces upregulation of proinflammatory markers, such as NF-κB (Cui et al., 2015), TNF-α, MCP-1, and ICAM-1, and

infiltration of monocytes/macrophages and neutrophils (Bledsoe et al., 2008). It is believed that oxidative stress is responsible for the activation and nuclear translocation of NF-κB, which then regulates activation of the proinflammatory cytokines, chemokines, and adhesion molecules (Bae et al., 2014). After 10 days of gentamicin treatment, myofibroblasts are found in the renal interstitium, though fibrosis has yet to develop; several weeks after cessation of gentamicin treatment, fibrosis can be found in the kidney. This suggests that the interstitial myofibroblasts, which secrete ECM proteins and TGF-β, may encourage the development of gentamicin-induced fibrosis (Bledsoe et al., 2008).

2.2.1.2 NUCLEOSIDES

Tunicamycin is the most common agent used to study the effects of nucleoside antibiotics on the kidney. It is also commonly used in vitro to study the effects of ER stress in various cell types (Bassik and Kampmann, 2011). Tunicamycin inhibits protein glycosylation, resulting in vacuolization of the renal tubular epithelium and acute tubular necrosis (Carlisle et al., 2014). Tunicamycin is typically administered intraperitoneally at a dose of 0.5–1.0 mg/kg for 3 days (Carlisle et al., 2014; Marciniak et al., 2004). The principal area of renal damage caused by tunicamycin occurs in the corticomedullary region of the kidney (Carlisle et al., 2014) (Fig. 16.2).

By inhibiting N-linked glycosylation, tunicamycin induces ER stress, such as increased GRP78, and the proapoptotic protein, CHOP. CHOP is upregulated specifically in proximal tubular cells (Carlisle et al., 2014). CHOP knockout mice and mice with mutant GADD34 are resistant to tunicamycin-mediated renal damage (Carlisle et al., 2014; Marciniak et al., 2004), suggesting ER stress-mediated apoptosis is the primary mechanism of renal damage. Male and female mice actually have different responses to tunicamycin; female mice are more susceptible to damage in the S3 segment of the proximal tubule (Fig. 16.2, female), while male mice, and female mice pretreated with testosterone, are more susceptible to damage in the outer cortex (S1 and S2 segments). Female mice also demonstrate reduced expression of ER stress markers and proapoptotic markers (Hodeify et al., 2013). While limited studies have been performed on tunicamycin and renal inflammation, it has been noted that knockout of the inflammatory cytokine TNF-α or its receptor TNF-α-R1 results in increased sensitivity to tunicamycin-mediated ER stress and renal injury (Huang et al., 2011). While it is unknown if tunicamycin induces a fibrotic response, it is a likely outcome, as ER stress tends to facilitate the development of fibrosis (Tanjore et al., 2013).

2.2.1.3 CALCINEURIN INHIBITORS

Calcineurin inhibitors are administered to transplant patients because of their immunosuppressive properties.

AKI: Intrinsic, TM
FIGURE 16.2 **Tunicamycin (TM)-induced acute kidney injury (AKI in cortex (Cx), outer medulla (OM), and inner medulla (IM) compared to sham.** Female mice were treated with saline (sham) or TM (single-bolus injection, 0.5 mg/kg) and sacrificed 3 days later. Periodic acid-Schiff staining revealed TM-induced damage to proximal convoluted tubules in Cx *(arrows)* and pars recta in OM *(asterisks)*. Images were taken with an Olympus BX41 microscope using 10× (scale bar: 500 μm) and 40× (scale bar: 200 μm) objectives.

The most common calcineurin inhibitors are cyclosporine and tacrolimus, which have both been used for decades (Naesens et al., 2009). Cyclosporine and tacrolimus competitively bind to molecules causing inhibition of the phosphatase activity of calcineurin. This alters the translocation of the nuclear factor of activated T cells (NFAT), and reduces T-cell activation (Naesens et al., 2009). It has been hypothesized that the immunosuppressive action of calcineurin inhibitors is correlated with their nephrotoxicity, suggesting that inhibition of calcineurin causes renal damage (Sigal et al., 1991). Apart from their immunosuppressive properties, calcineurin inhibitors also cause endothelial cell function impairment, resulting in vasoconstriction of glomerular arterioles and reduced blood flow. This leads to necrosis, hyalinosis of cells in afferent arterioles, and vacuolization of proximal tubular cells. These outcomes are consistent in both humans and animals, indicating translatability between species (Naesens et al., 2009).

In animals, cyclosporine is administered intraperitoneally or subcutaneously at a dose of 7.5–15.0 mg/kg/day (Islam et al., 2001; Pallet et al., 2008; Thomas et al., 1998). Tacrolimus is administered to the animal via ingestion or oral gavage (0.1–12 mg/kg/day) (Hoskova et al., 2014; Malinowski et al., 2010), intravenously at a dose of 0.5 mg/kg (McLaughlin et al., 2003), or intraperitoneally at 2 mg/kg/day (Al-Harbi et al., 2014).

ER stress is induced in the kidney, as demonstrated with increased GRP78 expression in rats (Pallet et al., 2008) and humans (Lhotak et al., 2012). It has been suggested that calcineurin inhibitors do not directly induce ER stress, but that vascular dysfunction causes hypoxia, which causes ER stress. As calcineurin inhibitors induce hypoxia (Zhong et al., 1998), it is likely that apoptosis occurs via the same mechanism as in IRI. Calcineurin inhibition may also directly induce proapoptotic genes, thereby increasing apoptosis in proximal tubular and interstitial cells (Servais et al., 2008). Calcineurin inhibitors are used as immunosuppressants and antiinflammatories; nonetheless, subclinical inflammation, with macrophage infiltration, is associated with calcineurin inhibition (Thomas et al., 1998). Cyclosporine induces fibrosis and fibrotic markers are increased, such as vimentin, fibronectin, type III collagen (Pallet et al., 2008), type I collagen, type IV collagen, and TGF-β1 (Islam et al., 2001). Interestingly, fibrosis and expression of fibrotic markers were prevented with ER stress inhibition (Pallet et al., 2008). Further, inhibiting TGF-β1 expression prevents renal function decline, arteriolar hyalinosis, and collagen expression; however, interstitial damage is worsened with TGF-β1 inhibition (Islam et al., 2001). In vitro work indicates that cyclosporine acts directly on tubulointerstitial fibroblasts and proximal tubular cells to increase collagen (Wolf et al., 1990). Acute renal damage caused by calcineurin inhibitors can progress to CKD, and can also cause hypertension (Naesens et al., 2009).

2.2.1.4 CHEMOTHERAPEUTICS

Chemotherapeutics, such as cisplatin, can cause AKI in up to one-third of patients. Cisplatin is a nephrotoxic antineoplastic drug used to treat solid-organ cancers (Miller et al., 2010). Cisplatin is freely filtered by the glomerulus, and becomes trapped in the renal cortex (Ozkok and Edelstein, 2014), causing acute tubular necrosis, dilation of proximal convoluted tubules, and sloughing of the epithelium, particularly in the corticomedullary region. Animals treated with cisplatin also display adverse clinical signs, such as altered behavior, anorexia, and dehydration (Peyrou et al., 2007).

Cisplatin is typically administered to mice or rats at a single intraperitoneal dose of 5–40 mg/kg; however, studies have used doses up to 100 mg/kg (Singh et al., 2012) or daily injections (Peyrou et al., 2007). Renal failure is induced within 72 h (Singh et al., 2012). The single-dose model is not directly translatable to human disease, as the animals are often administered a high dose of the drug, and then sacrificed days later. Low-dose/single-injection studies are somewhat relevant, as human patients often develop AKI after a single cisplatin treatment. A study providing mice with high-dose/single-injection or low-dose/weekly treatments of cisplatin, similar to what would be performed in human disease, revealed differences in renal function, renal injury, apoptosis, necrosis, inflammation, and fibrosis between the two treatments (Sharp et al., 2016).

Cisplatin has been shown to induce expression of ER stress markers in kidney cells both in vitro (Liu and Baliga, 2005) and in vivo (Peyrou et al., 2007). However, the UPR pathways do not appear to play a role in cisplatin-mediated apoptosis. ER stress–induced activation of caspase-12 appears to be responsible for cisplatin-induced cell death. Caspase-12 is induced by ER stress, but not by the pathways of the UPR (Mandic et al., 2003); thus, it is likely that caspase-12 is activated by protein aggregation and inhibiting protein misfolding could prevent cisplatin-induced acute tubular necrosis. Interestingly, inhibiting caspase activity, and thus preventing cellular autophagy, worsens renal damage and function in cisplatin-treated C57BL/6 mice (Herzog et al., 2012), though knockout of caspase-1 alone reduces injury (Faubel et al., 2004). The proinflammatory response induced by cisplatin results in infiltration of T cells, neutrophils, macrophages, and mast cells (Ozkok and Edelstein, 2014), as well as activation of cytokines, such as IL-1β, IL-6, NF-κB (Sung et al., 2008), TGF-β (Faubel et al., 2007), and TNF-α (Ramesh and Reeves, 2002). Inhibiting TNF-α expression, by pharmacological or genetic means, reduces cisplatin-mediated injury (Ramesh and Reeves, 2002), suggesting TNF-α is pivotal to cisplatin-mediated AKI. TLRs on renal parenchymal cells also play a significant role in cisplatin-mediated inflammation, activating the p38–MAPK

pathways (Zhang et al., 2008). Fibrosis can occur with single-dose (Yamate et al., 2005) or repeated-injection (Sharp et al., 2016) cisplatin treatment. Fibrosis occurs primarily in the corticomedullary region, and kidneys demonstrate increased TGF-β, fibronectin, collagen, and α-smooth muscle actin.

2.2.2 Heavy Metals

2.2.2.1 MERCURY

The nephrotoxic effects of mercury have been recognized for many years. However, the location of renal damage and physiological symptoms are dependent on the structure of the compound (Fowler, 1993). The inorganic mercuric chloride or organometallic methyl mercury are the compounds typically used in animal models, and induce damage in the S3 segment of the proximal tubule. Methyl mercury can also cause damage to the S2 segment of the proximal tubule, depending on the sex of the animal and dose and duration of exposure (Fowler, 1993). Mice and rats are given a subcutaneous injection of the mercuric compound, in doses ranging from 0.34 (Sanchez et al., 2001) to 10 mg/kg (Ahn et al., 2002), intraperitoneal injection of 6 mg/kg (Ewald and Calabrese, 2001), or 25 ppm in the drinking water daily (Abdel-Salam et al., 2010). Animals injected with 25 mg/kg mercuric chloride died within 2–4 min (Cunha et al., 2003). Animals are sacrificed at various time points, from 24 h (Stacchiotti et al., 2009) to 6 weeks (Abdel-Salam et al., 2010).

Mercury has a high bonding affinity with sulfur, specifically in the sulfhydryl groups in albumin, metallothionein, glutathione, and cysteine (Zalups, 2000). This leads to fragmentation of the plasma membrane (Kempson et al., 1977), mitochondrial swelling (Southard and Nitisewojo, 1973), and disruption of organelles (Fowler et al., 1975) in proximal tubular cells. Blebbing and sloughing of the brush border of proximal tubules (primarily the S3 segment) is also seen (Kempson et al., 1977).

It is unknown if heavy metal nephrotoxicity induces ER stress. While ER stress has not been examined in animals treated with mercury, rat renal epithelial cells treated with mercuric chloride have demonstrated increased GRP78 levels in vitro (Stacchiotti et al., 2009); this suggests that ER stress may be induced in the kidneys of treated animals. Apoptosis is present in the cortical proximal tubules, as demonstrated by transmission electron microscopy and TUNEL staining; severity of apoptosis is dependent on the dose and duration of treatment (Nava et al., 2000; Stacchiotti et al., 2009). Mercury sulfide, or cinnabar, a traditional Chinese medicine, has been studied as a source of mercurial nephrotoxicity. After daily ingestion, it increased inflammatory markers in rats, such as chemokines, selectins, ILs, and TIMPs. Further,

it causes renal tubulointerstitial fibrosis by 8 weeks of treatment (Wang et al., 2015b).

2.2.2.2 CHROMIUM

Acute exposure to chromium can cause many symptoms, such as gastrointestinal distress, fever, muscle cramps, liver damage, and renal failure. Hexavalent and trivalent chromium are used in many industrial and chemical processes, such as leather tanning, printing, and steel manufacturing (Singh et al., 2012). Hexavalent chromium is absorbed more readily than trivalent chromium, which must be reduced by glutathione, ascorbate, and hydrogen peroxide (Aiyar et al., 1991). Nephrotoxic effects of chromium are typically studied using mice, rats, or rabbits treated with potassium dichromate. Potassium dichromate is subcutaneously injected into the animal at a dose of 15 mg/kg (Appel et al., 1981), and the animal is typically sacrificed within 48 h (Khan et al., 2010). In humans, acute chromium exposure is normally due to ingestion, which differs from the animal model using subcutaneous injection.

The mechanisms by which chromium causes renal damage are largely unknown; damage includes tubular degeneration in the outer cortex, DNA damage, areas of interstitial inflammation, and intratubular protein cast formation (Sahu et al., 2014). Proapoptotic markers are increased, such as Bax and cleaved caspase-3, at 48 h postinjection. Levels of inflammatory markers, such as TNF-α and nuclear NF-κB, are also upregulated at this time point (Sahu et al., 2014). Research examining the fibrotic effects of chromium is lacking.

