The recent discovery of IAVs H17N10 and H18N11 in little yellow-shouldered bats (*Sturnira lilium*) in Guatemala and Neotropical fruit bats (*Artibeus* spp.) in Peru, Bolivia, and Brazil and of a distinct H9N2 IAV in Egyptian fruit bats (*Rousettus aegyptiacus*) has unexpectedly revealed the maintenance of highly divergent IAVs by the flying mammals (Tong et al. 2012, 2013a; Kandeil et al. 2019; Ciminski et al. 2020). Structural and phylogenetic analyses demonstrated substantial divergence and ancient evolutionary relationship between these viruses and other IAVs (Tong et al. 2012, 2013a; Zhu et al. 2012, 2013; Kandeil et al. 2019). Future studies on IAVs in bats are needed to unveil their epidemiology and the role these mammalian hosts have played in IAV evolutionary history. Bats or birds may have been the ancestral hosts of the diversity of IAVs and at the origin of most ancient cross-species transmission events. It is however a mystery why not more bat influenza viruses have been discovered to date.

Other host species of IAVs are usually considered spillover host species, as they initially acquired IAVs upon cross-species transmission from their ancestral, natural reservoirs (see below). However, IAVs have established in domestic animal species, including poultry, pigs, horses, and dogs, and in humans. These species now maintain distinct IAVs and have thus become their natural reservoirs and potential or actual new players in IAVs cross-species transmission.

22.2.1.1 Epidemiology

IAV epidemiology in wild water birds is characterized by annual epidemic cycles. IAVs typically infect juvenile birds of the year, immunologically naïve to IAVs, or young individuals with limited history of past infections that congregate during one

stage of their life history (Olsen et al. 2006; van Dijk et al. 2018). Morbidity and mortality burdens associated with IAV infection in wild water birds are low, with little evidence of disease or death of infected birds. Some effects of IAV infection on wild birds' health or behavior have been proposed, such as reduced food intake and delayed or shortened migration, but are difficult to evidence (Kuiken 2013).

Avian IAV epidemiology has been particularly studied in three natural host systems: dabbling ducks, waders, and gulls. In dabbling ducks, such as mallards (*Anas platyrhynchos*) and common teals (*A. crecca*), annual epidemics generally occur in juvenile birds in fall, as they congregate after annual molt and prepare for migration (Olsen et al. 2006; Munster et al. 2007; van Dijk et al. 2018). The arrival of migrants from other populations into these congregating groups may play an important role in IAV spread (van Dijk et al. 2013, 2018). A seasonal IAV hotspot in waders occurs at the Delaware Bay, in North America, likewise when migrants congregate at this important stopover site during spring (Webster et al. 1992; Hanson et al. 2008). Large populations of waders timely refuel during this migratory stopover on spawning horseshoe crabs (*Limulus polyphemus*), creating unique conditions for IAV spread. However, such conditions have not been observed in Europe where IAV prevalence in waders is reported low throughout the year (Olsen et al. 2006; Munster et al. 2007). Lastly, annual IAV epidemics were recently demonstrated in young black-headed gulls (*Chroicocephalus ridibundus*) in northern Europe, when fledging birds from breeding colonies leave their nests in early summer (Verhagen et al. 2014). Targeted sampling of other gull species at the time of fledging may unveil similar IAV dynamics in this family of birds.

Juvenile birds may be particularly important in the epidemiology of avian IAVs as their immune system matures and transitions from the bursa of Fabricius to the thymus. This period may enable prolonged shedding and high viral titers (Joseph et al. 2017). Premigrational staging and high concentration of juveniles likely fuel transmission, while mounting population immunity reduces spread in wintering areas. Little is known of the epidemiological dynamics of IAVs in birds belonging to other avian orders and whether they may act as maintenance hosts.

The aquatic habitat of wild freshwater birds and their feeding and social behavior likely favor IAV transmission in these species (for review see (Olsen et al. 2006; Reperant et al. 2013; van Dijk et al. 2018)). IAV infect wild water birds via a fecal-oral and possibly fecal-cloacal route of transmission, which can be enhanced in watershed habitats heavily contaminated by large groups of birds. IAV can persist several months in water, especially at low temperatures and low salinity levels, and such environmental persistence may be important for IAV year-round persistence in wild water bird populations (Stallknecht and Brown 2009). The route of transmission in birds from other orders, in particular terrestrial birds, may differ. The presence of IAV RNA in tracheal swabs may point to the possibility of transmission via the respiratory route (Caron et al. 2017).

22.2.1.2 Evolutionary Dynamics

The remarkable diversity of wild bird IAV lineages is puzzling. Environmental transmission, supported by avian IAV durability and stability in watershed habitats,

may be a key driver of their genetic diversity, due to a so-called "storage effect" (Roche et al. 2014). Heterosubtypic immunity likely further drives AIV subtype dynamics of emergence and replacement.

High mutation rates and frequent reassortment characterize IAV evolutionary dynamics in wild bird reservoirs (Chen and Holmes 2006; Dugan et al. 2008; Lowen 2017) (Fig. 1). However, these dynamics largely differ between genes coding for internal and surface proteins.

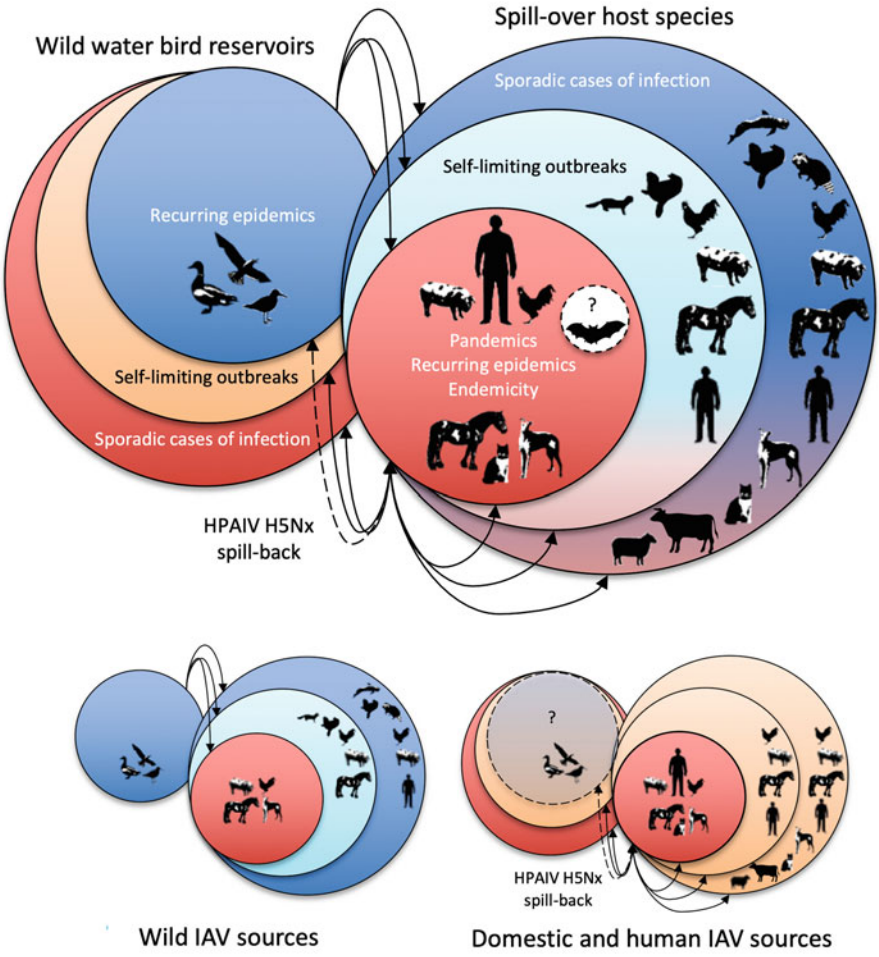

Fig. 1 Schematics of influenza A virus (IAV) diversity and evolutionary dynamics in natural reservoir and spillover host species (based on (Dugan et al. 2008)). IAV diversity in wild water birds is mainly characterized by co-circulation of a large number of subtypes and lineages and their frequent reassortment; in domestic animal species, by occasional IAV cross-species transmission, reassortment across subtypes, and genetic and antigenic drift; and in humans by rare IAV cross-species transmission, reassortment within subtype, and genetic and antigenic drift

IAV internal genes show high levels of genetic identity resulting in relatively conserved proteins. It suggests that these genes are under strong purifying selection, have reached fitness peaks, and may elicit immune response in wild birds. The conservation of these proteins allows widespread reassortment with exchange of functionally equivalent internal gene segments (Dugan et al. 2008; Lowen 2017). The NS gene may be under some form of balancing selection that has resulted in the co-circulation of two alleles that can be found in combination with any HA and NA subtype. In contrast, while the HA and NA genes within each subtype show high levels of genetic identity, the HA and NA genes of different subtypes are remarkably divergent. The absence of intermediate subtypes indicates strong natural selection likely resulting from cross-immunity. Frequent mixed infections are reported in wild birds, favoring reassortment between HA and NA subtypes, leading to many possible combinations. However, the current diversity of IAVs within each HA and NA subtypes in wild birds is recent and suggestive of population bottlenecks, during which IAV diversity may be periodically purged by the sweep of genes with high fitness, eliminating other lineages (Dugan et al. 2008).

IAVs circulating in gulls are generally distinct from those circulating in ducks and waders and mostly of the H13 and H16 subtypes. This demonstrates that for these subtypes, lineage divergence likely resulted from physical separation upon host switch. A limited number of IAV subtypes circulating in ducks have evolved in allopatry and geographical isolation, such as H15 present apparently exclusively in Australia. Most IAVs of wild water birds, however, can be grouped in large phylogenetic groups associated with broad geographical regions, corresponding to continents, hemispheres, or major water bird migration flyways, indicating limited geographical separation (Dugan et al. 2008). Reassortment is frequent between IAVs of different gene constellations within these groups but only occasional between IAVs of distinct geographical phylogenetic groups. Migratory birds breeding and wintering on distant continents can nonetheless disseminate avian IAVs between phylogeographical regions, as evidenced across the Bering Strait (Jeong et al. 2019).

22.2.2 Spillover Host Species

Several IAVs infect a wide range of host species other than wild water birds, including poultry, marine mammals, ungulates, carnivores, and humans, which all can be considered spillover host species (Table 1). In these species, IAVs may cause sporadic cases of infection, self-limiting outbreaks, pandemics, and recurring epidemics or even reach endemicity. IAVs infecting spillover host species, including those currently circulating independently of introductions from wild birds, have all originated from avian IAVs acquired upon cross-species transmission.

In contrast to what is observed in wild water birds, morbidity or mortality burdens can range from inapparent to high. Interestingly, most IAVs isolated from wild spillover host species cause sporadic cases of infection without further ongoing host-to-host transmission or cause self-limiting outbreaks that eventually die out in

Table 1 List of influenza A virus subtypes and lineages detected in spillover host species (based on following reviews: (Brown 2000; Swayne et al. 2019; Swayne 2007; Peiris 2009; Reperant et al. 2009; Taubenberger and Kash 2010; Reperant and Osterhaus 2012; Fereidouni et al. 2014; Yong-Feng et al. 2017; Borkenhagen et al. 2019, Philippon et al. 2020; Borland et al. 2020)

these species. In contrast, most IAV lineages that established and currently circulate in spillover host species, independently of cross-species transmission, emerged in domestic animals, including poultry, swine, horses, and dogs and in humans (Fig. 2). An exception warranting further research is bats, which may maintain distinct IAVs (Tong et al. 2013b; Ciminski et al. 2020). Domestic species and humans, which maintain distinct IAVs, have become their natural reservoirs and new players in their cross-species transmission.

22.2.2.1 Epidemiology

Nonestablished IAVs

Sporadic IAV infections or incidental serological evidence thereof have been reported in a wide range of avian and mammalian species, including humans, as well as in amphibians and reptiles (Table 1). Animal species that are in direct or indirect contact with IAV host reservoirs or spillover host species, e.g., due to predation, shared food and water resources, or overlapping habitat, may become infected with IAVs upon cross-species transmission (for review see (Reperant et al. 2009; Joseph et al. 2017)). IAV cross-species transmission between wild and domestic animal species and humans is not infrequent, including IAV transmission from humans to animals (Table 1). In humans, serological surveys demonstrated limited zoonotic exposure to IAVs in wild waterfowl hunters and bird banders (Gill et al.

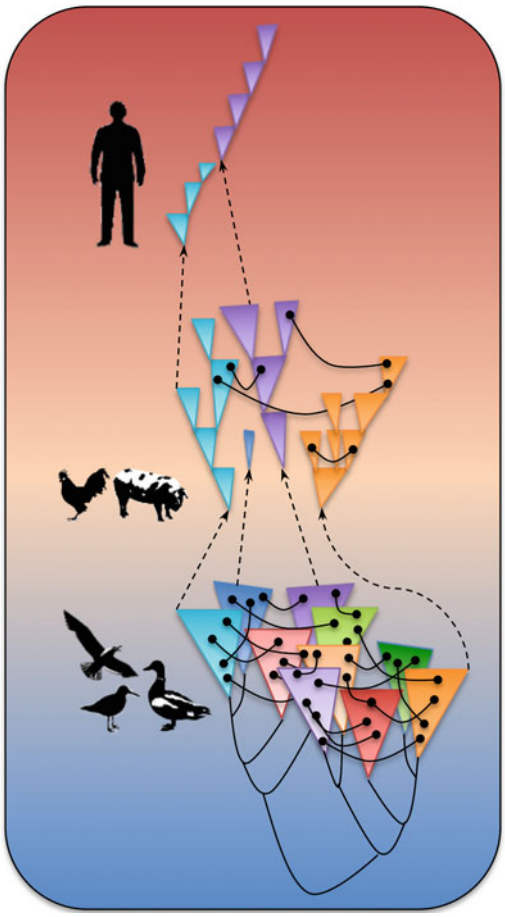

Fig. 2 Influenza A virus (IAV) epidemiological dynamics in natural reservoir and spillover host species. Wild water bird natural reservoirs sustain recurring IAV epidemics and may transmit these viruses to spillover host species, where they can cause sporadic cases of infection, self-limiting outbreaks, pandemics, and recurring epidemics or reach endemicity. Domestic animals and humans maintain adapted IAV, and bats may maintain evolutionary distinct IAV. Spillover species maintaining adapted IAV may also transmit these viruses to other host species, resulting in sporadic cases of infection and self-limiting and sustained outbreaks. These include spill-back infections and self-limiting outbreaks of highly pathogenic IAV (HPAIV) H5Nx in wild water birds

2006; Gray et al. 2011). Contact with domestic poultry and swine is associated with an increased likelihood of zoonotic IAV exposure (Gray et al. 2007). Outbreaks of zoonotic IAV infection in humans have increased in the past decades, in parallel with the relentless growth of domestic animal populations worldwide (for review see (Reperant and Osterhaus 2012; Parrish et al. 2015)). Subtypes known to have caused zoonotic human infections include swine H1N1, H1N2, and H3N2, avian H5N1, H5N6, H5N8, H6N1, H7N2, H7N3, H7N4, H7N7, H7N9, H9N2, H10N7 and H10N8, feline H7N2, and seal H7N7 (Borkenhagen et al. 2019**)**. Such infections may be at the basis of the emergence of novel pandemic IAVs (see below).

IAV cross-species transmission may lead to sustained spread of the virus, with ongoing host-to-host transmission in the new host species. This may result in self-limiting outbreaks that eventually die out or may spark large-scale epidemics that result in IAV establishment and continued circulation in the species concerned. Self-limiting outbreaks of IAV infection, following cross-species transmission, have been

reported in wild and domestic avian and mammalian species and in humans. The reasons behind the self-limiting nature of these outbreaks are little understood. IAVs may not acquire full adaptation to efficiently spread in a new host species upon cross-species transmission, and ongoing host-to-host transmission may remain limited below levels allowing sustained spread. In particular, adaptation of avian IAVs of wild bird origin to terrestrial poultry is thought necessary for their establishment in these species (Swayne 2007).

Alternatively, the number of immunologically naïve hosts in the population may be insufficient to sustain IAV transmission. This may be due to rapid depletion of the pool of susceptible hosts during outbreaks. For example, large self-limiting IAV outbreaks in wild harbor seals (*Phoca vitulina*) have resulted in high mortality and morbidity burdens, resulting in the death of up to 25% of local populations (Lang et al. 1981; Webster et al. 1981; Geraci et al. 1982; Hinshaw et al. 1984; Callan et al. 1995). A recent, similarly large yet self-limiting outbreak of AIV H10N7 infection erupted in harbor and grey seals (*Halichoerus grypus*) in North European waters in 2014 and killed over 10% of the seal population (Bodewes et al. 2015, Herfst et al. 2020). The depletion of the pool of susceptible hosts, associated with the patchy nature of seal populations and short annual breeding seasons—which replenish the pool of susceptible hosts only once a year—may explain the self-limiting nature of the outbreaks. There is currently no evidence of continued circulation of seal-adapted IAVs. Similarly, self-limiting outbreaks of avian IAVs in farmed American mink (*Vison vison*) (Klingeborn et al. 1985) and domestic swine (Brown 2000), resulting in high mortality or morbidity burdens, likely depleted the pool of susceptible hosts in the affected farms, and containment prevented further spread.

The presence of pre-existing immunity in spillover host populations may also contribute to the self-limiting nature of IAV outbreaks in domestic species and humans upon cross-species transmission. For example, IAV H3N8 of wild bird origin caused epidemics in horses in China during three consecutive years. Yet, the virus did not establish itself in the equine population (Guo et al. 1992). Circulation of a previously established equine IAV H3N8 and vaccination against this virus may have played a role in the eventual extinction of avian IAV H3N8 in horses. In humans, an outbreak of respiratory disease in a military camp in North America in 1976 caused by IAV H1N1 of swine origin turned out to be self-limiting (Goldfield et al. 1977; Top and Russell 1977). The simultaneous circulation of another IAV subtype—seasonal IAV H3N2—at the time of the outbreak and/or the presence of pre-existing immunity against AIV H1N1 may have contributed to limiting the spread of this virus in the human population (Gaydos et al. 2006).

Established IAV Lineages in New Animal Host Species

Occasionally, IAVs with efficient ongoing host-to-host transmission in a new host species may sustainably spread, reaching endemicity or causing recurring epidemics in the species concerned. A limited number of IAV lineages have adapted to domestic animals, including poultry, swine, horses, and dogs, and to humans. They are maintained independently of cross-species transmission from wild water

birds or other spillover host species. The conditions allowing IAV establishment and continued circulation in spillover host species remain little understood.

Domestic swine and poultry harbor the highest diversity of established IAVs in spillover host species, with several co-circulating subtypes and lineages (Brown 2000; Alexander 2007). A wide range of poultry species, including ducks, geese, chickens, and quails, are susceptible to IAV infection. Species diversity, high density and population turnover, and trade and mixing during co-raising or at animal markets are believed important determinants for the evolution, emergence, establishment, and diversification of swine and poultry IAV lineages (for review see (Reperant and Osterhaus 2012)). IAVs in swine and poultry typically are endemic over large geographical areas, if not globally, without displaying clear seasonal patterns of infection (Brown 2000; Alexander 2007; Henritzi et al. 2020). Endemicity in these species is likely maintained by the continued replenishment of susceptible hosts through trade or breeding. The growing diversity of swine and avian IAVs in livestock and of other IAVs in domestic species represents a major challenge to epidemic and pandemic preparedness (Parrish et al. 2015; Philippon et al. 2020; Anderson et al. 2021).

Endemic IAV infection may go unnoticed in swine and poultry, because of low morbidity and mortality burdens. However, IAV may cause detectable disease, especially in young animals immunologically naïve to IAV. In domestic poultry, IAV may also develop increased pathogenicity, defining IAV pathotype in these species. When IAV-associated mortality is low in poultry, IAVs are qualified as low pathogenic avian influenza viruses (LPAIV). In terrestrial poultry, mainly chickens and turkeys, LPAIV of the H5 and H7 subtypes can evolve into highly pathogenic avian influenza viruses (HPAIV), causing ravaging outbreaks with up to 100% mortality (Swayne 2007). High poultry density in industrial farms is thought to favor HPAIV evolution and emergence. Because of their high mortality burdens—also due to the rapid implementation of stamping out and other control measures—HPAIV may rapidly run out of susceptible hosts to infect, and outbreaks typically are self-limiting in adequately managed domestic poultry settings. HPAIV of the H5N1 subtype are a notorious exception. These viruses became endemic in poultry in Southeast Asia and Africa and rapidly diversified following their emergence more than 15 years ago (Chen et al. 2006; Li et al. 2010). They further have sprouted a growing diversity of HPAIV H5Nx subtypes (like H5N2, H5N3, H5N5, H5N6, H5N8, and H5N9) in poultry as well as in wild birds (see below; Pulit-Penaloza et al. 2020). While these viruses may silently circulate in aquatic poultry, they cause usually winter epidemics in terrestrial poultry, although most recently this pattern has changed to also include spring and summer (Pohlmann et al. 2019). Subclinically infected aquatic poultry may be crucial for the maintenance of HPAIV H5N1 and related viruses in domestic birds (Hulse-Post et al. 2005).

A limited diversity characterizes IAV circulating in horses and in domestic carnivores. Reports of equine epidemics of respiratory disease in past centuries suggest that equine IAVs have circulated in horses for several hundred years (Taubenberger and Morens 2009). However, only two IAV subtypes have been isolated from horses to date (for review see (Reperant et al. 2009)). Their emergence

likely resulted from IAV cross-species transmission from avian hosts. IAVs of the H7N7 subtype emerged in horses in the mid-1950s and have not been isolated since 1980. IAVs of the H3N8 subtype emerged in the early 1960s and currently cause recurring seasonal epidemics in equine populations worldwide, reminiscent of seasonal human influenza.

Equine IAVs H3N8 infected domestic dogs in the early 2000s and have subsequently become temporarily endemic in canine populations in North America and parts of Europe (Crawford et al. 2005; Daly et al. 2008). The canine H3N8 IAV eventually went extinct, perhaps because the density of the dog population is insufficient to indefinitely sustain host-to-host transmission (Wille and Homes 2020). In Southeast Asia, IAV H3N2 of avian origin have become endemic in canine populations in the late 2000s and have subsequently spilledover from dogs to domestic cats (Song et al. 2008; Song et al. 2011). These viruses may cause severe epidemics in both species. Canine H3N2 influenza emerged in North America in 2015, with multiple introductions and recurrent fade out of the epidemics (Voorhees et al. 2017; Voorhees et al. 2018). Ongoing studies are deciphering IAV evolutionary and epidemiological dynamics in domestic carnivores (Guo et al. 2021). They may represent new mixing vessels for the reassortment of novel IAVs (Parrish et al. 2015; Borland et al. 2020). The canine IAV H3N2 has reassorted multiple times with avian, swine, and human IAVs.

Established IAV Lineages in Humans

IAVs of animal origin with efficient human-to-human transmissibility can be at the origin of influenza pandemics in humans (Table 2). In particular, the high incidence of zoonotic IAV infections of any subtype in humans is feared to provide these viruses with opportunities to acquire efficient transmissibility, sparking an influenza pandemic. Outbreaks of sporadic IAV infections result from frequent cross-species transmission while ongoing host-to-host transmission remains limited. Recently, cross-species transmission of a number of swine and poultry IAVs to humans resulted in large outbreaks often associated with relatively high morbidity and mortality burdens. These include outbreaks of HPAIV H5N1, H5N6 and H7N7, swine IAV H3N2, and LPAIV H7N9 and H9N2, which have caused several hundred cases of human infection (Table 3). Evolution of these viruses by mutation and/or reassortment into a transmissible form may be at the basis of a novel pandemic IAV (Reperant et al. 2015).

Table 2 List of pandemic influenza A viruses in humans (for review see (Taubenberger and Kash 2010))

Influenza subtype	Lineage	Year of introduction	Years of circulation
H1N1	Avian	1918	1918–1957
H2N2	Reassortant avian/human	1957	1957–1968

H1N1	Swine	2009	2009–present

Table 3 List of recent zoonotic influenza A viruses causing large outbreaks in humans

Pathotype	Influenza subtype	Host of origin	Year	Number of cases	References
HPAIV	H7N7	Avian	2003	89	Koopmans et al. (2004)
HPAIV	H5N1	Avian	1997–present	>880	Philippon et al. (2020)
HPAIV	H5N6	Avian	2014–present	>20	Philippon et al. (2020)
LPAIV	H3N2	Swine	2011–present	>400	Anderson et al. (2021)
LPAIV	H7N9	Avian	2013–present	>1500	Philippon et al. (2020)
LPAIV	H9N2	Avian	2002–present	>50	Philippon et al. (2020)

Pandemic IAVs cause severe epidemic waves in humans, typically with high attack rates, morbidity, and mortality burdens. They infect a large proportion of the human population worldwide, with typically little pre-existing immunity against them (Taubenberger and Kash 2010; Saunders-Hastings and Krewski 2016). Introduction of a pandemic IAV in the human population results in the so-called antigenic shift, replacing one of the existing seasonal IAV subtypes. Pandemic waves in humans currently spread around the world within a matter of months. The viruses continue to circulate and evolve into seasonal influenza viruses after the pandemic that they caused, replacing one of the hitherto circulating seasonal IAVs. Such strain replacement suggests the existence of some levels of cross-immunity between IAVs of different subtypes. As a result, only a limited number of AIV subtypes have been established in the human population. The severity of the seasonal epidemics that follow pandemics typically declines with time, at least in part due to the building-up of specific immunity and the increasing inability of the IAVs to escape from the specific antibody landscape building up over time. However, ongoing seasonal drift can result in the emergence of immune-escape variants at the origin of more severe epidemics. As has been documented for IAV H3N2, seasonal waves of influenza tend to emerge in Southeast Asia, where multiple peaks of seasonal AIV infections are observed year-round. These viruses are seeded into countries of the northern hemisphere during the winter season, followed by their spread to countries of the southern hemisphere in the subsequent winter season there (Russell et al. 2008).

At least in part due to naïve, immature, or impaired immune responses, infants, the elderly, and individuals with comorbidities are particularly at risk of severe IAV infection that may be further complicated by bacterial infection (Taubenberger and Morens 2008). Because of limited pre-exposure and abundant social contacts, school-age children are considered major spreaders of IAVs in the human population. Serological surveys have established that most individuals of 7 years of age or older have been infected at least once by seasonal IAVs and are partially protected against IAV reinfection due to immune memory (Bodewes et al. 2011). Nevertheless,

healthy young adults may be severely affected during IAV pandemics, due to limited cross-protection from previous infections against a novel pandemic IAV (Saunders-Hastings and Krewski 2016).

Spilled-Over IAVs Spilling Back to Wild Bird Populations

IAVs circulating in spillover host species rarely spill back to wild bird populations. Adaptation of IAVs to spillover host species is thought to hinder their ability to infect wild water bird species. This has been demonstrated experimentally for a number of poultry IAVs, which inefficiently replicated in water birds (Swayne 2007). Yet, little is known about the extent of cross-species transmission of IAVs circulating in aquatic domestic poultry to related wild water bird species and their subsequent spread. LPAIV subtypes tend to be differently distributed in wild birds and poultry, suggesting different susceptibility to various subtypes (Verhagen et al. 2017).

Likewise, HPAIVs usually do not evolve in wild water birds, and if these birds become infected following cross-species transmission from poultry, the infection may not always be as severe as in domestic birds. However, since 2002, HPAIVs of the H5N1 subtype have spilled back from infected poultry to a wide range of wild bird species (Sturm-Ramirez et al. 2004), which can be considered spill-back hosts in this regard (for review see (Reperant et al. 2013)) (Fig. 2).

Infections with HPAIV H5N1 and related (reassortant H5Nx) viruses have caused inapparent to fatal disease in wild birds, following sporadic infection or during self-limiting outbreaks in Southeast Asia, the Middle East, Europe, Africa, and North America. Wild water birds, as well as birds from other orders, including corvids and birds of prey, can be severely affected. The routes of transmission of HPAIV H5Nx likely include the oral and respiratory routes, contrasting with the fecal-oral transmission of LPAIV. Predation or scavenging on infected carcasses may be a unique route of transmission of these viruses in corvids and birds of prey, as well as in wild carnivores, like seals, otters, and foxes.

Wild bird species little affected clinically by HPAIV H5Nx viruses may contribute to their geographical spread (Gilbert et al. 2006; Keawcharoen et al. 2008; Reperant et al. 2010; Lycett et al. 2016). In Europe, HPAIV H5N1 outbreaks in wild birds occurred during winter periods and were associated with the 0 °C isotherm, suggesting that congregation of water birds on open water bodies along freezing fronts fueled the epidemics (Reperant et al. 2010). For a long time, little evidence pointed to the maintenance of HPAIV H5Nx in wild bird populations, in the absence of repeated introductions from poultry. Yet in the past few years, successful clades of HPAIV H5Nx have repeatedly spread nearly globally with and among migratory and resident wild bird populations. This marks a major change in the epidemiology of AIVs in their natural reservoirs. Of note, HPAIV H5Nx introduced into North America in 2014 apparently went extinct after their control in poultry (Krauss et al. 2016).

The HPAIV H5N1 was first detected in a domestic goose in the Gangdong province of China in 1996. Over the following decades, it diversified into 10 genetically distinct virus clades numbered 0 to 9 and spread to over 80 countries in Asia,

Europe, Africa, and North America (Lee et al. 2017; Verhagen et al. 2021). HPAIV H5N1 caused mass mortality events in wild birds at Qinghai Lake in China in 2005, by members of the clade 2.2., and again in 2009, by members of the clade 2.3.2. Viruses of the clade 2.2 reached Europe from 2005 to 2009, following at least 3 separate introductions. Viruses of the clade 2.3.2.1c made incursions into European wild bird populations in 2010 and again in 2015. The HPAIV H5 clade 2.3.4—with first-time evidence of reassortments giving rise to H5N2, H5N5, and H5N8 subtypes—emerged in poultry in China in 2008 and further diversified into various subclades. Members of the subclade 2.3.4.4 reassorted with other clades of HPAIV H5N1 and with other local LPAIVs. In 2014, outbreaks of HPAIV H5N6 and H5N8 of the 2.3.4.4 subclade erupted in poultry and wild birds in China, Laos, and Vietnam and in Japan and Korea, respectively. Since 2014, these viruses and reassortants repeatedly spread with wild migratory birds from East Asia to North America, West Asia, and Europe. The number of outbreaks and the diversity of HPAIV H5Nx affecting wild birds and poultry populations in and across Asia, North America, Europe, and Africa since 2021 is unprecedented. Some of these viruses have spilled over to wild carnivores, including red foxes (*Vulpes vulpes*), Eurasian otters (*Lutra lutra*), and harbor and grey seals, with evidence of genetic adaptation to replication in mammals (Shin et al. 2019; Adlhoch et al. 2021; Postel et al. 2022). Serological evidence suggests exposure of wild boars (Schülein et al. 2021). The first local case of HPAIV H5N1 in a human in Europe was reported in the owner of Muscovy ducks affected by the disease at the end of 2021 in South West England (Oliver et al. 2022). These host jumps raise public health concerns as they may increase the risk of zoonotic transmission and of adaptation of HPAIV H5Nx to spreading in humans (Adlhoch et al. 2022). However, the mechanisms of maintenance and spread of these viruses in wild bird populations (comprising viruses of varying pathogenicity and virulence, bird species asymptomatically infected and highly susceptible species suffering high mortality) are little understood.

22.2.2.2 Evolutionary Dynamics

A limited number of IAV subtypes and lineages circulate in spillover host species, and most extant lineages emerged within the past hundred years. However, in domestic animals, like in humans, co-circulation of multiple IAV subtypes and lineages is reported. Although IAVs that are endemic in poultry and, to a lesser extent, in swine have diversified similarly to that in wild birds, the diversity in spillover host species is usually more restricted than that in wild water bird reservoirs (Fig. 1). Exceptions of growing concerns are the diversifying clades of HPAIV H5N1 and reassortants that circulate in poultry and wild birds. In humans, and to a lesser extent, in domestic animals, IAV lineages show evolutionary patterns associated with genetic and antigenic drift, whereby mutations in the antigenic sites of the surface glycoproteins allow IAVs to escape antibody mediated immunity that builds up in the population (Petrova and Russell 2018). IAV diversity is greatest in poultry and swine and results from repeated introductions of new IAVs, relatively frequent reassortment as well as genetic and antigenic drift in these species (Brown 2000; Olsen 2002; de Jong et al. 2007; Alexander 2007). In horses, two main lineages of

IAV H3N8 co-circulate (Lai et al. 2001). Distinct phylogenetic groups associated with broad geographical areas indicate some geographical isolation of IAVs of domestic species, despite international trade.

IAV antigenic drift is most pronounced in humans, probably due to a strong population herd immunity landscape associated with human population size, age structure, lifespan, and geographical structure (Taubenberger and Kash 2010; Petrova and Russell 2018). A limited number of combinations of amino-acid changes in HA antigenic sites of seasonal IAVs result in significant antigenic variations, leading to immune escape (Smith et al. 2004). Human seasonal IAVs antigenic drift is clustered, with such combinations of amino-acid changes occurring typically every 3 to 5 years—for yet unclear reasons. Single lineages usually predominate during human influenza seasons, with serial replacement of strains (Fig. 1). However, reassortment between IAV lineages within the same subtype appears more frequent than previously thought (Rambaut et al. 2008).

Although influenza vaccines have been available for over 80 years, most of those currently licensed still rely on decades-old technology, in particular on their production in embryonated chicken eggs, resulting in limitations in their effectiveness. Seasonal influenza vaccines furthermore need regular updating to attempt to best match upcoming circulating strains. Next-generation influenza vaccines building on alternative approaches for their design and production are currently being pursued to induce broader and longer-lasting immune responses to overcome seasonal influenza antigenic drift and to timely address the emergence of a new pandemic influenza virus (Becker et al. 2021).

22.3 Host-Level Pathogenesis of Infection

22.3.1 Natural Reservoirs

IAVs maintained in wild water bird reservoirs are typically of low pathogenic pathotype. However, the diversification, reassortment, and spread of HPAIV H5Nx in wild bird populations have lately challenged this paradigm (see below). LPAIVs typically cause inapparent intestinal tract infection in wild water birds. Cloacal shedding of high LPAIV loads lasts several days to a week, although prolonged shedding for weeks has been reported under experimental conditions. Wild water birds become infected following ingestion of water-borne IAVs that reach the intestine, or may contract the virus via the cloaca (Webster et al. 1992).

LPAIVs generally do not cause detectable damage in the intestinal tract of naturally or experimentally infected water birds, despite large numbers of infected cells detected by immunohistochemistry (for review see (Kuiken 2013)). Most infected intestinal epithelial cells are those of the intestinal crypts at the base of the villi of the large intestine and epithelial cells of the bursa of Fabricius. It has been suggested that the rapid turnover of intestinal epithelial cells coincides with the duration of LPAIV replication cycle (Daoust et al. 2011). Intestinal epithelial cells in the crypts continuously divide, pushing infected cells towards the tip of the intestinal

villi. Lytically infected cells may be released into the intestinal lumen, as they reach the tip of the villi and naturally shed into the lumen. Although visible intestinal damage may not occur, LPAIV infection of the gut may have clinical impact on wild water birds, such as impaired digestive functions. This may affect food intake, growth, migratory abilities, and reproductive success. Carefully designed studies are needed to address this unresolved issue (Kuiken 2013; Risely et al. 2018).

LPAIV infection can cause gross and histological lesions in other organs than the intestinal tract in experimentally infected water birds (for review see (Kuiken 2013)). In particular, tracheitis, pneumonia, and airsacculitis, associated with viral replication in respiratory epithelial cells in the airways and air sacs, have been described in several studies. Intranasal inoculation of mallards resulted in mild pharyngitis and tracheitis associated with LPAIV replication in respiratory epithelial cells, and this route of inoculation may reproduce respiratory infection of dabbling ducks during feeding. However, aerosol inoculation of domestic ducks with LPAIV resulted only in intestinal infection. Furthermore, neither lesions nor antigen-positive cells have been detected in the respiratory tract of naturally infected water birds, despite massive LPAIV infection of the intestinal tract. In accordance with these pathological findings, LPAIV pharyngeal shedding is typically limited in water birds.

Little is known about wild bird immune response to LPAI. The absence of lesions is associated with the absence of recruitment of inflammatory cells to the intestinal site of infection, suggesting a limited innate immune response (Daoust et al. 2011). However, immunoglobulins, including secretory IgX (equivalent of mammalian IgA), are produced and detectable within a few days following experimental infection in domestic ducks and may be present along the intestinal mucosa (Higgins et al. 1987; Magor et al. 1998). Avian adaptive immune responses against LPAIVs may protect at least in part against reinfection with IAVs of the same, and perhaps to a lesser extent, of different but related subtypes (Latorre-Margalef et al. 2013). The extent and duration of immunity against LPAIV reinfection in wild birds remain unknown yet may be essential in determining LPAIV epidemiological and evolutionary dynamics in their natural host reservoirs.

22.3.2 Spillover Host Species

22.3.2.1 Avian Spillover Host Species

LPAIVs of wild bird origin probably behave similarly in aquatic poultry as in wild water birds. In terrestrial poultry, LPAIVs of wild bird origin can cause clinical infection, principally of the respiratory tract and occasionally of the intestinal and urogenital tracts, with little mortality (Mo et al. 1997; Swayne et al. 2019). Infection with LPAIV results mainly in drop in egg production and respiratory signs, and occasionally, in intestinal and urogenital signs. Pharyngeal and cloacal shedding typically lasts several days to a week. Experimental inoculation of chickens demonstrated LPAIV replication in epithelial cells in the airways and lungs in association with inflammatory conditions like rhinitis, tracheitis, and pneumonia. LPAIV pathogenicity varies greatly between poultry species. Pneumonia may be complicated by

secondary bacterial infection. Rarely nephrosis and nephritis are observed. Intravenous inoculation of AIVs of wild bird origin has been shown to result in infection of renal tubular epithelial cells and intestinal epithelial cells in chickens (Swayne and Slemons 1990).

In naïve terrestrial poultry, LPAIVs of the H5 and H7 subtypes can evolve into HPAIVs. These viruses cause severe systemic infection resulting in more than 75% mortality, mainly in chickens and turkeys (Swayne et al. 2019; Swayne 2007). They are abundantly shed from both the respiratory and intestinal tracts. HPAIVs can infect endothelial cells and parenchymal cells in a wide range of organs, including respiratory tract, heart, pancreas, liver, intestine, kidneys, adrenal glands, and brain in poultry. HPAIV infection results in hemorrhages, coagulation failure and organ failure, and occasionally neurological signs, when birds survive the acute phase of the disease. However, gross and microscopic lesions of inflammation, necrosis, and hemorrhages may be rare, because sudden death can occur as early as 24 h after infection. Elevated pro-inflammatory immune responses are seen in chickens but not in ducks infected with HPAIVs; these may contribute to severe immune-pathology (Kuchipudi et al. 2014; Wang et al. 2021).

Most HPAIVs do not infect water birds or cause unapparent infection in these species. However, HPAIV H5N1 and related reassortant viruses have the ability to infect a wide range of avian hosts, including aquatic poultry and wild birds (for review see (Swayne 2007; Reperant et al. 2013; Alarcon et al. 2018)). HPAIV H5Nx pathogenicity in aquatic poultry and wild birds varies greatly and ranges from asymptomatic infection to fatal systemic disease, depending on the virus lineage and bird species involved. The timeframe of development of clinical signs also varies among wild bird species. Clinical disease may start a few days to more than a week after infection. Worryingly, recent HPAIVs H5Nx have caused unusually high mortality in ducks.

In contrast to LPAIV and HPAIVs of the H5N1 (clade 2.2) subtype were not found to infect the intestinal tract of water birds, and cloacal shedding was rare. HPAIV H5N1 was mainly shed from the pharynx of wild birds, and clinical signs included respiratory and neurological manifestations. Organs most often found infected were the respiratory tract, pancreas, liver, kidneys, adrenal glands, and brain in these species. Infected cells were parenchymal cells of most organs, and IAV antigen-expression in these cells was associated with lesions of inflammation and necrosis. In contrast to poultry, endothelial cells were not infected in most species of wild birds. Exceptions included whooper swans (*Cygnus cygnus*) and tufted ducks (*Aythya fuligula*), in which endothelial infection by HPAIV H5N1 and severe hemorrhages were reported (for review see (Reperant et al. 2013)).

Our current understanding of the immune response of poultry against LPAIV or HPAIV is incomplete (Suarez and Schultz-Cherry 2000; Swayne 2007). Neutralizing antibodies against the HA- and to a lesser extent NA-proteins provide protection against disease. The role of cellular immunity is less clear and may reduce viral shedding and help accelerate recovery upon infection. Overall, the immune response of terrestrial poultry against IAVs appears stronger than that of aquatic poultry. Vaccination of poultry against IAV elicits principally neutralizing antibodies against

the HA protein, but does not fully abrogate infection, and hence limited shedding can occur in vaccinated birds. Vaccination of poultry against HPAIV H5N1 may be an effective tool to reduce the virus prevalence in endemic countries, but stamping-out measures, combined with testing and reactive culling of poultry, are often necessary for the eventual eradication of HPAIVs.

22.3.2.2 Mammalian Spillover Host Species

IAVs that sporadically cross from avian to mammalian hosts, including zoonotic IAVs infecting humans, may cause from inapparent to severe respiratory and systemic infections. Clinical disease upon sporadic IAV infection is best documented in humans. In general, patients infected with zoonotic IAVs present with conjunctivitis or mild influenza-like illness (Peiris et al. 2007). However, in several cases, they may develop a severe or fatal lower respiratory tract infection characterized by necrotizing bronchiolitis, interstitial pneumonia, and diffuse alveolar damage.

Infections with HPAIVs of the H5N1 subtype display a unique pathogenesis. In addition to a respiratory route of infection, HPAIV H5N1 may infect mammalian species, including humans, via an intestinal route of infection. In most mammals, HPAIV H5N1 infections severely affect the lower respiratory tract as well as of other organs, including the liver, kidney, heart, pancreas, intestine, and brain (for review see (Reperant et al. 2009)). Lesions of inflammation and necrosis are associated with antigen-expression in parenchymal cells in these organs. Lungs, liver, and brain are the most frequently infected organs in most mammals, resulting in respiratory and neurological clinical signs. In humans, the lungs are the primary sites of infection, although evidence of HPAIV H5N1 replication in other organs has been reported, including in the brain and intestinal tract (Peiris et al. 2007). Lung lesions are typically severe, with diffuse epithelial necrosis, the presence of pulmonary edema and hemorrhage, and massive infiltration of inflammatory cells. Elevated levels of cytokines may contribute to the severity of the inflammatory response in fatal cases of human infection. These lesions can result in respiratory distress and death within 10 days.

The case-fatality rate of HPAIV H5N1 is above 50%. Severe respiratory infections similarly occur upon infection with HPAIV H5N6 (case-fatality rate of 70%), LPAIV H7N9 (case-fatality rate of 40%) and to a lesser extent LPAIV H9N2 (case-fatality rate of 2%). Interestingly, individuals most often infected with HPAIV H5N1 and LPAIV H9N2 are below 15 years of age, while those most often infected with LPAIV H7N9 are above 60. Bearing in mind the low number of cases, the highest incidence of cases of HPAIV H5N6 infection appears to be among the 30–44 age class (Philippon et al. 2020). It is not clear to what extent this is related to intrinsic age-related susceptibility or pre-existing immunity.

Most IAVs that efficiently transmit in mammalian species, including pandemic and seasonal IAVs in humans, typically cause both upper and lower respiratory tract infection, resulting in rhinitis, tracheobronchitis, bronchiolitis, and interstitial pneumonia (Kuiken and Taubenberger 2008). Clinical signs range from mild nasal secretions and coughing to severe pneumonia, which may be complicated by bacterial infection, acute respiratory distress, and death. In general, infection is more severe and located along the entire respiratory tract in individuals with

immature or impaired immune responses, with little history of past infections or with history of past infections by IAVs of a different subtype. These include infants and the elderly or individuals with comorbidity; individuals of a species occasionally infected by IAVs, like harbor seals and farmed mink; and individuals infected by a novel IAV subtype, like pandemic IAV in humans or a novel IAV strain in domestic species. In contrast, the infection is usually less severe and more localized to the upper region of the respiratory tract in individuals with optimal immune functions or a history of past infections with the same or related virus strains. These include healthy individuals infected with seasonal or endemic IAVs.

The pathogenicity of IAV infection in mammals appears also largely virus strain dependent. In general, IAVs that recently crossed the species barrier and some drift variants that escape population immunity tend to cause more severe disease, with the infection being located in both upper and lower respiratory tract in immunologically naïve individuals (Kuiken and Taubenberger 2008). In contrast, IAVs that recurrently circulate in mammalian populations tend to cause less severe disease, with the infection located in the upper regions of the respiratory tract. However, since IAV pathogenicity depends on both host and viral factors, the disease outcome upon IAV infection is highly variable. In humans, mild (e.g., 1968 and 2009), moderately severe (e.g., 1957), and severe (e.g., 1918) pandemics have occurred, with the severity of certain seasonal IAV epidemics matching that of mild pandemics (Taubenberger and Morens 2009).

In mammals, neutralizing immunoglobulins and secondary cellular immune responses, which tend to be stronger and longer-lived in the deeper regions of the respiratory tract, provide protection against reinfection with the same or closely related IAV (Doherty et al. 2006; Petrova and Russell 2018). While neutralizing immunoglobulins are largely strain specific, secondary cellular immune responses likely provide some cross-protection against heterosubtypic strains (Rimmelzwaan and Osterhaus 1995; Rimmelzwaan et al. 2007). Pre-existing immunological memory in mammalian populations may not only protect against severe lower respiratory disease upon reinfection but also exert selective pressures on IAVs, possibly resulting in changes in tropism patterns along the host respiratory tract (Reperant et al. 2012a).

22.4 Crossing Species, Crossing Scales: Adaptive Changes and Gain in Efficient Transmissibility

22.4.1 Host Switch

IAV crossing species barriers from natural host reservoirs to other avian or mammalian spillover hosts can be accompanied by differences in epidemiological and evolutionary signatures and different pathogenesis patterns. This may include changing tissue tropism patterns and variable severity of resulting disease. IAV tissue tropism and disease patterns are determined by the ability of the IAV to infect and replicate in target cells and stimulate host immune responses. These IAV replication

processes involve virus-host interactions that occur at molecular and cellular levels and govern the extent of IAV adaptation to avian and mammalian hosts.

22.4.1.1 IAV Adaptation to Avian Hosts

IAV tissue tropism and patterns of infection in avian hosts are largely determined by the distribution of IAV receptors in the avian intestinal and respiratory tracts and by IAV pathotype. The HA proteins of IAVs mediate their attachment to sialylated glycans of a variety of structural conformations, expressed on the surface of host cells. The HA proteins of IAVs circulating in wild water birds and in most poultry species have a preferred receptor binding affinity for sialic acids with α2,3 linkage to galactose (SAa2,3Gal) (for review see (Taubenberger and Kash 2010; Reperant et al. 2012b; Joseph et al. 2017)) and recognize both *N*-acetylneuraminic acids (Neu5Ac) and *N*-glycolylneuraminic acids (Neu5Gc) (Suzuki et al. 2000). In ducks and terrestrial poultry, these receptors predominate and are abundantly expressed on the surface of intestinal and respiratory epithelial cells (Kuchipudi et al. 2009; Pillai and Lee 2010).

Likewise, the NA proteins of IAVs circulating in avian hosts typically have sialidase specificity for SAa2,3Gal (Joseph et al. 2017). The frequent reassortment of IAV HA and NA genes in wild water birds indicates that these genes are generally compatible and balanced across subtypes and do not point to specific HA/NA combination with higher fitness (Dugan et al. 2008). In terrestrial poultry, an in-frame deletion of approximately 20 amino acids from the stalk region of the NA protein is associated with reduced enzymatic activity and may represent a common adaptive change in IAVs circulating in these species (Taubenberger and Kash 2010; Joseph et al. 2017).

In some terrestrial poultry species, such as quails and turkeys, the HA proteins of circulating IAVs can have a dual receptor binding affinity for both SAa2,3Gal and sialic acids with α2,6 linkage to galactose (SAa2,6Gal). The latter are expressed on intestinal and respiratory epithelial cells of terrestrial poultry but are absent or rare on those of ducks (Wan and Perez 2006; Kimble et al. 2010; Pillai and Lee 2010). Because SAa2,6Gal receptors are preferentially recognized by IAVs that spread efficiently in the human population, independently of cross species transmission (see below), terrestrial poultry may contribute to the generation of IAVs with pandemic potential.

The localized and systemic nature of LPAIV and HPAIV infection, respectively, in terrestrial poultry (and in other avian hosts for HPAIV H5N1) is determined by the HA protein cleavage site, mediating HA cleavage and fusion of the viral and cellular envelopes (for review see (Swayne 2007; Taubenberger and Kash 2010; Reperant et al. 2012b)). The HA protein cleavage site of most avian IAV and poultry LPAIV is composed of a conserved Q/E-X-R motif that requires the presence of extra-cellular trypsin-like proteases to be cleaved. Tryspin-like proteases are secreted in the intestine and are present in the respiratory tract of birds. In contrast, the HA cleavage site of HPAIV is characterized by the insertion of multiple basic amino acids, resulting in a R-X-R/K-R motif. It is recognized by ubiquitous intra-cellular furin-like proteases present in cells of many organs. HPAIV multi-basic cleavage site thus

contributes to the ability of these viruses to cause systemic infection beyond the intestinal and respiratory tracts in birds.

Little is known about the determinants of efficient replication of avian IAV in birds. However, avian IAV tends to be more sensitive to low temperatures than mammalian IAV. Avian IAV replicates efficiently at bird body temperature of 41 °C, while their replication at 33 °C is reduced in vitro. A glutamic acid residue at position 627 in the PB2 protein in part governs IAV cold-temperature sensitivity (Massin et al. 2001). The PB2 627E residue is highly conserved in avian IAVs, although a lineage of HPAIV H5N1 with substitution E627K in the PB2 protein has evolved and circulates in bird populations.

Upon infection, many host factors interact with the viral ribonucleoprotein to support viral replication. The polymerase activity of avian influenza viruses lately was shown to be supported by the host factor ANP32A (belonging to the acidic nuclear phosphoprotein 32 family), which has a special 33 amino acid deletion in birds (Zhang et al. 2019, 2021; Yu et al. 2022). The avian ANP32A as a result supports the polymerase activity of avian IAVs only. Structural studies demonstrated that the structure of this host factor allows it to bridge two asymmetric viral polymerases and mediates the assembly of the influenza virus replicase. Interestingly, the avian ANP32 proteins cannot support the activity of influenza B virus polymerase, which might explain why birds are rarely naturally infected with these viruses (Yu et al. 2022).

22.4.1.2 IAV Adaptation to Mammalian Hosts

The HA proteins of IAVs circulating in mammals have variable receptor binding affinity for SAa2,3Gal, SAa2,6Gal, or both types of receptors (for review see (Taubenberger and Kash 2010; Reperant et al. 2012b; Joseph et al. 2017)). In most mammalian species, the HA proteins of circulating IAVs recognize both Neu5Ac and Neu5Gc, except for human IAVs, which only recognize Neu5Ac (Suzuki et al. 2000). Intriguingly, bat IAVs H17N10 and H18N11 use major histocompatibility complex class II molecules (MHC-II) and not sialic acids for cell entry. The neuraminidase of these bat IAVs lacks sialidase activity and its function remains enigmatic (it may downregulate the surface expression of MHC-II molecules, facilitating viral release; Ciminski et al. 2020).

In general, in mammals, SAa2,3Gal receptors are abundantly expressed on respiratory epithelial cells located in the deeper regions of the respiratory tract, including bronchioles and alveoli (Shinya et al. 2006; van Riel et al. 2007; van Riel et al. 2010). The affinity of avian IAVs for these receptors coincides with the location of avian IAV infection in the lower respiratory tract of mammals, including humans, and in part determines the severity of the resulting disease.

Similar to avian IAVs, most IAVs circulating in seals, horses, and dogs, as well as the bat IAV H9N2, have a preferred receptor binding affinity for SAa2,3Gal (Connor et al. 1994; Matrosovich et al. 2000; Kandeil et al. 2019). In horses and dogs, SAa2,3Gal receptors are abundantly expressed on respiratory epithelial cells in the trachea and bronchi, as well as in the bronchioles and alveoli (Suzuki et al. 2000; Maas et al. 2007; Ning et al. 2012). The canine IAV H3N2 has a mutation in the HA

protein that may also increase its binding affinity for specific receptors with Neu5Aca2–3Galb1–4(Fuca-) or Neu5Aca2–3Galb1–3(Fuca-)-like structures that are present in dogs (Yang et al. 2013). In contrast, SAa2,6Gal are more rarely expressed. The abundance of IAV receptors in both upper and lower respiratory tract may partly determine the relative severity of IAV infection and frequent development of bronchiolitis and pneumonia in these species. However, the bat found infected with IAV H9N2 was asymptomatic.

Seals have both SAa2,3Gal and SAa2,6Gal distributed along their respiratory tract, especially in the bronchioles and alveoli. In these marine mammals, many self-limiting outbreaks have been caused by avian IAVs with a preferred affinity for SAa2,3Gal. However, avian IAVs of the H3N8 and H10N7 subtypes that emerged in seals in 2011 and 2014, respectively, demonstrated increased affinity for SAa2,6Gal (Karlsson et al. 2014; Herfst et al. 2020). These viruses accumulated mutations that may mark their adaptation to the marine mammals. While avian and early seal IAV H10N7 preferentially bond to SAa2,3Gal, later isolates demonstrated a decreased avidity for SAa2,3Gal and an increased affinity for SAa2,6Gal.

The HA proteins of IAVs circulating in humans typically have a preferred receptor binding affinity for SAa2,6Gal and in swine a dual receptor binding affinity for both SAa2,3Gal and SAa2,6Gal (for review see (Taubenberger and Kash 2010; Reperant et al. 2012b)). Some pandemic IAVs also have been shown to have dual receptor binding affinity; however, most seasonal IAVs, which evolved from pandemic IAVs, have predominant receptor binding affinity for SAa2,6Gal. This preferred affinity is associated with the widening of the binding pocket of the IAV HA protein. The receptor binding site of avian IAVs is narrower and typically results in a steric hindrance of the SAa2,6Gal (Joseph et al. 2017). The widening of the HA binding pocket—and potentially the creation of a hydrophobic environment—is mediated by IAV subtype-specific mutations in the HA protein, within and outside the receptor binding site. In parallel, an increase in NA enzymatic specificity for SAa2,6Gal typically accompanies the changes in HA affinity. It notably occurred over time in the human N2 neuraminidase, from the emergence of pandemic IAV H2N2 in humans in 1957 to recent seasonal IAV H3N2 (Kobasa et al. 1999).

In both swine and humans, SAa2,3Gal and SAa2,6Gal are expressed on the surface of different respiratory epithelial cells (van Riel et al. 2007, 2010; Van Poucke et al. 2010; Trebbien et al. 2011). SAa2,3Gal predominate in the deeper regions of the respiratory tract. They are expressed mainly on non-ciliated respiratory epithelial cells and type II pneumocytes, which are the most abundant cell types in the bronchioles and alveoli, respectively. In contrast, SAa2,6Gal predominate in the upper regions of the respiratory tract. They are mainly expressed on ciliated respiratory epithelial cells and type I pneumocytes. Ciliated respiratory epithelial cells are the most abundant cell type in the nasal cavity, trachea, and bronchi. A similar distribution of SAa2,3Gal and SAa2,6Gal receptors is described in the respiratory tract of the ferret, which provides a most relevant animal model of human IAV pathogenesis.

While the abundance of avian IAV receptors in mammalian lower respiratory tract correlates with the severity of avian IAV infection in mammals, the predominance of

SAa2,6Gal in the upper respiratory tract of humans, swine, and ferrets correlates with milder disease, as described for seasonal and/or endemic IAVs in humans, ferrets and swine. Remarkably, the presence of IAV receptors—whether SAa2,3Gal or SAa2,6Gal—in the upper regions of the respiratory tract, i.e., nasal cavity, trachea, and bronchi, is common to those mammalian species that sustain epidemic spread of IAVs. Infection of the upper respiratory tract is considered essential for ongoing host-to-host transmission of IAVs in mammals (for review see (Taubenberger and Kash 2010; Sorrell et al. 2011; Reperant et al. 2012b)) (see below).

The HA proteins of IAVs that efficiently spread in mammalian species all have a cleavage site with a single arginine motif, corresponding to LPAIV in poultry, and are cleaved by extracellular trypsin-like proteases. Such proteases are present in the respiratory tract of mammals (for review see (Reperant et al. 2012b)). In contrast, the multi-basic cleavage site of HPAIVs H5N1 contributes to the systemic nature of the infection in mammals.

The replication in mammalian cells of IAVs circulating in mammals is typically more efficient than that of avian IAVs. Mammalian IAVs typically replicate efficiently at low temperatures corresponding to those recorded in the mammalian upper respiratory tract. Substitution E627K in the PB2 protein is conserved among many mammalian IAVs and may confer resistance to cold temperatures (Massin et al. 2001). This PB2 substitution introduced in a range of IAV genetic backgrounds, including of avian and mammalian origin, increases IAV replication and pathogenicity in mammals (for review see (de Wit et al. 2008; Taubenberger and Kash 2010; Reperant et al. 2012b; Joseph et al. 2017)). It improves binding of PB2 and NP proteins to assemble into viral ribonucleoproteins (vRNP) in mammalian cells, increasing viral transcription, replication, and production. Most intriguingly, it was recently shown that this substitution overcomes the restriction of the human ANP32 proteins in supporting the replication of avian influenza viruses (Zhang et al. 2019). The human ANP32A and ANP32B host factors facilitate human IAV RNA synthesis but cannot efficiently support the polymerase activity of avian influenza viruses. Swine in contrast have an ANP32A host factor with a unique amino acid evolutionary pathway that allows it to support both avian and swine influenza viruses, in accordance with their known role of "mixing vessel" (Zhang et al. 2021; Yu et al. 2022).

Interestingly, however, the PB2 E627K substitution is not present in equine IAVs of the H7N7 subtype and in equine and canine IAVs of the H3N8 subtype, suggesting that other host factors likely affect the evolution of this mutation (Joseph et al. 2017). More surprisingly, this substitution is also absent in the pandemic IAV H1N1 of 2009, and introducing the mutation in this virus genome did not result in enhanced replication or increased pathogenicity of the virus (Herfst et al. 2010).

The nuclear transport of some mammalian IAV vRNPs is mediated by different importins-α than those mediating transport of avian IAV vRNPs (Gabriel et al. 2011). Six isoforms of importin-α, which recognize vRNP nuclear localization signals as part of the classical nuclear import pathway, have been described in humans and chickens. While avian IAV vRNP nuclear import was shown to be dependent upon importin-α1 and importin-α3, increased use of importin-α1 and a switch from

importin-α3 to importin-α7 correlated with efficient IAV replication in mammalian cells and impaired replication in avian cells. Interestingly, importin-α7 (encoded by the KPNA6 gene) interacts with the ANP32 proteins and affects polymerase activity (Yu et al. 2022). The changes in importin-α usage are associated with substitution D701N in the PB2 protein and N319K in the NP protein in a mouse-adapted strain of avian IAV H7N7. Substitution D701N in the PB2 protein is found in many mammalian IAVs, including in the seal IAV H3N8 of avian origin, and in avian IAVs that caused severe disease in humans, including HPAIV H5N1. It is considered one of several genetic markers differentiating avian from human IAV isolates. However, and again quite surprising, this substitution, like E627K, is absent in pandemic IAV H1N1 of 2009, and its introduction into the genome of this virus did not enhance replication nor increase pathogenicity (Herfst et al. 2010).

Elevated levels of pro-inflammatory cytokines have been reported in fatal human cases of 1918 pandemic IAV H1N1 infection and in fatal and severe cases of HPAIV H5N1 infection (for review see (de Wit et al. 2008; Taubenberger and Kash 2010; Reperant et al. 2012b). The NS1 proteins of these viruses are potent inhibitors of the antiviral effect of the innate immune response. Escape from host antiviral responses may lead to the development of a so-called cytokine storm, further contributing to the severe respiratory symptoms of these infections. However, NS1 mutations associated with such escape from host antiviral responses are not present in most IAVs circulating in humans and thus do not appear to be markers of IAV host adaptation.

22.4.2 Transmissibility

Although several markers of IAV adaptation to avian or mammalian hosts, associated with sustained IAV circulation in these species, have been identified, the determinants of the effective transmission of progeny viruses produced during infection to a new individual host are incompletely understood (Sorrell et al. 2011).

Receptor binding affinity for SAa2,6Gal and high replication levels in the upper respiratory tract appear essential for transmission of IAVs among humans. Only two amino acids, changing IAV H1N1 receptor binding affinity from SAa2,6Gal to SAa2,3Gal, abrogated contact transmission of 1918 pandemic IAV H1N1 in the ferret model (Tumpey et al. 2007). Conversely, the introduction of one mutation in the HA gene of avian IAV H9N2 conferred receptor binding affinity for SAa2,6Gal and improved contact transmission of the virus in ferrets (Wan et al. 2008). To date, specific residues of IAV HA proteins of the H1, H2, H3, H4, H5, H7, and H9 subtypes affecting their receptor binding affinity for SAa2,3Gal or SAa2,6Gal have been described (for review see (Reperant et al. 2012b)). However, receptor binding affinity for SAa2,6Gal is not sufficient to confer IAV transmissibility. A number of mutations have been found to decrease binding affinity of HPAIV H5N1 for SAa2,3Gal and increase their binding affinity for SAa2,6Gal; however, none of the mutated viruses efficiently spread by contact or aerosols in the ferret model (Chutinimitkul et al. 2010; Herfst et al. 2012).

Additional mutations, notably in the vRNP and matrix genes, affect IAV transmissibility in animal models. In particular, mutations improving IAV replication in mammalian cells were shown to confer or improve IAV transmissibility. In combination with the HA and NA proteins of the 1918 pandemic IAV H1N1 (with binding affinity for SAa2,6Gal), PB2 protein with E627K substitution allowed aerosol transmission of an avian IAV in ferrets (Van Hoeven et al. 2009). Conversely, substitution K627E in the PB2 protein of human seasonal IAV H3N2 impaired its aerosol transmission in guinea pigs (Steel et al. 2009). Substitution D701N in the PB2 protein also improved contact transmission of HPAIV H5N1 and aerosol transmission of human seasonal IAV H3N2 in guinea pigs (Steel et al. 2009). Lastly, the M gene was recently shown critical for the high transmissibility of 2009 pandemic IAV H1N1 in guinea pigs (Chou et al. 2011).

A set of mutations in the HA and PB2 proteins were found to allow aerosol transmission of HPAIV H5N1 in the ferret model (Herfst et al. 2012). These included two mutations in the HA gene known to change receptor binding affinity of HPAIV H5N1 from SAa2,3Gal to SAa2,6Gal; two additional mutations in the HA gene, of which one affected glycosylation of the protein; and PB2 E627K substitution. Reassortment of HPAIV H5N1 with 2009 pandemic IAV H1N1 also resulted in viruses that efficiently transmitted via respiratory droplets in ferrets and guinea-pigs (Imai et al. 2012; Zhang et al. 2013). In most of these reassortant viruses, mutations in the HPAIV H5N1 gene conferring SAa2,6Gal were present, while several genes of pandemic H1N1 origin were shown to improve transmissibility, including PA, NP, NA, M, and NS genes.

Importantly, thermostability of the HA and to pH of fusion may be additional prerequisites for aerosol or respiratory droplet transmissibility. In particular, compensatory mutations in the HA emerged and improved stability after the affinity switch from SAa2,3Gal to SAa2,6Gal in the seal H10N7 IAV (Herfst et al. 2020). Similar mutations improved respiratory transmission of HPAIV H5N1 and of the 2009 pandemic H1N1 virus. It is speculated that the HA stability phenotype may affect the stability of HA in aerosols, resistance to drought, stability in mucus, or resistances to changes in pH in the host environment (Herfst et al. 2020).

22.5 Conclusions

The highly diverse populations of IAVs circulating in wild bird species exist as a large pool of functionally equivalent and so often interchangeable gene segments that form transient gene constellations (Dugan et al. 2008). Occasionally, some of these gene constellations may lead to IAV infection of other avian or mammalian species, including humans. The ability of these viruses to productively replicate and sustainably spread among these new host species still poses numerous questions, likely to be addressed by studying more members of the wide diversity of IAVs in an increasing number of host species. IAV host switch and adaptation to novel host species, transmissibility, and pathogenicity are each dependent on complex multifactorial, interrelated, and mutual interactions between virus and host and are likely under

largely different selective pressures (Taubenberger and Kash 2010). Striking similarities though, in pathogenesis and transmissibility of IAV infections in newly invaded avian and mammalian species, including humans, may point to common pathways that lead to adaptation and sustained presence in newly "colonized" species.

https://doi.org/10.1007/978-3-031-27164-9_19

Abstract

The current review summarizes features of Parapoxviruses (PPV): virus properties, host range, epidemiology, clinical manifestation, diagnosis, immunology, and countermeasures. The zoonotic potential in transmission to man resulting in self-limiting local skin lesions is discussed and shown by case pictures. Successful usage of PPV, especially Orf virus, as vector vaccines is demonstrated. Future aspects such as PPV application for oncolytic therapy are discussed.

Keywords

Parapoxviruses · Zoonosis · Diagnosis · Vector vaccines · Oncolytic therapy

23.1 Introduction

The PPV species are assembled in the genus *Parapoxvirus* of the subfamily *Chordopoxvirinae* within the family *Poxviridae*. Currently five species of PPV are established: orf virus (ORFV), bovine papular stomatitis virus (BPSV), pseudocowpoxvirus (PCPV), PPV of red deer (previously red deer in New Zealand, PVNZ), and PPV of grey seal. There are other tentative species attributable to the genus such as camel and chamois contagious ecthyma virus. The prototype member of the PPV genus, *Parapoxvirus ovis* or ORFV, is endemic in most sheep and goat raising countries in the world causing contagious ecthyma (CE) or "Orf," a term probably derived from the old Icelandic word "hurf" meaning a wound scab. The worldwide awareness of *Parapoxvirus* (PPV) infections is high; however due to regional differences in occurrence, morbidity, and mortality (generally low) and the limitation of zoonotic infections to occupational contact, mostly clinical cases find a high degree of attention. On the other hand, PPV represent important examples for the demonstration of escape mechanisms in the pathogenicity of local skin and mucosal infections. In contrast, the complexity and multi-protein composition of the large PPV particles turned out to show beneficial immune modulation when applied systemically. A different field of attention is the use of PPV, especially of the prototype ORFV, as a potent viral vector for foreign gene expression in vaccinology. Finally, a more recent research area is oncolytic therapy using PPV.

23.2 Virus Properties

The ovoid PPV virion measures 220–300 nm in length and 147–170 nm in width and is surrounded by a tubule-like spiral structure resulting in the characteristic and distinct "ball-of-wool" appearance. The virion harbors a single linear, double-stranded DNA molecule of 130–140 kbp with an exceptional high G + C content of approximately 64%. The genomic termini are cross-linked by single-stranded hairpin loops and contain inverted terminal repeats (ITR) of 2.6 to 3.5 kbp in size, which can be enlarged by terminal genomic rearrangements after multiple cell culture passages. To date,

complete sequence information of 14 strains of ORFV, BPSV, and PCPV is available (Rziha and Büttner 2021). The genomes encode 124–134 genes, 88 are conserved in all *Chordopoxvirinae*. Central parts of the genome are highly conserved and contain genes essential for virus replication, particle packaging, and export (Rziha and Büttner 2021). Although the 132 putative genes in ORFV are present in different isolates, substantial sequence variations can occur (Mercer et al. 2006). Highest sequence differences among PPV species are found in the near terminal ends of the right and left genomic ends. PPV genomes show a remarkable plasticity when the viruses are subject to cell culture passages; already after six passages, gene deletions can occur (Rziha and Büttner 2021). After serial cell culture passages and adaption to cell lines gene, duplications, rearrangements, as well as major deletions of nonessential genomic regions can occur, which are accompanied by virus attenuation (Cottone et al. 1998; Rziha et al. 2019).

23.3 Immunomodulatory, Immune Evasion Genes of PPV

Poxviruses share many properties and particularly viral genes involved in evasion from and modulation of the immune response. An increasing number of genes encoding those immunomodulatory proteins (IMPs) become revealed in the PPV genome, which are also involved in regulation of virulence, pathogenesis, or host range (Fleming et al. 2015). These IMP genes are predominantly located close to the genomic termini, are early expressed, and are dispensable for virus replication. The first virulence determinant of PPV was described in ORFV, a functional homolog of the mammalian, angiogenic vascular endothelial growth factor (vegf), designated as vegf-e (Fleming et al. 2015; Meyer et al. 1999). The vegf-e gene is unique for PPV among *Chordopoxvirinae* and is suggested to be acquired by the virus from its mammalian host. It is responsible for extensive vascular proliferation beneath parapoxvirus lesions (Meyer et al. 1999). The construction of various apathogenic ORFV recombinants was enabled by the deletion of the vegf-e gene (Rziha et al. 2019). As shown in Fig. 1, no more formation of pustules and inflammatory vascularization was detectable after removal of the vegf-e gene from the attenuated ORFV strain D1701-B but could be restored after restoration of the vegf-e gene. The ORFV-encoded viral interleukin 10 (vIL-10) is an orthologue of the ovine IL-10 and might also be acquired by ORFV from its host. ORFV lacking the vIL-10 gene has reduced pathogenicity in sheep (Fleming et al. 2015). Two other secreted IMP have been discovered, a chemokine-binding protein (CBP) and the soluble protein inhibitor of ovine granulocyte-monocyte colony-stimulating factor and interleukin-2 (GIF), which both are important for infection, clinical course, and disease progression in sheep (Fleming et al. 2015; Sharif et al. 2019; Martins et al. 2021). Furthermore, ORFV encodes an interferon (IFN)-resistance gene (VIR or IFNR), which inhibits antiviral activity of interferon as its vaccinia virus homolog E3L (Fleming et al. 2015). Programmed cell death (apoptosis) represents a common innate host strategy to eliminate virus-infected cells. The ORFV-encoded Bcl2-like inhibitor of apoptosis can lead to the survival of infected cells (Fleming et al. 2015; Li et al. 2018). Signaling pathways of nuclear factor kappa B (NF-κB) represent

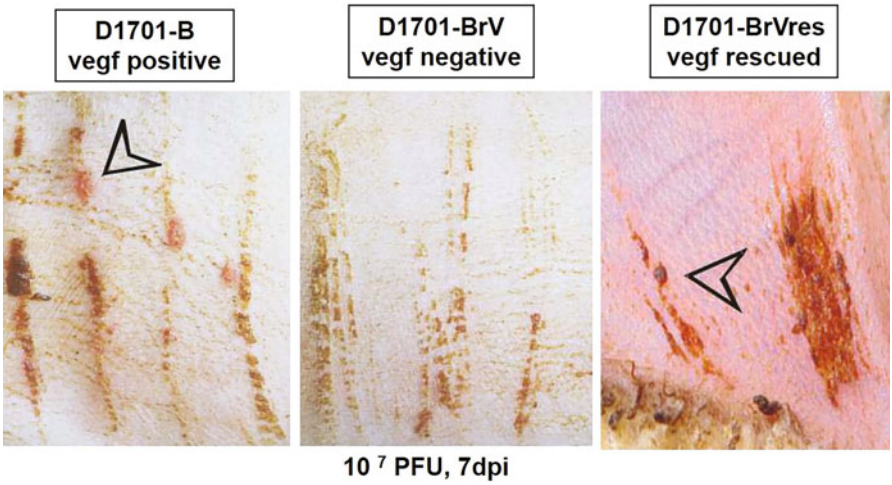

Fig. 1 Lesion development in sheep skin after scarification and application of 10^7 plaque-forming units (PFU) of the attenuated ORFV strain D1701 – day 7 after infection. The vegf-e gene deleted mutant (BrV) lacks induction of pustule formation and inflammatory vascularization as seen in the parental (D1701-B) and the vegf-e rescued virus (arrows). Derived from: M. Henkel, 2007, Parapockenvirus ORF-Virus D1701: Attenuierung und Herstellung einer Vektorvakzine gegen die Borna'sche Krankheit, Dissertation Eberhard-Karls-Universität, Tübingen, Germany

important regulators of innate immune response including apoptosis. For PPV until now, five encoded NF-κB inhibitors are known, some of them also shown to be involved in viral virulence (Khatiwada et al. 2017). A functional dUTPAse is encoded at the left genomic terminus of PPV, which is missing in some attenuated ORFV strains (Cottone et al. 2002). Poxviruses growing in the epidermis including ORFV encode a so-called *Poxvirus* APC/C regulator (PACR) involved in virus growth and replication (Fleming et al. 2015). Finally, as many other poxviruses also PPV contain several genes that express proteins comprising the so-called ankyrin repeat (ANK) consensus motifs (Rziha et al. 2003; Chen et al. 2017).

23.4 Host Range and Epidemiology

PPV infections and clinical signs occur worldwide but are predominantly restricted to domestic and wildlife ruminants. Natural infection has been reported in many wildlife and domestic small and larger ruminants such as bighorn, and thinhorn sheep, domestic and rocky mountain goat, Dall's sheep, chamois, ibex, Himalayan thar, muskox, reindeer, caribou, steenbok, and camelids from which all are transferable to humans. BPSV and PCPV both establish infection in cattle and humans, but all other species tested, including sheep, are resistant. Both, ORFV and PCPV can affect reindeer where ORFV infection caused the more severe lesions (Rziha and Büttner 2021). PVNZ originally found in New Zealand is also present in Europe is now consolidated to PPV of red deer, it induces only very mild lesions in sheep. The

new established species PPV of seals has been reported in different pinniped species, i. e., *Phocidae* (true seals), *Otariidae* (eared seals), and *Odobenidae* (walrus), and led to the inclusion of PPV of grey seal in the actual taxonomy. Recent sequence data propose the classification of all pinniped PPV under a species named "pinniped PPV" within the genus (Costa et al. 2021). PPVs do not infect poultry and do not produce lesions on the chorioallantoic membrane of the chicken embryo.

23.5 Zoonosis

The zoonotic transmission to man can be caused by all PPV species known so far. It leads to localized erythema, papules, or pustules commonly called milker's nodule (MN), paravaccina, or pseudocowpox (PCP). In general, a precondition for successful infection and manifestation of PPV lesion in man as well as in animals is broken skin or micro-wounds. PPV infections are occupational zoonoses mostly affecting veterinarians, farmers, hunters, butchers, abattoir workers, and all persons in close contact to sheep, goats, cattle, or infected wildlife. Frequent infections are reported at mass slaughtering of sheep or goats during religious feasts. Due to the frequent benign resolution of the lesions as well as the lack of specific etiology reports, cases are often underestimated. However, more dramatic disease with painful lesions can occur in severely immune-compromised persons, e.g., after burn accidents (Baj et al. 2020). As in animals, human infections with PPV occur worldwide, especially ORFV transmission is common in countries with intense sheep and goat breeding. The rate of subclinical infections in domestic small and large ruminants is unknown, but it is often reported that the contact animal(s) had no visible lesions. Nowadays, ORFV transmission from sheep and goats to humans dominates the zoonotic infections (Fig. 2). Little is known about immune reactions in PPV-infected persons. It can be assumed that immune responses in affected humans are similar as reported for sheep. In man cutaneous infiltrates have been characterized by immunohistochemistry showing an influx of CD3-positive T-lymphocytes of which the majority was CD4-positive. On infiltrated lymphocytes CD30 was detected as a marker for stimulated cells indicating a Th2 rather than a Th1 immune response (Rose et al. 1999). In humans, inter-individual transmission, e.g.. by close contact from a diseased individual to another is not evident.

For treatment of severe lesions (giant orf) in human PPV patients, cyclic nucleoside analogs, such as acyclovir ACV or cidofovir CDV, selectively interacting with poxviral DNA polymerase are effective. Topical treatment with CDV resulted in complete regression of lesions even in immunocompromised patients (Rziha and Büttner 2021).

23.6 Clinical Features and Pathology

PPVs cause inflammatory and/or proliferative lesions that are confined to the skin and oral mucosa with no evidence of systemic spread. Infection is initiated in abrasions and generally proceeds through an afebrile, self-limiting lesion that

resolves within 3–9 weeks without leaving a scar. Orf lesions are most generally seen around the mouth and nares; hence, the infection is commonly referred to as scabby mouth or sore mouth. Lesions are also observed on other parts of the body, for example, the coronet, udder, or vulva. Following experimental inoculation of scarified skin, lesions progress through erythema, papule, vesicle, pustule, and necrotic

Fig. 2 Series of orf manifestation at the fingers of a veterinary student handling infected sheep in Chile. Progress of lesions and beginning of wound healing. Courtesy of Carolina Madariaga, Universidad Santo Tomás, Chile and Carlos A. Flores Olivares, Universidad Pedro de Valdivia, Chile

Fig. 2 (continued)

scab before resolving. Large, proliferative, tumor-like lesions can be observed. It is likely that such lesions are a result of an immune impairment and bacterial super infection of the host animal.

23.7 Orf, Scabby Mouth, Contagious Pustular Dermatitis (CPD), Ecthyma Contagiosum

Lesions around the mouth can interfere with feeding or suckling and especially in young animals result in failure to thrive. Teating lesions can have similar effects through the inhibition of suckling. Lesions in sheep and goat can develop into tumor-like, cauliflower proliferative erosions usually accompanied by secondary bacterial infection (Fig. 3). Edema of the head and swelling of the regional lymph nodes are common but rather nonspecific signs of severe progression. In severe cases, glossitis phlegmonosa and ulcerosa with secondary bacterial infections can lead to starvation especially in young animals. Most common is the *labial form* that impressed the designation of the disease. Blisters and yellowish pustules that may reach pea size are formed on the lips and at the corners of the mouth and can extend up to the nose, ears, and eyelids. The mild labial form heals within 3–6 weeks. Pustules can develop on the udders of ewes shortly before the lambing period. Secondary bacterial infections cause complications. In sheep severe lesion development is known as bloody lesion that is probably linked the stimulation of vascular endothelial cells and to proliferation leading to a cauliflower tumor-like clinical outcome. The *podal form* (scabby foot) can occur simultaneously with the labial manifestation or independently. Lesions develop at the coroner edges of the hooves, at the pasterns and in the hoof gaps. The end of the digits are painful and lead to lameness and the refusal to stand. *The genital form* is less common. Typical pustule and crust formation occur on the udder mostly developing into mastitis. Skin lesions also can occur on the inner leg, the labia, or the prepuce.

Fig. 3 Orf (ecthyma contagiosum, scabby mouth) in a lamb: proliferative lesions complicated by bacterial superinfections

23.8 Milker's Nodule, Paravaccinia, Pseudocowpox

It is highly likely that all PPVs from susceptible domestic and wildlife animals can be transmitted to humans. Most frequent infections originate from contact with sheep or goats (human orf) followed by virus transmission from diseased cattle or reindeer (milker's nodule, paravaccinia, pseudocowpox**)** and wildlife. From human patients complete genome sequence is available from few ORFV an PCPV isolates (Friederichs et al. 2014; Andreani et al. 2019). The highest risk of infection is reported for handling of sheep fleece or wool and ritual slaughter of affected sheep, e.g., at religious feasts. Progression of the lesions is essentially as seen in sheep and cattle such that the infection is benign and confined to localized pustular lesions on the skin mainly at the hand and fingers at the points of virus entry (Fig. 2). *Restitutio ad integrum* without leaving a scar usually occurs after a few weeks post infection. More severe progressive disease can occur in immune-compromised individuals showing strong cellular proliferation, called giant orf. Such cases have also been recorded in otherwise normal individuals after burn events and in cases of atopic dermatitis. *Erythema multiforme* reactions in the form of rashes on the backs of the hands and on the legs and ankles are common.

23.9 Bovine Papular Stomatitis (BPS)

Bovine popular stomatitis normally is a mild form of inflammation around the muzzle and mucous membrane of the mouth in large ruminants (Fig. 4a, b). However, more severe lesions can occur resulting in extension of confluent inflammation to the hard gum, the tongue, and far down to the esophagus. Lesions on the teats (pseudocowpox) are less frequently seen but are painful and lead to rejection of the suckling calf. Pseudocowpox virus (PCPV) represents a unique species with molecular characteristics. Interestingly, BPSV and PCPV can be found associated with ticks infesting cattle in Africa indication possible longevity of the virus in skin (Ouedraogo et al. 2020). Pustular vulvovaginitis caused by PCPV is a rare and

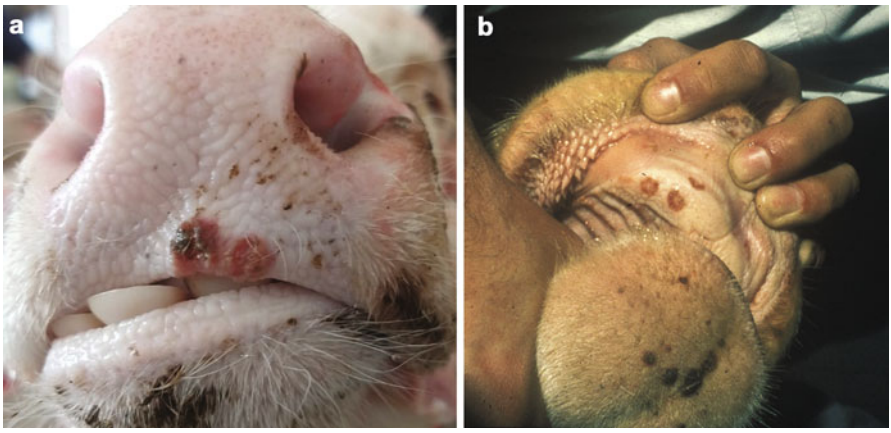

Fig. 4 Bovine popular stomatitis, local inflammatory circular lesion on the muzzle. (**a**) Planar herds of inflammation and necrosis at the muzzle of a cow from an outbreak of bovine papular stomatitis (BPS) in Argentina. (Micheloud JF et al. Tropical Animal Health and Production 2020, 52: 453–459. https://doi.org/10.1007/s11250-019-02006-w). Kindly provided by A. Peralta, Instituto de Agrobiotecnología y Biología Molecular (IABIMO), INTA, Consejo Nacional de investigaciones Científicas y Tecnológicas (CONICET), Hurlingham, Argentina. (**b**) BPS inflammatory lesions at the hard gum and tongue of a cow (arrows). In severe progressive cases, the lesions can spread deep down to the esophagus. Note the unprotected hand/fingers facilitating virus transmission to man

sporadic occurring disease. Signs of BPS may arise spontaneously in apparently healthy animals (especially young calves) without reports about skin damage or injury. Like infections with PPV of red deer, subclinical persistence of the virus cannot be excluded. The trigger of clinical manifestation can be either unusual virulence of BPSV or immune suppression or both in synergy.

23.10 Parapox of Red Deer

Initially described in red deer of New Zealand, it became evident that red deer in Europe and probably worldwide can become infected with this unique species of PPV. In Italy, clinical manifestation in red deer was seen as inflammation of the mouth whereas in Germany subclinical infection was diagnosed by viral DNA presence and virus isolation in cell culture (Rziha and Büttner 2021). For red deer in New Zealand, it is reported that PPV infection in growing deer antlers can affect antler growth and severely affect marketability of the product.

23.11 Patho-histology

Keratinocytes are key target cells in ORFV infection where in distinct areas a cytopathic effect (CPE) is seen as ballooning degeneration of the cells; vacuolization in the supra-basal layers and typical intra-plasmatic eosinophilic inclusion bodies

can be found (Muhsen et al. 2019). Ballooning in context with poxvirus infections is characterized by cell swelling and rounding of the cytoplasm and is caused by the rearrangement of the intermediate filaments of the cytoskeleton.

23.12 Diagnosis

Clinical diagnosis of BPS and Orf in sheep is complicated by different similar inflammatory disease manifestations in the skin and mucous membranes caused by other viruses such as foot and mouth disease (FMD), bluetongue (BT), bovine viral diarrhea and border disease (BVD, BD), and bovine herpesvirus (BHV-1) rhinotracheitis. Shortly after infection nonspecific clinical signs like head edema make it difficult to find a diagnosis. However, rapid and reliable differential diagnosis for such communicable and economically important diseases is essential.

Electron microscopy is a method of choice when enough virus particles can be expected (10^5 or more particles) in a sample (biopsy material, skin specimen). In samples from affected persons, it is extremely difficult to find PPV virions in electron microscopy because of a lack of sufficient tissue and frequent pre-diagnostic treatment of lesions. Therefore, currently electron microscopy has been replaced or at least is accompanied by molecular diagnosis, predominantly polymerase chain reaction (PCR). Several sensitive real-time PCR protocols became established for rapid and reliable detection of PPV genome presence in tissue samples. Conventional PCR followed by electrophoresis of amplified DNA fragments still is of importance for further molecular analysis, e.g., sequencing. The latter is used to differentiate PPV species and to perform molecular epidemiology. The most popular target region for this purpose is the open reading frame (ORF) 011 containing the B2L gene, an orthologue of the vaccinia virus Copenhagen F13L gene, that encodes the major envelope protein p37K (Sullivan et al. 1994).

Whole genome sequencing (WGS) techniques become increasingly popular and affordable, and direct WGS out of the sample is forward-looking. Nevertheless, for intense further studies, PPV laboratory strains are essential, although cell culture isolation of PPV out-of-field samples is tedious and time consuming. Primary ruminant or human fibroblasts are the most permissive cells followed by Vero cells that have been successfully used for virus propagation. Long incubation (up to 7 days) of inoculated cells and blind passages can become necessary for successful PPV isolation.

Serology is of little value in PPV diagnosis. Antibody development is readily induced, mainly directed against the major envelope protein (B2L gene), but antibody screening in ruminants is of poor significance due to the high and widespread subclinical infection prevalence in the population. There are no commercial antibody assays available. Therefore, only experimental ELISA protocols have been developed that can also be used to test human sera. Virus-neutralizing antibodies can only be generated by multiple experimental injections to produce hyper-immune sera or monoclonal antibodies.

23.13 Immune Reactions

PPV infections lead to antibody development that bind to virus components (Western Blot and ELISA reactive), but antibodies partially neutralizing the virus are only found after repeated infections or several booster injections. The ewe's colostrum does not protect her lambs from infection. Vaccines for sheep have been developed long time ago beginning with scarification trials using scab material, and nowadays attenuated cell culture-adapted ORFV strains are used as live vaccines, but with limited success. At least in sheep, vaccination can prevent the severity of pustule development in lambs and protect them for a certain time from reinfection in a flock. There are no special studies that evaluate the prevention of virus spread by consequent and repeated vaccination. The resistance of PPV, especially of the mature enveloped particles, against environmental influences must be taken in account about contaminated pastures, fodder, and wool of the animals.

23.14 Immune Stimulation

Following iatrogenic application, e.g., by intramuscular or subcutaneous injection, ORFV can exert a strong immune-stimulatory but well-balanced effect. This has been exploited especially in treatment of nonpermissive animals in veterinary medicine to counteract infectious diseases or stress situations at the innate level of immune defense. Whether the early expressed immune evasion genes of PPV are functional in vivo in nonpermissive cells is unknown, but the complex proteins and lipoproteins of the large particles stimulate a battery of cellular and humoral innate immune reactions, e.g., secretion of cytokines such as type I interferons (Büttner et al. 1995; Friebe et al. 2004; McGuire et al. 2012). In laboratory animals a beneficial effect of inactivated ORFV was reported in infection and even in tumor models. The nonspecific side effect of ORFV application also supports its extraordinary efficacy as a vector vaccine (see below) comprising its own adjuvant.

23.15 Biomedical Potency (Vector, Oncotherapy)

23.15.1 ORFV Vector Platform

The utility of poxviruses as expression vectors was first described in the early 1980s. Since then, poxviruses have been widely used as vaccine delivery platforms in human and veterinary medicine. Meanwhile also ORFV evolved as a novel poxvirus vector platform for delivering heterologous antigens without the risk of a vigorous immune response against the vector backbone. Additional advantages of the ORFV vector are the restricted host range, the lack of systemic spread even in immuno-compromised animals, and the induction of strong, balanced humoral and cellular immune responses against expressed foreign antigens (Reguzova et al. 2020). Importantly, ORFV-based

vaccines induce strong immune responses also in hosts nonpermissive for PPV. The ORFV inherent properties comprise the stimulation of strong innate immune responses. Dendritic cell activation via toll-like receptor 9 also potentiates the ORFV-induced immune response (von Buttlar et al. 2014). Those mechanisms can explain the potency of ORFV-based vaccines without the need of adjuvants.

For the first time, ORFV recombinants were generated from the attenuated strain D1701 by replacing the nonessential virulence vegf-e gene by foreign antigens (Rziha et al. 2016, 2019). This finding was the kickoff for the development of the ORFV strain D1701-based vaccine vector platform resulting in numerous protective vaccines (Rziha et al. 2019). One special feature of this platform is the use of early ORFV promoters**,** which regulate the expression of the heterologous antigens. Consequently, the successful expression and immune recognition of the foreign antigens needs neither replication nor production of the inoculated recombinant vaccines representing an additional safety aspect. Lately, new additional genomic loci or genes were described in ORFV D1701-V that are suitable for insertion and expression of foreign genes. This allows the generation of multivalent recombinant vaccines (Rziha et al. 2019). Just recently for the purification of D1701-V recombinants, a new strategy of a downstream process was reported combining filtration and chromatographic methods, which is adequate for safe application and within the regulatory limits for contaminant levels (Lothert et al. 2020).

The use of ORFV recombinants for delivery of heterologous proteins must not be restricted to apathogenic, attenuated virus strains. For instance, replacing one of the abovementioned IMP genes resulted in protective recombinant ORFV vaccines with reduced pathogenicity in sheep and goat (Joshi and Diehl 2021).

23.15.2 Oncolytic Potency

Oncolytic viruses that are selected or engineered for selective or preferential infection of tumor cells can be promising candidates for cancer treatment. Several members of *Poxviridae* were successfully used in oncolytic virotherapy, and PPV including ORFV, PCPV, and BPSV could be shown to possess oncolytic properties (Ricordel et al. 2018). In addition to immune stimulation by inactivated ORFV, also replicating ORFV was discovered to destroy human cancer cells in vitro and to reduce the tumor burden in different mouse tumor models including breast, lung, or colon cancer (Rintoul et al. 2012; Chen et al. 2021).

23.15.3 Prospects

PPV are deeply rooted in biocenosis. The species within the genus have adopted to successful infection, replication, and manifestation in the skin and mucous membranes. Although the animal host range of PPVs is limited, their transmission to man can be achieved under the precondition of micro-wounds or skin damage but is limited to the entry site. As a typical local infection, PPVs represent a major

difference in pathogenicity to members of the *Orthopoxvirus* genus. Thus, the impact of PPV as a zoonosis is of limited danger in comparison to manifestation of systemic infections with some *Orthopoxvirus*, e.g., cowpox virus. With respect to clinical outcome, some disturbance can arise concerning speculations about a possible PPV etiology probably flanked by unclear electron microscopical pictures. Recently, emergence of a new poxvirus in red squirrels (McInnes 2006) and the occurrence of skin pathology in horses led to the assumption of a PPV etiology. The equine skin disease turned out to be caused by a molluscum contagiosum-like virus (Ehmann et al. 2021). Nowadays progress in molecular diagnostics including WGS can rapidly clarify such uncertainties. The plasticity of the ORFV genome is demonstrated in vitro after serial cell culture passages and by growth adaptation to certain cell lines. It always led to attenuation and stability of genome alterations in laboratory strains providing a safe platform for its use as vector, as an immune-stimulating agent and probably a tool for oncotherapy.

Zoonotic Orthopoxviruses: Innocuous Rash or Global Public Health Threat?

24

Jesse Bonwitt, Jeffrey B. Doty, Andrea M. McCollum, and Yoshinori Nakazawa

Contents

Abstract

The *Orthopoxvirus* genus is a group of large DNA viruses with importance to both animal and human health. These viruses show a range of clinical presentations from localized lesions to generalized rashes; and have various degrees of complexity in their natural history involving one or multiple hosts. *Variola virus* is the most notable member of this genus and is the causative agent of smallpox, a disease that

A. Sing (ed.), *Zoonoses: Infections Affecting Humans and Animals*,
https://doi.org/10.1007/978-3-031-27164-9_62

was declared eradicated in 1980. Zoonotic orthopoxviruses include viruses known to infect multiple mammal species and pose a risk to animal (domestic and wildlife) and human health such as *Monkeypox virus* (endemic to Central and West African countries), *Cowpox virus* (endemic to Eurasia), and *Vaccinia virus* (endemic to South America and parts of Asia, also used in the smallpox vaccine). Recently described orthopoxviruses, *Alaskapox virus*, and *Akhmeta virus*, highlight the possibility of existence of unknown members of this genus with zoonotic potential. Circulation of cryptic orthopoxviruses, *Volepox virus*, *Racoonpox virus*, *Skunkpox virus*, exemplify viruses that appear to have more restricted ability to infect multiple hosts. Prompt identification followed by prevention and control of these viruses will prevent additional spread in animals and humans.

24.1 Introduction

Viruses in the genus *Orthopoxvirus* (family *Poxviridae*) are distinguished by their diversity in disease ecology, epidemiology, and natural history; and, subsequently, in the approach toward prevention, control, and treatment. Orthopoxviruses (OPXVs) are present throughout the globe and have a diverse host range, including both humans and animals; these viruses can cause a spectrum of disease ranging from localized skin lesions to fatal disease. OPXVs are double-stranded DNA viruses that contain large genomes, which includes all genetic material required for their replication once they enter a host cell. These viruses are capable of causing infections in a broad range of mammal hosts through multiple routes; furthermore, OPXVs employ strategies to evade the host's immune response (Reynolds et al. 2018).

Members of the *Orthopoxvirus* genus include *Abatino macacapox virus*, *Akhmeta virus*, *Camelpox virus*, *Cowpox virus*, *Ectromelia virus*, *Monkeypox virus*, *Raccoonpox virus*, *Skunkpox virus*, *Taterapox virus*, *Vaccinia virus*, *Variola virus*, and *Volepox virus* (ICTV 2022). In 2019, *Alaskapox virus* became the most recently described species within this genus (Gigante et al. 2019). Human infections originating from exposure to infected animals have been confirmed for *Alaskapox virus*, *Akhmeta virus*, *Cowpox virus* (CPXV), *Monkeypox virus* (MPXV), and *Vaccinia virus* (VACV). OPXVs have historically been named after the animal species from where they were first identified (i.e., MPXV, CPXV, *Skunkpox virus*, etc.), which has subsequently led to some misunderstandings about their reservoir species. For example, the name MPXV comes from the discovery of this distinct OPXV after it caused an outbreak in wild caught primates shipped to Europe for laboratory studies. Only since has the term become a misnomer, as MPXV is a pathogen of primates, but evidence does not support primates to be the reservoir host for the virus (Reynolds et al. 2012).

Variola virus, the causative agent of smallpox, was one of the most significant public health threats in history with high transmission and case fatality rates (20–60%), and permanently debilitating sequalae among some survivors (Breman and Henderson 2002). The host specificity of *Variola virus* and development of effective smallpox vaccines ensured that it became the first infectious disease to be eradicated. The eradication of *Variola virus* was made possible thanks to early efforts of Edward Jenner, who exploited observations that milk maids who were previously infected with CPXV did not develop smallpox after being exposed to smallpox patients. Anti-OPXV antibodies, as the result of infection or vaccination, engender significant immunological cross-protection against infection by other members of the genus. Jenner created the first smallpox vaccines using infectious material from cows and horses thought to be infected with CPXV or possibly *Horsepox virus*. By the twentieth century, VACV was used in pharmaceutical vaccine products as the smallpox vaccine during the global eradication campaign (Schrick et al. 2017; Li et al. 2007a).

Multiple strains of VACV exist following repeated cell passage and attenuation for creating smallpox vaccines. Some of these strains are thought to have escaped back into the wild via inoculation from an active vaccination site or when domesticated bovines were inoculated with VACV for propagation of the smallpox vaccine. VACV is currently endemic in parts of Asia and South America where it contributes to animal and human disease (Oliveira et al. 2017).

The cessation of smallpox vaccination in the 1980s has led to waning population-level immunity to OPXVs, raising concerns that an immunologically naïve population will no longer be afforded cross-protection against OPXV infections. These predictions have been most stark with regards to monkeypox, an emerging zoonotic disease in Central and Western Africa that causes relatively high mortality and morbidity in humans (Durski et al. 2018). MPXV is particularly concerning due to its unique ability among extant OPXVs to cause extended human-to-human transmission, with reported transmission chains of up to 7 generations (Nolen et al. 2016). Its recent resurgence in Nigeria (Yinka-Ogunleye et al. 2018); its high incidence rates in the Democratic of the Congo (Rimoin et al. 2010; Whitehouse et al. 2021); and increasing number of exportation events in humans and animals (Hutson et al. 2007; Mauldin et al. 2022) outside of its zone of endemicity draw even more attention to its global relevance.

24.1.1 Orthopoxvirus Relationships

OPXVs are brick-shaped viruses (220–450 nm) with large genomes (170,000–200,000 base pairs) that encode approximately 200 proteins with a core central region that is highly conserved (low genetic variability) across the genus (Hendrickson et al. 2010). The infectious particle (mature virion) is composed of a lipoprotein membrane that surrounds a core nucleoprotein containing the DNA. During infection, the virion fuses with the host cell membrane and it is brought into the cytoplasm through endocytosis (Bengali et al. 2012). Replication of OPXV

DNA occurs in the cellular cytoplasm, where intracellular mature virions and intracellular enveloped virions are produced and transported to the cell membrane, exiting the cell as extracellular enveloped virions (Smith and Law 2004).

Based on phylogenetic inferences, OPXVs have been grouped into New World (e.g., *Volepox virus*, *Raccoonpox virus*, *Skunkpox virus*) and Old World OPXVs (e.g., *Variola virus*, CPXV, VACV, MPXV) (Smithson et al. 2017; Carroll et al. 2011). New World OPXVs – also referred to as North American OPXVs – form a distinct group that appears to be ancestral to all other OPXVs and are thought to be endemic to North America; these viruses are not known to cause infections in humans. Similar to other OPXVs, they were named after the animal species in which they were initially identified (i.e., vole, skunk, raccoon); however, several aspects of their geographic distribution, host range, and transmission remain largely unknown. *Alaskapox virus*, a recently described OPXV from the Fairbanks region of Alaska, appears to naturally occur in this state, causes infections in humans, and is genetically more similar to Old World OPXVs than to those from North America, which poses interesting questions about the evolution of these viruses (Gigante et al. 2019). *Akhmeta virus* is another recently described OPXV that is genetically similar to Old World OPXVs. This virus was first detected in lesions from cattle herders from the Democratic Republic of Georgia near the town Akhmeta (Vora et al. 2015).

Among Old World OPXVs, CPXV, MPXV, and VACV are known to be zoonotic and have the largest impact on human and animal health. CPXV is known to have a broad geographic distribution across Eurasia. Recent phylogenetic analyses suggest that the group of viruses called CPXV are not necessarily the same virus and that genetic differences between them could support splitting this group into at least five different species (Mauldin et al. 2017). One of these proposed groups contains viruses that are genetically similar to VACV and *Horsepox virus*, which supports hypotheses of the origin of VACV strains used as smallpox vaccines (Esparza et al. 2017).

VACV products were used as smallpox vaccines during smallpox eradication campaigns in the twentieth century by inducing a cross-OPXV immune response; however, the origin of smallpox vaccines is obscured by propagation practices used in early stages of its use (Fenner 1993). Individual strains were replicated in laboratories around the world using standard practices to produce attenuated viruses to reduce the potential of adverse events from the use of the vaccine (Fenner et al. 1988). At the end of the 1990s, Brazil started reporting cases of VACV infections in humans and cows that eventually expanded to several states and regions of the country (Oliveira et al. 2017). Phylogenetic analyses of VACV isolates from Brazil suggest that the virus had been circulating in the wild before the smallpox eradication campaigns in the 1960s and 1970s, which may point to viruses brought into the country through early practices of arm-to-arm inoculations prior to eradication campaigns (Trindade et al. 2007). VACV isolates from Brazil are further divided into two groups (Groups 1 and 2) based on genetic differences (Oliveira et al. 2017). Colombia is another country from which zoonotic infections of VACV have been reported (Usme-Ciro et al. 2017), including one case involving an immunocompromised individual (Laiton-Donato et al. 2020). VACV infections have also been reported in parts of Asia (India and Bangladesh), where buffaloes are involved in its transmission (referred as Buffalopox) (Singh et al. 2006).

MPXV has two distinct genetic clades: Congo Basin and West Africa. West African MPXV has been described to have a more aggressive clinical presentation (Likos et al. 2005). The Congo Basin clade includes isolates from the Democratic Republic of the Congo, the Republic of Congo, Cameroon, and the Central African Republic, while the West Africa clade has been reported in Sierra Leone, Liberia, Côte d'Ivoire, Ghana, Nigeria, and northern Cameroon (Durski et al. 2018).

24.1.2 Ecology and Epidemiology

Animal and human infections occur throughout the endemic range of their respective reservoir hosts. CPXV spillover infections are restricted to Eurasia, VACV in South America (often referred to as bovine vaccinia), VACV in buffaloes and other bovine species on the Indian subcontinent (buffalopox), and MPXV is a significant human infection in Central and Western Africa (Oliveira et al. 2017; Durski et al. 2018; Eltom et al. 2020; Baxby et al. 1994). Camelpoxvirus (CMLV) occurs in areas with major camel production operations, except in Australia (Duraffour et al. 2011). OPXV cases have occurred outside of endemic areas due to travel and the movement of animals and people. This transboundary movement is best exemplified by MPXV, which caused an outbreak in humans and animals in the United States in 2003 due to a shipment of infected wild mammals from Ghana. The mammals were imported for the exotic pet trade and co-housed with prairie dogs (*Cynomys* sp.) that were subsequently adopted as pets and transmitted the infection to humans. This outbreak led to 47 confirmed and probable human cases, including veterinary staff and animal handlers (Croft et al. 2007; Reynolds et al. 2007). More recently, there have been a total of eight instances of travelers who left Nigeria and then sought care in the United Kingdom (4), USA (2), Singapore (1), and Israel (1) due to MPXV infections; secondary human-to-human transmission has occurred in two of these instances in the UK (healthcare worker and family members) (Mauldin et al. 2022; Vaughan et al. 2020; Hobson et al. 2021).

The incidence of OPXVs is not well understood because the infections are often not notifiable to animal or public health authorities, diagnostic capabilities are lacking in many endemic countries, and the viruses are responsible for relatively rare infections that often cause limited disease presentation (with the exception of MPXV) where care by veterinarians or physicians is often not sought by owners or patients. Moreover, OPXV incidence may be increasing across the globe due to cessation of routine smallpox vaccination and waning vaccine-derived immunity in humans. Traditional smallpox vaccines utilize a version of live VACV to elicit an immune response sufficient against OPXVs, including *Variola virus.* In the absence of vaccinations (lack of vaccine-derived immunity), marked increases in human monkeypox incidence and the discovery of new OPXVs (*Akhmeta, Alaskapox viruses*) have occurred (Durski et al. 2018; Vora et al. 2015; Springer et al. 2017); several other reasons for these observations could include changes in environmental and ecological factors that increase interactions between humans and animal hosts (Reynolds et al. 2012; Durski et al. 2018).

OPXVs are commonly transmitted through direct or indirect contact with an infectious host. Skin lesions are infectious through all lesion stages (including crusts); bodily fluids may be infectious (blood, urine, feces); contaminated household items (e.g., clothing, bedding, toys), healthcare items used for patient care, and farm equipment (e.g., milking machines, scratching posts, troughs) have all been implicated as fomites that may contain infectious virus (Duraffour et al. 2011; Prkno et al. 2017; Borges et al. 2017, 2014). The portal of entry is either via direct inoculation through the skin (e.g., wounds, abrasions, scratch, bite) or mucous membranes (e.g., ingestion of contaminated feed or water, or a splash of infected bodily fluids in the eye or mouth), or through inhalation of respiratory droplets (Oliveira et al. 2017; Prkno et al. 2017).

The epidemiology of zoonotic OPXVs is characterized by point-source exposure to reservoirs hosts (via direct contact with infected bodily fluids, skin lesions, or infected materials such as bedding or contaminated surfaces). The resulting transmission events will depend on the virus and strain involved, host susceptibility, and contact patterns between individuals. Animal crowding and species-mixing can lead to extensive multi-species outbreaks. For example, rodent-to-cat-to-human transmission of CPXV is frequently limited to a single individual or household, but can cause outbreaks if susceptible animals are housed together, as has been the case with infected pet rats (Campe et al. 2009). Another illustrative example involves an outbreak of MPXV in a zoo following the introduction of infected giant anteaters (*Myrmecophaga tridactyla*) that infected more than seven species of non-human primates (Peters 1966). Similarly, the importation of infected African small mammals for the pet trade in the United States resulted in transmission to at least 4 species of African mammals, 4 species of North American mammals, and 47 humans (Hutson et al. 2007).

CPXV has been isolated from a wide array of domestic and wild animals. This virus is maintained in nature by bank voles (*Myodes glareolus*), field voles (*Microtus agrestis*), and woodmice (*Apodemus sylvaticus*) (Bennett et al. 1997). Susceptible species include non-human primates, cats, dogs, horses, llamas, foxes (*Vulpes vulpes*), Patagonian cavies (*Dolichotis patagonum*), banded mongoose (*Mungos mungos*), jaguarundis (*Herpailurus yagouaroundi*), okapis (*Okapia johnstoni*), giant anteaters (*Myrmecophaga tridactyla*), African and Asian elephants (*Loxodonta africana*, *Elephas maximus*), rhinoceroses (*Ceratotherium simum*), and several species of big cats (Prkno et al. 2017; Baxby et al. 1982; Kik et al. 2006; Marennikova et al. 1977; Martina et al. 2006; Tryland et al. 2011; Zwart et al. 1971; Abrahao et al. 2010; Kurth et al. 2009). CPXV has been implicated in epizootics in captive wildlife and caused extensive multi-species outbreaks and deaths in zoo animals (Marennikova et al. 1977; Zwart et al. 1971; Kurth et al. 2009). Sequencing data confirmed that wild rats (*Rattus norvegicus*) were the source of the outbreak in a primate sanctuary and in a circus, and epidemiologic investigations indicated feeder rodents as the infection source in two zoo outbreaks (Marennikova et al. 1977; Martina et al. 2006; Kurth et al. 2008). In Europe, case investigations have demonstrated that pet cats have often acted as intermediate hosts between wild reservoir hosts and humans, with diagnoses and severe disease having

occurred in both the cats and humans (Eis-Hubinger et al. 1990; Haase et al. 2011). Human-to-human transmission has not been documented.

In contrast to CPXV, VACV is primarily a disease of bovids and horses in South America, and water buffalo in the Indian subcontinent (buffalopox), although it does not appear to cause outbreaks in horses (Borges et al. 2018). In the Indian subcontinent, however, bovine herds affected by VACV have had documented attack rates as high as 50% or more, causing significant morbidity and agricultural loss (Bhanuprakash et al. 2010; Gurav et al. 2011).

MPXV is capable of infecting a wide range of mammalian taxa, including rodents, marsupials, and primates, including chimpanzees (*Pan troglodytes*), orangutans (*Pongo pygmaeus*), sooty mangabeys (*Cercocebus atys*), baboons (*Papio cynocephalus*), cynomolgus monkeys (*Macaca fascicularis*), and marmosets (*Callithrix jacchus*), with cases also likely in gorillas (*Gorilla gorilla*), gibbons (*Hilobates lar*), squirrel monkeys (*Saimiri sciurea*), and owl-faced monkeys (*Cercopithecus hamlyni*) (Reynolds et al. 2018; Hutson et al. 2007; Arita and Henderson 1968). Since its initial discovery in wild caught primates, MPXV has caused significant outbreaks among captive chimpanzees housed at two independent sanctuaries in Cameroon and among wild chimpanzees in Ivory Coast, highlighting the threat of emerging infectious diseases to endangered wildlife. The source of these outbreaks is unknown (Patrono et al. 2020) (unpublished reports).

24.1.3 Zoonotic and Human-to-Human Transmission

As with most zoonotic infections, individuals most at risk of OPXV infection include people with close and frequent animal contact. This includes pet owners, animal workers (e.g., farmers, milkers, zookeepers, veterinarians, wildlife biologists), hunters, and people handling raw meat or unprocessed animal products. Laboratory workers, healthcare staff, and household members are also at risk of disease from secondary transmission, especially where personal protective equipment is inadequate. Additional risk factors may include daily exposure to an infected animal, cleaning cages and bedding of an infected animal, and providing clinical care to an infected animal (Croft et al. 2007; Reynolds et al. 2007).

Zoonotic transmission of CPXV and VACV are relatively well understood and invariably follow close contact with symptomatic animals, for example, during milking, providing veterinary care, or through close interactions with pets. Epidemiological and laboratory investigations have demonstrated zoonotic CPXV infection following contact with cats, wild and pet rats (Campe et al. 2009; Wolfs et al. 2002), and captive elephants (Hemmer et al. 2010). Veterinary staff are noted in several case reports after treating animals with cowpox, including one alarming self-report and warning for practicing veterinarians (Hall and Stevens 1987; Vestey et al. 1991; Glatz et al. 2010; Lawn 2010).

Animal infections with VACV have led to human cases among handlers and milkers (Bhanuprakash et al. 2010; Gurav et al. 2011; Venkatesan 2010; Trindade et al. 2006). Lesions often appear on the arms and hands of handlers who reported

touching the infectious lesions of ill bovids, which are often on the teats and in or around the mouth. Although human-to-human transmission is rarely noted for VACV, it can occur among close contacts (Oliveira et al. 2017). VACV has been isolated in dairy products, suggesting the potential for foodborne transmission, although epidemiologic evidence is lacking (de Oliveira et al. 2015, 2018). There has been a suggestion of milk-associated transmission to humans with no animal contact after drinking of unpasteurized buffalo milk (Gurav et al. 2011); this observation warrants additional attention and careful investigation for future cases.

Akhmeta virus isolates have been recovered from wild caught rodents of the genus *Apodemus*, which likely serve as the animal reservoir and maintains its circulation in nature (Doty et al. 2019). Zoonotic transmission of this virus probably follows a similar dynamic as VACV, requiring contact with infected bovines, but the evidence is extremely limited given that only three human cases have ever been reported (Vora et al. 2015). Risk factors for zoonotic transmission of *Alaskapox virus* are less clear. Only four unrelated laboratory-confirmed cases have been reported in humans. All the cases live within the same area of Alaska, all reported outdoor activities, and several reported contact with asymptomatic cats and residing in residences with wild rodents (Springer et al. 2017) (CDC unpublished data). The discovery of *Alaskapox virus* in rodents (*Myodes rutilus*) trapped in proximity to one of the cases suggests potential cat-borne exposures or contact with an environmental surface that has been contaminated by infected small mammals (CDC unpublished reports).

MPXV transmission via fomites, direct contact, and respiratory droplet (without direct contact) was demonstrated in the prairie dog model, and aerosol transmission was documented in cynomolgus macaques (Hutson et al. 2011). Although similar risk factors likely apply in the natural setting, there is no conclusive evidence for how zoonotic MPXV infections occur. Risk factors for acquisition of the virus in central Africa include school aged males, those who hunt, and those who have frequent contact with uncooked wild animal meat (Nolen et al. 2015). However, without knowledge of the specific wild animal species that are involved in maintaining the virus, definitive risk factors for zoonotic infection remain an open question in the field. There may indeed be a much wider role for wild animal products beyond wild animal meat, such as peri-domestic small mammal contamination of residences, or specific cultural behaviors that place individuals at greater risk of exposure and subsequent infections in endemic areas (Bonwitt et al. 2017; Friant et al. 2022). These factors may also explain the epidemiology of outbreaks in Nigeria, where virus sequencing data suggest multiple zoonotic introductions; probably as a result of an undetected epizootic, but where cases occurred in urban settings without reports of animal exposures (Yinka-Ogunleye et al. 2018).

CMLV is host-restricted, and its zoonotic potential is disputed. In a comprehensive study involving 465 herdsmen handling CMLV-infected dromedaries, not a single human skin lesion sample of 335 tested positive for the virus (Jezek et al. 1983). Epidemiologic, clinical, and non-specific laboratory findings supported zoonotic transmission, but not definitive confirmation of viral infection in three camel herders handling infected animals (Bera et al. 2011). Given the high incidence in camel herds and rarity (or absence) of human cases, CMLV is not known to present a major public health concern.

24.2 Clinical Features

In general, OPXV infection results in a febrile prodrome followed by the appearance of a typical pox exanthem on the skin and mucosa. The characteristic lesions of OPXV infections have similar appearance across species; photographs of the lesions are important tools for clinical consultation (Fig. 1). The exanthem progresses through macules (flat discoloration), papules (slightly raised, firm swelling), vesicles (fluid-filled sac), pustules (pus-filled blisters often with central umbilication), before crusting, desquamation, and healed, healthy skin. Extensive lesions present in the oral cavity and throat may cause pain and impact food and water intake (Reynolds et al. 2017). Lesions on the teats of bovids may impact milking or feeding; secondary infection and mastitis are concerns (Gurav et al. 2011). Viral multiplication occurs in the draining lymph nodes, and the lymph nodes are often enlarged early in the course of illness in humans and non-human primates. In severe cases, viraemia leads to dissemination to internal organs (including heart, lungs, gastrointestinal tract, liver, lymph nodes, placental and fetal tissues) causing systemic signs (Reynolds et al. 2017). In humans, with the exception of MPXV and *Variola virus*, OPXV infections cause localized lesions; however, individuals with immunosuppressive or dermatologic conditions (e.g., atopic dermatitis, eczema) are at risk for a disseminated rash and severe illness (Laiton-Donato et al. 2020; Lawn 2010).

The severity of disease depends on the viral species and strain, the susceptibility of the host species, and host immune status. Complications of the skin may include secondary infection of the skin and cutaneous necrosis; fluid loss may be a concern due to extensive skin perturbation. Ocular infections can lead to permanent corneal scarring and vision impairment. Fetuses of pregnant females are at risk of infection and death in humans (Reynolds et al. 2017; Mbala et al. 2017; Ferrier et al. 2021; Franke et al. 2016).

Clinicians should also consider parapoxviruses, cutaneous anthrax, varicella, herpes simplex, treponema, and rickettsial pox as differential diagnoses that may have presentation characteristics similar to OPXVs. Laboratory confirmation may be pursued to determine the cause of infection and pathological analyses can be performed from necropsy or biopsy specimens.

24.2.1 CPXV

CPXV exhibits fetal tissue tropism and can cause abortion, even in asymptomatic dams; this has also occurred in an elephant and two foals (*Elephas maximus*) (Franke et al. 2016; Ellenberger et al. 2005; Wisser et al. 2001). Infected domestic cats present with pyrexia, inappetence, depression, and mild respiratory infection in 20% of cases. Skin lesions typically begin at the bite site and 20% of cases have oral lesions. Infection is usually self-limiting and healing is complete within 6 weeks. Severe cases have been associated with immunosuppression, and these animals have presented with secondary bacterial infection, cellulitis, and necrotizing pneumonia, which is nearly always fatal (Bennett et al. 1990; Hoare et al. 1984; McInerney et al. 2016). Horses appear relatively refractory to infection; of 3 reported cases, two

Fig. 1 Vaccinia virus lesions on the teats (**a**) and muzzle of a cow (**b**) (Leite et al. 2005); Cowpox virus lesions on a pet rat (**c**) and neck (**d**) of a human (Campe et al. 2009); Cowpox virus lesions with ocular manifestations (**e**) (Wolfs et al. 2002); and disseminated lesions from a Cowpox virus infection in a pediatric patient with a history of atopic dermatitis (**f**) (Pelkonen et al. 2003)

involved aborted or neonatal foals without involvement of the dams (Franke et al. 2016; Ellenberger et al. 2005). Contemporary case reports do not include cattle or other bovids.

Alpacas and llamas are susceptible to infection with CPXV; signs include alopecia, local or generalized exanthem, and keratoconjunctivitis (Prkno et al. 2017; Cardeti et al. 2011). In susceptible wildlife species, ulcerated lesions are common and lesions in the oropharynx can manifest as anorexia, hypersalivation, and dysphagia. Wild felids and elephants are especially susceptible to infection and a number of deaths have been reported. In felids, disease severity ranges from ulcerated skin lesions to necrotizing pneumonia (Marennikova et al. 1977). Infection is particularly lethal in cheetahs (*Acinonyx jubatus*) (Baxby et al. 1982; Stagegaard et al. 2017). Zoo outbreaks in elephants used to be frequent in European zoos but have been largely brought under control thanks to routine vaccination with VACV (i.e., smallpox vaccine) (Kurth and Nitsche 2011).

In humans, CPXV is usually self-limiting and individuals have limited lesions notably at the site of existing disruptions to the dermal barrier, or at the location of animal bites or scratches. For patients who own pet rats, lesions have been noted to occur on the neck or face (Campe et al. 2009). Severe infections, including deaths, have been noted in individuals with underlying atopic dermatitis, immunosuppression, and pregnancy (Lawn 2010; Ferrier et al. 2021; Pelkonen et al. 2003); and complicated ocular infections have occurred (Schwarzer et al. 2013; Kiernan and Koutroumanos 2021).

24.2.2 VACV, Alaskapox Virus, Akhmeta Virus

VACV can infect a wide range of hosts but mostly causes disease in bovines. With high attack rates (as high as 80–100%) and significant morbidity, outbreaks in dairy herds can cause significant economic loss (Oliveira et al. 2017). After a 3–7 day incubation period, VACV causes vesiculation followed by an ulcerative exanthem that mostly affects teats and udders, but that can also progress to skin and mucous membranes (Leite et al. 2005). In water buffalos (*Bubalus bubalis*), clinical signs include a typical pox exanthema that appear on the face, proximal and distal limbs, udder, teats, and scrotum (Bhanuprakash et al. 2010; Gurav et al. 2011). Suckling calves of infected cows can present with oronasal lesions (Leite et al. 2005). Production losses occur due to secondary mastitis, reluctance to being milked, and cows avoiding suckling calves. In buffalo herds, infection can result in a 42–70% reduction in milk yield (Eltom et al. 2020). Systemic disease may result in a relatively high mortality (up to 11%) in buffalos (Gurav et al. 2011).

A VACV outbreak has been recorded in Brazilian horses, involving 14 horses and foals causing extensive coalescing pox lesions on the muzzle, external nares, and external and internal lips, but without systemic signs (Brum et al. 2010; Campos et al. 2011). VACV has also been isolated from non-human primates, cats, dogs, equids, marsupials, lagomorphs, rodents, and bats in South America (Oliveira et al.

2017; Costa et al. 2017, 2018). Unlike CPXV, however; infection in wildlife or other domestic animals were not accompanied by clinical signs.

Although *Akhmeta virus* has never been isolated from domestic animals, infection in cattle probably follows a similar course to CPXV or VACV. In the Democratic Republic of Georgia, 10 of 71 dairy cows with epidemiologic links to laboratory-confirmed human cases of *Akhmeta virus* presented with characteristic pox lesions on their udder and teats. All cows fully recovered except one, in which teat contracture resulted in reduced milk production (Vora et al. 2015).

In humans, zoonotic VACV infection often manifests as a self-limiting infection with few lesions, often appearing at the site of exposure (via milking or other handling), the hands, or the face (Gurav et al. 2011; Megid et al. 2012). A recent report documenting a severe form of VACV infection, progressive vaccinia, in a dairy cattle handler from Colombia highlights the severity of such an infection in an individual with underlying immunosuppression caused by HIV and subsequent AIDS (Laiton-Donato et al. 2020). Further, VACV is easily transferred from a contaminated surface or infected individual (via contaminated hands or contact with lesions) to another person and autoinoculation can occur to other sites of a patient's body. Nosocomial transmission of VACV has occurred in Pakistan (Zafar et al. 2007) and there is a body of literature documenting the risks of inoculation from VACV lesions via smallpox vaccination.

24.2.3 MPXV

Monkeypox (MPX) disease presentation is very similar in humans and non-human primates (Arita and Henderson 1968). After a prodromal period of fever, fatigue, respiratory symptoms, and often lymphadenopathy (cervical, maxillary, and/or inguinal), the characteristic rash is apparent, often first appearing in the mouth or face followed by dissemination to other parts of the body. A MPX rash is distinct in that it is generalized and often includes lesions in the palms of the hands and soles of the feet. This rash will slowly progress through different stages until desquamation and final healing of the skin. Severe disease can occur as indicated above, and death occurs in approximately 11% of humans without prior smallpox vaccination (Jezek et al. 1987). Respiratory complications can include bronchopneumonia and airway obstruction due to significant lymphadenopathy; the latter has contributed to deaths in chimpanzees infected with MPXV (personal communication) (Reynolds et al. 2017). Exposure via an animal bite or scratch versus a less invasive exposure has been associated with more severe forms of disease (Reynolds et al. 2006).

In-vivo bioluminescent imaging of infected prairie dogs has shown widespread dissemination in internal organs (lymph nodes, intestines, heart, lungs, kidneys, and liver) prior to the disseminated rash (Weiner et al. 2019). Separate studies have isolated MPXV from most internal organs of infected animals (Hutson et al. 2009; Marennikova et al. 1972; Guarner et al. 2004; Langohr et al. 2004). Higher doses cause a more severe presentation with widespread rash lesions, generalized hemorrhagic manifestations, and faster symptom onset in laboratory infected marmosets

(*Callithrix jacchus*) and prairie dogs (*Cynomys ludovicianus*) (Falendysz et al. 2014; Mucker et al. 2015). Susceptibility to MPXV varies across species, as evidenced during a multi-species outbreak in a zoo where clinical signs occurred along a spectrum of severity ranging from pox exanthems to anorexia, lymphadenopathy, dyspnea, nasal discharge, depression, secondary infections, and death (Peters 1966).

24.2.4 CMLV

In contrast to other zoonotic OPXVs, CMLV is thought to have a narrow host range, only affecting bactrian (*Camelus bactrianus*) and dromedary (*C. dromedarius*) camels. It is highly contagious and causes significant production losses (Duraffour et al. 2011). After a 9–13 day incubation period, camels may present with pox lesions on the rostrum, eyelids, margins of the ears, and oronasal mucosa. In severe cases, lesions may cover the entire body. Systemic signs include fever, anorexia, lymphadenopathy, and mucopurulent discharge (WOAH, 2019). Abortion rates can be as high as 87% (Al-Zi'abi et al. 2007). Mortality can exceed 30% in adults and up to 100% in calves (Jezek et al. 1983; Krizn 1982).

24.3 Laboratory Diagnosis

OPXV infections can be difficult to diagnose clinically; thus, laboratory diagnostic evaluation is essential for confirming infection in humans and animals, which can be achieved using a variety of techniques (Table 1). Different methods have a range of veterinary and public health utilities and require different sample types; however, OPXV diagnostic assays are largely the same for animals and humans. Understanding disease progression and transmission is key to identifying the appropriate diagnostic sample type and timing of sample collection in relation to disease onset or exposure; however, for some enigmatic viruses, little is known about disease progression and transmission routes. Lesion material is consistently the best diagnostic sample type and the primary clinical feature used to identify OPXV infections. The presence of characteristic pox-like lesions on the surface of the skin, in the oral cavity, or on the surface of organs often suggests possible infection with an OPXV. Samples from these lesions provide a relatively simple and less invasive sample to collect for acute (active) infections in living patients.

The most reliable way to diagnose and differentiate among OPXV species is the detection of viral nucleic acids, for which polymerase chain reaction (PCR)-based tests are the gold standard. PCR assays target a specific piece of viral DNA to amplify for detection and/or sequencing, and can use a conventional approach where a PCR product is visualized on an electrophesis gel, or they can utilize a real-time approach that is capable of quantifying viral DNA in a sample (Li et al. 2006, 2007b, 2010). Most PCR assays that are used to differentiate OPXV species and strains are real-time assays which target variable regions of the genome where only nucleic acids from one species of virus will be amplified. Skin lesions are the optimal specimen type for PCR

Table 1 List of diagnostic assays, preferred sample types, and utility

Assay	Target	Specimen type	Species specific	Utility
PCR	Nucleic acid	Lesion material	Yes	Gold standard for diagnostics, including conventional or real-time PCR and may include species-specific assays
Viral DNA sequencing	Nucleic acid	Lesion material	Yes	Can be used for diagnostics when no species-specific PCR assay exists, but generally utilized to examine evolution of viruses or other genetic features
Serology (ELISA, PRNT, Western blot)	Antibodies (IgG or IgM) and proteins	Serum or plasma	No	Retrospective case identification or serosurveys, can complement PCR
Immuno-histochemistry	Antigen	Lesion material; tissue biopsy	No	May be used to identify or rule out a biological agent in differential diagnosis
Viral culture	Viable infectious viral particles	Lesion material	No	May be used to generate sufficient material for whole genome sequencing, requires strict biosafety measures
Electron microscopy	Viral particles	Lesion material	No	Can identify poxvirus particles when poxvirus is not a primary differential during diagnosis of unknown pathogens

as they contain viral particles and nucleic acids. Blood is not an optimal specimen type, as the period of viremia in the blood is often short relative to the entire course of clinical presentation (Hutson et al. 2009; Nitsche et al. 2007).

Viral sequencing is a tool that has been increasingly used in recent years and can be used to determine the strain and species of a virus in a particular sample. Additionally, analysis of these sequences allows investigators to determine the relationships among viral strains and species, assess geographic variations, examine evolutionary diversification, and may provide insights into the epidemiology of the virus or the clinical presentation (Gigante et al. 2019; Likos et al. 2005; Gruber et al. 2018).

Serological assays are used for antibody detection in serum and plasma samples. Common assays include enzyme-linked immunosorbent assay (ELISA), plaque-reduction neutralization test (PRNT), Western blot, and hemagglutination-inhibition. ELISA is the most commonly used serologic assay and can detect either IgM or IgG antibodies. Serology is not recommended as a primary diagnostic tool because it lacks the ability to distinguish infections caused by different OPXV species; rather, they allow investigators to evaluate antibody response to OPXVs on the whole. In humans, this will include individuals who received prior smallpox vaccination with VACV. The utility and interpretation of antibody detection will depend on the intended use of the assay. Serological assays can be used as a tool to identify

retrospective cases, assess immune responses to smallpox vaccination, and are useful for a variety of research purposes (Doshi et al. 2019; Doty et al. 2017; Guagliardo et al. 2020; Townsend et al. 2013).

Antibody responses may vary from one individual to the next and may vary significantly based on the viral species of exposure (Gilchuk et al. 2016). Generally, IgM antibodies are present a few days after exposure and may be detectable for approximately 2 months. Conversely, IgG antibody production will rise following the acute phase of illness, suggesting it may not be detectable until a few weeks after exposure, but may remain at detectable levels for years. Given this information, the presence of IgM antibodies indicates a recent OPXV infection or exposure, whereas IgG antibodies indicate an exposure months to years before the serum samples were collected.

Immunohistochemistry (IHC) is conducted on lesion material from affected skin, including crusts and lesion biopsies. Staining is used to detect antigen within cells using an OPXV antibody that is cross-reactive with many (if not all) viruses in the genus. While this can be a powerful tool for pathological samples, the method is labor and reagent intensive, and requires specialized equipment (Sejvar et al. 2004).

Diagnostic electron microscopy was widely used for smallpox diagnosis until its eradication, with decreased use in favor of molecular diagnostic techniques (i.e., PCR); however, it still remains an important tool for the identification of novel OPXVs that may be divergent enough from known ones not detected by other diagnostic assays (Gelderblom and Madeley 2018).

While the majority of diagnostic assays require laboratories with specialized equipment and experienced laboratorians, novel point-of-care assays are currently being developed and tested for field deployment. While these assays are generally being developed for human diagnostics, they could potentially be used for animals in certain situations where OPXV diagnosis may be important for public health or veterinary outbreak response situations such as monkeypox infections in primate sanctuaries in monkeypox endemic regions).

24.4 Animal and Public Health Control Measures

Interventions against animal and human OPXV infections hinge on preventing epizootics in domestic and captive wild animals, reducing the risk of zoonotic exposures, and preventing human-to-human transmission. Given the broad host range of OPXVs, interrupting disease transmission between members of a same species, as well as across species (i.e., spillover transmission), is the cornerstone of a cohesive strategy to prevent infection in animals and humans alike. The survival of OPXV on surfaces and prolonged survival of virus in lesion material for years (McCollum et al. 2014) means that environmental disinfection is paramount.

In animals, prevention and control can only be achieved in domestic animals and captive wildlife. Infection control in free-ranging wildlife (reservoirs or spillover hosts) is currently impossible due to the absence of a licensed vaccine, logistical challenges of vaccine delivery, and broad host range. In domestic pets, infection

prevention can be achieved by reducing contact with susceptible hosts where the reservoir hosts are known; for example, by keeping cats indoors in areas endemic for CPXV. In herds, zoos, and wildlife sanctuaries, standard biosecurity precautions may be instituted to prevent pathogen introduction, including quarantine of new arrivals (21 days), and routine rodent control measures. Rodents fed to captive mammals should be bred in a closed system and feeding using wild rodents should be avoided. Off-label smallpox vaccination has been used for susceptible wildlife species kept in captivity, especially in outbreak situations (Kurth et al. 2009) or where prior cases have occurred indicating endemic circulation in wild rodents. Modified VACV Ankara (MVA) vaccine has been used in European zoos for captive elephants, rhinoceroses, and felids at risk of infection (Stagegaard et al. 2017; Wolters and van Bolhuis 2008). Researchers have demonstrated that MVA can provide protection against MPXV infection in non-human primates (Stittelaar et al. 2005), although its use and effectiveness at preventing outbreaks in captive non-human primates has not been assessed.

Symptomatic animals may be immediately isolated to prevent animal-to-animal and zoonotic transmission. Biosecurity measures for isolation pens may address the potential of fomite transmission via animal bedding, shared equipment (e.g., food troughs, milking machines), and animal handlers, as well as the potential for droplet transmission to susceptible species. OPXVs can be shed via infectious lesions and bodily fluids, including urine, feces, and milk, thus infected animals should be isolated from susceptible animals. Special attention should be paid to routine disinfection of the environment where the ill animals reside and rodent control to prevent further spread to wild rodents (Guedes et al. 2013; Rehfeld et al. 2017). Preventing infection in susceptible animals that have frequent and close contact with humans (e.g., cats) also serves to reduce zoonotic transmission and is especially important for individuals at higher risk of disease. Rodent control in houses (rodent proofing, removing rodent harborage and attractants) may be implemented to reduce animal-human contact and environmental contamination.

People at risk of severe disease from OPXV infection (including individuals with a history of atopic dermatitis or eczema, pregnant women, individuals with an immunosuppressive condition or taking medications that may cause immunosuppression) should not handle infected animals. Personal protective equipment is effective at preventing transmission: gloves, gown, rubber boots, eye and mouth protection (mask or face shield). MPXV infections may produce infectious respiratory droplets and additional PPE should also include a N95 or filtering respirator (CDC 2021a). Preventing zoonotic transmission of MPXV is challenging, as the reservoir species are unknown and the endemic range overlaps with areas of food insecurity where people principally rely on wild animals as a source of protein. In this setting, avoiding hunting rodents and animals found sick or dead is a measure to reduce the risk of zoonotic transmission. There are, however, a number of cases in urban environments of Nigeria with no known wild animal exposure (Yinka-Ogunleye et al. 2018), further complicating our understanding of MPXV control.

Control of human-to-human OPXV transmission relies on hygiene practices to avoid transmission from skin lesions, contaminated items, and surfaces, and for MPXV, respiratory droplets. Healthcare providers and family members should adopt

standard contact precautions with personal protective equipment with the addition of a N95 or filtering respirator for MPXV. MPXV patients should be isolated in a healthcare or home-based care environment (CDC 2021a). For patients with localized lesions (and not a disseminated rash), lesions may be covered with a non-adhesive dressing to prevent spread to close contacts. Coverage of an infectious lesion also reduces the risk of self-inoculation which can lead to significant complications such as an ocular infection. Clothing, linen, and towels carry a risk of fomite transmission and should be treated as biohazard; they should either be destroyed or washed using standard laundry detergents at the highest temperature setting. Surfaces and shared household items can be disinfected using household chlorine bleach or quaternary ammonium products (CDC 2021a).

Except for MPXV, human-to-human transmission of zoonotic OPXVs is rare but cannot be discounted, especially among immunosuppressed individuals, in healthcare settings, or among close contacts. For all OPXV infections, infection prevention measures should be maintained until all crusts separate and a fresh layer of skin forms at former lesion sites, at which time they are no longer infectious. Given the broad range of susceptible animals and potential introduction of OPXVs in new geographic areas, humans should avoid direct contact with mammals (e.g., pets and wild rodents) during their period of infectiveness until all lesions have resolved and a fresh layer of skin has formed, to prevent further spread and reverse zoonosis (CDC 2021a).

Smallpox vaccination has been shown to be effective against MPXV infection (Jezek et al. 1988) and is recommended in the United States for prevention of OPXV infections in specific occupational groups (Petersen et al. 2016). Traditional smallpox vaccines use attenuated VACV to deliver a controlled dose to stimulate an immune response via vaccination. More recently, a third-generation vaccine utilizing MVA (which does not replicate efficiently in human cells) has been approved in the United States and European Union for the prevention of monkeypox in adults at high risk of infection. Further studies are needed to evaluate its effectiveness in outbreak response and duration of immunity. Studies of its pre-exposure use are underway in areas endemic for MPXV in humans (Petersen et al. 2018).

Finally, disease reporting to animal and public health authorities is critical for localized and international control efforts. Many countries may deem OPXV infections in humans reportable under the International Health Regulations (IHR); animal infections may be reported to the World Organization for Animal Health. The presence of transboundary events and viral spread to non-endemic areas may lead to a Public Health Emergency of International Concern under the IHR. These events can be serious and have led to traveler's health notices (CDC 2021b) and the ban of African rodent importation to the United States (Bernard and Anderson 2006; CDC 2015).

24.5 Future Perspectives & Conclusions

Following decades of research, our understanding of OPXVs is extensive, but many features of their ecology, epidemiology, and natural history continue to elude us. Enhanced human and animal surveillance, including confirmation by laboratory

diagnostics, will be critical to detect emerging zoonotic OPXVs, especially in the face of a global waning smallpox immunity, increased susceptibility to infection as result of immunosuppressive conditions (e.g., HIV/AIDS pandemic, immunosuppressive therapies, etc.), and increasing movement of humans and animals. Equally, animal surveillance will be key to monitor OPXV infections that threaten animal production and welfare in the context of livestock practices. OPXV surveillance is challenging, as many occur in areas with poor laboratory capacity or are considered relatively benign and are therefore not reportable. Similarly, detailed epidemiological investigations, including relevant zoonotic parameters, need to be pursued to elucidate the role of atypical transmission (e.g., via zootherapy and dairy products) and that of unrecognized domestic or peri-domestic reservoir hosts (e.g., dogs, cats, and coatis) (Costa et al. 2018). By harnessing the high degree of cross-reactivity and long duration of immunity, vaccine research is critical to protect persons at risk, reduce animal production losses, and hedge against disease emergence and bioterrorism. It is no exaggeration to say that poxviruses have shaped and are being shaped by human behaviors and practices. In all certainty, they will continue their evolutionary trajectory with humans and animals, and will continue to surprise us for years to come, for better or for worse.

Abstract

Rabies is the oldest diseases known to mankind. Occurring on all continents, except Antarctica, rabies remains one of the neglected tropical diseases (NTD) that predominantly affects the poor of the poor particularly in Asia and Africa still causing tens of thousands of lives lost every year. This chapter 'Elimination of Rabies—A Missed Opportunity' provides an up-to-date review of information known about the etiology and epidemiology of the disease, the rabies situation worldwide, human rabies prevention, prophylaxis and experimental therapy, rabies control in wildlife and dogs as well as road blocks on the way to global elimination of dog mediated rabies from a "One Health" perspective.

Keywords

Control · Dogs · Epidemiology · Humans · Prevention · Prophylaxis · One health · Rabies · Wildlife

25.1 Rabies – Fascinating Backgrounds of a Deadly Disease[1]

Ancient world writings from as early as Mesopotamian and Greek times suggest that rabies (lyssa, hydrophobia) is the oldest recognized zoonosis, perhaps as old as mankind. The first written record of rabies is in the Mesopotamian Codex of Eshnunna of Babylon (circa 1930 BC) and mentioned preventive measures to be taken by owners of dogs supposed of having contracted rabies and further detailed heavy sentences for dog owners in case another person being bitten by their rabid dog later died (Dunlop and Williams 1996). Rabies is defined as an acute, progressive, incurable viral encephalitis that is transmitted following bites of infected mammals. While the name rabies is derived from the Latin name for "madness," the old Greeks derived the word lyssa from lud or "violent"; this root is used in the name of the genus lyssavirus (Rupprecht et al. 2020a).

For millennia, the disease has been considered a scourge for its prevalence as well as a dual public horror and biomedical travesty (Rupprecht et al. 2008). There is probably no other zoonosis known today, which has been eliciting such anxiety to people, has been so intensively studied, and about which so many common and scientific reports have been published. It is a tragedy that despite the pioneering work of Louis Pasteur, more than 150 years ago, who with his first vaccination trials in man paved the way for today's efficient pre- and post-exposure rabies prophylaxis in humans and preventive vaccination in animals, rabies still is an imminent danger for humans and animals alike.

25.1.1 Virological Background and Diversity of Lyssaviruses

For a long time, rabies was believed to be caused by a single virus and it was not until the first discovery of bat-associated lyssaviruses in the second half of the last century that this perception changed. Today it is commonly accepted that rabies as a disease is caused by a plethora of different negative-strand RNA viruses of the Lyssavirus genus, family Rhabdoviridae of the Mononegavirales order (Fooks et al. 2017; Fisher et al. 2018).

Currently, the genus has been subdivided into 17 recognized and 2 putative virus species (Walker et al. 2020; Amarasinghe et al. 2018). Intriguingly, *Chiroptera* appear to be the reservoir for almost all lyssaviruses thus putting rabies in the list of the most significant viral zoonosis associated with bats (Luis et al. 2013). While all lyssaviruses share certain morphological and structural characteristics, on the basis of their genetic and antigenic relatedness as well as their biological properties, e.g., pathogenicity, induction of apoptosis, cell receptor recognition, and immunogenicity, lyssaviruses can be further segregated into at least three phylogroups (Badrane et al. 2001). The great majority of lyssaviruses are considered members of phylogroup I, including the prototypic rabies virus (RABV), European bat

[1] Authors: Thomas Müller and Conrad M. Freuling

lyssavirus-1 (EBLV-1), EBLV-2, Australian bat lyssavirus (ABLV), Aravan virus (ARAV), Khujand virus (KHUV), Irkut virus (IRKV), Bokeloh bat lyssavirus (BBLV), Duvenhage virus (DUVV), Gannuruwa bat lyssavirus (GBLV), and Taiwan bat lyssavirus (TWBLV). The African lyssaviruses Lagos bat virus (LBV), Mokola virus (MOKV), and Shimoni bat lyssavirus (SHIBV) were assigned to phylogroup II, while the genetically more diverse lyssaviruses including West Caucasian bat virus (WCBV), Ikoma virus (IKOV) and Lleida bat lyssavirus (LLEBV) are likely representatives of other phylogroups (Walker et al. 2020; Kuhn et al. 2020). Recent discoveries of one further novel lyssavirus, Kotalahti bat lyssavirus (KBLV) and two sequences from a potentially novel lyssavirus named Matlo bat lyssavirus (MBLV) in European and African bats, respectively (Fooks et al. 2021), clearly indicate that there is reason to believe that with reinforced and enhanced surveillance, particularly in bats, the diversity of lyssaviruses will further evolve. Interestingly, the recent detection of lyssavirus-like sequences in frogs and anoles challenges the host restriction to mammals (Horie et al. 2020). Further research is needed to corroborate such findings and assess their relevance for, e.g. virus origin.

Although lyssaviruses are capable of infecting all mammals, onward transmission in a new host population requires adaptation of the virus, in a number of stages with both host and virus factors determining the outcome. Within each lyssavirus species, genetic diversity may vary more or less within sublineages corresponding to distinct variants circulating in specific geographical regions and/or particular reservoir hosts in complex ecological communities. It is assumed that limited diversity of a specific variant corresponds to a dynamic equilibrium (or genetic stasis) resulting from a relatively conserved and long-term virus-host coevolution and coadaptation (Mollentze et al. 2014). Such stability is observed frequently among bat lyssavirus variants. While in general, the immune status of the host, the nature of exposure and strain differences influence infection and transmission dynamics (Fisher et al. 2018), modeling studies suggest that increased virulence in a novel host might act as a limiting factor preventing onward transmission (Mollentze et al. 2020). Interestingly, RABV has successfully crossed species barriers and established infectious cycles in new hosts to become the global multi-host pathogen it is today, while other lyssaviruses appear very restricted in hosts, suggesting that RABV is the exception but not the rule among lyssaviruses (Marston et al. 2018).

25.1.2 Reservoir Hosts of Classical Rabies

While all mammals are susceptible for the prototypic RABV, yet its lyssavirus reservoir in its entire complexity is cryptic (Fisher et al. 2018). Intriguingly, RABV is the only lyssavirus known to have primary reservoirs in species of the orders *Chiroptera* (bats) and *Carnivora*, where lineages of RABV circulate independently. Particularly canine species (family Canidae) are reservoir hosts of RABV in most parts of the world (Müller and Freuling 2020a). Next to wild carnivores, rabies virus maintained and transmitted by domestic dogs (*Canis familiaris*) by far poses the most serious threat to public health. Dog-mediated rabies is responsible for

more than 95% of the tens of thousands of human rabies casualties reported every year and results in millions of exposure contacts that require costly medical intervention. Mainly developing countries from Asia and Africa suffer from the burden of dog-mediated rabies (Hampson et al. 2015).

25.1.3 Americas

The Americas are the only continents where just one single lyssavirus species is present – the classical rabies virus (RABV); the reason for this paradox remains elusive. In North America, terrestrial rabies is a multispecies reservoir problem. Here, independent infectious cycles exist in raccoons (*Procyon lotor*), skunks (*Memphitis ssp*), red foxes (*Vulpes vulpes*), gray foxes (*Urocyon cinereoargenteus*), coyotes (*Canis latrans*), and arctic foxes (*Alopex lagopus*) (Ma et al. 2021) with the latter contributing to the circumpolar transmission of arctic variants of RABV (Mork and Prestrud 2004; Hanke et al. 2016; Mansfield et al. 2006b).

Historically, it has not been fully elucidated up to now whether rabies was present in the New World prior to the arrival of the first European settlers in the mid of the previous millennium (Vos et al. 2011; Rupprecht et al. 2017). It is certain, however, that canine RABV was introduced to the Americas during European colonization causing many human casualties. The same applies to the small Indian mongoose (*Herpestes auropunctatus*), a small terrestrial carnivorous mammal introduced during the latter part of the nineteenth century, which is now implicated as the principal wildlife reservoir for rabies on many Caribbean islands (Seetahal et al. 2013, 2018; Zieger et al. 2014). While enzootic rabies elimination from dogs has been almost achieved in many countries in the Americas (Vigilato et al. 2013a; Velasco-Villa et al. 2017a), the disease seemed to have reemerged in wild terrestrial carnivores (Velasco-Villa et al. 2008). In South America, other species including the Crab-eating fox (*Cerdocyon thous*), the Hoary fox (*Lycalopex vetulus*) (Antunes et al. 2018; Bernardi et al. 2005; Silva et al. 2009), and the Peruvian fox (*Lycalopex sechurae*) have been identified as wildlife reservoirs maintaining species adapted RABV variants (Velasco-Villa et al. 2017a). Interestingly, recent detections of a new RABV variant in marmosets (*Callithrix jacchus*) suggest the first independent infectious cycle in monkeys (Favoretto et al. 2001).

The Americas are also unique for their chiropteran rabies reservoirs as almost any indigenous species of bats on both continents ranging from insectivorous, frugivorous, nectarivorous to hematophagous bats has been identified to harbor distinct well-adapted RABV variants (Banyard et al. 2020b). While RABV in insectivorous bats only causes sporadic spillovers, vampire bat (*Desmodus rotundus*) transmitted rabies poses a serious threat to public and animal health in Central and South America (Johnson et al. 2014). It has been hypothesized that an ancient chiropteran origin of RABV might be the most likely explanation for the existence of the independently evolved "indigenous American" virus lineages as well as for the absence of RABVs in related bat species in the Old World (Rupprecht et al. 2017). Indeed, phylogenetic analysis suggests that RABV first evolved as a bat virus and subsequently crossed the

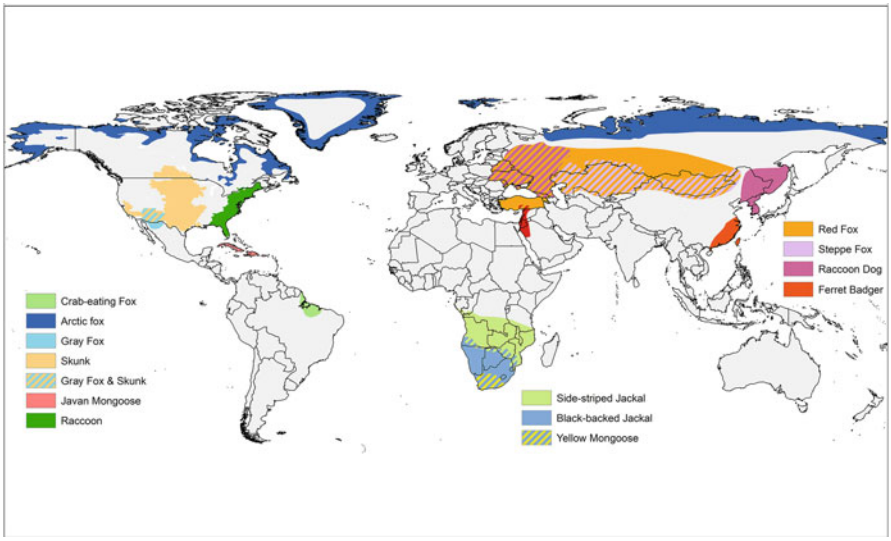

Fig. 1 Distribution of terrestrial wildlife rabies caused by RABV in different reservoir. The individual ranges are based on data provided by the IUCN

species barrier from Chiroptera to the Carnivora order (Badrane and Tordo 2001). In fact, both the raccoon as well as the skunk variant of RABV in Southern USA have been shown to descent from an ancestral bat origin (Velasco-Villa et al. 2017b). Even today, cross-species transmission events are documented regularly. While most of these spill-over events lead to dead-end infections, molecular inferences suggest multiple sustained spillovers of RABV from bats to mesocarnivores in North America as documented for foxes (Daoust et al. 1996); skunks (Leslie et al. 2006), and gray foxes (Kuzmin et al. 2012), hence, confirming the possibility of such historical events (Marston et al. 2017, 2018) (Fig. 1).

25.1.4 Africa

Next to the diversity of lyssaviruses found in Mega- and Microchiroptera, the current epidemic of classical rabies probably is a result of a more recent event because both historical records and phylogenetic analysis prove that the cosmopolitan lineage of canine RABV was introduced during European colonization (Rupprecht et al. 2020a). Apart from independent introductions in space and time, translocation, emergence among feral dogs, and adaptation to wildlife species are considered important dissemination mechanisms of canine rabies that are supposed to have peaked early in the twentieth century (Rupprecht et al. 2008). Classical rabies cycles are sustained by many carnivorous hosts of the family Canidae. Alongside the domestic dog, which is the major host reservoir of classical RABV in Africa, evidence is mounting that other wildlife canids such as jackals (*Canis adustus* and

C. mesomelas) and bat-eared foxes (*Otocyon megalotis*) are reservoirs for RABV in Southern Africa too (Bingham et al. 1999; Sabeta et al. 2003). While usually RABV variants are independently maintained in these species, in some areas common dog-jackal transmission cycles have been reported resulting in a rather complex epidemiological situation (Bellan et al. 2012). There has been no sustained progress yet in eliminating dog-mediated rabies on the continent (Haselbeck et al. 2021).

Also, members of the family Herpestidae appear to be responsible for the transmission cycle of a distinctive variant of RABV (Nel et al. 2005) as suggested for the Yellow mongoose (*Cynictis penicillata*) and the Slender mongoose (*Galerella sanguinea*) (King et al. 1993; Foggin 1988). Uniquely, for a long period of time independent horizontal transmission of the cosmopolitan RABV lineage among kudu antelopes (*Tragelaphus strepsiceros*) has been suspected, a phenomenon exclusively found in Namibia (Scott et al. 2012). However, phylogenetic and experimental research suggest that jackal and kudu may form part of the same epidemiological cycle of rabies in Namibian wildlife (Mansfield et al. 2006a) and that rabies epidemics in this herbivorous species is rather a combination of spill-over events and perhaps locally restricted horizontal transmission (Hassel et al. 2018).

25.1.5 Europe

The earliest references to rabies coming from ancient sources clearly indicate that terrestrial rabies has been endemic in Europe for centuries (Neville 2004). Until the nineteenth century, historical records mainly refer to dog-mediated rabies, while anecdotal reports also mention outbreaks of rabies in wolves and foxes (Blancou 2004; Rupprecht et al. 2020a). So, there is reason to believe that variants of RABV proceeded to involve not only dogs, but also other wild canids over vast areas. While dog-mediated rabies has been successfully controlled in Europe (Müller and Freuling 2018; Rupprecht et al. 2020a), Turkey remains the only country, where dog-mediated rabies persists (Johnson et al. 2010).