2.2.2.3 URANIUM

Acute uranium poisoning is studied in animal models involving uranyl nitrate or uranyl acetate (Singh et al., 2012). These animals develop reduced renal function, proteinuria, glucosuria, and tubular damage (Blantz, 1975). Uranyl-mediated damage occurs primarily in the S3 region of the proximal tubule (Bulger, 1986), causing a reduction in proximal tubular reabsorption of amino acids and low–molecular weight proteins. This leads to tubular necrosis, hyaline cast formation, vacuolization of tubules, and widening of the Bowman's capsule (Martinez et al., 2003). Animal models for uranium nephrotoxicity are typically performed in rats or mice, but vary with regards to dose of uranyl nitrate or uranyl acetate, as well as delivery method. Some studies reported using intravascular injection (5–25 mg/kg) (Avasthi et al., 1980; Kim et al., 1998), whereas others report intraperitoneal administration (0.5–10 mg/kg) (Priyamvada et al., 2010; Tolson et al., 2005) or subcutaneous injection (5 mg/kg) (Domingo et al., 1997). Each of these models develops renal failure within 3–5 days. Martinez et al. (2003) employed an oral gavage method, using 350 mg/kg uranyl nitrate in BALB/c mice, which developed AKI within 48 h.

As mentioned, renal damage, and thus apoptosis, occurs primarily in renal proximal tubular cells; electron microscopy demonstrates condensed chromatin and relatively intact cell organelles at 5 days posturanyl administration. Proximal tubules also demonstrate high expression levels of Bax and reduced levels of Bcl-2 (Sano et al., 2000). In vitro work demonstrates that uranium causes mitochondrial damage, decreasing MMPs, which produces ROS. Increased ROS ultimately leads to the activation of caspase-9 and caspase-3 (Thiebault et al., 2007). This pathway has yet to be confirmed in vivo. Inflammation occurs, with decreased innate and cellular immune function, and abnormal humoral immune function. Zheng et al. (2015) suggest that increased ROS activate the TNF-α pathway, leading to inflammation. Gene expression of other proinflammatory marks is also increased after acute exposure to uranium (Taulan et al., 2006). Uranium has been shown to cause renal interstitial fibrosis after chronic exposure (Zhu et al., 2009), but data on acute exposure are incomplete.

2.2.2.4 NONSTEROIDAL ANTIINFLAMMATORY DRUGS

Acetaminophen is an analgesic and antipyretic drug that is safe to use within the recommended doses; however, it can cause hepatic necrosis and renal failure in overdoses (Singh et al., 2012). Nonsteroidal antiinflammatory drugs (NSAIDs) typically cause damage through ischemia- or immune-related mechanisms. NSAIDs can cause reduced renal function, acute tubular necrosis, and acute interstitial nephritis, especially in the corticomedullary region (Choudhury and Ahmed, 2006). Animal models use a variety of NSAIDs, such as acetaminophen (Singh et al., 2012), indomethacin (Nagappan et al., 2015), and the NSAID metabolite p-aminophenol (Peyrou et al., 2007). Acetaminophen is typically used in a dose range of 375–13000 mg/kg via intraperitoneal injection (Singh et al., 2012), though occasionally ingestion is used as the delivery method (Kadowaki et al., 2012). Indomethacin is administered via oral gavage at a dose of 20 mg/kg (Nagappan et al., 2015), and p-aminophenol is administered by a single intraperitoneal injection at a dose of 225 mg/kg. Renal function is reduced in rodents within 6–24 h of NSAID treatment (Cekmen et al., 2009; Peyrou et al., 2007).

Information on the induction of ER stress by NSAID overdose is somewhat lacking. Treatment with the acetaminophen metabolite, p-aminophenol, resulted in increased expression of select ER stress markers (GRP94 and XBP1), but not others (GRP78) (Peyrou et al., 2007). Conversely, low-dose acetaminophen (30 mg/kg/day) was shown to reduce ER stress markers in obese kidneys (Wang et al., 2014a), suggesting more research on this topic is required. Indomethacin was shown to induce ER stress, but not apoptosis in the kidney (Nagappan et al., 2015). However, acetaminophen and

p-aminophenol promote apoptosis, as demonstrated by pyknotic nuclei (Ortiz, 2000) and increased cleaved caspase-12 (Peyrou et al., 2007). Proinflammatory cytokines, such as TNF-α and IL-6, are increased in rats overdosed with acetaminophen (Cermik et al., 2013), and a chronic inflammatory reaction is seen in response to a single dose of *p*-aminophenol (Green et al., 1969). In vitro data demonstrate that renal epithelial tubular cell death and fibroblast proliferation occur in response to acetaminophen (Yu et al., 2014). Further, chronic high doses of NSAIDs can cause medullary fibrosis (Choudhury and Ahmed, 2006), though it is unclear if acute overdose causes similar results.

2.2.2.5 RADIOCONTRAST MEDIA

Iodinated radiocontrast media are used in radiological imaging and cause AKI. Patients with volume depletion, congestive heart failure, preexisting renal failure, or diabetes mellitus (DM) are more likely to develop impaired renal function and renal damage (Singh et al., 2012). Radiocontrast medium is more viscous and has a higher osmolality than blood. As radiocontrast media travels through the kidney, water is reabsorbed, while the radiocontrast media is not. This increases the tubular fluid viscosity significantly, reducing perfusion and causing hypoxia (Seeliger et al., 2014). Radiocontrast medium causes renal damage by reducing blood flow and GFR, causing vasoconstriction of the vasa recta, and direct tubular toxicity, such as acute tubular necrosis, interstitial inflammation, and tubular cytoplasmic vacuolization (Deray, 1999). Risk of AKI increases with increasing dose volume and repeated administrations. Larger volumes are used for coronary angiography compared with other imaging studies; thus, AKI is more likely to develop in patients undergoing coronary angiography (Andreucci et al., 2014). Animal models involve intravascular iodinated contrast media of varying types, such as diatrizoate, ioxaglate, iohexol, and sodium iothalamate.

Similar to human studies, radiocontrast agents are administered to animals intravascularly, typically via aortic or jugular injection. Varying doses are used, depending on the specific agent; diatrizoate is used at 2–10 mL/kg for 2–5 min (Colbay et al., 2010; Erley et al., 1997; Yen et al., 2007), ioxaglate is used at 1 mL/min for 3 min (Touati et al., 1993), iohexol is used at 1.5–3 g/kg (Lee et al., 2006), and sodium iothalamate is used at 6 mL/kg for 2–3 min (Agmon et al., 1994). Renal failure can be induced within 1 h of administration (Agmon et al., 1994), though 24–48 h is more common.

Radiocontrast media induces ER stress, activating the PERK pathway, in rat renal proximal tubular cells in vitro (Wu et al., 2010a), but it is yet unknown if results are similar in vivo. As mentioned, radiocontrast agents induce apoptosis due to their hyperosmolality (Hizoh and Haller, 2002) and viscosity (Andreucci et al., 2014).

Radiocontrast media induce significant apoptosis within 24 h, particularly in the corticomedullary region, as demonstrated by caspase-3 and -9 upregulation (Ko et al., 2016) and decreased Bcl-2 expression (Wang et al., 2014b). Inhibiting autophagy, with 3-methyladenine, exacerbates apoptotic cell death (Ko et al., 2016), suggesting autophagy is renoprotective. Further, erythropoietin administration provides renoprotective effects, maintains renal function, and prevents apoptosis (Yokomaku et al., 2008). Interstitial inflammation is induced by contrast media, as demonstrated by macrophage infiltration (Ko et al., 2016) and increased proinflammatory cytokines IL-6 and TNF-α (Deng et al., 2015). Much like the apoptotic response, inflammatory response is worsened by inhibiting autophagy (Ko et al., 2016). Typically, radiocontrast agents do not cause renal fibrosis; however, gadolinium-based contrast agents, such as those used for MRI imaging, are associated with renal fibrosis, as well as fibrosis in other organs (Kallen et al., 2008). Radiocontrast medium–induced AKI does not develop into CKD, though it can increase the rate of progression if the patient already has CKD (Singh et al., 2012).

2.2.2.6 RHABDOMYOLYSIS

Rhabdomyolysis is a condition involving the breakdown of striated muscle fibers and release of myoglobin into the bloodstream. Myoglobin is typically filtered in the kidneys, but excessive levels can cause kidney damage. In humans, rhabdomyolysis is often caused by intrinsic muscle dysfunction, such as physical trauma, burns, disease, or excessive physical exertion; however, it can also be the result of certain metabolic disorders, hypoxia, drugs, toxins, infections, or temperature extremes.

Animal models of rhabdomyolysis include intramuscular injection of glycerol. Standard protocol calls for 50% glycerol–saline at a dose of 8 mL/kg (Savic et al., 2002), though 10 mL/kg has also been used (Vlahovic et al., 2007). The intramuscular injection is administered equally between both hind legs. Animals are usually, but not always, deprived of food and water 18–24 h prior to injection and sacrificed 24–48 h after injection (Sauriyal et al., 2012; Vlahovic et al., 2007), though longer time points are also observed (Korrapati et al., 2012). It has been suggested that models of sucrose injection or hemorrhage be performed, instead of dehydration, as this bears a more similar resemblance to clinical cases where humans are not chronically dehydrated prior to rhabdomyolysis (Zurovsky, 1993). Typically, animals used in rhabdomyolysis experiments are restricted to mice, rats, and rabbits (Singh et al., 2012).

While the mechanisms of glycerol's pathogenic effect on muscle are incompletely understood, it is known that the excessive myoglobin in the kidney causes tubular nephrotoxicity. Acute tubular necrosis develops

as excessive levels of myoglobin form intratubular protein casts, obstructing tubules (Vanholder et al., 2000). Further, there appears to be ischemic injury, possibly caused by intrarenal vasoconstriction, and the kidney undergoes ER stress, apoptosis, inflammation (Korrapati et al., 2012), and eventual fibrosis. While it is known that GRP78 levels are increased in the corticomedullary region of the kidney (Zhao et al., 2016), very little research has been performed on ER stress and rhabdomyolysis. Unfortunately, research demonstrating which of the three UPR pathways are activated has not been completed. Apoptosis occurs primarily in the renal tubular epithelial cells in this model of AKI (Komada et al., 2015; Singh et al., 2012). Increased expression of apoptotic markers, such as caspase-1 and -12, are found in the kidney (Komada et al., 2015; Zhao et al., 2016). Inflammatory markers include neutrophil and monocyte infiltration into the corticomedullary region and increased IL-1β, IL-6, and NF-κB activation (Komada et al., 2015; Korrapati et al., 2012). Komada et al. (2015) suggest that NLRP3 inflammasomes play a crucial role in the initial inflammation and injury caused by the glycerol injection, demonstrating that the inflammatory response, tubular apoptosis, and tubular injury precede leukocyte infiltration into the kidney. After 48 and 72 h of glycerol injection, TGF-β1 expression is increased, suggesting profibrotic activity (Korrapati et al., 2012). Mice injected with glycerol demonstrate fibrosis predominantly found in the interstitium and perivascular regions of the kidney; increased ECM deposition is made up of fibronectin, type IV collagen, and α-actin smooth muscle (Rubio-Navarro et al., 2015). Interestingly, macrophage depletion reduces renal fibrosis for up to 7 months after rhabdomyolysis initiation (Belliere et al., 2015).

2.2.2.7 SEPSIS

In humans, sepsis involves two stages that occasionally overlap, a proinflammatory stage that causes hypotension and organ dysfunction, and an antiinflammatory stage that leads to immunosuppression through reduced lymphocyte proliferation and increased lymphocyte apoptosis (Doi et al., 2009). The mechanism of renal damage is not completely elucidated; proposed mechanisms include endothelial dysfunction-mediated glomerular hypoperfusion, intraglomerular thrombosis, intrarenal hemodynamic changes, inflammatory response induced by systemic or local cytokines, and tubular dysfunction causing obstruction (Doi et al., 2009).

Animal models include endogenous toxin [lipopolysaccharide (LPS) injection], dysfunction of endogenous protective barrier (cecal ligation and puncture or colon ascendens stent peritonitis), or infusion of exogenous bacteria (Doi et al., 2009). LPS is typically administered intraperitoneally at a dose of 0.075–60 mg/kg (Cunningham et al., 2002; Szabo et al., 1994). The cecal ligation and puncture model involves ligating the cecum, below the iliocecal valve, and then puncturing the cecum with a needle. A small amount of feces is gently forced from the cecum through the perforation sites, and the animal is sutured and resuscitated (Toscano et al., 2011). This model is often touted as the "gold standard" sepsis model, as it is most similar to the complex response seen in humans (Dejager et al., 2011). The colon ascendens stent peritonitis method is performed by inserting a cannula into the ascending colon, and gently squeezing the colon to force feces into the cannula. This allows a continuous flow of intestinal bacteria into the peritoneum (Traeger et al., 2010). The infusion of exogenous bacteria model is not often used, as it is requires large animals, is labor intensive, and is less translatable than other methods (Doi et al., 2009). Septic AKI is usually induced in rodents, though sheep, pigs, and nonhuman primates have also been used. Results from these models may be variable due to different strains, species, and age (Zarjou and Agarwal, 2011).