In the mid-twentieth century, wildlife rabies emerged in and was maintained by the red fox (*Vulpes vulpes*) as the new main reservoir host, spreading the disease throughout the continent within a few decades (Wandeler 2004, 2000). While due to oral vaccination of foxes large parts of Western and Central Europe have been declared free from fox-mediated rabies (Müller et al. 2012, 2015), it is still endemic in Eastern parts of the continent (Müller and Freuling 2018). Besides the red fox, the raccoon dog (*Nyctereutes procyonoides*), an alien species to Europe is supposed to be another wildlife rabies reservoir. Rabies cases have also been reported in golden jackals (*C. aureus*) on the Balkan Peninsula. However, it is not yet clear whether the raccoon dog or the golden jackal represent independent rabies reservoir hosts (Johnson et al. 2008; Müller et al. 2015). In the northernmost parts of Europe, conspecifics of the Arctic fox (*Alopex lagopus*) are involved in the circumpolar transmission cycle of arctic rabies (Mork and Prestrud 2004; Johnson et al. 2007).

Also, other alien species including the North American raccoon (*Procyon lotor*) and the small Indian mongoose (*Herpestes auropunctatus*) are now firmly established in parts of Europe often reaching higher population densities compared to their areas of origin (Cirovic et al. 2011; Vos et al. 2012). Sustained introductions of RABV variants into these species would pose a significant challenge in terms of rabies control (Vos et al. 2012; Müller et al. 2015).

25.1.6 Asia

Domestic dogs represent the major reservoir and vector for the disease in large parts of Asia (Müller and Freuling 2020a), and dog transmitted RABV causes thousands of victims per year (Song et al. 2014; Sudarshan et al. 2007). The veterinary public health focus on dogs may mask the presence of rabies in wildlife. In fact, the disease has also been reported from wildlife species in many Asian countries (Müller and Freuling 2020a). In Russia and other countries of the former Soviet Union, rabies is also maintained by wild canids, particularly foxes, while local dog epizootics occurred only sporadically in some territories. The red fox serves as the main reservoir, but the steppe fox (*Vulpes corsac*) and the golden jackal participate in RABV circulation in the steppe and desert territories (Kuzmin et al. 2004; Shulpin et al. 2018). Phylogenetic data indicate that except for arctic foxes in the polar region and raccoon dogs in Far East Russia an association of RABV variants with host species was less obvious (Shulpin et al. 2018). In Central Asia, fragmentary surveillance data indicate that the majority of cases are reported from dogs. Although wildlife rabies has been reported only scarcely, it seems to play a role in the epidemiology of the disease (Gruzdev 2008; Sultanov et al. 2016). In the Middle East region, besides dogs, also wild canid species, i.e., golden jackals and fox species are considered reservoirs. Turkey is a country, where a host switch from dogs into red foxes was reported that lead to an epidemic in the Aegean region of Turkey (Johnson et al. 2006; Vos et al. 2009; Marston et al. 2017). Sri Lanka may also serve as an example of the coexistence of dog-mediated and wildlife-mediated rabies, with the latter associated with mongoose and jackals (Karunanayake et al. 2014). Also, in China and Taiwan, rabies is associated with the Ferret badger (Lan et al. 2017; Zhang et al. 2009).

25.1.7 Other Lyssaviruses

Intriguingly, all recognized and proposed lyssavirus species within the genus *Lyssavirus* have reservoirs in Chiroptera, except for MOKV and IKOV (Banyard et al. 2020a)

Bats have particular traits that may promote the maintenance and transmission of lyssaviruses. It is hypothesized that all lyssaviruses originated from a precursor bat virus and therefore, bats with their more than 1100 recognized species to date (more than 16% of mammalian species) are the ultimate historical source of carnivore

rabies infections, based in part upon epidemiological, ecological, and phylogenetic inferences (Badrane and Tordo 2001; Calisher et al. 2006). In Europe, bat rabies is caused by various lyssaviruses. EBLV-1 accounts for more than 95% of all bat rabies cases in Europe and is mainly found in Serotine bats (*Eptesicus serotinus*) and Isabelline bats (*E.isabellinus*) (Schatz et al. 2013). In contrast, EBLV-2 has only been detected sporadically, always associated with Myotis bats (*M. daubentonii* and *M. dascyneme*) in the Netherlands, United Kingdom, Switzerland, Germany, Norway, and Finland (McElhinney et al. 2018). Bat rabies cases in Europe are seemingly less frequent than in the Americas; however, in many European countries bat rabies surveillance is still inadequate, despite international recommendations (Schatz et al. 2013). Discoveries of novel bat lyssaviruses WCBV (2001 from *Miniopterus schreibersii*), BBLV (2010 from *M. nattererii*), LLEBV (2012 from *M. schreibersii*), and KBLV (2019 from *M. brandtii*) (Freuling et al. 2011; Aréchiga Ceballos et al. 2013; Nokireki et al. 2018; Kuzmin et al. 2005) indicate the diversity of lyssaviruses in Europe that is likely to expand in the future.

In Africa, bat-associated LBV and DUVV have been associated with several taxa, including Eidolon, Epomophorus, Miniopterus, and Nycteris species (Hayman et al. 2012; Markotter et al. 2020). SHIBV was isolated from an insectivorous Hipposideros bat in Kenya (Arai et al. 2003; Botvinkin et al. 2003), and recently a novel virus, tentatively named Matlo bat lyssavirus (MBLV), that is closely related to WCBV, was detected in Natal long-fingered bats (*Miniopterus natalensis*) in South Africa (Coertse et al. 2020).

There is increasing knowledge on the diversity of lyssaviruses known to circulate also in Asian bat populations. Single representatives of ARAV and KHUV were isolated from Eurasian Microchiroptera, i.e., *Myotis blythi*, and *M. mystacinus* (Arai et al. 2003; Botvinkin et al. 2003). IRKV was isolated from infected *Murina leucogaster* in Irkut (Kuzmin et al. 2005) and China (Liu et al. 2013b). Also, one human rabies case after IRKV infection was reported in the Russian Far East (Leonova et al. 2009). More recently, rabies cases in the Japanese pipistrelle bat (*Pipistrellus abramus*) in Taiwan were characterized as the novel lyssavirus TWBLV (Hu et al. 2018). Also, genetic analyses confirmed that rabies cases in Indian flying foxes (*Pterpus medius*) in Sri Lanka were caused by the novel lyssavirus GBLV (Gunawardena et al. 2016). In Australia, variants of ABLV exist among several species of Pteropus, as well as in insectivorous Yellow-bellied sheath-tailed bats (*Saccolaimus flaviventris)* (Foord et al. 2006; Iglesias et al. 2021) (Fig. 2).

Despite MOKV being isolated from a variety of mammal species including shrews (*Crocidura* spp.), rodents (*Lophuromys* spp.), unvaccinated and vaccinated domestic cats and dogs (Sabeta and Phahladira 2013), and IKOV from an African civet (*Civettictis civetta*) from Tanzania (Marston et al. 2012), these species are the only lyssaviruses never to have been isolated from bats. Given the fact that C*hiroptera* are considered key reservoir species for lyssaviruses, there is reason to believe that the reservoir hosts of those lyssaviruses are bats too. However, such reservoirs for MOKV and IKOV still remain to be identified.

Now that it is understood that each lyssavirus has evolved to fit a particular ecological niche and that continuing evolutionary progression yields new variants

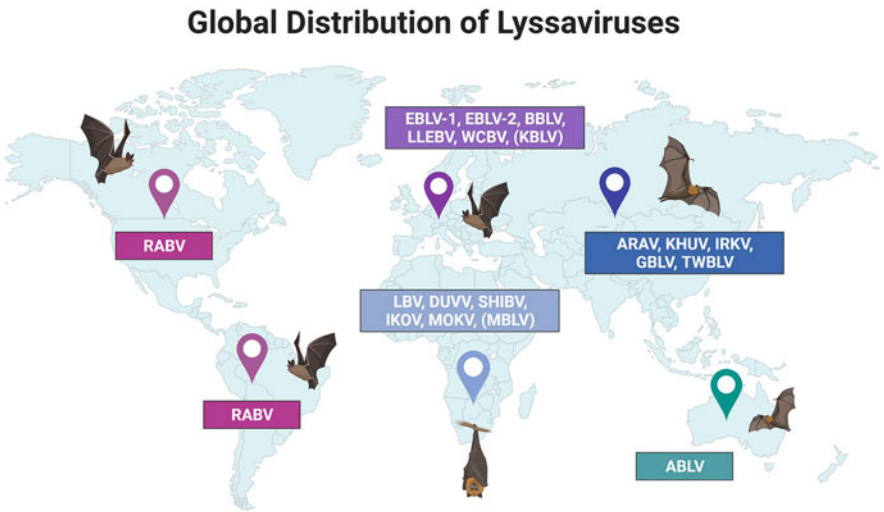

Fig. 2 Lyssaviruses associated with bats. Of note: Mokola virus (MOKV) and Ikoma lyssavirus (IKOV) were isolated from terrestrial animals and the reservoir host is unknown. Figure created with Biorender.com

and new threats to human and animal health, concerted global actions to combat rabies in terrestrial animals become increasingly important.

25.1.8 Self-Made Problems

The underlying diversity of the neurotropic, negative-stranded RNA viruses responsible for infection, combined with adaptation to the central nervous system in a broad spectrum of abundant, widely distributed mammalian hosts, may seem to hinder serious contentions for disease abatement (Rupprecht et al. 2008; Rupprecht and Salahuddin 2019). For a long time, unfortunately, the global rabies situation has not changed dramatically, despite local successes in rabies control in particular reservoir hosts, such as dogs or foxes in Europe (Müller et al. 2012), Latin America (Vigilato et al. 2013a) and North America (Ma et al. 2020). Hence, disease distribution still encompasses all continents, with the exception of Antarctica. There is ample evidence that for centuries human sociocultural evolution as well as population growth and human-related activities (e.g., the introduction of alien wildlife species, livestock, the translocation of domestic and wild animals) has affected its epidemiology and control. It is likely that in the future these factors will also affect the (re) emergence of rabies (for review see (Freuling et al. 2013). Furthermore, ineffective rabies control measures at the animal source may well create new rabies-related problems in wildlife. Mongoose rabies on the Caribbean islands and emergence of fox rabies in Turkey, for example, are considered a result of independent spillover infections from rabid dogs (Nadin-Davis et al. 2006b; Johnson et al. 2003;

Vos et al. 2009). The latter phenomenon is observed in many other countries in Asia, Africa, and the Americas as well.

It is speculated that growing urbanization, man-made environmental changes (e.g., deforestation), or climate change will put human populations at risk of exposure to zoonotic pathogens including lyssaviruses (Allen et al. 2017; Grange et al. 2021).

25.2 Human Rabies Prevention, Prophylaxis, and Experimental Therapy[2]

Rabies is a highly neglected, but also a vaccine-preventable, zoonotic disease (Briggs 2012; Fooks et al. 2017). For practical purposes, rabies should be considered as universally fatal, once clinical symptoms manifest (Fooks et al. 2014). However, progress is being made in the basic understanding of the design and application of biologics and anti-viral drugs to prevent, and in the future potentially treat, clinical rabies (Ledesma et al. 2020; Du Pont et al. 2020; Smith et al. 2020; Smith et al. 2019a; Rupprecht et al. 2006). Vaccines may be applied to at-risk populations prior to exposure (pre-exposure immunization or PrEP), or biologics are provided through post-exposure prophylaxis (PEP), administered to individuals after viral exposure, but before the onset of illness (Tables 1 and 2).

Not all animal exposures are "rabies-prone" and human rabies prevention should occur via an integrated bite case management approach (Undurraga et al. 2017). The administration of PEP occurs only after a thorough risk assessment, predicated in part by viral pathogenesis, the local epidemiology of rabies, the mammalian species involved, and the circumstances of each specific exposure (Table 2). Exposure is defined as occurring either via the bite (any penetration of the skin by the teeth of a rabid animal) or non-bite (transdermal or mucosal contact with virus-infected material, such as brain tissue) routes. Almost all human cases are caused after the bite from a rabid mammal. After such an event, PEP begins by thorough washing of the wound with soap and water. In previously unvaccinated persons, rabies immune globulin (RIG) is infiltrated into and around the bite, as an initiation of passive immunization. The RIG may be human in origin (HRIG), heterologous (obtained from other species), or monoclonal antibody (mAb)-based therapies. The first of several doses of rabies vaccine is also administered at the same time as RIG. The use of RIG on day 0 bridges the time after viral exposure, but before the active induction of rabies virus neutralizing antibodies (VNA) from vaccine administration (Rupprecht et al. 2020b).

While cases of PEP failure exist (Tinsa et al. 2015; Shantavasinkul et al. 2010b; Wilde 2007), many are attributed to errors in PEP administration (Wilde 2007; Wilde et al. 1989) or possible direct inoculation of RABV into the CNS or other neural tissues (Bharti et al. 2019). Therefore, survivorship is almost certain if prophylaxis is

[2] Authors: Charles E. Rupprecht, Anthony R. Fooks, Leo Both, and Samuel P. Smith

Table 1 Rabies Immunization Recommendations

Criteria for pre-exposure immunization			
Exposure category	Nature of risk	Typical populations	Pre-exposure regimen
"Continuous"	Virus present continuously, usually in high concentrations. Specific exposures may be unrecognized. Bite, non-bite, or aerosol exposures	Rabies research workers.[c] Rabies biologics production workers	Primary course. Serologic testing every ~6 months. Booster immunization if antibody titer falls below "acceptable" level[c,d]
Frequent	Exposure usually episodic, with source recognized, but exposure also may be unrecognized. Bite, non-bite, or aerosol exposures	Rabies diagnostic workers,[c] cavers, veterinarians and staff, and animal control and wildlife workers in areas where rabies is enzootic. All persons who handle bats	Primary course. Serologic testing every ~2 years. Booster vaccination if antibody titer is below "acceptable" level
Infrequent (greater than population-at-large)	Exposure nearly always episodic with source recognized. Bite or non-bite exposures	Veterinarians and animal control staff working with terrestrial animals in areas where rabies is uncommon to rare. Veterinary students. Travelers visiting areas where rabies is enzootic and immediate access to appropriate medical care including biologics is limited	Primary course. No serologic testing or booster vaccination
Rare (population-at-large)	Exposure always episodic. Bite or non-bite exposure	Population-at-large, including individuals in rabies-epizootic areas	No vaccination necessary, unless exposed

[a] Adapted from recent WHO and US Advisory Committee on Immunization Practices (ACIP) guidelines

[b] Pre-exposure immunization. Pre-exposure immunization consists of three doses of cell culture vaccine, ID or IM (i.e., deltoid area), one each on days 0, 7, and 21 or 28. Administration of routine booster doses of vaccine depends on exposure risk category as noted above

Post-exposure immunization. All PEP should begin with immediate thorough cleansing of all wounds with soap and water. Persons not previously immunized: Three PEP regimens are available depending on severity of exposure. Category I exposures only require washing exposed skin. RIG (40 IU/kg for ERIG, and 20 IU/mL for HRIG) is only indicated in category III exposures. Currently, vaccination regimens and recommendations do not differ between category II and III exposures and one of three vaccination regimes may be adhered to; first, a 1-week, two-site ID regimen involves ID injection of vaccine on days 0, 3, and 7; second, a 2-week IM PEP regimen (Essen regimen) involves a single site IM injection of vaccine on days 0, 3, 7, and between day 14–28; lastly, a 3-week IM PEP regimen (Zagreb) includes delivery into two intramuscular sites on day 0, and delivery into a single intramuscular site on days 7 and 21. For persons previously immunized: only wound washing is required for category I exposures and RIG is not indicated for any category of exposure. Furthermore, three vaccination regimes are suggested; first, a single ID vaccination on days 0 and 3; second, vaccination administered at four sites on day 0; third, a single-site IM vaccination on days 0 and 3. These vaccination regimes do not differ between category II and category III exposures. Furthermore, immediate vaccination is not needed if the individual has received a complete PEP course within the last 3 months. Pre-exposure immunization with modern cell culture vaccine; prior PEP with modern cell culture vaccine; or persons previously immunized with any other type of rabies biologic and a documented history of an "acceptable" rabies virus neutralizing antibody response to the prior vaccination

[c] Assessment of relative risk and any extra monitoring of immunization status of laboratory workers is the responsibility of the laboratory supervisor (as an example, see guidelines in the current edition of the United States Department of Health and Human Services' Biosafety in Microbiological and Biomedical Laboratories)

[d] Routine Pre-exposure booster immunization consists of one dose of modern cell culture vaccine, ID or IM (i.e., deltoid area). An acceptable antibody level is 0.5 IU/ml. Boost if the VNA titer falls below this level, as long as the person remains at risk of viral exposure

Table 2 Rabies risk assessment and prophylaxis considerations

Animal type	Evaluation and disposition of animal	Post-exposure prophylaxis recommendations
Dogs and cats	Healthy and available for 10 days observation	Should not begin PEP unless animal develops signs of rabies[a]
	Rabid or suspected rabid	Initiate PEP immediately[b]
	Unknown (escaped)	Consult public health officials
Bats, foxes, mongoose, raccoons, skunks, other carnivores	Regard as rabid unless geographic area is known to be free of rabies or until animal is proven negative by diagnostic tests	Initiate PEP.[c] Consider factors such as provocation, suggestive clinical signs, severity of wounds, type of exposure, and timeliness of diagnostic results (24–48 h) for decisions regarding immediate initiation, or to delay pending test results
Livestock, insectivores, most rodents, and lagomorphs (rabbits and hares)	Consider individually	Consult public health officials; bites of rats, mice, hamsters, guinea pigs, gerbils, chipmunks, squirrels, shrews, and other small mammals almost never require PEP

Adapted from recent WHO and US Advisory Committee on Immunization Practices (ACIP) guidelines

[a]If clinical signs compatible with rabies develop during a ~ 10-day confinement and observation period, the animal should be euthanized and tested immediately. Depending on circumstances, initiation of PEP may be delayed pending a laboratory report, if results may be obtained promptly in ~24–48 h

[b]If the bite was unprovoked or resulted in severe wounds, prophylaxis of the bitten person should begin immediately with rabies immune globulin and modern cell culture vaccine. Rabies PEP may be discontinued if the test is negative

[c]If available, the animal should be euthanized and tested as soon as possible. Holding for an observation period is not recommended since the potential viral shedding period prior to clinical signs has only been determined for dogs, cats, and ferrets

begun in a timely and appropriate manner after exposure. However, there is no proven treatment after the manifestation of rabies as an acute progressive encephalomyelitis in humans or other animals.

25.2.1 Preventive Vaccination

Vaccination of certain occupational groups, such as first responders in rabies management, is recommended due to the higher risk of viral exposure in comparison to the population-at-large (Table 1). PrEP simplifies PEP, priming the immune response (Mills et al. 2021) and potentially providing a degree of protection against minor, unrecognized exposures. Such exposures, if proper personal protection equipment (PPE) is used, appropriate, well recognized techniques are employed, and exposure protocols are followed, should by definition, be negligible. If recipients of PrEP are exposed to RABV, booster doses of vaccine are used to induce an anamnestic

response. RIG is unnecessary under such circumstances due to the preexistence of VNAs and additional RIG may form immune complexes and interfere with development of a normal anamnestic response. However, individuals who receive PrEP should remain vigilant in recognizing potential viral exposures and seek appropriate PEP ad hoc.

If exposures occur, but are unrecognized, the recipient of PrEP may still succumb to rabies after exposure, albeit very rarely. One documented case of mortality despite previous vaccination occurred in a Peace Corps volunteer in Kenya. This volunteer had completed a standard three-dose intradermal vaccination regimen using human diploid cell rabies vaccine, but upon being bitten by her own puppy died of a disease compatible with rabies (Bernard et al. 1985). Travelers should be advised to consider PrEP based upon their planned activities and destination, as certain critical biologics may not be always readily available (Jentes et al. 2013).

25.2.2 PrEP of Children?

An estimated 10–16 million people undergo PEP worldwide each year following exposure to proven or suspected rabid animals (Both et al. 2012). Of special importance is the pediatric population (Kessels et al. 2017). Of note, the first ever patient to receive Pasteur's rabies vaccine was a child presenting with multiple deep bite wounds during July 1885. This case exemplifies that children in particular are at a high risk of exposure to rabid dogs. On average, 50% of rabies deaths are estimated to occur in children under 18 years of age. Children 5–10 years of age are particularly exposed, because they are often unable to discern abnormal animal behavior, they may be watched less by their parents than younger children, they enjoy playing with dogs, and, due to their size, they are frequently bitten on the head and neck, which carries a higher risk of contracting rabies (Ichhpujani et al. 2008; Knobel et al. 2005). Because of the large numbers of affected children, rabies is the seventh most relevant global infectious disease with regard to the years of life lost (Jackson 2008).

Surveys have confirmed the disproportionate toll of rabies among children, resulting from an insufficient supply of rabies biologics, including RIG and modern cell-culture vaccines (Pancharoen et al. 2001a; Wilde et al. 1996; Sriaroon et al. 2006; Pancharoen et al. 2001b; Kularatne et al. 2016; Ngugi et al. 2018; Kessels et al. 2017). Studies in Tanzania have shown that up to 55% of victims are children (Mazigo et al. 2010; Hampson et al. 2008). In a survey from South African, 49% of rabies exposures were children <10 years and 22% were 11–20 years (Weyer et al. 2011). One study in Kenya between 2011 and 2016 revealed 36% of all recorded cases affected children <14 years of age, and a 17% incidence in ages 15–24 (Ngugi et al. 2018). A study across eight Asian countries revealed that 43% of all patients were children and teenagers (Dodet et al. 2008). A study focusing on rabies in China demonstrated that children under 15 years of age constituted 25% of the nation's rabies deaths (Song et al. 2009). Another study in Cambodia showed that, among 44 human rabies cases, 37% were 15 years old or younger, and RIG was administered free of charge only for children with wounds on their upper arms and faces (Ly et al. 2009).

The need for RIG can be avoided by the use of PrEP, as previously vaccinated bite victims only receive two booster doses with vaccine and no RIG is required (O'Brien et al. 2019). PrEP may be useful for certain populations at high risk of RABV infections, e.g., veterinarians, animal handlers, diagnostic workers, vaccine producers, research scientists, cavers, wildlife biologists, children in endemic areas containing many unvaccinated stray dogs, or those in very remote areas, such as the Amazon who suffer routine exposure to vampire bat bites (Fooks et al. 2017). PrEP may also be considered for certain international travelers (Fooks et al. 2003). In the UK, an annual number of 3,700–5,700 rabies vaccine prescriptions were dispensed between 2009 and 2011. The field of rabies immunization benefits from over a century of classical scientific insights, but also lingers in the legacy of Pasteur toward certain conservative tendencies, particularly related to the basic use, types, doses, routes, and schedules of biologics (Wu et al. 2011). As background, several publications have reviewed in depth the history, basic approach, available products, and biological basis for rabies immunization (World Health Organization 2013; Smith et al. 2019a; Ertl 2019; World Health 2018; Fooks et al. 2019). For other updates, specific details and current recommendations on rabies immunization may be found at the websites (http://www.who.int/rabies/en/) of the World Health Organization (WHO) and the Advisory Committee on Immunization Practices (ACIP), United States (http://www.cdc.gov/vaccines/acip/recs/index.html).

The etiological agents of rabies consist of diverse RNA viruses in the Family Rhabdoviridae, Genus Lyssavirus (Kuzmin et al. 2009). While all lyssaviruses cause rabies, historical and rabies biologics are produced only using RABV strains. Modern rabies biologics will protect against all known RABV variants As there is evidence for broad spectrum cross-neutralization and cross-protection within lyssavirus phylogroups, current commercial rabies vaccines are known to cross protect against all members of phylogroup I (Brookes et al. 2006; Fekadu et al. 1988; Hanlon et al. 2005; Liu et al. 2013a; Malerczyk et al. 2009, 2014). However, little to no protection is evident against phylogroup II lyssaviruses (Servat et al. 2019; Malerczyk et al. 2014; Hanlon et al. 2005; Fekadu et al. 1988; Banyard et al. 2018; Horton et al. 2014). Cross-protection against phylogroups I and II has been achieved in a variety of experimental studies by either creating chimeric lyssavirus glycoproteins (Evans et al. 2018; Fisher et al. 2020) or the sequential insertion of glycoproteins within a viral backbone (Kgaladi et al. 2017; Weyer et al. 2008).

The original anti-rabies biologics of the late nineteenth and early twentieth century consisted of RABVs propagated in mammalian nervous tissues, such as in rabbits, small ruminants, nonhuman primates, or suckling mice. These nerve tissue origin (NTO) vaccines are no longer recommended for human immunization, although such products are still in use in a few developing countries, such as in Ethiopia. Due in part to poor potency, over the course of a month, 14–21 administrations of NTO vaccines occurred by the intracutaneous route applied over the abdominal region. Such NTO biologics were gradually replaced by safer and more potent cell culture vaccines during the late twentieth century. Modern rabies cell culture vaccines include the human diploid cell vaccine (HDCV), purified chick embryo cell vaccine (PCEC), purified duck embryo vaccine (PDEV), and purified

Vero cell rabies vaccine (PVRV). Besides an improvement in overall quality, the use of HDCV, PCEC, PDEV, and PVRV allowed for a decrease in the total number of vaccine doses applied to ~ 4–5 by the end of the twentieth century, and the application via the intramuscular (IM) route at a volume of 0.5–1.0 mL.

Rabies vaccines and RIG are listed among the WHO Essential Medicines for both adults and children, but access across the developing world is often insufficient (Li et al. 2019). In fact, shortages of rabies vaccine and especially RIG are common in developing countries. Bite victims may need to travel long distances to obtain any PEP and may present to medical personal with substantial delays. Also, costs are a restriction, since the price for modern tissue-culture vaccine vials ranges from $7–20 in many low-income countries and multiple vials are required per patient depending upon the PEP regimen used (Hampson et al. 2011; Quiambao et al. 2005). To save costs compared to IM vaccination, intradermal (ID) vaccination makes use of less vaccine, with smaller amounts of vaccine being injected into the skin at multiple sites on the first day of the course to elicit a potent immune response (0.1 ml for each ID injection versus a single 0.5 or 1 ml vial for each IM injection) without limitations in safety, immunogenicity, or efficacy for both PrEP as well as in use for PEP (Shantavasinkul et al. 2010a, c; Khawplod et al. 2012; Warrell 2012; Shantavasinkul and Wilde 2011; Gongal and Sampath 2019; Denis et al. 2019; Kessels et al. 2019).

The disadvantage of ID regimens is that vaccine leftovers in partially used vials must be discarded after several hours to avoid the risk of contamination. Additionally, ID vaccination is technically more demanding, is subject to pharmaceutical regulations, and may result in more frequent local adverse events. However, where feasible, due to a high turnover of animal bite victims, local health clinics, and well-trained staff, switching from IM to ID immunization will make rabies PEP more accessible and affordable (Hampson et al. 2011; Gongal and Sampath 2019). Besides alternative routes, shorter vaccine schedules, based in part upon the evidence provided in animal models, the basic immunological response to rabies vaccines, epidemiological investigations, and human clinical trial data have been investigated (Rupprecht et al. 2009, 2010; Robertson et al. 2010; Khawplod et al. 2012). While some studies have focused on the reduction of PrEP regimens to 7 days (Soentjens et al. 2019) other studies have addressed reductions in PEP regimens (Warrell 2019a, b).

After vaccination, antibody titers serve as surrogates of response, but do not directly correlate with absolute protection against a fatal productive infection, because other immunological factors also play a role in prevention of disease (Briggs 2011). Hence, there is no known absolute "protective antibody" level for all humans. Minimum arbitrary standards are based empirically on presumed activity of rabies virus-specific antibodies, e.g., VNA, for a given exposure scenario and on repeatable values for paired sera. For example, a VNA titer of 0.5 IU/mL by WHO standards is evidence of adequate immunization in persons at either constant or frequent risk of exposure, at 6-month or 2-year intervals, respectively, as a measure of baseline immunity. A single booster vaccine dose is administered if the VNA level is lower than recommended, based on a determination of risk (Table 1). After a century of use, several generalizations are apparent in the application and use of human rabies

Table 3 Ten generalized observations on human rabies immunization in the twenty-first century

Antibodies to the viral glycoprotein appear to be the most important in rabies immunization
Anti-IgG antibodies begin to appear within ~7–14 days of rabies vaccination in healthy subjects
A basic prime-boost strategy seems most effective in rabies pre-or post-exposure vaccination
Modern cell culture vaccines are superior to nerve tissue origin products in safety and immunogenicity
Intradermal vaccine regimens provide comparative effectiveness compared to intramuscular use
Routine serologic monitory is unnecessary except in the immune-compromised or after major deviations from standard recommendations
Host factors, such as age, genetic background, etc., will affect an ideal immune response to vaccine
The role of cell-mediated immunity is not well documented in rabies prophylaxis
Timely and appropriate wound care, infiltration of rabies immune globulin, and administration of potent cell culture vaccines virtually assure human survivorship, even after severe bite exposures
Most people die of rabies because they do not receive appropriate access to modern rabies biologics

Adapted from (Rupprecht and Plotkin 2013)

biologics today (Table 3). Future alterations in the methods used to measure basic rabies vaccine potency are anticipated to reduce the dependency on the use of animals and to more effectively resolve a cumulative understanding of human response to precise doses of vaccine by more comparative techniques (Stokes et al. 2012).

25.2.3 Improvements to PEP

While current biologics to prevent rabies are extremely effective, progressive development of other products is necessary. Modern inactivated cell culture vaccines and RIG are vastly improved over historical NTO vaccines, but such products are expensive (especially in the developing world where they are most needed), are often in scarce supply, and may carry a perceived theoretical risk of adventitious agents. Hence a major focus in rabies prevention has concentrated on the need for potent, inexpensive PEP, especially different routes, fewer vaccine doses, shorter schedules, and replacement of costly RIG, while retaining activity against a wide variety of diverse lyssaviruses (Both et al. 2012). While advances have been made in rabies PEP regimens as discussed previously (Warrell 2019a, b), PEP remains costly and is still in short supply in areas that need it most.

Besides HRIG, there are other products to provide passive immunity. In contrast to the relatively poor-quality equine rabies immunoglobulin serum used in the past that resulted in high adverse reactions, such as serum sickness in up to 40% of human recipients, modern purified equine rabies immune globulin (ERIG) products are safer, more potent, and more affordable than older cruder products, and are less expensive than HRIG. For example, in Bhutan, prophylaxis of an adult with HRIG is approximately 20 times more expensive than equivalent treatment with

ERIG (Tenzin et al. 2012). Due to its potency and apparent lack of significant local or systemic effects, purified ERIG products have traditionally been seen only as immediate alternatives to HRIG, if supply should be threatened by shortages, contamination, or other limitations (Quiambao et al. 2009). However, ERIG has been used effectively in conjunction with vaccine in human rabies PEP, particularly in developing countries, and no preference between HRIG and ERIG is currently given by WHO recommendations (Sparrow et al. 2019). The use of such heterologous HRIG/ERIG products may be considered a temporary antecedent until the widespread and commercial availability of more novel replacements, such as mAbs (Both et al. 2013a, b). Particularly, countries with chronic shortages of RIG would benefit greatly from replacement of these scarce and expensive polyclonal preparations, especially in Africa which suffers from an estimated 24,000 rabies deaths, with less than 2% of exposed patients receiving RIG (Knobel et al. 2005). Studies into RIG alternatives have revealed the potential of neutralizing camelid variable domain on a heavy chain (VHH) antibodies, mAb, and scFv proteins. VHHs, also called nanobodies, are the antigen-binding variable domain of *Camelidae* antibodies and are able to recognize more epitopes, are more thermostable, and have faster tissue penetration than traditional antibodies (Harmsen and Haard 2007). One VHH cocktail of note is Rab-E8/H7, a combination of two monovalent VHHs (E8 and H7). E8 and H7 were discovered when two phage-display libraries were constructed after the immunization of llamas with an inactivated HDCV vaccine (Hultberg et al. 2011). Further study of Rab-E8/H7 has revealed its effectiveness in preventing the onset of disease if given as either PrEP or PEP when given, like RIG, in the context of vaccination (Terryn et al. 2014, 2016).

Hybridomas that secreted RABV antigen-specific mAbs have been generated during the 1970s. The resulting mAbs were selected on the basis of isotype, antigen and epitope specificity, virus strain specificity, affinity, and neutralizing activity. The administration of mAbs have various theoretical advantages over RIG: Firstly, mAbs need comparatively small volumes for equivalent active protein content as specific neutralizing activity per mass of protein is higher, so mAbs may be optimal for lessening the trauma and pain of local wound infiltration with a source of passive antibodies. Second, safety issues arising from the possibility of adventitious agents associated with human or animal blood products would be alleviated by bulk production under modern GMP conditions in cell culture. In a WHO consultation during 2002, a number of mAbs were proposed for inclusion into an antibody cocktail (Müller et al. 2009) and several mAb combinations were designed based on stringent criteria (Table 4). Fifteen years later, the Strategic Advisory Group of Experts reviewed its recommendations for the inclusion of anti-Rabies mAbs into PEP. This, in concert with the publishing of a WHO position paper during 2018, encouraged the use of mAbs within PEP where available (Meeting of the Strategic Advisory Group of Experts on immunization, October 2017 – conclusions and recommendations 2017; World Health Organization 2018a; Sparrow et al. 2019). Since 2002, these RABV-specific mAbs have

Table 4 Criteria for antibody selection and testing by the WHO Rabies Collaborating Centres

a) **Criteria for mAb selection**
The history of hybridomas, including relative risk of contamination with certain agents (e.g., FMDV, TSE agents) and use of FCS (fetal calf serum) should be available
A production of a minimum of 100 IU per ml of crude hybridoma supernatant should be obtained
Stability expressed as loss of antibody secretion production should not exceed 10% upon passaging
In-vitro cross-reactivity should be measured by RFFIT or FAVN on a selection of RABV and phylogroup I lyssaviruses isolated from major of reservoir host species and geographical areas, including dogs from Asia, Africa, and the New World
At least two broadly cross-reactive mAbs should be selected recognizing different G protein epitopes
The mAbs should not interfere with each other during neutralization testing
The mAbs should not be inferior to RIG with regard to viral reactivity
b) **In vitro testing of candidate mAbs**
History of hybridomas should be established in writing
Use of FCS should be avoided. Low serum or no serum media must be preferred
Each laboratory should establish a mini master cell bank with a minimum of 10 vials
Tests for mycoplasma, bacteria, etc., in T25 cm^2
Thirty passages must be performed (with freezing aliquots after every 10 passages)
Culture batch (500 ml) on roller bottles
Purify IgG on protein A column and determine IU/mg.
Compare supernatant of passages 0, 10, 20, 30 (a 30% variation +/- for naturalization from test to test is acceptable) and determine isotype at passages 0 and 30
Purify IgG at a concentration of at least 1000 IU/ml

(WHO consultation, 2002)

been under investigation and some are either in advanced stages of clinical development or have been licensed for use in humans.

Two mAbs have now been licensed for use: Rabishield and Twinrab (Rabimab) in India. Rabimabs is a cocktail of two mAbs antibodies docaravimab (62-71-3) and miromavimab (M777-16-3). These mAbs bind two distinct nonoverlapping epitopes and have the ability to neutralize a wide variety of RABVs and related escape mutants (Müller et al. 2009). In a Phase 3 noninferiority trial, Twinrab™ was assessed at 40 IU/kg (in combination with rabies vaccination during PEP) in 124 patients who had a category III exposure and were aged ≥5. No deaths or serious adverse events were recorded, and no statistically significant difference was observed between HRIG and Twinrab™ (Kansagra et al. 2020).

Rabishield consists of a single IgG1 mAb,17C7. Developed by Massachusetts Biologic Laboratories, 17C7 was generated using transgenic mice expressing human antibody genes (Bakker et al. 2008; Sloan et al. 2007). Multiple preclinical studies have shown that mAb 17C7 was able to neutralize street RABVs and can confer protection equivalent to HRIG in hamster challenge models, tested either alone or in combination with rabies vaccine (Sloan et al. 2007; Wang et al. 2011b). The 17C7 mAb, also known as RAB1 or SIIR mAb, has also been investigated in randomized, dose-escalation phase 1 safety study in adults. Rabishield was found to be well

tolerated and reached comparable antibody titers to vaccine and HRIG cohorts (Gogtay et al. 2012). In phase 2/3 trials with patients (> age 5) suffering from a category III exposure, no deaths, severe adverse events, or anti-mAb antibodies were recorded. Rabishield elicited rabies virus neutralizing activity that was noninferior to HRIG (Gogtay et al. 2018).

25.2.4 Treatment of Clinical Rabies?

Prevention of viral exposures is still the optimal approach in rabies prevention, or when this fails, application of modern PEP before onset of illness. However, in some circumstances, alternatives regarding experimental treatment of clinical rabies may be warranted (Willoughby 2007). Unfortunately, the use of many different products such as cytosine or adenine arabinoside, interferon-α, ketamine, amantadine, minocycline, acyclovir, antithymocyte globulin, steroids, vidarabine, ribavirin, favipiravir, and inosine pranobex have been unsuccessful (Jackson et al. 2003; Appolinario and Jackson 2015). Historically, there have been <30 cases of rabies recovery. Of the cases where patients were treated until recovery (or died within recovery) and the outcome is known, only 18% completely recovered while 82% of patients were left with mild to severe sequelae (Nadeem and Panda 2020). From human case studies and findings of apparent natural acquired immunity, these data suggest that human rabies may not be uniformly fatal but rather behave as a continuum (Feder et al. 2012; Gilbert et al. 2012). Furthermore, the observation that over 90% of human rabies survivors receive at least one of either antivirals, vaccination, or RIG, suggests that host defenses may be further exploited for the treatment of symptomatic rabies.

One classical example in aiding the host immune response for the treatment of symptomatic rabies is in the treatment of a 15-year-old female Wisconsin resident who was bitten by a bat on her hand during 2004. The small wound on her finger was cleaned; however, PEP was not administered. Approximately a month later, she developed generalized fatigue and paresthesia of her left hand, diplopia, ataxia, nausea, and vomiting. On the fourth day of illness, blurred vision, left leg weakness, and ataxia were noted, and later fever, slurred speech, nystagmus, and tremors of her left arm, and she was admitted to a pediatric facility. On the second day of care, the presence of rabies virus-specific antibodies in the patient's CSF and serum were documented. However, attempts to isolate virus, detect viral antigens, or amplify viral nucleic acids from skin biopsies and saliva samples were unsuccessful. An experimental treatment, termed the "Milwaukee Protocol," was initiated, which combined anti-excitatory and antiviral drugs, including ketamine, ribavirin, and amantadine, in conjunction with supportive intensive care (Willoughby et al. 2005). Neither rabies vaccine nor RIG was administered because of the patient's VNA response and the theoretical potential for harm from an altered immune response. After more than 70 days of hospitalization, the patient recovered, with only minor neurologic sequelae (Hu et al. 2007). She became the first person to survive clinical rabies without a history

of prior vaccination. While promising, this experimental protocol has been attempted in approximately 40 patients with only 6 documented survivors (Ledesma et al. 2020).

While there have been no recent advances in the treatment of symptomatic rabies in humans, significant advancement has been made during in vivo studies. This has included the use of either live attenuated vaccine viruses (LAVVs) or mAbs. As reviewed extensively much progress has been made in the attenuation of live RABVs by the insertion of either nonviral elements (Smith et al. 2019a) or the multiplication (Faber et al. 2002, 2009) of attenuated RABV glycoproteins. Many of these are effective in causing a strong influx of T cells, B cells, and APCs into the CNS and brain after inducing permeabilization of the blood–brain barrier (Smith et al. 2019a). Studies have investigated the use of LAVVs in preventing mortality when given intracranially up to 6 days after peripheral lethal rabies virus challenge. These studies have used either TriGAS (also known as SPBAANGAS-GAS-GAS) (Faber et al. 2009), SRV9 (Huang et al. 2014; Huang et al. 2015), or a GM-CSF expressing LBNSE rabies virus vector (Wang et al. 2011a). All attenuated viruses used in these studies were effective in preventing mortality in a minimum of 20% of mice peripherally lethally challenged with RABV. In addition to LAVVs use as alternatives to inactivated rabies vaccines (Smith et al. 2019a), these studies also indicated that LAVVs represent a potential avenue for the post-clinical onset treatment of rabies. However, these LAVVs were only administered prior to the onset of clinical signs, with diminishing effectiveness as the number of days after lethal challenge increased, so further research may be needed before they are used for true post-onset treatment.

One area that has seen notable improvement in post-onset treatment is mAb therapy in murine in vivo models. For example, one study was able to successfully treat rabies in mice using a combination of two human monoclonal mAbs (RVC20 and RVC58) (Melo et al. 2020). The RVC20, able to bind antigenic site I of the RABV glycoprotein, neutralizes almost all phylogroup I lyssaviruses in addition to Shimoni bat virus (SHBV) and Ikoma lyssavirus (IKOV) from phylogroups II and III, respectively. The RVC58, able to bind antigenic site III, was also able to potently neutralize all phylogroup I lyssaviruses tested. By combining RVC20 and RVC58 into a single 1:1 cocktail these were able to neutralize 100% of non-rabies lyssavirus phylogroup I viruses tested. For comparison, HRIG was able to neutralize only 38% of non-rabies lyssavirus phylogroup I viruses tested (Benedictis et al. 2016). Firstly, the ability of the RVC20/58 cocktail to prevent the onset of rabies if administered peripherally was evaluated. Here, two doses were assessed via IM injection (2 and 20 mg/kg); however, while earlier timepoints were more effective, even the higher dose was only able to protect 1/5 mice when administered 6 days after lethal challenge. These data suggest that peripheral immunity alone is unable to effectively prevent clinical rabies. The study was repeated with daily intracerebral ventricular (IVC) mAb cocktail infusions alongside a single IM dose, starting at 6/7/8 days after lethal challenge, where data had suggested that RABV had already accessed the CNS, was impacting motor performance, or was resulting in clinical signs. Here, mice were equipped with automated microinfusion pumps, which administered 2 mg/kg/day IVC for 20 days of each mAb. A second IM injection was also included after the cessation of IVC mAb infusion. This

treatment regime was able to prevent mortality in 100% of mice when begun on day 6 (virus in CNS) and 55% of mice when treatment began on day 7 (affected motor performance). Most importantly, when treatment began after the onset of clinical signs, 33% of mice recovered from infection. However, of the 10/15 mice that did not survive when treatment was initiated on day 8, three of these died during IVC infusion, and one that died after treatment had ended presented low viral loads in their brain, suggesting that viral clearance had already started. They also explored the necessity of the Fc portion of mAbs through the use of antibody LALA mutations, which have been shown to abrogate Fc-gamma receptor binding (Saunders 2019). Here, LALA-mutation mAbs promoted lower survival rates when administered at 7 and 8 days after lethal challenge, where only 20% and 0% of animals were protected, respectively. In summary, this regime of IM and IVC administration of mAbs represented a possible avenue for future rabies treatments in humans (Melo et al. 2020).

Despite recent advances in the field of post-onset treatment, no established therapies exist for patients who develop rabies. Efforts should continue on basic viral pathogenesis research, design of anti-viral compounds, development of relevant surrogate animal models and protocols that mimic supportive intensive care, and experimental applications in human cases where ethical/legal approvals and modern teams and facilities exist for thorough application and evaluation (Willoughby et al. 2008, 2009; Smith et al. 2011; Franka and Rupprech 2011; Lingappa et al. 2013; Jackson 2013; O'Sullivan et al. 2013)

25.3 Rabies Control in Wildlife – An Innovative and Demanding Idea

Historically, rabies control in wildlife had long been disregarded since dog rabies control was given priority. It was only during the second half of the twentieth century that the existence of wildlife reservoirs for rabies was slowly becoming acceptable. In Europe and North America, at around the same time when dog-mediated rabies was about to be eliminated, the disease emerged in wildlife spreading quickly through vast parts of the continents and since then has been maintained in multiple species of mesocarnivores (Müller et al. 2012; Blanton et al. 2012).

Theoretically, wildlife rabies can be controlled either by drastic decimation or mass vaccination of the primary reservoirs, and thus reducing the number of susceptible animals below an endemic threshold, where disease transmission is interrupted to $R_{eff}<1$ (Aubert 1992). Early attempts aiming exclusively at a drastic decimation of reservoir populations (e.g., by hunting, trapping, poisoning, and gassing) failed (Aubert 1999; Rosatte 2013). In fact, elimination of a reservoir species outweighs any advantages as it is impractical, expensive, and ethically and ecologically unacceptable (Rupprecht et al. 2001). Parenteral vaccination of trapped wild animals works in principle (Aubert 1994; Rosatte et al. 1990) and has been part of common campaign tactics such as trap–vaccinate–release (TVR) and point infection control (PIC). However, TVR and PIC are labor-intensive and the most

expensive tactics per unit area and therefore, are no options for large-scale control of wildlife rabies (Sterner et al. 2009). Clearly, given their biodiversity, distribution, and abundance, novel methods were necessary to consider meaningful control of rabies in these wildlife reservoir species.

25.3.1 Innovative Approach

The discovery that foxes could be effectively immunized orally using highly attenuated RABV vaccines (Baer et al. 1971) along with the first proof-of-concept field trial (Steck et al. 1982) made oral rabies vaccination (ORV) a preferential and evolving rabies control technology for use in wildlife. This involves large-scale distribution of machine-made baits containing orally immunogenic vaccines across the landscape, thereby targeting wildlife to establish population immunity and prevent spread or eliminate specific rabies variants (Johnston and Tinline 2002).

During the past four decades ORV programs had been implemented in 30 European countries, Canada, and the USA (Müller and Freuling 2018; Fehlner-Gardiner 2018; Freuling et al. 2013) with more than 1.28 billion baits containing different oral rabies vaccines distributed in Europe and North America (Müller and Freuling 2020b). Recent ORV successes include the elimination of fox-mediated rabies in Ontario, Canada, and in almost the entire territory of the European Union (Robardet et al. 2019; MacInnes et al. 2001) as well as of the domestic dog-coyote variant of rabies from the USA (Maki et al. 2017). Due to ORV raccoon rabies has also been successfully eliminated in Ontario and prevented incursions of raccoon RABV variants from neighboring US states (Stevenson et al. 2016). Furthermore, in the USA, ORV programs stopped the expansion of a gray fox-mediated rabies outbreak and the westward spread of raccoon rabies into naïve raccoon populations (Sidwa et al. 2005; Sterner et al. 2009). ORV campaigns in wildlife were also conducted in Turkey (Ün et al. 2012) and Israel (Linhart et al. 1997).

25.3.2 Challenges

Although control and elimination of RABV variants in certain reservoir species is possible, one has to confess that wildlife-mediated rabies is not a candidate for eradication. Despite numerous success stories, diverse complexities and challenges are commonplace when applying ORV to control rabies in wild meso-carnivores (Slate et al. 2009).

Given the huge areas that would need to be covered with vaccine baits to eliminate wildlife rabies in Europe, Asia, North America, and other parts of the world, the planning, implementation, and management of ORV programs may require considerable long-term expenditures. This would affect the USA, Canada, and Russia in particular, but also other bigger countries in Asia and Africa where wildlife rabies is commonplace. Costs may even arise when areas have been freed from wildlife rabies because vaccination belts would need to be established to prevent reintroduction from adjacent areas where wildlife rabies is still endemic

until ORV campaigns are being implemented there (Freuling et al. 2008; Robardet et al. 2019). Novel cost-effective vaccination strategies to be applied under different ecological conditions are therefore required.

Generally, RABV spillover events and subsequent establishment in several sympatric mesocarnivores as well as disease emergence in the absence of effective oral vaccines in the new reservoir host pose another major challenge in achieving tangible objectives in wildlife rabies control (Rupprecht et al. 2008; Slate et al. 2009; Müller et al. 2015). Notable examples are maintenance of the Arctic variant of RABV in striped skunks (Nadin-Davis et al. 2006a) and sustained spillover infections of bat-associated RABV variants into skunks in Arizona (Leslie et al. 2006). While the control and elimination of fox- and raccoon dog-mediated rabies seems to be relatively simple, effective, and easy to implement, it is evident that other wildlife reservoir hosts for rabies including raccoons and skunks appear more refractory to vaccination by the oral route, even when high virus titers were administered. The biological background for these species-specific differences in vaccine efficiency is poorly understood. However, recent results of a comparative study in various reservoir species support a model in which the susceptibility to oral live RABV vaccine infection of lymphatic tissue is a major determinant in vaccination efficacy (Te Kamp et al. 2020). This might explain why the effectiveness of current commercial oral rabies vaccines appears to be adequate to prevent further expansion of rabies in raccoons but may not support disease elimination in this species in the near future (Slate et al. 2009). Apart from efficient oral rabies vaccines, the development of species-specific baits is often underestimated but of utmost importance because a highly potent oral rabies vaccine is useless without an attractive bait. Also, a bait specifically developed for one reservoir species might not be necessarily attractive for other species. For example, ORV campaigns in raccoons require a multiple of commercial baits per unit area as does the control of fox rabies (Rosatte 2013). While current oral rabies vaccines are safe and immunogenic in the small Indian mongoose (Berentsen et al. 2020, 2021; Vos et al. 2013; Ortmann et al. 2018) suitable baits would still need to be developed. In contrast, there are no effective oral rabies vaccines and baits available for skunks yet. Adaptive reservoir species-specific bating strategies for enhanced effectiveness in rabies control require attention to a broad range of research needs. This includes an understanding of the ecology of reservoir species, the target and nontarget species foraging behaviors, community dynamics of the meso-carnivore complex, bait uptake relative to a suite of species-specific spatiotemporal variables, and model development to support ORV decision-making (Slate et al. 2009)

25.3.3 Rabies Control in Bats?

Although bats are considered the true reservoirs for lyssaviruses, considering the sheer abundance of bat species across the world (Agnarsson et al. 2011) the question is not whether the plethora of lyssavirus infection can be controlled. In addition, control measures would be per se limited by the accessibility and often protected status of bats in many parts of the world. Especially from a nature conservation

perspective, targeted population control measures to reduce the spread and incidence of lyssavirus infections in bats are inappropriate and should therefore be critically questioned, if not banned, if they are still used (Brass 1994). Rather, in keeping with conservation rules and measures, activities should focus on (i) the establishment of adequate rabies surveillance, (ii) increasing public awareness, and (iii) targeted pre- and post-exposure prophylaxis (PEP).

One exception often discussed is vampire bat rabies – a medically and economically important zoonosis in Latin America. The ecology of vampire bats as obligate hematophagous bats provides a unique transmission route for RABV to humans and animals alike (Johnson et al. 2014; Streicker et al. 2012). Culling of parts of the vampire population is the policy currently implemented in North, Central, and South America to control vampire bat–mediated rabies. While this strategy is considered to reduce the burden of bat bites on humans and livestock, the real effects of this measure on rabies transmission and the population dynamics remain highly controversial. Oral vaccination may be an alternative to control the disease as vampire bats respond well to experimental oral rabies vaccinations (Stading et al. 2017; Setien et al. 1998; Aguilar-Setien et al. 2002). Also, linking field studies with fluorescent biomarkers to mathematical models indicated that spreadable vaccines, e.g. vaccines that autonomously transfer among individuals of inaccessible wildlife populations asuc as bats, may provide substantial advantages over culling vampire bats (Bakker et al. 2019); however, from a scientific and practical point of view this strategy is far from becoming a reality in the near future.

25.4 Elimination of Dog-Mediated Rabies – Possible But Unlikely?![3]

Canine-mediated rabies is a driver of inequality and poverty in developing countries around the world, posing a threat to over 6.2 billion people in 122 countries (Wallace et al. 2017). The close, interwoven ecology of domestic dogs and humans in many parts of the world allows for frequent opportunity for zoonotic transmission of the virus, accounting for 99% of human rabies deaths (Knobel et al. 2005). The risk of death from canine-transmitted rabies is drastically skewed by factors of geographic isolation and economic hardship due to the need for prompt post-exposure prophylaxis following a bite from a rabid animal, making canine rabies elimination a complex sociopolitical issue to solve (Shwiff et al. 2013). A century of scientific toil is yet to translate into widespread political momentum for national and multinational control interventions; however renewed international focus on rabies in the early twenty-first century offers hope for new inroads to combat the disease at scale (Cleaveland and Hampson 2017; Rohde and Rupprecht 2020; Umeno and Doi 1921).

[3] Authors: Andy P. Gibson and Frederic Lohr

25.4.1 Intractable Neglect

The protracted incubation period and relatively low transmissibility of the RABV result in a chronic, slow-moving endemic picture, with canine rabies cases occurring sporadically in any community or even city over a period of months or years. For example, in the rabies endemic Central African Republic capital city of Bangui, long periods of canine RABV absence were observed even though the region had never experienced mass dog vaccination (Bourhy et al. 2016). This natural fluctuation in disease incidence and heterogeneous epidemiological picture makes the disease inconspicuous to individuals and communities at large, as if it is rarely present. It is only when rabies incidence is monitored throughout a region that the continuous, widespread impact of the disease on a district, state, and nation as a whole becomes apparent (Colombi et al. 2020; Shwiff et al. 2018). Without robust data on dog rabies incidence, it is impossible to communicate a clear narrative of the true impact and extent of the disease to politicians, decision makers, funders, and the public alike. News headlines appear in sporadic bursts of activity covering events of individual rabies cases, which soon abate to the characteristic chronic periodic endemic pattern even in the absence of control intervention. This fleeting spotlight on canine-transmitted rabies in the media and public at large only propagates political torpor on the subject.

Political inaction is exacerbated by the weighted impact of the virus falling on marginalized communities lacking visibility and influence in society to lobby for change. The suffering, death, and economic consequences of rabies for people of low socioeconomic background go undocumented and unreported to health authorities and therefore remain invisible to high-level policy makers (Hampson et al. 2008). Unlike diseases of production animals, rabies affects a species of no direct economic value; however, many studies have revealed the true substantial economic impact of rabies resulting from loss of workforce, impact on livestock, and provision of post-exposure treatment (Anderson and Shwiff 2013; Hampson et al. 2015; Shwiff et al. 2013). While pilot initiatives exploring mass dog vaccination implementation must forge ahead without delay, systems to effectively monitor rabies incidence will be critical in shining a spotlight on the true burden of disease to stimulate and sustain political support for widespread control.

The global efforts to eliminate smallpox, polio, and rinderpest, and the more recent action to control COVID-19, have shown that sustained political commitment stimulates and enables scientific advancement to meet priorities. The scientific community continues to gain a deeper theoretical understanding of rabies transmission and control; however, until large-scale government-led initiatives are actioned, the most relevant and critical gaps in knowledge needed to eliminate the disease will remain opaque (Bardosh et al. 2014; Filla et al. 2021; Mpolya et al. 2017; Zinsstag 2013).

Despite these constraints, progress has been made toward greater prioritization of rabies in international agendas through high-level consensus among the scientific community, political advocacy, and core partnerships, culminating in the formation

of the Zero by 30 Global Strategic Plan in 2018 (World Health Organization 2018b). This unified international strategy serves as a single point of reference and guidance as countries consider rabies control as a viable national undertaking.

25.4.2 The One Health Case

The close connection between dogs, their owners, and the communities in which they live make canine-transmitted rabies control exemplary of the One Health concept. Effective control of the RABV both requires and benefits human health, animal health, and environmental management sectors; however, this multi-disciplinary approach presents administrative and managerial challenges at the point of implementation (Coetzer et al. 2016; Lechenne et al. 2017). Funding, operational, and reporting systems are most often structured vertically within government departments, making joint-departmental complex to realize. Success has been seen in the formation of taskforces or intersectoral zoonotic units, which simplify administrative processes for such undertakings (Belotto 2004; Buregyeya et al. 2020).

Domestic dog populations have remained dependent on human habitation, surviving and reproducing due to the resources provided either intentionally or unintentionally by people (Butler and Bingham 2000; Perry 1993). As a result, there is a predictable association between human and dog populations, with expansion in the former providing opportunity for growth in the latter. The size of the canine rabies reservoir species is therefore expected to rise over the coming decades and unless measures are taken to control rabies in dogs, the disease will pose an increasing threat to people. This growing disease burden will also have the potential to drive emergence and re-emergence in wildlife species, as has been seen in mongoose populations in the Caribbean and foxes in Turkey, respectively (Nadin-Davis et al. 2006b; Vos et al. 2009).

The importance of the sustained collective contribution and support from a broad majority of society must not be underestimated in the success of mass immunization programs. Top-down, government-led initiatives can carry the risk of misalignment with the health and social priorities of people most needed to contribute. National dog vaccination campaigns require the mobilization of a huge workforce who must be united in their understanding of the purpose and benefit of the initiative to be able to deliver sustained success. Furthermore, the perceived importance and benefit of such a visibly enormous undertaking to address the singular issue of rabies must be perceived as worthwhile by the general population, whose contribution in facilitating dog vaccination is critical for achieving high vaccination coverage (Bardosh et al. 2014). Grounding the planning and implementation of rabies control efforts within the wider social and cultural context of the local area is imperative. Building relationships and trust with leaders and gatekeepers at the community level provides the opportunity for two-way information exchange, not only helping to improve contribution from important groups of society, but in garnering grassroots feedback to iteratively adjust the campaign strategy in response to concerns and issues.

25.4.3 An Integrated Approach to Bite Management and Rabies Surveillance

In most instances the point of rabies transmission to people is not occult, it involves the violent event of a bite from an infected animal. The requirement for immediate prophylactic intervention at the time of the exposure creates a scenario in which the One Health concept has a direct tangible impact at this interface between animal and human disease.

Bites inflicted by rabid dogs may not constitute a high proportion of bite presentations at medical clinics, making up just 3% of bites in a study in Haiti (Medley et al. 2017). Therefore, health systems indiscriminately administering PEP to all dog bite presentations result in dispensation of vaccine to individuals at no risk of rabies, while people with high-risk exposures may go without treatment due to stock shortages (Lushasi et al. 2020). Methods of integrated bite case management (IBCM) combine veterinary assessment of the biting animal with the human PEP decision-making for post-exposure to improve the prioritization of vaccine to those at risk of rabies infection. This approach has not only been shown to be cost-effective, but also improved compliance in individuals with high-risk exposures to complete the full course of treatment (Etheart et al. 2017; Lushasi et al. 2020; Undurraga et al. 2020).

In addition to the benefits to human health outcomes and economics, the veterinary components of IBCM contribute to the objectives of canine rabies control. In the first instance, active removal of rabid dogs from the population during the animal investigation prevents continued viral transmission and supports the hastened control of the disease in dogs (Laager et al. 2019; Wallace et al. 2015). Additionally, the data generated on canine rabies incidence and distribution provides insight into the burden of disease and forms a basis on which to plan and adapt mass dog vaccination and community engagement strategies. Finally, the increased submission of field samples from suspect rabies cases provides demand and incentive for sufficient laboratory capacity to be developed for timely rabies diagnosis (Lushasi et al. 2020).

Progress has been made to increase access to post-exposure treatment, to reduce human deaths from rabies; however challenges remain in reaching many at-risk individuals (Madjadinan et al. 2020; Sudarshan and Ashwath Narayana 2019). Dose-sparing intra-dermal regimens requiring fewer clinic visits not only reduce the cost to the individual seeking treatment, but also enable existing stocks of vaccine to treat more people (WHO Rabies Modelling Consortium 2019; Hampson et al. 2019; World Health Organization 2018a). These advances in PEP usage, along with improved mechanisms of IBCM will amplify the potential impact of the inclusion of rabies vaccination in the 2021–2025 strategy of Gavi, the Vaccine Alliance (Gavi - the Vaccine Alliance 2021).

25.4.4 Prospects for Rapid Field Diagnosis

Rabies surveillance is a core tenet to rabies control with significance to understanding disease burden, monitoring the efficacy of vaccination activities, and in

validating rabies freedom status (Office International des Epizooties 2021; World Health Organization 2018b). Establishing functional processes for reporting, investigation, and diagnosis of suspect cases are central to the success of rabies surveillance.

Establishing and sustaining the laboratory infrastructure needed for rabies diagnostic tests has been a major barrier to effective surveillance across much of the rabies endemic world. The need for experienced laboratory personnel, specialized equipment, and costly reagents are barriers to building subnational laboratory capacity. Innovations in tests such as direct rapid immunohistochemical test (dRIT) and real time PCR overcome the need for rabies-specific equipment or expertise, respectively (Office International des Epizooties 2021); however, developing regional laboratory testing capacity remains an expensive and resource intensive undertaking.

In addition to laboratory constraints, ensuring the logistical feasibility of sample collection and safe transport to the laboratory is fraught with challenges. From maintaining a secure cold chain during the journey to timely transport links from remote areas, the chances of samples being of diagnostic quality on arrival at the laboratory is minimal. The considerable effort needed to safely take brainstem samples is only worth undertaking if there is a high confidence that a rabies diagnosis will result. And so, when many submitted samples fail to provide timely diagnosis, the rate of submission will invariably be low, which in turn reduces the justification for maintaining laboratory capacity for rabies diagnostic testing. The recent development of cadaver-side lateral-flow diagnostic tests present the possibility of increasing confirmation of the presence of RABV in resource limited settings and in turn may increase the chances of sample submission to laboratories (Yale et al. 2019).

Lateral flow assays (LFAs), also known as rapid immunochromatographic diagnostic tests, are inexpensive, are easy to perform, and do not require expensive equipment (Mauti et al. 2020). Virus is inactivated by the LFA buffer solution and fixed in the test strip during the test and can therefore be shipped to laboratories at ambient temperature for molecular confirmation and genotyping where available. A number of recent evaluations of these tests, however, have highlighted concerns over unsatisfactory sensitivity of all devices tested, with wide variation between manufacturers and batches (Eggerbauer et al. 2016; Klein et al. 2020). Two field evaluations of the Anigen, Rapid Rabies Ag Test Kit manufactured by Bionote Inc, Republic of Korea, reported sensitivities of 95.3% and 96% (Léchenne et al. 2016; Yale et al. 2019). If consistent performance can be demonstrated, LFAs are likely to increase sampling and submission of suspect rabid animals due to the opportunity to gain immediate information and improving the ease of shipping (Léchenne et al. 2016; Yale et al., 2019).

25.4.5 The Complexities of a Dog Population Reservoir

The frequent, unrestricted interaction between free-roaming dogs provides sufficient opportunity for the RABV to transmit through contact during the infectious period and to propagate within the dog population. This epidemiology was exploited in the elimination of canine rabies from the UK by 1902 through enforcement of strict dog

confinement laws (Carter 1997); however such measures are impossible to implement to the degree required to eliminate the virus in modern day endemic settings.

Rabies virus transmission dynamics are influenced by myriad factors of dog demography, ecology, and human behavior; however the basic reproductive number (R_0) for canine rabies, that is, the average number of secondary cases from an infectious individual in a naïve population, is consistently low across numerous settings (Bourhy et al. 2016; Coleman and Dye 1996; Hampson et al. 2009; Hou et al. 2012; Kitala et al. 2001; Zinsstag et al. 2009). Estimated values for R_0 vary between 1.2 and 2.4, as compared to R_0 estimates of 6.9 for smallpox, 15.7 for measles, and 2.87 for SARS-CoV-2 (however these vary considerably by location) (Billah et al. 2020; Eichner and Dietz 2003; Guerra et al. 2017). The proportion of the population that must be vaccinated to impact RABV transmission is therefore low in comparison to other diseases, estimated to be 30–40% of the dog population. Nevertheless, high rates of population turnover rapidly diminish vaccination coverage achieved during a single pulse vaccination effort and human-mediated transport of dogs poses high risk of viral reintroduction from endemic regions, adding complexity to the potential for canine rabies elimination (Hampson et al. 2007; Laager et al. 2019; Layan et al. 2021).

Contact rates between dogs vary within dog populations at the community level, with some dogs posing a greater potential for RABV spread through their increased connectivity within the population (Castillo-Neyra et al. 2017; Hudson et al. 2019; Laager et al. 2019; Leung and Davis 2017). Dog ownership and confinement practices have been shown to influence dog contact networks and therefore may be of significance to both RABV transmission and dog vaccination campaign strategies (Warembourg et al. 2021). It is yet to be determined whether targeting vaccination efforts at subpopulations of dogs estimated to be more connected has a positive impact on RABV elimination or even whether such a campaign would be feasible to implement at scale (Hou et al. 2012; Laager et al. 2019; Leung and Davis 2017).

The role of dog density in sustaining and driving RABV transmission is still unclear. Although the areas of high density may have the highest canine rabies incidence (Laager et al. 2019), there are several examples where these regions have been demonstrated not to be the sole drivers of RABV transmission (Bourhy et al. 2016; Laager et al. 2019; Zinsstag et al. 2017). Furthermore, endemic RABV transmission is supported even at low population densities, with efforts to eliminate the virus through population reduction invariably failing (Hossain et al. 2011; Tenzin et al. 2015; Windiyaningsih et al. 2004). As a result, interventions focused on culling and dog population control are unlikely to be effective at controlling rabies (Townsend et al. 2013); however increasing the lifespan of dogs through dog population management may reduce the loss of immunity and therefore, benefit control efforts (Laager et al. 2019).

25.4.6 Canine Rabies Control at Source

Elimination of the canine RABV has been demonstrated through annual vaccination of 70% of the dog population (Cleaveland et al. 2003; Cleaveland and Dye 1995;

Kitala et al. 2001), which is advocated for as the target for mass dog vaccination campaigns (World Health Organization 2018b) Several examples have reported substantial reductions in incidence following two effective annual campaigns; however the time taken to achieve elimination is dependent upon the dog population size, distribution, connectivity, demography, and vaccination coverage (Brunker et al. 2020; Cleaveland et al. 2003; Ferguson et al. 2015; Zinsstag et al. 2017).

Large-scale, effective campaigns require sustained support over many years to develop from concept and intention through to enduring high-coverage interventions across large expanses of a country (Mpolya et al. 2017; Vigilato et al. 2013a; Wallace et al. 2017). The early stages of development involve field studies generating data about the dog population, refining the campaign strategy, and creating training processes. This is followed by a progressive scale-up of methods in which logistical, administrative, and operational challenges must be overcome. Finally these activities are sustained with continued evaluation to impact of RABV transmission over a large area (Wallace et al. 2017).

25.4.7 Approaches to Mass Dog Vaccination

Parenteral dog vaccination approaches include central point (CP), door-to-door vaccination (DDV), and capture-vaccinate-release (CVR). From CP, to DDV and CVR, the approaches increase in intensity from aspects of cost per vaccination team unit, campaign logistical complexity, and human resource requirement. Each approach has advantages in accessing particular demographics within the dog population and so the approach, or combination of approaches selected for a mass dog vaccination campaign, must be matched to the makeup of the local dog population to achieve the desired immunization coverage at the lowest cost and effort (Undurraga et al. 2020). Tools have been developed to aid campaign planners in the exercise of programmatic alchemy required to design the optimal campaign strategy (Mazeri et al. 2021; Wallace et al. 2019). A vaccination campaign that fails to immunize a sufficient proportion of the dog population to interrupt enzootic rabies transmission has limited benefit other than to build expertise, experience, and infrastructure. Therefore, campaign implementation should remain an iterative process of reflection and refinement, adapting and intensifying in areas where insufficient coverage is achieved or surveillance data indicate that rabies is persisting (Mazeri et al. 2021).

Dog ownership offers an opportunity to confine dogs at periods, both to limit the risk of RABV transmission and also to avail of opportunities for vaccinations. In such settings communities can be engaged to bring dogs to temporary central vaccination points for inoculation. Mobilizing the general populous into a dog transportation workforce in this way has huge efficiency savings at the campaign level and was the basis for the vaccination of over 15 million dogs in Mexico during 1 week every year in the early 2000s (Velasco-Villa et al. 2017a). Similar CP approaches have been used to achieve high vaccination coverages in African cities of Chad and Malawi; however, these are yet to be expanded to the national level (Gibson et al. 2015; Lechenne et al. 2016; Mazeri et al. 2021; Mpolya et al. 2017; Zinsstag et al. 2017).

CP strategies fail to achieve sufficient vaccination coverage in areas where a high proportion of dogs are unowned or where dog owners are unable or unwilling to bring them to CP vaccination clinics during the campaign (Muthiani et al. 2015; Tohma et al. 2016). With awareness of the vaccination campaign being a major reason cited for lack of turn-out to CP clinics, mass SMS messages were recently demonstrated to be of benefit in broadcasting campaign dates and locations (Cleaton et al. 2018). In another recent study, the strategic adjustment of the distribution of CP clinics enabled vaccination coverage to be increased in an urban setting of Malawi, dramatically increasing campaign efficiency (Mazeri et al. 2021). Where the coverage of CP vaccination cannot be increased to the required level, more costly and resource-intensive methods of Door-to-Door vaccination (DDV), either in combination with CP or alone may be required and has been demonstrated to be effective in a number of African settings, where most dogs are owned and can be manually restrained for parenteral vaccination (Jibat et al. 2015).

In contrast to many areas of Africa, dog populations of Asia often comprise a higher proportion of unowned dogs (Gibson et al. 2015; Sánchez-Soriano et al. 2019; Sudarshan et al. 2001). As a result, CP and DDV methods, relying on the manual restraint of dogs by their owner, are ineffective at achieving sufficient vaccination coverage throughout the population (Belsare and Gompper 2013). CVR strategies using highly skilled teams to catch large numbers of dogs using nets has been shown to access 70% of dogs; however such resource-intensive approaches are unlikely to be feasible for national implementation in the short term (Gibson et al. 2020).

The ability to efficiently immunize dogs that are not amenable to handling has consequently become a central barrier to scaling dog vaccination efforts in these areas and has reignited discussion on the use of oral rabies vaccination (ORV) of dogs (Cliquet et al. 2018; Gibson et al. 2020; Wallace et al. 2020). Global health authorities have renewed their support for this well-established tool for rabies control to be used in conjunction with parenteral vaccination approaches in mass dog vaccination campaigns (Wallace et al. 2020). The efficacy of ORV in dogs has been demonstrated in a number of locations, both from immunological and operational perspectives (Chanachai et al. 2021; Gibson et al. 2019; Smith et al. 2019b), and the improved safety profile of modern third generation modified live ORVs would enable the investigation of ORV campaign strategies in urban settings (Head et al. 2019).

25.4.8 Dog Vaccination Campaign Evaluation

The vaccination coverage achieved by a particular vaccination method, or combination of methods, will be affected by the composition of the local dog population, community engagement, and sociocultural factors. During the initial phases of campaign development, it is beneficial to evaluate vaccination coverage to assess the efficacy of a particular vaccination approach in a specific locality (Sambo et al. 2017). This enables the strategy to be refined in the short term to reach a target vaccination coverage across much of the population and thus increase the chances of achieving the objective of rabies control. Ultimately the vaccination requirement to successfully control rabies at the community level will vary depending on local

epidemiological factors, with viral elimination occurring at lower coverages in some areas than others. Therefore, monitoring canine rabies case incidence through robust surveillance is essential for guiding vaccination strategy through the course of a control effort, determining regions where vaccination must persist or be intensified and areas that have achieved elimination.

Homogeneity of vaccination coverage across a region is thought to be of central importance to the successful local elimination of the canine RABV. A "Swiss-cheese" appearance to vaccination penetration across the dog population of a region (heterogeneous coverage) allows for sustained RABV transmission within unvaccinated pockets of dogs. This persistence of the virus through the vaccination campaign undermines prospects for elimination through rapid reintroduction into vaccinated areas as coverage wanes (Ferguson et al. 2015; Kitala et al. 2002; Townsend et al. 2013).

Mobile technologies and internet connectivity are transforming capabilities for communication and data sharing to benefit public heath interventions, with the term mHealth referring to systems in this space (World Health Organization 2011). Several tools have been developed to support the spatial coordination of dog vaccination workforces, with the specific focus of improving vaccination coverage homogeneity and robust post-vaccination evaluation (Gibson et al. 2018). These tools also improve the ability to capture high-resolution campaign data, at the individual dog, including time, date, GPS location, and demographic data offering deeper insights into campaign output, efficiency, and operational effectiveness (Athingo et al. 2021). The considerable resources required for the centralization and aggregation of campaign data using paper-based approaches are eliminated, as data are immediately available for remote review in a standardized digital format upon upload to a central server. The timely availability of granular operational data make it possible for campaign planners to redirect vaccination team movements during the course of a campaign (Gibson et al. 2015) as well as between campaigns (Mazeri et al. 2021) for maximum effect. This real-time oversight of field data was pivotal to the successful coordination of a multinational response to a rabies outbreak at the border of Haiti and the Dominican Republic in 2019 (Adrien et al. 2019; Mandra et al. 2019). The benefits of mHealth are also being applied to rabies surveillance systems to support the intersectoral sharing of information for efficient investigation and management of suspect rabid animals (Lushasi et al. 2020; Mtema et al. 2016).

25.4.9 Conclusion

The COVID-19 pandemic has shown the huge effort and expense that governments will expend and the disruption they will impose on their citizens to control a disease that has a broad impact on society. Rabies has been perceived by key decision makers not to be worth the investment in resources required to control it. However, with increased experience from implementing mass dog vaccination at scale enabling improvements in operational efficiency, while improving visibility of the significance of rabies control through improved surveillance, it may be possible to

bring rabies control into the realms of political feasibility. Ultimately a greater awareness of the global and individual human impact of canine rabies is needed and as global momentum builds through initiative such as ZeroBy30, the question of whether ours will be the generation to write history on global canine rabies control will need to be answered.

25.5 Road Blocks on the Way to Global Elimination of Dog-Mediated Rabies[4]

25.5.1 Introduction

Rabies is widely recognized as a public health threat in large parts of the globe, most markedly in Asia (Kole et al. 2014; Miranda and Miranda 2020) and Africa (Haselbeck et al. 2021; Sabeta and Ngoepe 2018). Human rabies, despite being preventable with existing tools, still claims an estimated 35 000–60 000 lives annually (Hampson et al. 2015). Even though these deaths could be prevented using post-exposure prophylaxis (PEP), the high costs for human vaccines as well as limited availability of these biologics are prohibitive to this solution. The elimination of rabies at its source – in over 95% of human cases, rabid dogs – is of a higher benefit both from an economical and a sustainability point of view. The elimination of canine rabies is considered a feasible objective (Lembo et al. 2010), although the RABV is characterized by multiple hosts and a range of variants (Rupprecht et al. 2008). The example of Latin America (Del Rio Vilas et al. 2017), as well as national and local efforts in other endemic regions have proven this principle (Le Roux et al. 2018; Mpolya et al. 2017; Lionel Harischandra et al. 2016). The international community, with more than 100 endemic countries, has set a global target of reaching zero human deaths from dog-transmitted rabies ("Zero by 30") worldwide by 2030 (Minghui et al. 2018). Through these efforts, health decision makers are increasingly aware that this fatal disease could be eliminated as a public health problem cost effectively in a relatively short time (World Health Organization 2015c; Shwiff et al. 2013; WHO and OIE 2016). As of today, however, rabies remains neglected in many places and progress remains slow on a global scale; the disease still being endemic in far more than 100 countries globally (Wallace et al. 2017; Fahrion et al. 2017).

This section describes some frequently cited main constraints to the prevention and elimination of dog transmitted rabies. It has to be recognized that most of the topics mentioned in this chapter are interconnected and fit under more than one subheading. For example, the presence of basic financial means is essential for any initiative, not to mention for running a program, and directly associated with the awareness and will of (political and financial) decision makers. Therefore, other

[4] Author: Anna Fahrion. Of note, this section contains extracts from last edition´s section, "What hampers global human rabies elimination?" by Tiziana Lembo, Lea Knopf, and Deborah J Briggs.

points mentioned here cannot be regarded in separation from the funding issue. The same is true, e.g., for the implementation of a One Health approach.

25.5.2 Awareness and Political Will

Rabies imposes huge burdens on individuals, families, societies, and economies (Hampson et al. 2015). Awareness of the disease is necessary to promote the ambitious but feasible goal of ending human rabies deaths, but is often lacking, on different levels and layers throughout society. Rabies needs to be on the agenda of politicians and decision makers globally, nationally, and locally, but this depends on and is intertwined with public perception and societal awareness. As communities become more aware of the threat and burden through dog rabies, political pressure to act will accumulate and raise the prestige of such activities. Champions at all hierarchy levels who directly advocate for the cause can make a significant difference (Balaram et al. 2016; World Health Organization 2015c). Building a proactive society, fully engaged in the dog rabies elimination efforts, through community involvement and education on rabies is therefore essential in mobilizing a country toward the elimination of rabies.

25.5.3 Public and Society

25.5.3.1 Low Awareness and Education in the Public/Community Engagement

Many unnecessary human rabies deaths occur because of insufficient awareness on effective post-exposure preventive measures at the community level, which is particularly marked in very remote areas. Increasing awareness about how to avoid and treat rabies exposures can therefore save lives. This has been successfully achieved by involving communities in the prevention and control process (Hampson et al. 2008). However, questions remain regarding the most effective avenues to reach communities at risk. For instance, while it is recognized that children are an important risk group (Kilic et al. 2006), uncertainties remain about the type of interventions that may be most effective for this audience. The emphasis so far has been on school-based interventions (Lapiz et al. 2012), despite the fact that in remote rabies-endemic areas non-schooled children still represent a large proportion of the community. Furthermore, interventions at the school level rarely involve parents, who are likely to play an important role in shaping children's health behavior, or key community members (e.g., community leaders), despite their potential role in encouraging community participation in rabies management initiatives. In many cases, efforts to raise public awareness mainly consist of promoting rabies information, but its translation into the desired behavioral changes remains unclear. Therefore, it is recommended to design communication strategies using the science of behavioral change, embracing the diversity of behavioral drivers, motivations, and larger sociocultural context of the targeted audience (Fahrion et al. 2017).

25.5.3.2 Companion Animal Health Issues Are Considered Low Status Activities in Rabies Endemic Countries

It has to be considered that in many rabies-endemic countries, the capacity within veterinary services is highly limited, especially when it comes to companion animals, given the greater focus on livestock health and agricultural problems. This problem could be overcome by providing training and support for veterinary services to handle dogs and dog diseases – resources and knowledge to run vaccination campaigns, however, can hardly be provided by veterinary services alone (see also sect. 25.5.10). Another challenging issue to address is that for most veterinary and medical professionals in Africa and Asia interventions involving domestic dogs are viewed as low status because they target an animal species of no economic value and an underrepresented segment of the human population, the rural poor. Yet, lessons can be learnt from areas of the world, such as Latin America, where national elimination programs led by an influential government sector (public health) have resulted in dramatic declines in human and canine rabies (Schneider et al. 2007).

25.5.4 Political Leadership

25.5.4.1 Lacking Prioritization at High Level Decision-Making

Community-level awareness alone is not sufficient to improve the rabies situation. There is also a need for commitment on the policy-making level to support the transition toward freedom from human rabies in a cohesive way (Fahrion et al. 2017). Too often, diseases of the rural poor slip the attention of political leadership and therefore face limitations in prioritization, leading to lacks of institutional and programmatic anchoring in the veterinary and public health systems, accompanied by lacking resource attribution. This issue is complicated by the necessary involvement of different sectors increasing the complexity of organization (see: intersectoral collaboration) and the lack of reliable numbers and data (see: surveillance). Increasing the awareness of political leaders and decision makers about the horrible fate of rabies victims, the high number of children affected, the well-known and proven principal interventions and their relatively rapid onset of measurable effects, as well as the potential benefit on other zoonotic diseases and on national, regional, and international recognition could make the case and raise the pressure for more engagement.

25.5.5 Surveillance, Data, and Diagnostics

One important key toward building awareness and investment of resources for a disease is recognition and prioritization by political leadership (Mangen et al. 2010). To this end, it is key to demonstrate the impact it has on public health and the economy and the potential benefit of targeting the disease. Very often, the true scale of the human disease problem on local communities and national economies (as stated by Knobel et al. 2005) is still unknown or ignored by high-level policy-making bodies. This might be due to insufficient science communication and simply

due to the fact that rabies is a neglected disease of the poor, with an animal reservoir often seen as "low status" and as a veterinary issue in the first place.

25.5.6 Underreporting

A lack of surveillance and diagnostic capacity is an enduring issue in regions of the world where the highest number of rabies deaths occurs. As a disease most of the times occurring in the remotest and poorest parts of the population that do not have a voice (Hampson et al. 2008), rabies deaths often go undiagnosed and unreported. It is estimated that human rabies deaths are commonly underreported 100-fold (Taylor et al. 2017a; Scott et al. 2017). This absence of solid evidence induces a cycle of neglect: because of the resulting underreporting and under-diagnosis, rabies is falsely perceived as an insignificant health issue leading to low priority, hence further neglect (Taylor and Nel 2015). Vice versa, a surveillance system that delivers better data, flowing from local authorities up to the international level is a precondition to increased awareness. In the presence of data, where quantitative assessments or prioritization exercises have been run, rabies consistently came up among the priority zoonotic diseases in different geographic locations (Yasobant et al. 2019; Sekamatte et al. 2018; Salyer et al. 2017). A way to formally establish reporting is declaring a disease notifiable (Taylor et al. 2015) as advised by OIE. For reasons of practicability and cost effectiveness, it seems advisable to integrate reporting on well-described rabies indicators solidly into the functionality of the general national surveillance system. Where the reporting happens in an isolated manner, without a clear data flow mechanism and dependent on individual's personal motivation, it is not likely that the data chain can work reliably. Often, a lack of such integrated surveillance systems, involving both the central- and local-level human and animal health sectors, remains a key gap in surveillance capacity in developing countries (Banyard et al. 2013; Molyneux et al. 2011).

25.5.7 Limited Diagnostic Capacity for Reporting According to International Standards

Testing animals to confirm rabies cases allows for better decision-making on the follow-up of human exposures and can generate data for program evaluation. In humans, diagnostics can yield results only by the time of disease manifestation, therefore limiting the purpose of testing to case confirmation either *intra vitam* or *postmortem*. Due to sophisticated laboratory requirements, the reference fluorescent antibody test is not an option in many rabies endemic settings. To this end, simplified techniques requiring less specialized equipment such as Direct Rapid Immunohistochemical Test (Dürr et al. 2008) and lateral flow devices have been developed, even though quality of these may be uncertain (Klein et al. 2020). However, international standards for rabies surveillance and evaluation of interventions are entirely reliant on laboratory confirmation of cases postmortem, which requires the establishment of rigorous systems for the collection and submission of

samples, and adequate laboratory infrastructure and capacity to perform rabies diagnostics (Meslin et al. 1999; Fooks et al. 2009; Banyard et al. 2013). On the other hand, the reality is that very few countries in rabies-endemic areas are likely to meet global surveillance and diagnostic standards in the foreseeable future and this should not further delay the implementation of large-scale rabies elimination programs. Approaches based on clinical case finding by local communities were the primary surveillance tool in the final stages of rinderpest eradication (Mariner et al. 2012; Mariner and Roeder 2003). Given the distinctive nature of rabies, recognition among local communities in affected areas is high (Hampson et al. 2009) and therefore participatory surveillance has the potential to play a key role in assessing the impacts of rabies interventions. Efforts should therefore be made to provide affected communities with user-friendly tools for rapid case reporting (using, for example, mobile phone technologies (Gibson et al. 2018)), and to shift the focus from laboratory-based surveillance as the sole means to evaluate intervention efforts.

25.5.8 Coordination and Implementation

25.5.8.1 Lack of Intersectoral Collaboration

The key justification why rabies is a prime example of a disease that needs to be resolved through applying a One Health approach lies in the realization that the one key strategy to avoid human deaths is interrupting transmission through the reservoir: by dog vaccination (Cleaveland and Hampson 2017). In other words: generating human public health benefits from a veterinary intervention. If a veterinary perspective is not included from the beginning, public health deciders too often ignore the economic savings from dog vaccination over just providing PEP to humans as they are used to focus solely on supplying the human population with medical treatment. However, providing PEP without interventions on dogs is expensive and purely symptomatic, lacking any perspective of sustainable improvement of the situation. Building the body of evidence by demonstrating the cost-beneficial impacts of dog rabies control due to reduced expenditure on costly human post-exposure vaccines is an important step toward the integration of budgets across ministries so to ensure sustained financial support (Hampson et al. 2011; González-Roldán et al. 2021). Beyond the veterinary and public health sectors, close involvement of social sciences, the education sector, and municipalities is now equally recognized (Srinivasan et al. 2019), for example, as a powerful method for preventing dog bites in children, increasing knowledge and awareness about rabies, and in sustainably managing dog populations in affected communities (Lapiz et al. 2012).

The effectiveness of intersectoral strategies for canine rabies elimination has been proven, e.g., in the Americas (Laing et al. 2020; Vigilato et al. 2013a) and elsewhere (Léchenne et al. 2021; Pudjiatmoko and Kadun 2013; Changalucha et al. 2019; Lushasi et al. 2020). While in general, the benefits of a One Health approach are more and more recognized at the highest international level (Seifman and Kaplan 2021), One Health operationalization at national or local levels remains a challenge

in many countries. The bottleneck frequently seems to be the question how to adjust existing systems and habits to realize working in an intersectoral manner (Belot et al. 2021). Given the nature of rabies, the responsibility for its control should be borne by a broad range of sectors. However, the range of "players" that ought to be involved makes operationalization problematic because of difficulties in harmonizing administrative and management structures and budget lines across sectors, and planning and implementing joint financing mechanisms involving different ministries (Jerolmack 2013). The creation of intersectoral zoonotic units or task forces, and integrating intersectoral processes in national rabies plans and guidance from the beginning, can help crossing these burdens. Integrated bite case management (IBCM) is an example of a locally implemented coordinated activity (Lushasi et al. 2020). Various international and national efforts exist to strengthen intersectoral, One Health collaboration. One example is the so-called IHR-PVS National Bridging Workshops (Belot et al. 2021). This methodology is currently being adapted specifically for rabies to enable countries to improve and strengthen the intersectoral network and collaboration at significant technical areas, providing them with a better organizational equipment to tackle the disease under a One Health approach.

25.5.8.2 Lack of Cohesive and Strategic Implementation Guidance

While challenges of One Health operationalization are often located at subnational levels (Munyua et al. 2016), it is the National authorities who prepare the ground for the general direction of rabies control and elimination efforts as well as the way the sectors will work together, by deciding on the national approach and its implementation. The authorities are mainly responsible for developing national strategies and implementing programs, but can easily be overwhelmed by multiple human and animal disease priorities and the challenges associated with programs stretched across sectors and administrative levels (Fahrion et al. 2017). A range of tools and materials that provide guidance are available but may lack cohesion, complicating the selection of a starting point and the most crucial measures to implement. For example, the Stepwise Approach Toward Rabies Elimination (SARE), which is embedded in the rabies blueprint (Global Alliance for Rabies Control), is a guidance and evaluation tool that has been used by countries across three continents, mostly at national or regional stakeholder consultations, to kick-start coordinated rabies control (Coetzer et al. 2016). More recently, additional tools and international mechanisms have been added and continue to evolve (United Against Rabies Collaboration 2019).

25.5.9 Challenges of Cross-Border Collaboration

Rabies, as other pathogens, does not stop at borders. For transboundary diseases, cross-border collaboration, cooperation, and transparency can only be of benefit for disease control. However, admittance of public health problems being perceived as "failures," authorities might tend not to share information with their neighbors (Fahrion et al. 2017). This represents a missed opportunity to address potential

transboundary issues and more general, bilateral or multilateral collaboration to jointly tackle infectious diseases, catalyzing more awareness and activity and an expanding, more sustainable approach. On a larger scale, regional approaches have been fundamental for the most successful rabies control and elimination efforts, e.g., in Western Europe (World Health Organization 2018b) and Latin America (Vigilato et al. 2013a. b). Regional efforts are also being undertaken in other parts of the world (Miranda and Miranda 2020; Pieracci et al. 2017; Taylor et al. 2021; Scott et al. 2015) and will continue to require strong commitment.

25.5.10 Issues Related to Dog Vaccination

Rabies is integrally linked to the proximity and the ways people and dogs live together. Most of the constraints around rabies elimination can be understood when taking a look at what is recognized as the single, most effective intervention to prevent and control transmission: dog vaccination. The constraints around this one key activity demonstrate the entire significance and difference that a true One Health approach could make if fully implemented: as a primarily veterinary intervention, dog vaccination is not firmly rooted in public health awareness, often underfunded and understaffed, linked with difficult logistics, research gaps and a need for high level of perseverance to make it sustainable.

Rabies control requires an adequate understanding of the dog ecology and dog-keeping practices in a country in locally differing sociocultural contexts (e.g., urban vs rural, among different economic, religious, or ethnic groups). Achieving the 70% dog vaccination coverage that is recognized to provide herd immunity (Conan et al. 2015) is often hampered by rapid population turn over, partly despite dog population management attempts (Taylor et al. 2017b). As rabies threatens communities, the fear of rabies also leads to unnecessary cruel treatment of dogs such as culling (Hiby et al. 2017). Especially free-roaming dog population act as drivers of rabies transmission cycles (Gamble et al. 2018), a population that has a growing tendency especially in connection to progressing urbanization (Krystosik et al. 2020). The problem is further aggravated by the associated increased solid waste production and mismanagement of waste disposal where dogs are attracted in high numbers and compete for food, increasing the risk for aggressive behavior (Wright et al. 2021). Proper management of poorly managed garbage disposal sites and landfills certainly benefits a broad range of public and veterinary health issues and should therefore be prioritized by the responsible authorities. When implementing dog vaccination campaigns, knowledge of the local dog population is essential (Gamble et al. 2018). In circumstances where dogs are privately owned or community owned, it might be the case that almost all dogs can be handled and vaccinated by the parenteral route (Morters et al. 2014) despite being free roaming. In other cases, inaccessible dogs may jeopardize vaccination coverage. Empirical work (e.g., on area-specific basic reproductive ratio (R_0)) suggests that vaccination strategies and coverages should be adapted to the local context to control rabies successfully. High vaccination coverage in high-risk areas may be more crucial than medium coverage across the whole country, but clear guidance on this is lacking. Better knowledge of area and country-

specific factors related to dog keeping practices, dog population turnover, and contact rates between dogs and wildlife can help in determining a more flexible, realistic required dog vaccination coverage (Sparkes et al. 2014). Research on oral rabies vaccination has recently delivered increasing evidence to be a well-suited complement to parenteral rabies vaccination activities in different contexts, especially with free roaming dogs (Gautam et al. 2020; Wallace et al. 2020).

25.5.11 Limited Availability of and Access to Rabies Biologicals

In addition to the problem that dog bite victims might not be aware of a potential rabies risk (see: awareness and political will), a common constraint following a potentially rabid dog bite is that of inaccessibility or unaffordability of rabies biologicals (Hampson et al. 2011). The fact that a course of rabies PEP, combined with potentially long travel routes to get the vaccine, just exceeds the household´s resources, remains a bitter truth for many. Newer developments to fill this gap including shortened PEP regimens (requiring fewer health facility visits), changed recommendations toward vaccine-saving intradermal administration and new technologies such as thermostable vaccines and monoclonal antibodies could contribute to alleviate the problem (see part on human prevention). However, a broad, general change toward better supply and distribution of these biologicals warrants systematic improvement of universal health coverage. A global push in these discussions and a decisive, facilitating shift for many countries seems possible through the recent uptake of human rabies vaccine on the portfolio of Gavi, the Vaccine Alliance (WHO Rabies Modelling Consortium 2019) (Mohammadi 2016). On the manufacturing level, an absence of accurate forecasting data on vaccine needs impairs production and procurement and can lead to shortages of stock and impaired long-term planning (Wallace et al. 2017). (Interrupted delivery chains in turn could cause countries to purchase at a higher cost or to turn to manufacturers not meeting international vaccine quality standards.) Vaccine banks or stockpiles at regional levels as managed by OIE or WHO have become a solid mechanism for countries to maintain the supply of quality-assured vaccines and allow manufacturers to forecast and stabilize their production over years with lowered pricing through bulk purchase (WHO and OIE 2015). Vaccine banks have contributed demonstrably to the scaling up and maintenance of local, national, or subregional programs in Asia and Africa (World Health Organization 2015a) and incentivized recipient countries to increase data collection, as reporting on vaccine use and results is required (Fahrion et al. 2017).

25.5.12 Funding and Sustainability

Like with all veterinary and public health issues, allocation of resources and the lack thereof is to be considered a root cause for the barriers to advance toward elimination of this horrifying disease that should be consigned to the history books (M. Chan, Director General of WHO (World Health Organization 2015b). It can be hoped that

the investment case will become more and more obvious to countries with the realization that investing, e.g., in dog vaccination is cost effective (Shwiff et al. 2013) (Anderson and Shwiff 2013). Setting up rabies programs and improving surveillance for rabies, integrated with other diseases and interventions, provides multiple public health benefits and strengthens the veterinary and public health systems in their entirety. Savings that can be made to reduce running costs, e.g., for PEP, such as intradermal vaccine administration, have been mentioned above. Private–public partnerships might provide ways to fund rabies control for countries (Taylor and Partners for Rabies Prevention 2013). Internationally, while there is no single pooled fund for rabies elimination and investments are small and fragmented, the United Against Rabies Forum has been set up as a platform, among other tasks, to secure funding resources from the international community (United Against Rabies 2021). However, it is up to countries to understand that investment in rabies is a long-term, but potentially highly cost-beneficial commitment, bringing along significant improvements to public health and to the life of people.

source of zoonotic transmission until now, the spectrum of chlamydial zoonoses has broadened in recent decades.

In the present chapter, we summarize current knowledge on etiology, pathology, epidemiology, and genomic markers of zoonotic chlamydial infections. In particular, *Chlamydia (C.) psittaci*, the agent of avian chlamydiosis, is continuing to affect human individuals in contact with birds. Clinical signs can range from flu-like to those of severe systemic illness. *C. abortus*, a pathogen causing enzootic abortion in small ruminants, was repeatedly shown to be responsible for cases of human abortion. *C. caviae*, an agent of ocular disease in guinea pigs, is known to have caused conjunctivitis in guinea pig owners. Also *C. felis*, which can cause acute and chronic conjunctivitis in cats, has a zoonotic potential and was associated with ocular disease in contact persons.

We outline the main characteristics of the agents' animal reservoirs, describe transmission routes, and summarize recent reports on outbreaks and individual cases of human infections by *Chlamydia* spp. The relatively low number of officially notified cases is probably due to underdiagnosis, since *C. psittaci* and other chlamydiae are usually not part of routine diagnosis in human medicine. As research in the past decades has led to the extension of the genus *Chlamydia* to 14 species and 4 taxa at *Candidatus* rank, the scope of zoonotic agents can be expected to rise in the future.

Chlamydia psittaci · *Chlamydia abortus* · *Chlamydia caviae* · *Chlamydia felis* · Zoonosis · Transmission route · Human disease · Atypical pneumonia · Abortion · Conjunctivitis · Genome analysis

26.1 Introduction

Bacteria of the family *Chlamydiaceae* are defined as "coccoid, non-motile, obligate intracellular organisms of 0.2–1.5 μm diameter that reside in vacuole-like inclusions of eukaryotic cells, where they parasitize and multiply in a unique developmental cycle" (Sachse et al. 2015a). In the course of that cycle, chlamydiae appear in two different morphological forms, the small infectious elementary body (EB) and the larger intracellular reticulate body (RB). EBs enter the host cell using different routes involving various receptor molecules. Once within the cell, they initiate the formation of a vacuole-like inclusion, where they multiply in the RB form through binary fission. Finally, while RBs are transforming back into EBs, it comes to rupture of the inclusion with the release of newly infectious chlamydiae.

The fact that *Chlamydia* spp. rely on eukaryotic cells to survive and proliferate was always a great obstacle to culture and *in vitro* studies. While the first successful isolations of chlamydial strains were achieved in embryonated chicken eggs, nowadays cell culture is widely used in research and diagnostic laboratories.

Until very recently, all known species of the family *Chlamydiaceae* were taxonomically classified in a single genus *Chlamydia*, which currently comprises 18 species, among them four at *Candidatus* rank. Basic characteristics of these bacteria are given in Table 1.

Table 1 Basic characteristics of currently known *Chlamydia* spp.[a]

Species	Main hosts	Clinical manifestations	Zoonotic potential
Chlamydia abortus	Ruminants, swine	Abortion[b], vaginitis, endometritis, seminal vesiculitis, (latent) mastitis	Yes
Chlamydia avium	Pigeon	Enteritis and respiratory disease (link to pathology still uncertain)	Unclear
Chlamydia buteonis	Hawks	Conjunctivitis, respiratory disease (link to pathology still uncertain)	Unclear
Chlamydia caviae	Guinea pig	Conjunctivitis[b], keratitis, pneumonia[c]	Yes
Chlamydia felis	Cat	Conjunctivitis[b], rhinitis	Yes
Chlamydia gallinacea	Birds	No apparent pathology yet described	No
Chlamydia muridarum	Mouse, hamster	Pneumonitis, ileitis	No
Chlamydia pecorum	Ruminants Swine Koala	Encephalitis, polyarthritis, pneumonia, enteritis, vaginitis, endometritis Polyarthritis, serositis, enteritis, pneumonia Keratoconjunctivitis, vaginitis, ovarian cyst, infertility	No No No
Chlamydia pneumoniae	Koala, other marsupials, Horse	Rhinitis, pneumonia, conjunctivitis	No
	Reptiles, amphibians	Conjunctivitis, enteritis, granulomatous inflammation of internal organs	No
Chlamydia poikilotherma	Snakes	No apparent pathology yet described	No
Chlamydia psittaci	Birds Horse	Conjunctivitis, pneumonia, atypical pneumonia[b], enteritis, hepatitis Abortion, pneumonia[c]	Yes Yes
Chlamydia serpentis	Snakes	No apparent pathology yet described	No
Chlamydia suis	Swine	Conjunctivitis, pneumonia, enteritis, polyarthritis	Under debate
Chlamydia trachomatis	Human	Genital tract infections, ocular disease (trachoma)	No
Ca.[d] Chlamydia corallus	Snakes	No apparent pathology yet described	No
Ca. Chlamydia ibidis	Birds	No apparent pathology yet described	No
Ca. Chlamydia sanzinia	Snakes	No apparent pathology yet described	No
Ca. Chlamydia testudinis	Tortoise	Conjunctivitis, nasal discharge (link to pathology still uncertain)	No

[a]Adapted from reference (Sachse and Borel 2020)
[b]In both animal and human infection
[c]In cases of zoonotic transmission
[d]*Candidatus*

The most important members include the human pathogens *Chlamydia (C.) trachomatis*, *C. pneumoniae*, and the zoonotic agent *C. psittaci*, as well as *C. abortus, C. caviae*, and *C. felis*, which also have a zoonotic potential. Current knowledge on sources and reservoirs of zoonotic transmission of *Chlamydia* spp. is given in Fig. 1.

In 2021, new members of the family *Chlamydiaceae* were presented, when Vorimore et al. (Vorimore et al. 2021) defined the new genus *Chlamydiifrater*. These authors were able to show that their new chlamydial isolates from flamingos belonged to the species *Chlamydiifrater phoenicopteri* and *Chlamydiifrater volucris*, respectively. While the etiologic importance of these new taxa is still unknown, it seems certain that wild birds may harbor a large variety of yet unknown chlamydial organisms.

One of the main disease manifestations of zoonotic infections in humans is the so-called community-acquired pneumonia (CAP), defined as pneumonia acquired outside the hospital. CAP can be of zoonotic or non-zoonotic (*Chlamydia pneumoniae*, *Mycoplasma pneumoniae, Legionella pneumophila*) origin. Among atypical agents of CAP, the zoonotic pathogens *Chlamydia psittaci* (avian chlamydiosis, psittacosis, ornithosis), *Francisella tularensis* (tularemia), and *Coxiella burnetii* (Q fever) often remain undetected, because they are not included in routine procedures of human microbiology laboratories. *C. psittaci* is a rare cause of CAP (approximately 1%, Hogerwerf et al. 2017) but often remains undiagnosed because of the lack of rapid and accurate diagnostic methods in human microbiology laboratories. Underdiagnosis of this zoonosis is a serious problem as this may delay or prevent appropriate therapy. Moreover, the professional guidelines recommend beta-lactam antibiotic therapy for clinically diagnosed CAP, which is not effective against *C. psittaci*. Veterinarians and physicians are the key professionals to recognize and report zoonotic events; however, a lack of communication between these two healthcare fields often delays or even prevents the timely workup of such cases.

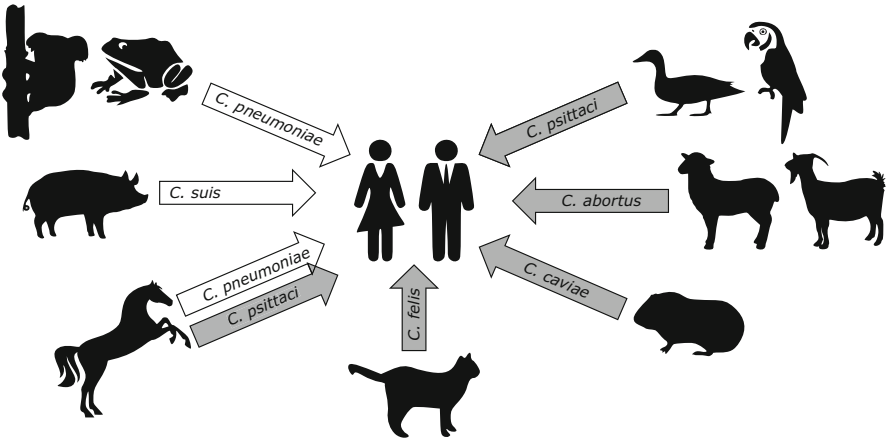

Fig. 1 Schematic presentation of zoonotic reservoirs and transmission routes of *Chlamydia* spp. Filled arrows, proven zoonotic transmission; empty arrows, zoonotic potential under debate

Current knowledge on chlamydial infections in animals and their zoonotic implications was compiled in a recent review (Sachse and Borel 2020). In the present chapter, we focus on those chlamydial species that have a proven zoonotic potential and discuss a few more whose status in terms of zoonosis is still uncertain.

26.2 Epidemiology of Zoonotic Infections in Animals

26.2.1 *Chlamydia psittaci*

C. psittaci, the causative agent of avian chlamydiosis and human psittacosis, is probably the most important veterinary chlamydial pathogen from economic and sanitary viewpoints.

This bacterium is disseminated worldwide, with birds representing its natural host. It was encountered in 9 domestic fowl species and at least 460 free-living or pet bird species of 30 different orders (Kaleta and Taday 2003).

Transmission of *C. psittaci* occurs through inhalation or ingestion of infected dust particles, as well as nasal and ocular discharges and droppings from infected birds. Many factors on both pathogen and host side can influence the course of infection, which is known to cover all stages from acute to chronic to subclinical. The acute form is more often observed in young birds, whereas adult birds tend to develop milder forms. Affected birds show signs of respiratory disease, conjunctivitis, coryza, mucopurulent discharge from nose and eyes, cough, dyspnea, or greenish to greyish feces, none of which can be regarded as specific. Generally speaking, subclinical or latent infection occurs more frequently than acute cases and outbreaks (Sachse et al. 2015b; Vanrompay 2013). Characteristic features of the various forms of avian chlamydiosis are summarized in Table 2.

Historically, chlamydial infections first gained public attention in the second half of the nineteenth century, when many cases of atypical pneumonia among the human population occurred in Europe and North America (Hegler 1930; Lepore 2009; Meyer and Eddie 1935; Ritter 1879). The larger outbreaks were associated with the arrival of parrot shipments from South America (see section below). Due to

Table 2 Characteristics of the disease course of avian chlamydiosis in birds[a]

Course	Incubation time (d)	Duration of disease	Symptoms
Acute (lethal systemic form)	3–7	8–14 d	Anorexia, apathy, dyspnea, diarrhea
Subacute to protracted	7–14	>3 weeks	Milder clinical signs of anorexia, apathy, dyspnea, diarrhea
Chronic	30–90	>2 months	Apathy, cachexia, diarrhea, dyspnea
Subclinical persisting	None	None	No clinical signs
Activated persisting	>3 months	>2 months	Clinical signs of chronic course (after activation by endogenous and exogenous factors)

[a]Modified from (Taise 2013)

crowding and poor housing conditions during the passage, the infectious agent (still unknown at that time) could spread unimpededly among the birds, so that many of them died while survivors transmitted the infection to humans. Meanwhile, fulminant and devastating outbreaks of avian chlamydiosis have become rare events. Nowadays, such infections lead to reduced feed intake and respiratory signs of affected birds. Due to the availability of antimicrobials, mortality can be kept low.

C. psittaci was reported to be nearly endemic in turkey flocks, where coinfection with *Ornithobacterium rhinotracheale* could exacerbate the course and sequelae (Van Loock et al. 2005). This finding may be exemplary for chlamydial coinfections with other microbial agents, but epidemiological or experimental evidence is still lacking.

Infections in flocks of domestic ducks have been reported from Europe (Haas et al. 2007; Laroucau et al. 2009) and Asia (Yin et al. 2015). The agent is also frequently encountered in pigeons. In a number of epidemiological studies in urban or feral pigeon populations, *C. psittaci* prevalence values from 12 to nearly 100% were reported (Magnino et al. 2009). However, these findings need to be rechecked in the light of the recent discovery of *C. avium*, another chlamydial species typically found in *Columba livia* (Sachse et al. 2014). Initial studies also suggest that coinfections involving *C. psittaci* and *C. avium* are quite common (Burt et al. 2018; Krautwald-Junghanns et al. 2013).

Until a few years ago, *C. psittaci* was believed to be endemic in domestic chicken flocks. However, following the discovery of *C. gallinacea* (Sachse et al. 2014), more recent studies suggest that this is the predominant chlamydial species in chickens, whereas *C. psittaci* is rare (Hulin et al. 2015). The risk assessment study by Dickx et al. (Dickx et al. 2010), which found 85% of chicken flocks *C. psittaci*-positive at slaughtering, is in contrast to studies from 2017 and later. Li et al. (Li et al. 2017) in the USA, Donati et al. (Donati et al. 2018) in Italy, and Heijne et al. (Heijne et al. 2018) in the Netherlands presented findings underpinning the predominant presence of *C. gallinacea* in chicken flocks. Finally, a large epidemiological survey in commercial and backyard poultry flocks in Mexico revealed *C. gallinacea* as the only chlamydial agent present, while no *C. psittaci* was detected (Ornelas-Eusebio et al. 2020).

The effects of *C. psittaci* outbreaks in the poultry industry are measurable as the health of affected birds is deteriorated, thus reducing production output. Unfortunately, systematic studies are missing. Therefore, the consequences on bird health and economic parameters of prolonged subclinical carriage are still poorly understood. Based on studies in cattle (Reinhold et al. 2011), it is anticipated that carriage of *C. psittaci* over a long period could result in chronicity and, consequently, retarded development and reduced weight gain of infected birds.

The main reason why these issues have not been systematically studied is probably the easy access to antibiotic therapy. To prevent zoonotic transmission, tetracycline was added to feedstuff of imported parrots as early as in the 1950s. Later on, this practice was also introduced in poultry farms as a measure of prophylaxis or metaphylaxis (Page and Grimes 1978; Wachendorfer and Luthgen 1974). More recently, legislation in Europe and elsewhere has been encouraging abandonment or at least substantial reduction of the use of antimicrobials in the poultry industry.

In horses, *C. psittaci* infection has been linked to conjunctivitis, respiratory disease, polyarthritis, and abortion (Borel et al. 2018). *C. psittaci*-induced equine abortion cases have been observed throughout Europe for decades, but associated zoonotic events were not reported (Henning et al. 2000; Szeredi et al. 2005). More recently, a cluster of human respiratory illness in a veterinary school in Australia was linked to equine reproductive failure (Chan et al. 2017). Limited epidemiological studies of *C. psittaci*-related equine abortion cases are available reporting prevalences ranging from only 0.6% in Switzerland (Baumann et al. 2020) to up to 14% in Hungary (Szeredi et al. 2005) and 20% in Australia (Taylor et al. 2018), the latter at a sentinel site in Australia where the initial outbreak was reported. A retrospective study in Australia (1994–2019) detected *C. psittaci* in 6.5% of equine abortion cases indicating that *C. psittaci* is not an emerging cause of equine abortion but was rather underdiagnosed in the past (Akter et al. 2021). In mares, the disease manifests as late-term abortion and neonatal losses; the pathogen can be detected in fetal membranes or fetal organs (lung, liver). Coinfections with *C. psittaci* and equine Herpesvirus type 1 (EHV-1) have been reported (Anstey et al. 2021; Baumann et al. 2020). In most countries, detection of chlamydial pathogens is not part of routine veterinary diagnostic procedures for equine abortion cases; therefore, *C. psittaci*-induced cases might be missed.

26.2.2 *Chlamydia abortus*

C. abortus is the cause of enzootic abortion in ewes (EAE), also known as ovine enzootic abortion (OEA) or ovine chlamydiosis, which is present worldwide except in Australia and New Zealand. *C. abortus* is causing economic losses and is relevant for public health as well. It is the most common cause of infectious abortion in sheep and goats in Europe and can also occur in cattle, pigs, horses, wild ruminants, and yaks, but to a lesser extent. *C. abortus* infection causes late-term abortion (last 2–3 weeks of pregnancy), stillbirth, and newborn lambs or kids that are weak and often die within 48 hours (Longbottom and Coulter 2003).

When the pathogen is first introduced in a naïve sheep or goat flock, small numbers of abortions occur in the first year, followed by an abortion storm of 30% or more animals (more than 60% in goats) in the second and third years. In endemically infected flocks, only 1–5% of abortions are observed, mostly affecting primiparous females or newly introduced animals.

Horizontal transmission is the main route, with the pathogen spreading from one animal to another (Longbottom and Coulter 2003). The oronasal route of exposure is considered the primary way of transmission, and this can occur through direct contact between animals, their abortion premises (placental membranes, dead fetuses, coat of live/dead lambs/kids born to infected mothers), or the contaminated environment (pasture, bedding). Very little evidence supports a role for sexual transmission. After abortion, ewes can shed the pathogen during the following periovulation period and subsequent lambing, but evidence from molecular analysis of vaginal swabs taken at these points suggests that such shedding poses a minimal

risk of transmission to naïve animals (Livingstone et al. 2009). Following *C. abortus* infection via the oronasal route, a complex host-pathogen interaction is established with a latent phase in nonpregnant sheep, followed by an active disease phase in the placenta during pregnancy (Longbottom et al. 2013). Latency can be achieved by experimental infection with relatively low doses of the organisms inoculated intranasally (Longbottom et al. 2013). It has been suggested that the primary infection is first established in the tonsils, from where it is disseminated via blood and lymph to other organs. During pregnancy, *C. abortus* travels to the placenta, initiating placental inflammation and insufficiency resulting in abortion or stillbirth. In the placenta, chlamydial growth and pathology are not observed until around day 85–90 of gestation (Buxton et al. 1990; Maley et al. 2009). From then on, rapid chlamydial replication and pathological changes occur in the placenta, including necrosis, inflammation, and arteritis (Buxton et al. 2002; Sammin et al. 2009). An experimental infection model reproduced latency of *C. abortus* infection in nonpregnant sheep but failed to identify a correlation between disease outcome and humoral immune responses (Longbottom et al. 2013). Cellular immunity seems to be important for the control of *C. abortus* infection, but several cytokines have been shown to be elevated during the active and the latent phase in protected but also in aborting sheep. This means that protection cannot be correlated to specific cellular responses (Wattegedera et al. 2020).

Infectious elementary bodies massively shed during abortion are the source of environmental contamination and can remain viable in the environment up to months, depending on climate conditions (Longbottom and Coulter 2003).

Prevention of chlamydial abortion is possible using inactivated or attenuated vaccines. However, the live *C. abortus* vaccine strain 1B is not attenuated and has the potential to cause disease in sheep and is hazardous to pregnant women (Longbottom et al. 2018). Protective immunity is most likely caused by the administration of high doses of *C. abortus* elementary bodies contained in the vaccine, which induces similar placental pathology as the experimental infection with a wild-type strain (Caspe et al. 2021).

26.2.3 *Chlamydia caviae*

The guinea pig is the main host of *C. caviae*, although this chlamydial species has also been reported in rabbits, a dog, a cat, and in horses (Gaede et al. 2010; Lutz-Wohlgroth et al. 2006; Pantchev et al. 2010). In research settings, *C. caviae* is commonly used as an ocular and genital experimental guinea pig model to study human chlamydial infections (Zhang et al. 2020). Initially, *C. caviae* was isolated from the conjunctiva of an infected young laboratory guinea pig and originally named the guinea pig inclusion conjunctivitis (GPIC) virus (Murray 1964). *C. caviae*-induced GPIC implies clinical signs ranging from mild to severe keratoconjunctivitis with serous to purulent ocular discharge, conjunctival chemosis, follicular hypertrophy, and pannus formation. This keratoconjunctivitis is usually self-limiting and clears within 3–4 weeks. Apart from ocular disease, *C. caviae* can

also induce rhinitis, pneumonia, as well as genital tract infection and abortion, but the infection can also remain asymptomatic (Borel et al. 2018). Transmission can occur through close contact between animals or sexually, spreading fast within one husbandry (Mount et al. 1973). Outbreaks in guinea pig farms with high *C. caviae* prevalence (48%) associated with clinical signs, such as conjunctivitis, ocular discharge, pneumonia, and abortion, have been reported in the literature (Lutz-Wohlgroth et al. 2006). It can be assumed that the prevalence is much lower in clinically healthy guinea pig husbandries. Moreover, juvenile guinea pigs might have a higher risk to get *C. caviae* infected than adults or older animals (Lutz-Wohlgroth et al. 2006).

26.2.4 *Chlamydia felis*

C. felis has a predilection for conjunctival epithelial cells in cats and is an important cause of feline acute and chronic conjunctivitis. The conjunctivitis usually starts unilaterally but frequently extends to the other eye and is characterized by conjunctival chemosis, blepharospasm, ocular discharge, and hyperemia of the nictitating membrane (Sykes 2005). The discharge is initially serous but can then become more mucoid to mucopurulent. Some cats may show additional clinical signs, such as fever, lethargy, inappetence, sneezing, as well as nasal discharge (Sykes 2005). Submandibular lymph node enlargement, lameness, and reduced weight gain can also be present, mostly in kittens (Sykes 2005). Moreover, *C. felis* has also occasionally been detected in the reproductive tract of experimentally and naturally infected cats (Sykes 2005).

Usually, the clinical signs appear after an incubation period of 2–7 days (Gruffydd-Jones et al. 2009) and last for a few weeks to months (Sykes 2005). Spontaneous recovery is possible, but most untreated cats develop chronic conjunctivitis with ocular signs persisting for 22–45 days. The duration of ocular shedding can last up to 60 days, but intermittent shedding up to 8 months has also been observed in experimental cats, suggesting an asymptomatic carrier state (Sykes 2005). Experimental infections were successful using the ocular or intranasal application route (Baker 1944; Shewen et al. 1978; Sykes et al. 1999b; TerWee et al. 1998) and not only resulted in conjunctivitis and mild respiratory symptoms as expected but also led to vaginal and rectal excretion of the bacteria in 50% and 40% of the infected animals, respectively (Wills et al. 1987). *C. felis* has also been isolated from internal organs of cats, such as the lung, peritoneum, liver, and spleen, but it remains unclear so far whether those findings are clinically relevant (Sykes 2005). The bacterium is shed in ocular secretions and requires close contact between cats for transmission. Natural transmission of *C. felis* occurs most likely by aerosols when either symptomatically or asymptomatically infected cats are in close contact to healthy cats (Sykes 2005).

C. felis was first isolated from a cat with respiratory disease in 1942 and originally called the feline pneumonitis agent (Baker 1942, 1944). However, only experimental intranasal infection caused pneumonia (Baker 1944; Hoover et al. 1978). Moreover,

the term feline pneumonitis agent is misleading as proof is missing that *C. felis* has ever been involved in natural cases of lower respiratory tract disease (Bart et al. 2000; Schmal-Filius et al. 2020).

Studies from different countries show that *C. felis* is more frequently detected in cats suffering from conjunctivitis than in healthy animals (Low et al. 2007; McDonald et al. 1998; Rampazzo et al. 2003) and that stray cats are more commonly affected compared to pet cats (Halánová et al. 2011; Yan et al. 2000). In pet cats, the chlamydial prevalence in different countries assessed by PCR, isolation, or immunofluorescence assays ranges from 0% to 10% in healthy animals and 5.6% to 30.9% in cats with conjunctivitis. In stray cat populations, the prevalence usually reaches positivity rates from 24.4% to 35.7% up to 65.8% in subgroups with conjunctivitis. *C. felis* is more common in younger cats with a prevalence significantly higher in cats aged 5 weeks to 9 months (Sykes et al. 1999a; Wills et al. 1987). Sex predisposition is not observed, although one study reported that male cats had a significantly higher prevalence of chlamydial infections than females (Wills et al. 1987).

The gold standard for diagnosing a *C. felis*-induced conjunctivitis is made by using flocked swab samples or cytobrushes from the conjunctiva and performing PCR on these samples (Bressan et al. 2021). In positive cases, treatment with doxycycline is indicated (Sykes 2005). Live and inactivated vaccines for *C. felis* are available, and combination vaccines for common viral diseases exist.

26.3 Epidemiology of Chlamydial Zoonoses in Humans

26.3.1 *Chlamydia psittaci*

The zoonotic properties of *C. psittaci* are well-documented in the literature (see reviews in (Beeckman and Vanrompay 2009; Knittler and Sachse 2014; Sachse et al. 2015b).

The first case of human psittacosis reported in a scientific journal dates back to 1879, when Ritter (Ritter 1879) described an outbreak of "typhoid pneumonia" involving seven members of a family, with three deaths. The author associated this endemic infection with sick parrots living in that household. In 1892, the first major epidemic occurred in Paris. Two merchants sold more than 100 parrots that had become infected during their shipment from South America. As a result, 49 individuals fell ill, of which 16 died (Dujardin-Beaumetz 1893).

The term "psittacosis" was first used by Morange in a paper describing the clinical course of this zoonosis and its association with imported psittacine birds (Morange 1895). The first world war and the years of crisis following it put a temporary end to the import of exotic birds. Psittacosis became a temporarily forgotten disease, while its causative agent still remained unknown.

This changed at the end of the 1920s, when local fairs with large-scale parrot sales in the Argentinian towns of Córdoba and Tucumán triggered numerous human infections and a number of casualties (Barros 1929). Later, a number of larger

outbreaks of human psittacosis occurred in Europe and North America, and all of them could be traced back to parrot shipments from South America (Lepore 2009; Meyer and Eddie 1935; Winkle 2000). As more and more veterinarians and laboratory workers fell ill with psittacosis while trying to isolate the causative agent, this gave rise to the assumption that the infection could be acquired through inhalation. The hypothesis of airborne transmission also provided an explanation of the annually occurring respiratory disease on the Faroe Islands in the first half of the twentieth century. It affected those inhabitants who took part in the capture or processing of young fulmars *(Fulmarus glacialis)*, which were part of their diet at that time (Haagen and Mauer 1938).

In the late twentieth and early twenty-first centuries, mass outbreaks seem to have disappeared altogether. A typical episode of psittacosis now affects individuals or small groups with previous contact to birds, while fulminant manifestations in humans usually occur only when antimicrobials are not administered in time.

The course of the human disease ranges from asymptomatic to flu-like to severe systemic illness, with the latter manifesting as pneumonia, myocarditis, encephalitis, or sepsis. Most frequently, mild symptoms are seen in affected individuals, whereas immunocompromised persons are more likely to develop clinical signs. But, occasionally, also apparently healthy individuals can be severely affected (Arenas-Valls et al. 2017; Gaede et al. 2008).

Typical sources of human *C. psittaci* infections nowadays include psittacine birds (Ferreira et al. 2017), as well as ducks (Hinton et al. 1993; Vorimore et al. 2015), turkeys (Van Droogenbroeck et al. 2009), and mixed domestic poultry (Gaede et al. 2008). A major outbreak leading to hospitalization of eight individuals, who had worked at a mixed poultry farm in France, could be attributed to *C. psittaci ompA* genotype E/B, which was present in the duck flocks of the farm. Interestingly, those workers were also exposed to *C. gallinacea* when handling chickens carrying this agent. While not detected in any of the patients, the question remains whether previous *C. gallinacea* infection could have contributed to the outbreak (Laroucau et al. 2015). Generally speaking, zoonotic cases ascribed to contact with chickens have become rare lately (Lagae et al. 2014), as it is known that *C. psittaci* is not the predominant chlamydial agent in chicken flocks. *C. psittaci* genotype E/B, which is typically encountered in ducks and chickens, was reported to have occasionally caused mild human infections (Vanrompay et al. 2007).

Wild birds are another known reservoir of the pathogen, as was documented in a number of cases (Haagen and Mauer 1938; Herrmann et al. 2006; Rehn et al. 2013; Wang et al. 2020). Although direct contact to humans is rare, zoonotic transmission can occur in specific circumstances, e.g., at avian refuge centers. Thus, *C. psittaci* genotype B found in three birds of such a center was later detected in three workers, who developed more or less pronounced clinical signs (Kalmar et al. 2014). In this context, bird handlers at avian refuge centers are also at risk.

More recently, *C. psittaci* infections from non-avian sources were associated with psittacosis as well. Thus, *C. psittaci*-induced equine abortion cases and ensuing zoonotic infections in Australia have raised public awareness (Jelocnik et al. 2017; Polkinghorne and Greub 2017). A 2014 outbreak of human psittacosis in New South

Wales, Australia, was linked to contact with *C. psittaci*-infected placental material from a horse (Polkinghorne and Greub 2017), representing the first report of mammal-to-mammal *C. psittaci* transmission and a novel zoonotic risk for this well-known avian pathogen (Polkinghorne et al. 2019). Human patients showed clinical signs of pneumonia after direct exposure to the equine fetal membranes of a mare who delivered a foal that subsequently died (Chan et al. 2017). Staff from an equine stud farm, veterinary staff and veterinary students, were affected as they got infected either during the delivery of the foal or the handling of abnormal placental membranes. Genetic typing revealed *C. psittaci* strains belonging to the 6 BC clade, originating from native Australian parrots (*ompA* genotype A; Jelocnik et al. 2017; Branley et al. 2016) or a pigeon-type *C. psittaci* strain (*ompA* genotype B′; Jelocnik et al. 2017). It is hypothesized that these virulent *C. psittaci* strains can be transmitted through indirect contact, presumably via fecal environmental contamination from *C. psittaci*-infected birds shedding the pathogen in their feces. Free-roaming parrots might be the most likely reservoir in Australia, whereas free-roaming pigeons could play a role in Europe. *C. psittaci* should be considered in the differential diagnosis of acute febrile illness in humans occurring after exposure to horses, in particular equine abortion (Polkinghorne and Greub 2017).

The main transmission routes of *C. psittaci* to humans involve inhalation of infectious aerosol or dust and direct contact with contaminated feces or feathers. Human-to-human transmission was long thought to be irrelevant, but recent reports of such cases suggest that it should be taken into consideration as well. For instance, a psittacosis outbreak in Scotland originated from a pneumonia patient and subsequently affected four family members and one healthcare worker. Four of these developed severe clinical signs, with two even requiring intensive care unit admission (McGuigan et al. 2012). A Swedish group reported transmission from a severely ill psittacosis patient to ten contact persons, i.e., two family members, one hospital roommate, and seven hospital caregivers (Wallensten et al. 2014). This study is remarkable because, unlike in most others, the diagnostic testing used was specific for *C. psittaci*. Nosocomial transmission had already been suggested in 1997, when a cluster of seven pneumonia cases was attributed to a pet shop worker hospitalized with psittacosis (Hughes et al. 1997). Single cases of possible person-to-person transmission were also reported from Japan (Ito et al. 2002) and Germany (Fischer et al. 2014).

Professions at elevated risk include veterinarians, poultry workers, birdkeepers, and pet shop employees (Arenas-Valls et al. 2017; Deschuyffeleer et al. 2012).

The current epidemiological situation is difficult to assess, because comprehensive studies are rare. In a recent meta-analysis, it was estimated that 1% of the cases of CAP were caused by *C. psittaci* (Hogerwerf et al. 2017). Examination of pharyngeal swabs from 780 CAP patients in Germany revealed a *C. psittaci* detection rate of 2.2% (Dumke et al. 2015). In most, if not all, countries of Europe and North America, a steady decline of notified cases of human psittacosis has been observed over the last two decades. However, as mentioned above, *C. psittaci* is usually not part of the routine laboratory diagnosis, so that many cases may remain unreported and official numbers may be an underestimation of the true incidence.

26.3.2 *Chlamydia abortus*

Human abortion due to *C. abortus* has been reported in several European countries, such as France, Switzerland, and the Netherlands and also in the USA (Longbottom and Coulter 2003; Rodolakis and Mohamad 2010). These human abortion cases, some with severe complications, have been associated with exposure to *C. abortus*-infected placentas of ewes and does but not of bovine origin (Buxton 1986; Essig and Longbottom 2015; Hyde and Benirschke 1997; Meijer et al. 2004; Pospischil et al. 2002; Roberts et al. 1967; Walder et al. 2003, 2005). The isolation of the bacteria from the placenta and fetus of a young woman who had assisted with lambing on her husband's farm, on which ewes had aborted, corroborated the zoonotic risk of *C. abortus* (Buxton 1986). The worldwide prevalence of these abortions is not known and might be underestimated, as the causes of infectious abortion are often not investigated in humans. The infection via ingestion or inhalation is usually acquired from infected abortion products or at parturition. In nonpregnant women and in men, *C. abortus* can cause subclinical infection to acute influenza-like illness, but this seems to be rare (Rodolakis and Mohamad 2010). In contrast, the consequences for pregnant women after close contact with infected sheep and goats are severe. *C. abortus* colonizes the human placenta causing abortion, stillbirth, and maternal illness (Essig and Longbottom 2015). In pregnant women, fever, headache, malaise, nausea, and vomiting are usually the first symptoms associated with lower abdominal pain followed by abortion. If left untreated, severe complications, such as acute renal failure, disseminated intravascular coagulation, or respiratory distress necessitating mechanical ventilation, might ensue. Transmission is mostly associated with exposure to infected sheep and goats, but indirect transmission from contaminated clothing, food, and other sources as well as through inhalation is also possible (Longbottom and Coulter 2003). Pregnant women should avoid exposure to small ruminants, particularly during the lambing and kidding periods. Ewes should be immediately separated; all dead fetuses, placental membranes, contaminated material, and bedding should be carefully disposed. Lambing pens must be cleaned and disinfected to limit the spread of infection and the possibility of zoonotic transmission. In general, chlamydial infections must be considered as an occupational hazard for pregnant women who come into contact with domestic ruminants (Essig and Longbottom 2015).

A zoonotic risk is not only relevant for pregnant women but also for laboratory workers when handling infectious material as they could subsequently develop atypical pneumonia (Ortega et al. 2015). Diagnosis of such an infection is best accomplished using PCR-based detection of *C. abortus* in bronchoalveolar lavage. This implies that *C. abortus* should be included as differential diagnosis for atypical pathogens in CAP in humans. In particular, farmers, veterinarians, laboratory personnel, and public health officials are at risk. The zoonotic potential of novel avian *C. abortus* strains (Longbottom et al. 2021; Szymanska-Czerwinska et al. 2017), which seem to be distributed worldwide in diverse bird families, is unknown and needs further investigations.

26.3.3 *Chlamydia caviae*

C. caviae can cause conjunctivitis in guinea pig owners (Lutz-Wohlgroth et al. 2006). The owner of the latter study reported mild serous ocular discharge, while *C. caviae* was detected in the conjunctival swab by PCR, suggesting a zoonotic infection. Between 2013 and 2018, severe CAP cases in human patients due to *C. caviae* after contact to guinea pigs emerged in the Netherlands (Ramakers et al. 2017; van Grootveld et al. 2018). Clinical signs in human patients included fever, malaise, coughing, headache, and myalgia, resulting in diagnosis of pneumonia and severe respiratory insufficiency with intensive care unit admission and mechanical ventilation. Sequencing of the *ompA* gene confirmed transmission between the guinea pigs and their owners. While contact to ill guinea pigs (respiratory signs, conjunctivitis, rhinitis) were confirmed in all three cases of the first outbreak (Ramakers et al. 2017), an additional case of severe CAP in an older patient remained unexplained, as no previous contact to guinea pigs was reported (van Grootveld et al. 2018). Diagnosis is best made on bronchoalveolar lavage samples using species-specific PCR protocols, including *ompA* genotyping based on variable domain 4, or whole-genome sequencing. Treatment of human patients with doxycycline is usually successful. *C. caviae* bears a zoonotic potential that should not be underestimated, especially since guinea pigs are beloved pets, in particular for children. Veterinarians should be aware of the potential zoonotic risk of infection when handling ill guinea pigs. Moreover, researchers handling experimentally *C. caviae*-infected guinea pigs might be at risk too. A single paper (Gaede et al. 2010) reported *C. caviae* in horses on a farm suffering from conjunctivitis and mucopurulent rhinitis but without contact to guinea pigs, thus illustrating that this chlamydial species is able to cross host barriers.

26.3.4 *Chlamydia felis*

In 1969, *C. felis* was isolated from conjunctival scrapings of a 25-year-old man with follicular keratoconjunctivitis (Schachter et al. 1969). Apparently, he got infected through close contact to his cat that had previously suffered from rhinitis and conjunctivitis. This case report was the first documentation of probable zoonotic transmission of *C. felis* from a cat. Chronic conjunctivitis due to *C. felis* acquired from a cat was also reported in a HIV-positive patient (Hartley et al. 2001), and isolation of the agent could confirm the link between the owner and the kitten. Apart from this latter confirmed case, no serious systemic disease or pneumonia have been reported (Browning 2004). More reports of zoonotic infections originate from the pre-PCR era, but evidence remains circumstantial (Browning 2004). In summary, a zoonotic potential due to *C. felis* in cats could be real, but the risk appears to be low. Still, cat owners and professionals working with cats might be at risk due to their exposure to potentially infected animals (Di Francesco et al. 2006; Wons et al. 2017), and precaution is warranted when handling diseased cats (Sykes 2005). Moreover, uncontrolled, non-vaccinated stray cat populations might also pose a zoonotic risk.

Table 3 Epidemiological and clinical features of *Chlamydia* spp. with confirmed zoonotic potential

	Animal infection		Human infection	
Species	Natural host (occasional hosts)	Disease(s) and clinical signs in the main host	Transmission	Disease(s) and clinical signs
C. psittaci	Birds (cattle, horse, swine)	Respiratory disease, conjunctivitis, coryza, mucopurulent discharge from nose and eyes, cough, dyspnea, greenish to grayish feces	Inhalation	From flu-like symptoms to severe systemic illness; atypical pneumonia
C. abortus	Sheep, goat (cattle, deer, horse, swine)	Enzootic abortion	Inhalation, ingestion	Abortion in pregnant woman, atypical pneumonia
C. caviae	Guinea pig (horse)	Conjunctivitis, pneumonia, abortion	Direct contact	Conjunctivitis, severe atypical pneumonia
C. felis	Cat	Conjunctivitis	Direct contact	(Kerato-) conjunctivitis

A summary of the epidemiological and clinical features of *Chlamydia* spp. with confirmed zoonotic potential is provided in Table 3.

26.3.5 Other Chlamydial Species

C. pneumoniae is considered a primary human respiratory pathogen (Hahn 1999) but has also been found in a variety of animal species including horses, marsupials, amphibians, and reptiles (Borel et al. 2018). Molecular data suggests that human *C. pneumoniae* originated from animals and cross-transmission to humans occurred earlier (Myers et al. 2009). However, no transmission events of *C. pneumoniae* from animals to humans have been observed to date.

C. suis is a ubiquitous pathogen in domestic pigs and has been associated with conjunctivitis, diarrhea, failure to gain weight, and other clinical signs (Schautteet and Vanrompay 2011). Though the zoonotic transmission of *C. suis* from pigs to humans has not yet been demonstrated, its DNA has been found in conjunctival swab samples of Nepalese trachoma patients (Dean et al. 2013). *C. suis* has also been detected in mucosal swab samples (rectal, conjunctival, pharyngeal) collected from farmers and slaughterhouse workers in Belgium and the Netherlands (De Puysseleyr et al. 2014a, b, 2017), including the detection of species-specific antibodies (Kieckens et al. 2018). These individuals did not have any clinical signs, but the concern is more related to the tetracycline resistance present in *C. suis* and its potential of transfer to the closely related human pathogen *C. trachomatis* (Suchland

et al. 2009). *C. suis* is the only chlamydial species harboring a stable tetracycline resistance (Sandoz and Rockey 2010). So far, all *C. suis* strains found in humans were tetracycline-susceptible.

Other veterinary chlamydial species, such as *C. pecorum* and *C. muridarum*; the new avian chlamydial species *C. avium* and *C. gallinacea* (Sachse et al. 2014), *C. buteonis* (Laroucau et al. 2019), and *Candidatus* Chlamydia ibidis (Vorimore et al. 2013); as well as the newly emerging chlamydial strains retrieved from snakes (*C. serpentis, C. poikilotherma*, Candidatus C. sanzinia, Candidatus C. corallus) (Staub et al. 2018; Taylor-Brown et al. 2016; Taylor-Brown and Polkinghorne 2017) or tortoises (Candidatus Chlamydia testudinis) (Laroucau et al. 2020) are not considered of zoonotic importance based on today's knowledge.

26.4 Genome Analysis of Zoonotic Agents

Recent advances in sequencing technology have enabled whole-genome sequencing of many chlamydial strains. Currently, sequences of the human pathogen *C. trachomatis* still make up the majority of database entries, but the main zoonotic agents *C. psittaci* and *C. abortus* are also well represented. Comparative studies of these data were conducted with the aim of understanding specific properties of *C. psittaci* and *C. abortus* (Holzer et al. 2020; Joseph et al. 2015; Read et al. 2013; Seth-Smith et al. 2017).

26.4.1 Common Genomic Elements

Sized approximately 1000 kbp, *Chlamydia* spp. have a small genome compared to most other bacteria. When it comes to comparison among *Chlamydia* spp. genome sequences, the high proportion of common coding sequences (CDS) is the most striking feature. A recent study involving 33 strains of 12 chlamydial species revealed that chlamydiae share about four-fifths of their genome (Holzer et al. 2020). The core genome, i.e., the number of CDS shared by all 33 strains, comprised 784 genes. This part of the genome is assumed to be indispensable and responsible for the typical properties of chlamydiae, such as the main stages of the obligate intracellular lifestyle. However, despite the highly conserved gene content of *Chlamydia* spp. genomes, the species belonging to this genus show significant diversity in terms of tissue tropism, host preference, immune and stress response patterns, as well as pathogenicity. Therefore, it seems straightforward to assume that the more variable genomic regions should account for species-specific features.

In this context, the following genomic regions are of major interest:

The plasticity zone (PZ), i.e., the hypervariable region near the predicted replication termination region, the families of polymorphic membrane proteins (Pmps) and inclusion membrane proteins (Incs), and a few others. As a general conclusion

from recent literature, the expectations on genomic studies should be realistic, since analysis of genome sequences can provide many hints and suggestions, but conclusive answers often will require additional functional studies.

In the following, we will summarize the data on characteristic genomic features of zoonotic chlamydiae.

26.4.2 *Chlamydia psittaci*

This species is rather heterogeneous from the genetic point of view. A serotype classification scheme for *C. psittaci* strains had been introduced more than three decades ago, which was later transformed into a genotyping system based on nucleotide sequences of the outer membrane protein A (*ompA*) (Vanrompay et al. 1997). Fifteen *ompA* genotypes are currently used, i.e., A to F, E/B, M56, WC, 1 V, 6 N, Mat116, R54, YP84, and CPX0308 (Sachse et al. 2008; Sachse and Ruettger 2015).

About 70 genome sequences of *C. psittaci* strains have been deposited to date in public databases. Genome size varies between 1.14 and 1.17 Mbp, and the number of CDS is approximately 1000 (Holzer et al. 2020).

The PZ of *C. psittaci* is sized in the range of 29,929 (strain MN) to 24,603 nt (strain WS-RT-E30), which is relatively small compared to *C. suis* (82,805 nt, strain 1–25a), *C. muridarum* (82,115 nt, strain Nigg), and *C. trachomatis* (55,445 nt, strain D-UW-3-CX). Among the major PZ constituents are genes encoding biotin modification (*accB, accC*), purine synthesis (*guaA, guaB* and ADA), a MAC/perforin, and an additional MAC/perforin domain-containing protein. Moreover, the large cytotoxin gene *toxB* was found in all strains examined so far, with type strain 6 BC harboring the largest version (10,074 nt). A typical characteristic of the *C. psittaci* genome is the absence of a tryptophan operon.

C. psittaci strains possess 21 different *pmp* genes, numbered *pmp1–17* and *pmp19–22*, which are classified into subtypes A, B, D, E G, and H. While 14 of these family members belong to subtype G and 3 to E, the other subtypes are represented by a single *pmp* gene.

An exhaustive description of the Inc. protein family in *C. psittaci* has not been achieved to date. So far, six different subtypes have been identified: A, B, C, V, X, and Y. The latter two were only found in *C. psittaci* and *C. abortus*, while subtype V is characteristic for the "psittaci cluster," which also includes *C. caviae* and *C. felis*.

26.4.3 *Chlamydia abortus*

This chlamydial species is distinguished by its remarkable genetic homogeneity. A recent genomic study involving 57 *C. abortus* isolates demonstrated unusual stability and lack of interspecies diversity (Seth-Smith et al. 2017).

The genome size of *C. abortus* strains sequenced to date ranges from 1.13 to 1.17 Mbp. The PZ is smaller than that of *C. psittaci*, but, at the same time,

characteristic differences between the typical ruminant strains and the recently discovered avian strains of *C. abortus* need to be taken into account. Ruminant strains, such as type strain B577 and strain S26–3, contain a PZ sized 11.7 kbp (ca. 17,770 nt), while the same region is 22,240 bp in the avian strain 16 DC122. Only the latter was found to have a *toxB* gene of 9312 nt reminiscent of *C. psittaci*. Furthermore, the PZ of *C. abortus* lacks a tryptophan operon and a CDS for MAC/perforin. Purine synthesis genes as present in *C. psittaci* have either evolved to pseudogenes or are absent altogether.

Strains of this species harbor 18 different *pmp* genes numbered 1–18 and belonging to subtypes A, B, D, E G, and H. Also here, subtype G is the most extensive one comprising 11 members, and E comprises 3. As mentioned above, Inc subtypes A, B, C, V, X, and Y are encountered.

26.4.4 *Chlamydia caviae*

The only genome sequence available is from the type strain GPIC. Its size is 1,173,390 bp.

Although the PZs of *C. caviae* and *C. felis* are not the most extensive ones (those of *C. suis* and *C. muridarum* are about twice as large), they possess the most complete set of genes and operons in this genomic region. Thus, the 34,753 nt PZ of *C. caviae* contains a *toxB* gene of 10,041 nt, the biotin modification genes (*accB, accC*), the purine synthesis genes (*guaA, guaB*, ADA), as well as a complete tryptophan operon (*trpA, trpB, trpD, trpF, trpR, kynU*).

Only the MAC/perforin seems to be missing.

Eighteen *pmp* genes were identified in the genome of this species. Subtype E/F, which was introduced here instead of E, has 5 representatives and G has 9. *Inc* genes were assigned to subtypes A, B, C, and V.

26.4.5 *Chlamydia felis*

The genome of strain Fe/C-56 is sized 1,166,239 bp. The PZ sized 39,924 nt contains a 9897 nt *toxB* gene, a CDS encoding MAC/perforin and, as *C. caviae*, the biotin modification genes, the purine synthesis genes and a complete tryptophan operon.

Furthermore, the *C. felis* genome harbors 20 *pmp* genes distributed among subtypes A, B, D, E G, and H, with 11 classified as subtype G and 4 as E. The *inc* genes of this species belong to subtypes A, B, C, and V (Holzer et al. 2020).

26.5 Unresolved Issues and Outlook

Animal chlamydiae are not a part of the traditional microbiological diagnostic procedure in human laboratories. Therefore, human chlamydial infections of zoonotic origin often remain underreported, misdiagnosed, or undiagnosed. Chlamydial

infections can be identified as a diagnosis of exclusion if routine diagnostic tests on blood, sputum, BAL fluid, and cultures remain negative. For example, *C. psittaci* is widely underdiagnosed as a cause of CAP, as pan-chlamydial PCRs do not identify the pathogen and species-specific diagnostics are not included in the routine evaluation of human cases. This omission can result in severe disease and empiric CAP treatment, which is not effective against chlamydiae.

Concerning laboratory diagnosis, successful approaches include the combined use of highly sensitive *Chlamydiaceae*-specific qPCR with species-specific qPCR to be supplemented by melting curve analysis, or sequencing, or microarray detection. Serological methods are not very sensitive and usually not species-specific. In older studies, *C. psittaci* was detected by complement fixation test, which is known to be neither sensitive nor specific. Moreover, serology requires the testing of paired sera, which delays the final result for 2 or more weeks. Using DNA-based methods, human samples can be further genotyped and matched with animal or environmental samples to search for the infection source.

New typing techniques, such as multilocus sequence typing (MLST) or culture-independent genome sequencing technologies, are helpful to interrogate strains of the same chlamydial species from different hosts to gain insight into their relationship, origin, and the potential for cross-host transmission.

Another important point to highlight is the choice of the appropriate sample type, which depends on the organ affected and chlamydial species involved. For the diagnosis of a *C. psittaci* infection, lower respiratory specimens are more suitable than nasopharyngeal swabs, albeit the latter are easier to collect (McGovern et al. 2021).

More recently, the use of metagenomic next-generation sequencing (mNGS) was suggested as a diagnostic tool for psittacosis. In a retrospective study by Chen et al. (2020), blood and BALF samples of nine psittacosis patients were subjected to mNGS to explore the suitability of this technology for diagnostic purposes. The presence of *C. psittaci* was revealed within 48–72 h.

However, although mNGS showed a satisfying diagnostic performance and had an overall superior detection rate to culture in initial studies (Zhang et al. 2020), it does not seem to offer advantages over established qPCR assays in terms of time and, more important, costs. While mNGS may provide a greater amount of information in the form of sequences, the question remains whether this is required in a clinical setting, where rapid pathogen identification enabling efficient treatment of the patient at the earliest time point is crucial.

Chlamydial infections in wildlife and spillover infections to domestic animals and humans (Burnard and Polkinghorne 2016) have to be carefully monitored, with wildlife hosts including birds, mammals, marsupials, amphibians, and reptiles. So far, mainly wild birds are considered to play a role as reservoir hosts for *C. psittaci*, but they might only represent the "tip of the iceberg." *C. abortus* has been detected in free-living frogs, marine reptiles and crocodiles, as well as wild ungulates (Burnard and Polkinghorne 2016). Chlamydial species in new and/or uncommon hosts, as exemplified by the zoonotic transmission of *C. psittaci* from equine abortion cases, require surveillance of transmission events and spreading. Recently, a case of a fatal

C. psittaci infection in a domestic kitten suffering of hepatitis and pneumonia was reported (Sanderson et al. 2021), but the source of infection remained unclear.

Novel and uncommon hosts or reservoirs for zoonotic chlamydiae might play an increasing role in the future. For example, ticks (*Ixodes ricinus*) removed from pet cats in Italy were PCR positive for *C. abortus* and *C. psittaci* (Chisu et al. 2020). Ticks are vectors for a wide variety of pathogens, including chlamydiae. In addition, chlamydia-like organisms (CLOs) and members of the family *Chlamydiaceae* have been found in bats, thus raising the question of the importance of bats as reservoir hosts or transmission source as known for other pathogens, especially viruses. More recently, ectoparasites of bats have been identified as potential vector candidates for chlamydial bacteria. These findings illustrate that our understanding of the ecology, diversity, and epidemiology of *Chlamydiaceae* and CLOs is still limited and further research is required.

Zoonoses in Domestic Animals

Dogs and Transmission of Infection to Man, "Respected Member of the Family?" 27

Paul Overgaauw and Frans van Knapen

Contents

Abstract

Many reviews on dog zoonoses address long-lasting lists of zoonotic infections, either observed worldwide or very specifically only in certain regions. In this chapter, the average pet dog in the western hemisphere will be described. It is assumed that the dog is owned by an average family with limited knowledge of the potential hazards their pet might be carrying, and possibly transmitting to family members.

It is based on semiquantitative risk analysis in order to rank potential health risks transmitted from pet dogs to humans. Surprisingly, everyday risk is different from the expected general potential risk according to the traditional ranking of hazards (zoonoses) in dogs. Attention will be given to human behavior regarding

pet dogs and to responsible dog ownership. Modern trends include pet importation from endemic to non-endemic areas, without sufficient knowledge among pet owners or public health institutes. In Europe, the advice provided by ESCCAP (www.esccap.org) is of great value to veterinarians and pet-owners alike and includes information about prevalence and the prevention of parasitic infection in dogs and cats in the major European languages.

Other new trends include feeding bones and raw meat to dogs, which may have serious consequences for the spread of zoonoses like *Salmonella* and parasitic infections not only between dogs, but also to family members.

Finally, yet importantly, is the prevention of attracting wildlife zoonoses, via dogs, to family members (e.g., *Echinococcus multilocularis* and *Baylisascaris* spp.). Public health authorities should be encouraged to pay more attention to this, not only by increased regulation, but primarily by enforcing existing rules and encouraging responsible pet ownership. Companion animal veterinarians and (local) public health authorities, including physicians, should contribute equally in zoonosis prevention programs ("One Health" approach).

Zoonoses · Emerging zoonoses · Dogs · Risk analysis · Human behavior · Trends

27.1 Introduction

Until around the turn of the twenty-first century, zoonoses were regarded by the medical profession as "just a number" of well-known infectious diseases in the modern ("western") world. As infectious diseases in that part of the world were abated by increased public hygiene, food safety, vaccinations, and proper antibiotic treatment, there seemed no need for further attention. However, a number of events causing human casualties have alarmed public health authorities in many countries and have sparked public and political awareness for new and reemerging zoonoses. Such events include the rapid spread of severe acute respiratory syndrome SARS in 2002 (Peiris et al. 2003), the outbreaks of avian influenza in South East Asia, but also in Europe (Shortridge et al. 2003) with varying types (H5N1, H7N7), West Nile virus throughout the United States (Shephard et al. 2006), Middle East Respiratory Syndrome-CoV coronavirus MERS (Zaki et al. 2012), the Zika-virus in 2013 (Cao-Lormeau et al. 2014), and the COVID-19 coronavirus in 2020 (WHO 2020).

In 2004, a joint WHO/FAO/OIE consultation on emerging zoonoses was held in Geneva (WHO/FHO/OIE 2004). Other incidents fostered this change such as antibiotic resistance believed to be related to animal treatments (MRSA, ESBL) (Weese 2010; Friese et al. 2013), and the significant spread of ordinary gray ticks (*Ixodus ricinus*) and consequently Lyme disease in man (Giessen et al. 2010). A central question to be answered is what role do veterinarians play in public health in the twenty-first century? (WHO 2002).

As a result of emerging and reemerging diseases, the One Health concept became important as a worldwide initiative recognizing that public health relates to animal

health and the environment. The multidisciplinary collaboration between physicians, veterinarians, environmental scientists, public health professionals, and other experts enhances the knowledge of how zoonotic diseases can be shared between animals and people with the goal of achieving optimal health outcomes (Overgaauw et al. 2020). The World Small Animal Veterinary Association (WSAVA) One Health Committee identified three key areas regarding companion animals: the human–companion animal bond, comparative and translational medicine, and zoonotic infectious disease (WSAVA 2011).

A traditional approach to dealing with zoonoses is to use a model, which includes the biology of the germ, epidemiology, disease in man and animals, diagnosis and prevention or control of the disease. Often it involves a simple enumeration of zoonoses found in dogs, without exploring the relative health risks for dog owners or the population at large through environmental pollution (Macpherson et al. 2012; Baneth et al. 2016). Depending on endemicity in certain areas of the world, more attention could be paid to zoonoses such as echinococcosis and toxocarosis (Carmena and Cardona 2013; Deplazes et al. 2011).

In this chapter, we will concentrate on relevant dog zoonoses and the role of the pet owner in an average (north) western European country without endemicity for diseases such as leishmaniosis, rabies, or heartworm disease. We will focus on an average family dog, within an average household and will assume limited awareness of the potential health risks of enjoying a pet at home.

27.2 Risk Analysis

The relative risks to human health or the attribution of a huge variety of dog zoonoses to having dogs, are either largely unknown or studies remain inconclusive. This is due to failure in examining both pet owners and their pets simultaneously, and by not comparing isolates by genotyping, serotyping, or other identification methods to suggest a one-way cross infection or a common source of infection elsewhere. There are, however, also indications that some infections may be transferred from humans to their dogs, which is called reverse zoonotic disease transmission or zooanthroponosis. For companion animals, MRSA infection was especially reported but *M. tuberculosis*, influenza A, *Candida albicans*, *Microsporum* spp., and *Trichophyton* spp. were also discussed (Lefebvre et al. 2009; Messenger et al. 2014). The zoonotic potential of *G. duodenalis* is considered evident, based on findings of assemblages A and B in humans, as well as in dogs. Authors automatically concluded therefore a one-way transmission route to the human (Marangi et al. 2010; Dado et al. 2012). The risk of transmission from dogs and cats to humans is, however, considered very low. Dog- and cat-specific *Giardia* assemblages are very rarely found in humans, but human assemblages A and B may circulate within dog and cat populations and therefore it could be that humans are a source of infection to a dog or cat, which may then in turn represent a zoonotic risk. Evidence on the contribution and frequency of the zoonotic potential is (still) lacking (Sprong et al. 2009).

Each risk analysis begins with an assessment of the potential dog zoonoses in an area, depending on the endemicity (the hazard, H). Hazard characterization also

includes prevalence in animals (the reservoir), virulence to man, transmission routes, and survival of the agent in the environment. These criteria are then weighed, mostly based on expert opinion.

The second step is exposure assessment (E). Who is exposed to the potential hazard and for how long or how often? How much of the potential pathogen is needed to become a health risk? This is inevitably directly related to human behavior in relation to their dog.

The third step is to assess the impact of getting infected. How serious is the disease, what is the chance of complications, and what economic consequences may be expected (e.g., labor hours lost)? For this purpose, the disease burden can be expressed in disability adjusted life years (DALYs). This quantifies health loss based on two components: life years lost due to premature death and the proportional loss of quality of life as a result of the disease.

Each of the parameters can be ranked in order from negligible (1) to the most serious possibility (5). Ranking is based on literature data, own observations (measuring), or expert opinion, thus arbitrarily.

The final risk assessment can be achieved by multiplying the outcome of hazard characterization, exposure assessment, and impact ($H \times E \times I = a$ number). The outcome is nothing more than a ranking of the potential health hazards and as such, can be compared with other zoonotic agents.