ER stress appears to be induced with LPS-mediated septic AKI. GRP78, GRP94, spliced XBP1, and CHOP levels are upregulated 6 h after LPS injection. ER stress may play a protective role, as knockout of CHOP exacerbated LPS-mediated apoptosis, proinflammatory cytokine production, and inflammatory cell infiltration (Esposito et al., 2013). LPS injection induces proinflammatory cytokines, such as IL-1 and TNF-α (Okusawa et al., 1988; Tracey et al., 1986). Inhibiting either of these cytokines provides protection against renal damage (McNamara et al., 1993; Tracey et al., 1987). Further, genetic knockout of TNF-α-R1 protects against LPS-induced apoptosis and inflammation (Cunningham et al., 2002). Endotoxin-induced septic AKI induces interstitial and glomerular fibrosis within 9 h of treatment. Renal endothelial cells exhibit myofibroblast markers (Castellano et al., 2014), indicating that intrarenal vascular dysfunction may contribute to renal fibrosis.

2.3 Postrenal Acute Kidney Injury

Postrenal AKI is caused by an obstruction in the urinary tract, which increases intratubular pressure, reducing GFR. It also can reduce renal blood flow and activate inflammatory pathways that exacerbate the reduced GFR. Postrenal AKI can be caused by many factors, such as prostate cancer, gynecologic cancers, and renal or ureteral stones. Studies indicate that postrenal AKI accounts for less than 5% of all AKI cases (Basile et al., 2012).

2.3.1 Kidney Stones

Nephrolithiasis, or kidney stones, cause renal damage by acting as an obstruction in the kidney, which allows filtrate to build up and stretch the proximal ureter and collecting ducts. Kidney stones are derived from

crystal-forming substances, typically calcium, oxalate, and uric acid, and can form in the interstitium or in tubules (Khan, 2010). Crystals tend to aggregate at the corticomedullary region, papillary tips, and fornices, as these areas have reduced luminal diameter and crystal movement is blocked. The most common type of stone in humans is composed of calcium oxalate, though stones can also be composed of struvite or cystine (Khan, 2010). Formation of stones results in desquamation of epithelial cells in collecting ducts, aggregation of desquamated cells in the tubular lumen, degenerative alterations in the epithelium (Khan et al., 2006), and pyknosis of nuclei.

There are a number of animal models of kidney stone–mediated AKI, which are usually performed in rats (Oh et al., 2011), though mice (Okada et al., 2007), rabbits (Sarica et al., 2001), and pigs (Mandel et al., 2004) are also used. Hyperoxaluria can develop into calcium oxalate stones, and can be induced in animals by treatment with sodium oxalate, ammonium oxalate, hydroxyl-L-proline, ethylene glycol, glycolic acid, or glyoxalate (Khan, 2010). The features of calcium oxalate kidney stones are incredibly similar between human and rat subjects. Kidney stones develop acutely when animals are administered treatment via intraperitoneal injection (Khan, 1997), while ingestion leads to chronic development of stones (McMartin, 2009). Supplementing the animals with vitamin D or calcium chloride produces more acute results (Asplin et al., 1996). There are also a number of genetic models of nephrolithiasis and hyperoxaluria, though they simulate chronic renal damage and are inferior to the inducible models (Khan, 2010).

It is yet undiscovered if kidney stones induce ER stress in the kidney; however, levels of free radicals are increased (Thamilselvan et al., 1997) and oxidative stress is induced (Bas et al., 2009) in the early stages of kidney stone development. While crystals originally develop in renal tubules, they translocate to the interstitium; this movement is associated with an inflammatory response, characterized by leukocytes, monocytes, and macrophages (de Water et al., 1999). Renal fibrosis is present in human patients with kidney stones (Boonla et al., 2011), though it has yet to be thoroughly examined in animal models. In vitro studies suggest that the fibrotic response may be TGF-β dependent (Kanlaya et al., 2013).

2.3.2 Ureteral Obstruction

Ureteral obstruction is studied in animals using the unilateral ureteral obstruction (UUO) model, which involves obstructing one ureter. Ureteral obstruction induces TGF-β signaling, causing increased activation of Smad2/3 (Fu et al., 2006). The kidney develops tubular dilatation, flattening, and atrophy, as well as infiltration of inflammatory cells, and expansion of the interstitial area with ECM proteins (Yang et al., 2010). Originally, this model was performed in rabbits and dogs, though it has become more common to use rats and mice (Chevalier et al., 2009).

The UUO model can be used to study acute or chronic obstruction. Acute obstruction, where the insult is removed, can prevent or reverse renal injury, while chronic obstruction results in irreversible renal injury (Chevalier et al., 2009). UUO is an excellent model to use when studying the fibrotic response in the kidney, as exogenous toxins that can have additional effects on the kidney are not involved. Renal function cannot be measured in the UUO model, unless contralateral nephrectomy is performed. The UUO model is most commonly performed by ureteral ligation; in models of acute obstruction, where the insult is removed, tissue expansion around the ligation site can make removing the obstruction difficult (Chevalier et al., 2009). Alternatively, this model can be performed using microvascular clamps placed around the ureter (Puri et al., 2010). If used incorrectly, the microvascular clamps can injure the ureter or only partially obstruct the ureter. Partial UUO models are also sometimes studied, using silastic tubing (Hesketh et al., 2014) or partially ligating the ureter of a neonatal mouse (Thornhill et al., 2005). Loss of renal function typically occurs within 24 h, with fibrosis developing by 1–2 weeks of obstruction (Chevalier et al., 2009).

UUO induces ER stress in the kidney, particularly in the renal tubular cells, as demonstrated by increased GRP78 and CHOP expression (Fan et al., 2015; Liu et al., 2015). UUO-mediated renal tubular epithelial cell injury is partially caused by ischemia (Chevalier et al., 2009), which may contribute to the induction of ER stress. ER stress–dependent apoptosis is subsequently induced in the renal tubules (Liu et al., 2015; Yoneda et al., 2001). Genetic knockout of MKK3, which can be activated by ER stress (Darling and Cook, 2014), prevents UUO-mediated apoptosis and an early inflammatory response, but not fibrosis (Ma et al., 2007). Further, genetic knockout of Smad3 [which is also activated by ER stress (Tanjore et al., 2013)] prevented apoptosis, inflammation, and fibrosis mediated by UUO. It was suggested that apoptosis is induced indirectly of Smad signaling, while inflammation and fibrosis are directly caused by Smad3 activation (Inazaki et al., 2004). Apoptosis and inflammation can lead to a profibrotic response in this model. Apoptosis leads to atubular glomeruli and tubular atrophy, while cytokines that induce fibroblast proliferation and activation are released from macrophages in the interstitium (Chevalier et al., 2009). It has also been suggested that cells undergo cellular plasticity, with tubular epithelial cells, vascular endothelial cells, and pericytes differentiating into a myofibroblast phenotype (Chevalier et al., 2009).

3 CHRONIC KIDNEY DISEASE: ANIMAL MODELS

CKD is an important degenerative disease of the organs with an increasing prevalence and incidence (Jha et al., 2013). CKD is more likely to occur in older individuals, and the demographic shift in many societies toward a more aged population may, in part, explain its increasing prevalence (Jha et al., 2013). The prevalence of CKD on a global basis is about 10%–15% (Jha et al., 2013). The disease is not curable; although, interventions to slow its progression to ESRD are prevalent. Unlike AKI, the damage that occurs in the kidney is permanent, thus preventing disease progression and preserving organ function is of great importance. Strategies to prevent CKD progression, according to the 2013 KDIGO guidelines, include blood pressure control and renin/angiotensin/aldosterone system (RAAS) blockade, tight glycemic control in the case of diabetic nephropathy (DN) (target A1C of 7%), lowering of salt intake below 2 g of sodium in adults unless contraindicated, and lifestyle modification with physical activity, BMI (20–25), and smoking cessation. However, animal models are leading to an increasingly detailed understanding of the pathophysiology of CKD progression. This in turn offers real opportunities to specifically target the aspects of CKD pathology that leads to progression, including the activation of the immune system, renal interstitial fibrosis, and proteinuria/albuminuria as key mediators of progression. As such, animal models of CKD offer appropriate preclinical test systems for novel therapeutics aimed at preventing CKD progression.

3.1 Hypertensive CKD

Hypertension has been reported to occur in 85%–95% of patients with CKD (stages 3–5) (Rao et al., 2008). Hypertension has been considered a cause for CKD development and is an independent risk factor for CKD progression to ESRD, as well as cardiovascular events in CKD patients, such as myocardial infarction and stroke (Barri, 2008). In the RENAAL study, every 10-mmHg rise in systolic blood pressure increased the risk for ESRD or death by 11% (Bakris et al., 2003). Further, antihypertensive drugs, such as β-blockers and dihydropiridine calcium channel blockers, are widely used in the treatment of CKD patients. Along with increased blood pressure, hypertensive CKD in humans is characterized by proteinuria and glomerulosclerosis, resulting in declining GFR (Rao et al., 2008). Renal histological analysis shows interstitial fibrosis and associated renal inflammation, where T cells and macrophages have been implicated in the pathogenesis and progression of CKD (Silverstein, 2009). The accumulation of unfolded proteins in the ER has been reported in human CKD (Wu et al., 2010c), and results in the activation of the UPR. The UPR results in the dissociation of GRP78, an important regulatory chaperone protein, from three ER transmembrane proteins: PKR (double-stranded RNA-dependent protein kinase)–like ER protein kinase (PERK), inositol-requiring enzyme 1 (IRE1), and activating transcription factor 6 (ATF6) (Cybulsky, 2010; Dickhout and Krepinsky, 2009; Inagi, 2010). These three pathways are important in determining the fate of renal glomerular and tubular cells during CKD. The IRE1α and PERK pathway activate important apoptosis, autophagy, and inflammatory pathways that have been implicated in CKD pathogenesis (Mohammed-Ali et al., 2015a; Sano and Reed, 2013). Animal models of hypertensive CKD discussed here display most of the features of human hypertensive CKD and its associated comorbidities, particularly cardiovascular disease.

3.1.1 Spontaneously Hypertensive Rat Model

The spontaneously hypertensive rat (SHR) is the most commonly used model of hypertension and cardiovascular disease. The SHR strain was produced by Okamoto and Aoki (1963) by selective inbreeding of Wistar–Kyoto (WKY) rats with high blood pressure. Therefore, normotensive WKY rats are employed as normotensive controls in studies on SHRs. Hypertension starts to develop in these rats at 5–6 weeks of age, and blood pressure plateaus at approximately 50–60 days of age to remain stable or slightly decrease thereafter (Bianchi et al., 1974; Dickhout and Lee, 1997). In the early stages of hypertension, SHRs experience increased cardiac output and normal total peripheral resistance; however, as the hypertensive state stabilizes, cardiac output returns to normal and hypertrophied blood vessels produce a higher total peripheral resistance (Dickhout and Lee, 1997; Smith and Hutchins, 1979). Proteinuria, glomerulosclerosis, and interstitial fibrosis along with characteristics of cardiovascular disease, such as cardiac hypertrophy, begin to develop between the initiation of hypertension and its plateau phase at 40 weeks (Conrad et al., 1995; Feld et al., 1981; Ofstad and Iversen, 2005). Between 14 and 15 weeks, renal pathology begins to appear and may be exacerbated by a high-salt diet (HSD); however, this animal model is mostly salt resistant (Fig. 16.3). Between 30 and 32 weeks, male SHRs exhibit a 20%–30% decrease in GFR (Reckelhoff et al., 1997) as renal pathology progresses. Age-related GFR decrease is absent in female SHRs. Female SHRs also have approximately sixfold lower proteinuria (Reckelhoff et al., 1997). Some level of protein cast formation can be seen at 40 weeks and this increases with time (Ofstad and Iversen, 2005). Inflammation in the form of lymphocyte and macrophage infiltrates, as well as the increased expression of cytokines and chemokines has been observed at the prehypertensive stage (3 weeks) in renal tissue of SHRs (Biswas and de Faria, 2007; Rodriguez-Iturbe et al., 2004). Treatment
FIGURE 16.3   The effects of high- or normal-salt diet (HSD and NSD) on spontaneously hypertensive rats (SHR) compared to normotensive Wistar Kyoto (WKY) control rats. (A) Control WKY rats and (B) SHRs were given NSD (0.4% NaCl) or HSD (8% NaCl) for 4 weeks from 12 weeks of age. WKY rats fed NSD demonstrated normal renal histology, but WKY rats that were given HSD showed nephropathology, such as glomerular alterations in Bowman's space in the Cx *(arrow head)* and tubular dilation *(asterisk)* in the OM. SHRs that were given NSD suffered from minor protein cast nephropathy *(arrows)* in IM, and tubular dilation *(asterisk)* in OM. SHRs that were fed HSD showed similar pathology. Images were taken with an Olympus BX41 microscope using 10× (scale bar: 500 µm) and 40× (scale: bar 200 µm) objectives. CKD, chronic kidney disease.

with antiinflammatory agents leads to a reduction in blood pressure and inflammation in adult SHRs (Rodriguez-Iturbe et al., 2002, 2005). Oxidative stress precedes inflammation (occurs at 2 weeks) in SHR kidneys (Biswas and de Faria, 2007). Inflammatory and ER stress marker expression have been reported in the blood vessels and cardiac tissue of SHRs (Carlisle et al., 2016;

Guo and Yang, 2015; Miguel-Carrasco et al., 2010; Sanz-Rosa et al., 2005; Spitler et al., 2013; Sun et al., 2015). Compared to other models of hypertensive CKD, such as the Dahl S model, SHRs develop a much lower level of renal injury. The absence of progressive renal damage has been attributed to enhanced preglomerular vasoconstriction, which prevents systemic hypertension from

being transmitted to the glomeruli (Arendshorst and Beierwaltes, 1979; Kimura and Brenner, 1997). Combining UNX with the SHR model intensifies and accelerates glomerulosclerosis, urinary protein excretion, and fibrosis (Dworkin and Feiner, 1986; Kinuno et al., 2005). These changes have been reported due to inhibition of vascular narrowing of the preglomerular resistance vessels by UNX. Adaptations to UNX, such as glomerular enlargement are also impaired in the SHR (Kinuno et al., 2005). Alternatively, placing SHRs on high salt accelerates the development of hypertension and cardiac remodeling (Yu et al., 1998). Further, HSD–fed SHRs have higher urinary protein excretion and glomerular damage than those fed low-salt diets (Blizard et al., 1991). The SHR has become the model of choice to test antihypertensive drugs. Another valuable contribution of the SHR is in mapping and identification of genes responsible for the development of hypertension. Although, just like humans, the SHR model experiences a progression starting with a prehypertensive, developing, and sustained hypertensive phase, the life spans of SHRs (1.5–2.5 years) and their normotensive controls (2.5–3 years) are short. This makes the SHR convenient for the study of hypertension and aging. Furthermore, the SHR model is also suited for the study of gender in hypertension. Moreover, SHR has been crossed with other strains to create new models, such as the SHR heart failure (SHHF) rat to model congestive heart failure secondary to essential hypertension and the stroke-prone SHR (SHRSP), a unique model of severe hypertension and hemorrhagic stroke.