An example of such a risk assessment was carried out in a large companion animal referral clinic in the Netherlands (Berends 2006). Table 1 shows the top five dog zoonoses from this study, according to the hazard characterization ranking order. Table 2 shows the ranking order of exposure to these zoonoses. In Table 3, the top five most important dog zoonoses in an average small animal clinic are listed, based on the multiplication of hazard, exposure, and impact. This can be used as the point of departure because the intensive contact that clinicians have with dogs will certainly be comparable to that of an owner, with only one important exception: the duration of exposure. Since this is also subject to the owner's behavior, this will be discussed in sect. 27.22.

Table 1 Ranking order of biological hazard characterization in dogs

1.	Rabies

1.	*Campylobacter*
2.	*Pasteurella* spp.
3.	*Salmonella* spp.
4.	*Staphylococcus* spp.
5.	*Listeria* spp.

27.2.1 Dog Ownership

Companion animals have an important emotional value and promote socialization among the lonely elderly because they facilitate additional contact with people. Pets create purpose in life, reduce stress, and encourage physical activity. Most research, addressing the health benefits of pet ownership, shows a reduction in distress and anxiety, a decrease in loneliness and depression, and an increase in physical condition (Friedmann and Son 2009).

Dogs also play an increasing role as co-therapist or supporter for people with psychological or physical disabilities. The benefits of these animal-assisted activities are improved mood and decreased physiological distress, depression, dementia, and loneliness (Olsen et al. 2016).

Animal-assisted therapies can be used alongside other methods to facilitate psychotherapy or to provide specific types of therapeutic interventions such as improving motor skills or behavior. Such interventions were effective in improving the health status of children or adults with, or at risk of developing, mental disorders (Friedmann and Son 2009).

Dogs play an important role in the development and treatment of behavioral problems in children, the well-being of the elderly, and in decreasing absenteeism due to illness and visits to the doctor (Purewal et al. 2017; Hoagwood et al. 2017). Pet ownership has certainly been associated with health benefits, although not all (social) studies have been based on correct methodologies (Koivusilta and Ojanlatva 2006; Wells 2019).

On the other hand, more than six out of ten known infectious diseases in people can be spread by animals, and three out of four new or emerging infectious diseases in people are derived from animals (CDC). The recent pandemic of the COVID-19 coronavirus (SARS-CoV-2) that may originate from bats, is a good example of a recent emerging zoonotic infectious disease. A few dogs have tested positive but are not considered a source of infection for humans.

Here we deal with potential biological hazards (zoonoses) that may have negative health consequences for the owner. The starting point is Table 3, which ranks the zoonoses by potential health risks for individuals with short but intensive contact, such as veterinarians or breeders. It may be assumed that exposure to the potential hazards mentioned will be much higher and longer lasting when the owner (family) is involved. The actual top five zoonoses will, however, remain similar and concern the fecal-oral route of transmission (*Campylobacter, Salmonella, Giardia*), direct contact (*Staphylococcus* spp.), and injuries as result of bite incidents, licking, and scratching (*Pasteurella multocida, P. canis*).

27.2.2 Human Behavior

In 80–90% of households, pets are considered members of the family, therefore physical contact is very common. Cuddling, stroking, and playing with animals is normal among dog owners, and especially their children. It is all part of enjoying pet animals, but pets have increasingly become substitutes for childbearing and childcare, sometimes leading to excessive pet care and intensive contact (Chomel and Sun 2011). This kind of behavior is the result of attributing human cognitive processes and emotional states to animals, such as feelings of happiness, love, or guilt. This perception that animals have awareness, thoughts, and feelings is called anthropomorphism (Szánthó et al. 2017).

It is remarkable that some owners allow their dogs to approach the table, beg for snacks, are often stroked or even worse are allowed to join the table at mealtimes. Therefore, washing hands before a meal would demonstrate an awareness of hygienic practice. The number of potential pathogens such as enterobacteriaceae (Westgarth et al. 2008) or parasite eggs (Keegan and Holland 2010) from the fur of most animals, including dogs, is easily detectable and can be washed off by using water and ordinary household soap. It is self-evident behavior to do so before sitting down for dinner or after visiting the toilet and is all part of upbringing and education.

Licking the face or sharing an ice cream is a sign of mutual affection for some and is allowed by as much as 50% of households (Westgarth et al. 2008; Overgaauw et al. 2009). The notion that a dog's tongue is clean and may even be used to cleanse wounds is widespread among the general public and sometimes even among first aid health professionals (Verrier 1970; Overgaauw et al. 2020). Dogs regularly lick their anus and it has been found that over half of all dog and cat owners allow their pets to lick their hands or faces. By doing this, bacteria may be spread. Literature increasingly indicates that dogs licking humans may lead to infections (Booij-Vrieling et al. 2010; Haesebrouck et al. 2009); or serious health consequences in individual cases (Shewring and Rushforth 1990; Wade et al. 1999; Overgaauw and van Knapen 2012).

Allowing dogs to sleep in the bedroom (33–56%) or to even sleep in the owner's bed (18–50%) is certainly contributing to the transmission of zoonoses, including parasites (Overgaauw et al. 2020; Chomel and Sun 2011). Intensive contact with the skin and nose, (*Staphylococcus* spp.) even when the dog is healthy and without skin lesions, may lead to contamination with antimicrobial resistant strains (MRSA) (Manian 2003; Cain 2013).

Having one or more dogs in the household means that soil from outdoors is regularly spread throughout the house. Dogs were regularly reported to have soil-transmitted parasitic infections in their fur (Keegan and Holland 2010) with, as yet, unknown consequences for the owner. However, it should be kept in mind that even *Toxocara* eggs may easily be found in household dust taken from the houses of dog owners (Overgaauw and Boersema 1998; Panova and Khrustalev 2018).

Among soil-transmitted diseases, serious consideration must be given to toxoplasmosis because dogs might act as active distributors of oocysts from the environment. Dogs regularly and actively roll in the feces of other animals or eat them (Frenkel et al. 1996; Nijsse et al. 2014).

An important role of the veterinarian is to make owners aware of the potential risks and to emphasize the importance of personal hygiene and thorough cleaning of the house/kitchen, without causing alarm (Stull et al. 2015). Awareness and responsible pet ownership are the key issues in achieving a healthy relationship between owner and dog.

27.2.3 Responsible Pet Ownership

The benefits of pet ownership come with certain obligations. This concept is called responsible pet ownership and includes, among other things, providing the preventive (e.g., vaccinations, parasite control) and therapeutic healthcare needs for the duration of the pet's life (AVMA 2021; Overgaauw et al. 2020) to prevent the transmission of pathogens to humans. Responsible pet ownership also means recognizing that the other half of the population does not own a dog or may not even like dogs. Annoyance over dog feces in the streets or noisiness is common. Dog owners can contribute to public discussions within communities to demonstrate their positive attitude toward regular deworming or parasite control, health certification, and cleaning up their dog's feces while out walking. It is surprising to see the difference in dog owners' attitudes between the various countries of Europe. While British dog owners are used to cleaning up dog feces, Dutch citizens are less likely to do so. Only 39% of Dutch dog owners report to regularly clean up their dog's feces (Overgaauw et al. 2009).

27.3 New Trends

27.3.1 Emerging Zoonoses

"Emerging zoonoses are zoonoses that are newly recognized or newly evolved or that have occurred previously but show an increase in incidence or expansion in the geographic host, or vector range" (WHO/FAO/OIE 2004). There is an increasing trend to rescue and import dogs from endemic, predominantly Mediterranean regions, with stray animal problems. Another trend is the increasing puppy trade from Eastern Europe. In the EU without borders, such transportation only requires a minimum age, mandatory health certificate (signed by an official veterinarian), and proper vaccinations (e.g., rabies). Rabies, *Echinococcus granulosus* and *Leishmania infantum* are therefore "imported" infections in many countries (Menn et al. 2010; Otranto et al. 2017). The import and settlement of canine babesiosis in Western Europe, including its vector (*Dermacentor reticulatus*), is a clear sign of transport and spreading of (zoonotic) infections (Daugschies 2001). The harmonization of parasite control in Europe has taken place by the independent organization ESCCAP (www.esccap.org) to enable veterinarians to inform clients about the differing endemic diseases in the various European countries and how to prevent contracting or importing infectious diseases when traveling with

dogs (holidays, assistance dogs) or purchasing dogs from abroad. Obviously, this is not only of value regarding parasitic infections, but also for bacterial or viral zoonoses (e.g., brucellosis, rabies).

27.3.2 Feeding Raw Meat to Dogs

Although many dog owners in the Western world feed their pets industrially processed food, an upward trend is emerging toward feeding homemade food instead of pre-prepared food, which may consist of leftovers, homemade and prepared meals, bones, raw meat, and offal. Publications were found reporting the presence of *Escherichia coli* O157, *Salmonella* spp., *Listeria* spp., *Campylobacter* spp., and antibiotic-resistant bacteria in the feed (Van Bree et al. 2018). Outbreaks of *Salmonella* have been described, which could be linked to contaminated animal food. Caregivers and family members can become infected with the *Salmonella* bacteria, not only when preparing food that contains raw meat, but also after being in contact with infected animals that secrete the bacteria (Finley et al. 2006; Lefebvre et al. 2008; Schlesinger 2002; Davies et al. 2019) and after being in contact with infected food bowls, for example, when cleaning them (Weese and Rousseau 2006).

We traditionally know that young children (younger than 5 years), the elderly (older than 65 years), patients with an impaired immunity, and pregnant women carrying a fragile fetus are at more than average risk of becoming ill after an infection. Moreover, they may have more severe disease, have symptoms for a longer duration, or develop more severe complications compared to other patients (Stull et al. 2015). Therefore, it is recommended that animals living with these risk groups or those being used therapeutically to care for people, are not allowed to eat raw meat. Health authorities warn, therefore, that raw pet food diets can be dangerous to the owner and their pets (FDA, Nemser et al. 2014). If dogs are fed with commercially (complete) canned or dry food, which are free from pathogens, there will be no danger in becoming infected through the food chain.

27.3.3 Contact with Wildlife Zoonoses

Hunting dogs that are allowed to feed on the carcasses of wild animals or free-ranging dogs hunting or scavenging for their own food are at an increased risk of picking up zoonoses that may have serious consequences for their owner's health. In *Echinococcus multilocularis* (fox tapeworm) endemic areas (see www.esccap.org), there is a real risk that (hunting) dogs become infected with this tapeworm. Because *E. multilocularis* easily grows in dogs, the threat of it spreading to their owners is also realistic. Monthly deworming in endemic areas is strongly recommended (Hegglin and Deplazes 2013). Moreover, in large areas of Europe home to wild raccoons and raccoon dogs, another emerging zoonosis is the appearance of *Baylisascaris* spp. in dogs. This may cause severe larva migrans infection in animals and humans, but infection in children particularly needs further attention (Okulewicz and Bunkowska 2009; Lee et al. 2010).

5.	*Rhipicephalus sanguineus*
6.	(Influenza/norovirus)
7.	(*Toxoplasma*)

27.3.4 Dogs and Transmission of Human Viruses

The increasing role of the influenza A virus and human disease and the threat of new pandemics of new types (hemagglutinin (H) and neuraminidase (N)) also affects dogs and cats. So far, canine influenza (H3N8) has not caused harm to humans, but pathogenic avian influenza (H3N2) and human influenza (H1N1) isolates are able to infect dogs and cats. These animals may therefore play a role in interspecies transmission and the spread of the influenza virus (Song et al. 2008; Tangwangvivat et al. 2019). Small animal practitioners may play an important role in early warning systems for influenza in humans and dogs (Beeler 2009).

Recently, it was shown that human noroviruses can survive in dogs' gastrointestinal tracts. It is suggested that this major source of human diarrheal disease worldwide is transmitted from man to dog and consequently, may be transferred to others (Summa et al. 2012; Caddy et al. 2015).

Additional potential health risks for dog owners (depending on behavior, traveling, or importation of dogs from areas endemic for zoonoses) not covered by Table 3 are presented in Table 4.

27.4 Authorities' Involvement

Emerging zoonoses, early warning, and surveillance are all important issues (van der Giessen et al. 2010). Although active surveillance systems exist, particularly for livestock and wildlife, no such system exists for pet animals. Notifiable diseases from pet animals in the Netherlands include brucellosis, campylobacteriosis, echinococcosis, leptospirosis, rabies, salmonellosis, toxoplasmosis, tuberculosis, and yersiniosis. Data are scarce however and underreporting undoubtedly occurs. This may be due to improper diagnoses or ignorance. Enforcement of existing legislation should be the first goal for authorities. Community administration however is regularly confronted with complaints from citizens about dogs and their behavior and indirectly about dog owner behavior. This was previously mentioned and requires more attention from local authorities. Responsible pet ownership should get more attention and could be encouraged locally. Dogs undergoing health certification by a veterinarian at regular intervals, including proper parasite control, vaccinations, and general health checks, could be rewarded with a recognizable medal for their collar. By doing so, the dog owner would demonstrate his or her public responsibility (social control). Moreover, the obligation to clean up dog feces

should be encouraged by the national governments in those countries where this is not yet commonly practiced.

27.5 Conclusions

The role of the companion animal veterinarian is not only to care for animals with diseases but is increasingly becoming important in the field of veterinary public health.

Livestock veterinarians and official veterinarians have long since taken up this responsibility. Disease detection, reporting, and prevention are important issues. Companion animals, including dogs, may act as important sentinels for public health. Veterinarians should advise pet (dog) owners more about health education with regard to husbandry, dog behavior, and responsible pet ownership. Cooperation with community health services and local government should be part of the contribution of small animal practitioners in the twenty-first century "One Health" approach (Trevejo 2009; Gyles 2016).

Abstract

In many countries worldwide, cats – revered and reviled – have become "man's really best friend." In the following chapter the public health relevance of cats will be highlighted by introducing its most relevant zoonotic pathogens including *Toxoplasma gondii, Bartonella henselae*, *Toxocara cati*, *Rickettsia felis*, enteropathogenic bacteria and parasites, as well as the emerging cat-related pathogen *Corynebacterium ulcerans.* Moreover, cats and their role in the SARS-CoV-2 pandemic will also be discussed.

28.1 Introduction

The family *Felidiae* of the Order *Carnivora* is of comparatively recent evolutionary origin with a proposed common ancestor living <11 million years ago (Agnarsson et al. 2010; Johnson et al. 2006). Based on morphological and molecular data at least 38 extant and two extinct species can be divided into eight major lineages: the two "big cat" clades of the pantherine lineage with four roaring and one non-roaring species and the Asian leopard cat group, the ocelot lineage, the caracal group, the puma group, the baycat group, the *lynx* genus, and the domestic cat lineage (Agnarsson et al. 2010; Serpell 2000; Johnson and O'Brien 1997; Johnson et al. 2006; Kitchener et al. 2017).

The latter lineage originated in the Mediterranean region about 6–7 million years ago (Johnson et al. 2006; Driscoll et al. 2007; Crowley et al. 2020) and consists of six small cat species from which four, i.e., the domestic cat (*Felis catus*), the European wildcat (*F. silvestris*), the African wildcat (*F. libyca*), and the sand cat (*F. margarita*), diverged later on. Based mainly on morphological, archeological, and behavioral findings, *F. libyca* is hypothesized to be the most likely ancestor of the domestic cat. Even etymological findings support this idea, since the word for cat in many languages (e.g., English *cat*, fourth century Latin *cattus*, the ancient Greek

καττος, the medieval Byzantine Greek *κατης* [Nicholas 1999], Spanish *gato*, French *chat*, German *Katze*, Lithuanian *katė*, the modern Arabic *quttah*) is thought to be derived from the Nubian word for cat, *kadiz*.

Domestication of cats started presumably 10,000–25,000 years later than the domestication of dogs (Germonpré et al. 2009) and probably began in Egypt about 4000 years ago, where cats even enjoyed a sacred status and were associated with the cult of the cat-shaped deity Bastet. One strain of etymological speculation links the English diminutive *pussy* and the Romanian word for cat *pissica* to this Egyptian goddess (Serpell 2000). Several reasons for cat domestication have been discussed in the literature based on its hunting properties: (i) protection of grain storages by killing small rodents (indirect benefit from hunting); (ii) use as a companion animal for bird hunting (direct benefit from hunting); (iii) use for religious reasons or as status symbol due to its resemblance of a lion, the king of the carnivorous hunters (Serpell 2000; Jores 2004).

Interestingly and in a pronounced contrast to dogs, the domestication process of cats did not induce major changes either in the physical shape or in the behavior of domestic cats when compared to wildcats. This process is sometimes referred to as "self-domestication" probably driven by a fortuitous combination of ecological and sociocultural circumstances (Crowley et al. 2020). Modern cats still remain capable of sustaining themselves without human assistance; this independence from human support is reflected by the increasing number of the so-called "feral cats" raising major problems in many human societies and ecological settings, e.g., due to their carnivore and predator lifestyle contributing even to the extinction of other animals especially in islands or certain geographic areas (Crowley et al. 2020; Parliament of the Commonwealth of Australia 2020).

From its sacred origins in Ancient Egypt, the domestic cat spread – supported by its remarkable "sea sickness resistance" – often by ships across the Mediterranean – first throughout Europe and finally worldwide (Engels 1999; Jores 2004). While during the first millennia of the human–cat relationship the animal enjoyed valuable respect nearly in all human cultures, the esteem of cats dramatically changed in the Middle Ages at least in Christian Europe and Japan when demonic features were attributed to them; the respective iconic pictures commonly propagated in fairy tails are those of a cat sitting on the hunchback of a witch or even being a companion of the devil. Probably the previously as benevolent cat attributes described features such as (female) fertility and sexuality were now disregarded as demonic for cultural or religious reasons and consequently the cat was transformed into a symbol of these now as vicious connotated features. These associations were also based on facets of the natural behavior of cats, e.g., their obvious independence, affectionate nature, search for physical caresses, sexual behavior, and promiscuity, which all were now interpreted in the light of a sexualized, often misogynic perspective (Serpell 2000). After this emotional setback in the history of the human–cat relationship things clearly improved in the last few centuries making the cat now in many countries "man's really best friend" with the numbers of household cats outnumbering those of domestic dogs. However, the ambiguous nature of cat's image as revered and reviled still prevails in many human societies and subgroups (Crowley et al. 2020; Vocelle 2017).

28.1.1 Cat Demography

The worldwide domestic cat population is estimated to exceed 500 million of which about 58% are thought to be be "stray" or "feral" (International Companion Animal Management Coalition 2011; Hiby et al. 2013). The largest pet cat population lives in the USA with about 74 million cats present in 32–38% of US households (Rowan 2018, Humane Society of the USA 2022), followed by China (53 million), Russia (17.8 million), and Brazil (12.5 million) (www.mappr.co/thematic-maps/world-pet-ownership/). In Europe about 110 million cats are living in about 25% of European households; Russia (22.7 million), Germany (15.7 million; 2012: 8.2 million), France (15.1 million; 2012: 11.4 million), UK (7.9 million; 2012: 8.5 million), and Italy (7.9 million; 2012: 7.5 million) ranked as the five countries with the highest pet cat populations in Europe in 2020 (FEDIAF 2014, 2021). Interestingly and similarly to 2012, the highest rates of households with cat ownership in Europe are found in the East, e.g., in Romania and Poland (42% of households), the Czech Republic (41%), Lithuania (37%), Hungary (34%), and Slovenia (31%) with Portugal being the only exception from this geographical trend (38%) (FEDIAF 2021). The Parliament of the Commonwealth of Australia reported 3.77 million pet cats in 27% of Australian households and 2.8. million feral cats, respectively (Parliament of the Commonwealth of Australia 2020). Cat ownership is relatively low in African countries besides South Africa (2 million) and Spanish-speaking Southern America besides Argentina (3.0 million).

In a random sample of 2,980 UK households in 2007 pet cat ownership was significantly correlated with female sex of the owner (OR 1.63), having a garden (OR 3.66), living in a semi-urban or rural environment (OR 1.30), and having a higher education degree (OR 1.36) (Murray et al. 2010). In an Irish study, pet cat ownership was significantly associated with house type (apartment compared with detached housing, OR: 0.13), female sex (OR: 1.48), age (55–64 years compared with 18–24 years, OR: 2.25) and the presence of a pet dog in the house (compared with no pet dog, OR: 1.85) (Downes et al. 2009). Similarly, in a British study, the presence of an adult female in the household or of people in the age groups 20–29 years and 30–59 years were associated with increased odds of owning a cat (Westgarth et al. 2010). Female sex, age class between 40–59 years, separated marital status, and living in a rural area were associated with cat ownership in a study from Central Italy (Carvelli et al. 2006). In the USA more than 75% of the persons taking care of a cat within a household are women; this rate is highest among 19–29 year-old women (AVMA 2012). Indirect evidence for a higher proportion of women caring for cats might be drawn from a US multicenter study on 110 patients with pet-afflicted bite wounds showing that 72% of people bitten by cats were women, while only 38% of dog bites documented in the study population affected women (Talan et al. 1999). In a 2003 population-based study from California, female single respondents had a higher odds of owning a cat; smaller household sizes, home ownership, living in a home, full time employment of the household, and more rural location were associated with higher odds of cat ownership (Saunders et al. 2017).

28.1.2 Public Health Impact of Cats

Cats may kill humans directly by attacking, violating or – seldomly and then reaching literally fame (Anderson 1955) – eating them. About 14,009 deadly attacks by large carnivorous cats on humans have been recorded worldwide in the twentieth century, the vast majority caused by tigers – probably a gross underestimation (Löe and Röskaft 2004). In the nineteenth and early twentieth centuries, tigers killed approximately 34,075 persons in the Indian subcontinent, in the twentieth century another 12,600 persons resulting in 600 to 800 human deaths per year from tiger attacks in Asia (Shepherd et al. 2014). The utmost unfriendly behavior, i.e., man-eating, was mainly reported for tigers in Singapore, India, Russia, and South China. For other big feline carnivores available twentieth century data allow the conservative estimate that lions and leopards have killed 552 and 840 people, respectively, in their natural African and Asian habitats (Shepherd et al. 2014), with more scaring man-eating events reported than for tigers giving rise to eternal fame, for instance, for the Tsavo brothers, two lion man-eaters (Peterhans et al. 2001), and the Panar man-eating leopard (Corbett 1954).

Not only wildlife felines or captive carnivores such as Siegfried and Roy's Montecore, but also pet cats may attack humans: about 400,000 cat bites occur every year in the USA (WHO 2018), in Bologna/Italy the incidence of cat-bite-related injuries was estimated to be 17.9/100,000 (Ostanello et al. 2005), in Brazil a national health survey calculated 76,512 cat bites/year corresponding with an annual incidence of 41 cat bites/100,000 (Benavides et al. 2020).

While these literally crude data show quite obviously a direct impact of cats on human health, the zoonotic health risks of cats to humans are much less visible and indirect.

Starting from a comprehensive risk assessment review on companion animal-associated zoonoses by the Robert Koch-Institut, Germany (Weber and Schwarzkopf 2003), and based on an intensive literature review as well as expert interviews of 14 scientists from the fields of veterinary medicine, human medicine and microbiology, a list of eight, three, and six pathogens with a public human health risk scored as "high," "low," and "unsure," respectively, for the German situation was compiled at the Veterinary University Hannover (Möbius 2013). *Bartonella henselae*, *Capnocytophaga* spp., *Pasteurella multocida*, Orthopoxvirus, *Cryptosporidium parvum*, *Toxoplasma gondii*, *Microsporum canis*, and *Trichophyton* spp. were ranked among the "high risk" zoonotic pathogens, *Coxiella burnetii*, *Dipylidium caninum*, and *Echinococcus* spp.) among the "low risk" group and *Campylobacter jejuni*, *Escherichia coli*, *Leptospira* spp., *Salmonella* spp., *Toxocara* spp., and *Giardia* spp. among the ambiguous zoonotic agents. Pathogens for which only a theoretical transmission risk exists (e.g., Lyssa viruses in a rabies-free country) or for which only anecdotal case reports could be found in the literature were excluded. A similar, but not risk-oriented list on zoonotic infectious diseases of companion animals including cats was published by Day et al. as an electronic document for the *Emerging Infectious Diseases* journal of the CDC, Atlanta, USA (Day et al. 2012), while in a more recent document the US CDC list on their homepage cat

scratch disease, roundworms, toxoplasmosis, rabies, campylobacteriosis, salmonellosis, cryptosporidiosis, giardiasis, hookworm, MRSA, plague, ringworm, different tick-borne diseases, and sporotrichosis as diseases associated with cats (CDC 2021). The American Association of Feline Practitioners (AAFP) mentions in their 2019 Feline Zoonoses Guidelines 14 enteric, seven scratch-, bite-, or exudate-associated, six ocular or respiratory, eight flea- and tick-borne zoonotic agents of cats, respectively, without further weighting (Lappin et al. 2019). Table 1 comprises the most important cat-associated zoonotic pathogens.

In the following we will mainly concentrate on pathogens with significant public health importance or a quite unique association with cats. Mainly bite-transmitted pathogens (e.g., *Capnocytophaga* spp. and *Pasteurella* spp.) and dermatophytes (e.g., *Microsporum* spp. and *Trichophyton* spp.) will not be dealt due to their quite special transmission pathways. Antibiotic resistant bacteria with the potential of zoonotic transmission, especially Methicillin-resistant *Staphylococcus aureus* will also not be addressed in this chapter.

28.2 The Usual Suspects

28.2.1 *Toxoplasma gondii*

28.2.1.1 The Pathogen – Life Cycle and Transmission

Three remarkable, if not ironical, events mark the first descriptions of *T. gondii* in 1908 by the French Nobel laureates Charles Nicolle and Louis Herbert Manceaux and the Calabria-born microbiologist and physician Alfonso Splendore (Meira 2010): (i) although spanning perhaps the widest host range of any parasite *T. gondii* was discovered independently not in wildlife, but in two laboratory animals, i.e., a North African comb rat named gundi in the Pasteur Institute in Tunis/Tunisia and a rabbit in the Hospital da Real Sociedade de Beneficência Portuguesa in São Paulo/Brazil, respectively (Dubey 2008, 2020). (ii) the two French microbiologists misspelled the Maghreb Arabian name of the rodent gundi as "gondi" resulting in the parasite's proposed species name as *gondii*; (iii) funnily, both the French and the Italian researchers misidentified the parasite discovered in their laboratory animals as a *Leishmania* species (Dubey 2008).

The parasitic life cycle of this coccidian protozoan of the Phylum Apicomplexa depends on the carnivorous lifestyle of felids and was finally resolved as late as the 1970s by the work of Frenkel and Dubey (Dubey 2008). Despite the parasite's extremely wide host range in air (birds [Dubey et al. 2021a]), on earth (nearly all warm-blooded animals), and in sea (maritime mammals) (see an extended list of animal species in Hill et al. 2005 and of rodents alone in Dubey et al. 2021b, respectively), the only known definitive hosts for *T. gondii* are members of the family Felidae. The important role of cats in the natural transmission of *T. gondii* is underlined by seroepidemiological studies on isolated Pacific, Australian, or US islands showing very low seroprevalence for *T. gondii* in the absence of cats (Wallace 1969; Munday 1972; Dubey et al. 1997); higher *T. gondii* seroprevalences on basically cat-free Arctic islands have been linked to migratory birds (Prestrud

et al. 2007). The obligate intracellular parasite can only sexually reproduce and, thereby, complete its life cyle in felids, the only mammals lacking delta-6-desaturase activity in their intestines resulting in a systemic excess of linoleic acid needed for *Toxoplasma*'s sexual reproduction (Martorelli Di Genova et al. 2019; English and Striepen 2019) manifesting in the subsequent production of the massive numbers of unsporulated oocysts. These oocysts are shed in the cat's feces and need to sporulate for 1–5 days in the environment to become infective. Intermediate hosts, e.g., birds and rodents, but principally any warm-blooded species including humans, get infected by ingesting oocysts-contaminated soil, water, or plant material. Shortly after ingestion, oocysts transform within the intermediate host into tachyzoites, which travel mainly within macrophages primarily into neural or muscular tissue (but principally in any tissue) where they develop into bradyzoites. Several thousands of bradyzoites form tissue cysts, which are ingested by cats when feeding on their prey, e.g., the "regular" intermediate hosts. Moreover, cats may also become infected directly by ingestion of sporulated oocysts. The infectious dose for cats is estimated to be around 100 oocysts or one bradyzoite, respectively (Dubey 2020). Infection of cats via tissue cysts is probably more effective than via oocysts resulting in a higher percentage of oocyst shedding (Zhu et al. 2021).

Humans may become infected (i) by slowly dividing bradyzoites, e.g., when eating undercooked meat of animals harboring tissue cysts[1], (ii) by sporozoites-containing oocysts, e.g., when consuming food or water contaminated with cat feces or when ingesting environmental items – either directly contaminated by a cat (e.g., via fecally contaminated soil or pet cat litter boxes) or indirectly by another animal (e.g., by dogs carrying oocysts in their fur after having rolled in cat feces due to their behavioral trait of the so-called xenosmophilia [Frenkel and Parker 1996]), (iii) by rapidly dividing tachyzoites, e.g., via blood transfusion or transplacentally, and (iv) by bradyzoites, e.g., via organ transplantation when transplanting tissue cysts-containing transplant material (Hill and Dubey 2002; Flegr et al. 2014).

As derived from toxoplasmosis outbreaks, neither disease severity nor clinical symptoms are probably related to the parasitic stage, i.e., oocysts vs. bradyzoites, ingested (Dubey 2021; Pinto-Ferreira et al. 2019).

28.2.1.2 Epidemiology in Cats and Humans

T. gondii strains are highly diverse, but only a few lineages are widely spread. In Europe, North America, and Africa there are three dominant clonal lineages, i.e., the more mouse-virulent I and the less mouse-virulent II and III; in South America the variety of genotypes is much more diverse and comprises more atypical strains, possibly due to more frequent sexual replication of *Toxoplasma* in this part of the world and associated with higher pathogenicity (Flegr et al. 2014; Su et al. 2012;

[1] Human transmission by different stages of undercooked meat (esp. lamb chops) or raw meat juice was shown in a French study with hospitalized children, supplemented by a detailed diet survey on beef, lamb, and horse meat preparing habits („*très cuit*," „*á point*," „*saignant*," „*très saignant*," and „*cru*"); while the culinary procedures are described in a quite sophisticated manner, no information is given regarding an ethical approvement of the performed diet studies (Desmonts et al. 1965).

Amouei et al. 2020; Bertranpetit et al. 2017; Galal et al. 2019; Lehmann et al. 2006; Khan et al. 2007).

Cats have been implicated to be involved in shaping the global phylogeny of *T. gondii* by two major spreading events: (i) after the reconnection of the Panamian land bridge 1-2 Mya comigration of feline definite hosts with the parasite might have resulted in the genetic divergence of both felids and *Toxoplasma* in South America (Khan et al. 2007); (ii) sixteenth century transatlantic slave trade by ships populated with rodents and domestic cats might have enforced the spread of *Toxoplasma* and its clonal formation in Europe, North America, and Africa (Lehmann et al. 2006).

Globally, seroprevalence in cats ranges from around 5% to more than 90% and is higher in feral and stray cats than in domestic pets (Dabritz and Conrad 2010; Dubey and Jones 2008; Nutter et al. 2004; Dubey et al. 2020; Zhu et al. 2021) with an estimated global pooled seroprevalence of 35% and 59% in domestic and wild felis, respectively (Montazeri et al. 2020). Seroprevalence rises with cat age (Vollaire et al. 2005); e.g., in a Belgian study on 567 health domestic cats seroprevalence increased from 2% in kittens below 12 months of age to 44% in 7-year old cats (De Craeye et al. 2008). Probably less than 1% of mainly young cats – often being infected for the first time during their first outdoor hunting experiences – are shedding oocysts once in their lifetime for an average period of 1 week and up to 3 weeks, although data from experimentally infected cats suggest that re-excretion of oocysts is possible (Dubey et al. 2020) questioning the previous assumption of a single oocyst shedding period (Zhu et al. 2021). Reported rates of shedding domestic cats range from 0% to 34% in microscopic (Dabritz and Conrad 2010; Barutzki and Schaper 2011; Epe et al. 2004) and up to 20% in DNA studies (Dubey et al. 2020). A single cat may excrete more than 50 million oocysts per day (Dabritz and Conrad 2010: data are based on 73 experimentally or naturally infected cats from five different studies) with 3 to 810 million oocysts per cat infection. With an estimated 40 g of daily feces production per cat, the amount of annual fecal production by feral cats was calculated to reach up to 2.4×10^6 tons in the USA matching up to 2.4×10^{15} oocysts deposited in the US environment (Dabritz and Conrad 2010; Torrey and Yolken 2013). It should be noted, however, that laboratory methods for oocyst detection especially in environmental samples are not very sensitive; direct measurements and source detection in outbreak situations are therefore often not possible.

Toxoplamosis is probably the most prevalent infection in humans affecting 30–50% of the world population thus outnumbering even latent tuberculosis (Flegr et al. 2014). It ranks among the three most important food-borne diseases at least in industrialized countries (Aguirre et al. 2019; WHO 2015) with the highest disability-adjusted life years (DALY) among food-borne infections (Flegr et al. 2014).

Seroprevalence in humans shows a similar range as in cats, i.e., from about 3% to around 90% in different human populations and geographical regions (Dabritz and Conrad 2010; Bigna et al. 2020). In most European, Central/South American, and North American countries, about one-fourth to two thirds – from a public health point of view – of the most relevant human population, i.e., pregnant women or women of child-bearing age, show anti-*Toxoplasma* IgG antibodies (Dabritz and Conrad 2010; Nogareda et al. 2014; Galvan-Ramirez et al. 2012), with the Americas

as the WHO region with the highest (around 45%) and the Western Pacific with the lowest (around 11%) IgG prevalence, respectively (Bigna et al. 2020). In some countries, including France, the prevalence has fallen in the last two decades, probably due to hygienic and awareness building measures (Petersen et al. 2010; Nogareda et al. 2014).

The global annual incidence of the most severe form of toxoplasmosis, i.e., congenital toxoplasmosis, was estimated in a WHO review to be 190,100 cases matching an incidence of 1.5 cases of congenital toxoplasmosis per 1,000 live births (Torgerson and Mastroiacovo 2013). A recent review found the highest incidences for congenital toxoplasmosis in Brazil, France, and Austria, respectively (Dubey et al. 2021c).

28.2.1.3 Disease in Cats

Infection in cats is usually asymptomatic or subclinical with only minor symptoms such as short-term diarrhea, lymphadenopathy, or fever. Overt disease is more likely in cats with immunosuppression, including young kittens and cats with, e.g., feline leukemia virus (FELV) or feline immunodeficiency virus (FIV) infection. During the parasite's extraintestinal tachyzoite phase and depending on the affected organ system, pneumonia with cough and breathing problems, longer episodes of diarrhea, uveitis, iritis, chorioretinitis, myocarditis, or encephalitis may develop. Very rarely, sudden death may occur especially in very young kittens (Dubey et al. 2020).

28.2.1.4 Disease in Humans

Most infections affecting humans are asymptomatic. If symptomatic, mainly immunosuppressed people are concerned. Lymphadenopathy, sometimes associated with fever, fatigue, muscle pain, sore throat, and headache, is the most frequently observed acute clinical form of postnatally acquired toxoplasmosis in humans.

In striking contrast, multivisceral symptomatic infection, sometimes referred to as "Amazonian toxoplasmosis," acute and severe ocular forms (e.g., retinochoroiditis), and even deaths among immunocompetent patients have been reported mainly in connection with both oocyst- and bradyzoites-associated outbreaks in South America and the Carribean, sometimes linked to atypical and more pathogenic *Toxoplasma* strains or genetic host susceptibility (Galal et al. 2019; Carme et al. 2009; Dubey 2021).

Most important clinical findings in immunosuppressed patients include encephalitis, chorioretinitis, or pneumonitis due to reactivation of bradyzoites, which are otherwise immunologically well controlled in tissue cysts and might develop into tachyzoites during phases of immunosuppression. Recently, evidence is rising that latent *Toxoplasma* infection might be linked to behavioral or mental changes and psychiatric disease (Flegr and Horáček 2020), e.g., an association with self-directed violence (Pedersen et al. 2012), suicidal behavior (Groër et al. 2011; Postolache et al. 2021), or automotive accidents (Flegr et al. 2002); however, if and which *Toxoplasma*-specific underlying causes might be involved is not yet understood (Flegr 2013). These findings are paralleled by behavioral changes observed in experimentally infected mice, which have been linked to *Toxoplama*'s life cycle postulating that the parasite manipulates its intermediate hosts to lose their innate fear of

predators including cats or to feel attracted to cat urine thus increasing the probability to be devoured by their definite hosts (Vyas et al. 2007; Boillat et al. 2020; Aguirre et al. 2019; Tong et al. 2021). Congenital toxoplasmosis is caused by transplacental infection when a non-immune mother infected for the first time during pregnancy transmits tachyzoites to her fetus. The clinical spectrum of congenital toxoplasmosis ranges from asymptomatic infection to severe syndromes including hydrocephalus, microcephaly, or intracranial calcifications – leading to mental and/or psychomotoric retardation – and chorioretinitis causing vision impairment or even blindness. Stillbirth or death in the neonatal period may also occur.

28.2.1.5 Public Health Importance

A WHO review estimates the global burden of congenital toxoplasmosis to be as high as 1.20 million DALYs (Torgerson and Mastroiacovo 2013). The highest burdens were seen in South America and in some Middle Eastern – especially in low-income – countries. For their calculations, the WHO review authors took into account different disease patterns, manifestations, and severities possibly due to different pathogenic strains and their respective geographical distribution.

In the 1990s, about 750 deaths per year were attributed to toxoplasmosis in the USA (Mead et al. 1999), while more recent estimates report 327 deaths per year making *Toxoplasma* the food-borne pathogen with the second most annual deaths after *Salmonella* spp. (Batz et al. 2021). These estimates of lethal outcomes might mainly refer to infections acquired by immunosuppressed people via ingestion of tissue cysts. However, due to the larger amount of people affected, oocyst-transmitted infections may be both clinically and from a public health point of view more severe than tissue cyst-induced infections as mainly concluded from outbreak situations (Beneson et al. 1982; Burnett et al. 1998; Teutsch et al. 1979; Bowie et al. 1997).

On a global scale, the relative contribution of human infection via oocysts from food or drinking water contaminated with cat feces on the one hand and from tissue cysts by eating undercooked meat on the other hand is very difficult to establish and probably differs in different geographical locations and human populations due to different environmental conditions, sociocultural customs, and also the pathogenicity of the prevalent *Toxoplasma* strain (VanWormer et al. 2013; Milne et al. 2020). Interestingly, case-control studies failed to explain up to 40% of human infections due to any known risk factor (Petersen et al. 2010). In a European multicenter study from France, Italy, Belgium, Denmark, and Sweden, between one and two thirds of infections could be attributed to consumption of undercooked meat products and 6–17% to soil contact (Cook et al. 2000). However, considerable seroprevalence data in vegetarian human populations from India (Rawal 1959: 21%), among Seventh Day Adventists in the USA (Roghmann et al. 1999: 18%) and in Amerindian aborigines from Venezuela (Chacin-Bonilla et al. 2001: 43.5% to 62.4%) as well as symptomatic outbreaks of human toxoplasmosis mainly linked to probably contaminated drinking water sources (Balasundaram et al. 2010; Petersen et al. 2010; Dabritz and Conrad 2010; Dubey 2021; Pinto-Ferreira et al. 2019), e.g., the most prominent and best analyzed 1995 Vancouver outbreak

presumably caused by cougars shedding oocysts (Aramini et al. 1998, 1999; Bowie et al. 1997), or to contaminated vegetables (Ekman et al. 2012) suggest a significant proportion of oocyst-transmitted toxoplasmosis at least in some circumstances (Peterson et al. 2010). Moreover, when finding with a novel sporozoite-(and therefore oocyst-)specific serological test that 78% of 76 mothers of congenitally infected infants in a US-wide survey had a primary infection with oocysts, Boyer et al. speculated that a major number of congenital toxoplasmosis cases and at least four North American epidemics are due to infection via oocysts (Boyer et al. 2011). Similarly, based on sporozoite-specific seroprevalence studies (Hill et al. 2011), *T. gondii* transmission has been largely attributed to oocysts for regions of Brazil with poor socioeconomic and hygienic conditions and oocyst-favorable warm, humid climate (Milne et al. 2020). In contrast, in Poland with approximately 80% of livestock reported as *T. gondii* seropositive, bradyzoites from undercooked meat have been implicated to be the most significant source of infection (Flegr et al. 2014).

Data from 11 epidemiological studies performed from 1990 to 2006 in different European, African, and American countries analyzing soil contact associated with seropositivity found odds ratios (OR) from 1.4 to 10.3 suggesting a possible risk of oocyst-transmitted infections via cat feces (Dabritz and Conrad 2010). However, direct daily contact with cats or cat-ownership was not associated with an increased risk of *T. gondii* infection in one USA and two European case-control studies (Cook et al. 2000; Kapperud et al. 1996; Jones et al. 2009) or in studies from South Korea (Jung et al. 2017) or the UK (Flatt and Shetty 2013), respectively. In contrast, the OR for owing a cat was 1.25 in a study from the Czech Republic (Kolbekova et al. 2007). Seroprevalence studies in pregnant women from Iran (Foroutan-Rad et al. 2016) and France (with an OR of 4.5 for cat ownership [Baril et al. 1999]), in hemodialysis patients (OR 3.73) and a healthy control group (OR 1.80) in Iran (Soltani et al. 2020), in a population-based control study from Taiwan (OR of 2.9 [Chiang et al. 2014]) and in school children in central China (Wang et al. 2020) identified cat ownership as an independent risk factor for *Toxoplasma* infection. Interestingly, owing three or more kittens was associated with an adjusted OR (aOR) of nearly 28 in the very same US study which showed a "protective" effect of owing one or two cats (aOR 0.6) (Jones et al. 2009).

In conclusion, there is considerable indirect evidence for a direct role of oocyst-shedding cats in *Toxoplasma* transmission to humans. Unfortunately, although oocysts have been detected both in environmental and in water samples by different methods (Dabritz and Conrad 2010), often the implicated sources suggested by epidemiological considerations cannot be corroborated or certified by direct detection of oocysts due to the lack of laboratory facilities or methodologically based sensitivity problems. Therefore, the public health impact of directly cat-associated, i.e., oocyst-transmitted, toxoplasmosis cannot be clearly calculated.

28.2.1.6 Public Health Measures

When assessing the risk of directly cat-associated transmission, it should be noted that probably one oocyst might be enough to cause infection as data from

experimentally infected swine suggest (Dubey et al. 1996). Considering the mean of 50 million oocysts daily excreted by a single freshly infected cat methods preventing oocyst contact, ingestion or inhalation are obviously reasonable. Care should especially be taken when dealing with sandboxes where cats that do usually not defecate randomly, but rather select places for defecation, often deposit and subsequently cover their feces resulting in the accumulation of more than 1 million oocysts per square foot in certain areas of sandboxes (Torrey and Yolken 2013).

Interestingly, in a 19 months lasting German study on more than 18,000 feline fecal samples the proportion of *T. gondii*-positive samples collected between January and June was significantly lower than between July and December (Herrmann et al. 2010).

Cat-related public health measures for reducing the risk of toxoplasmosis might therefore include (i) hygienic measures such as wearing gloves when and washing hands after gardening, working with soil (especially in places where domestic and above all feral or stray cats might defecate) or having contact with cat feces; (ii) thoroughly washing of vegetables and fruits; (iii) restricting pet cats', especially kittens', access to wild rodents (although estimated bradyzoite rates for rodents are quite low, e.g., 0.1–0.4% in Germany); (iv) avoiding disposal of cat feces into drinking water sources (e.g., the respective Californian legislation [Dabritz and Conrad 2010]); (v) adopting a stray cat policy reducing roaming of unowned and not sufficiently supervised cats; (vi) preventing contact of cats and their feces to highly susceptible intermediate host animals such as swine, lambs, or chicken (Dubey 2010); (vii) development of a feasible and robust vaccine for cats (Dabritz and Conrad 2010; Petersen et al. 2010; Aguirre et al. 2019). Recently, a CRISPR/Cas9-based genetically attenuated live vaccine generating defective oocysts failing to produce sporozoites was succesfully shown to completely prevent oocyst excretion thus blocking *T. plasma* transmission (Ramakrishnan et al. 2019).

28.2.2 Bartonellosis

28.2.2.1 The Pathogen

The genus *Bartonella* comprises a group of Gram-negative facultative intracellular bacteria with a unique life cycle involving one or few closely related mammals as reservoir hosts and different bloodsucking arthropods as vectors. Currently, 37 *Bartonella* species/subspecies and additional candidates, e.g., not fully characterized and named species, are listed (www.bacterio.net), which have been identified in a wide range of domestic and wild animals, including at least 16 causing disease in humans and 10 zoonotic species from cats and/or dogs (Cicuttin et al. 2014; Chomel et al. 2012; Harms and Dehio 2012; Zangwill 2013; Okaro et al. 2017). Following transmission by an arthropod vector, bartonellae colonize a not yet definitely identified primary niche, which probably involves migratory cells as well as additional cell types and are transported to the vascular endothelium where they persist intracellularly (see Harms and Dehio 2012 for an intense review of the molecular pathogenesis of *Bartonella* spp.). *Bartonella* is known to infect a range of host cells,

but the endothelial cell is thought to be the primary niche location (Okaro et al. 2017). From the primary niche the bartonellae invade erythrocytes where they finally persist to be again taken up by bloodsucking arthropods for transmission to another host. Both vector (including its ecology) and host (including the primary niche as first step in the intrahost replication cycle) factors are responsible for the reservoir host specificity of the respective *Bartonella* species (Harms and Dehio 2012). Their lifestyle both in the primary and the intraerythrocytic niches allow the bartonellae to escape the immune system, to replicate within their host, to relapse from time to time and to evade antibiotic treatment.

The majority of human infections is caused by three *Bartonella* species (*B. henselae*, *B. bacilliformis*, and *B. quintana*) of which one is zoonotic and has cats as reservoir hosts, i.e., *Bartonella henselae*. Cats are also the main reservoir for *B. clarridgeiae* and *B. koehleae* that may be both causative agents of cat-scratch disease and endocarditis in humans (Cheslock and Embers 2019; Alvarez-Fernandez et al. 2018). The natural and most important arthropod vector both for direct intra- (i.e., cat-to-cat) and probably also for indirect interspecies (i.e., cat-to-human) transmission is the cat flea *Ctenocephalides felis* (Breitschwerdt and Kordick 2000; Mosbacher et al. 2011; Harms and Dehio 2012). Transmission to humans is thought to occur mainly via *B. henselae*-contaminated cat flea feces after inoculation by a cat scratch or a cat bite; interestingly, *B. henselae* DNA could be isolated from gingiva and claw beds of domestic cats in the USA (Lappin and Hawley 2009).

Besides, in cat fleas, *B. henselae* has also been identified in hard ticks from Europe and North America (i.e., *Ixodes ricinus* and *Ixodes pacificus*) suggesting a possible role of *Ixodes* spp. as vectors as it is proven for another *Bartonella* species (Mosbacher et al. 2011; Reis et al. 2011; Regier et al. 2016). Furthermore ticks have been clinically implicated in the transmission of *Bartonella* infection to humans in the absence of other known transmission modes (Maggi et al. 2013).

While cats are the natural reservoir host for *B. henselae*, infection has also been shown serologically or by DNA detection in a variety of accidental hosts including dogs, coyotes, cattle, horses, and deers (Mosbacher et al. 2011; Regier et al. 2019). In addition, bats and wild rodents were found to be novel hosts for potentially zoonotic *Bartonella* spp. (Stuckey et al. 2017; Rozental et al. 2017).

28.2.2.2 Epidemiology in Cats and Humans

Bartonellosis has a worldwide distribution. In cats, seroprevalence usually ranging from 40% to 70% is much higher in warm, humid regions in which high flea infestation is expected (Breitschwerdt and Kordick 2000; Mosbacher et al. 2011; Alvarez-Fernandez et al. 2018). In Europe seroprevalence for pet cats was determined to be, for instance, 23% in Austria (Skerget et al. 2003), 24.7–71.4% in Spain (Aylo et al. 2012; Solano-Gallegro et al. 2006), 41.1% in France (Gurfiel et al. 2001), 18.8–68.7% in Germany (Mietze et al. 2011; Morgenthal et al. 2012), 10.9–57.1% in Italy (Zobba et al. 2009; Mansueto et al. 2012), and 41.2 in the UK (Barnes et al. 2000). An absolute exception is the seroprevalence of 0% in 100 domestic and feral cats from Norway (Bergh et al. 2002).

In Africa 21% and 59.6% of the investigated cats in South Africa and North Africa, respectively, had antibodies against *Bartonella* spp. (Kelly et al. 1996; Al-Kappany et al. 2011). On the Asian continent the seroprevalence of cats ranged from 1.5 to 68% in the Middle East and the Philippines, respectively (Alvarez-Fernandez et al. 2018) and the main clinico-epidemiological studies from America report on 3.7 –75% (Jameson et al. 1995; Case et al. 2006; Nutter et al. 2004) and 5.6–75% (Levy et al. 2008; Müller et al. 2017) serogical positive cats in North and South America, respectively.

Hunting for prey, having access to outdoor environments, living previously as a stray cat or living with other pet cats in the same household were found to be associated with a higher risk of seropositivity (Al-Majali 2004; Gurfield et al. 2001). When compared with pet cats from the same geographical region, feral cats show usually significantly higher seroprevalence rates, e.g., in Sicily (35.4% vs. 68.3%; Mansueto et al. 2012), in North Carolina, USA (75% vs. 93%; Nutter et al. 2004), in Taiwan (26.7% vs. 40%; Chang et al. 2006) or in Turkey (22.9% vs. 31.7%; Guzel et al. 2011). In contrast, seroprevalence in shelter cats seems to be bimodal, i.e., either most cats or only very few show a positive serology (Breitschwerdt and Kordick 2000) with flea infestation as the most important risk factor. Prevalence of bacteremia in both domestic (DC) and stray cats (SC) is usually lower than the respective seroprevalence with 0% in DC in Madrid, Spain (Gil et al. 2013), 4% in Catalonia and northeastern Spain (Pons et al. 2005; Solano-Gallego et al. 2006), 3% in Brazil (DC; Braga et al. 2012), 5.8% (DC) and 18.6% (SC), in China (Yuan et al. 2011), 16% (DC) and 40% (SC), in Australia (Branley et al. 1996), 14.9% in Argentina (Cicuttin et al. 2014), 15.7% (DC) and 35.5% (SC) in La Rioja, Spain (Gil et al. 2013), 16.5% (DC; Gurfield et al. 2001) and 37.2% (SC; Heller et al. 1997) in different parts of France, 16.7% (DC) and 31.3% (SC) in Taiwan (Chang et al. 2006), 17% in Algeria (SC; Azzag et al. 2012) and New Zealand (DC; Joseph et al. 1997), 25% (DC) and 26% (SC) in the Netherlands (Bergmans et al. 1997) or 39.5% in California, USA (Chomel et al. 1995). Risk factors for *B. henselae* bacteremia are grossly those associated with seroprevalence.

In free-ranging or captured big cats such as lions, panthers, and cougars *B. henselae* infection could also be documented serologically or directly by PCR and/or bacterial culture. Seroprevalence rates ranged from 0% in 44 Amur tigers (Goodrich et al. 2012), 18% for panthers in Florida, USA and 28% for cougars from Texas, USA (Rotstein et al. 2000), 17% for lions and 31% for cheetahs in Africa collected between 1982 and 2002 (Molia et al. 2004), 29% in African lions (Pretorius et al. 2004), 37% for Californian mountain lions (Girard et al. 2012), 30% in captive wild felids, 35% for mountain lions, to 53% in bobcats from California, USA, respectively (Yamamoto et al. 1998). Bacteremia with *B. henselae* detected either by culture and/or PCR was found in 1.5% in 65 African lions (Pretorius et al. 2004), in 3.4% of 58 lions (Molia et al. 2004), in 6% of in Iriomote wildcats (*Prionailurus iriomotensis*) from Japan (Tateno et al. 2013), in 15% of neotropical felids mostly of the genus *Leopardus* from a Brazilian shelter (Guimaraes et al. 2010), and in 35% in feral cats (*Felis catus*) from St. Simons Island, Georgia, USA (Hwang and Gottdenker 2013).

In humans, the annual number of infections has been estimated to range between 22,000 and 24,000 in the USA, with about 2,000 cases requiring hospitalization (Jackson et al. 1993; Nelson et al. 2016; Okaro et al. 2017). Thousands of cases may occur yearly in Europe (Chomel et al. 2006; Blanco et al. 1998; Müller 2016). In the USA, there seems to be a seasonal distribution of human cat-scratch disease (CSD) incidence, with the majority of cases occurring between July and January (Carithers 1985; Reynolds et al. 2005; Jackson et al. 1993). This pattern might be due to the seasonal breeding patterns of domestic cats, the acquisition of kittens as family pets, and the peak temporal presence of the cat flea among cats (Anderson and Neuman 1997).

Screening of healthy human blood donors in different industrialized countries, e.g., Sweden, France, Austria, and the USA, found a seroprevalence with anti-*B. henselae* antibodies of 2–22% (Mosbacher et al. 2011; Müller et al. 2016; Breitschwerdt and Kordick 2000). However, studies in certain human populations with a presumably higher risk of attracting infection, e.g., veterinarians, cat owners, hunters, or farm workers, detected higher seroprevalence rates. Seropositivity was 9.6% in Chinese farm workers (Zhang et al. 2008), 15% in Japanese veterinarians (Kumasaka et al. 2001), 45% and 53.3% in Polish veterinarians and cat-owners, respectively (Chmielewski et al. 2007), and 51.1% in veterinarians from Austria (Nowotny et al. 1997). In Austrian hunters, seropositivity was found in 23% (Müller et al. 2016). In contrast, a Taiwanese study among veterinary clinic staff found only a seropositivity of 1.7% (Chang et al. 2006). Also, a seroprevalence rate of 7.1%, which is in the range of that found in the normal population, was detected in attendees of a veterinary conference in Ohio, USA (Noah et al. 1997). Moreover, no association of anti-*B. henselae* antibody positivity with cat ownership was seen in two studies from Austria (Skerget et al. 2003) and Germany (Rath et al. 1997), respectively. Taken together, these data suggest that frequent or even close contact with cats per se does not necessarily lead to *B. henselae* infection and other factors, e.g., flea infestation of cats, have also to be considered.

Only very few studies analyzing anti-*B. henselae* antibody seroprevalence in HIV-positive CSD- or bacillary angiomatosis (BA)-asymptomatic patients have been published; most of them do not differentiate between *B. henselae* and other *Bartonella* spp., have only very small study population sizes and/or lack control groups. Despite these biases and shortcomings, most of the study authors, however, postulate a higher seroprevalence in HIV-patients than in the HIV-negative population (Blanco et al. 1998; Frean et al. 2002; Pons et al. 2008; Trataris et al. 2012), while other studies found no significant differences between both groups (Tsukahara et al. 1999; Pawelczyk et al. 2019).

28.2.2.3 Disease in Cats

Naturally infected cats are usually asymptomatic, although *B. henselae* might cause chronic, relapsing bacteremia for months to years (Alvarez-Fernandez et al. 2018). In experimentally infected cats, in cats infected with non-reservoir-adapted *Bartonella* species (i.e. non-*B.henselae* species) or in immunosuppressed cats, e.g., with a coinfection with Feline Immunodeficiency Virus (FIV), symptoms such as lymphadenopathy, fever, mild transient anemia, or cardiac and renal lesions might be present (Breitschwerdt and Kordick 2000).

28.2.2.4 Disease in Humans

Cat scratch disease (CSD) in immunocompetent people and bacillary angiomatosis (BA) in mainly immunosuppressed patients are the prominent clinical syndromes caused by *B. henselae* (Zangwill 2013). Typically, CSD is a benign and self-limiting disease in humans, presenting with lymphadenopathy (> 90% of patients) mainly of an upper extremity or the neck and often showing suppuration (15–30%), low-grade fever (26–60%), a primary cutaneous lesion at the inoculation site (25–90%), malaise and weight loss (10–45%) (Zangwill 2013). Rare symptoms include erythema nodosum, figurate erythemas, thrombocytopenic purpura, Perinaud's oculoglandular syndrome, encephalopathy, hepatic granulomas, osteomyelitis, pulmonary disease, optic neuritis, and endocarditis. In most cases, the clinical findings resolve spontaneously after 6–12 weeks, while lymphopathy may persist for weeks to months. BA is an uncommon, but severe and potentially fatal disease especially seen in AIDS patients and caused by the pathogen's direct and indirect pro-angiogenic features (Harms and Dehio 2012). Hallmarks of cutaneous manifestations are often multiple (up to hundreds) erythematous, highly vasculated exophytic lesions, or subcutaneous nodules. Basically, any organ might be involved, but besides the skin mainly bones, liver (i.e., peliosis hepatitis), and spleen are affected. Due to their intracellular lifestyle as "intruders below the radar," bartonellae in their niches are difficult to reach by antibiotics (Harms and Dehio 2012). So far, no randomized clinical trials showing an effective antibiotic treatment for CSD exist (Prutsky et al. 2013), although guidelines based on expert consensus have been published (Rolain et al. 2004).

Angioproliferative dieseases such as BA and peliosis hepatitis can be fatal and are usually treated with macrolides or tetracyclines (Zangwill 2013; Rolain et al. 2004; Regier et al. 2016). *Bartonella* spp. have been reported to be the emerging cause of culture-negative endocarditis or fever of unknown origin with high anti-Bartonella-IgG antibody-titers (Regier et al. 2016). Especially, *B. henselae* and *B. quintana* harbor special surface adhesins, which may be an important factor for auto-aggregation, biofilm formation, and, potentially, persistence in vegetative masses in endocarditis. Thus, current recommendations for treatment of *Bartonella* endocarditis include a two drug regimen including aminoglycosides (Okaro et al. 2017).

28.2.2.5 Public Health Importance

Data obtained by multi-locus sequence typing (MLST) of feline and human *B. henselae* isolates indicate that certain sequence types (ST), e.g., ST1, ST2, ST5, and ST8 might be associated with zoonotic transmission and human disease, while others, e.g., ST6 and ST7, are more restricted or even exclusively found in cats (Arvand et al. 2007; Iredell et al. 2003). However, due to different geographic distributions, e.g., in Asia, which differs significantly from that in other parts of the world, a bias regarding an overemphasized association of certain STs with human disease cannot be excluded (Arvand et al. 2007; Bouchouicha et al. 2009; Li et al. 2006; Gil et al. 2013). An overrepresentation of ST1 among human isolates was reported by Arvand analyzing 182 strains from Europe, North America, and Australia by Iredell on 37 strains from France, Germany, the USA, and Australia

and – together with ST8 – by Gil et al. from northeastern Spain (Arvand et al. 2007; Iredell et al. 2003; Gil et al. 2013). Moreover, among 26 *B. henselae* strains isolated from stray cats in China comprising 18 different STs nearly two thirds belonged to ST1, which is associated with human disease (Yuan et al. 2011). ST1 was also predominant in 9 *B. henselae* strains obtained from cats in Buenos Aires, Argentina, followed by ST8, ST5 and ST6 (Cicuttin et al. 2014). In contrast, ST1 does probably not present the greatest public health risk in the UK: in an England-based MLST study on 118 *B. henselae* strains isolated from humans and cats, the vast majority (85%) of zoonosis-associated strains belonged to ST2, ST5, and ST8, respectively, while 74% of the feline isolates belonged to ST4, ST6, and ST7 also indicating that a few, uncommon STs were responsible for the majority of symptomatic human infections in the UK (Chaloner et al. 2011). Interestingly, ST1 and ST5 were found to be significantly more common in countries outside Europe than in England, ST5 and ST7 more common in continental Europe than in England, and ST4 and ST6 more common in England than in the rest of the world (Chaloner et al. 2011). ST1 was also found to be only rare or even absent in North West European countries, but dominating in the Mediterranean region (Arvand et al. 2007). In a Spanish study analyzing both 35 feline strains and the to date largest number of human isolates (n=46), ST5 was by far the most frequent ST among both feline and human isolates comprising more than half of all STs in the respective group (humans: 54.3%; cats: 61.5%) (Gil et al. 2013). Moreover, ST5 – besides ST7 – was also the most often identified ST in 42 German pet cat isolates (Mietze et al. 2011). Both in England (Chaloner et al. 2011) and Spain (Gil et al. 2013), ST5 and ST8 were among the three STs most frequently associated with symptomatic human infection.

However, in contrast to most studies using MLST or MLVA as molecular epidemiological tools, two complementary French studies (Li et al. 2006, 2007) and one Japanese study (Yanagihara et al. 2010) performing the more discriminatory multispacer typing (MST) did not find statistically significant differences in genotypic diversity between human and feline isolates. The reason for this discrepancy is not yet clear, but may be explained by the predominance of different zoonosis-associated strains in different geographic regions.

Not only an association between certain *B. henselae* strains and zoonotic transmission, but also with clinical presentation in humans, either with CSD or endocarditis, has been shown in different studies suggesting the existence of strains with a higher pathogenic potential for humans (Bergmans et al. 1996; Gil et al. 2013). Interestingly Boulouis et al. found specific MVLA profiles in free-ranging and captive wild felids suggesting that these *B. henselae* strains are highly adapted to a specific feline reservoir (Boulouis et al. 2020).

28.2.2.6 Public Health Measures

Except for recommendations to avoid cat contact, cat owners should be advised to screen their cats for fleas and ticks and should be protected year-round from infestation by the regular use of acaricides in spot-on or oral formulations thus prohibiting exposure in- and outside of human habitats (Alvarez-Fernandez et al. 2018; Mosbacher et al. 2011; Breitschwerdt 2008). Immunosuppressed people

should be advised not to adopt stray or flea-infested cats (Stützer and Hartmann 2012). Antibiotic treatment of individual cats has not been proven to be effective in eliminating the carrier status (Mosbacher et al. 2011) and is useless in cats older than 2 years of age due to the self-limiting character of the disease (Breitschwerdt 2008; Stützer and Hartmann 2012). However, it has been proposed to consider doxycycline treatment of both symptomatic and asymptomatic cats younger than 2 years of age when living in the same household with an immunosuppressed human to reduce the bacterial load (Stützer and Hartmann 2012). On a public health scale the development of vaccines to protect pets against *Bartonella* infections and thus reduction of the zoonotic risks would be eligible (Alvarez-Fernandez et al. 2018).

28.2.3 *Toxocara cati*

28.2.3.1 The Pathogen – Life Cycle and Transmission

Toxocara cati, the cat roundworm, first described as *Ascaris cati* in 1788 by the Bavarian Jesuit priest, botanist, and entomologist Franz von Paula Schrank (Schrank 1788), is the most common endoparasite in cats. As its close relative, *Toxocara canis*, it belongs to the ascarid nematodes in the order *Ascaridida*, superfamily Ascaridiodea, family Toxocaridae. Its definitive hosts are cats, in which they live as adults within the lumen of the small intestine. Cats might get infected by ingesting viable, embryonated eggs from contaminated sources (e.g., soil or paratenic[2] hosts such as mice, other rodents, earthworms, ants, or soil-dwelling invertebrates). After ingestion within 2–4 h, the eggs hatch in the duodenum to release juvenile larvae, which penetrate the small intestine, enter the circulation, migrate via the bloodstream or the lymph vessels throughout the body and may invade any organ, especially the liver (after 24 h), the heart, or the lungs (after another 12–24 h). Similarly to the human roundworm *Ascaris lumbricoides*, the larvae migrate especially in young kittens through the lungs, penetrate the trachea, enter the esophagus, get swallowed, and finally reach the lumen of the small intestine where they mature and mate. A single female worm produces about 200,000 non-embryonated eggs/day. After a prepatent period of around 8 weeks the eggs are excreted *per vias naturales* together with the cat feces into the environment. Embryonation occurs in the soil within 2–6 weeks after deposition depending on the temperature and environmental conditions. In adult animals with some degree of acquired immunity the larvae may also remain as dormant larvae in any tissue without reaching the intestine. Besides infection by ingestion of eggs, transmammary or lactogenic transmission is also possible and probably the major route of infection in kittens; larvae migrated to the mammary

[2] The phrase „paratenic host" was introduced by the Swiss parasitologist Jean Georges Baer in 1951, It is derived from the Greek παρατειvω meaning „to prolong, to draw out, to expand, to pass from one to another" or – in Baer's words – „to complicate the life cycle." A paratenic host is „an optional intermediate host (. . .) which the larvae usually enters passively, (. . .) such larvae will invariably remain at the same stage of development as when first swallowed by this host" (Baer 1951; Bowman 2020).

glands of lactating queens when infected late in pregnancy may infect nursing kittens throughout the entire lactation period (Coati et al. 2004; Traversa 2012; Swerczek et al. 1971; Baneth et al. 2016; Morelli et al. 2021). Vertical transmission and infection by the ingestion of paratenic hosts (preferably mice, but also earthworms, cockroaches, or other invertebrates), which harbor encapsulated larvae may also happen. The latter is supposed to be particularly important in cats due to their predatory lifestyle, while dogs might be more prone to infection via the fecal-oral route ingesting *Toxocara* eggs when sniffing or licking at feces-contaminated surfaces (Morelli et al. 2021). Encapsulated larvae may stay infective within paratenic hosts for up to 10 years allowing the parasite to continue their life cycle at prolonged periods waiting to be eaten by the final feline host (Strube et al. 2013; Beaver 1969). In contrast to *T. canis* in dogs, where transplacental transmission is of major importance for the completion of the parasite's life cycle, this route of transmission has not been described for *T. cati* in cats (Macpherson 2013; Strube et al. 2013; Rubinsky-Elefant et al. 2010; Carlin and Tyungu 2020; Rostami et al. 2019; Morelli et al. 2021).

Humans may become infected by accidental ingestion of embryonated infective third-stage larvae (L3) containing eggs present in cat-feces contaminated soil (therefore its classification as a primarily telluric zoonosis or saprozoonosis by the WHO) via geophagy (a certain type of pica), contaminated hands or onychophagy or – less frequently – food or water (Fillaux and Magnaval 2013; Deshayes et al. 2016; Rostami et al. 2019). The infectious dose of 100–200 eggs has been determined for *T. canis* in a single human volunteer (Chaudhuri and Saha 1959) and two "mentally defective children" (Smith and Beaver 1953), respectively[3]. Probably, more rarely, transmission can be achieved through consumption of encysted larvae in raw or undercooked paratenic hosts (e.g., chicken, ducks, sheep, cattle, especially raw liver) (Bowman 2020; for a review of cases see: Hoffmeister et al. 2007). Mainly children may also get infected by eating invertebrate paratenic hosts, e.g. earthworms (Macpherson 2013). Transmission by direct animal contact, e.g. via eggs in fur, might also be possible, although only a low percentage of detectable eggs sticking to cat fur were found to be embryonated and therefore infective in studies from Iran and Turkey (Bakshani et al. 2019; Öge et al. 2014).

In contrast to cats, humans are aberrant or dead-end hosts with respect to the completion of the *Toxocara* life cycle. Infective larvae may hatch after ingestion of eggs, but – in contrast to the human-adapted *A. lumbricoides* larvae – the juvenile stages fail to develop to mature adult worms. Instead, they may migrate throughout the human body and finally get encysted for months or years in basically any organ, causing inflammatory or immunologically driven damage to the respective tissue they happen to reach (Macpherson 2013; Overgaauw 1997; Despommier 2003). Since larvae do not develop to adult worms in humans, reports on finding adult *T. cati* worms in the human gut or in human feces (Rodan and Buckley 1969; Bisseru

[3] Unfortunately and sadly, no information on the circumstances of these *in vivo* experiments, esp. on an ethic approval of these studies, is given in the two publications.

et al. 1966) can only be explained by ingestion of advance-staged larvae in or from feline feces (Beaver 1969); the same holds true for the unique report on – most likely – *T. cati* eggs in the intestinal region of an eighteenth century Franciscan from a Portuguese monastery (Sianto et al. 2017).

28.2.3.2 Epidemiology in Cats and Humans

The epidemiology of toxocarisasis in cats and humans is difficult to assess for several reasons: (i) Most infections in humans, but also in cats are asymptomatic. (ii) *T. canis* and *T. cati* eggs are morphologically very similar and basically only distinguishable by slight size differences (74.8 x 86.0 µm vs. 62.3 x 72.7 µm, respectively [Fahrion et al. 2011]) making microscopical species differentiation probably impossible in a routine laboratory setting (Macpherson 2013; Uga et al. 2000), while molecular diagnostic tools for differentiating *T. canis* from *T. cati* eggs or larvae have been developed only recently (Jarosz et al. 2021; Durant et al. 2012). (iii) Serological techniques to differentiate reliably between *T. cati*- and *T. canis*-specific antibodies in either definite host species or humans do not yet exist (Macpherson 2013; Fillaux and Magnaval 2013; Poulsen et al. 2015; Holland 2017).

Therefore, most epidemiological data on *Toxocara* spp. or toxocariasis, esp. from the pre-molecular era, are not *T. cati*-specific, but will reflect more likely the situation for both *Toxocara* species. It is likely that for convenience reasons most studies deduct the respective *Toxocara* species from the name-giving animal in which they were detected. However, both *T. cati* and *T. canis* can be found in the respective name-giving mammal species. Interestingly, in a study applying species-specific ITS-2-based PCR only about two third of *Toxocara* eggs were *T. canis* and about one third *T. cati* in dog feces, while all eggs from cats were *T. cati* (Fahrion et al. 2011); the finding was explained by the canine behavior of coprophagy causing *T. cati* to be present also in dog feces. Moreover, also *T. malaysiensis*, a potentially zoonotic species first described in 2001 (Gibbons et al. 2001), which is genetically more closely related to *T. cati* than *T. canis* (Fava et al. 2020), shows a similar egg morphology as the two other species and has been found so far only in cats in Vietnam, China, and Malaysia (Gasser 2013; Le et al. 2016).

A recent systematic review and meta-analysis of cross-sectional studies covering more than 2 million cats from 51 countries estimates the global pooled prevalence of *Toxocara* infection in cats at 17.0%, being highest in African (43.3%) and lowest in South American (12.6%) countries (Rostami et al. 2020). For other WHO regions, the respective prevalence rates of *Toxocara* in cats were calculated as follows: Eastern Mediterranean (21.6%), North America (18.3%), Europe (17.8%), Western Pacific (17.3%), and South-East Asia (14.9%). In studies from different European countries, infection rates for *T. cati* in cats are reported to range from 6.2% to 76% (Strube et al. 2013; Epe et al. 2004; Barutzki and Schaper 2003; Chen et al. 2018 [Table S3]).

While prevalence studies of *Toxocara* spp. in cats from 26 European countries performed over the past 25 years found a prevalence rate of 24.5% for *T. cati* (Overgaauw and Nijsse 2020), a multicenter study from seven European countries (Austria, Belgium, France, Hungary, Italy, Romania, and Spain) found an overall

T. cati prevalence in cats of 19.7% with a range from 7.2% (Liège/Belgium) to 25.2% (Bari and Naples/Italy) (Beugnet et al. 2014). Systematic reviews on *Toxocara* prevalence in cats revealed prevalences of 22% in China (Zhang et al. 2020), 16.7% (range: 0.3–43.1%) in Brazil (Dantas-Torres 2020), 5.0–78% in South America (excluding Brazil) (López-Osorio et al. 2020), 3.5–5.1% in the USA on a national level (Ketzis and Lucio-Forster 2020; De Santis et al. 2006, Lucio-Forster et al. 2016), 11% in Canada (Jenkins 2020), 20.7–50.3% in Mexico (Ketzis and Lucio-Forster 2020), 6–52% in Russia (Lukashev et al. 2020), 9% in Sub-Saharan Africa (Omonijo et al. 2019), 9–55.9% in different African countries including Egypt, Ethiopia, Kenya, Nigeria (Chidumayo 2020), and 32.6% resp. 37% in Iran (Eslahi et al. 2020; Abbaszadeh Afshar et al. 2020), respectively. A national survey for *T. cati* in cats in Australia found a prevalence of only 3.2% (Palmer et al. 2008).

In a global perspective, the prevalence of *Toxocara* is higher in low-income tropical countries and also in stray (28.6%) and young ($\leq$12 months of age) (27.7%) cats than in pet (11.6%) and older cats (>12 months of age) (23.8%) (Rostami et al. 2020). A decline in *T. cati* prevalence in cats over the last 20 years is observed in countries with wider use of anthelmintics in the pet population, more stringent fecal hygiene practices in the pet environment, and increased feeding of commercial pet foods, e.g. in Canada and the USA (Jenkins 2020).

Toxocariasis is one of the most prevalent parasitic zoonoses worldwide occurring from the sub-arctic to the tropics (Rubinsky-Elefant et al. 2010; Macpherson 2013). About 1.4 billion humans (one fifth of the world population) and 118–150 million cats (a fourth to a third of the world cat population) are estimated to be affected by toxocariasis (Rostami et al. 2019, 2020). Thus, toxocariasis is probably the most common zoonotic helminthiasis at least in temperate climates (Deshayes et al. 2016).

Estimates of the *Toxocara* and esp. *T. cati* prevalence in humans has several important immanent methodological limitations: (i) due to the *Toxcara* life cycle with humans serving only as paratenic non-definite hosts, fecal examination for eggs is not possible in contrast to the situation in cats; therefore only indirect laboratory methods, i.e., serology, have to be used; (ii) indirect serological methods have immanent sensitivity and specificity problems; especially specificity might be affected by cross-reactivity with antigens from other nematodal helminths, e.g., *Ascaris* spp. or *Toxascaris* spp. (iii) serological methods to differentiate between *T. canis* and *T. cati*, if available at all, are not widely distributed.

Mainly for theoretical considerations the majority of human toxocariasis infections have been considered to be caused by *T. canis*. These arguments are mainly based on data from Iceland (Overgaauw 1997; Rubinsky-Elefant et al. 2010), where the importation of foreign dogs was banned for *Echinococcus* control reasons from 1909 to 1991, dog ownership was prohibited in the capital Reykjavík since 1924, and a serological study failed to detect anti-*Toxocara* antibodies in 307 adult Icelanders (Woodruff et al. 1982). This study, however, did not give any epidemiological information on the study population, e.g., on any exposure risks such as cat contact, on *T. cati* prevalence in cats, cat population density, environmental load of *T. cati* eggs, or their survival in soil under Iceland's climate conditions. Moreover,

neither was *Toxocara* infection completely absent in dogs from Iceland during this time period or shortly thereafter (Richter 1981) nor was the percentage of *Toxocara* eggs shedding cats (12.5%) very high when compared to the situation in cats from other countries (Ágústsson and Richter 1993; Sandholt 2004) making it an over-simplification to claim that a lack of *Toxocara* seropositivity in the study population proves a much lesser transmission risk of *T. cati* to humans when compared to *T. canis*. Besides that, this belief might also be fostered by experimental data showing that *T. canis* larvae migrate faster than *T. cati* through the body of infected mice (Overgaauw and van Knapen 2013; Strube et al. 2013).

Very recently, the global human seroprevalence of anti-*Toxocara* spp. antibodies was estimated in a systematic review and meta-analysis comprising the results of 253 databases on more than 250,000 participants in 71 countries (Rostami et al. 2019) to be 19.0% (Rostami et al. 2019). Seroprevalence was highest in the African region (37.7%), followed by the WHO regions of South-East Asia (34.1%), the Western Pacific (24.2%), the Americas (22.8%), Europe (10.5%), and lowest in the Eastern Mediterranean region (8.2%). More detailed subregional meta-analyses show often wide ranges of human *Toxocara* seroprevalence, e.g., from 3.9% to 84.6% in Southeast Asia (Chou and Fan 2020), from 1% to 56% in Turkey (Taylan-Ozkan 2020), from 4.7% to 13.8% in Mexico (Ponce-Macotela and Martínez-Gordillo 2020), from 6.6% to 9.3% and 11% in Iran (Shafiei et al. 2020; Eslahi et al. 2020; Abbaszadeh Afshar et al. 2020), from 12.1% to 44.8% in China (Kong and Peng 2020), and 16% in Russia (Akhmadishina et al. 2020). In Europe, the overall seroprevalence was estimated at 6.2% (Strube et al. 2020), while the most recent national *Toxocara* survey in the USA revealed a seroprevalence of 5.1% (Farmer et al. 2017; Liu et al. 2018), considerably lower than two decades ago (Bradbury and Hobbs 2020). The highest prevalences with more than 50% in basically healthy people were found in subpopulations, mostly from rural locations or other remote areas: for instance in Africa (Lötsch and Grobusch 2020) in La Réunion (92.8%) (Magnaval et al. 1994), Nigeria (92.5%; Ikotun et al. 2020 or 86.1%, Gyang et al. 2015), Gabon (59.9%) (Lötsch et al. 2016), Ghana (53.5%) (Kyei et al. 2015), and Burundi (50.8%) (Nicoletti et al. 2007); in South-East Asia in Indonesia (84.6%) (Hayashi et al. 2005), Nepal (81.0%) (Rai et al. 1996), Taiwan (76.6%) (Fan et al. 2004), Bali/Indonesia (63.2%) (Chomel et al. 1993), and Thailand (58.2%) (Phasuk and Punsawad 2020); in the Western Pacific region in the Marshall Islands (68.7%) (Fu et al. 2014) and in the Philippines (66.7%) (Rostami et al. 2019); in the Americas in St. Lucia (86%) (Thompson et al. 1986), Colombia (79.3%) (Waindok et al. 2021), Brazil (71.8%) (Araújo et al. 2018), and in Trinidad and Tobago (62.3%) (Rostami et al. 2019); and in Europe in Romania (40.8%) (Cojocariu et al. 2012).

The global prevalence in humans is influenced by a variety of environmental, geographic, cultural, and socioeconomic factors as well as individual components, e.g., susceptibility to *Toxocara* infection due to immunity, coinfection, genetics, age, gender, nutrition, and the behavior of both the human and the definitive hosts (Congdon and Lloyd 2011; Macpherson 2013). Poverty as measured by lower income levels and a lower human development index, lack of education, a high

percentage of untreated or uncontrolled definitive hosts, poor hygienic conditions both for humans and the definitive hosts, lower geographical latitude, a climate showing higher humidity, higher temperature, and higher precipitation thus allowing embryonation of *Toxocara* eggs to infective stages (optimum temperatures: 20–30 °C, detrimental effects at <10 °C or > 37 °C [Gamboa 2005, Azam et al. 2012]) or longer survival of embryonated eggs in the environment are associated with higher prevalences (Macpherson 2013; Rostami et al. 2019). Human seroprevalence in industrialized countries ranges from 0.7% to 44% with the majority of studies indicating prevalences far below 20% (Macpherson 2013); in children who are most at risk prevalences between 1.0% and 17.1% in European countries with a pooled prevalence of 7.8% for children and young adults up to 20 years of age as compared to 4.6% in the 21–50 years old population (Strube et al. 2020), 2.5% in Germany (Overgaauw and van Knapen 2013), and 12.0% in the USA (Bradbury and Hobbs 2020) are reported. In tropical and/or less industrialized countries seroprevalences are much higher ranging from 30% to 92,8% (Strube et al. 2013; Overgaauw and van Knapen 2013; Macpherson 2013; for an intensive review of human seroprevalence surveys published since 1990, see Rubinsky-Elefant et al. 2010; and for the period 1980 to 2019 Rostami et al. 2019, respectively).

28.2.3.3 Disease in Cats

Usually, adult *Toxocara* living in the lumen of the small intestine of their definite hosts do not cause pathological changes. Therefore, mild infections are mostly subclinical. Clinical signs are more often evident during larval migration causing respiratory symptoms (e.g., pneumonia, cough, nasal discharge) or intestinal infections with a moderate or high parasitic load of adult worms (Morelli et al. 2021). Infected kittens may show a catarrhal enteritis with loss of appetite, vomiting, diarrhea alternated with constipation, developmental disturbances, anemia or anorexia, esp. after heavy infections. In adult cats *T. cati* may cause vomiting (e.g., of adult worms), abdominal enlargement, anorexia, or intestinal obstruction with subsequent rupture of the intestine (Traversa 2012; Morelli et al. 2021).

28.2.3.4 Disease in Humans

T. cati larvae may reach basically any organ where they finally get encysted. Therefore, there is a considerable variability in clinical presentation depending on the systemic migration pattern of the active larvae or the final destination of the encysted larvae. Experimental data with mice suggest that *T. cati* migrate more slowly and/or less often into the CNS or the eye when compared to *T. canis* (Overgaauw and van Knapen 2013; Strube et al. 2013). Most authors differentiate between four (or five) different syndromes of toxocariasis: (i) visceral larva migrans (VLM), which might be characterized by fever, hepatosplenomegaly, abdominal pain, pulmonary disease, asthma-like symptoms, anorexia, weight loss, fatigue, occasionally urticaria, and eosinophilia; (ii)ocular larva migrans (OLM; also known as ocular toxocariasis, OT), characterized by a usually unilateral granulomatous retinitis causing visual impairment and possibly blindness; (iii) neurotoxocariasis (NT), characterized by progressive neurologic disease (Deshayes et al.

2016); (iv) and covert or common toxocariasis (CT; occasionally also as two separate, but overlapping entities named covT and comT [Auer and Walochnik 2020]), in which chronic abdominal pain or other nonspecific symptoms can develop (Despommier 2003; Macpherson 2013; Rubinsky-Elefant et al. 2010; Chen et al. 2018; Ma et al. 2018). Both VLM and OLM most frequently affect children, VLM more often those aged less than 5 years of age, OLM usually those 5–10 years old. OLM is considered to be much rarer than VLM and probably caused by a lower level of infection. Human toxocariasis is usually diagnosed serologically and can be treated with albendazole.

28.2.3.5 Public Health Importance

Toxocara eggs need 2–6 weeks outside the definitive host to finally contain infective larvae.

In a recent meta-analysis of 42,797 soil samples from 40 countries, the pooled global prevalence of *Toxocara* eggs in public places was 21%, ranging from 13% to 35% (in descending order: Western Pacific: 35%; Africa: 27%; South America: 25%; South-East Asia: 21%; Middle East and North Africa: 18%; Europe: 18%; North and Central Americas: 13%) (Fakhri et al. 2018). Some recent surveys from Poland (Mizgajska-Wiktor et al. 2017), Portugal (Otero et al. 2018), and the USA (Tyungu et al. 2020) indicate that *Toxocara* eggs are found more commonly in sandpits rather than in the soil of parks and in household-near backyards than in public places, respectively, with sandy, silty, and loamy soil textures more prone for *Toxocara* contamination than clay grounds (Paller and Chavez 2014) and *T. cati* being more abundant than *T. canis* in public places (Mizgajska-Wiktor et al. 2017). In contrast, using a mathematic modeling approach a UK-based study estimated the *T. canis*-linked burden in the Bristol area to be much higher than the *T.cati*-caused environmental contamination and as a consequence also the relative contribution of dogs to *Toxocara* contamination when compared to cats (Morgan et al. 2013). Similar data using a stochastic model were obtained for the Netherlands (Nijsse et al. 2015).

Since the most important *Toxocara* transmission pathway for humans is ingestion of soil resulting in "contact with soil" as the factor with the highest odds ratio (OR: 2.1) for seropositivity in a global meta-analysis (Rostami et al. 2019), children are more at risk than adults due to their less strict hygienic behavior and their tendency to put possibly egg-contaminated objects and soil or larvae-containing paratenic hosts such as earthworms into their mouth.

Direct cat contact is obviously of minor importance, since studies have shown conflicting results on a possible association between seropositivity and cat ownership or close contact with cats (Rostami et al. 2019: OR 1.61 in a global meta-analysis of 16 studies; Paludo et al. 2007: OR 1.957 in Brazil; Negri et al. 2013: OR 1.647; Jarosz et al. 2010: OR 2.0; Won et al. 2008: OR 1.2 in the USA; Rubinsky-Elefant et al. 2008: OR 0.57 in Brazil; Woodruff et al. 1982). A possible infection route by *Toxocara* eggs sticking on the cat's fur seems unlikely, since eggs have to be embryonated to cause infection, which would need time. Moreover, cats – when compared to dogs – show less often xenosmophilic behavior, which might lead to get contaminated with soil- or feces-derived embryonated *Toxocara* eggs.

28.2.3.6 Public Health Measures

To date, no specific national control programs against *Toxocara* spp. have ever been attempted.

Of the four main reservoirs of parasite infection (intestinal infections in the definitive host, eggs in the environment, larvae in paratenic hosts, larvae in the definitive host), the easiest to control are the definitive hosts, e.g., cats and dogs (Macpherson 2013). Therefore, prevention of the initial contamination of the environment is the most obvious approach, for instance, by regularly deworming cats (and dogs) [see recommendations from CAPC or ESCCAP], preventing defecation of pet animals in public areas (especially in playgrounds), reduction of free-roaming cats and dogs, fostering pet hygiene, and educating the public (Overgaauw and van Knapen 2013). However, the paradoxical finding known for *T. canis* eggs that low levels of egg exposure are more successful in establishing patent infections in dogs than larger egg amounts might hamper public health measures, if this finding is also valid for *T. cati* and cats (Macpherson 2013).

When addressing hygienic measures for animals, the differences in canine and feline defecation patterns is important: in contrast to dogs, cats tend to defecate in more thoroughly selected and less open places, e.g., in corners, often covering and hiding their feces thereafter. Therefore, playgrounds and especially sandpits are probably much more important for cat-transmitted *Toxocara* eggs than for those excreted by dogs.

For exposure prophylaxis with respect to *Toxocara* eggs, especially children should be educated about hand hygiene and taught to avoid geophagy.

28.3 Eponymous, But Probably Seldom (or Not Relevant): *Rickettsia felis*, *Chlamydia felis*, *Cryptosporidium felis*, and *Opisthorchis felineus*

28.3.1 The Enigmatic *Rickettsia felis*

28.3.1.1 The Pathogen

Rickettsia felis is an obligate intracellular Gram-negative bacterium, which is commonly attributed to the spotted fever group (SFG) – more recently to the transitional group (TG) – of *Rickettsia* (Caravedo Martinez et al. 2021; Blanton and Walker 2017; Shpynov et al. 2018; Parola 2011; Reif and Macaluso 2009; Pérez-Osorio et al. 2008; Abdad et al. 2011). It has been definitely described in 2002 (La Scola et al. 2002). The cat flea (*Ctenocephalides felis*) is the primary and so far only known natural vector and the reservoir of *R. felis*, although *R. felis* has been found in more than 40 other arthropods including ticks, fleas, chigger mites (Reif and Macaluso 2009; Legendre and Macaluso 2017; Brown and Macaluso 2016), and even non-hematophagous organisms such as booklice (*Liposcelis bostrychophila*) (Behar et al. 2010) and moths (*Phereoeca* spp) (Araújo et al. 2021). *R. felis* was shown to be prevalent in cat fleas from more than 20 countries on 5 continents with positivity rates ranging from 2% to 70% (Parola 2011). It has been detected in several

peri-domestic species including cats, dogs, raccoons, rodents, and opossums, but the definitive mammalian host(s) has not yet been identified. However, very recently, a possible role for the domestic dog (*Canis familiaris*) as a vertebrate reservoir of *R. felis* has been shown (Ng-Nguyen et al. 2020). Humans might possibly get infected via flea saliva and flea bites (Brown et al. 2015; Blanton and Walker 2017) or – as it is the case with *R. typhi* and *R. prowazekii* – via flea feces through dermal micro-traumas (Legendre and Macaluso 2017).

28.3.1.2 Epidemiology in Cats and Humans

Due to antibodies cross-reacting against antigens from different *Rickettsia* spp., species-specific seroprevalence data are often difficult to obtain. In seroprevalence studies, *R. felis*-specific antibodies have been found in 4–15% of mainly client-owned cats from several parts of the USA (Bayliss et al. 2009; Case et al. 2006) and Italy (Ebani et al. 2021; Morganti et al. 2019; Morelli et al. 2019). So far, the highest antibody positivity rate with up to 70% was found in 22 cats from a single household in Chile (Labruna et al. 2007). In contrast, outside from experimental infection settings, *R. felis* DNA has only extremely rarely been detected in blood of cats making it very unlikely that cats serve as an important reservoir for *R. felis* (Hoque et al. 2020).

In humans, serological studies have shown an antibody prevalence of 2.7% in German forest workers (Wölfel et al. 2017), of 4.4% in HIV-positive patients from Spain (Nogueras et al. 2014), of 3.2% and 6.5% in healthy individuals from Catalonia (Nogueras et al. 2006) and from southern Spain (Bernabeu-Wittel et al. 2006), respectively, of 16.1% and 22.5% in healthy farm workers and indigenous Orang Asli people from Malaysia (Kho et al. 2017), and of 17.8% and 24% in volunteers (Hidalgo et al. 2013) and symptomatic patients (Pérez et al. 2021), respectively, from the Caldas province, Colombia.

So far, more than 100 human clinical infections have been described either in case reports or in diagnostic studies from more than 20 countries of 5 continents including Brazil, Mexico (Zavala-Castro et al. 2009), the USA, Sweden (Lindblom et al. 2010), France, Germany, Spain, Thailand, Sri Lanka (Angelakis et al. 2012), Taiwan (Yang et al. 2021), South Korea, Laos, Israel, Tunesia (Kaabia and Letaief 2009), Algeria (Taleb et al. 2013; Mokrani et al. 2012), Egypt, Kenya (Maina et al. 2012; Richards et al. 2010), Senegal (Socolovschi et al. 2010), St. Kitts from the West Indies (Kelly et al. 2010), Australia (Williams et al. 2011), New Zealand (Lim et al. 2012), Indonesia (Mawuntu et al. 2020), and China (Zeng et al. 2021; Ye et al. 2021) (countries not specified by an own reference were cited in Renvoisé et al. 2009, Parola 2011 and Pérez-Osorio et al. 2008).

28.3.1.3 Disease in Cats

The majority of cats are probably asymptomatic (McElroy et al. 2010).

28.3.1.4 Disease in Humans

Clinical manifestations of human *R. felis* infection, sometimes referred to as flea-borne spotted fever, may include fever (>90%), fatigue, headache, dermatological

symptoms such as maculopapular rash (>70%) and – less frequently – an eschar (>10%) (Legendre and Macaluso 2017), less frequently neurological signs (15%) including meningitis-like symptoms (Lindholm et al. 2010, Ye et al. 2021, Zeng et al. 2021, Mawuntu et al. 2020), hepatosplenomegaly (Zavala-Castro et al. 2009), intestinal disease (<10%), or pneumonia (<10%) (Parola 2011; Renvoisé et al. 2009; Caravedo Martinez et al. 2021; Legendre and Macaluso 2017). The disease is usually self-limiting and is most often treated with doxycycline. So far, there have been no reports of flea-borne spotted fever causing death (Abdad et al. 2011) except for two fatal cases presenting with acute meningoencephalitis in whom alternate diagnoses could not be definitely ruled out (Mawuntu et al. 2020).

Importantly, so far laboratory diagnosis of human *R. felis* infections basically relies on serology or PCR (and subsequent sequencing) from blood, CSF, or skin lesions, while cultivation of the organism from clinical samples has not yet been achieved (Blanton and Walker 2017; Caravedo Martinez et al. 2021). Therefore, pathological and clinical findings are at least in some cases difficult to interpret. This holds especially true for two clinical syndromes suspected to be linked to *R. felis*: (i) increasing reports from Sub-Saharan Africa and also Asia finding *R. felis* DNA in the blood of a considerable proportion of febrile patients suggested the pathogen to be an important cause of uneruptive "fever of unknown origin" (FUO) esp. in Africa (Socolovschi et al. 2010; Mediannikov et al. 2013b; Maina et al. 2012). However, in recent years, *R. felis* DNA has been also detected in nonfebrile controls as well as in febrile patients with simultaneous *Plasmodium* parasitemia complicating the previously suggested interpretation of the pathological role of *R. felis* in FUO (Caravedo Martinez et al. 2021). (ii) Similarly enigmatic is the finding of *R. felis* DNA in two cutaneous manifestations, a vesicular fever disease known among the local population in Senegal as "yaaf" (Mediannikov et al. 2013a) and in maculopapular rash reported in three patients from Yucatan, Mexico (Zavala-Velázquez et al. 2000), when considering that *R. felis* DNA has also been found on the skin of healthy afebrile people in Africa (Mediannikov et al. 2013a; Caravedo Martinez et al. 2021).

28.3.1.5 Public Health Importance

The geographic distribution of *R. felis* in the cosmopolitan cat flea reinforces the hypothesis that *R. felis* might be found in most, if not all, human populations where cats and other domestic animals are kept as pets (Abdad et al. 2011). Unfortunately, most human case reports do not comment on possible animal contact. One report from Australia indicates that direct contact with cat fleas harboring cats might be a risk for transmission, since three siblings, their grandmother and a neighbor showed serological and clinical signs of *R. felis* infection, all of them having had contact to a cat family, while the children's parents without cat contact remained asymptomatic (Williams et al. 2011). However, in several studies *R. felis* DNA has been detected in cat fleas (*Ctenocephalides felis*) harvested from pet cats (Abdullah et al. 2020; Kamrani et al. 2008; Noden et al. 2017); in contrast, the finding of *R. felis* DNA in naturally infected pet cats seems to be rare and was reported only very recently (Muz et al. 2021; Hoque et al. 2020).

28.3.1.6 Public Health Measures

The individual and public health measures recommended for prevention of bartonellosis might also be useful for avoiding *R. felis* infection due to the supposed similar transmission via *Ctenocephalides felis*.

28.3.2 Chlamydia felis

28.3.2.1 The Pathogen

Chlamydia felis (previously named as *Chlamydophila felis and earlier Chlamydia psittaci* var. *felis*) is an obligate intracellular bacterium, which grows in the cytoplasm of epithelial cells where it produces inclusion bodies. Other species in the genus include the epidemiologically by far more important *Chlamydia pneumoniae* and *Chlamydia psittaci* as well as *Chlamydia pecorum, Chlamydia abortus*, and *Chlamydia caviae* (Sachse et al. 2015). Transmission occurs via aerosols or secretions from the eyes or noses of infected cats (Sykes 2005).

28.3.2.2 Epidemiology in Cats and Humans

Feline chlamydiosis is the most common cause of acute or chronic conjunctivitis, particularly in kittens, but occasionally also in adult cats (TerWee et al. 1998; Yan et al. 2000; Sykes 2005). Moreover, *C. felis* may also cause upper respiratory tract infection in cats. Seroprevalence data range from 2.5% to 58% in studies from China (Wu et al. 2013; Kang et al. 2016), Slovenia (Dovč et al. 2008), Spain (Millán and Rodríguez 2009; Ravicini et al. 2016), Sweden (Holst et al. 2006), Japan (Yan et al. 2000), Slovakia (Halánová et al. 2011), Italy (Di Francesco et al. 2004), and the USA (Nasisse et al. 1993). Stray cats, cats from catteries or animal shelters, and cats younger than 1 year of age seem to be more affected by *C. felis* infection in different studies including PCR surveys (Bressan et al. 2021; Halánová et al. 2019). PCR studies showed only a low *C. felis* prevalence in asymptomatic cats of less than 5–11% (Sykes 2005; Bressan et al. 2021; Barimani et al. 2019). Not many studies were done in human populations; seroprevalence in the normal population and in veterinarians was 1.7% and 8.8%, respectively, in a study from Japan (Yan et al. 2000). In all serological studies, however, cross-reacting antibodies might affect the positivity rate.

28.3.2.3 Disease in Cats

Clinical signs of *C. felis* infection are conjunctivitis, sneezing, transient fever, inappetence, weight lost, nasal discharge, rarely lameness or lethargy, and possibly, but not yet proven, reproductive tract disease including stillbirth or abortion (Sykes 2005). Chlamydial disease may be complicated by coinfection with other microorganisms. Cats are usually treated with doxycycline for several weeks (Sykes 2005).

28.3.2.4 Disease in Humans

C. felis infection may be associated occasionally with conjunctivitis and/or very rarely respiratory tract disease (Browning 2004). In a few serological studies using

antibodies reported to be relatively specific for *C. felis*, *C. felis* was found to be at best an uncommon cause of community-acquired pneumonia (CAP) in less than 0.5% of CAP patients from Canada (2/539; Marrie et al. 2003) or Japan (1/506; Miyashita et al. 2005).

28.3.2.5 Public Health Importance

Exposure to *C. felis* is possible when handling infected cats via contact with their aerosols or contaminated body fluids, e.g., tear fluid, but maybe also by feces, since *C. felis* DNA was recently detected in rectal samples (Bressan et al. 2021). The zoonotic potential of *C. felis*, however, appears to be very low. Only sporadic cases with possible cat-to-human transmission have been reported (Browning 2004). So far, only two PCR-proven cases have been published showing identity of a human and a feline isolate in an HIV-positive patient with chronic conjunctivitis and his recently acquired cat (Hartley et al. 2001; Wons et al. 2017). Moreover, in one Japanese patient presenting with CAP and serological evidence of possible *C. felis* infection cat contact was documented (Miyashita et al. 2005).

28.3.2.6 Public Health Measures

Care should be taken especially by immunosuppressed people when handling cats with conjunctivitis and/or upper respiratory tract infection. A vaccine for cats is available.

28.3.3 Cryptosporidium felis

28.3.3.1 The Pathogen

Cryptosporidium spp. are coccidian obligate intracellular parasites mainly infecting epithelial cells of the gastrointestinal tract. They have been reported from a large variety of different hosts including humans. The most important species for humans infections are the zoonotic *C. parvum* and the host-adapted *C. hominis* (Ryan et al. 2014, 2021), while *C. felis* is one of several species identified in different mammals and the most commonly species found in cats (Li et al. 2021; Meng et al. 2021; Taghipour et al. 2021). Infection occurs via ingestion of viable oocysts, often by drinking contaminated water, eating contaminated food and/or fecal-orally.

28.3.3.2 Epidemiology in Cats and Humans

Fecal oocyst shedding by cats ranges from 0% to around 30% according to data from Spain (Gracenea et al. 2009; Gil et al. 2017), the Netherlands (Overgaauw et al. 2009), Denmark (Enemark et al. 2020), Greece (Kostopoulou et al. 2017), Australia (Palmer et al. 2008; Yang et al. 2015), Canada (Shukla et al. 2006), Colombia (Santin et al. 2006), Brazil (Coelho et al. 2009; Alves et al. 2018; de Oliveira et al. 2021), the UK (Gow et al. 2009; Tzannes et al. 2008), Italy (Rambozzi et al. 2007), Thailand (Tangtongstrup et al. 2020), Japan (Ito et al. 2017; Ito et al. 2016; Yoshiuchi et al. 2010), China (Li et al. 2015, 2019a, b, 2021; Xu et al. 2016), Iran (Homayouni et al. 2019), and the USA (Ballweber et al. 2009; Mekaru et al. 2007; Nutter et al. 2004;

Lucio-Forster et al. 2010) with most of the studies reporting prevalences below 10% or even lower (Li et al. 2021). In most cases, younger age of the cats and living outside a household were risk factors for *C. felis* infection in cats.

Worldwide, far more than 100 findings of *C. felis* from humans have been reported to date (for a review see Lucio-Forster et al. 2010; Raccurt 2007; Ryan et al. 2014, 2021; Jiang et al. 2020; Das et al. 2006; Cieloszyk et al. 2012; Llorente et al. 2006; Cama et al. 2008; Elwin et al. 2012; Matos et al. 2004). In the majority of cases immunosuppressed people were affected, previously mainly HIV-positive adults (about two thirds of all *C. felis*-positive individuals for whom clinical information regarding their immunostatus is known), but in recent years also obviously immunocompetent children mainly from developing countries and patients presenting with diarrhea (Lucio-Forster et al. 2010; Jiang et al. 2020; Liu et al. 2020). For instance, *C. felis* was the underlying *Cryptosporidium* species in 0.4% of 14,469 human stool samples obtained in England and Wales between 2000 and 2008 (Elwin et al. 2012), in 1% of 108, 98, and 175 samples from Spain (Llorente et al. 2007), from the Netherlands (Wielinga et al. 2008) and from children in Kenya (Gatei et al. 2006), respectively, in 2.5% from 40 samples from India (Das et al. 2006), in 0.3% of 394 samples from Nigeria (Ukwah et al. 2017), and in 4.3% from 109 *Cryptosporidium*-infected children from Peru (Cama et al. 2008).

Very recently, the development of a *gp60* gene subtyping tool for *C. felis* (Rojas-Lopez et al. 2020) dividing the species in so far five different subtype families called XIXa to XIXe allows a clearer picture of the molecular epidemiology of the cat-adapted species *C. felis* due to its highly polymorphic composition (Li et al. 2021). Since XIXa and XIXb have been found both in humans and cats, while XIXc-e has nearly exclusively been detected in humans, it has been suggested that the latter subtypes might be (more) human-adapted (Li et al. 2021; Jiang et al. 2020).

28.3.3.3 Disease in Cats

Oocyst shedding cats are most often asymptomatic. Occasionally, infection may be associated with persistent diarrhea, especially in younger and/or immunocompromised cats (Lucio-Forster et al. 2010).

28.3.3.4 Disease in Humans

In humans, *Cryptosporidia* may cause an enteric disease with watery diarrhea, abdominal pain, and nausea, occasionally accompanied by low grade fever or headache. Immunocompromised individuals and children are especially at risk of developing prolonged or profuse diarrhea. Deaths due to exsiccation may occur mainly in severely immunosuppressed patients or malnourished children in developing countries. In rare cases, mainly in immunocompromised patients, also other organ systems might be infected, e.g., the respiratory tract, the pancreas, or the bile ducts. Asymptomatic infections have also been reported.

28.3.3.5 Public Health Importance

Case-control studies from several countries were not able to show that contact with companion animals is associated with an increased risk of acquiring cryptosporidiosis (for a review see Xiao and Feng 2008). While in some of the few case reports on human *C. felis* infections the patients had previous cat contact (Matos et al. 2004), no anamnestic cat contact was reported in others (Pedraza-Díaz et al. 2001; Cacciò et al. 2002; Llorente et al. 2006; de Lucio et al. 2017). Similarly, in a Swiss-US American study by Morgan et al. three HIV-positive *C. felis*-infected patients were reported to have had contact with a cat, while two others denied the presence of cats in their household (Morgan et al. 2000). So far, only one case of possible cat-to-human transmission has been documented based on molecular subtyping showing an identical *C. felis* strain in a pet cat and its owner, both suffering from diarrhea (Beser et al. 2015). Taken together, it may be concluded that pet cats impose only a minimal risk for zoonotic transmission of cryptosporidiosis in general and for *C. felis* in peculiar (Lucio-Forster et al. 2010; Raccurt 2007).

28.3.3.6 Public Health Measures

Despite an only minimal risk of zoonotic transmission, especially immunocompromised persons should be advised to minimize contact to cat feces and to observe basic hand hygienic measures.

28.3.4 Opisthorchis felineus

Opisthorchis felineus and its close relatives *O. viverrini* and *Clonorchis sinensis* are the three most common liver flukes involved in human health. *O. felineus* was named after one of the definite host species in which it was first described, e.g., cats from Pisa, Italy (Rivolta 1884). Although the species name suggests a zoonotic risk due to cat contact, humans – as other fish-eating mammals including cats – acquire an infection by eating raw fish harboring the trematode's metacercariae (Pozio et al. 2013; Petney et al. 2013; Fedorova et al. 2020). Therefore, cats do not pose a direct zoonotic risk for human infections, although in some regions they might be required for maintaining the parasite's life cycle (Scaramozzino et al. 2018).

28.4 The (un)usual Suspects from the Gut

Cats may excrete a plethora of bacteria, viruses, and parasites via their feces (Barutzki and Schaper 2003, 2011; Gow et al. 2009; Waap et al. 2014; Weber et al. 1995; Weese 2011; Spain et al. 2001; Philbey et al. 2009; Paris et al. 2014; Hill et al. 2000; Morato et al. 2009; Dantas-Torres and Otranto 2014; Ballweber et al. 2010; Hoelzer et al. 2011; Esch and Petersen 2013; Oh et al. 2021). However, for most of the respective pathogens the presumed zoonotic potential is mainly based on isolation of identical species, subtypes, serotypes, or – in better circumstances – of similar genotypic strains from within the pet and human population. However,

clearly defined outbreak or case reports with molecular proof of cat-to-human transmission are still lacking for most enteric pathogens. Moreover, the relative contribution of cat-associated transmission to the overall zoonotic disease load for most of these pathogens is not clear and probably very low for most of them when compared to other zoonotic sources, as it is the case with campylobacteriosis or salmonellosis in which chicken predominate the picture when compared to pet animals.

Recent reviews and studies on the zoonotic potential of *Giardia* spp., of which different genotypic assemblages are relatively host-specific with assemblage F found almost exclusively among cats and assemblages A and B in a wide range of species including cats and humans (Ballweber et al. 2010; Morelli et al. 2021; Lecová et al. 2020; de Lucio et al. 2017; Ramírez-Ocampo et al. 2017), and non-typhoidal salmonellosis (Hoelzer et al. 2011) suggest only a minimal risk of cats as source for human infection with the respective pathogens. However, indirect epidemiological data suggest at least a potential zoonotic risk, since a multivariable analysis matched on age group, which was conducted in Michigan, USA revealed that children with *Salmonella* infections had reported more commonly than controls contact with cats (matched OR = 2.53) (Younus et al. 2010). Interestingly, seasonal outbreaks of *Salmonella* Typhimurium among wild birds, domestic cats, and humans have been linked to cats preying on salmonellosis-diseased singing birds or passerines subsequently transmitting the bacteria to their respective owners (Tauni and Österlund 2000; Söderlund et al. 2019).

Importantly, also antibiotic-resistant *Salmonella* strains have been isolated from cats and partly linked to human outbreaks (Low et al. 1996; Van Immerseel et al. 2004; Wright et al. 2005).

Carriage of thermotolerant *Campylobacter* spp. by cats ranges between 9.9% and 41.9% (Thépault et al. 2020) suggesting a potential source of pet cats as source for human exposure. However, data on zoonotic transmission between cats and humans are scarce. An analysis of *Campylobacter* strains isolated from humans and animals in Switzerland using different genotyping methods showed that only very few genotypes among human and cat isolates were similar (Keller et al. 2007). Similarly, a recent study from France showed only very minor cluster prevalence similarities between *Campylobacter* spp. from cats and humans (Thépault et al. 2020). In an extensive study from the Netherlands comparing *Campylobacter* genotypes of strains obtained from pet cats, pet dogs, pet-owners, and non-pet owners by MLST, an increased risk for human *C. jejuni* or *C. coli* infection was associated with dog-ownership (OR 2.5 in an overall model, 9.2 in a model for campylobacteriosis of probable pet origin), but not with cat-ownership (Mughini Gras et al. 2013). In contrast, another Dutch study found an OR of 1.7 and 2.0 of cat-ownership for human infection with *C. jejuni* and *C. coli*, respectively (Doorduyn et al. 2010), but interestingly no association with visiting other cat-owning households. Although pet ownership was estimated in both studies to contribute in 10–25% to human *Campylobacter* infections, the route of transmission – e.g., pet-to-human or human-to-pet or a common infection source such as food items – cannot be inferred from these modeled attributions (Mughini Gras

et al. 2013; Doorduyn et al. 2010). In general, the risk of human infection via pet cat contact is low (Thépault et al. 2020).

With respect to pathogenic *Escherichia coli*, only a few genetic association studies and/or case reports exist indicating a minor zoonotic potential for cat-related human infections.

A Brazilian MLST analysis of Enteropathogenic *Escherichia coli* (EPEC) strains has shown close genetic similarity between O111:H25 and O125:H6 strains of human and cat origin (Morato et al. 2009). Two case reports on human and cat infections caused by a molecularly identical strain of *Enterohemorrhagic E. coli* (EHEC) have been published from Germany (Busch et al. 2007) and Argentina (Rumi et al. 2012), respectively. However, infection of pet cats with the classical *E. coli* O157:H7 has not yet been described (Kataoka et al. 2010; Persad and Lejeune 2014).

Since most of the cat infections due to the above mentioned enteric bacteria are asymptomatic and remain unnoticed, it might be reasonable to advise immunosuppressed people, especially people with HIV-infection, not only to get their pets tested for *Salmonella*, *Campylobacter*, or *Cryptosporidium* when these develop diarrhea, but also to educate about proper hygienic measures when handling animals in general or to avoid exposure to them even if they are asymptomatic (Spain et al. 2001).

28.5 An Emerging Cat-Related Pathogen: Toxigenic *Corynebacterium ulcerans*

28.5.1 The Pathogen

C. ulcerans are facultative anaerobic, nonmotile, non-sporulating, unencapsulated, pleomorphic, partially acid-fast Gram-positive rods. Similar to *Corynebacterium diphtheriae*, the classical diphtheria agent of humans, and *Corynebacterium pseudotuberculosis*, the agent of caseous lymphadenitis in sheep and goats and a very rare zoonotic pathogen, *C. ulcerans* may harbor a lysogenic beta-corynephage bearing the *tox* gene. Toxigenic strains may produce the *tox*-encoded diphtheria toxin (DT), which is responsible for the systemic symptoms of diphtheria. Additionally, pathogenicity of *C. ulcerans* arises from the production of phospholipase D (Hacker et al. 2016). Domestic animals such as cats, dogs, and pigs serve as reservoirs for possible zoonotic *C. ulcerans* infection (Meinel et al. 2014; Schuhegger et al. 2009; Berger et al. 2011a, b). Moreover, it has been found in many non-domestic animals, such as macaques, ferrets, red foxes, and hedgehogs (Hirai-Yuki et al. 2013; Marini et al. 2014; Sting et al. 2015; Berger et al. 2019). Recently a toxigenic *C. ulcerans* diphtheria like infection in a horse was reported (Zendri et al. 2021).

C. silvaticum, formerly called *C. ulcerans* wild boar cluster, was previously described as a novel potentially zoonotic NTTB (non-toxigenic tox gene-bearing) species in wild boars and deers (Dangel et al. 2020; Möller et al. 2020). Since the

final taxonomic description of *C. ulcerans* is only from 1995 (Riegel et al. 1995) and the differentiation between *C. ulcerans*, *C. pseudotuberculosis* and *C. silvaticum* by classical biochemical tools might be difficult or is not possible at all in case of *C. silvaticum* (Torres et al. 2013; Berger et al. 2014), prevalence data on, or case reports of, *C. ulcerans* infections, which were published before 1995 or which do not explain their differentiation methods used have to be handled with care. Today MALDI-TOF mass spectrometry and Fourier-transform infrared (FT-IR) spectroscopy are suitable tools to identify these isolates (Rau et al. 2019; Berger et al. 2019; Dangel et al. 2020).

28.5.2 Epidemiology in Cats and Humans

Epidemiological data on the prevalence of diphtheria-causing *Corynebacterium* spp. in cats are sparse. Since the first description of *C. ulcerans* in two cats from Scotland in 2002 (PHLS 2002; Taylor et al. 2002), only sporadic and often asymptomatic infections have been identified in cats mostly as part of public health measures during the search for an infectious source in case of a human index patient. A recent study report carriage rates of *C. ulcerans* in healthy animals were 0.42% (2/479) in dogs and 0.00% (0/72) in cats, whereas in animals with signs of upper respiratory tract infection prevalence rates were 0.53% (1/189) in dogs and 6.25% (4/64) in cats (Abbott et al. 2020).

Human diphtheria is a WHO-notifiable disease. In 2020, there were 22,916 cases reported globally (WHO 2020), most of them in Nigeria, India, and Ethopia. On a global scale, no WHO data exist on the relative contribution of the three potentially toxigenic *Corynebacterium* species. In 24 member countries of the European Diphtheria Surveillance Network (DIPNET) except the high diphtheria endemic country Latvia, *C. diphtheriae* and *C. ulcerans* accounted for 53 reported human infections each between the period 2000 and 2009 (Wagner et al. 2012). In many industrialized countries, cases of diphtheria-like infection caused by toxigenic *C. ulcerans* have recently outnumbered those caused by toxigenic *C. diphtheriae* (Wagner et al. 2010; Bonmarin et al. 2009; Zakikhany and Efstratiou 2012; Torres et al. 2013; Gower et al. 2020). In Germany, we observe between 2 and 20 cases of *tox+C. ulcerans* infections (usually skin located) in humans per year since 2007 (https://survstat.rki.de).

28.5.3 Disease in Cats

In most cases in which human *C. ulcerans* infections were associated with pet cat contact, the respective cats were either asymptomatic or presented with bilateral nasal discharge probably due to an underlying Feline Calicivirus (FCV) infection (Hatanaka et al. 2003; De Zoysa et al. 2005). In analogy to dogs (Lartigue et al. 2005), also skin ulcers and bronchopneumonia might be expected (Abbott et al. 2020).

28.5.4 Disease in Humans

Toxigenic *C. ulcerans* may cause classical respiratory diphtheria or diphtheria-like syndromes as well as cutaneous diphtheria (Berger et al. 2011a; Schuhegger et al. 2009). Classical diphtheria is an upper respiratory tract illness characterized by sore throat, low fever, and an adherent eponymous pseudomembrane (Greek: διφθέρα "pair of leather scrolls") on the tonsils, pharynx, and/or nasal cavity (Bonnet and Begg 1999). Systemic sequelae may appear after several days including myocarditis and peripheral neuropathy (Haywood et al. 2017; Schuhegger et al. 2009). Fatal cases of zoonotic *C. ulcerans* infections have also been reported (Hatanaka et al. 2003; Wellinghausen et al. 2002; Hogg et al. 2009; Mattos-Guaraldi et al. 2008; Tiwari et al. 2008; Gower et al. 2020). Treatment of respiratory diphtheria is by immediate antitoxin application and subsequent antibiosis with usually penicillin or erythromycin (Bonnet and Begg 1999; Marosevic et al. 2020).

Cutaneous diphtheria usually presents as skin ulcer and is often caused by a minor skin trauma; frequently, toxigenic *C. ulcerans* are isolated from an infected wound together with *Staphylococcus aureus* and *Streptococcus pyogenes* as additional pathogens.

Non-toxigenic strains may very rarely be associated with human disease, e.g., as cause of bacteremia or skin ulceration (Corti et al. 2012; Gower et al. 2020).

28.5.5 Public Health Importance

C. ulcerans infection was originally associated with consumption of raw milk and dairy products or contact with cattle, but since the first isolation of toxigenic *C. ulcerans* from two domestic cats from the same household in Scotland (PHLS 2002; Taylor et al. 2002), *C. ulcerans* has increasingly been isolated from domestic animals such as pet dogs (Lartigue et al. 2005; Hogg et al. 2009) and cats (De Zoysa et al. 2005). Although most human cases reported in the last decade in the UK (Wagner et al. 2010), France (Bonmarin et al. 2009), and Germany (Sing and Heesemann 2008; Berger et al. 2011a; Meinel et al. 2014) were associated with pet animal contact – this sums up to 94% of case-patients for which the respective information was available within Europe from 2000 to 2009 (Wagner et al. 2012) – epidemiological links of human infections by toxigenic *C. ulcerans* exclusively restricted to cat contact have only been reported in two patients from Japan with six and nearly twenty pet cats, respectively (Urakawa et al. 2013; Hatanaka et al. 2003), one patient with four cats from Belgium (Detemmerman et al. 2013) and in two patients from France (Bonmarin et al. 2009). A recent study in the UK reported on 15 toxigenic *C. ulcerans* from 2009 to 2017 with exposure to domestic animals as the major risk factor. Exposure to either dogs or cats was documented for 12/15 and 7/15 *C. ulcerans* cases, respectively (Gower et al. 2020).

In the last years molecular strain typing methods have improved for the epidemiologic research of *C. ulcerans* infections (Both et al. 2015; König et al. 2014) in order to enable the confirmation of strain transmissions between animals and

humans. Isolation of an identical toxigenic *C. ulcerans* strain from a cat and its owner has been documented in a few cases, for example, of an asymptomatic pet cat and a person with pharyngeal diphtheria-like illness (Berger et al. 2011a), in an HIV-patient with an axillary lymph node abscess (Yoshimura et al. 2014) and a patient with flu-like symptoms, dyspnea, and pseudomembrane formation (Wake et al. 2021). Meinel et al. demonstrated the superior resolution of next generation sequencing compared to multi-locus sequence typing for epidemiologic research of *C. ulcerans* zoonotic transmissions including three cat-associated cases (Meinel et al. 2014). Indirect evidence for zoonotic transmission comes from a case of cat-bite-transmitted cutaneous diphtheria in which toxigenic *C. ulcerans* was isolated from the infected wound; however, no *C. ulcerans* could be detected in the biting cat (Berger et al. 2011b). Additionally, toxigenic *C. ulcerans* was isolated from a pharyngeal pseudomembrane of a Japanese woman with refractory pharyngitis and discharge material from her cat's eyes suggesting zoonotic transmission (Kamada et al. 2012). Interestingly, when ribotyping 50 human and 7 feline *C. ulcerans* isolates from the UK, all ribotypes generated by the cat isolates were found among the human isolates; moreover, six out of seven of the cat strains belonged to one of the predominant ribotypes seen among the clinical strains, i.e., U1, U2, and U4 (De Zoysa et al. 2005).

Besides toxigenic *C. ulcerans*, also non-toxigenic *tox*-bearing (NTTB) *C. diphtheriae* strains have been isolated during contact tracing due to a human diphtheria index patient from the ears of two pet cats with otitis in the USA (Hall et al. 2010) and from an asymptomatic cat in Belgium (Detemmerman et al. 2013). Interestingly, all feline isolates from both continents showed a 1-bp deletion at nucleotide 55 in the *tox*-gene explaining the non-production of a functional DT; moreover, the *rpoB* sequence of the US strains showed less than 98% identity when compared to other *C. diphtheriae* suggesting a novel subspecies. The authors of both studies speculate that cats might also serve as reservoirs for – a possibly cat-specific subspecies of – *C. diphtheriae*.

28.5.6 Public Health Measures

Although diphtheria is rare in humans in industrialized countries due to vaccination programs, it is a notifiable disease that has to be reported to the relevant health authorities. In contrast to *C. diphtheriae*, *C. ulcerans* was for a long time thought to be exclusively transmitted from animal to human. However, in one instance from 1996 person-to-person transmission has been suspected due to isolation of *C. ulcerans* from two siblings (Bonnet and Begg 1999 citing a personal communication). Another report on a possible human-to-human transmission of toxigenic *C. ulcerans* between a 13-year-old girl suffering from tonsillitis and her asymptomatic grandmother harboring the identical sequence type ST 332 is documented (Konrad et al. 2015). The authors suggested an initial zoonotic transmission and a subsequent human-to-human transmission event because the family lived on a farm with many domestic animals. Gower et al. documented the transmission of a

toxigenic strain from a fully vaccinated individual to an unvaccinated contact in the UK (Gower et al. 2020).

Although probably only a very minor risk of human-to-human spread might exist, the English public health authorities have recommended that the public health response to human *C. ulcerans* infection should be the same as that for *C. diphtheriae*, e.g., isolation and treatment of the index case, tracing and taking nose and throat swabs from close contacts, as well as providing prophylactic antibiotics and booster vaccination for close contacts (Bonnet and Begg 1999; Public Health England 2015). Additionally, effective management of a *C. ulcerans* case also requires coordination between human and animal health agencies, especially because of several ethical and practical issues, including the lack of legal compulsion for owners to treat non-symptomatic companion animals harboring a toxigenic *C. ulcerans* strain (Hogg et al. 2009). In some instances dogs or cats as zoonotic sources of a human index case have successfully been treated using antibiotics, sometimes over a prolonged period (Berger et al. 2011a, b; Hogg et al. 2009; Abbott et al. 2020). There are also no proven vaccines specifically directed against *C. ulcerans*. Scanty data from clinical case reports showing attenuated clinical symptoms in some patients as well as from cytotoxicity assays using a very limited number of clinical isolates indicate that despite differences in the aminoacid sequence of DT from *C. diphtheriae* and *C. ulcerans* the currently used diphtheria toxoid vaccine might also protect from diphtheria due to infection with toxigenic *C. ulcerans* (Schuhegger et al. 2008; Gower et al. 2020).

28.6 SARS-CoV-2: A Reason for Cats (or Us) to Pan(dem)ic?

28.6.1 The Pathogen

Coronaviruses (CoVs) belonging to the order Nidovirales, suborder Cornidovirineae, family Coronaviridae, and subfamily Orthocoronavirinae, are pleomorphic, enveloped, positive-sense, single-stranded RNA viruses containing the largest viral RNA genomes known so far of around 30 kb. The Orthocoronavirinae subfamily comprises four genera, i.e., alpha-, beta-, gamma-, and delta-CoVs (Maurin et al. 2021; Ghai et al. 2021; Parkhe and Verma 2021). Common human coronaviruses (HCoVs) usually cause mild disease, mainly common cold, and include two α-CoV (HCoV-229E and HCoV-NL63) and two β-CoV (HCoV-OC43 and HCoV-HKU1) strains. Besides these seasonal, non-zoonotic and endemic human coronaviruses, three β-CoVs of animal origin have led to severe epi- or pandemics in the twenty-first century, i.e., the successfully eradicated SARS-CoV-1 causing Severe Acute Respiratory Syndrome (SARS) in 2002/3, the Middle-Eastern Respiratory Syndrome virus (MERS-CoV) enzootic in dromedary camels and having emerged in 2012, and the COVID-19 agent SARS-CoV-2 (genus: Betacoronavirus, subgenus: Sarbecovirus) first identified in Wuhan, China, at the end of 2019.

Host susceptibility and organotropism are dependent on the presence and cellular distribution of the SARS-CoV-2 receptor angiotensin-converting enzyme 2 (ACE2) interacting with the viral spike (S) protein and its receptor-binding domain (RBD) (Hoffmann et al. 2020; Fischhoff et al. 2021). Human and domestic cat ACE2 sequences show a high degree of protein homology > 85% (Ekstrand et al. 2021; de Morais et al. 2020) esp. in the predicted RBD key binding sites (Wei et al. 2021; Piplani et al. 2021; Mathavarajah and Dellaire 2020). Additionally, SARS-CoV-2 cell entry is also supported by the transmembrane serine protease 2 (TMPRSS2) (Hoffmann et al. 2020), which shows a 79.7% identity between human and domestic cat (Huang et al. 2021). Not to be confused with the three β-CoVs SARS-CoV-1 and -2 as well as MERS-CoV, respectively, are feline coronaviruses (FCoV) belonging to the α-CoVs. In contrast to SARS-CoV-2 with several thousands of sublineages, there are only two FCoV, i.e., type I and type II. FCoV may cause mild enteric infections to fatal Feline Infectious Peritonitis (FIP) and differ in many aspects from SARS-CoV-2, e.g., cell receptor (feline aminopeptidase, fAPN, at least for type II FCoV), cellular tropism (enterocytes, but also monocytes and macrophages), and route of infection (fecal-oral) (Paltrinieri et al. 2021).

28.6.2 Epidemiology in Cats and Humans

SARS-CoV-2 is responsible for one of the most severe pandemics in human history causing more than 300 million human infections and more than 5 million deaths worldwide by the beginning of 2022 as updated routinely on the Johns Hopkins University Coronavirus Resource Center (https://coronavirus.jhu.edu/map.html) as well as the WHO dashboard (https://covid19.who.int/). Molecular database platforms (https://www.gisaid.org; https://cov-lineages.org/) allow an intense and unprecendented real-time surveillance of the pandemic helping to identify new SARS-CoV-2 variants of concern (VOCs) with the potential to supersede previous prevalent virus lines due to higher transmissibility or immune escape. In most countries and regions, different waves of the pandemic were caused or at least intensely influenced by certain rapidly spreading VOCs, e.g., the third wave by Alpha (B.1.1.7), the fourth wave by Delta (B.1.617.2) including its numerous sublines and the fifth wave by Omicron (B.1.1.529).

Although felines belong to the most SARS-CoV-2-susceptible animal species as known from experimental (Shi et al. 2020; Halfmann et al. 2020; Bosco-Lauth et al. 2020; Gaudreault et al. 2020) as well as sequence- or structure-based modeling data (Fischhoff et al. 2021; for a review see Ekstrand et al. 2021; Dróżdż et al. 2021; Giraldo-Ramirez et al. 2021), only 124 SARS-CoV-2-infections in cats have been documented globally until 15 March 2021 (Giraldo-Ramirez et al. 2021, similar: Dróżdż et al. 2021 and OIE 2021), when already more than 120 million humans had been infected. Most recently, Islam et al. reported 156 domestic cats infections worldwide (Islam et al. 2021), while as of 15 January 2021 for the USA alone only 132 (of 3625 tested) SARS-CoV-infected animals and more than 27 million human cases were counted (Davis and Innes 2021).

The first case of SARS-CoV-2 infection in a domestic cat was reported from Belgium approximately 6 weeks after the first human case in this country in March 2020 (Garigliany et al. 2020). Subsequent domestic cat infections during the first (or second) wave have been found mostly within 3 months after the onset of the COVID-19 pandemic in Hong Kong (Barrs et al. 2020), Germany (Schulz et al. 2021a), the USA (Newman et al. 2020; UDSA 2020), Spain (Segalés et al. 2020), Chile (Neira et al. 2021), France (Sailleau et al. 2020), and the UK (Hosie et al. 2021a). Infected cats were identified 4–6 months after the first documented human case in Italy (Klaus et al. 2021a; Musso et al. 2020), Russia (OIE 2021), and Thailand (Jairak et al. 2021), while in some countries it took even longer until the first feline infections were reported (6 months in Japan [OIE 2021], more than 8 months in Switzerland [Chan et al. 2021] and more than 11 months in Canada [OIE 2021]) and South Korea (Han et al. 2021).

Similarly, in later pandemic waves it took at least 3 months until the respective VOC was detected in domestic cats after the first human case in the respective country, e.g., Alpha (B.1.1.7) in the USA (Hamer et al. 2021a), Italy (Zoccola et al. 2021), the UK (Ferasin et al. 2021), France (Krafft et al. 2021), and Germany (Keller et al. 2021) or Delta (B.1.617.2) in Harbin, China (Kang et al. 2021). Alpha and Delta genome sequences were also reported from Thailand and the USA as well as from Belgium, respectively (Islam et al. 2021).

In conclusion, the comparatively very low number and delayed detection of SARS-CoV-2 infections in domestic cats suggest that cats are not of major importance for the ongoing COVID-19 pandemic. Interestingly, so far all described pet cat infections detected by RT-PCR were linked to a human index case including reports showing the same viral strain in human and pet cat (Garigliany et al. 2020; Zoccola et al. 2021; Barrs et al. 2020; Han et al. 2021); up to now, cat-to-human "re-spillback" transmission of SARS-CoV-2 is extremely rare and has not been reported prior to July 2022 (Dróżdż et al. 2021; Giraldo-Ramirez et al. 2021; Maurin et al. 2021), when a suspected (and NGS-corroborated) cat-to-human Alpha SARS-CoV-2 transmission from a sneezing pet cat to a veterinarian was published having taken place in Thailand in August 2021 (Sila et al. 2022).

Interestingly, during a country-wide SARS-CoV-2 outbreak in Dutch mink farms, mink-to-(stray) cat transmission has been shown resulting in an estimated 12% chance of cats being infected by minks (van Aart et al. 2021) and indicating that cross-species animal-to-animal transmission might be relevant not only in experimental settings, but also in natural situations. Similarly, one of 24 farm cats (4.2%) from two COVID-2 affected Dutch mink farms were SARS-CoV-2 PCR positive, while seven of them seroconverted (29.2%) (Oreshkova et al. 2020). Moreover, in Danish mink farms SARS-CoV-2 was detected in a single domestic farm cat, but not in 30 stray cats (Boklund et al. 2021), indicating the possibility of mink- or- human-to-cat transmission in a similar setting.

The first documented natural SARS-CoV-2 infections in nondomestic animals (being also the first animal infection in the USA) happened in two Malayan (*Panthera tigris jacksoni*) and Amur (*Panthera tigris altaica*) tigers, respectively, and in three lions (*Panthera leo krugeri*) in March 2020 in the Bronx Zoo, New York

(McAloose et al. 2020), about 2 months after the first human case had been detected in the USA. All except one big cat of this outbreak were symptomatic. Whole genome sequence data suggested at least two independent SARS-CoV-2 introductions from zoo staff to the animals. Since then, more than 45 SARS-CoV-2 infections in zoo-kept *Panthera, Puma*, and *Prionailurus* spp. were described (Giraldo-Ramirez et al. 2021; OIE 2021; Islam et al. 2021), e.g., in pumas in South Africa and the USA, in a lynx in Croatia, in a fishing cat (*Prionailurus viverrinus*) in the USA (www.aphis.usda.gov), in three snow leopards (*Panthera uncia*) in the USA, in lions in Croatia, Colombia, Estonia, Singapore, South Africa, Spain (Fernández-Bellon et al. 2021), Sweden, and the USA, in tigers in Indonesia, Sweden, the UK, and the USA (for all: OIE 2021; Islam et al. 2021). Infections by Delta (B.1.617.2) variants including possible lion-to-lion transmission events were recently described in 12 *Panthera leo persica* from zoos and safari parks in Tamil Nadu (Mishra et al. 2021), Uttar Pradesh, and Rajasthan/India (Karikalan et al. 2021). In nearly all reported SARS-CoV-2 infections of big cats a human-to-animal transmission was proven or at least suspected; most of the animals were symptomatic, primarily with respiratory symptoms, but also more systemic signs, e.g., loss of appetite and lethargy (Giraldo-Ramirez et al. 2021). Alpha genome sequences were also documented from a lion, a leopard, and three tigers from the Czech Republic and the USA, respectively (Islam et al. 2021). Until December 2021, no SARS-CoV-2 infections affecting free-ranging wildlife big cats have been reported. Very recently, a systemic SARS-CoV-2 Delta variant infection affecting brain, spleen, lymph nodes, and lungs of a free-ranging non-captive leopard (*Panthera pardus fusca*) probably killed by another carnivore has been reported from Uttar Pradesh/India (Mahajan et al. 2022).

Several seroprevalence studies have been carried out to evaluate the burden of SARS-CoV-2 infections in pet cats. Three of the first studies were performed in China including the city of Wuhan from where the COVID-19 pandemic started. Deng et al. found no SARS-CoV-2 antibodies in 66 pet and 21 stray cats sampled between November 2019 and March 2020 (Deng et al. 2020a) confirmed by a subsequent study from the same group finding no SARS-CoV-2 antibodies in 423 cats from 20 Chinese cities (including 48 from Wuhan and 42 from the province of Hubei) sampled between February and April 2020 during the first wave (Deng et al. 2020b); a strictly Wuhan-based study performed between January and March 2020 yielded a seroprevalence of 14.2% in 102 cats; 3 of 15 (20%) pet cats from COVID-19 families were seropositive, six of 46 (13%) cats from shelters and six of 41 (14.5%) from animal hospitals, respectively (Zhang et al. 2020). The three cats with the highest titers were patient-owned suggesting potential direct human-to-cat transmission rather than cat-to-cat transmission.

Serological studies in cats were also conducted in other hotspots during the first pandemic wave, esp. in Northern Italy, yielding similar or even lower seroprevalence rates, e.g., 0% among 24 cats in Lombardy (Klaus et al. 2021a); 0.95% in 105 stray and shelter cats from Lombardy (Spada et al. 2021) 5.8% among 191 cats mostly from Lombardy (Patterson et al. 2020) with a positivity rate of 4.5% (1/22) and 2.6% (1/38) in COVID-19 positive and negative households, respectively; 16.2% among

68 cats from all over Italy (with all positive-tested pet cats living with COVID-19 positive owners; seropositivity rate in these animals was 20.4%) (Colitti et al. 2021); 0.4% in 500 cats from the Netherlands (Zhao et al. 2021); 0.69% in 920 cats from Germany (Michelitsch et al. 2020); 0.76% in 131 cats from Croatia using micro-neutralization assays (Stevanovic et al. 2021); 3.3.%, 4.2%, 4.2%, and 6.4% in domestic cats in 331, 333, 1136, and 360 domestic cats from the UK, Italy, Germany, and Spain (Schulz et al. 2021b); 3.5% in 114 stray cats from Zaragoza/Spain (Villanueva-Saz et al. 2021); 8% in 239 cats from Minnesota/USA (Dileepan et al. 2021).

Studies covering a longer period of the pandemic or later waves found similarly low or even lower seroprevalence rates, e.g., 0% in 99 stray cats from Lodi/Italy sampled throughout the first year of the pandemic until end of 2020 (Stranieri et al. 2021), 0% in 80 domestic cats during the second wave in Thailand (Jairak et al. 2022); 0.42% (4/956) in cats from 48 US states sampled between March and November 2020 (Barua et al. 2021); 0.8% (2/240) in shelter cats in the Netherlands during the second wave (van der Leij et al. 2021); 1.36% in 1173 cats in second wave in Germany (Michelitsch et al. 2021), double as high as the seropositivity rate detected by the same group in the first wave (Michelitsch et al. 2020); and 1.79% in 279 domestic cats in Poland during the second and third wave (Pomorska-Mól et al. 2021). The constantly low seroprevalence rates indicate that neither domestic pet nor stray cats are heavily affected by the SARS-CoV-2 pandemic or by "re-spillback" effects.

In contrast, in studies performed in households with confirmed human COVID-19 cases, the seroprevalence was usually higher than in random or convenient sample studies, e.g., 23.5% (8/34) in Eastern France being significantly higher than in pet cats from households with unknown COVID-19 status (6.3%; 1/16) (Fritz et al. 2021); 17.1% (7/41) to 31.7% (13/41) in Peru (Jara et al. 2021); 30.1% (4/11) in Utah and Wisconsin/USA (Goryoka et al. 2021); 40% (4/10) in Brazil (Calvet et al. 2021); and 43.8% (7/16) in Texas/USA (Hamer et al. 2021b). The only exception from this trend is a study from France among a cluster of COVID-19 patients from a veterinary campus living in close proximity with their pets, where no SARS-CoV-2 antibodies could be detected in nine cats (Temmam et al. 2020). Most interestingly, seroprevalence in 44 stray cats from Dutch SARS-CoV-2-affected mink farms (22.7%) was significantly higher than in a convenience sample of cat sera from the Netherlands (0.4%) (Zhao et al. 2021).

As expected, SARS-CoV-2 viral prevalence in cats as detected by RT-PCR was usually even lower than seroprevalence, e.g., 0% in 99 stray cats from Lodi/Italy sampled during the first pandemic year (Stranieri et al. 2021); 0% in 93 cats from five different subdistricts of Thailand during the second wave (Jairak et al. 2022); 0.17% in 569 randomly selected and 1.63% in 184 COVID-19 and/or COVID-19 symptomatic cats, respectively, from different regions of Spain sampled between July 2020 and April 2021 (Barroso-Arévalo et al. 2021); 0.38% in 260 cats mainly from first wave hotspot areas in Munich/Germany and in Lombardy or Piedmont/Italy with the only positive cat living in a COVID-19 household (Klaus et al. 2021a); 0.8% in domestic cats from northwestern Iran (Mohebali et al. 2022); 2.4% in

asymptomatic cats from France sampled from April 2020 to April 2021 (Krafft et al. 2021).

SARS-CoV-2 viral prevalence was higher in some outbreak investigations from cats living in COVID-19 positive households, e.g. 11.1% (1/9), 12% (6/50), 12.5% (1/8) and 17.6% (3/17) in studies from Thailand (Jairak et al. 2021), Hong Kong (Barrs et al. 2020), Spain (Ruiz-Arrondo et al. 2021), and Texas/USA (Hamer et al. 2021b), respectively. However, also instances of zero SARS-CoV-2 RT-PCR positivity in outbreak settings have been reported, e.g., in 19 cats from Utah and Wisconsin (Goryoka et al. 2021) and in 9 cats from France (Temmam et al. 2020).

One of the key parameters in epidemiology indicating the transmissibility of a pathogen and therefore the risk of epidemic transmission is the basic reproduction number R_0. A value for $R_0 > 1$ suggests sustained transmission, while $R_0 < 1$ indicates a likely tapering off of an ongoing epi- or pandemic. Using experimental and household observational data the SARS-CoV-2 reproduction number R_0 in cats was calculated to be 2.3–3.3 (Gonzales et al. 2021), while R_0 of the ancestral SARS-CoV-2 strain in humans was estimated to be 2.5–3.8 (Liu and Rocklöv 2021; Anderson et al. 2021). For subsequent variants dominating the human pandemic, e.g., Alpha, Delta, and Omicron, significantly higher R_0 values have been estimated (Davies et al. 2021; Liu and Rocklöv 2021; Nishiura et al. 2021).

28.6.3 Disease in Cats

After experimental (mostly intranasal and/or oral) infection cats, esp. when older than 4 months, remained basically asymptomatic exhibiting generally mild-to-moderate pathological changes mainly in the respiratory tract in several studies (Gaudreault et al. 2020; Shi et al. 2020; Bosco-Lauth et al. 2020; Bao et al. 2021; Patania et al. 2021). Juvenile cats might be more susceptible and prone to more severe overt disease as indicated in one study (Shi et al. 2020). Viral replication was found predominantly in the upper respiratory tract, while SARS-CoV-2 RNA could be detected in a wide range of tissues corresponding with the wide distribution of ACE2 in many organs (e.g., lymph nodes, liver, heart, kidney) (Gaudreault et al. 2020; Meekins et al. 2021).

Regarding natural infections observed in animals, a selection bias is to be expected with a focus on testing symptomatic animals or animals with close contact to COVID-19 human patients therefore probably overrepresenting the tip of the iceberg in the clinical spectrum of SARS-CoV-2 infection. However, even in a review of the first 124 SARS-CoV-2 reports in cats, the majority of cats with available clinical information were completely asymptomatic, i.e., 54% (corresponding to 38/70) (Giraldo-Ramirez et al. 2021). The wider clinical spectrum of symptomatic pet cats in this review comprised mainly respiratory signs (sneezing [41%], dyspnea [13%], nasal or ocular discharge [both 9%]), but also digestive (diarrhea [6%], emesis [3%]), systemic (lethargy [38%], loss of appetite [16%], fever [6%]), and cardiovascular (congestive heart failure [25%], ventricular arrhythmia [13%], hypertrophic cardiomyopathy [9%]) symptoms (Giraldo-Ramirez et al.

2021). Some of the more severe symptoms in naturally vs. experimentally infected cats might be due to preexisting comorbidities (Meekins et al. 2021) including very few fatal outcomes complicated by underlying coinfections or severe systemic disease (Segalés et al. 2020; Giraldo-Ramirez et al. 2021). Moreover, myocarditis has been described in SARS-CoV-2 infected pet cats, most of them associated with the Alpha variant (Ferasin et al. 2021; Chetboul et al. 2021). Usually, the disease is self-limiting in naturally infected domestic cats.

In big cats the data situation is different. For obvious reasons no experimental data are available. In contrast to the published evidence involving naturally infected domestic cats, the infections reported in captive big cats were usually symptomatic, with coughing (97%), sneezing (79%), and loss of appetite (51%) being the most prevalent clinical signs (for a review Giraldo-Ramirez et al. 2021; Maurin et al. 2021; see also case and outbreak reports in McAloose et al. 2020; Mishra et al. 2021; Fernández-Bellon et al. 2021). However, these findings might be biased due to the symptom-driven diagnostic work-up of the diseased zoo animals. Disease was usually self-limiting, however, sometimes with a prolonged course of infection; deaths due to COVID-19 were also reported for at least two lions (Mishra et al. 2021).

28.6.4 Disease in Humans

SARS-CoV-2-caused COVID-19 is a systemic disease affecting many different organ systems due to the abundance of the SARS-CoV-2 receptor ACE2 in the respective tissues (for a review see Synowiec et al. 2021). Accordingly, many different short-term symptoms and long-term effects of the disease have been described.

The major organ system affected is the respiratory system, but direct viral as well as indirect host immune response effects may cause cardiovascular, gastrointestinal, renal, neurological, ocular, cutaneous, musculoskeletal, hematological, and endocrine symptoms (Mehta et al. 2021). In general, COVID-19 tends to be a mild to moderate disease in 80–85% of infected humans (including basically asymptomatic people); severe disease is often associated with elder age over 65 years, comorbidities including diabetes, hypertension, cardiovascular, or respiratory disorders, or other chronic conditions, e.g., obesity. However, severe and lethal infections may also be observed in previously healthy and young patients. The global gross case fatality rate (CFR) may be calculated as about 1.7% using data from WHO (January 18, 2022), the infection fatality rate (IFR) was estimated to be 0.68% in 2020 (Meyerowitz-Katz and Merone 2020); IFRs and CFRs, however, largely depend on many different parameters including test policies and differ between countries, populations, and over time (Anderson et al. 2021; Levin et al. 2020).

During the first wave of the pandemic caused basically by the ancestral SARS-CoV-2 Wuhan strain, the most common initial clinical manifestations of COVID-19 included fever (82%), cough (61%), myalgia and/or fatigue (36%), shortness of breath (26%), headache (12%), sore throat (10%), and gastrointestinal symptoms

(9%) (Yazdanpanah et al. 2021). According to the report from WHO-China-Joint Mission on COVID-19, the most prevalent respiratory and systemic symptoms during the first Corona wave in China comprised fever (87.9%), dry cough (67.7%), fatigue (38.1%), sputum production (33.4%), difficulty breathing (18.6%), sore throat (13.9%), chills (11.4%), nasal congestion (4.8%), and hemoptysis (0.9%) (WHO-China Joint Mission 2019). Of special interest in the course of and at different time-points during the pandemic became – among a plethora of other symptoms – mostly self-limiting hyp- or anosmia (in nearly half of the patients) (Karamali et al. 2022), cardiac arrhythmias (in about 5–10% of hospitalized patients) (Pandat et al. 2021), thromboembolic events (in 5–17% of patients) (Gorog et al. 2022). Depending on the human population (e.g., vaccination status, age distribution, underlying diseases) and the predominant variant (e.g., Alpha, Delta, Omicron) the distribution of clinical symptoms and entities may differ. Additional concerns arise from the Pediatric Multisystem Inflammatory Syndrome temporally associated with COVID-19 (PIMS-TS or PIMS) or Multisystem Inflammatory Syndrome in Children (MIS[-C]) (Hoste et al. 2021; Case and Son 2021) as well as from long COVID-19 entities including post-COVID-19 (Jennings et al. 2021).

28.6.5 Public Health Importance

As known from experimental data, domestic cats can transmit SARS-CoV-2 to co-housed cats via close contact and to a lesser degree via aerosols (Bao et al. 2021; Shi et al. 2020; Halfmann et al. 2020; Gaudreault et al. 2020). Interestingly, with respect to transmission by close contact, SARS-CoV-2 RNA has been detected on fur and/or bedding swabs from cats in studies from Switzerland (Klaus et al. 2021b), Spain (Barroso-Arévalo et al. 2021), and the USA (Hamer et al. 2021a) indicating environmental contamination as a possible source for cat-to-cat transmission. Importantly, in experimental settings, previously SARS-CoV-2 infected cats could be successfully reinfected, but did not transmit SARS-CoV-2 to other co-housed naïve sentinels (Gaudreault et al. 2021).

In contrast to intraspecies transmission, situations with cats as inter- or cross-species SARS-CoV-2 spreaders have been described so far only in a single case of cat-to-human transmission involving a sneezing pet cat and its veterinarian during a medical procedure in Thailand (Sila et al. 2022), suggesting only a very low risk for cat owners to attract COVID-19 from their pet. Importantly, also in the large SARS-CoV-2 outbreaks on mink farms in Denmark and the Netherlands, no cases of cat-to-mink transmission were suspected, while all SARS-CoV-2 infected domestic pet and stray cats with farm contact were probably infected by minks as indicated at least in some cases by whole genome-based viral typing (van Aart et al. 2021).

In contrast to the sustained human-to-human transmission observed over time, cat-to-cat transmissibility is reduced after serial passaging of the virus in co-housing experiments (Bao et al. 2021) suggesting limited transmission in the cat population after viral entry, e.g., from humans. More disturbing, however, is the observation that

despite a narrow bottleneck of 2–5 virions expected to help slowing down the pace of viral adaptation and shown to leave SARS-CoV-2 consensus sequences largely unchanged over time SARS-CoV-2 (Braun et al. 2021; Bao et al. 2021) variants involving amino acid mutations such as D614G, D138Y, or H655Y also found in VOCs known from human infections may develop very rapidly and even get fixed in infected cats (Bashor et al. 2021; Braun et al. 2021). These findings illustrate that reverse zoonosis can result in the emergence of new SARS-CoV-2 variants. Therefore, monitoring of SARS-CoV-2 evolution in animals is important, even in cases where transmissibility to humans seems to be very low (Bashor et al. 2021; Davis and Innes 2021).

28.6.6 Public Health Measures

According to the high susceptibility of cats for SARS-CoV-2 and their very low potential as SARS-CoV-2 transmitters to humans (Ekstrand et al. 2021), public health recommendations primarily target humans, e.g., infected cat owners or zoo staff, to prevent human-to-cat transmission. In comparison, "One Health/One Medicine" aspects to avoid (i) cat-to-cat transmission (ii) cross-species "spill-over" to other animals; or (iii) cat-to-human "spill-back" effects are only in second line of current recommendations.

Several public health and veterinary public health institutions as well as animal or pet welfare organizations have issued guidelines and recommendations, e.g., the US Centers for Disease Control and Prevention (https://www.cdc.gov/coronavirus/2019-ncov/daily-life-coping/animals.html), the World Organization for Animal Health OIE (https://www.oie.int), the American Veterinary Medical Association (AVMA) (https://www.avma.org/resources-tools/animal-health-and-welfare/covid-19), or the European Advisory Board on Cat Diseases (ABCD) (http://www.abcdcatsvets.org/sars-coronavirus-2-and-cats/).

Most documents recommend that (i) SARS-CoV-2 infected people should restrict contact with mammalian animals, including pet cats, and apply good hygiene practices when having to care for their pets (e.g., wearing a mask, handwashing, avoiding kissing their pets, or sharing food, towels, or the bed with them); (ii) cats from SARS-CoV-2-infected households should be kept indoors; (iii) animals with suspected or confirmed SARS-CoV-2 infection should remain separated from other animals and humans; (iv) pet owners should monitor their pets to detect any health problems suggestive for SARS-CoV-2 infection; (v) pet owners should not abandon their animals or compromise their welfare during the COVID-19 pandemic (Huang et al. 2020; Hosie et al. 2021b).

On a more general "One Health/One Medicine" scale, it is of utmost importance to establish both national and international surveillance systems to closely monitor the development and occurrence of SARS-CoV-2 and other agents of public health relevance in animals with respect to possible "spill over" and "spill-back" effects thus contributing substantially to the urgently needed global pandemic preparedness efforts (Giraldo-Ramirez et al. 2021).

Public Health and Rodents: A Game of Cat and Mouse

29

Bastiaan G. Meerburg

Contents

Abstract

Rodents are the most abundant order of living mammals, distributed on every continent except Antarctic and represent 43% of all mammalian species. Beside causing food losses and infrastructural damage, rodents can harbor pathogens that may cause serious problems to human and animal health. Unfortunately, rodent-associated problems are not an issue of the past as some may have thought, even not in the developed world. This chapter describes four factors that determine the risk and severity of human infection by zoonotic pathogens of rodents: human behavior, human health condition, rodent ecology & behavior, and pathogen ecology & persistence. It provides an overview of these factors, their interrelation and also some directions for further research. Main conclusion of this chapter is that although science has come a long way already and we have won some small victories over the rodents, the game of cat (i.e., humans) and mouse is far from being settled.

29.1 Introduction

The order of *Rodentia* is the most abundant and diversified order of living mammals and represents in total about 43% of all mammalian species (Wilson and Reeder 1993; Huchon et al. 2002). Rodents are distributed on every continent except Antarctica and include many of the most abundant mammals. For many centuries, opportunistic rodent species have been considered as serious pests because of the damage they cause to crops, stored produce or infrastructure and the role they play in the transmission of pathogens to humans and livestock. Improved public sanitation conditions like safe drinking water, the introduction of sewers and the development of efficient anticoagulant rodenticides in the 1950s resulted in an improved public health situation and created the illusion that rodent-associated problems in the developed world had become an issue of the past.

More recently, however, the concern about rodents in both the developing and developed world has grown again because of various reasons. These reasons are the following:

- The distribution and abundance of various rodent species may be significantly affected by changes in land use (e.g., reforestation projects, urbanization).
- Climatic change may improve living conditions for certain rodent populations.
- Growing outdoor leisure activities increase the exposure of humans to rodents and their excrements and hence the transmission risk of rodent-borne pathogens.
- In some countries the government has receded from rodent control and put it out to contract to private companies. This has led to a serious lack of insight in the spreading and abundance of rodent populations, which is important to monitor the potential introduction and spread of rodent-borne pathogens.
- The human world population is growing rapidly and thus more food is needed. Rodents are responsible for huge pre- and postharvest losses (Meerburg et al. 2009b; Htwe et al. 2012).
- Environmental concerns, toxicological safety regulations, and budget reductions have diminished rodent surveillance and rodenticide-based control in many countries.
- The increasing extent of resistance of rodents against second-generation rodenticides has reduced the efficacy and flexibility of rodent control (Pelz 2007; Buckle et al. 2013; Endepols et al. 2012; Meerburg et al. 2014).
- Rodents still play an important role in spreading (re-)emerging zoonotic diseases (Meerburg et al. 2009a).

29.2 Rodents: Both Reservoirs and Carriers

Rodent presence can have serious implications for public health and be potentially hazardous as they amplify pathogens from their environment by forming reservoirs of zoonotic disease (Webster and Macdonald 1995; Gratz 1994). With reservoirs it is meant that rodents can harbor disease-causing organisms and thus serve as potential

sources of disease outbreaks, but always via a vector (tick, sand-fly etc.). Besides as reservoirs, rodents can also act as carriers, which means that rodents that show no or limited disease symptoms but harbor the disease-causing agent are capable of passing it directly onto humans (Meerburg et al. 2009a).

Two main transmission routes of pathogens can be distinguished (Meerburg et al. 2009a): the direct route (when rodents are carriers) or the indirect route (when rodents function as reservoir and transmit a pathogen through means of a vector), see Fig. 1. In the latter, this vector is often an arthropod, but can also occasionally be other animals, such as livestock. Rodents that are (either by accident or on purpose) ingested by livestock can transfer pathogens. When food originating from this livestock is not thoroughly cooked, this may lead to human morbidity (Meerburg et al. 2004).