3.1.2 Dahl Salt-Sensitive Rat

The Dahl salt-sensitive (DSS) rat is another model of hypertensive CKD and develops hypertension when fed an HSD (Dahl et al., 1962, 1963). In experiments with this strain, low-salt diet generally involves 0.1%–0.4% NaCl, whereas high salt refers to 4%–8% NaCl diet (De Miguel et al., 2010; Hayakawa et al., 1997; Rapp and Dene, 1985; Yu et al., 1998). Upon high-salt feeding, these rats rapidly develop significant hypertension, mesangial expansion, and glomerulosclerosis (Raij et al., 1984). Salt-resistant Brown–Norway (BN) and consomic rats (SS. BN13) in which chromosome 13 from the BN has been introgressed into the Dahl S genetic background are included as salt-resistant controls in experiments with the Dahl S (Cowley et al., 2001; Hoagland et al., 2004). The increase in mean arterial pressure is attributed to sodium retention, and can be prevented through the use of diuretics (Greene et al., 1990; Tobian et al., 1979). Along with hypertension, Dahl S rats experience endothelial dysfunction and cardiac hypertrophy and fibrosis (Hayakawa et al., 1997; Yu et al., 2003). Cardiac hypertrophy is comparable to that seen in the SHR, but cardiac failure occurs much earlier in the Dahl S than in the SHR (Hasenfuss, 1998). Urinary excretion of protein, albumin,

and nephrin has been shown in Dahl S rats on high salt (Hye Khan et al., 2013). Protein cast formation has been reported in the medulla (Hye Khan et al., 2013; Rapp and Dene, 1985; Yu et al., 2003) and can also be observed in the cortex (Fig. 16.4). Renal interstitial fibrosis and inflammation in the form of T-cell and macrophage infiltrates has been documented in the cortex and medulla associated with renal damage in this model (De Miguel et al., 2010; Hye Khan et al., 2013; Mattson et al., 2006). High-salt Dahl S rats also show an increased renal expression of ER stress genes (Hye Khan et al., 2013). As with most rat models, the DSS model is cost effective, easily manageable, time efficient, and noninvasive. Salt sensitivity makes the Dahl S clinically relevant. Renal injury in this model is similar to that seen in patients with DN (O'Bryan and Hostetter, 1997; Ritz and Orth, 1999) and in hypertensive black Americans (Campese, 1994; Cowley and Roman, 1996), who are 5 times more likely to progress to ESRD than white Americans (Hsu et al., 2003; Norris et al., 2006).

3.1.3 Renal Mass Reduction: 5/6 Nephrectomy

The 5/6 nephrectomy model entails reducing the total mass of the kidney by 5/6th. The most common technique involves a two-step procedure. A full UNX is performed on one kidney. Two-thirds of the remnant kidney is then ablated either by anterior (Al Banchaabouchi et al., 1998) or posterior (Ma and Fogo, 2003) renal artery branch ligation or by kidney pole resection (Kren and Hostetter, 1999; Leelahavanichkul et al., 2010). The ligation method is not feasible in the mouse due to limited artery branching; however, the polar excision method can be used in both rats and mice (Yang et al., 2010). Various mouse and rat strains are differentially responsive to renal mass reduction in terms of CKD progression (Fleck et al., 2006; Ortiz et al., 2015). Both mice and rats experience hypertension, glomerular and tubulointerstitial damage, and proteinuria as a result of this model, but CKD progression is accelerated in some strains. The CD-1 strain of mice has shown progressive increase in albuminuria, severe glomerulosclerosis, hypertension, and renal interstitial and cardiac fibrosis by 4 weeks in the model (Leelahavanichkul et al., 2010). Swiss–webster mice, the 129/Sv strain and its inbred substrain (129S3) develop disease in 9–12 weeks (Leelahavanichkul et al., 2010; Ma and Fogo, 2003). The C57BL/6 strain, however, is the most resistant strain to this model, showing increased albuminuria at 16 weeks without the development of hypertension, progressive CKD, or cardiac fibrosis (Leelahavanichkul et al., 2010; Ortiz et al., 2015; Yang et al., 2010). Rats generally show more susceptibility to CKD induced by renal mass reduction. However, a report by Fleck et al. (2006) showed that Sprague–Dawley rats were less susceptible than Wistar rats. Rats show the development of hypertension and proteinuria
FIGURE 16.4 **Introgression of Brown Norway chromosome 13 (BN13) into Dahl salt-sensitive (DSS) rat improves its nephropathy.** (A) BN13 and (B) DSS rats were fed either normal-salt diet (NSD, 0.4% NaCl) or high-salt diet (HSD, 8% NaCl) for 4 weeks from 12 weeks of age. BN13 rats fed NSD showed normal renal histology, but BN13 rats that were fed HSD demonstrated minor protein cast nephropathy *(arrows)* in OM and IM. DSS rats that were fed either NSD or HSD showed nephropathy such as protein casts *(arrows)* in Cx, OM, and IM; shrinkage of glomerular capillaries in Cx *(arrow head)*; and tubular dilation *(asterisk)* in OM. Images were taken with an Olympus BX41 microscope using 10× (scale bar: 500 μm) and 40× (scale bar: 200 μm) objectives. CKD, chronic kidney disease.

at 4 weeks and glomerulosclerosis, renal fibrosis, and mesangial expansion by 8 weeks (Fleck et al., 2006; Ma et al., 2005; Zhao et al., 2012). Progressive CKD is also denoted by tubular protein cast formation (Li et al., 2012; Zhao et al., 2012), as well as renal inflammation and oxidative stress (Ghosh et al., 2009; Kim and Vaziri, 2010; Romero et al., 1999). ER stress inhibition has been shown to ameliorate renal injury, heart dysfunction, myocardial fibrosis, and apoptosis (Ding et al., 2016). Immune suppression has also been shown to significantly reduce fibrosis and inflammation in this model (Romero et al., 1999). Renal mass reduction is a reliable model for

the induction of CKD in rodents, as it provides robust readouts in terms of glomerulosclerosis, proteinuria, and hypertension. It is ideal to model decline in renal function in humans through loss of nephron number. The main limitation of the 5/6 nephrectomy is the need for two surgical interventions requiring technical expertise for successful surgeries. Additionally, the remnant kidney is small and, especially in the mouse, provides very little renal tissue for analysis. Another disadvantage is the variability in responses from different strains and the variability, which may be created in the model itself. As the surgery is technically demanding, and their is a direct correlation between disease severity and the amount of renal mass removed or infracted, variation in surgical technique or renal anatomy between animals will cause wide variability in disease severity requiring a large sample size to adequately power statistical tests.

3.1.4 Deoxycorticosterone Acetate Salt

This model entails the administration of deoxycorticosterone acetate (DOCA), an aldosterone precursor, combined with a unilateral UNX and an HSD. DOCA is administered through subcutaneous injection or implanted as a pellet, while salt loading involves 1% NaCl in drinking water (Dobrzynski et al., 2000; Hartner et al., 2003; Jadhav et al., 2009; Xia et al., 2005). This model exhibits a suppressed renin–Ang system with decreased plasma renin concentrations. The increased aldosterone results in increased sodium and water reabsorption from epithelial cells in the distal nephron of the kidney, thereby increasing blood pressures. Clinically, primary aldosteronism or a decrease in renin-to-aldosterone ratio is an important cause of hypertension (Drenjancevic-Peric et al., 2011; Iyer et al., 2010; Tomaschitz et al., 2010). This model has been performed in both mice and rats, and hypertension and renal damage is more severe in males than in females (Bubb et al., 2012; Karatas et al., 2008). The response to DOCA salt is strain dependent in mice, where the 129/Sv strain has shown more susceptibility to progressive renal damage and hypertension than C57BL/6 mice (Hartner et al., 2003). This model produces hypertension, proteinuria, luminal protein cast formation, and glomerulosclerosis (Hartner et al., 2003; Jadhav et al., 2009; Xia et al., 2005). Renal interstitial fibrosis and inflammation are indicated by the increase in TGF-β and collagen deposition, as well as the upregulation of proinflammatory transcription factors: NF-κB and AP-1, and immune cell infiltrates (Elmarakby et al., 2008; Jadhav et al., 2009). DOCA salt administration also results in oxidative stress through superoxide formation in the vasculature and the kidney. The mineralocorticoid receptor that aldosterone binds to is not only present on renal epithelia, but is also found on vascular smooth muscle cells, cardiac fibroblasts, and the brain. Therefore, the DOCA salt model also manifests chronic cardiovascular

remodeling, such as cardiac hypertrophy and fibrosis in both the left and right ventricles, resulting in inflammatory cell infiltration into the cardiac tissue and upregulation of hypertrophy markers ANP and BNP (Dobrzynski et al., 2000; Karatas et al., 2008). Morphological changes are accompanied by function changes that include an increase in action potential duration at 20, 50, and 90% of repolarization (Loch et al., 2006). This model is known to cause smooth muscle and endothelial dysfunction and vascular hypertrophy in small and large arteries (Cordellini, 1999; Deng and Schiffrin, 1992; Iyer et al., 2010). The DOCA salt model is a model of human primary aldosteronism and volume-dependent hypertension. The technical requirements of this model are somewhat invasive and two surgeries would be required if a DOCA pellet is implanted subcutaneously instead of injections. However, this model has a lower risk of mortality due to procedures alone in comparison to the 5/6 nephrectomy model. This model generally lasts for no more than 8–12 weeks and is, therefore, not a good model to study the effects of aging on aldosterone-induced hypertension. However, the DOCA salt model is a popular choice in the study of the effect of high–dietary salt intake on CKD progression.

3.1.5 Angiotensin II Infusion

Chronic Ang II infusion, usually through the implantation of Ang II osmotic minipumps, has been used as a model of progressive CKD in mice and rats. Sustained elevations in circulating levels of Ang II result in renal dysfunction, proteinuria, and focal tubulointerstitial and vascular damage (Ortiz et al., 2015). The pleiotropic actions of Ang II encompass Ang II-mediated vasoconstriction and hypertension, as well as stimulation of aldosterone secretion, superoxide production, TGF-β–mediated fibrosis, and inflammation via NF-κB activation (Agarwal et al., 2004; Muller et al., 2000; Ozawa et al., 2007; Ruiz-Ortega et al., 2006). Moreover, ER stress genes have been reported to be upregulated in the kidney and cardiac tissue with Ang II infusion in mice (Kassan et al., 2012; Wang et al., 2015a). In fact, ER stress inhibition has been shown to attenuate cardiac hypertrophy, cell death, and fibrosis (Kassan et al., 2012). Ang II infusion has also been combined with models of reduced renal mass and with the DOCA salt model. Ang II administration has been shown to overcome the resistance of C57BL/6 mice to CKD induction and results in hypertension, albuminuria, and severe glomerulosclerosis by 4 weeks instead of 16 weeks (Leelahavanichkul et al., 2010). The Ang II/DOCA salt model that involves a UNX following by Ang II infusion through an osmotic minipump, a DOCA pellet implantation and high salt were also designed to overcome the resistance of C57BL/6 mice to CKD development (Kirchhoff et al., 2008; Mohammed-Ali et al., 2015b) (Fig. 16.5).

CKD: Hypertensive, AngII/DOCA salt
FIGURE 16.5 **Anatomical structures affected by angiotensin (Ang) II/deoxycorticosterone acetate (DOCA) salt treatment compared to sham.** Mice had an Ang II-infused osmotic mini-pump and DOCA pellet subcutaneously implanted and were given 1% salt water (operated, OP), or had sham surgeries and provided with sterile water (sham). OP mice suffered from severe nephropathy depicted in the micrograph by protein cast area density *(arrows)* in Cx, OM, and IM; shrinkage of glomerular capillaries in Cx *(arrow head)*; and tubular dilation *(asterisk)* in OM. Kidney sections were periodic acid-Schiff stained and images were taken with an Olympus BX41 microscope using 10× (scale bar: 500 μm) and 40× (scale bar: 200 μm) objectives. CKD, chronic kidney disease.

Female mice experience less severe CKD in this model compared to male mice (Mohammed-Ali et al., 2015b). Increases in systolic blood pressure and proteinuria are seen after the first week on the Ang II/DOCA salt model (Kirchhoff et al., 2008; Mohammed-Ali et al., 2015b). Renal damage involves protein cast formation, glomerulosclerosis, apoptosis, and renal interstitial fibrosis and inflammation. Inflammation resultes in both T cell and macrophage infiltration and upregulation of inflammatory mediators: MCP-1 and IP-10 (Kirchhoff et al., 2008; Mohammed-Ali et al., 2015b). Cardiac hypertrophy and fibrosis, as well as pulmonary edema also manifest in this model (Kirchhoff et al., 2008; Mohammed-Ali et al., 2015b). The intrarenal renin–Ang system is important in the pathophysiology of hypertension and hypertensive nephropathy. CKD management guidelines emphasize Ang-converting enzyme inhibitors or Ang II type 1 receptor blockers as antiproteinuric and renoprotective therapy, regardless of their effect on hypertension (Griffin and Bidani, 2009). Therefore, models of Ang II–driven CKD are clinically relevant. The C57BL/6 mouse serves as a genetic background for several transgenic and gene knockout models. However, this strain is highly resistant to CKD development. Therefore, the development of a model with stable CKD development in this strain would widen the scope of experiments focused on CKD progression.

3.2 Diabetic Nephropathy

DM is a growing worldwide epidemic and DN is one of the most important DM complications, as it is a major cause of ESRD (Martinez-Castelao et al., 2015). In humans, DN is characterized by albuminuria and progressively declining GFR. DN is primarily considered a glomerular disease based on structural abnormalities observed in patient biopsy material. Mesangial matrix accumulation affects all segments of the glomeruli (global) and all glomeruli within the cortex (diffuse) (Alpers and Hudkins, 2011; Breyer et al., 2005). This process is referred to as diffuse mesangial sclerosis (DMS) or diffuse intercapillary glomerulosclerosis and is a hallmark lesion of diabetic glomerulopathy. A reduction in podocyte number, as well as glomerular basement membrane (GBM) thickening, resulting in the loss of charge and permselectivity of the glomerular filtration barrier, which is a feature of DN (Alpers and Hudkins, 2011). Along with tubulointerstitial fibrosis, DN in animal models and in humans has been shown to induce the UPR, oxidative stress, key inflammatory mediators NFκB, MCP-1, adhesion molecules, and chemokines that aid in leukocyte migration and infiltration (Navarro-Gonzalez et al., 2011; Zhuang and Forbes, 2014). The National Institutes of Health-supported Animal Models of Diabetic Complications Consortium (AMDCC) has proposed a

list of criteria for an ideal DN mouse model. These criteria include: (1) progressive renal insufficiency in the setting of hyperglycemia; (2) greater than 50% decline in GFR over the lifetime of the animal; (3) greater than 10-fold increase in albuminuria compared with controls for that strain at the same age and gender; and (4) pathologic changes in kidneys, such as advanced mesangial matrix expansion with or without nodular sclerosis and mesangiolysis, any degree of arteriolar hyalinosis, GBM thickening by >50% over baseline, and tubulointerstitial fibrosis (Alpers and Hudkins, 2011). These criteria were aimed at standardizing the phenotyping methodology to allow better comparison of results obtained by different groups and ensure that future studies will increasingly adopt models that reliably model human disease. These criteria, however, represent goals and not absolute standards and should be used to address limitations of current models and identify models of DN that meet most of these criteria as useful research tools.

3.2.1 Streptozotocin-Induced Diabetes

Streptozotocin (STZ)-induced pancreatic injury is commonly used as a rodent model of type I diabetes mellitus (T1DM) and generally presents similar features to those found in human diabetic nephropathy. STZ, originally identified as an antibiotic, is an analog of *N*-acetylglucosamine, which is transported into pancreatic β-cells by GLUT-2 and causes β-cell toxicity, resulting in insulin deficiency (Tesch and Allen, 2007). Animal models of STZ-induced DN are usually performed in mice, Sprague–Dawley, WKY, and SHR rats. STZ is usually administered intraperitoneally in mice and intravenously (IV) in rats (Tesch and Allen, 2007). The two main type of STZ administration include multiple low-dose and moderate-to-high dose. The moderate-to-high dose model was designed to overcome the resistance of certain mouse strains to STZ-induced injury. This model involves using a single high dose of STZ (≥200 mg/kg) or a two-dose regimen of STZ (2 × 100–125 mg/kg) given on two consecutive days (Fujimoto et al., 2003; Itagaki et al., 1995). Increasing the STZ dose translates to greater cytotoxicity and a more rapid destruction of pancreatic β-cells and more severe diabetes. However at high doses, STZ has been shown to cause acute kidney damage in animals due to its non-specific cytotoxicity. This aspect also makes it difficult to differentiate between the direct toxic effect of STZ and lesions caused by hyperglycemia (Breyer et al., 2005). Thus, the low-dose STZ model was created to reduce the nonspecific nephrotoxic effects of STZ. This model involves the administration of a low dose of STZ, 40–60 mg/kg, for 5 consecutive days (Leiter, 1982, 1985; Qi et al., 2005). Inbred strains of mice have been reported to exhibit varying susceptibilities to diabetes induced by low-dose STZ and an order has been identified: DBA/2 > C57BL/6 > MRL/MP > 129/

SvEv > BALB/c (Gurley et al., 2006). Whereas in high dose–induced diabetes where increased urinary albumin excretion and GBM thickening occurs at 4 weeks postdiabetes induction (Fujimoto et al., 2003), the low-dose model requires months to induce these changes (Qi et al., 2005). In the rat models of STZ-induced diabetes, male rats at 8 weeks of age (200–250 g) are starved for 16 h and injected once into the tail vein with STZ (SD = 55 mg/kg, WKY = 60 mg/kg, SHR = 45 mg/kg) in sodium citrate buffer (1 mL/kg) (Cooper et al., 1988; Ma et al., 2004). The development of renal injury is more severe in SHR compared to normotensive (WKY) rats, and urine albumin excretion has been shown to be three-fold higher in diabetic SHR (149 ± 1 mg/24 h) compared with control SHR (49 ± 1 mg/24 h) at 32 weeks post-STZ administration (Davis et al., 2003). Vascular hypertension that occurs alters renal hemodynamics and causes GBM thickening along with inflammation and fibrosis (Allen et al., 1997). Alongside the renal damage induced in all types of STZ-induced DN, ER stress markers (GRP78 and CHOP) display an increase and are associated with apoptosis and inflammation (Liu et al., 2008; Luo et al., 2010; Wu et al., 2010b). With all types of STZ-induced diabetes, 1 week after STZ administration, rodents are assessed for hyperglycemia and those with fasting blood glucose over 15 mmol/L (280 mg/dL), which is generally the majority of them, should be included in studies of DN (Tesch and Allen, 2007). Diabetic animals in rat models of STZ-induced DN and the high-dose STZ model in mice are given insulin injections to maintain blood glucose levels in a desirable range (16–33 mmol/L) (Tesch and Allen, 2007). The STZ model in both mice and rats is sometimes performed following a UNX to accelerate the progression of renal injury (Tesch and Allen, 2007). However, it becomes difficult to interpret results from this model as one has to distinguish the effects of STZ-induced hyperglycemia from the changes induced by UNX and each of their relative contributions to renal injury.

3.2.2 Insulin 2 Akita Mouse

Akita mice develop T1DM due to a mutation in the insulin 2 (Ins2) gene that results in the abnormal folding of insulin protein, toxic injury to pancreatic β-cells, and, therefore, a decreased capacity to secrete insulin (Kong et al., 2013). The Akita mouse was originally generated on the C57BL/6 background in Akita, Japan, but is currently available commercially on various genetic backgrounds. Mice homozygous for this mutation die in the perinatal period (within 1–2 months). The heterozygous mutant mice develop hyperglycemia, hypoinsulinemia, polydipsia, and polyuria at approximately 3–4 weeks of age (Kong et al., 2013). Hyperglycemia in Ins2 Akita mice is sexually dimorphic, where males develop substantially worse hyperglycemia than females (Gurley et al., 2006).

Ins2 Akita mice develop modest levels of albuminuria and mild-to-moderate glomerular mesangial expansion; however, renal phenotype is largely dependent on their genetic background strains. C57BL/6, DBA/2, and 129/SvEv mice with the mutation develop similar degrees of hyperglycemia, but differ in their manifestation of nephropathy (Gurley et al., 2010). DBA/2 mice exhibit higher albuminuria, but only C57BL/6 and 129/SvEv strains show mesangial matrix expansion. Nevertheless, Ins2 Akita mice experience higher levels of hyperglycemia, albuminuria, blood pressure, and more consistent structural changes of the kidney compared with STZ-induced DN (Gurley et al., 2006).

3.2.3 Nonobese Diabetic Mice

The nonobese diabetic (NOD) genetic mouse model is one of the most thoroughly studied models of T1DM. The induction of diabetes in this model is due to the spontaneous autoimmune destruction of β-cells, which begins with the infiltration of innate immune cells into the pancreas as early as 3 weeks of age (Pearson et al., 2016). These cells include dendritic cells, macrophages, and neutrophils that attract CD4 and CD8 T cell subsets into the islets at 4–6 weeks of age. Studies have shown a delay in diabetes induction in this model with the depletion of dendritic cells, monocytes, and macrophages. Moreover, CD4 and CD8 T cells are required for diabetes development (Pearson et al., 2016). Overt diabetes arises at the age of 24–30 weeks and insulin is required to maintain NOD mice for any extended period of time after the onset of hyperglycemia. As opposed to enhanced susceptibility to STZ-induced DN in male mice, female NOD mice experience 4 times higher incidence of diabetes than male NOD mice (Breyer et al., 2005). Albuminuria develops in hyperglycemic NOD animals and albuminuria is sevenfold higher than in NOD mice before the development of hyperglycemia (Doi et al., 1990). Islets isolated from NOD mice display an increase in ER stress markers: XBP1s and CHOP, as well as NFκB; these results show similarity to human T1DM (Tersey et al., 2012). The involvement of TGF-β and advanced glycosylation end products has been shown to mediate the pathogenesis of mesangial proliferation and sclerosis in NOD mice (Doi et al., 1990; He et al., 2000; Pankewycz et al., 1994; Sharma and Ziyadeh, 1994). This model shares key similarities with human T1DM, such as the inheritance of specific MHC class II alleles and many non-MHC loci as polygenic susceptibility loci, transmission of disease by hematopoietic stem cells, the development of insulitis, and a strict dependence on T cells (Breyer et al., 2005).

3.2.4 OVE26 Mice

The OVE26 mouse on the FVB inbred strain is a transgenic mouse model of severe early-onset T1DM characterized by transgenic overexpression of calmodulin in pancreatic β-cells, leading to deficiency in the production of insulin (Alpers and Hudkins, 2011). These mice exhibit severe hyperglycemia 2–3 weeks after birth. Progressively increasing albuminuria has been reported to be 305 μg/24 h by 2 months to 15,000 μg/24 h by 9 months of age (Kong et al., 2013; Zheng et al., 2004). GFR decreases between 5 and 9 months, and the development of hypertension in this model coincides with albuminuria. Renal nephropathy in OVE26 mice includes enlarged glomeruli, mesangial matrix expansion, GBM thickening, global glomerulosclerosis, tubular atrophy, mononuclear cell infiltration, and tubulointerstitial fibrosis (Kong et al., 2013). The degree of renal injury is highly influenced by the mutation being expressed on the FBV mouse strain. The introduction of the transgene into the C57BL/6 or the DBA/2 mouse strains significantly diminishes albuminuria and increases mesangial matrix and fibrosis, which are key features of this model (Xu et al., 2010). Therefore, there is a limitation, as genetic mutations from a variety of backgrounds cannot be used in this model.

3.2.5 Db/db Mice

The db/db mouse model of leptin deficiency is currently the most widely used mouse model of type 2 diabetes mellitus (T2DM). This mouse has a mutation in the gene encoding the leptin receptor, and leptin deficiency confers susceptibility to obesity, insulin resistance, and T2DM (Alpers and Hudkins, 2011). Experiments using db/db mice are more widely conducted with the C57BLKS/J strain, as C57BL/6 mice do not develop significant nephropathy (Kong et al., 2013). Db/db mice in the C57BLKS/J strain display hyperinsulinemia at 10 days of age and significant hyperglycemia is reported at 8 weeks (Susztak et al., 2004). Albuminuria is detected as early as 3–4 weeks after the onset of hyperglycemia (Susztak et al., 2003). DN develops slowly, where remarkable GBM thickening, podocyte loss, and mesangial matrix expansion is observed by 18–20 months (Susztak et al., 2004). These mice do not develop mesangiolysis or nodular mesangial sclerosis, and do not experience progressive renal insufficiency. Therefore, they are good models of early changes in human DN, but fail to manifest advanced features of DN (Alpers and Hudkins, 2011). To address advanced DN experimentally, db/db mice are uninephrectomized to accelerate the development of DN. UNX at a young age was associated with increased albuminuria and severe glomerulosclerosis in 37% of glomeruli at 24 weeks of age, as compared to sham-operated db/db mice (Ninichuk et al., 2007). Additionally, uninephrectomized db/db mice displayed significant tubular atrophy and tubulointerstitial fibrosis (Ninichuk et al., 2007). Db/db mice have also been crossed with endothelial nitric oxide synthase (eNOS)–deficient mice to create eNOS$^{-/-}$/db/db mice (Kong et al., 2013).