If we now look at the risks and severity that are imposed by rodents to human health, there are several factors that are of importance (Fig. 2).

The first one is human behavior. People with frequent outdoor leisure activities or which fulfil specific occupations (e.g., in the military, animal trapping, or forestry) or those that live in degraded environments will be more exposed to rodent-borne zoonoses than others (Clement et al. 1997; Muliæ and Ropac 2002; Hukic et al. 2010; Sauvage et al. 2007; Bonnefoy et al. 2008). Exposure is the key word here, thus, for example, also people that keep rodents as pets may experience higher risks of zoonotic infection. The risk of keeping pet rodents will be discussed more in detail later in this chapter.

It is good to understand that especially for commensal rodents human behavior and rodent ecology and behavior are often strongly linked. If humans dispose their garbage in a wrong way, this will provide opportunities for growth of commensal rodent populations. Moreover, following the widespread closures of food-related businesses due to efforts to curtail the spread of the SARS-CoV2 pandemic, public health authorities reported increased sightings of rats in close vicinity of people (Parsons et al. 2020), although the signals about an increasing or decreasing number of rat reports differs between countries.

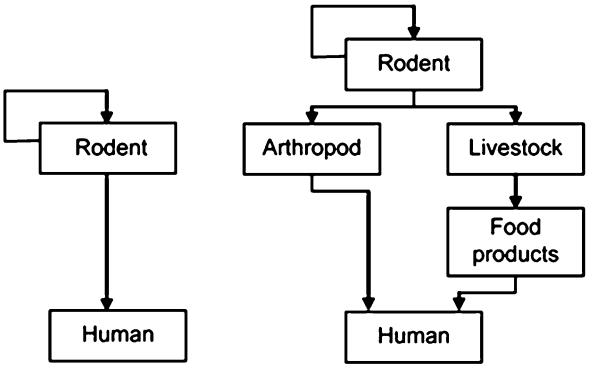

Fig. 1 The two main transmission routes, the direct route (left) and the indirect route (right). (Reproduced from Meerburg et al. 2009a)

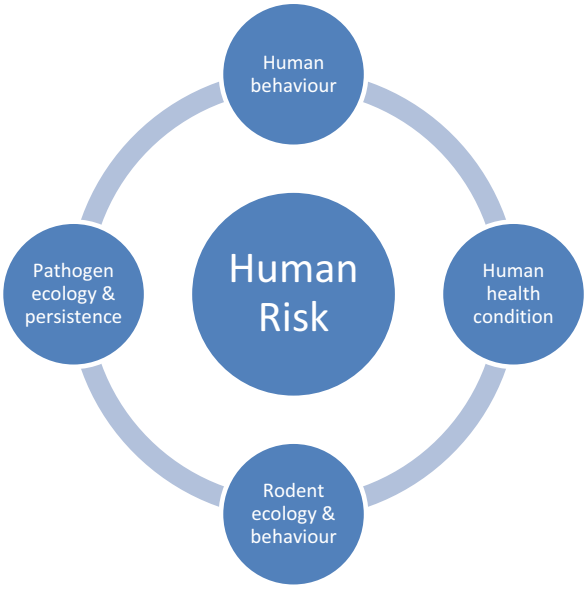

Fig. 2 Four factors determine the risk and severity of human infections by zoonotic pathogens of rodents: human behavior, human health condition, rodent ecology & behavior, and pathogen ecology & persistence

The second factor is the human health condition. Generally, zoonoses pose unique transmission and disease risks if people are not in good health, such as immunocompromised persons, neonates, the elderly, or pregnant women (Mani and Maguire 2009; Hemsworth and Pizer 2006) or may effect persons in specific age groups. As an example Streptobacillus moniliformis may be mentioned, the primary cause of rat bite fever in North America. Children under 12 years of age are mainly infected, and demonstrate an acute syndrome of fever, rash, and polyarthritis. Some years ago, a fatal case-report was reported, a 14-month-old-boy, who was exposed to filthy living conditions and whose family had pet ferrets. Presumably, the boy was bitten by rodents as autopsy revealed a possible bite mark (Banerjee et al. 2011).

Also aspects such as vaccination coverage may influence the factor human health condition. From a number of studies, it is known that wild rodents can be reservoirs for orthopoxviruses (Tryland et al. 1998; Kinnunen et al. 2011). More recently, pet rats were discovered as a new potential source of local outbreaks with cowpox. However, smallpox-vaccinated patients tend to develop less severe reactions and heal more quickly (Vogel et al. 2012). Thus, there is a direct link between actions of public health services (vaccination) and the recovery rate (severity of infection) of infected persons.

A third factor of importance is rodent ecology and behavior. As mentioned in the introduction, rodent ecology may differ over the years, depending on climatic factors, feed abundance, and predation (Witmer and Proulx 2010). Moreover, differences in the ecology and behavior of rodent species may emerge depending whether they are in a rural or urban environment (Feng and Himshworth 2014).

Unfortunately, the knowledge about behavior of rodent pest species is still quite limited. Rodent management could become more efficient and effective when concentrating efforts on areas where rodents perceive the least levels of predation risk (Krijger et al. 2017).

During a study in Namibia, mice entered buildings during the post-harvest stage, which may represent a period of food shortage for these mice in the field (Monadjem et al. 2011). If these species are coincidently contracted with zoonotic pathogens, this may increase the risk of human infection. In a study from Cambodia, it was demonstrated that the rainy season is favorable for transmission of leptospires in rodents, particularly in rain-fed fields (Ivanova et al. 2012). Here, the human risk of contracting *Leptospira* spp. is determined strongly by the ecology of the rodents: in rice-fields, forest, secondary forests, and their interface with agricultural fields the potential of humans for contracting leptospirosis infection is the highest (Ivanova et al. 2012).

But the link between rodent ecology and human health risks is not depending solely on one rodent species. Also the presence of other non-reservoir rodent species is important. In a recent study from Panama it was demonstrated that hantavirus prevalence in wild reservoir (rodent) populations and reservoir population density increased when small-mammal species diversity was reduced (Suzán et al. 2009). These authors thus claim that high biodiversity is important to reduce transmission of zoonotic pathogens among wildlife hosts (Suzán et al. 2009). Also host relationships form part of the rodent ecology and there can be significant differences in such relations within the same rodent species. In a study where host-tick relationships of the yellow-necked mouse (*Apodemus flavicollis*), a critical host in the maintenance of the zoonotic disease tick-borne encephalitis, were investigated it was demonstrated that the transmission potential was not evenly distributed among the yellow-necked mice population. The authors found that 20% of hosts most infested with ticks were accountable for 80% of the transmission potential, and that these hosts were identified as the sexually mature males of high body mass (Perkins et al. 2003). This leads to the impression that control efforts targeted at this host group would reduce the transmission potential significantly.

In the past, seasons of exceptionally high rainfall were thought to increase rodent populations (because plant growth would lead to abundant seeds and insects) and thus outbreaks of some rodent-borne diseases (Engelthaler et al. 1997; Brown and Ernest 2002). However, we now start to discover that such relationships between rodent population dynamics and precipitation are complex and non-linear. This was also the main conclusion after some scientists studied the El Niño phenomenon in deserts of southwestern North-America (Brown and Ernest 2002). In agricultural contexts, it is also difficult to predict exactly the breeding ecology of species. A recent study from the Philippines compared two rodent species *R. argentiventer* and *R. tanezumi* during four cropping seasons (two dry and two wet). The expectation was that *R. tanezumi* breeding would occur throughout the season, whereas the breeding of *R. argentiventer* would be strongly cued to the generative stage of rice crops (Htwe et al. 2012). However, it was found

that their breeding ecology was exactly similar, with the onset of the breeding season at the tillering stage of the rice crops. The conception of adult females was highest during booting and ripening of the rice and the highest litter size occurred at booting and ripening of the rice (Htwe et al. 2012). Such information is essential in order to optimize the management of rodents in order to reduce harvest losses and pathogen transmission risks.

The fourth factor is pathogen ecology and persistence. Many of the mechanisms that mediate pathogen ecology and persistence only start being uncovered. Concerning hantaviruses in rodents, several host factors, including sex steroids, glucocorticoids, and genetic factors, are reported to alter host susceptibility and may contribute to the persistence of hantaviruses in rodents (Easterbrook and Klein 2008). Moreover, because of the recent discovery of structural and non-structural proteins in humans that suppress type I interferon responses, it is now thought that immune responses of rodent hosts could be mediated directly by this virus (Easterbrook and Klein 2008). In laboratory rats it was observed that *Leptospira interrogans* serovar Copenhageni initially disseminates extensively throughout the host, prior to clearance from all tissues except the kidneys, suggesting that the kidneys are immune privileged sites and that this is not caused by tissue tropism (Athanazio et al. 2008). In a study in black rats (*Rattus rattus*) in Madagascar, an important difference in plague resi *s*tance between rat populations from the plague focus (central highlands) and those from the plague-free zone (low altitude area) was confirmed to be widespread (Tollenaere et al. 2010). Moreover, these authors discovered that sex-influenced plague susceptibility, with males slightly more resistant than females (Tollenaere et al. 2010). It is difficult whether this phenomenon is caused by rodent ecology, pathogen ecology, or a combination of both. This is also the case with other findings. In Belgium, a close association between the distribution of hantavirus-infected bank voles and wet habitat types was found (Verhagen et al. 1986). In another, more recent, study from this country, a direct relation between climate and the incidence of human cases of nephropathia epidemica (NE) due to Puumala virus (PUUV) infection was found. High summer and autumn temperatures, 2 years and 1 year respectively before NE occurrence, relate to high NE incidence (Tersago et al. 2009). In the United States, human cases of Hantavirus Pulmonary Synodrome (HPS) were clustered seasonally and temporally by biome type and geographic location. In this study, exposure sites were most frequently found in pinyon-juniper woodlands, grasslands, and Great Basin desert scrub lands, at elevations of 1800 m to 2500 m (Engelthaler et al. 1997). This might be caused by presence of rodent reservoir hosts in these areas, but perhaps also because of favorable environmental conditions for pathogen survival. Pathogens do not only persist in the host itself, but may also survive for longer periods of time throughout the environment. For example, *Yersinia pestis* biotype Orientalis remains viable and fully virulent after 40 weeks in the soil and is then able to continue its role in plague epidemiology (Ayyadurai et al. 2008). Moreover, if factors such as pH, viscosity, and salt concentration are optimal, *Leptospira* spp. are thought to be able to survive in fresh water under low-nutrient conditions for over 100 days (Trueba et al. 2004).

29.3 Conclusion

It is clear that for eradication strategies, more work has to be done on the pathogenesis of the various zoonotic pathogens which can be transferred by rodents. Especially the further development of genetic tools could lead to a better understanding of the virulence and survival mechanisms that are used by pathogens to ensure their persistence in different ecological niches and host reservoirs.

Often, there is a relation between the different factors and complex relationships between pathogen prevalence and rodent density appear likely. In North-Western Europe, the main disease-causing hantavirus species is the Puumala virus (PUUV). The reservoir species for PUUV is the bank vole (*Myodes glareolus*), which exists in specific habitats. The risk for PUUV transfer from the bank vole to the human population via excretion of the virus in the environment is dependent on a myriad of biotic and abiotic risk factors, either rodent-, virus-, or human-related, that vary in time and space. In a study from Finland, the effect of PUUV infection on the winter survival of bank voles was investigated (Kallio et al. 2007). These authors demonstrate that PUUV infected bank voles had a significantly lower overwinter survival probability than antibody negative bank voles. Thus, the pathogen is able to influence the host population dynamics. During a study on the ecology and demographics of hantavirus infections in rodent populations in the Walker River Basin of Nevada and California, it was found that antibody prevalence could vary within repeatedly sampled sites from 0 to 50% over the course of several months (Boone et al. 1998). In Tanzania, an African rodent (*Mastomys natalensis*) is thought to be the principal source of human infections with *Leptospira* spp. In a study where the dynamics of infection were modelled and in which the climatic conditions in central Tanzania were included, a strong seasonality was visualized in the force of infection on humans with a peak in the abundance of infectious mice between January and April in agricultural environments (Holt et al. 2006). In urban environments, however, dynamics were predicted to be more stable and the period of high numbers of infectious animals runs from February to July (Holt et al. 2006). In countries in Northern-Europe (Germany, Denmark), there are also regional differences visible in the level of encountered *Leptospira* spp. infected-rats (Runge et al. 2013; Krøjgaard et al. 2009). Why these differences occur, is not yet fully understood.

As mentioned before, the risk of transmitting zoonotic pathogens to humans is largest if the exposure risk is maximal. Handlers and owners of pet rodents are often in direct contact with them and may experience significant risks. Some years ago, there was an outbreak of 28 cases of multidrug-resistant *S. enterica* Serotype Typhimurium in the United States. After the outbreak, 22 patients were interviewed. Of them, 13 (59%) had had contact with rodents purchased from retail pet stores (Swanson et al. 2007), while 2 patients (9%) acquired salmonellosis through secondary transmission from a primary patient who had been exposed to rodents. Moreover, 7 patients (32%) had no identified rodent exposure. Matching isolates were obtained from one submitted urine specimen and 27 stool specimens from patients (Swanson et al. 2007). These authors warn that consumers and animal workers should be aware that rodents can shed salmonellae and should expect rodent

excrements to be potentially infectious. Thus, handling of pet rodents may result in health risks, especially for children. When handling pet rodents, their cages, or bedding, the hands should be thoroughly rinsed with water and soap. Animal vendors should be aware if substantial diarrhea-associated complications or death occurs among rodents intended for sale (Swanson et al. 2007).

Some years earlier, an human infection with Lymphocytic Choriomeningitis Virus (LCMV) in the United States was found by the CDC to be associated with pet rodents (hamsters and guinea pigs). Here, the risks extended also beyond the owners of these pets. In this particular case, LCMV was responsible for the death of three immunocompromised persons (organ transplant recipients) who received these organs from pet rodent owners (Anonymous 2005). More recently, workers at a rodent breeding facility in the United States were confronted with a LCMV infection. In total, 52 current and former employees of the facility were tested, and 13 of them (25%) demonstrated a recent LCMV infection (Anonymous 2012).

Exotic rodents may introduce pathogens that were previously unknown to continents. For example, in 2003 a monkeypox outbreak in pet distribution facilities in the USA occurred after import of infected African prairie dogs (Anonymous 2003). In total, monkeypox was confirmed in 35 persons, of which none died, but the outbreak required vaccination of 30 persons with smallpox vaccine.

Commercially-traded wild prairie dogs were also responsible for an outbreak caused by *Francisella tularensis* type B in Texas. Antibodies to this pathogen were found in one person that was exposed, thus leading to the first evidence of tularemia transmission from prairie dog to human (Avashia et al. 2002). Problematic was that in the period June–July 2002, more than 1000 prairie dogs were distributed from the facility where the pathogen emerged, to locations in 10 other US states and 7 other countries (Avashia et al. 2002). These had to be traced back and were all euthanized. However, this case underlines the health risks to humans who handle wild-caught animals and underscores the speed of transportation of exotic species and their pathogens over the globe (Avashia et al. 2002).

A human cowpox virus infection is an uncommon and potentially fatal skin disease, which is confined to major parts of Europe. Patients may sporadically contract the pathogen by contact with infected cows, cats, or small rodents. However, recently there is also a report from Germany (Munich), where 8 patients were infected by pet rats they had purchased at a local supplier (Vogel et al. 2012). Thus, pet rats can be considered as a novel potential source of local outbreaks of human cowpox virus infections.

Also, dermatophytes can be transferred to humans by rodents. In Switzerland, for example, 9 isolates of the fast-growing dermatophyte species *Arthroderma benhamiae* were isolated from 8 children and 1 adult. Eight of the 9 patients had had previous contact with rodents, mostly with guinea pigs (Fumeaux et al. 2004). In another study, where the frequency and types of dermatophytes among both Guinea pigs and rabbits were determined (Kraemer et al. 2012), *Trichophyton mentagrophytes* was determined to be the most common dermatophyte in pet Guinea pigs and rabbits, but asymptomatic carriers were regularly observed only in Guinea pigs. Consequently, pet guinea pigs carrying dermatophytes can be considered as a serious zoonotic risk for their owners, especially children (Kraemer et al. 2013).

An Australian patient who experienced an infection with *Streptobacillus moniliformis*, the causative agent of rat-bite fever, obtained this pathogen not because she was bitten by rats, but because she had had contact with her pets, including cuddling and kissing them (Papanicolas et al. 2012). This is a risk as *S.* moniliformis forms part of the commensal flora of the rat's oropharynx (Elliott 2007).

But not only handling or keeping pet rodents can impose a risk. Also commensal rodent species (species that live in or around a house or a farm) may lead to health risks. The risk of bites by rats inflicted in urban environments (often in substandard dwellings) and the spread of infection to humans is substantial. In the United States, there a hundreds of rat bite reports each year, while the number may even be underreported by a factor of at least ten (Bonnefoy et al. 2008; Hirschhorn and Hodge 1999). Next to rat bites, ectoparasites that are associated with these rodents can spread additional infectious organisms. The rodents are sometimes also carrying endoparasites or other pathogens which may contaminate the local environment. A literature review on helminths in rodents in South East Asia showed that the highest helminth species richness was found in *Rattus tanezumi*, *Rattus norvegicus*, and *Rattus argentiventer*, which are found in more human-dominated habitats such as agricultural areas or human settlements (Chaisiri et al. 2010). In a study in Tokyo, Japan, 17% of the brown rats (*Rattus norvegicus*) from urban areas carried leptospires in their kidneys and cases in human patients could directly be linked to these rats via DNA-analysis (Koizumi et al. 2009). Moreover, rodents in agro-ecological surroundings can be infected with *Salmonella* spp. and *Campylobacter* spp. and transfer these bacteria to livestock or amplify their number in the farm environment (Meerburg and Kijlstra 2007). In this way, a resident infected rodent population could lead to continuously returning infections in the farm environment, with all the negative consequences for both livestock and farmers. The exact risk dimension of livestock-pathogen-human-wildlife interactions is not yet known for many pathogens. Two pathogens may serve as an example here: *Coxiella burnetii*, the causative agent of Q-fever, and Hepatitis E virus (HEV). Concerning *Coxiella burnetii,* it has been implicated in many studies that rodents function as reservoirs for Q-fever, but their exact role in pathogen maintenance, geographic spread, and transmission still remains to be clarified (Meerburg and Reusken 2011; Webster et al. 1995). Problematic in determining the exact contribution of rodents is that basic wildlife and domestic cycles of *C. burnetii* infection can operate independently, but will overlap in many instances as many areas in the world are occupied by both domestic and wild animals (Meerburg and Reusken 2011), which makes it hard to unravel their exact contribution. In a recent study from Japan (Kanai et al. 2012) in which wild *Rattus norvegicus* were caught near a pig farm where HEV was present, it was demonstrated that in these rodents there was a relatively high prevalence (17.9%). Consequently, these authors conclude that *R. norvegicus* may be a carrier of swine HEV in endemic regions, but that the HEV contamination risk due to rats in human habitats remains unclear (Kanai et al. 2012).

Consequently, there remains much work for scientists to be done. Concerning the factor human behavior, the use of Geographical Information System (GIS) technology could prove to be a useful tool for the identification of endemic foci and high-risk areas

for numerous pathogens that are transmitted by rodents. Such technology was recently tested in a study in Cyprus (Psaroulaki et al. 2010), where rats were used as disease sentinels and tested for seropositivity on six microbial agents. In the Philippines, dogs were responsible for human schistosomiasis infection, but the authors claim that rats could be useful as schistosomiasis sentinels to monitor infection levels in the environment (Carabin et al. 2014). By optimizing this technology, more information could be acquired about possible outbreak areas, which facilitates informing the general public by public health officials.

When considering the factor human health condition, one should remember that the world population will increase the coming decades and also that the average age of the world population will increase. Thus, the number of people that may experience significant health effects when infected by zoonoses is growing. We do not yet know the exact dimension of the problem, but it is something to keep in mind.

High resolution remote-sensing could also prove useful to monitor the factor rodent ecology and behavior. This was recently done in Kazakhstan, where great gerbil burrow systems were observed by means of satellite images (Addink et al. 2010). The occupancy rate of these burrows is a strong indicator for the probability of a plague outbreak. By monitoring the density of great gerbil burrow systems, or locating new or expanding foci, a direct contribution could be made to surveillance and control efforts (Addink et al. 2010). Of course, with such techniques it is not possible to monitor the ecology and behavior of all rodent species. To gain more insight into the population dynamics and habitat preferences of rodents, field studies will remain necessary. By collection of small mammals in several habitat types, an action which was recently undertaken in Albania (Rogozi et al. 2012), one can gain more knowledge of the reservoir ecology in a country, and thus acquire more possibilities for reliable risk assessments for rodent-borne diseases. Moreover, also rodent identification via molecular methods, e.g., molecular barcoding using short genetic markers (Galan et al. 2012) may be useful as this will lead to a quicker and more accurate species identification. The previous will also prove its worth, if rodent dynamics and ecology will change in the future because of climatic change. The use of digital monitoring techniques, e.g., traps that are directly linked to GSM, Wifi, or other types of networks, will provide data that is very relevant for control of commensal rodents.

Concerning the factors pathogen ecology and persistence, there are also new opportunities. Fecal samples of wild rodents that were collected in California and Virginia were surveyed in order to obtain an initial unbiased measure of the viral diversity in the enteric tract (Phan et al. 2011). Viral RNA and DNA were randomly amplified. Phylogenetic analyses of full and partial viral genomes revealed many previously uncharacterized viral species, genera, and families, and close genetic similarities between some rodent and human viruses even reflected past zoonoses (Phan et al. 2011). In another recent study, a comparative approach was used to study microparasite species richness across rodent species according to the latitude where they occur (Bordes et al. 2011). The results demonstrated that virus species richness increased toward tropical latitudes, and that rodent litter size seemed to decrease when microparasite species richness increased independently from the latitude. The

authors thus claim that rodent species in the tropics harbor higher parasite species loads effectively, at least in terms of species richness for viruses, and that parasite species richness influences rodent life-history traits (Bordes et al. 2011). This information is also important for reliable risk assessments.

Finally, we may conclude that humankind has come a long way. We increased our knowledge and understanding and have gained some small victories over the rodents. However, there is no definitive victory over them yet, and although they are not able to defeat the cats (in this case the humans), they do still pretty well in avoiding capture. Let's hope that further scientific progress will lead to a better understanding about rodents and their risk for public health and that the contest between cat and mouse may end in a favorable way for humankind.

Camel-Related Zoonoses: A Light on "Ship of the Desert"

30

Camels and Public Health

Alireza Sazmand and Alireza Nourian

Contents

Abstract

With a worldwide population of over 37 million, camels are an important source of meat, milk, and labor in many regions of the world, mainly in Africa and Asia. The one-humped camel, also known as dromedary (*Camelus dromedarius*), accounts for approximately 95% of the whole population of camelids and is distributed in at least 47 countries of the world. Despite being extremely resistant to harsh environmental conditions, camels can get infected with several zoonotic pathogens, thus posing a public health's risk. In this chapter most important parasitic, bacterial, viral, and fungal zoonoses related to camels are discussed.

30.1 Introduction

One-humped camels, also known as dromedary (*Camelus dromedarius*) are specifically adapted to live in hot, arid areas of the world, notably the Middle East, Africa, and India. With a worldwide population of over 37 million, camels are an important source of meat and milk in many marginal, desert areas of the world where they survive under harsh conditions, with a considerable feral population in Australia (Camel-Scan 2019; Diall et al. 2022; FAOSTAT 2019) (Fig. 1).

Although compared with other animal species (*e.g.*, dogs), the domestication of the dromedary camel took place rather late in human history, approximately 3000 years ago (MacHugh et al. 2017), nowadays this livestock species is distributed in at least 47 countries, playing a crucial role in their economy; for example, in the year 2019, camels produced about 3,111,462 tons of milk and 653,135 tons of meat (FAOSTAT 2019). Unique physiological peculiarities of dromedaries in their circulatory system, respiratory system, water economy mechanism, heat tolerance, etc. enable them to survive almost 1 week with little or no food and water (Ouajd and Kamel 2009), making them suitable also for trade and trafficking over longer distances in arid areas. Indeed, they are utilized since ancient times for transportation of people, goods, warfare, and as draft animals including in agriculture and in local industry. Furthermore, they provide food (meat and dairy products) with great nutritional value, wool and leather in regions of the globe where the common

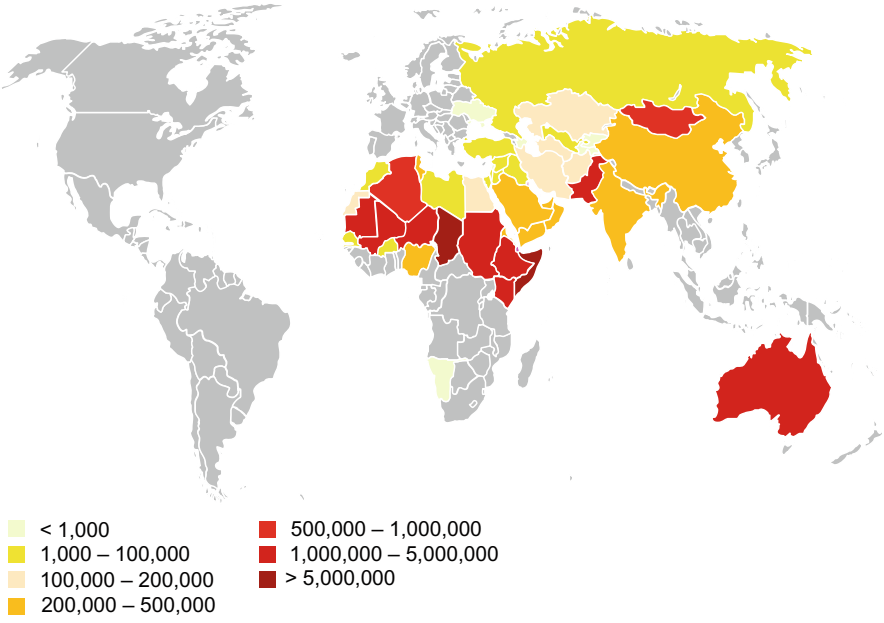

Fig. 1 Map of dromedary camel population by 47 countries in 2019. (Camel-Scan 2019; FAOSTAT 2019)

ruminant livestock species (cattle, sheep, and goats) cannot be used for these purposes. Therefore, as they are important food sources in semi-arid and arid zones, the picture of camelids transformed from "ship of the desert" to a "food security livestock" species. One evidence is that between the years 2009 and 2019, the world's camel population increased by 29% compared to only 7%, 12%, 19%, and -12% for cattle, sheep, goats, and pigs, respectively (FAOSTAT 2019). This trend recognizes the economic value of this livestock species as a food source, consequently implying the need for research on its pathogens and their zoonotic implications. This is also emphasized by the expansion of the human population in some developing countries by at least double their current size. It has been estimated that the world human population will reach 9.7 billion in 2050, mainly in developing countries of the southern hemisphere (United Nations 2019), which will parallel an increased need for food resources in these areas, including camel meat and milk. Overall, this could make camels an increasingly important source for zoonotic disease transmission to humans, especially in resource-poor communities with improper sanitation and medical access.

30.2 Public Health Impact of Camels

Adult camels are large animals standing about 2 m at the shoulders and weighing up to 600 kg. They may kill or injure humans by bites, falls from their backs, kicks, or collisions with motor vehicles; however, the relative magnitude of each mechanism has never been extensively studied. Furthermore, the incidence of camel-related injuries is not known worldwide but scant information is available, such as the study of Abu-Zidan et al. in Al-Ain city, United Arab Emirates, where the incidence of hospitalized camel-related injured patients in the city was estimated as 6.88 per 100,000 population per year (Abu-Zidan et al. 2012b). In Saudi Arabia more than 600 camel–vehicle collisions occur each year, out of which the fatality rate is 0.25; about six times that of all types of traffic accidents in the country (Al-Ghamdi and AlGadhi 2004).

Camel bite injuries occur more often during the rutting season (November–March) when they behave unpredictably. Injuries are usually severe and are including penetrating and crushing injuries by the camel jaw and blunt injuries when patients are picked up and thrown away (Abu-Zidan et al. 2012a). The head and neck sustain frequent and severe injuries which may involve facial wounds, skull fractures, intracranial bleeding, and cervical neurovascular injuries (Balac et al. 2019). Patients who sustain camel bites are prone to infection with *Staphylococcus*, *Aeromonas*, *Pasteurella*, and *Actinobacillus* species. Infection rates from camel bites have been reported to be as high as 86%. Furthermore, patients are at risk for tetanus and rabies (Calleo et al. 2018). Other causes of deaths associated with camels involve kicking, stomping, kneeling or sitting on a victim, or biting and shaking and throwing. Lethal mechanisms include hemorrhage from vascular injuries and internal organ disruption, crush asphyxia, and blunt craniospinal injuries (Gilbert and Byard 2021).

While direct impact of camels on human health is obvious, the zoonotic health risks of camels to humans are indirect and much less visible. As stated before, camels are extremely resistant to harsh environmental conditions; however, dromedaries can get infected with several zoonotic pathogens, thus posing a public health's risk. Literature review on camel-borne zoonotic diseases revealed that the majority of publications within 1970 and 2018 focused on four pathogens, i.e., Middle East respiratory syndrome (MERS), hydatidosis, brucellosis, and Rift Valley fever (Zhu et al. 2019). In this chapter 14 most discussed parasites (*Echinococcus granulosus* sensu lato, *Toxoplasma gondii*, *Cryptosporidium* spp., *Trypanosoma* spp., *Balantidium coli*, *Sarcoptes scabei*), bacteria (*Brucella* spp., *Mycobacterium tuberculosis* complex, *Yersinia pestis*), viruses (Middle East respiratory syndrome, Crimean–Congo hemorrhagic fever, Rift Valley fever, West Nile virus), and ringworm causing fungi related to zoonoses will be addressed.

30.3 Major Zoonotic Pathogens of Camels

30.3.1 Parasites

Relatively few parasites of camels are specific for this host species (Schuster 2018), whereas many others that infect camels are (i) non–zoonotic but with a large host range, or, (ii) of zoonotic concern. Camel echinococcosis is the most studied zoonotic parasitic infection affecting humans but *Toxoplasma gondii*, *Cryptosporidium* spp., *Fasciola* spp., *Trichinella* spp., and *Linguatula serrata* originating from camels are also considered as major public health risks (Zhu et al. 2019).

Transmission of zoonotic parasites includes different routes of infection such as fecal contamination (*e.g.*, *Cryptosporidium* spp., *Giardia duodenalis*, *Balantidium coli*, *Blastocystis* spp., *Enterocytozoon* spp., or consumption of raw or undercooked infected tissues and milk (*e.g.*, *Toxoplasma gondii*, *Trichinella* spp., *Linguatula serrata*). In addition, camels serve as reservoir hosts for *Trypanosoma* spp. or may be infected by gastropod–borne trematodes (*e.g.*, *Fasciola* spp., *Dicrocoelium dendriticum* and *Schistosoma* spp.) or metacestode larvae of zoonotic tapeworms, such as *Echinococcus granulosus* sensu lato (Sazmand and Joachim 2017; Sazmand et al. 2019b). Moreover, camels are blood source for several hematophagous ectoparasites, such as ticks and fleas, which ultimately transmit zoonotic viral and bacterial pathogens (*e.g.*, Crimean–Congo hemorrhagic fever virus, *Coxiella burnetii*, *Rickettsia* spp., *Bartonella* spp., and *Yersinia pestis*) (Bahari et al. 2021; Sazmand et al. 2019a; Wernery et al. 2014).

30.3.1.1 *Echinococcus granulosus* sensu lato

Cystic echinococcosis (CE) is a major zoonotic infection worldwide caused by larval stage of the tapeworm *Echinococcus granulosus* sensu lato. It causes considerable medical costs and economic losses in endemic areas (Deplazes et al. 2017). More than one million people are affected with echinococcosis at any one time, and it is estimated that echinococcosis to be the cause of 19,300 deaths and around 871,000

disability-adjusted life-years (DALYs) globally each year. Annual global costs associated with CE including treating cases and losses to the livestock industry are estimated to be 3 billion USD (WHO 2015). These costs might comprise 0.01% to 0.04% of nation's gross domestic product (GDP) in low- and middle-income countries (Harandi et al. 2012). Transmission typically occurs between canid definitive hosts and intermediate hosts such as human through the ingestion of parasite eggs shed in the feces of infected definitive hosts in the environment or dog's coat (Thompson 2017).

Among species and genotypes of *Echinococcus* (Vuitton et al. 2020), G6 genotype of *E. canadensis* that was formerly known as "camel strain" is particularly well adapted to camels but dromedaries are also important in the epidemiology of *E. granulosus* sensu stricto (G1–G3) and *E. ortleppi* (G5) (Sazmand et al. 2019b). Interestingly, it has been suggested that *E. canadensis* may have an affinity for the brain in humans (Sadjjadi et al. 2013; Shirmen et al. 2018). A recent article estimated that 23.75% of camels across the world harbor hydatid cysts (Anvari et al. 2021). In a study from Africa where pooled CE prevalence in different intermediate host species was compared, camels had the highest prevalence (Ohiolei et al. 2020). Cysts are commonly found in the lungs and, to a lesser extent, the liver of camels resulting in carcass condemnation and, subsequently, great economic losses. In Iran where CE is endemic, the annual monetary burden of CE has been estimated at 232.3 million USD, out of which the economic loss due to condemnation of infected camel livers amounts to approximately 600,000 USD (Harandi et al. 2012).

Major obstacles in controlling CE include the inability of local authorities and owners in poor environments to handle the costs of deworming treatment of dogs, to maintain proper abattoirs, to control stray dog populations, to vaccinate lambs, and the lack of public education (Otranto et al. 2017).

30.3.1.2 *Cryptosporidium* spp.

A wide range of gastrointestinal protozoan parasites such as *Eimeria* spp., *Cystoisoispora orlovi* and camel-specific *Sarcosystis* species develop exclusively in camels (Sazmand et al. 2012; Hamidinejat et al. 2013; Dubey and Schuster 2018); however, there are scientific data about infections of camels with several species of protozoan parasites of zoonotic importance including *Cryptosporidium* spp. (Phylum: Protozoa; Subphylum: Sporozoa; Class: Gregarinomorphea; Subclass: Cryptogregaria; Order Cryptogregarida; Family: Cryptosporidiidae).

Cryptosporidium spp. are highly successful parasites causing diarrhoeal disease in both people and animals worldwide. Due to their large host range, high oocyst output from infected individuals, water- and food-borne transmission routes, and low infectious dose from as low as one oocyst these protozoan parasites are responsible for >eight million cases of food-borne illness annually (Innes et al. 2020). Considering the fact that one infected neonatal calf sheds around 40 billion infectious oocysts in feces during the acute infection, we can understand the massive environmental contamination and a huge risk for other vulnerable hosts such as humans (Nydam et al. 2001). In children younger than 5 years, *Cryptosporidium* is responsible for 12,868,500 DALYs considering both acute effects of diarrhea and

associated growth faltering (Khalil et al. 2018). Outbreaks of cryptosporidiosis associated with contaminated water supplies can result in significant economic and health impacts. Costs associated with two outbreaks in Wisconsin and Ireland were estimated as high as 96.2 million and 22.44 million USD, respectively (Chyzheuskaya et al. 2017).

At least 48 *Cryptosporidium* species are considered valid and > 100 genotypes yet to be formally described, due to lack of biological and/or genetic data (Ježková et al. 2021). Over 20 species and genotypes have been reported in human patients (Feng et al. 2018). In dromedary camels so far, infection with *C. parvum* subtype IIaA17G2R1, a common zoonotic subtype reported in humans and animals worldwide, which is genetically related to the *C. hominis* of the If subtype family, *C. andersoni*, *Cryptosporidium* rat genotype IV and *Cryptosporidium* camel genotype have been confirmed (Baroudi et al. 2018; El-Alfy et al. 2019; Gu et al. 2016; Zahedi et al. 2018). Furthermore, natural infection of closely related species *Camelus bactrianus* (two-humped camel) with *C. occultus*, *C. ubiquitum*, *C. bovis*, and *C. muris* (Cao et al. 2020; Wang et al. 2021) suggests that dromedaries might also get infected with a wider range of species and genotypes than we know today. There is only one documentation on zoonosis linked with camels from Iran where 24 of 100 people in long-term contact with camels were found infected with *Cryptosporidium* spp. (Sazmand et al. 2012). Although *C. parvum* and *C. andersoni* identified in camels are potentially infectious for humans, no confirmed direct association between camels and human infections have been reported, in contrast to other livestock such as cattle (Lal et al. 2016) warranting further investigations.

30.3.1.3 *Toxoplasma gondii*

Due to its exceptionally wide range of warm- and cold-blooded hosts, *T. gondii* is one of the most successful zoonotic parasites on earth. One third of the world's human population are infected with this cosmopolitan food– and waterborne parasite, albeit with high heterogeneity between countries and regions (Djurković-Djaković et al. 2019). In the USA alone, toxoplasmosis accounts for 32,700 DALYs annually, being also responsible for 8% of foodborne–illnesses hospitalizations with 86,700 confirmed patients and 330 deaths (Scallan et al. 2015; Scallan et al. 2011). Like other livestock, camels acquire *T. gondii* infections through ingestion of sporulated oocysts shed by cats or wild felids in the environment (Hamidinejat et al. 2013). Antibodies against *T. gondii* in sera of dromedaries from different countries have been determined using various techniques, reporting seroprevalences as high as 67% (Dubey 2021; Gebremedhin et al. 2014; Nourian 1992). It has been estimated that 36% of camels in Africa have anti-*T. gondii* antibodies (Tonouhewa et al. 2017). Our knowledge about clinical and congenital toxoplasmosis in camels, however, is limited to few reports and the significance of infection is probably underestimated (Hagemoser et al. 1990; Ishag 2003; Ishag and Majid 2008; Riley et al. 2017). *Toxoplasma gondii* cysts have been isolated from camel meat (Gebremedhin et al. 2014) but predilection sites of *Toxoplasma* cysts have not been comprehensively investigated in this host species. The rooted habits of nomadic populations of some African and Asian communities of raw camel liver

consumption (Bin Saeed et al. 2005; Gebremedhin et al. 2014) could represent a risk factor for infection of humans, as *T. gondii* is frequently isolated from the livers of domestic ruminants and horses (Belluco et al. 2016). In addition, consumption of camel milk is becoming increasingly popular in recent years, as it is richer in vitamin C and iron than cow's milk, with suggested therapeutic effects on type 1 diabetes and reduction of allergies in children (Boughattas 2017). The implication of unpasteurized camel milk as a source of human toxoplasmosis (Medani and Mohamed 2016) suggests that consuming raw milk or dairy products derived from it (*e.g.*, Shubat, a beverage of fermented camel milk, sparkling white with a sour flavor, popular in Central Asia) could be a risk for human health. Little is known about the genetic characteristics of *T. gondii* genotypes infecting camels. Some surveys showed the occurrence of all three conventionally defined clonal lineages (Types I, II and III) in camel meat and milk (El-Alfy et al. 2019; Elfadaly et al. 2017; Tavakoli Kareshk et al. 2018). All of these types have also been isolated from human patients (Ajzenberg et al. 2009). Since the conventional nomenclature of *Toxoplasma* isolates does not sufficiently delineate the plethora of existing genotypes (Shwab et al. 2014), multilocus PCR-RFLP genotyping should be applied to elucidate potential links with disease manifestations in people consuming meat and dairy products of camels.

30.3.1.4 *Trypanosoma* spp.

Camels are affected by several *Trypanosoma* species (Roettcher et al. 1987). *Trypanosoma evansi*, the etiologic agent of "Surra" is the more prevalent trypanosome species of camels (Desquesnes et al. 2013). It was the first trypanosome to be described and identified as the causative agent of mammalian trypanosomosis. The earliest report on *T. evansi* was published by Griffith Evans who associated it with an endemic disease in equids in the Dera Ismail Khan district of Punjab in Pakistan (Evans 1880). While *T. evansi* is the more prevalent trypanosome species of camels, *T. brucei*, *T. congolense*, and *T. vivax* are found at lower infection rates (Al Malki and Hussien 2022; Birhanu et al. 2015; Dirie et al. 1989; Mossaad et al. 2017). However, in a recent report that described *T. vivax* for the first time in dromedaries of central desert of Iran this infection was more prevalent than *T. evansi* (Asghari and Rassouli 2021).

Due to a partial loss of *T. evansi* mitochondrial DNA, which occurred during its segregation from *T. brucei* (Lai et al. 2008) and acquiring the capacity for mechanical transmission by virtually all biting flies its geographical distribution is potentially unlimited. *Trypanosoma evansi* affects a wide range of domestic and wild mammals in Africa, Asia, and South America (Desquesnes et al. 2022; Sazmand et al. 2022), and recent outbreaks of infection among camelid populations on the Canary Islands, in mainland Spain, and France demonstrated the potential of the parasite to spread rapidly even in non–endemic areas (Gutierrez et al. 2010). In dromedaries, the infection may cause significant morbidity and great impairment of productivity and mortality (Sazmand et al. 2016; Sazmand et al. 2011). It is assumed that the spread of *T. evansi* among camels with the consequence of fatal anemia weakened the Arab–African Muslim forces in their prolonged battle against Christendom, as they relied heavily on camels and equids for transport and economy

(Clarence-Smith 2013). *Trypanosoma evansi* has its highest prevalence in camels compared to other animal hosts such as buffaloes, cattle, dogs, equids, and small ruminants (Aregawi et al. 2019), but in contrast to other livestock species, the economic burden of this infection has not been evaluated in camels (Reid 2002). Human cases of *T. evansi* infection have been reported from India, Sri Lanka, Egypt, Thailand, and Indonesia (Joshi et al. 2005; Sawitri et al. 2019; Sengupta et al. 2022; Truc et al. 2013; Van Vinh Chau et al. 2016). For a decade it was hypothesized that human susceptibility to *T. evansi* could be linked to insufficient or missing levels of human trypanocide apolipoprotein L1 (APOL1), a trypanocidal component of normal human serum (Vanhollebeke et al. 2006). However, report of infection in a patient with no previous immunological risk, 2 wild–type APOL1 alleles and a normal serum APOL1 concentration confirmed that *T. evansi* is a true zoonosis with a risk of infection for the general population (Van Vinh Chau et al. 2016).

30.3.1.5 *Balantidium coli*

Balantidiasis caused by *B. coli* is a zoonotic disease with domestic and wild pigs, non-human primates and humans as reservoirs. Cysts of this large ciliated protozoan live in cecum and colon of the hosts, are shed in feces, and transmitted to susceptible hosts via fecal-oral route. *Balantidium coli* is the only ciliated protozoan that is pathogenic for humans, being most common in the Philippines, but is also reported in Central and South America, Papua New Guinea, and parts of Western Asia (Chalmers 2014). Although the worldwide prevalence is estimated at 0.02 to 1%, it varies widely by geographic location as, for instance, in New Guinea and Altiplano area of Bolivia, infection rates of as high as 28% and 29% have been reported (Schuster and Ramirez-Avila 2008). Indeed, human populations living in close proximity to domestic pigs are naturally resistant and mostly without any clinical manifestation, though a case fatality rate of 30% has been reported in acute balantidiasis with intestinal perforation or fulminating hemorrhagic dysentery and shock (Schuster and Ramirez-Avila 2008). Rare cases of balantidial appendicitis, and extension to extraintestinal sites causing, for example, urinary tract infection and vaginitis, and lung infections, have been reported (Chalmers 2014). Because of the pleomorphism of balantidial trophozoites and the host range, taxonomy of this genus is controversial.

In absence of pig raising, such as in Middle-Eastern countries, camels play a major epidemiological role in the transmission of *B. coli* (Cox 2005). As for other mammalian hosts (Nakauchi 1999), balantidia from camels, provisionally named *Balantidium cameli* (Hegner 1934), are now referred to as *B. coli*. The infection is widespread in camel populations and infection rates up to 53% have been reported from Algeria, Bahrain, Egypt, India, Iran, Iraq, Nigeria, and Saudi Arabia (Ahmed et al. 2020a; El-Khabaz et al. 2019). Infected camels can shed very large number of cysts and trophozoites *e.g.,* 15,000 per gram (Tajik et al. 2013), therefore, may have a significant role in transmission of the infection to people in contact with them. There is only one documentation on zoonosis linked with camels from Iraq where 10 of 25 camel breeders and 50% of their camels were found infected with *B. coli* (Hussein et al. 2016). Recent studies on the genetic diversity of *Balantidium* spp. and *Balantidium* – like cyst – forming ciliates, such as *Buxtonella*, suggest that genetic

analyses are needed to explain the real spectrum of intestinal ciliates as the cysts are morphologically indistinguishable. *Buxtonella sulcata,* another ciliate with world-wide distribution, is mainly found in the cecum of cattle but also of camels (Taylor et al. 2016). Finding of *Buxtonella*-like ciliates in primates opened the hypothesis that *Buxtonella* may also be a pathogen in humans (Pomajbíková et al. 2013), and the possible transmission from camels to humans should be further investigated.

30.3.1.6 *Sarcoptes scabei*

Camels can be infested by a wide range of external parasites such as mites and tick that irritate, injure, or debilitate them. Camel mange caused by *Sarcoptes scabiei* var. *cameli* is a worldwide major threat to camel health and production. It is extremely contagious and the infestation rate can reach up to 83% in camels, causing loss of condition, decreased work tolerance, and, in extreme cases, death (Al-Rawashdeh et al. 2000; Wernery et al. 2014). Initially camels rub the affected areas against inanimate objects or against one another causing erythema with numerous papules and nodules. With advancement of the infection alopecia to complete baldness patches are observed, and in severe cases the skin is thickened, wrinkled, and thrown into folds, is covered with thick crusts, and shows extensive fissuring and cracking. In terminal stages of the disease, camels decrease their food and water intake and become emaciated. There is marked edema of the legs, especially on the footpads, and the skin becomes soft, and pits on pressure. Urination and defecation are not affected, but the animals are unable to work or to walk for long distances and eventually die (Nayel and Abu-Samra 1986).

Sarcoptic mange is considered second only to Surra trypanosomosis in terms of losses in camels (Pegram and Higgins 1992). Overcrowding, temperature, and the skin microclimate have been suggested as important factors in the epizootiology of the disease in Sudan (Nayel and Abu-Samra 1986). Furthermore, camels older than 2 years, female camels, and winter season were found to be the higher risk of exposure in Egypt (Ahmed et al. 2020b). Transmission of *S. scabiei* var. *cameli* to humans, particularly camel attendants and riders, is well–known since ancient times (Tadjbakhsh 1994). Although *S. scabiei* of camels' origin cannot multiply in the human host, it causes pseudoscabies that usually takes place during milking, handling, or riding. In herdsmen, the lesions are observed mainly in the interdigital spaces of the hands, the flexor surface of the wrists, the forearms, the elbows, and axillary folds. In the case of camel riders, the lesions occur between the thighs. Treatment of both animals and the camel handlers can help in controlling this zoonotic problem (Schillinger 1987).

30.3.2 Viruses

30.3.2.1 Middle East Respiratory Syndrome (MERS)

The highly lethal Middle East respiratory syndrome (MERS) was initially reported in April, 2012 (WHO 2021a). The causative coronavirus, MERS-CoV was first isolated from a man with severe pneumonia in Saudi Arabia, which was died of

multiple organ dysfunctions (Zaki et al. 2012). The virus which is enlisted in the WHO blueprint list for highly concerned pathogens (WHO 2020b), is circulating among societies, and several outbreaks of the disease have been occurred in the Middle East (WHO 2019) and South Korea (Kim et al. 2017). By the end of July 2021, a total of 2578 laboratory-confirmed human cases have been reported globally including 888 deaths, majority of which have been occurred in Arabian Peninsula (WHO 2021b). The clinical manifestation of the disease may range from mild to severe, which the latter usually occurs in individuals older than 65 years. The infection is mainly limited to the respiratory tract; however, also, the viral particles have been detected in the kidney of one autopsied human body (Memish et al. 2020). MERS-CoV is a zoonotic virus with dromedary camels being considered as the host reservoir for the pathogen (Drosten et al. 2014). Experimentally infected camels could shed the virus through nasal secretions with rhinorrhea as the only clinical sign of the disease (Adney et al. 2014). Although nosocomial transmission of MERS-CoV in health-care facilities has been proposed to be responsible for almost half of the cases reported to WHO (Hui et al. 2018), humans may acquire the infection through direct or indirect contact with infected patients or camels (Azhar et al. 2014; Conzade et al. 2018). Infected camels may shed the pathogen via nasal and eye discharge and feces. People may also get the infection through consumption of various raw or undercooked camel products such as milk, meat, urine, and blood. Individuals with underlying medical conditions are at high risk of severe illness (WHO 2018b). To prevent further outbreaks of the disease, it is crucial to maintain good hygiene, especially among individuals working in health care and people in contact with camels. The genome of MERS or MERS-like coronaviruses have been detected in viscera or droppings of bats in Switzerland, Italy, and South Korea (Hardmeier et al. 2021; Kim et al. 2016; Moreno et al. 2017), implicating the potential role of bats in the spread of the pathogen to other parts of the planet.

30.3.2.2 Crimean-Congo Hemorrhagic Fever

Crimean-Congo hemorrhagic fever (CCHF), an important tick-borne zoonotic disease is caused by a virus from genus *Nairovirus* of the family *Bunyaviridae* (OIE 2021), which has been detected in arid regions of Eastern Europe, throughout the Mediterranean, northwestern China, central Asia, Africa, the Middle East, and the Indian subcontinent (Hoogstraal 1979; Wernery et al. 2014). The virus is chiefly spread by ticks of genus *Hyalomma*, and circulates in a tick-vertebrate-tick cycle, however also, vertically and horizontally within the arthropod vector (OIE 2021). The presence of pathogen has been confirmed in a wide range of wild and domestic animals such as sheep, goats, cattle, camels, horses, pigs, dogs, hedgehogs, chicken, ostriches, *and* vectors including ticks and biting midges of the genus *Culicoides* (Causey et al. 1970; Hassanein et al. 1997; Khamassi Khbou et al. 2021; Mostafavi et al. 2013; Schwarz et al. 1996). Animals usually act as reservoirs with no obvious clinical signs of the disease, hence, the infection has little if any considerable effect on the animal health and animal production industry; however, the virus can cause a lethal disease in humans (OIE 2021), with the case-fatality ratio of as high as 73% (Schwarz et al. 1997). Despite many

investigations, the pathogenesis of CCHF is not fully understood. The main cells affected are endothelial and immune cells, and the main organs with histopathological changes are liver and spleen (Akıncı et al. 2013). Human can be infected by tick bite or through contact with tissues, blood, and body fluids of infected animals or other individuals (Bente et al. 2013). The sexual route of viral transmission among people has also been suggested (Ergonul and Battal 2014). The presence of the CCHFV has been confirmed in the camels of different countries. While the importance of CCHFV for camels is not elucidated yet, it has been shown that CCHFV strains in some regions are specifically associated with camels and camel ticks (Camp et al. 2021; Khalafalla et al. 2021). In one study on the UAE camels, CCHFV antibodies were detected in the serum of 67% of animals, and the majority of infesting ticks were *Hyalomma dromedarii* (Camp et al. 2020). In a study from Iran, antibodies against CCHFV were found in 5.3% of camels and genome of the virus was detected in 10.2% of ticks collected from camels (Champour et al. 2016). As the CCHFV is widespread in many regions of the world (Msimang et al. 2021), it is suggested that exposure to the virus in people who work in camel-related settings is more common than generally assumed, therefore, public education on the risk factors associated with the infection are needed to control the disease. Besides, the detection of CCHFV RNA in ticks of migratory birds from different countries of Asia, Africa, and Europe (Leblebicioglu et al. 2014; Mancuso et al. 2019; Palomar et al. 2013), as well as finding the CCHFV reactive antibodies in migratory bats of Africa (Müller et al. 2016), indicate the very possibility of CCHFV transportation to other countries and continents by these flying animals.

30.3.2.3 Rift Valley Fever

Rift Valley fever (RVF) is an arthropod-borne viral zoonosis which is endemic in sub-Saharan African countries and the Arabian Peninsula (Khalafalla 2016). The causative virus belongs to the genus *Phlebovirus* from the family *Bunyaviridae* (Flick and Bouloy 2005). RVFV affects ruminants (*e.g.,* cattle, sheep, and goats), camels, and humans. The virus can produce an acute to peracute disease in animals; however, the infection in camels is mostly manifested by abortion. Both New World and Old World camelids can become infected. The presence of serum RVFV-specific antibodies in blood serum of up to 57% of camels have been documented (Britch et al. 2013), and the virus has been isolated from camels (Faye et al. 2014). In at least one outbreak in Mauritania, in which 13 people died, dromedary camels played a major role in the epidemiology and transmission of RVF to humans (El Mamy et al. 2011). The disease has also been detected in young llamas and alpacas of South Africa (Wernery et al. 2014). RVF epidemics have been occurring for more than 70 years in southern and eastern Africa before 2000 in which for the first time, the virus infected humans and animals out of Africa in Saudi Arabia and Yemen (Shoemaker et al. 2002). In one study in the UAE, out of 1119 dairy dromedary camels, four adults (0.35%) were seropositive with ELISA (Wernery et al. 2008). The disease causes serious economic costs to animal owners through loss of production and death. The infection may even lead to 100% abortion in animals. It is believed that RVF outbreaks usually occur following heavy raining, which indicate

the appearance of a very high population of vectors, mainly the mosquitoes of *Anopheles*, *Culex*, *Aedes,* and *Mansonia* genera (Wernery et al. 2014). Humans can get the infection mainly through contact with infected animal carcasses (Hoogstraal et al. 1979) with a fatality rate of approximately 1% (WHO 2018a). In most cases, the clinical disease in humans is similar to influenza, and may easily be confused with malaria. The severe disease may be manifested in the forms of ocular, meningo-encephalitic, and hemorrhagic, the latter being fatal (CDC 2020). No licensed vaccine is available for human use. However, several vaccines have been developed for livestock, albeit not for use outside the endemic areas (Faburay et al. 2017). Camels imported from countries with confirmed RVF outbreaks should be tested for the infection. People should avoid contact with blood, body fluids, and tissues of infected animals, and all animal products should be cooked before consuming. Protection against blood-sucking insects especially mosquitoes is of importance (CDC 2020).

30.3.2.4 West Nile Virus

The zoonotic West Nile Virus (WNV) is a member of the Japanese Encephalitis virus (JEV) serocomplex, and belongs to the *Flavivirus* genus of the family *Flaviviridae* (Fall et al. 2017). The WNV normally exists in nature circulating between birds and mosquitos, with *Culex* spp. as the principal vectors for the pathogen. Human and other mammals are accidental hosts. The virus was first isolated in 1937 from a woman in Uganda (Smithburn et al. 1940), after which, it has been detected in all continents. In infected human, the clinical manifestation ranges from asymptomatic to encephalitis (and resulted paralysis) and death. The nervous symptoms of WNV may easily be confused with similar infections such as viral encephalitis and bacterial meningitis (Rossi et al. 2010). Less than 1% of infected individuals develop a serious illness (CDC 2021), and the infection is more life-threatening in immuno-compromised and old people. Among animals, birds are the most susceptible to the infection; however, serum antibodies against WNV has been frequently detected in many other animals. For instance, using ELISA method, some personnel and different birds, mammals, and reptiles from the Yum-Ká zoo in Mexico were found seropositive for the WNV (Hidalgo-Martinez et al. 2008). Although there have been several serologically confirmed WNV infection in camels from the Middle East, North Africa, and Europe (Mentaberre et al. 2013; Touil et al. 2012; Wernery and Wernery 1990), the virus was isolated for the first time in 2016 from a dromedary camel calf in the UAE. Pallor of skeletal and myocardial muscles, massive lung congestion, and colitis were seen at necropsy (Joseph et al. 2016). The presence of virus in camels may lead to spread of the infection to the neighboring human and animal populations. It has been proposed that geographic correlation of seropositive animals with positive veterinarians suggests predictability of the risk in humans (Venter et al. 2017). While there are several vaccines available for immunizing horses against WNV, no licensed vaccine exists for use in humans and camels (Saiz 2020). It is essential to detect new cases in birds and other animals including horses and camels to provide early warning for veterinary and public health authorities (WHO 2017).

30.3.3 Bacteria

30.3.3.1 *Brucella* spp.

Brucellosis, a contagious disease caused by a zoonotic bacterium of the genus *Brucella*, is of greatest concern, not only because it is zoonotic but also due to its severe economic losses for farmers and ranchers across the world in terms of lost milk, reduced fertility, stillbirths, and abortions (Tibary et al. 2006; Wernery 2014). Humans generally acquire the disease through direct contact with infected animals, by eating or drinking contaminated animal products, or by inhaling airborne agents (Hekmatimoghaddam et al. 2013). Camels can be infected with different biovars of either *B. abortus* and *B. melitensis*, both of which being the main causative agents of human brucellosis (Abbas and Agab 2002).

Camel brucellosis is endemic in all camel-rearing countries with exception of Australia (Gwida et al. 2012). In East Africa, the seroprevalence of brucellosis can reach to 40% at the herd level; however, in a recent study, *B. melitensis* was isolated from lymph nodes of two seronegative camels highlighting the challenges in the diagnosis and control of camel brucellosis (Dadar and Alamian 2020). Human infection occurs via the mucous membranes, mostly through consumption of raw milk but also through cutaneous abrasions (Wernery 2014). Several outbreaks of human infection linked to consumption of traditionally (Garcell et al. 2016) and even commercially sold camel milk (Bardenstein et al. 2021) have been reported. Furthermore, *B. abortus* was detected in the camel liver (Bahari et al. 2021) suggesting that eating raw or undercooked liver – which is popular in some African and Asian regions – can be a health hazard. As clinical signs of brucellosis are mild and the antibody concentrations are low (Gwida et al. 2012), dromedaries might act as silent carriers of the pathogen. In the absence of standardized serological camel-specific tests for active and passive case findings, education of the society such as heat treatment of the milk and avoiding mixed farming of camels with ruminants are advocated.

30.3.3.2 Tuberculosis

The zoonotic disease, tuberculosis (TB), remains among the most serious important public health problems of the twenty-first century (Furin et al. 2019). TB is a chronic granulomatous disease, which is one of the top 10 causes of death worldwide, and the deadliest infectious disease of humankind. It is estimated that about 25% of the world's population is infected with the causative *Mycobacterium* bacilli (WHO 2020a), belonging to the *Mycobacterium tuberculosis* complex (MTC). TB has infected ten million persons worldwide in 2019, and about 1.4 million individuals were died of the disease in the same year (Fukunaga et al. 2021). The same year, approximately 140,000 new human cases of zoonotic TB occurred globally. According to the most recent comprehensive report of the WHO, most people who become infected with TB are living in South-East Asia, Africa, and the Western Pacific (WHO 2020a). While *M. tuberculosis* is responsible for the infection in most human cases, *M. bovis*, the causative agent of bovine TB also can affect people through drinking raw milk and inhalation of infectious droplets (Thoen et al. 2006).

TB infects many vertebrates including camels. Camelids are being considered as a source of TB, as the infection is detected in many countries around the world, *e.g.*, Ethiopia (Gumi et al. 2012), Kenya (Lamuka et al. 2018), India (Ranjan et al. 2018), UAE (Kinne et al. 2006), Spain (Infantes-Lorenzo et al. 2020), and America (Bush et al. 1990). Since 1997, Australia is officially free of *M. bovis* as the most common cause of TB in camels (Brown 2004).

Although is not clear yet, the principal mode of TB transmission between camelids is suggested to be via infected aerosols (Twomey et al. 2009). Disseminated infection of cow and camel with *T. bovis* highlights the probability of TB transmission between livestock species (Ahmad et al. 2019). Despite the very low occurrence of natural cases of TB in the South American camelids (Fowler and Bravo 2010), llamas and alpacas have shown to be very susceptible to *M. bovis* in experimental infections (Stevens et al. 1998), implicating the lack of exposure to the pathogen in their normal habitats (Wernery et al. 2014). In camelids, the lungs and associated thoracic lymph nodes are the most frequently affected organs, where extensive caseonecrotic lesions occur (Wernery and Kinne 2012). Camel farming in many parts of the world is no longer limited to nomadic conditions; therefore keeping camels in close proximity to other animals and humans may increase the risk of zoonotic transmission of the pathogen (Mustafa 1987). To control the disease, all infected animals should be removed from the herd, and further introduction of infection to other animals has to be prevented; however, before the infection is controlled in reservoir hosts, TB will not be eradicated in camels (Thoen et al. 2006).

30.3.3.3 Plague

The deadly zoonotic disease, plague, is an important infectious illness affected many countries around the world. The disease is caused by bacterium *Yersinia pestis*, which is responsible for several devastating pandemics in human history. Based on the European sources, at least two pandemics have been occurred in Europe, the second of which was called "Black Death" and killed about one-third of the continent's population (Mordechai et al. 2019; Slack 1989). The third pandemic was occurred in China and spread to other parts of the world (Tan et al. 2002). In recent history, Africa has faced the vast majority of world plague cases (Nyirenda et al. 2016), and the last outbreak occurred in late 2017 in the island of Madagascar with 202 deaths (Mead 2018).

The causative agent of plague is mainly transmitted by rodents' related fleas. Rodents are the main reservoirs for *Y. pestis*, and camels can be infected with the pathogen. The role of camel in the plague epidemiology has been known for centuries (Gatt Rutter and Mack 1963). In recent decades, *Y. pestis* infection in camels has been reported from several countries such as Libya (Christie et al. 1980), Jordan (Arbaji et al. 2005), Saudi Arabia (Bin Saeed et al. 2005), Afghanistan (Leslie et al. 2011), and Kazakhstan (Lowell et al. 2007). The common clinical manifestations of plague in camels are cutaneous, pulmonary, and septicemic (Wernery et al. 2014). Camels can become infected following contact with dead rodents or rodent-contaminated carnivore carcasses or their excrement (Andrey et al. 2004). Since *Y. pestis* has been isolated from *Xenopsylla cheopis* rat fleas captured near camel pens (Bin Saeed et al. 2005), it

is assumed that this arthropod may act as vector for plague in camels, which in turn, can infect humans directly or carry infected fleas close to humans. Infection of camels with plague has been suspected for a long time (Fedorov 1960), and the role of this animal species in outbreaks in different countries have been documented although infection might show no overt symptoms (Stenseth et al. 2008).

Transmission of plague form camels to humans has been reported in in Kazakhstan, where from 1907 to 2001, human plague was acquired from camels in 400 instances (Aikimbayew et al. 2003). Several outbreaks of plague in humans are believed to have been in association with the consumption of raw or undercooked camel meat or liver in Central Asia (Leslie et al. 2011) and the Middle East (Arbaji et al. 2005; Bin Saeed et al. 2005). Plague is a re-emerging threat to the modern world, and prevention is the best defense strategy against the disease. Vaccination is an efficient tool for protection of human and animals live in high-risk areas. Although several vaccine candidates exist, no licensed plague vaccine is available yet (Sun and Singh 2019).

30.3.4 Fungi

30.3.4.1 Ringworm

Superficial fungal infections are zoonotic diseases caused by taxonomically related fungi known as dermatophytes, which involve the skin, hair, and nails. Infection of the skin is called ringworm (tinea, dermatophytosis), a ring-shaped skin patch with worm-like edges. The causative microorganisms are a group of fungi that require keratin for their growth. Around 40 species of dermatophytes have been described and are classified in three genera of *Trichophyton*, *Microsporum*, and *Epidermophyton* (Weitzman and Summerbell 1995). Although zoophilic dermatophytes such as *Microsporum canis* and *Trichophyton mentagrophytes* are primary animal pathogens, they can infect human beings, too (Zachary 2017). Generally, dermatophtes grow in dead and keratinized cells of stratum corneum or growing hair, and the growth stops when reaching the live tissue (Wernery et al. 2014). These pathogens produce a number of diverse lesions with characteristic distributions, including Tinea capitis, Tinea barbae, Tinea corporis, Tinea cruris, Tinea pedis, and Tinea versicolor (Kumar et al. 2021). Infection can be transmitted to others through direct or indirect contact with infected humans or animals including camels, and contaminated fomites (Wernery et al. 2014). In camelids, the infection is more common in Old World camels under 3 years of age, and is rare in New World camels (Fowler and Bravo 2010). In affected camel herds, up to 80% of calves may show clinical signs of the disease. Dermatophytes are more common in warm and humid environments, and young animals are more susceptible than adults (Wilson 1998). Mixed infection of *T. verrucosum* and *Nocardia asteroides* in dromedary camels has been reported from Iran (Khosravi et al. 2007). Clinical appearances of camel dermatophytoses are quite various. The typical clinical features are either small, round grey-white lesions occurring on the legs, head and neck of young animals, or generalized lesions similar to of mange (Manefield and Tinson 1997).

Histopathological manifestations of the lesions are hyperkeratosis, parakeratosis, and acanthosis in the cornified layer of the skin, stratum corneum, and dermal inflammation (Zachary 2017). It has been estimated that chlamydospores of *T. verrucosum* and *T. mentagrophytes* can remain viable for up to 4.5 years in skin debris and fomites (Fowler and Bravo 2010), therefore public knowledge on the different aspects of the disease and particularly the zoonotic nature of the infection is important.

30.4 Conclusions

This chapter introduced the main parasitic, bacterial, viral, and fungal zoonotic diseases of camels as important livestock animals especially in developing countries. Infective zoonotic agents may be transmitted to humans directly via close contact to the infected camels, consumption of their products, or indirectly through invertebrate vectors. The role of camels in the epidemiology of zoonotic diseases is not fully understood, thus further investigation through transmissible infections between these animals and humans is warranted. In addition, the knowledge and awareness of the communities/individuals in close contact with these animals should be raised through education, in order to lessen the risk of zoonotic infections from animals to humans and vice versa.

types of animals. In general, the oral flora of the biting animal will be concordant with the bacteria isolated from the wound. These oral flora organisms often originate from the normal oral residents and environmental flora as well as the skin and intestinal bacteria of the animals' food sources and prey.

31.1 Introduction

A wide variety of domestic and wild animals are reported to bite people worldwide each year causing injuries that range from minor infections to debilitating and even lethal injuries. The increasing population, continued spread of habitation, and popularity of owning various types of both traditional and nontraditional pets have made it easier for humans to have contact with various types of animals. It is therefore not surprising that this increased exposure can consequently result in more bite injuries.

Most bite wounds are minor injuries that go unreported. Patients often self-administer first aid and usually do not seek or require medical attention. In rural areas and non-industrialized settings, medical care is often hard to obtain and not readily available. In contrast, residents of industrialized countries, especially those in urban and suburban areas, often seek care when incurring moderate to severe bite injuries in an emergency department or in a physician's office. When these injuries are reported, it is usually from small, limited studies that focus on a specific aspect or complication of injury or concentrate on unusual or resistant organisms. These small often retrospective studies form the only basis for the medical decision-making and treatment of bite wounds that is currently employed worldwide.

Bite wounds can consist of lacerations, evulsions, punctures, scratches, and crush injuries. Although the majority of patients never seek or do not require extensive medical care, awareness of the magnitude of the infectious complications from bites is necessary. The bacteria associated with bite infections may come from the environment, the victim's skin flora, or most frequently, the oral flora of the biter which can also be influenced by the microbiome of their ingested prey and other food.

The public health implications for animal bite wounds include not only the cost of therapy but that of resultant physical disability, both acutely and in the long term, days lost from work or school, costs of hospitalization, and insurance claims. According to an analysis of homeowners' insurance claims data in 2021, the average cost of dog bites per claim was $49,025. This reflects an increase of 39% in the average cost per claim nationally from 2012 to 2021 (https://www.iii.org/article/spotlight-on-dog-bite-liability).

31.2 Animal Ownership/Contact

It is estimated that five million households in the United States own at least 1 pet (approximately 70 million own at least 1 dog and 45 million own at least 1 cat) (https://petkeen.com/pet-ownership-statistics/). In addition, based on the 2021–2022 American Pet Products Association's survey, approximately 12 million households own freshwater fish, ten million own pet birds, and six million own small animal or reptiles (https://www.iii.org/fact-statistic/facts-statistics-pet-ownership-and-insurance).

Based on a survey conducted in 2018, approximately 45% of households in the United Kingdom had pets (26% with dogs; 18% with cats) (https://www.pfma.org.uk/pet-population-2018). In a 2021 report, it was estimated that 90 million European Union households (46%) owned at least 1 pet animal (25% cats or dogs) (https://europeanpetfood.org/about/statistics/). According to a report in 2011, there is an estimated 30 million pet cats and 21 million pet dogs in Russia, ranking second only to the United States on the number of pets per capita (https://apps.fas.usda.gov/newgainapi/api/report/downloadreportbyfilename?filename=Pet%20Food%20Market%20Brief_Moscow_Russian%20Federation_4-21-2011.pdf#:~:text=According%20to%20recent%20research%2C%20there%20are%20about%2030,own%20a%20cat%20and%2035%20percent%20a%20dog). In 2010, the Australian Companion Animal Council reported 3.4 million dogs in 36% of households and 2.4 million cats in 23% of Australian households (https://pijaccanada.com/wp-content/uploads/2017/07/Australian-Companion-Animal-Council-report-2010.pdf).

As more people begin to backpack, enjoy ecotourism, and push habitations into more rural areas, there is a potential for increased contact with wild animals. Although no estimates exist for the numbers of these contacts, this growing trend and exposure could certainly result in a higher incidence of bite injuries.

31.2.1 Dog Bites

The Health Care Utilization Project reported on emergency department visits and hospital stays related to dog bites for 2008 noted 316,200 emergency department visits (103.9 per 100,000 population) and 9500 hospital admissions (2.5% of patients with bite injuries) related to dog bites which had increased to 86.3% since 1993 (Emergency Department Visits and Inpatient Stays Involving Dog Bites 2008). Children less than 10 years old had a higher rate of emergency department visits (199.3/100,000 population) than other age groups. Patients residing in rural areas were more likely to visit emergency departments (119.3/100,000 population) and be hospitalized than those from urban settings (29.4/100,000 population). Emergency department visits for dog bites were more common in the Midwest and Northeast United States and lowest in the Western United States. Skin and soft-tissue infections were the cause of 43% of hospitalizations followed by open wounds to the extremities (22.1%).

The average cost of a dog bite hospitalization was $18,200 which was about 50% more than for other injury-related hospital admissions with an average stay of 3.3 days. Approximately 58% of dog bite admissions required a surgical procedure, most commonly debridement of an infected wound followed by suturing of wounds, muscle- and tendon repair-related procedures and incision, and drainage of abscesses. In the United Kingdom, Hospital Episode Statistics recorded 6450 admissions for dog bites or "strikes" in a period of 12 months in 2012, a 5.2% rise compared to the prior 12-month period (https://www.pfma.org.uk/pet-population-2018; https://apps.fas.usda.gov/newgainapi/api/report/downloadreportbyfilename?filename=Pet%20Food%20Market%20Brief_Moscow_Russian%20Federation_4-21-2011.pdf#:~:text=According%20to%20recent%20research%2C%20there%20are%20about%2030,own%20a%20cat%20and%2035%20percent%20a%20dog). The incidence of dog bites worldwide has been estimated by extrapolating similar above information and using population statistics to estimate their occurrence (https://www.dogsbite.org/dog-bite-statistics-study-emergency-visits-involving-dog-bites-ahrq-2008.php).

It has been estimated that one of every two Americans will be bitten in their lifetime, usually by a dog. Dog bites occur in 4.7 million Americans yearly (Sacks et al. 1996) and account for 800,000 medical visits, including approximately 1% of all emergency department visits (Weiss et al. 1998). Most dog bites (85%) are provoked attacks by either the victim's own pet or a dog known to the victim and occur during the warm weather months (Goldstein et al. 1980). Bite wounds that require attention are often those to the extremities, especially the dominant hand. Facial bites are more frequent in children younger than 10 years and lead to 5–10 deaths per year, often because of exsanguination (Lockwood 1997).

Larger dogs can exert more than 450 lbs./in.^{2} of pressure with their jaws, which can lead to extensive crush injuries. Home insurance companies may decline to insure homeowners with certain breeds of dogs that are considered to be more aggressive than others. Even insured owners may not be able to find insurance again, once a dog has been reported as a biter. These breeds often include chows, Rottweilers, Dobermans, Akitas, wolf hybrids, bull terriers, pit bulls, and shepherds.

Patients who present early after an incident often are concerned about crush injuries, care of disfiguring wounds, or the need for rabies or tetanus immunization (Goldstein et al. 1980). Between 2% and 30% of wounds will become infected and may require hospitalization (Goldstein 1992; Brook 1987; Talan et al. 1999). Patients presenting later than 8 hours after injury usually have established infection. Infections can range from localized cellulitis or abscess to septic arthritis, osteomyelitis, tenosynovitis, and rarely, severe sepsis and septic shock. The distribution of bite wounds is shown in Fig. 1 (Talan et al. 1999). Fatal infections may occur in certain compromised hosts, as in patients with asplenia and cirrhosis or on steroids which may be due to *Capnocytophaga canimorsus* (Brenner et al. 1989). Women who have undergone radical or modified radical mastectomy or patients with pre-existing edema of an extremity due to any cause are at increased risk of infection.

Dog bite wound infections are predominantly related to the microbiology of their oral flora (Goldstein et al. 1980; Brook 1987; Talan et al. 1999). Table 1 lists

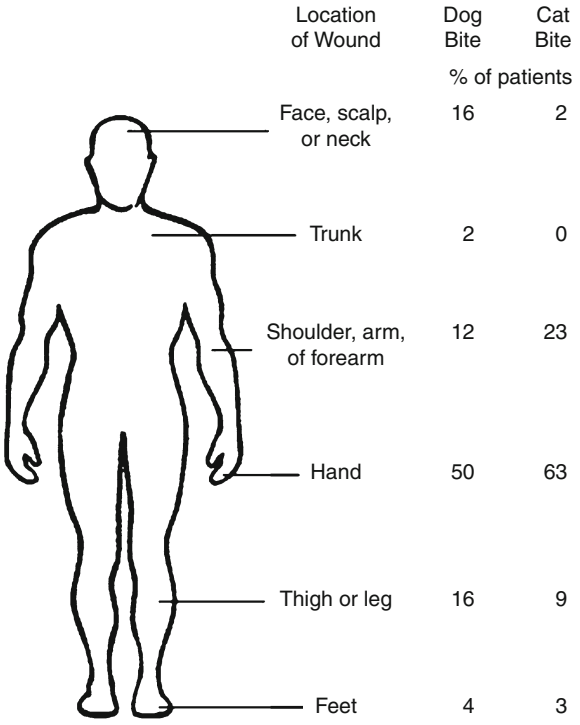

Fig. 1 Anatomic distribution of 50 dog and 57 cat bite wound infections. (Based on reference (Talan et al. 1999) (with permission))

common pathogens found in dog wound infections (Talan et al. 1999). *Pasteurella multocida* is a major and important pathogen but one should note that *Pasteurella canis* is more frequently isolated than *Pasteurella multocida* subspecies *multocida*. Compared to cat bites, this may, in part, account for the greater potential for infection from cat bite wounds. The spectrum of organisms associated with dog bite wound infections is much greater and includes streptococci, staphylococci as *Staphylococcus intermedius* and *Staphylococcus aureus*, and anaerobic organisms (Talan et al. 1999). In one large study, the median number of strains isolated from infected dog bite wounds was 2–7.5. Non-purulent but infected wounds had 2 strains per specimen compared to 7.5 strains for abscesses (Talan et al. 1999). Forty-eight percent of dog bites grew both aerobes and anaerobes, including 67% of abscesses, 62% of purulent wounds, and 13% of non-purulent wounds (Talan et al. 1999). No growth occurred less than 10% of the time which may suggest that other fastidious organisms may be involved in infected bite wounds.