Research has shown an association between decreased eNOS expression via endothelial dysfunction and the development of DN in T1DM and T2DM (Neugebauer et al. 2000; Zanchi et al., 2000). Along with hyperglycemia, hyperinsulinemia, hypertension, albuminuria, and decreased GFR, eNOS$^{-/-}$/db/db mice develop features of advanced DN, such as mesangiolysis, focal segmental and nodular glomerulosclerosis, striking fibronectin accumulation in glomeruli, and tubulointerstitial fibrosis (Alpers and Hudkins, 2011; Kong et al., 2013).

3.2.6 BTBR ob/ob Mice

Ob/ob mice possess a recessive mutation in leptin, the ligand for the leptin receptor, and exist in the C57BL/6J, DBA2/J, and FVB stains (Kong et al., 2013). The T2DM induced by the ob/ob mice displays only mild functional and morphological changes in the C57BL/6J strains and are, therefore, not widely used as models of DN. However, when the ob/ob mutation is generated in the BTBR strain, the resultant BTBR ob/ob mice are insulin resistant, hyperinsulinemic, severely hyperglycemic, obese, and uniformly develop features of DN (Hudkins et al., 2010). Progressive proteinuria develops by 4 weeks of age, whereas early characteristics of DN, such as glomerular hypertrophy, mesangial matrix expansion, podocyte loss, and mesangiolysis, can be detected by 8 weeks (Hudkins et al., 2010). More advanced DN is seen by 22 weeks, where there is a 20% increase in GBM thickness, 50% increase in mesangial matrix, DMS, focal arteriolar hyalinosis, and mild focal fibrosis (Hudkins et al., 2010). The relatively rapid onset and progressive nature of DN in these mice is a major advantage of this model. Moreover, the BTBR ob/ob mice allow the investigation of the therapeutic effect of leptin administration in DN as opposed to db/db mice, which are deficient in the leptin receptor. However, limitations of this model include high cost and infertility of the BTBR ob/ob mice (Kong et al., 2013).

3.2.7 New Zealand Obese Mice

The New Zealand obese (NZO) mouse was created by the selective inbreeding from polygenic mice displaying obesity and T2DM in New Zealand. These mice are hyperleptinemic by 9–12 weeks of age due to leptin resistance and have been reported to be hyperphagic and obese (Leiter and Reifsnyder, 2004). These mice are also hyperinsulinemic as a result of hepatic insulin resistance from an early age. High blood glucose levels indicate impaired glucose tolerance that worsens with age and approximately 50% of males develop diabetes by 24 weeks (Haskell et al., 2002). NZO mice are prone to autoimmune disease and develop circulating antibodies to native and single-stranded DNA (Melez et al., 1980). Renal injury in these mice exhibits features seen in both lupus nephritis (LN) and DN, such as glomerular proliferation, mesangial deposits, mild GBM thickening, and glomerulosclerosis. Eosinophilic nodules in some glomeruli are observed with occasional hyalinization of the glomerular arterioles and healing arteriolar inflammation (Melez et al., 1980). This model is a good choice for the study of the relationships between obesity and T2DM.

3.2.8 KK-Ay Mouse

The KK mouse is a polygenic mouse model of T2DM. These mice exhibit mild insulin resistance, hyperglycemia, glucose intolerance, hyperinsulinemia, mild obesity, and albuminuria (Tomino, 2012). The severity of hyperglycemia and insulin resistance is exacerbated by the introduction of the agouti (Ay) allele into the KK background (Suto et al., 1998). The Ay gene is expressed during the hair growth cycle in neonatal skin, where it functions as a paracrine regulator of pigmentation. Further, an Ay-related protein is a potent and selective antagonist of melanocortin receptors 3 and 4 that are expressed in the hypothalamus and implicated in weight regulation (Ollmann et al., 1997). Mice homozygous for the Ay mutation die before implantation or shortly after, however, heterozygous mice are viable. KK-Ay mice exhibit obesity and hyperglycemia, as well as albuminuria (Breyer et al., 2005). Renal histological changes, such as podocyte loss, diffuse mesangial expansion with mesangial cell proliferation, and segmental sclerosis in KK-Ay mice, are more severe than those that develop in KK mice (Tomino, 2012). Another manipulation of this model includes UNX of KK-Ay mice and supplementation with a HSD, resulting in a more severe decline in renal function and accelerated DN (O'Brien et al., 2013).

3.2.9 Goto Kakizaki Rat

The Goto Kakizaki (GK) rat is a spontaneously polygenic model of T2DM and has been created by repeated inbreeding of glucose-intolerant Wistar rats over many generations (Janssen et al., 2004). Characteristics of this model include moderate hyperglycemia, peripheral insulin resistance, and nonhyperlipidemic and nonobese phenotype (Kong et al., 2013). T2DM in this model is primarily caused by β-cell deficit, where there is a decrease in pancreatic cell proliferation and pancreatic cell apoptosis at the embryo stage (Kong et al., 2013). Early renal morphological changes are similar to those observed in early stages of human DN, such as glomerular hypertrophy and GBM thickening (Phillips et al., 2001). At 24 months of age, GK rats have been reported to display albuminuria, segmental glomerulosclerosis, and tubulointerstitial fibrosis, and thus the late stage of this model resembles progressive human DN (Sato et al., 2003).

3.2.10 Zucker Diabetic Fatty Rat

The Zucker diabetic fatty (ZDF) rat has a missense mutation in the gene coding the leptin receptor (fa/fa)

(Phillips et al., 1996) and spontaneously develops insulin resistance, T2DM, hyperlipidemia, moderate hypertension, and obesity, as well as progressive renal injury (Kong et al., 2013). Hyperglycemia can be detected at 12 weeks (Chen and Wang, 2005), whereas albuminuria is seen at 14 weeks (Figarola et al., 2008) followed by focal segmental glomerulosclerosis (FSGS) at 18–20 weeks of age (Coimbra et al., 2000; Hoshi et al., 2002). Additionally, renal pathology also involves mesangial expansion, macrophage infiltration, and interstitial fibrosis (Kong et al., 2013). ZDF male rats are more widely used as models of T2DM and DN because, although ZDF female rats display insulin resistance and obesity comparable to male rats, they only develop hyperglycemia when placed on a diabetogenic diet (Corsetti et al., 2000). A cross between a ZDF female and a SHHF male rat has been carried out to create the Zucker fatty/spontaneously hypertensive heart failure F1 hybrid (ZSF-1) rat (Ortiz et al., 2015). The ZSF-1 rat combines the most common contributors to the current epidemic of CKD, hypertension, obesity, T2DM, and hyperlipidemia. The high cost and large size of the animals added to their slow progression to CKD are barriers to the wider use of this model (Ortiz et al., 2015).

3.2.11 Otsuka Long-Evans Tokushima Fatty Rat

The Otsuka Long-Evans Tokushima fatty (OLETF) rat is a spontaneously diabetic rat with polyuria, polydipsia, mild obesity, hypertension, dyslipidemia, and advanced DN (Kawano et al., 1999; Kong et al., 2013). Between 12 and 20 weeks, OLETF rats exhibit mild obesity and hyperinsulinemia with a late onset of hyperglycemia at 18 weeks of age (Choi et al., 2011). Overt albuminuria occurs at 22 weeks, while at 40 weeks, proliferation of the mesangial matrix, GBM thickening, and diffuse glomerulosclerosis were observed (Kawano et al., 1994). By 70 weeks of age, nodular lesions can be seen expanded to the proliferated mesangial matrix along with tubular atrophy and associated mononuclear cell infiltration and fibrosis (Kawano et al., 1992). Just as in human disease, the progression of T2DM in OLETF rats can be prevented by exercise and caloric restriction (Kong et al., 2013). Multiple recessive genes are associated with the induction of diabetes, such as the odb-1 on X-chromosome of OLETF rats. Moreover, a major quantitative trait locus colocalizing with cholecystokinin type A receptor gene influences poor pancreatic proliferation in OLETF rats (Moralejo et al., 1998).

3.3 Glomerular Disease

3.3.1 Focal Segmental Glomerulosclerosis

FSGS can be defined as the sclerosis of some "focal" but not all glomeruli. Obliteration of the glomerular capillaries by ECM, often accompanied by hyalinosis, only affects a "segment" of the glomerular tuft. With progression, more global glomerulosclerosis occurs (Ichikawa and Fogo, 1996). In 20% of children and 40% of adults, FSGS is the underlying cause of nephrotic syndrome (D'Agati et al., 2011). Nephrotic syndrome is defined by urinary protein levels exceeding 3.5 g/1.73 m^2 of body surface area per day, hypoalbuminemia, and hyperlipidemia in the absence of systemic disease (Orth and Ritz, 1998). Proteinuria is a defining feature of FSGS with the main cellular target of disease onset being the podocyte, resulting in a compromised glomerular filtration barrier. Moreover, 80% of FSGS is idiopathic. The remaining 20% occurs secondary to other underlying diseases that cause mechanical stress on the podocytes, such as hypertension, diabetes, and obesity that increases glomerular hypertension (de Mik et al., 2013; Ichikawa and Fogo, 1996). Podocytes are terminally differentiated cells; therefore, their depletion through detachment, apoptosis, or necrosis is critical to the development of glomerulosclerosis. Experimental models have shown that a 20% decrease in podocyte number causes FSGS and low-level sustained proteinuria, whereas a 40% decrease results in high-level sustained proteinuria and a decrease in renal function (de Mik et al., 2013; Wharram et al., 2005). The ECM deposition associated with sclerosis is influenced by numerous growth factors, cytokines, and chemokines. Local stress, heightened levels of ROS, and abnormal homeostasis can modulate these factors. As such, podocyte injury has been associated with the induction of ER stress genes: GRP78, GRP94, ORP150, and CHOP (Cybulsky et al., 2011). FSGS causes TGF-β activation that results in the recruitment of monocytes, macrophages, and T cells; upregulation of other proinflammatory mediators, such as TNF-α and IL-1; and fibrosis (Imig and Ryan, 2013; Kim et al., 2003; Noel, 1999). An ideal model for human FSGS would be one where glomerular scarring develops spontaneously and has a slow chronic progression.

3.3.2 Minimal Change Disease

Minimal change disease (MCD) is the most common cause for nephrotic syndrome in children and 15%–20% of cases in adults (Fogo, 2001). MCD is characterized by explosive edema, selective proteinuria, and clinical response to glucocorticoid therapy, as T cell–related mechanisms are implicated in pathogenesis (Saleem and Kobayashi, 2016). The majority of MCD cases are idiopathic; however, the development of edema and proteinuria are preceded by upper respiratory tract infections, allergic reactions, and the use of certain drugs, such as NSAIDs (Glassock, 2003). MCD shows normal appearance of glomeruli on light microscopy, but nevertheless extensive effacement of foot processes of the podocytes

on electron microscopy. Another important feature of MCD involves lack of tubulointerstitial fibrosis despite heavy proteinuria (Saha and Singh, 2006; Saleem and Kobayashi, 2016).

3.3.3 Animal Models of FSGS and MCD

3.3.3.1 HYPERTENSIVE CKD MODELS TO STUDY FSGS

The remnant kidney model in the rat is the most commonly used animal model for FSGS. Most studies use 5/6 nephrectomy, which is also a model for hypertensive CKD. However, the 4/6 renal mass reduction is also used, as it is milder and does not induce hypertension, but only moderate renal dysfunction and glomerulosclerosis (de Mik et al., 2013). Glomerular sclerosis is seen by week 4, postrenal ablation by ligation with segmental sclerosis in about 20% of the glomeruli and by week 8, tubulointerstitial fibrosis (Hostetter et al., 1981; Yoshida et al., 1988). Renal mass reduction decreases the number of glomeruli available to filter the same amount of serum. Glomerular growth through both cellular hypertrophy (increase in cell size) and hyperplasia (increase in cell number) occurs in FSGS. Age is a contributing factor in glomerular hypertrophy, where it determines the relative contributions of hypertrophy and hyperplasia. Hyperplasia is predominant in young animals showing more severe sclerosis after renal ablation than adults (Fogo, 2003). Glomerular enlargement due to injury results in epithelial cell detachment where denuded areas are associated with hyalinosis and cause progressive scarring through the hyperfiltration of plasma proteins. Other hypertensive CKD models, such as the Dahl S rat, SHR, and chronic Ang II infusion combined with renal mass reduction have also been reported to cause FSGS. However in these models, damage to the glomerular vessels occurs secondary to hypertension. FSGS induced by renal hypertension has been detected in Sabra hypertension-prone rats; they are salt-sensitive rats that develop hypertension when chow diet and drinking water is loaded with 8% NaCl (Yagil et al., 2002). The remnant kidney model provides a limited representation of human FSGS, as glomerular damage is induced via an acute procedure, whereas in humans, FSGS onset is much slower. As only 20% of FSGS occurs due to underlying secondary causes, the FSGS seen in hypertensive CKD model can only represent a small segment of FSGS in the human population.

3.3.3.2 DRUG-INDUCED FSGS AND MCD

Adriamycin is an anthracycline, a class of antitumor drugs widely used to treat human cancers. Adriamycin induces direct toxic damage to the glomerulus, where it alters the glomerular filtration barrier; charge selectivity is reduced and podocyte cell foot processes are fused. Slit diaphragm abnormalities are critical and early events in the pathogenesis of adriamycin-induced FSGS, where the expression patterns of slit diaphragm proteins, nephrin, podocin, and NEPH1 are altered (Lee and Harris, 2011). Adriamycin is administered intravascularly in most studies; however, other routes include substernal, intracardiac, and intrarenal administration. Adriamycin doses range from 1.5 to 5 mg/kg in rats and from 10 to 15 mg/kg in mice (de Mik et al., 2013). Male rats are more susceptible than females, and BALB/c mice are used in mouse experiments, as C57BL/6 mice are the most resistant to adriamycin-induced FSGS (de Mik et al., 2013). Intravascular administration of Adriamycin at 2 mg/kg results in early phase proteinuria with focal foot process effacement after the second injection. Segmental glomerulosclerosis occurs after 16 weeks with global glomerulosclerosis and tubulointerstitial fibrosis at 24 weeks and some animals dying of uremia at 28 weeks (Fogo et al., 1988; Okuda et al., 1986). Adriamycin given in a single dose intravascularly (5 mg/kg) resulted in sclerosis in 50% of rats by 6 months (Bertani et al., 1986). Puromycin aminonucleoside (PAN) is an antibiotic that inhibits protein synthesis and has been administered subcutaneously, intravenously, and intraperitoneally to induce both MCD and FSGS (de Mik et al., 2013; Pippin et al., 2009). The degree of renal injury and onset of proteinuria are influenced by the rat strain, PAN dose, and route of administration; however, it is the cumulative exposure to PAN that determines whether rats develop MCD or FSGS (Pippin et al., 2009). The administration of five subcutaneous injections of PAN (1.5 mg/100 g body weight) produced glomerular damage and apoptosis resembling human MCD; the administration of five additional doses of PAN led to the development of irreversible sclerotic lesions characteristic of FSGS (Shiiki et al., 1998). A single dose of 50 mg/kg of PAN in the rat produces early phase proteinuria peaking at 10 days that is similar to MCD with complete effacement of foot processes. Proteinuria in this model almost resolves after this early phase followed by a progressive, lower-level proteinuria between week 10 and 13 that is associated with early segmental sclerotic lesions (Diamond and Karnovsky, 1986). The tubulointerstitial fibrosis that occurs with the progression of adriamycin- and PAN-induced nephropathy is correlated with the severity of proteinuria, and associated with macrophage and T cell infiltration and the release of chemokines: MCP-1 and -3 and RANTES (Fogo, 2003). These drugs exert direct toxicity to podocytes through the production of ROS (Fogo, 2003). The strengths of drug-induced glomerular disease models include their high reproducibility with robust degree of tissue injury and relatively low mortality and morbidity. Structural and functional injury in these models greatly resembles human FSGS and MCD,

and the administration of the drugs, albeit requiring a certain level of skill, is much less demanding than the surgery involved in remnant kidney models. The duration of these models is short, where proteinuria onset is early and glomerulosclerosis occurs within weeks. The limitations of these models include batch variability with regards to the drugs, whereby certain brands or batches of drug will produce different severity in disease. Another source of variability involves differences in susceptibility across strains of rodents. Further, the issue of drug toxicity might require the optimization of doses for experimental use, particularly in the case of adriamycin where doses as little as 0.5 mg/kg lower or higher than the optimum may lead to either lack of renal injury or toxicity leading to death, respectively (Lee and Harris, 2011).

3.3.3.3 VIRUS-INDUCED FSGS

Virus-induced FSGS occurs due to the direct infection of the podocyte or through the release of inflammatory cytokines from infected cells. HIV-associated nephropathy (HIVAN) is the most common animal model used to induce FSGS via viral infection. This transgenic model was produced using a replication-deficient version of HIV as the integrated transgene. These mice, referred to as the transgenic 26 (Tg26) mice (Dickie et al., 1991), develop proteinuria at 24 days of age with 18% of mice dying between 2 and 6 months with heavy proteinuria, elevated blood urea nitrogen, edema, and hypoalbuminemia. Focal changes were limited and described as mild to severe in animals under 2 months of age. Tg26 mice over 2 months of age had diffuse segmental and global glomerulosclerosis, as well as lymphocytic infiltrates. The severity of renal damage in Tg26 mice depends on the animals' genetic background, with the FVB/N strain being the most susceptible. Various HIVAN models have been produced, such as transgenic mice that express HIV-1 accessory genes, such as Vpr and nef, which synergistically damage podocytes, resulting in glomerulosclerosis (Rosenstiel et al., 2009). The glomerular pathology seen in HIVAN models resembles human HIVAN; however, HIVAN is a secondary cause of FSGS, therefore these models do not widen our understanding of primary FSGS, which is the most common.

3.3.3.4 GENETIC MODELS

3.3.3.4.1 PODOCYTE-SPECIFIC GENE DISRUPTION Both human and mouse studies show that FSGS is initiated by podocyte dysfunction. Mutations in nephrin (NPHS1) and podocin (NPHS2), key components of the podocyte slit diaphragm, have been shown to result in congenital nephrotic syndrome of the Finnish type and steroid-resistant nephrotic syndrome of the podocin

type, respectively in humans (Boute et al., 2000; Putaala et al., 2001). NPHS1 knockout mice die within 24 h after birth due to edema and massive proteinuria with the absence of the slit diaphragm and effacement of podocyte foot processes (Putaala et al., 2001). Similarly, humans with NPHS1 mutations are diagnosed with nephrotic syndrome at birth and albuminuria starts in utero (Patrakka et al., 2000). NPHS2 knockout mice are massively proteinuric at birth and die within the first 5 weeks of life with ESRD. NPHS2$^{-/-}$ mice do not show FSGS lesions, but exhibit DMS characterized by mesangial accumulation of ECM proteins without mesangial cell proliferation (Roselli et al., 2004). In contrast, humans with NPHS2 mutations are not proteinuric at birth, and progress slowly to ESRD through progressive FSGS (Roselli et al., 2004). Podocin inactivation in the adult mouse kidney using Cre-LoxP technology, however, presents FSGS within 4 weeks followed by diffuse glomerulosclerosis and tubulointerstitial injury (Mollet et al., 2009). Mutations in α-actinin-4 (ACTN4) have been shown to cause an autosomal dominant form of human FSGS, and decreased ACTN4 expression is seen in humans with primary glomerulopathies, such as sporadic FSGS and MCD (Feng et al., 2015; Yao et al., 2004). The ACTN4 gene encodes the production of an actin cross-linking protein and is widely expressed in the kidney. In addition to bundling F-actin, ACTN4 interacts with various proteins to modulate focal adhesion and links the cytoskeleton to the ECM, and is part of the nephrin multiprotein complex that maintains glomerular structure integrity (Feng et al., 2015). A significant percentage of ACTN4 knockout mice suffer perinatal death; however, survivors develop albuminuria and FSGS at about 10 weeks of age (Kos et al., 2003). In an effort to model human disease, certain research groups have generated transgenic mice with ACTN4 mutations. Particularly, transgenic mice with the K256E mutation (homologous to human K255E mutation) had higher expression of mutant ACTN4 and exhibited significant albuminuria, glomerulosclerosis, and foot process effacement at 10 weeks (Michaud et al., 2010).

3.3.3.4.2 INDUCIBLE FSGS USING TRANSGENIC ANIMALS As Thy1.1 cell surface antigen is not expressed on normal mouse podocytes, transgenic mice have been generated by injecting hybrid human–mouse Thy1.1 into the pronuclei of zygotes of Thy1.2 CBA + C57BI/10 parents. The injection of anti-Thy1.1 monoclonal antibodies into these mice results in rapid onset of albuminuria within 10 min to 24 h, and is strongly correlated with FSGS lesion formation. FSGS lesions developed within 3 weeks in a dose-dependent manner (Assmann et al., 2002; Smeets et al., 2004). Another model of FSGS induction includes transgenic rats with the human diph-

theria toxin (DT) receptor (hDTR) specifically expressed in podocytes (Wharram et al., 2005). Fisher 344 rats were used for these experiments and the hDTR rats were injected with DT (1 mg/10 g) when they reached 100 g body weight. This setup allows the transport of DT into podocyte cytoplasm, thereby causing podocyte depletion. Over 40% podocyte depletion in this model translated to FSGS and global glomerulosclerosis, high-grade proteinuria, and reduced renal function. Increasing the dose of DT to >50 ng/kg causes proteinuria within 7 days of toxin administration, where the mice progress to ESRD within 10 days to 3 weeks.

3.3.3.4.3 SPONTANEOUS FSGS IN THE BUFFALO/MNA RAT The Buffalo/mna rats spontaneously develop FSGS by 2 months of age in addition to proteinuria, with epithelial cell alterations with foot process flattening and vacuolization at the ultrastructural level. Lesion formation has been attributed to a circulating factor, as kidneys from other rat strains transplanted into the Buffalo/mna rats also develop proteinuria within 10 days, progressing to FSGS (Le Berre et al., 2002). However, Buffalo/mna kidneys show regression of lesions when transplanted into healthy Lewis rats. At 6 months, these rats exhibit FSGS similar to that found in humans. Early lesions have been characterized as "tip lesions," as they occur at the glomerular junction with the proximal tubule; sclerosis extends to all parts of the glomerulus later (Nakamura et al., 1986). The rats are normotensive and nonuremic and are particularly relevant in modeling the recurrence of FSGS after transplantation in humans (Nakamura et al., 1986).

3.3.3.4.4 NPHS2-ANGPTL4 TRANSGENIC RATS TO MODEL MCD Increased expression of angiopoietin-like-4 (ANGPTL4), a secreted glycoprotein, has been noted in the glomeruli, urine, and serum in patients with MCD. Whereas ANGPTL4 is normally expressed in podocytes at relatively low levels, it is highly upregulated in MCD (Chugh et al., 2012). NPHS2-ANGPTL4 transgenic rats overproduce ANGPTL4 specifically from the podocyte and exhibit several features of human MCD (Clement et al., 2011). These rats develop selective proteinuria where albumin is the dominant protein in urine and albuminuria develops at 1 month of age. Effacement of podocytes is first noted at 3 months, and increases to an extensive degree by 5 months of age. Similar to human MCD, these rats do not show tubulointerstitial fibrosis despite early and severe onset of proteinuria (Chugh et al., 2012). Studies have shown that the NPHS2-ANGPTL4 rat is the most accurate model for human MCD. However, this model shows gradual progression in renal injury, which is in contrast to the explosive onset of MCD seen in adults.

3.4 Autoimmune Kidney Diseases

3.4.1 Heymann Nephritis Model of Membranous Nephropathy

Membranous nephropathy (MN) is the leading cause of idiopathic nephrotic syndrome in adults, with approximately 40% of patients developing progressive renal insufficiency resulting in ESRD (Fervenza et al., 2008). MN is initiated by immunoglobulin G (IgG) antibodies (mostly of the IgG4 subclass) produced against autoantigens expressed by podocytes (e.g., human PLA2R, rat megalin) or antigens planted in the subepithelial space, such as cationic proteins (cBSA and α3NC1) (Jefferson et al., 2010). Upon antigen binding, the antibodies form immune complexes that deposit subepithelially, on the outer side of the GBM, resulting in complement activation that causes podocyte injury, foot process effacement, and GBM thickening. The glomerular filtration barrier is, therefore, compromised in MN, resulting in proteinuria and progression to nephrotic syndrome (Borza et al., 2013). The rat Heymann nephritis (HN) model has been established as the best model to study MN disease mechanisms, as it recapitulates the clinical and pathological aspects of human MN (Borza et al., 2013). The model is based on the use of antibodies targeted against HN antigenic complex consisting of two proteins: megalin and receptor-associated protein (RAP). Megalin forms a heterodimeric complex with RAP, and several epitopes on this complex are involved in the formation of immune deposits (Farquhar et al., 1995). There are two types of HN, active HN, where the animal's own immune system produces antibodies usually in response to an injection of kidney extracts with adjuvant, and passive HN, where rats are injected with antiserum generated in another animal to elicit immune complex formation. Although it more closely resembles human MN, active HN is rarely used, as it takes substantially longer to induce disease and MN development is very variable (Jefferson et al., 2010). In passive HN, antibodies are generated against the pelleted renal tubular epithelial fraction (Fx1A). Adult rats from various strains, Sprague Dawley, Wistar, Munich Wistar, Lewis, and Piebold Viral Glaxo, are used. The rats receive a single dose of anti-Fx1A antibody and doses range from 2 to 7 mL/kg for serum and 20–240 mg/kg for isolated IgG. UNX and multiple injections followed by sensitization with rabbit IgG have been used to accelerate passive HN (Jefferson et al., 2010). The formation of immune deposits occurs in the subepithelial space upon anti-Fx1A administration. This process obstructs the slit diaphragm and activates complement. Deposition of terminal components of complement C5b–9 is seen in both passive HN (Cybulsky et al., 1986) and in human MN (Cosyns et al., 1986). The onset of severe proteinuria manifests 4–7 days after

the injection and ranges between 100 and 500 mg/day (Nakatsue et al., 2005). The main histological changes include GBM thickening and foot process effacement progressing to glomerular and tubulointerstitial sclerosis, features resembling human MN (Beck and Salant, 2014). Limitations of this model include the fact that megalin is not expressed on human podocytes and so it not a pathogenic human antigen. Further, this model shows tubular immune deposits that do not reflect pathology in human MN. Dipeptidyl peptidase IV (DDPIV) is another major antigen that has been used in a model of MN. Administration of rabbit anti-DPPIV antibody into 6-week-old Lewis rats led to proteinuria on day 1, peaking at day 2, followed by a gradual decline. In this model, however, the immune deposits are transient and disappear within 5 days (Natori et al., 1994; Ronco et al., 1984).

3.4.2 IgA Nephropathy

IgA nephropathy (IgAN) is one of the most common forms of glomerulonephritis in the world, representing 25%–50% of patients with primary glomerulonephritis (Suzuki et al., 2014). Characteristic features of IgAN include mesangial cell proliferation, matrix expansion accompanied with granular mesangial immunodeposits of IgA, comprised of polymeric IgA1, complement 3, with variable IgG and/or IgM codeposits (Barratt and Feehally, 2005). With disease progression, crescentic changes can be superimposed on diffuse mesangial proliferative glomerulonephritis. Patients may develop nephrotic-range proteinuria at different stages of the disease from mild glomerular injury to advanced glomerulosclerosis (Barratt and Feehally, 2005; Suzuki et al., 2014). The ddY mouse strain is a well-characterized model of spontaneous IgAN, which develops glomerulonephritis and a remarkable deposition of IgA in the mesangium accompanied with codeposits of IgG, IgM, and C3 (Imai et al., 1985). However, the high degree of variability in the age of onset and severity of disease in this model presents a disadvantage. Interbreeding ddY strains with high serum levels of IgA produced the high-IgA (HIGA) mouse strain (Muso et al., 1996). However, it was observed that although HIGA mice have high IgA levels, serum IgA levels are not associated with severity of glomerular injury and incidence of disease (Suzuki et al., 2005). Another method used to overcome the high variability in ddY mice involves the selective intercrossing of early IgAN onset ddY mice for over 20 generations. This strategy established a novel 100% early-onset ddY mouse (Okazaki et al., 2012). Electron-dense deposits in these mice are manifested in the paramesangial area, similar to those found in humans. Further, glomerular deposits of IgA with IgG and C3 codeposits also occur in this model. All early-onset ddY mice develop proteinuria within 8 weeks of birth, which is higher than urinary protein excretion in HIGA mice at 8 weeks. These mice exhibit severe glomerular and tubulointerstitial lesions characterized by mesangial proliferation, mesangial matrix expansion, and tubulointerstitial infiltrations (Okazaki et al., 2012).

3.4.3 Thy-1 Nephritis

Thy-1 nephritis is an experimental rat model of membranoproliferative glomerulonephritis (MPGN). MPGN is characterized by glomerular mesangial expansion due to increased matrix and increased cellularity, thickening of peripheral capillary walls, and GBM with accumulation of subendothelial and intramembranous immune deposits (Alchi and Jayne, 2010; Smith and Alpers, 2005; Yang et al., 2010). Antigen-triggered immune MPGN in humans occurs in IgAN and Henoch–Schönlein purpura nephritis and can be modeled using the Thy-1 nephritis rat model (Alchi and Jayne, 2010). In Thy-1 nephritis, MPGN is induced by a single injection of rabbit anti-thymocyte serum or mouse anti-Thy1 monoclonal antibody through a tail vein (Ishizaki et al., 1986). The Thy-1 antigen is found on thymocytes and also is present on rat glomerular mesangial cells; therefore, an immune attack is induced. Monocyte/macrophage infiltration manifests 2 days postinjection along with mesangiolysis due to necrosis and fibrin deposition. Mesangial cell proliferation peaks at about 1 week, where mesangial matrix and small crescent formation can also be seen (Liu et al., 2004). Proteinuria and hematuria are seen but without hypertension development. The nephritis in this model repairs after 3 weeks; however, repeated injections of Thy-1 can result in chronic sclerosis and proliferative lesions with interstitial fibrosis and progressive CKD (Yabuki et al., 2006).

3.4.4 Anti-GBM Models

Anti-GBM glomerulonephritis is a category of crescentic glomerulonephritis, a morphological expression of severe glomerular injury. Crescent formation is caused mainly by rupture of glomerular capillaries, which allows cellular and humoral inflammatory mediators to spill into Bowman's space (Jennette and Thomas, 2001). Anti-GBM glomerulonephritis is caused by autoantibodies directed against the α3 chain of type IV collagen. Clinically, Goodpasture's Syndrome is an autoimmune disease where autoantibodies to the GBM and alveoli basement membrane result in pulmonary hemorrhage and anti-GBM glomerulonephritis (Jennette and Thomas, 2001). To produce a rat model of anti-GBM nephritis, anti-GBM antiserum is produced by immunizing rabbits with rat GBM. Nephritis is then induced by intravascular injection of rabbit anti-GBM IgG (Isome et al., 2004; Kim et al., 2004). Mesangial proliferation, severe necrotizing lesions, crescent formation, increased urinary protein excretion, and interstitial fibrosis are all features observed within 1–2 weeks after anti-GBM injection (Isome et al.,

2004; Kim et al., 2004; Reynolds et al., 1998). Macrophage infiltration (Isome et al., 2004) and inflammatory and fibrogenic activities of NFκB and TGF-β1 have been implicated in anti-GBM nephritis pathology (Kim et al., 2004). This model can be induced in both mice and rats; however, there is a significant variation in susceptibility among different strains. The WKY rat is highly susceptible to the development of crescentic glomerulonephritis, whereas the Lewis rat is resistant (Reynolds et al., 2006). In mice, BUB/BnJ, DBA/ 1J, and 129/svJ mice are more susceptible than A/J, AKR/J, C3H/HeJ, DBA/2J, MRL/MpJ, NOD/LtJ, P/J, SJL/J, and SWR/J mice (Xie et al., 2004).

3.4.5 Lupus Nephritis

Lupus nephritis (LN) is a form of glomerulonephritis that is clinically observed in 50%–80% of patients with systemic lupus erythematosus (SLE) and results in ESRD in 10%–20% of patients (Cameron, 1999; Ginzler et al., 1982; Peutz-Kootstra et al., 2001). SLE is an autoimmune disease affecting multiple organs and affects 1 of 750 people in Northern Europe and North America, with 80% of cases occurring in women during their childbearing years (Mills, 1994). LN is characterized by the presence of Igs of almost all isotypes in the glomerulus, as well as activation of complement components. A spectrum of glomerular lesions manifests, ranging from a complete absence of abnormalities or mild mesangial proliferation to proliferative and crescentic glomerulonephritis (McGaha and Madaio, 2014; Peutz-Kootstra et al., 2001). There are three widely used mouse models of LN: (1) (NZB × NZW) F1 hybrid (called the NZB/W F1 mice), (2) MRL/lpr, and (3) BXSB strains. NZB/W F1 mice are produced by crossing New Zealand white (NZW) mice with New Zealand black (NZB) mice (Knight and Adams, 1978). Both the NZB and the NZW strain have elevated levels of anti-DNA antibodies; however, on their own these strains develop mild pathology. The NZB/W F1 hybrid mice experience severe LN with mesangial proliferation, thickening of the glomerular capillary wall, glomerulosclerosis, tubular atrophy, and interstitial inflammation (Andrews et al., 1978; Lambert and Dixon, 1968; Peutz-Kootstra et al., 2001). Mice die of ESRD with proteinuria and azotemia between 6 and 12 months of age and females are more severely affected by the disease (McGaha and Madaio, 2014). The MRL/lpr mice show a broad spectrum of SLE features, such as arthritis, inflammatory skin lesions, and glomerulonephritis. MRL/lpr mouse pathology involves endothelial and mesangial cell proliferation; GBM thickening; macrophage, neutrophil, and T cell infiltration at 6 months of age (Andrews et al., 1978; Hahn, 1993). Glomerular Ig deposits begin to appear at 2 months accompanied with significant complement C3 deposits (Bao et al., 2011). These mice, however, have a lower incidence of glomerular crescent formation than the other models of LN (McGaha

and Madaio, 2014). MRL/lpr mice die within a year due to massive proteinuria and azotemia resulting in ESRD (Hahn, 1993; Peutz-Kootstra et al., 2001). Although both males and females are affected by the lymphoproliferation (lpr) mutation, the disease is more severe in females (Andrews et al., 1978). In contrast, the BXSB strain show a weaker disease phenotype where female mice have 50% mortality at 15 months compared to male mice, which have 50% mortality at 5 months (Andrews et al., 1978; McGaha et al., 2005; Theofilopoulos and Dixon, 1981). This effect is attributed to the presence of the Y-linked autoimmune accelerator (Yaa) driving autoimmunity (Hudgins et al., 1985; Murphy and Roths, 1979). Nevertheless, both male and female mice die due to glomerulonephritis and ESRD (McGaha and Madaio, 2014).

3.5 Hereditary/Genetic Diseases

3.5.1 Alport Syndrome

Alport syndrome is an inherited disorder due to the mutations of the α3, α4, or α5 chains of type IV collagen (COL4A3, COL4A4, and COL4A5). Characteristics include progressive glomerulosclerosis, patchy thickening and thinning of the GBM, splitting of the lamina densa, as well as deafness and retinal abnormalities (Barker et al., 1990; Kashtan, 2002). Alport mice are genetically deficient in the α3 (IV) collagen chain on a 129Sv background and are commercially available. These mice exhibit irregular thickening and splitting of GBM by 4 weeks, and experience proteinuria with mild hematuria by 5 weeks (LeBleu et al., 2009; Sugimoto et al., 2006; Yang et al., 2010). Severe glomerular sclerotic lesions and tubulointerstitial fibrosis have been seen at 10 weeks. There is a rapid decline of renal function after 14 weeks and only 5% of mice survive past 4 months (Cosgrove et al., 1996; Miner and Sanes, 1996). While highly representative of the renal pathology found in human Alport syndrome, the murine model progresses very rapidly. This aspect is not representative of the slow progression of the disease in humans between late childhood and age 40 (Pierides et al., 2009). In addition, these mice also show extracapillary crescentic proliferation in the first 4 weeks, a feature not seen in typical human Alport syndrome (LeBleu et al., 2009).

3.5.2 Polycystic Kidney Disease

Polycystic kidney disease (PKD) is a group of disorders inherited in an autosomal dominant (ADPKD) or recessive (ARPKD) fashion; however, ADPKD occurs more frequently and is in fact one of the most common genetic diseases in humans (Happe and Peters, 2014; Nagao et al., 2012). Further, 50% of patients with ADPKD develop ESRD by age 60 (Nagao et al., 2012). About 85% of ADPKD cases occur as a result of mutations in the PKD1 gene, whereas 15% occur as a result

of mutations in PKD2. ARPKD with a lower incidence is caused by a mutation in the polycystic kidney and hepatic disease 1 (PKHD1) gene, which encodes fibrocystin/polyductin (Harris, 2002; Turkbey et al., 2009). PKD is characterized by abnormal cellular proliferation, fluid accumulation in numerous cysts, remodeling of ECM, inflammation, and fibrosis in the kidney and liver. Overt proteinuria is uncommon in ADPKD with only 27% demonstrating 300 mg/day and proteinuria >2 g/day is unusual and is suggestive of the presence of another kidney disease (Chapman, 2007). There are two main types of PKD animal models: spontaneous hereditary models identified by manifestations of PKD and modified models generated by mutation of human orthologous genes (Nagao et al., 2012). Established, spontaneous hereditary models include PCK rats, Pcy mice, and juvenile cystic kidney (Jck) mice. The gene responsible for PKD in the PCK rat is orthologous to human Pkhd1. The life span of PCK rats is approximately 1.5 years, and numerous cysts are observed on the kidney and liver surface at 1 year of age. The initial cysts originate from the collecting duct and the growing cysts diffusely affect whole nephron segments with disease progression (Nagao et al., 2012). In Pcy mice, the gene target is orthologous to human Nphp3-encoding nephrocystin-3, a protein expressed in primary cilia of epithelial cells in the kidney, pancreas, heart, and liver. Numerous cysts are observed at 30 weeks of age and this is associated with the occurrence of ESRD (Nagao et al., 2012). These mice have a life span of 30 weeks on the DBA/2 or ICR strain background, but 2 years on the C57BL/6 background. Jck mice have a mutated Nek8 or Nphp9 gene, where the mutated gene product is found on primary cilia and affects the normal expression of PKD1 and PKD2 gene products: PC1 and PC2. The life span of Jck mice is 20–25 weeks and initial cysts are observed at 4 weeks (Nagao et al., 2012).

4 CONCLUSIONS

As illustrated in this work, kidney disease represents a wide range of human pathologies affecting this organ and its function. The ultimate adverse consequence for patients with kidney disease is renal failure. In this work, we have described numerous animal models and illustrated their main pathophysiological features. We have also attempted to detail the similarities, from a pathophysiological perspective, that these models share with human diseases. The goal of modeling kidney disease in animals is to better understand its underlying mechanisms of initiation and progression, thereby allowing intervention strategies to be developed that ultimately prevent renal failure. It is our hope that this work contributes to that goal.