Methicillin-resistant *Staphylococcus aureus* (MRSA) has been cultured from a variety of companion animals including dogs, although not yet reported as isolated from infected dog bite wounds in humans. MRSA should be considered as a potential causative secondary invader, especially in patients who are not responding to initially administered antibiotics that often do not exhibit activity against MRSA and those known to be colonized or have had prior infections with MRSA.

Table 1 Common aerobic and anaerobic bacteria isolated from infected dog and cat bite wounds

Organism	Frequency (%)	
	Dog ($n = 50$)	Cat ($n = 57$)

Adapted from reference (Talan et al. 1999) (with permission) and updated

The antimicrobial treatment of non-infected dog bite wounds that present less than 24 hours after injury remains a controversial issue. The Cochrane reports do not recommend prophylactic antimicrobials for these wounds but the data is flawed as it is based on only a few biased studies with small numbers of patients and incomplete bacteriology (Medeiros and Saconato 2001). Recently, a report (Quinn et al. 2010) on the outcomes of 94 patients and in a cost model using sensitivity analysis across rates of infections from 0% to 16% determined that "if the risk of wound infection was greater than 5%," then antibiotics could decrease that rate and be "cost effective." It is the authors' opinion that all moderate to severe bite wounds, especially those to the hands, injuries associated with moderate to severe swelling (pre-existing or as a result of trauma), and bites in immunocompromised hosts and in proximity to a bone or joint, except those not clinically infected and more than a few days old, should be considered contaminated with potential pathogens and treated.

31.2.2 Cat Bites

Worldwide, cat bites account for 2–50% of injuries related to animal bites. They are second only to dog bites in terms of incidence. In Italy, the incidence of cat-related injuries is 18 per 100,000 population, while in the United States, there are an estimated 400,000 cat bites and 66,000 related visits to emergency departments every year (http://www.who.int/mediacentre/factsheets/fs373/en/).

Wounds inflicted by cats are frequently scratches or tiny but somewhat deep punctures located on the extremities, which are at higher risk of becoming infected (Lucas and Bartlett 1981). Figure 1 shows the comparative distribution of cat bite wounds compared to dog bite wounds (Talan et al. 1999). Deep puncture wounds over or near a joint, especially on the hands, may result in osteomyelitis and septic arthritis. *Pasteurella multocida* has been isolated from 50% to 70% of healthy cats and is a frequent pathogen in cat-associated wounds (Goldstein 1992; Talan et al. 1999).

Patients who present with an infected cat bite often have more severe infections than those with infected dog bites, which may be attributed to the higher incidence of *Pasteurella multocida* and *Pasteurella septica* in cat bites compared to dog bites (Table 1). Cat scratches are likely to get infected from the cats grooming themselves and inoculating *Pasteurella multocida* onto their claws. *Erysipelothrix rhusiopathiae* has been isolated from 4% of cat bite wounds (Talan et al. 1999).

Most cat bite wounds are mixed aerobic infections (64%) with a median number of isolates per wound of 5–7 per specimen. There are 5 isolates per specimen (range, 0–12) for non-purulent but infected wounds compared to 6.5 per specimen (range, 0–13) for purulent wounds and 7 per wound (range, 3–13) for abscesses (Talan et al. 1999). Five percent of infected wounds do not grow a pathogen, suggesting that there are other fastidious organisms present that require special media for isolation. Cougar, tiger, and other feline bites also yield *Pasteurella multocida* (Burdge et al. 1985; Kizer 1989). Tularemia has likewise been transmitted by cat bites (Capellan and Fong 1993). Cat bites may be treated differently in a court of law as cats are more independent and therefore are not subject to the same scrutiny as dog bites.

31.2.3 Venomous Snake Bites

Approximately 600 species of venomous snakes exist worldwide with an estimated five million people bitten annually. In the United States, only 50–70% of venomous snake bite victims are envenomated as the remainder are "dry" bites. Still, considerable morbidity and mortality occur from these injuries. There are an estimated 2.4 million envenomations and 94,000–125,000 deaths annually, resulting in 400,000 amputations and other complications, such as infection, tetanus, scarring, contractures, and psychological consequences. Access to health care and the availability of antivenom decreases the severity of the injuries and improves patient outcomes (http://www.who.int/news-room/fact-sheets/detail/animal-bites).

The majority of snake bites occur in Africa and Southeast Asia and are most common among people living in rural, resource-poor settings, especially agricultural workers, women, and children. The socioeconomic impact and burden of snake bites on these families and communities is increased in these settings (http://www.who.int/news-room/fact-sheets/detail/animal-bites). While snake bites are uncommon in Europe, a review of the literature from 1970 to 2010 found 7992 snake bite reports with an even distribution between Northern, Southern, and Central Europe, including Russia and Turkey (Chippaix 2012). Most bites occurred between May and September, and 15% were considered severe.

Venomous snakes, usually vipers (rattlesnakes, copperheads, cottonmouths, and water moccasins), bite approximately 8000 people in the United States yearly, of which 5 or 6 result in death, usually in children or the elderly, who receive either no or delayed antivenom therapy (Russell 1969). The majority of bites occur in young men in the Southwestern United States between April and September (Gold et al. 2002).

Envenomation can cause extensive tissue destruction and devitalization that predisposes to infection from the snake's normal oral flora. Sparse data exists on the incidence and bacteriology of snakebite infections. In rattlesnakes, the oral flora

appears to be fecal in nature because the live prey usually defecates in the snake's mouth coincident with ingestion. Common oral isolates include *Pseudomonas aeruginosa,* coagulase-negative staphylococci, *Proteus* and *Clostridium* species, *Bacteroides fragilis*, and *Salmonella arizonae (Salmonella* groups IIIa and IIIb) (Russell 1969; Goldstein et al. 1979).

Several treatment guidelines have been published (Lavonas et al. 2011; Walk 2012). In Nigeria, the Health Ministry has attempted to make antivenom more readily available to rural endemic areas and has created a "hub-and-spoke" strategy as a component of "antivenomics" to improve the selection and purchasing of locally appropriate antivenoms (Habib 2013).

31.2.4 Monkey/Simian

Bites from monkeys typically occur in people who keep them as pets, use them for medical research, and those who travel to cities and countries that have a high prevalence of free-roaming monkeys (e.g., Gibraltar, Bali, certain parts of India). Monkey bites account for 2–21% of animal bite injuries (http://www.who.int/mediacentre/factsheets/fs373/en/). In India, for example, monkeys are second to dogs for animal bite injuries. Approximately, 11% of bite wounds in US military personnel stationed in Afghanistan are due to *Macaca mulatta* monkeys, often kept by locals as pets (Mease and Baker 2012).

An emergency department in Los Angeles (Kizer 1979) reported that 1.7% (5/332) of patients who presented during 1975 for bite wounds had monkey bites. Rates of the percentage of monkey bite wounds have been reported from a number of countries and range from 3.2% in India to 0.7% in Israel (Eslamifar et al. 2008; Gross and Torok 1984; Ichhpujani et al. 2008). In the United Kingdom, an animal facility reported 85 (67 incidents in men and 18 in women) monkey bites in handlers over a 6-year period (Tribe and Noren 1983). In addition, persons who visit or work in wilderness areas and national parks worldwide where monkeys reside are also at higher risk. These animals are often considered "mischievous" and will scour for food if hungry. Simple wound management of monkey bites may not prevent potential infectious complications and a protocol for post-bite exposure treatment has been published (Tregle Jr et al. 2011; Newton F. United States Armed Forces 2010).

The spectrum of isolates from humans bitten by monkeys is similar to those isolated from human bite wounds. There is a predominance of α-hemolytic streptococci, enterococci, *Staphylococcus epidermidis*, *Neisseria* and *Haemophilus* species, *Eikenella corrodens*, and anaerobes including *Bacteroides* and *Fusobacterium* species (Goldstein et al. 1995). Monkeys can naturally acquire *Bartonella quintana* (trench fever) and they may potentially act as vectors (O'Rourke et al. 2005). Transmission of viral diseases is a major health and economic concern with monkey contact and bites (Estrep et al. 2010). Non-human primates are susceptible to a variety of pathogens that bear significant homology to human pathogens. These same viruses pose a potential health issue to humans and can include herpes B virus, simian varicella virus, rhesus cytomegalovirus, gamma-herpesviruses, lymphocryptoviruses, herpes saimiri, rhesus macaque rhadinoviruses, and others (Estrep et al. 2010).

In monkeys from Nepal the prevalence of selected enzootic primate-borne viruses through positive antibody response among 39 rhesus monkeys in Katmandu has been reported (Jones-Engel et al. 2006). The various viruses found included simian foamy virus (97.4%), *Cercopithecine herpesvirus* 8 (94.9%), simian virus 40 (89.7%), and *Cercopithecine herpesvirus* 1 (64.1%; also known as B virus). Documented cases of B virus infection in humans have mostly been attributed to monkey bites. However, other less commonly reported modes of transmission have been due to scratches and percutaneous inoculation with infected materials (Centers for Disease Control and Prevention 1998). A fatal case of B virus infection has been reported following a mucocutaneous exposure (Centers for Disease Control and Prevention 1998).

Other reports of bite-related primate-borne viral infections in humans have included simian foamy virus (especially from ape bites) and monkeypox infections (Calattini et al. 2007; Mutombo et al. 1983; Schweizer et al. 1997) and yellow fever virus with the arbovirus carried from one host to another, primarily between monkeys, from monkeys to humans, and from person to person. Sylvatic (or jungle) yellow fever occurs in tropical rainforests where monkeys are infected by wild mosquitoes and then pass the virus to other mosquitoes that feed on them. The infected mosquitoes bite humans entering the forest, resulting in occasional cases of yellow fever. The majority of infections occur in young men working in the forest (e.g., for logging) (http://www.who.int/mediacentre/factsheets/fs100/en/).

Hepatitis A virus can infect various monkey species such as chimpanzees, owl monkeys, cynomolgus monkeys, rhesus monkeys, stump-tailed monkeys, African green monkeys, tamarins, marmosets, and squirrel monkeys. The transmission of human hepatitis A virus from experimentally infected animals to humans has occurred and been documented (http://www.who.int/mediacentre/factsheets/fs100/en/). Still unknown is the susceptibility of humans to true simian hepatitis A virus strains (http://www.who.int/mediacentre/factsheets/fs100/en/).

While man is the natural host for hepatitis E virus, chimpanzees, cynomolgus monkeys, rhesus monkeys, pigtail monkeys, owl monkeys, tamarins, and African green monkeys are reported to be susceptible to natural infection with human strains of hepatitis E virus making transmission possible.

The monkeypox virus can cause a fatal disease in humans. It is similar to human smallpox, although typically much less serious. It occurs primarily in remote villages in Central and West Africa, near tropical rainforests. The monkeypox virus is transmitted to people from a variety of wild animals and it spreads in the human population through human-to-human transmission (http://www.who.int/mediacentre/factsheets/fs100/en/).

Malaria due to *Plasmodium knowlesi* also known as "monkey malaria" can occur in humans while staying in rainforests or their fringe areas in Southeast Asia, within the range of the natural monkey hosts and mosquito vector of this infection. These areas include parts of Cambodia, China, Indonesia, Laos, Malaysia, Myanmar, the Philippines, Singapore, Thailand, and Vietnam. Travelers to forested areas of Southeast Asia where human *Plasmodium knowlesi* infections have been reported should protect themselves against mosquito bites between dusk and dawn to prevent infection and take the usual chemoprophylaxis where indicated (http://www.who.int/mediacentre/factsheets/fs100/en/).

31.2.5 Bears

Bear attacks occur worldwide and are, in part, an ecological conflict, often where humans visit or decide to work or live in areas where these large carnivores inhabit (Cardall and Rosen 2003; De Giorgio et al. 2007; Frosch et al. 2011; Herrero 1970; Herrero and Fleck 1990; Mihailoviv et al. 2011; Nabi et al. 2009; Risholt et al. 1998; Tough and Butt 1993; Vougiouklakis 2006). In Norway, from 1971 to 1995 there were 80 incidents involving human-bear interactions of which there were 4 fatalities and 6 injuries, many of which were due to bites (Risholt et al. 1998). A review of wild animal bites in Kashmir from 2005 to 2007 noted that 51.2% (104/203) were caused by black bears (Nabi et al. 2009). In North America, human injuries from grizzly bears (*Ursus arctos horribilis*) in the national parks have been reported at a rate of one person per two million visitors (Herrero 1970).

From 1900 to 1985, 162 bear-inflicted injuries (approximately 2 attacks per year) were reported in the United States and Canadian national parks (Herrero and Fleck 1990). Although bear-inflicted human injuries and death are uncommon (Floyd 1999), as the remote bear habitat decreases and humans enter wilderness areas for living and recreation, there are more chances of encounters between bears and humans. These have occurred in all hemispheres where bears are resident and some have even occurred in zoos (Mihailoviv et al. 2011).

The bacteriology of bear oral flora and bear bite wounds to humans is limited to a few studies and case reports (Floyd et al. 1990; Kunimoto et al. 2004; Lehtinen et al. 2005; Parry et al. 1983; Rose 1982). The bacteria isolated from bear bite wounds include *Serratia fonticola*, *Serratia marcescens*, *Aeromonas hydrophila*, *Bacillus cereus*, and *Enterococcus durans*. Lehtinen et al. reported a case of a 56-year-old male who sustained several bite wounds from a brown bear (*Ursus arctos*) that grew *Streptococcus sanguinis*, *Neisseria sicca*, *Bacillus* species, and *Mycobacterium fortuitum* (Lehtinen et al. 2005). Those patients that survived a bear attack required air-lifting to nearby medical facilities.

Rabies virus infection in bears has also been reported (Centers for Disease Control and Prevention 1999). However, to our knowledge there have not been any reports of rabies transmission from bears to humans.

31.2.6 Pigs

Pigs are aggressive animals and their bite injuries are a common occupational hazard and may also occur to those who own pigs as pets. Nogalski et al. reported 5.13% (96/1872) of animal-related injuries seen between 2001 and 2004 were related to pigs, either bites or battering or both (Nogalski et al. 2007). These injuries were more often from rural (88.5%; 85/96) areas than urban (11.5%; 11/96). Injuries, often on extremities, commonly occur during capture, transport, or immobilization of the pig (Barnham 1988; Nishioka et al. 1994; Van Demark Sr and Van Demark Jr 1991). Unusual pig bites have included a de-gloving injury to the penis and the prolapsed rectum of a child (Georgiou et al. 2001; Gangopadhyay et al. 2002). In Southeastern

Brazil, a case series from a teaching hospital reported 23 pig bites from 1987 to 1990 and estimated the annual incidence to be 1.5/100,000 population (Nishioka et al. 1994). They reported a male to female ratio of 6.7:1 and a median age of 36 years for victims.

Only a few human wound infections after a pig bite have been reported (Barnham 1988; Ejlertsen et al. 1996; Escande et al. 1996; Goldstein et al. 1990). Organisms isolated from these patients included *Streptococcus agalactiae, Streptococcus equisimilis, Streptococcus suis, Pasteurella aerogenes, Proteus species, Escherichia coli, Bacteroides* species including *Bacteroides fragilis*, *Pasteurella multocida*, coagulase-negative *Staphylococcus*, *Streptococcus milleri*, and *Myroides odoratimimus* (Ejlertsen et al. 1996; Escande et al. 1996; Goldstein et al. 1990; Maraki et al. 2012). Identification of bacteria isolated from pig bites in humans is problematic because they cannot be identified or are misidentified by commercial kits and conventional methods (Lindberg et al. 1998).

Recent studies have shown a high prevalence of nasal MRSA colonization in people commonly in contact with live pigs (Khanna et al. 2008; Köck et al. 2009; Smith et al. 2009; Van Cleef et al. 2010). Molecular characterization of MRSA found in pigs and humans in contact with pigs has revealed a *Staphylococcus aureus* protein A (spa) type t108 and sequence type (ST) 398 (van Belkum et al. 2008; van Loo et al. 2007; Huijsdens et al. 2006). Clonal spread of MRSA and transmission through family members of a pig farmer, his co-workers, and his pigs have been reported (Huijsdens et al. 2006).

Although rare, rabies infection has been reported worldwide in pigs (DuVernoy et al. 2008; Morehouse et al. 1968; Yates et al. 1983; DuVernoy et al. 2008; Luo et al. 2013). However, to our knowledge there have not been any reports of rabies transmission from pigs to humans, although there is a report of a rabid pig biting humans playing golf in India (https://timesofindia.indiatimes.com/city/chennai/Rabid-pig-bites-two-golfers-washerman-done-to-death/articleshow/12092460.cms). Although there are no reports of bite transmission, hepatitis E virus infections in humans have been associated with pig contact and ingestion of raw pig products (Ruggeri et al. 2013; Dalton et al. 2013).

Pigs may also carry *Clostridium difficile* (Fry et al. 2012), and toxigenic PCR ribotypes found in pigs correspond to PCR ribotypes associated with human disease in hospitalized patients in the Netherlands (Koene et al. 2012). Although not a bite-related infection, *Clostridium difficile* disease may potentially be transmitted to humans.

31.2.7 Horses

Humans and horses have shared a close relationship with one another for over thousands of years. Throughout the world, millions of people have had contact with horses through recreation and sporting or for occupational reasons. It is estimated that there are 893,152 pet horses in the United States (https://www.avma.org/KB/Resources/Statistics/Pages/Market-research-statistics-US-pet-ownership.aspx). In the United Kingdom, it is estimated that there are 374,000 horse-

owning households (https://petkeen.com/horse-statistics-uk/). Horse riding is estimated to be a more popular sport than rugby, cricket, or fishing, with greater than 7% of the population riding at least one time annually.

It is estimated that between 3% and 4.5% of all animal bites are due to horses (Langley and Morris 2009). Carithers reported that 5 out of 157 (3%) animal bites seen in children in Jacksonville, Florida, over a 20-month period were due to horse bites (Carithers 1958). In England, over a 2-year period, a local hospital reported 622 patients with horse-related injuries, of which 24 (3.8%) were bite wounds (Edixhoven et al. 1981). In that series, few had extensive muscle damage and most injuries healed uneventfully. In Lublin, Poland (Nogalski et al. 2007), it was noted that 2.4% of animal-related injuries were due to horses and that they occurred in equal frequency in urban and rural areas. In contrast, horse bites accounted for 17% of animal bite injuries and were second only to dog bites (69%) in eastern Turkey, during a period of 2 years (Emet et al. 2009). However, in Pune, India, only 0.4% of bite cases were due to horses (Shetty et al. 2005).

Horses and zebras share the same genus, so we suspect that their oral flora will likely be similar. Most reports of the bacteriology of horse bite wounds in humans have revealed infections to be polymicrobial with a mixture of aerobic and anaerobic organisms (Dibb et al. 1981; Peel et al. 1991; Benaoudia et al. 1994). *Actinobacillus lignieresii* has often been reported in infected wounds of humans bitten by horses (Dibb et al. 1981; Peel et al. 1991; Benaoudia et al. 1994). *Actinobacillus* species, specifically *Actinobacillus suis*, has been found to be a part of normal horse oral and upper respiratory tract floras (Bisgaard et al. 1984; Kim et al. 1976) and has been isolated from a horse bite (Peel et al. 1991). Horses are known to carry MRSA (Hartmann et al. 1997; Van den Eede et al. 2013; Schwaber et al. 2013), including the ST398 and ST568 strains (Gómez-Sanz et al. 2013), but no reports of horse bite infection due to MRSA have yet been reported.

31.2.8 Komodo Dragon

Komodo dragons migrated from Australia to the Indonesian Islands of Rinca, Flores, and Gili Motang. These largest living lizards can reach a length of approximately 10 feet and weigh up to 150 pounds. They are held in captivity in many zoos around the world. They are carnivores and eat mostly carrion but will prey on birds and mammals. Komodo dragons can bite people and some attacks may lead to death.

The myth of the Komodo bite's lethal ability related to its oral bacterial flora has recently been disproven by the finding of venom glans in their oral cavity (Fry et al. 2009). It is postulated that the venom is able to kill smaller, more appropriate sized prey but that the larger prey die from delayed wound sepsis due to open tear wounds and secondary infection obtained at watering holes. Goldstein et al. (2013) studied captive Komodo oral flora and found a variety of aerobic gram-negative rods (1–8 per specimen), especially *Enterobacteriaceae*; aerobic gram-positive bacteria (2–9 per specimen), especially *Staphylococcus sciuri* and *Enterococcus faecalis*; and anaerobes (1–6 per specimen), especially *Clostridia*. As with other carnivores,

captive Komodo oral flora is simply reflective of the gut and skin flora of their recent meals and environment and is unlikely to cause rapid fatal infection. To our knowledge, there have not been any reports on the bacteriology of infected human wounds from Komodo bites.

31.2.9 Alligator/Crocodile

Both the alligator population and human encounters with alligators have increased in the United States (Langley 2005). The same situation exists for crocodiles in Australia and Asia (Caldicott et al. 2005; Gruen 2009; https://www.outback-australia-travel-secrets.com/crocodile-attacks.html). From 1948 to 2004, there were 376 injuries and 15 deaths reported from alligators in the United States (Langley 2005). In 2009, 11 provoked and 8 unprovoked alligator attacks were reported in Florida (Florida Fish and Wildlife Conservation Commission Historic Alligator Bites on Humans in Florida) (Langley 2005). Unprovoked bites were defined as bites on human beings by wild alligators, which were not provoked by handling or intentional harassment. A review of crocodile attacks in Asia notes that the Nile and salt water crocodiles are most likely to prey on humans, the former most commonly in sub-Saharan Africa and the latter in New Guinea, Borneo, and the Solomon Islands. They also note 18 of 31 fatal attacks by salt water crocodiles occurred in Australia between 1970 and 1996 (https://www.outback-australia-travel-secrets.com/crocodile-attacks.html).

The microbiology of human wounds inflicted by alligators or crocodiles is limited to a few case reports where wound cultures grew mainly aquatic environmental organisms as well as bacterial flora from the skin and intestines of prey such as *Aeromonas hydrophila*, *Enterobacter agglomerans*, *Citrobacter diversus*, *Enterococcus* species, and *Clostridium* species (Flandry et al. 1989; Wamisho et al. 2009). In Malawi (Wamisho et al. 2009) a review of five patients bitten by crocodiles showed wound cultures grew *Citrobacter* species and other investigators have isolated *Vibrio vulnificus*, *Citrobacter* species, *Burkholderia pseudomallei*, *Pantoea agglomerans*, *Bacteroides melaninogenicus*, *Aeromonas hydrophila*, *Serratia fanticola*, *Clostridium perfringens*, *Pseudomonas aeruginosa*, and *Proteus vulgaris*. Caimans are very aggressive and bites from Brazil have been reported. It was speculated that the oral flora of the caiman might be similar to that of the alligators in the United States (Hertner 2006). The oral and cloacal flora of wild crocodiles in the Mexican Caribbean included *Aeromonas hydrophila* and also *Salmonella arizonae* and *Salmonella typhi* which could pose a threat to humans from both bites and from the aquatic environment (Charruau et al. 2012).

31.2.10 Rodents/Rats

It is estimated that annually there are 20,000 rat bites in the United States with children the most common victims and most wounds to the face or hands (Hirschhorn and Hodge 1999; Ordog et al. 1985; Elliott 2007; Glaser et al. 2000).

Most cities in the United States are populated by the Norway rat, black rat, or the house mouse. Rats and other rodents have also gained popularity as pets. The Centers for Disease Control and Prevention (CDC) in the United States initiated a limited national surveillance program for animal bites in 1971 and reported that 4.3% of the 196,684 cases were due to rat bites (Moore Jr et al. 1977). In Philadelphia, 622 rat bite cases were confirmed from 1974 to 1996 (Hirschhorn and Hodge 1999). It is estimated that approximately 100 persons are bitten by rats in New York City annually and the Department of Health has a proactive, active surveillance "rat-indexing" program that inspects properties and tries to abate substandard living environments to reduce this number (Bragdon et al. 2012; Childs et al. 1998).

Infections from rat bites occur in less than 2% of bitten individuals. Ordog et al. (Ordog et al. 1985) conducted a prospective study of 50 patients with uninfected rat bite wounds and found that only 1 patient developed an infection. The bacterial isolates they cultured from wounds were mostly skin flora organisms such as *Staphylococcus epidermidis, Bacillus subtilis*, alpha-hemolytic *Streptococcus*, and diphtheroids. In Tanzania, 34 Type-II male diabetic patients with peripheral neuropathy were bitten by rats during sleep which resulted in 4 deaths and 17 minor or major amputations (Abbas et al. 2005). *Actinobacillus equuli* has been isolated from the nasopharynx of laboratory mice and rats and *Actinobacillus lignieresii* has been isolated from the nasopharynx of laboratory rats (Lentsch and Wagner 1980). Cases of rat bite-associated infections in humans with *Corynebacterium kutscheri* (Holmes and Korman 2007) and *Leptospira* (Gollop et al. 1993; Luzzi et al. 1987) have also been reported.

Most attention has been focused on rat bite fever, an ancient disease caused by *Streptobacillus moniliformis*, a fastidious highly pleomorphic, filamentous, gram-negative rod, and *Spirillum minus*, a short, tightly coiled gram-negative rod (Elliott 2007). *Streptobacillus moniliformis* infection is more common in North America, while *Spirillum minus* is more common in Asia. Rat bite fever is rare in the United States and its incidence is unknown since it is not a nationally reportable disease.

From 1996 through 1998, Norway rats (*Rattus norvegicus*) from downtown Los Angeles were examined and seroprevalence rates in rats were 25.9% for *Rickettsia typhi*, 6.7% for Seoul virus, and 73.1% for hepatitis E virus (Smith et al. 2002). Fifty-two percent of blood specimens collected from rats grew *Bartonella elizabethae*-like isolates when cultured. However, in local skid row residents, the prevalence of antibodies to hepatitis E virus was 13.6%, *Bartonella elizabethae* 12.5%, *Bartonella quintana* 9.5%, Seoul virus 0.5%, and *Rickettsia typhi* 0%.

31.2.11 Sharks

The International Shark Attack File reported 118 alleged shark attacks in 2012, of which 80 were confirmed as unprovoked and 16 were provoked. The number of unprovoked attacks has steadily increased since the early 1900s and may reflect increased opportunities of interaction due to water sports and time spent in the seas by humans. Conversely, the shark population has declined worldwide. From 1999 to 2009 there were 455 shark attacks in the United States, and the United States (including Florida, Hawaii, and Puerto Rico) is the most common country where

they occur (http://www.flmnh.ufl.edu/fish/sharks/isaf/isaf.htm). The majority of attacks occurred in Florida (294 attacks), Hawaii (42 attacks), South Carolina (32 attacks), and California (30 attacks). Worldwide, during the same period, 700 shark attacks were reported with 51 (7.3%) being fatal attacks.

The highest numbers of attacks worldwide, in order of decreasing frequency, were reported from Florida, Australia, Hawaii, South Africa, and California. There were 7 fatalities due to unprovoked shark attacks reported in 2012 resulting in a fatality rate of 8.8% (http://www.flmnh.ufl.edu/fish/sharks/isaf/isaf.htm). The US fatality rate was 1.9% compared to 22.2% in the rest of the world. Approximately 60% of incidents occur in surfers and boarders compared to 22% in swimmers and 8% in divers. Shark attacks obviously have an economic impact on the specific vacation spots and beaches involved.

The oral aerobic flora of a male great white shark from Connecticut waters was obtained and various isolates of *Vibrio* species such as *Vibrio parahaemolyticus*, *Vibrio alginolyticus*, and *Vibrio fluvialis* were recovered. Other isolates included *Pseudomonas putrefaciens*, "gold-pigmented" *Staphylococcus* species, *Citrobacter* species, and *Micrococcus* species (Buck et al. 1984).

Vibrio carchariae has been isolated from an infected wound in a shark bite victim swimming off the South Carolina coast (Pavia et al. 1989), and in two cases of infections following shark bites in Australia, the wound cultures grew *Vibrio parahaemolyticus* and *Aeromonas caviae* and the other *Vibrio alginolyticus*, *Aeromonas hydrophila*, *Proteus* species, *Klebsiella oxytoca*, *Klebsiella pneumoniae*, *Clostridium freundii*, and an *Enterococcus* species (Royle et al. 1997). Most of these isolates are aquatic organisms and should be considered when selecting antimicrobial prophylaxis (Rtshiladze et al. 2011).

Interaminense et al. (2010) cultured the oral flora of sharks involved in human attacks in Recife, Brazil, and found the majority were enterobacteria such as *Enterobacter*, *Citrobacter*, and *Proteus* species, *Providencia alcalifaciens, Escherichia coli, Moellerella wisconsensis,* and *Leclercia adecarboxylata*. Other gram-negative organisms isolated included *Vibrio* species, *Burkholderia cepacia, Acinetobacter* species, and *Pseudomonas* species. Gram-positive strains were also isolated including coagulase-positive and coagulase-negative *Staphylococcus* species, *Enterococcus* species, *Micrococcus* species, and viridans streptococci.

31.3 Conclusion

In conclusion, worldwide, animal bite-related injuries to humans are a common daily occurrence. Injuries can range from minor puncture wounds to extensive crush injuries and even amputations and death. Increasing population, continued spread of habitation, and the popularity of owning various types of both traditional and nontraditional pets has made it easier for humans to have contact with various types of animals. In general, the oral flora of the biting animal will be concordant with the

bacteria isolated from the wound. These oral flora organisms often originate from the normal oral residents and environmental flora as well as the skin and intestinal bacteria of the animals' food sources and prey.

Zoonoses of Wildlife Animals

Zoonotic Pathogens of Reptiles: An Unregarded Slithery Matter

32

Jairo Alfonso Mendoza Roldan, Marialaura Corrente, and Domenico Otranto

Contents

Abstract

Increased urbanization and introduction of exotic species of reptiles may act as drivers for the transmission of zoonotic pathogens through the environment. Reptiles are reservoirs of a wide range of pathogens, including viruses, bacteria, protozoa, helminths, pentastomids, and arthropod parasitic species, some of which may represent a public health concern. Reptiles can also be a source of life-threatening parasitoses through uncooked or raw meat ingestion. The main zoonotic disease associated to reptiles is salmonellosis, yet other less regarded diseases are equally devastating, such as spotted fever, sparganosis, or pentastomiasis.

32.1 Introduction

Reptiles represent a diverse and successful group of vertebrates, including more than 1200 genera and around 11,000 species (Roll et al. 2017). This class, however, is considered artificial, given the paraphyletic origin of the group, where also birds are included (Pincheira-Donoso et al. 2013). Moreover, non-avian reptiles are divided in four main orders: The largest order being Squamata (i.e., 10,417), which is represented by snakes, lizards, and amphisbaenas. Other orders are represented by *Testudines* (i.e., 351), which are turtles and tortoises; *Crocodylia* (i.e., 24), which includes species of crocodiles, alligators, caimans, and gavials; and, finally, *Rhynchocephalia*, represented by a single species of living fossils named tuataras (*Pincheira-Donoso* et al. 2013). Reptiles are considered a successful class due to having endured with scarcely changes in their morphology, biology, and ecology, since their appearance of reptiles, 310–320 million years ago in the late Carboniferous (Lepetz et al. 2009). However, a dwindling number of species survived the mass extinction events during the Cretaceous-Paleogene period (i.e., around 65 million years ago). Yet, those that survived spread through all biomes, diverging into the high species richness recorded in present times (Mohabey and Samant 2019). Through these epochs represented by millions of years, pathogens (e.g., bacteria, parasites, viruses) coevolved with reptiles to the present diseases associated to this cold-blooded class (Mendoza-Roldan et al. 2021a). Indeed, reptiles are hosts of viral, bacterial, and parasitic pathogens, some of which may have a zoonotic importance (Mitchell 2011; Mendoza-Roldan et al. 2020). For example, *Salmonella* species have been historically associated as the most common cause of zoonotic disease, given their natural affinity with reptiles, especially those with aquatic behavior (i.e., freshwater terrapins; Bertrand et al. 2008; Sodagari et al. 2020). Yet, other bacteria, viruses, and parasites associated to reptiles can also represent a risk to public health. Nonetheless, these other pathogenic agents have been less studied, and information on the biology, ecology, and zoonotic potential of most of them is scarce, being historically neglected even in endemic areas. Furthermore, the transmission pathways of reptile-borne zoonoses have been divided in three main routes: (i) through consumption raw or uncooked meat of reptiles, (ii) environmental contamination or direct contact, and (iii) through reptile zoonotic vector-borne diseases (Mendoza-Roldan et al. 2020, 2021a). These routes are also influenced by other factors, such as geographical area and human level of interaction with reptiles (i.e., herpetophagy, reptile kept as pets, synanthropy). In this chapter, the main reptile-associated zoonotic diseases in different contexts from veterinary and medical perspective are discussed.

32.2 Reptiles in Culture and Religion

Like a boa snake constricting its prey, myths and legends have always wrapped reptiles, associating them with positive or negative beliefs in religion and folklore. This can be observed in the symbolic usage in art and literature in many cultures all over the world. The relationship human beings have developed with reptiles through time are studied in the field of ethnoherpetology (Costa et al. 2021). For example,

while in Western cultures, snakes are mostly feared because of their association with evil in Judeo-Christian religions, in Africa and in Asian cultures, they are often seen as good omens and even worshipped. Accordingly, reptiles are represented as real or imaginary in the mythology and in the religions around the word (Crump 2021). One of the most popular legendary creatures with snake-like traits is the dragon embodying both awe and respect in European as well as East Asian (e.g., China, Japan, Korea) cultures. In Greek mythology, snakes are personified as antagonists of many heroes, such as for the nine-headed Lernaean Hydra that was defeated by Hercules and the three Gorgon sisters with snakes instead of hair.

In the opposite part of the world, in Latin America, Aztec and other Nahua people worship Cipactli, the giant earth crocodile, and in Andean and South American, a serpent-like God known as Amaru (Steele and Allen 2004). Conversely, Christianity and Judaism have historically portrayed reptiles as fearful and evil beings fear. As paradigmatic example, from the very beginning of the ancient testament (Genesis 3:1) the evil, under the shape of a slithery serpent, caused Adam and Eve to be expelled from the Eden.

32.3 In Sickness and in Health: Public Health Impact of Reptiles

In general, having a healthy and species-rich population of reptiles is beneficial for humans. Indeed, some reptiles are of great ecological significance, as they represent in nature either the first (e.g., small lizards and snakes) or the higher level (e.g., crocodiles and large snakes) of the food chain (Cortéz-Gómez et al. 2015). In the latter case, given their aquatic habits and longevity (generally >60 years), crocodilians may be useful as potential indicators of environmental pollution, as they are sentinels of environmental stability and health (Briggs-Gonzalez et al. 2021). However, reptiles may represent public health concerns in some regions. For example, snakebite envenomation is still considered an important yet neglected disease in tropical countries in the developing world (Ruiz de Castañeda et al. 2021). Indeed, more than two million people worldwide, per year, suffer from snakebite accidents, with more than 130,000 deaths every year (Gutiérrez et al. 2017). However, given anthropic pressures, such as rising urbanization, habitat fragmentation, and deforestation, reptiles and their zoonotic pathogens have become even more close contact with human populations. These pathogens are represented by bacteria, such as *Salmonella* spp., and to a lesser extent and importance species from the genera *Aeromonas, Pseudomonas, Citrobacter*, *Vibrio*, *Klebsiella*, *Enterobacter*, *Shewanella*, *Acinetobacter*, *Yersinia*, as well as *Campylobacter*, *Arcobacter*, *Chlamydia*, *Leptospira*, and *Mycobacterium* (Table 1). The beforementioned genera of bacteria are mainly transmitted through the direct contact or environmental contamination through reptiles' secretions/excretions. Moreover, zoonotic bacterial RVBDs are represented by microorganisms of the genera *Aeromonas, Anaplasma, Borrelia*, *Coxiella, Ehrlichia,* and *Rickettsia* (Mendoza-Roldan et al. 2021a). On the other hand, parasitic zoonotic diseases associated to reptiles are mainly represented by food-borne pathogens, such as pentastomids and cestodes, while other zoonotic

Table 1 Main zoonotic reptile-associated bacteria

Pathogen[a]	Animal disease	Human disease	Transmission
Enterobacteria			
Salmonella spp.	Reptiles are carriers and rarely show clinical disease Intermittent shedders	Gastroenteritis Bloody mucoid diarrhea, nausea, vomiting, fever Meningitis, osteomyelitis septicemia	Direct contact handling Ingestion Contaminated water Indirect
Klebsiella spp., *E. coli, Proteus* spp., *Citrobacter* spp., *Yersinia* spp.	Mostly asymptomatic ulcerations, stomatitis	Opportunistic infections	Direct contact handling Ingestion
Non-fermentative, Gram-negative organisms			
Vibrio spp., *Aeromonas* spp., *Pseudomonas* spp.	Mostly asymptomatic	Opportunistic infections	Direct contact handling Ingestion
Campylobacter spp.	Mostly asymptomatic	Infections in immunocompromised patients	Direct contact handling Ingestion Contaminated water
Other			
Mycobacterium spp.[b]	Granulomatous disease ulcerative stomatitis	Granulomatous disease at infection site Disseminated granulomatous disease in immunocompromised patients	Handling, puncture wounds, scratches, inhalation

[a]Name of the genus
[b]Nontuberculous mycobacteria

parasitic agents can be transmitted by direct contact (i.e., *Cryptosporidium*) or by vectors (i.e., *Trypanosomatidae*; Mendoza-Roldan et al. 2020). Finally, also associated to vector transmission, arboviruses may be associated to reptilian reservoirs which, given the low host specificity of mosquitoes, may be then transmitted to humans.

32.4 Zoonotic Pathogens Associated to Reptiles

32.4.1 Bacteria

32.4.1.1 Salmonellosis

The Pathogen

Reptiles are natural reservoirs of *Salmonella*, and they may harbor a wide variety of *Salmonella* serotypes in their intestine, even simultaneously (Chiodini and Sundberg 1981; Willis et al. 2002). The so-called "exotic" *Salmonella* serotypes, belonging to

Salmonella bongori and *Salmonella enterica* subspecies II, IIIa, IIIb, IV, and VI, are mainly isolated from reptiles and from the environment where reptiles live (Pignato et al. 1998). However, in free-living and captive reptiles, the isolation of *Salmonella enterica* subspecies I is also a frequent finding (Mitchell and Shane 2000). *Salmonella* strains are well-adapted to reptiles, eventually causing mostly asymptomatic infections and only occasionally disease and death (Le Souëf et al. 2015). Nonetheless, those strains may retain pathogenicity for warm-blooded animals. Reptiles and amphibians are estimated to account for 6% of all *Salmonella* spp. infections in the United States and Europe (Mermin et al. 2004; De Jong et al. 2005; Corrente et al. 2006; Wilkstrom et al. 2014). Most of reptile-associated salmonellosis (RAS) are mainly reported in children younger than 5 years, elderly people, or immunocompromised persons (CDC 1992a, b, 1999; Woodward et al. 1997; Friedman et al. 1998; Meyer Sauteur et al. 2013; Pees et al. 2013; Ricard et al. 2013; Murphy and Oshin 2015). In those population groups, RAS may be fatal. A literature review conducted by Meyer Sauteur et al. (2013) examined published studies from 1965 to 2012, describing RAS in children aged less than 18 years, with a total of 182 cases identified. The primary reptiles associated with gastrointestinal salmonellosis were turtles; however, exposure to iguanas was significantly more prevalent in children with invasive *Salmonella* diseases, causing septicemia or meningitis. In addition, *Salmonella* multidrug-resistant (MDR) strains emerge as a potential concern for public health safety, with implications of increased disease severity, longer hospitalizations, and higher cost rates. It has been shown that also reptiles may hold MDR *Salmonella* (Seepersadsingh and Adesiyun 2003; Wei et al. 2019). The widespread use of antibiotics against *Salmonella* has been described in the international trade of pet reptiles, to prevent economical losses, as well as in animal welfare in crowded farms and long-distance transport (Goławska et al. 2019).

Epidemiology of Salmonellosis

High prevalence of *S. enterica* has been reported for pet reptiles, estimated to be 48–50% in lizards, 7–10% in chelonians, and 51–83% in snakes (Fagre et al. 2020). Since the difference in prevalence detected may be linked to intermittent excretion, every animal could be potentially considered as a potential shedder (Corrente et al. 2004). In addition, vertical transmission of *Salmonella* spp. in reptiles has been demonstrated (Schröter et al. 2006). The infection to other animals, such as pets, and to humans can be transmitted by both direct and indirect contact, as *Salmonella* strains display good resistance in the environment (Winfield and Groisman 2003). For example, turtles are small enough to be kissed and held by children, which increases the likelihood of direct transmission of *Salmonella*. In addition, indirect transmission of this pathogen can occur through cross-contamination by cleaning reptile habitats in a kitchen sink or bathtub (Corrente et al. 2017).

Prophylaxis. As a high prevalence of carriers is generally found in reptiles, antibiotic prophylaxis does not seem useful and appropriate to solve this problem. Nevertheless, it is important to remind that all *Salmonella* spp. strains isolated from reptiles retain pathogenicity for humans and that some health measures are necessary. For RAS surveillance, the identification of *Salmonella* carriers, the control of health practices, and a good knowledge of the zoonotic risks linked to reptile

husbandry are of outmost importance. In a recent survey related to the attitudes of reptile owners, the prevalence of *Salmonella* spp. colonization was correlated to several factors (Corrente et al. 2017). Indeed, when animals shared the terrarium with other reptiles, they were at least two times more exposed to *Salmonella* spp. than the animals living alone. Regarding the practice of handwashing after contact or husbandry of the animals, the prevalence of *Salmonella* spp. was three times higher in animals handled by owners who were not used to washing their hands. In the same survey, as many as 62% of the interviewed admitted ignoring the risk of RAS and other health problems associated with cold-blooded animals. Accordingly, prevention of RAS must rely mainly on information and education, with the veterinarian health bodies primarily involved in this task.

32.4.1.2 Miscellaneous Bacterial Infections: Other Gram-Negative Microorganisms

The microbiota of reptiles is mainly composed by Gram-negative bacteria. In the gut, the microbiota is influenced by the diet and the environment, especially in captivity, when a shift to gut colonization by zoonotic organisms is observed (Kohl et al. 2017). In fact, the captivity significantly alters both bacterial community membership and structure in lizards kept for 8 weeks. Notably, they showed an invasion of the gut community by *Enterobacter* spp. and *Salmonella* spp., potentially pathogenic bacterial genera (Colston 2017).

Reptiles are prone to infection by a variety of predominately Gram-negative commensal bacteria, including those in the genera *Aeromonas, Klebsiella, Proteus, Pseudomonas,* and *Yersinia* (Table 1).

Among Gram-negative organisms, *Aeromonas* spp., *Pseudomonas* spp., *Citrobacter* spp., and *Vibrio* spp. were reported in reptiles, both from clinical cases (bronchopneumonia, ulcerations, stomatitis, septicemia, etc.) and healthy animals as carriers (Goławska et al. 2019). *Klebsiella* spp., *Enterobacter* spp., *Shewanella* spp., *Acinetobacter* spp., and *Yersinia* spp. were reported as opportunistic bacteria found in Testudines. Both pathogenic and opportunistic bacteria might cause infections in other poikilothermic and homoeothermic animals as well as humans, particularly those with immune deficiency (Goławska et al. 2019).

As for *Salmonella* spp., the zoonotic potential of all those bacteria may be exacerbated by the acquisition of AMR genes. Golawska et al. found in tortoises a high prevalence of MDR *E. coli* and the horizontal genetic transfer of AMR genes among Gram-negative organisms is very frequent (Goławska et al. 2019).

32.4.1.3 The Heterogeneous World of Epsilonproteobacteria

Ectothermic reptiles display a distinct and largely unique Epsilonproteobacteria community, including taxa, which can cause disease in humans. Several *Arcobacter* taxa are widespread among reptiles and often show a broad host range. Similarly, reptiles carry a large diversity of unique and novel *Helicobacter* taxa, which apparently evolved in an ectothermic host. Some species, such as *Campylobacter fetus*, display a distinct intraspecies host dichotomy, with genetically divergent lineages (Gilbert et al. 2019).

The presence of Epsilonproteobacteria in many different reptiles without clinical symptoms indicates that most of them are carried without adverse health effects. Most of the *Arcobacter* and *Campylobacter* species found in reptiles are associated with disease in humans, although infections are often sporadic and mainly affecting immunocompromised hosts (Collado and Figueras 2011).

Campylobacteriosis

The genus is composed by Gram-negative, microaerophilic bacteria that inhabit the intestinal tract of various animals, as either commensals or pathogens (Rukambile et al. 2019). Human campylobacteriosis is the most frequently reported foodborne zoonosis in the European Union (EFSA and ECDC 2018). Sources of human infections are consumption of raw or undercooked meat, unpasteurized milk, and untreated water or direct contact with colonized animals that carry *Campylobacter* spp. asymptomatically. In reptiles, especially chelonians, *Campylobacter* spp. occurrence ranged from 9.7% in Taiwan (Wang et al. 2013) and 10.2% in Italy to 25.3% in the Netherlands (Gilbert et al. 2014).

Currently, *C. fetus* is the only species for which an association between reptile contact and human infection has been demonstrated (De Luca et al. 2020). A novel subspecies of *C. fetus*, named *C. fetus* subs. *Testudinum*, has been described in chelonians (Fitzgerald et al. 2014). Following this discovery, *C. fetus* isolated from human infections has been increasingly identified as subsp. *testudinum* (Choi et al. 2016), and two new other *Campylobacter* species were identified in reptiles. *Campylobacter iguaniorum* was isolated from lizards, such as *Iguana iguana* and *Pogona vitticeps* (Gilbert et al. 2014), and tortoises, like *Stigmochelys pardalis* (Benejat et al. 2014) and *C. geochelonis* (Piccirillo et al. 2016).

Besides from humans, *C. fetus* subsp. *testudinum* has only been isolated from reptiles, with a reported culturing-based prevalence of 5.5–6.7% in reptiles and 7.1–9.7% in chelonians (Wang et al. 2013; Gilbert et al. 2014). Reptile-associated *C. fetus subsp. testudinum* showed a remarkable epidemiology, as all human cases were in men, most of whom were of Asian origin (Patrick et al. 2013).

Infections by *C. fetus* subsp. *testudinum* were in humans >60 years of age or immunocompromised. Humans may contract *C. fetus* subsp. *testudinum* through exposure to reptiles, possibly by ingestion or by contact with feces or the environment.

After the finding of *Campylobacter*, also Arcobacter and *Helicobacter* species have been reported to be isolated from reptiles. *Arcobacter butzleri* and *Helicobacter* species have been isolated from tortoises (Stacy and Wellehan Jr. 2010).

Helicobacter taxa have only been isolated from reptiles and have not been associated with infection in humans thus far, except for a case of bacteremia caused by a urease-negative *Helicobacter* strain, isolated from blood cultures of a 28-year-old man with a severe agammaglobulinemia (Schwarze-Zander et al. 2010).

32.4.1.4 Mycobacteriosis

The genus *Mycobacterium* includes over 200 species classified as tuberculous and not tuberculous mycobacteria (NTM), on the basis of biological and genetic

characteristics (Armstrong and Parrish 2021). NTM have a cosmopolitan distribution and have been isolated from all the major classes of animals. Many of the NTM that can infect animals can also infect humans (Ebani et al. 2012). In reptiles, several species, such as *Mycobacterium chelonae, M. fortuitum, M. intracellulare, M. marinum, M. phlei, M. smegmatis, M. ulcerans, M. confluentis, M. haemophilum, M. hiberniae, M. neoaurum,* and *M. nonchromogenicum*, have been isolated, provoking granulomatous disease and ulcerative stomatitis. Systemic infections have been also reported (Soldati et al. 2004). NTM can be transmitted to humans and herpetofauna through aerosolization of contaminated respiratory secretions or direct skin contact, soil, or water. Reptiles and amphibians can harbor *Mycobacterium* species that can also be found as opportunistic pathogens in humans, especially those who are immunocompromised. Infections by *M. marinum*, *M. chelonae*, and *M. abscessus* have been reported (Soldati et al. 2004). Pet owners should always practice strict disinfection protocols when handling their pets and limit contact when they have an open wound on their hands (Ebani 2017).

32.4.1.5 Chlamydiosis

Several *Chlamydia* species have been isolated from reptiles, such as *C. psittaci*, *C. abortus*, and *C. pneumoniae,* causing granulomatous lesions in various organs and pneumonia. Despite their zoonotic potential, no cases of transmission from reptiles to humans are reported (Ebani 2017).

32.4.1.6 Leptospirosis

Leptospira spp. are organisms diffused worldwide and responsible for a reemerging zoonosis. Data about *Leptospira* spp. and the infection in reptiles are very scant. *Leptospira* spp. serovars are traditionally related to aquatic habitat. Specific antibodies in reptiles living in aquatic habitat such as crocodiles have been detected. However, no symptoms related to leptospirosis were reported. A role of those animals in the epidemiology of leptospirosis may be hypothesized, but no reptile-associated cases in humans have been described (Ebani 2017).

32.4.2 Zoonotic Bacterial Reptile Vector-Borne Diseases (ZBRBVDs)

Reptile vector-borne diseases (RVBDs; Table 2) of zoonotic concern are caused by bacteria, protozoa, and viruses transmitted by arthropod vectors, included in the subclass Acarina (i.e., mites and ticks; Fig. 1) or the order Diptera (i.e., mosquitoes, sand flies, and tsetse flies). Zoonotic bacterial RVBDs (ZBRBVDs) belong to the genera *Aeromonas, Anaplasma, Borrelia, Coxiella, Ehrlichia,* and *Rickettsia*. Moreover, *Bartonella henselae* or a species genetically related to *Bartonella vinsonii* subsp. *berkhoffii* was recorded in marine turtles (Valentine et al. 2007). Of these genera of bacteria, reptiles may play an important role as reservoirs of Lyme disease and spotted fever group *Rickettsia*.

Main vectors of granulocytic anaplasmosis (GA) caused by *Anaplasma phagocytophilum* (i.e., *Ixodes pacificus* in North America and *Ixodes ricinus* in

Europe) occasionally can feed on reptiles, especially in their immature stages (i.e., larvae and nymphs). However, studies have showed that these ectothermic tetrapods play a minor role as reservoirs of GA (Nieto et al. 2009). *Anaplasma* is a genus of Gram-negative bacteria that includes pathogenic species transmitted mainly by ticks. These bacteria can cause severe disease and even death (Rymaszewska and Grenda 2008). Additionally, other species of *Anaplasma* have been molecularly detected in ticks associated to reptiles (e.g., *I. ricinus* in Central and Western Europe; Mendoza-Roldan et al. 2021b). On the other hand, *Ehrlichia* spp. have been detected in different tick of reptiles. For example, *Ehrlichia chaffeensis* and *Candidatus* Neoehrlichia mikurensis were detected in *Amblyomma* ticks from reptiles imported to Japan (Andoh et al. 2015).

32.4.2.1 Lyme Disease and Borrelioses

The *Borrelia* genus comprises spirochete bacteria separated in four main groups (i.e., relapsing fever group, reptilian-*Borrelia* group, monotreme-associated *Borrelia* group, Lyme borreliosis group). Importantly, the Lyme disease group includes more than 20 species that are under the *Borrelia burgdorferi* sensu lato complex. Nine of these species have pathogenic potential (Majláthová et al. 2008; Mendoza-Roldan et al. 2019).

Borrelia lusitaniae is associated with lacertid lizards from Western Europe. Moreover, Lyme disease species are likely associated to these group of lizards, acting as natural reservoirs (Majláthová et al. 2006; Mendoza-Roldan et al. 2019), or being refractory to infection by means of complement-mediated killing effect, which has been described in species of lizards in the United States (Kuo et al. 2000). Indeed, some species of lizards may reduce the presence of bacteria producing a zooprophylactic effect (Tijsse-Klasen et al. 2010).

32.4.2.2 Spotted Fever Group Rickettsioses

Rickettsia bacteria comprise a large group of Gram-negative, intracellular pathogens associated with invertebrate vectors (Abdad et al. 2018). Reptiles have a direct role in the epidemiological cycle of some pathogens within the Rickettsiaceae family (Novakova et al. 2015). Indeed, most of the *Rickettsia* species of zoonotic concern, associated to reptiles' Acarina ectoparasites, are within the spotted fever group (SFG). One of the first solely associated to a reptilian tick *Rickettsia* species was *Rickettsia honei*, the causative agent of Flinders Island spotted fever, in Southern Australia. This species was described infecting *Bothriocroton hydrosauri*, a tick that feeds primarily from lizards and snakes (Stenos et al. 2003; Whiley et al. 2016). Furthermore, eight other species of SFG *Rickettsia* have been detected in ectoparasites and some even in reptiles. In Europe, SFG *Rickettsia* have been identified in reptiles, including species such as *Rickettsia helvetica* and *Rickettsia monacensis* detected in *I. ricinus* ticks, and in blood and tail of lacertid lizards (Mendoza-Roldan et al. 2021b). Other rickettsial agents detected in ticks and mites collected from reptiles are *R. aeschlimannii*, *R. amblyommatis, R. hoogstraalii, R. massiliae*, *R. raoultii*, *R. rhipicephali*, *R. tamurae*, and *R. typhi* (Sánchez-Montes et al. 2019).

On the other hand, *Rickettsia* species have been detected in *Amblyomma*, *Bothriocroton*, *Dermacentor*, *Haemaphysalis*, *Hyalomma*, and *Ixodes* ticks and in mites from families *Ixodorhynchidae*, *Macronyssidae*, *Pterygosomatidae*, and *Trombiculidae* (Sánchez-Montes et al. 2019; Mendoza-Roldan et al. 2021a).

32.4.2.3 Other Zoonotic Reptile Vector-Borne Diseases (ZRBVDs)

Protozoa

Vector-borne zoonotic protozoa associated to reptiles are represented by trypanosomatid flagellates, such as *Leishmania* and *Trypanosoma* (Kinetoplastida: *Trypanosomatidae*) (Table 2; Poinar Jr and Poinar 2004). For example, *Trypanosoma brucei*, which causes sleeping sickness in Africa, was detected in monitor lizards from Kenya (Njagu et al. 1999), serving as an important blood

source for the tsetse fly (*Glossina fuscipes fuscipes*) also in Uganda (Waiswa et al. 2006). Indeed, experimental evidence indicates that some species of reptiles could be potential reservoirs of this pathogen (Woo and Soltys 1969).

32.4.2.4 Leishmaniases in Reptiles: Is It a Big Deal?

The species of *Leishmania* that infect reptiles belong to the subclade *Sauroleishmania*, which is a sister clade of the pathogenic species of mammalian-associated *Leishmania*, with around 21 species infecting reptiles, mainly lizards (Ticha et al. 2021). These genetic and phylogenetic similarities suggest that species of *Leishmania* typical of reptiles could transiently infect mammals and vice versa (Klatt et al. 2019). For example, *Leishmania adleri* from lacertid lizards in Kenya may produce cutaneous leishmaniasis in mammals (Coughlan et al. 2017). Also, *Leishmania tarentolae* from geckoes has been molecularly detected in human mummies from Brazil (Novo et al. 2015), human blood (Pombi et al. 2020; Iatta et al. 2021), and shelter dogs in Italy (Mendoza-Roldan et al. 2021c). Additionally, *Sergentomyia minuta* sand fly, the natural vector of *L. tarentolae*, has been detected feeding from humans and other mammals (Abbate et al. 2020). Given the genetic similarity with *Leishmania infantum*, *L. tarentolae* natural infection could, to a certain extent, protect mammals against other pathogenic *Leishmania* spp., yet this issue needs further investigation also considering the promising results of vaccination attempts using this species of *Leishmania* (Klatt et al. 2019). On the other hand, reptiles could potentially have a role as reservoirs of pathogenic *Leishmania* spp. in areas where primary hosts do not occur or where reptiles and natural hosts live in sympatry. For example, *Leishmania tropica*, *Leishmania donovani*, and *Leishmania turanica* were molecularly detected in lizards and snakes from Northwestern China (Chen et al. 2019; Zhang et al. 2019), and *L. infantum* was molecularly detected in lizards collected from dog shelters in Southern Italy (Mendoza-Roldan et al. 2022b), both areas being endemic for leishmaniases.

32.4.3 Viruses

32.4.3.1 COVID-19 and Other Viral Diseases Associated to Reptiles

At the beginning of the COVID-19 pandemic, some studies initially hypothesized that the origin of the SARS-CoV-2 was from snakes, which were kept alive in the Wuhan meat market (Ji et al. 2020). Later, bats and/or pangolins were pointed out as the more probable reservoirs of this viral disease, given that coronavirus species are associated to endothermic tetrapods (i.e., mammals and birds; Gautam et al. 2020). Conversely, snake venom from vipers, such as *Bothrops jararaca*, contains peptides that could be useful for the treatment of COVID-19 (Gouda and Mégarbane 2021) or complications associated to the disease, such as thrombo-cardiovascular disorders (Kalita et al. 2021). Hence, snakes in the COVID-19 pandemic went from villains to potential heroes.

On the other hand, ectothermic tetrapods (i.e., reptiles and amphibians) may play a role as reservoirs for arboviruses (Table 2). Medically important anthropophilic species of mosquitoes, such as *Aedes aegypti* and *Aedes albopictus*, may

opportunistically feed on reptiles, and most of the orders of reptiles have been found by molecular and serological assays infected with arboviruses of zoonotic concern (Marschang 2011). Indeed, reptiles can be reservoirs of important arboviruses, such as Western and Eastern equine encephalitis, Venezuelan equine encephalitis, West Nile virus, and most recently Chikungunya virus (Bingham et al. 2012; Bosco-Lauth et al. 2018). Moreover, reptiles, specifically non-native lizards, can be important blood source of vectors (i.e., *Culex* spp.) of *Flavivirus* (Reeves and Burkett-Cadena 2022). In fact, blood meal identification indicated that arbovirus vectors may predominantly feed on reptiles (Burkett-Cadena et al. 2008). For example, *Culex tarsalis* mosquitoes can feed on garter snakes, which may maintain the virus of the Western equine encephalitis during winter (overwintering). Other reptile-associated viruses are the Japanese encephalitis and Zika viruses (Oya et al. 1983; Bueno et al. 2016).

Conversely, viral zoonotic diseases may be also vectored by ticks, such as *Hyalomma aegyptium*, that may be a putative vectors of Crimean-Congo hemorrhagic fever (CCHF), associated to tortoises. This zoonotic neglected disease is widely distributed through Africa, the Balkans, the Middle East, and Western Asia (Kar et al. 2020), where tortoises and their ticks may play a role in the cryptic transmission cycle (Kar et al. 2020).

32.4.4 Helminths and Other Zoonotic Endoparasites Associated to Reptiles

Reptiles represent essential part of the food webs in many ecosystems (Valencia-Aguilar et al. 2013), both as top predators (i.e., large carnivorous reptile species such as crocodilians, monitor lizards, pythons) and as prey for many carnivores (e.g., smaller Squamata reptile taxa). Therefore, many heteroxenous metazoan parasites cycle through reptiles, using them as intermediate or final hosts (Table 3; Greiner 2003), eventually infesting humans. This may happen when reptiles are used as part of the human diet throughout the world (Klemens and Thorbjarnarson 1995). Thus, reptiles may transmit some zoonotic helminths, mainly through their consumption or usage in medicinal practices (Magnino et al. 2009). For example, nematodes (e.g., *Angiostrongylus cantonensis*, *Anisakis* spp., *Gnathostoma* spp., *Eustrongylides* spp., *Trichinella* spp.), cestodes (e.g., *Spirometra* spp.), trematodes (e.g., *Alaria*), and several pentastomids, including *Armillifer* spp. (*A. armillatus; A. moniliformis; A. grandis, A. agkistrodontis*) and *Raillietiella hemidactyli*, may have a zoonotic potential. Most of the times, parasites do not complete their biological life cycles in humans rather these represent aberrant or dead-end hosts.

32.4.4.1 Nematodes

Along with amphibians, reptiles represent paratenic hosts for *Angiostrongylus cantonensis* (Strongylida, Angiostrongylidae), a metastrongyloid nematode causing eosinophilic meningitis in humans (Barratt et al. 2016). While rats represent the definitive hosts and molluscs the intermediate hosts, reptiles may cumulate infective L3 larvae in the liver and other tissues (Johny et al. 2018), therefore being important

Table 3 Zoonotic helminths and other endoparasites of reptiles

Pathogen	Reptile host	Region	Disease in humans	Transmission
Spirometra spp.	Snakes	Americas, Europe, Asia, Australia	Sparganosis Blindness, paralysis, death	Ingestion of the plerocercoid
Armillifer spp.	Snakes	Asia, Africa	Pentastomiasis Organ damage by larvae	Ingestion of embryonated eggs or larvae
Raillietiella hemidactyli	Lizards	Southeast Asia	Creeping disease Subcutaneous pentastomiasis	Ingestion of embryonated eggs or larvae
Trichinella spp.	Crocodiles Snakes Monitor lizards Turtles	Worldwide	Trichinosis Fever, myalgia, gastrointestinal symptoms	
Anisakis spp.	Worldwide	Crocodiles	Anisakiasis Eosinophilic granulomas	
Gnathostoma spp.	Snakes	Asia Central America	Gnathostomiasis Cutaneous or visceral *larvae migrans* symptoms	
Angiostrongylus cantonensis	Monitor lizards	Worldwide	Neuro-angiostrongyliasis Eosinophilic meningitis	

for the maintenance and amplification of the infection. The consumption of raw meat of varanid lizards was documented as an infection route in Asia (Parameswaran 2006; Johny et al. 2018). As the disease in humans is difficult to identify at a preoperative stage, the anamnesis is pivotal for an expedite diagnosis and treatment.

Within the genus *Trichinella* (Adenophorea, Trichinellidea), two non-encapsulated species – *Trichinella zimbabwensis* and *Trichinella papuae* – have been found in crocodiles and monitor lizards (Pozio et al. 2004). Though this genus includes nematodes with high zoonotic potential and most encapsulated ones are infective only for mammals, the zoonotic role of *Trichinella* spp. of reptiles is not well elucidated. For example, infections in humans due to the consumption of meat of monitor lizards and a turtle have been reported in Thailand, even though the *Trichinella* species involved was not identified (Khamboonruang 1991). Nonetheless, reptiles seem to be the main hosts for *T. zimbabwensis* and *T. papuae* as confirmed also experimentally (Pozio et al. 2004).

32.4.4.2 Sparganosis (Cestoda)

Spirometra (Diphyllobothriidae) are pseudophyllidean tapeworms, which develop as adults in carnivorous mammals (definitive hosts) and as larvae in freshwater crustaceans (i.e., cyclops) and poikilothermic vertebrates, being first and second intermediate hosts, respectively (Denegri 1993). This genus of cestode includes the most reported reptile-borne zoonotic helminths caused mainly by *Spirometra erinaceieuropaei*, *Spirometra*

mansonoides, and *Spirometra proliferum*. Humans may be infected by eating contaminated uncooked meat with infective larval stages (i.e., plerocercoids, also referred to as *sparganum*). In humans, visceral migration of plerocercoids may be disseminated in various organs and tissues (e.g., subcutaneous tissue, muscles, lungs, pleural cavity, urogenital, and abdominal viscera) (Presti et al. 2015). Depending on the invaded organs, sparganosis may be of minor to middle severity, as in the case of subcutaneous migrations, or even life-threatening (e.g., visceral sparganosis) and fatal, when localized in the central nervous system (e.g., ocular and cerebral forms) (Liu et al. 2015). A severe clinical condition in humans is also caused by the proliferative sparganosis, which is caused by the asexual multiplication of plerocercoids in human body (Anantaphruti et al. 2011). Sparganosis is described mainly in Asian countries, associated to the consumption of raw or inadequately cooked meat of snakes, frogs, and tadpoles infected with the plerocercoid forms. In Europe, cases of people infected with sparganosis were reported in foreigners coming from continents where the disease is endemic (Presti et al. 2015). However, humans may get infected even by drinking untreated water with infected copepods (i.e., first intermediate hosts) or transcutaneous, applying the flesh of infected snake or frog as a poultice to a wound as prescribed in Asian traditional medicine (Liu et al. 2015).

32.4.4.3 Pentastomiasis

Pentastomids are a subclass of parasitic arthropods that represent a unique lineage deriving from crustaceans. These exceptional parasites thrive within the respiratory tract of vertebrates, such as Squamata reptiles (snakes and lizards), mammals (canids), birds, and some species that are well-adapted to parasitize fishes (Gomez-Puerta et al. 2020). However, species of pentastomids that represent a zoonotic concern are typically associated with reptiles. Snake-associated pentastomids of the genus *Armillifer* are highly pathogenic to their ophidian host, and several species may cause zoonotic infections in Africa, such as *Armillifer grandis* and *Armillifer armillatus*, and in Asia, particularly *Armillifer moniliformis and Armillifer agkistrodontis* (Chen et al. 2010). Additionally, species of the genus *Porocephalus* (Brookins et al. 2009) have been recorded infecting humans and dogs, whereas *Raillietiella* infecting humans (Tappe et al. 2016). *Armillifer* parasitize snakes in Africa and Asia and *Porocephalus* in America. The life cycles of *Armillifer* and *Porocephalus* are heteroxenous, where adults are large and vermiform and infect the lower respiratory tract of snakes, laying infective eggs with typical larvae, that are excreted in the snakes feces. Intermediate hosts are represented by small mammals (i.e., rodents), in which larvae develop to nymphs in connective tissues and parenchymatous organs (i.e., liver, spleen, lungs) (Tappe et al. 2014). On the other hand, the genus *Raillietiella* (Fig. 2) is cosmopolitan, mainly recorded in in Africa, Asia, Australia, and the Americas (Kelehear et al. 2011). Differently from *Armillifer* and *Porocephalus*, *Raillietiella* spp. develop initially in insects as intermediate hosts (e.g., cockroaches), whereas adults thrive in the lung of lizards or snakes and amphibians (Walden et al. 2020).

Furthermore, species of pentastomids have been recorded in new geographical areas other than those of their original description (Walden et al. 2020), associated to invasive

Fig. 2 *Raillietiella hemidactyli* found in the lung of *Tarentola mauritanica* gecko

reptile species (e.g., *Raillietiella orientalis* in Burmese pythons in United States; Mendoza-Roldan et al. 2020), representing a risk of introduction of new zoonotic species. For example, *Raillietiella hemidactyli* was recorded infecting *Tarentola mauritanica* geckoes in a Southern island of Italy (Mendoza-Roldan et al. 2022).

Disease in Humans

Human pentastomiasis is associated with the consumption of raw reptile flesh, and occasionally infection through contaminated environment by eggs represents a risk in endemic areas (Tappe et al. 2011). Humans act as dead-end hosts where larvae cannot develop, thus they ultimately encyst in connective tissues and parenchymatous organs. Massive infections, which rarely lead to lethal cases, are believed to be associated with ingestion of gravid females of *Armillifer* spp. (Ette et al. 2003). Even though they occur frequently in some areas of West and Central Africa, human infections are usually asymptomatic and are diagnosed incidentally by X-ray, ultrasonography, or autopsy (Tappe et al. 2014). Indeed, postmortem prevalence in humans may be up to 23% in Central Africa and 40% in SA Asia (Burns-Cox et al. 1969). On the other hand, *R. hemidactyli* was reported as a potential causative agent of "creeping disease" in humans from Asia, probably due to *larva migrans* dwelling in the subcutaneous tissue (Dollfus and Canet 1954). This infection was associated to the consumption of raw meat of lizards. However, the ingestion of reptile secretions and feces may represent another transmission route of pentastomids to humans (Mendoza-Roldan et al. 2020).

32.5 Conclusions

Reptile-associated zoonotic diseases have historically received little attention. Although salmonellosis, pentastomiasis, and sparganosis are among the main zoonotic diseases, the role of reptiles as reservoirs and hosts of zoonotic pathogens, mainly for vector-borne diseases (VBDs), has not been fully elucidated.

Furthermore, the recent COVID-19 pandemic has highlighted the risk that anthropic pressures may exert on wild-animal populations, resulting in the emergence of new zoonotic diseases. Certainly, studies focusing on monitoring reptile-borne pathogens are advocated, in order to elucidate the origin of introduced parasites and the role of reptiles as definitive, intermediate, and paratenic hosts in non-endemic areas. This could contribute to reduce the risk of zoonotic transmission and, at the same time, improve welfare and conservation efforts for these cold-blooded animals.

Wild Birds and Zoonotic Pathogens

33

Beware of the Fowl Feces

Nadine A. Vogt

Contents

Abstract

Wild birds are an extraordinarily diverse group of species that occupy a variety of ecological niches. Concerns about the ability of birds to transmit pathogenic organisms have arisen, mainly due to their ability to fly and travel long distances, as well as their tendency to gather and travel in flocks. This chapter will address the most relevant zoonotic agents and related public health risks associated with wild birds, including *Salmonella*, *Campylobacter*, *Chlamydophila psittaci*, and *Escherichia coli*, as well as agents for which wild birds may act as a reservoir species (e.g., West Nile virus), and zoonoses that may be acquired from direct exposure to or handling of wild birds (e.g., mites, ticks). Bacterial, viral, fungal, and parasitic zoonoses with a minor, theoretical, or potential emerging risk of infection will also be briefly discussed (e.g., avian influenza).

33.1 Introduction

An estimated 10,000 different species of birds inhabit the earth (Li and Jiang 2014). With the sheer number and diversity of species that exist, wild birds have adapted to a vast number of ecological niches, and at least one species from the avian kingdom can be found on every continent. The diversity of biological adaptations exhibited by wild birds is impressive, with specializations in vision, smell, speed, and, most importantly, flight (Caspermeyer 2016; Laguë 2017; Ponitz et al. 2014; Potier et al. 2020). Birds (even flightless ones) have hollow bones, feathers, and a unique respiratory system without dead space that allows them to take in oxygen during inspiration as well as expiration. These, along with other physical adaptations, allow birds to migrate exceedingly long distances (Hedenström 2008). In fact, the artic tern (*Sterna paradisaea*) performs a record total migration of approximately 50,000 km every single year, from the Artic to the Antarctic pole (Alerstam et al. 2019). Birds-of-paradise are exotic and colorful birds with incredible displays of courtship that are found in New Guinea and its surrounding islands, and are yet another sight to behold (Irestedt et al. 2009). Members of the Psittacidae family (parrots) also exhibit marked diversity in their coloration and appearance, and certain species have the unique ability to learn and mimic human language, to communicate with us on our own terms (Colbert-White et al. 2011). Birds of prey, or raptors, have particularly specialized adaptations for hunting, with exceptional vision two to five times better than humans (Guzman-Pando and Chacon-Murguia 2021), allowing them to maintain a visual target in a diving stoop at speeds the fastest of any living creature on earth, achieving over 300 km/h for the peregrine falcon (*Falco peregrinus*) (Ponitz et al. 2014; Tucker 1998). Another raptor, the vulture, performs Mother Nature's garbage disposal and is renowned for its ability to consume rotting flesh without any adverse effects and, interestingly, can also safely consume animals that have succumbed to anthrax, botulism, and other infectious diseases (Chung et al. 2015; Zepeda Mendoza et al. 2018).

33.2 Wild Birds in Human History

In addition to their roles in the ecosystem as pollinators, food sources, and agents of seed dispersal and pest control, birds have long been valued in practical, cultural, and religious contexts across the world, throughout human history. Nearly every country has its own recognized national bird, many of these chosen carefully for their

symbolic value. Owls are widely recognized as a symbol of wisdom and knowledge, eagles symbolize royalty and power, and the peacock is used as a symbol of protection against evil spirits in Indigenous cultures. The dove is the ultimate symbol of peace, innocence, and purity. Birds have also appeared in classic folklore and mythology to convey important cultural messages, such as that of renewal and rebirth, as with the immortal phoenix which cyclically dies in a burst of flames and regenerates from its own ashes. Birds have also served practical purposes in human culture, as with pigeon post, the ancient art of falconry, the ancient Japanese tradition of cormorant fishing (i.e., birds trained to retrieve fish) (Kurihara et al. 2020), and the infamous honeyguides, which are a species of African bird that are purportedly self-trained to guide humans to wild beehives (Spottiswoode et al. 2016). Wild birds have been hunted by humans, both for sport and as a source of food, and, in some cases, they have been overhunted and are now gone forever, as with the passenger pigeon (*Ectopistes migratorius*) (Horns and Şekercioğlu 2018). For certain cultures, the use of falconry birds to hunt other animals is a 2000-year-old tradition; the Mongolian rite of passage for young boys involves using golden eagles (*Aquila chrysaetos*) on horseback to take down and capture other apex predators such as foxes and wolves (Bolat 2016). Finally, wild birds are relied upon for more somber purposes in Buddhist sky burial practices in China, Tibet, Mongolia, Bhutan, and surrounding regions, in which the bodies of the deceased are prepared for consumption by vultures; this practice has deep spiritual meaning and significance, but also averts the practical challenges of performing burials or cremations in high-altitude areas which are above the tree line and have permafrost (Lu et al. 2009).

33.3 Public Health Impacts of Wild Birds

Wild birds are widely regarded as sentinels of environmental pollution, since they are often the first class of animal species to show signs of illness from toxins (e.g., DDT or dichloro-diphenyl-trichloroethane, Teflon™), hence the expression, "canary in the coal mine" (Espín and Sánchez-Virosta 2021; Golden and Rattner 2003). Conversely, there is an emerging body of evidence that suggests wild birds may be an important source of pathogenic organisms that cause illness in people (Bengis et al. 2004; Hamer et al. 2012; Sauvala et al. 2021). Over 50 different bacterial pathogens have been isolated from a diversity of wild bird species, including *Salmonella*, *Campylobacter*, *Chlamydophila psittaci*, *Clostridioides difficile* (formerly *Clostridium difficile*), and *Pseudomonas* (Chung et al. 2018; Greig et al. 2015; Rodrigues et al. 2021; Sevilla et al. 2020; Stokes et al. 2021). In some cases, it remains unclear whether wild birds are acting primarily as sentinels of environmental contamination with these pathogenic organisms, or if birds play a more substantial role in the transmission and dissemination of these agents within the environment (Smith et al. 2020). Challenges with sampling of wild birds further complicate the study of potential zoonotic risks posed by birds; most research sampling of wild birds (and indeed, other wildlife as well) is opportunistic, often resulting in limited sample sizes with limited generalizability to the general

population of wild birds being sampled (Vogt et al. 2020; Wobeser 2007). It appears, however, that the prevalence of a given pathogen in a certain bird species can vary greatly depending on the geographic region and season of sampling, as well as access to features of the local environment (e.g., sewage, landfills) (Broman et al. 2002; Chung et al. 2018; Girdwood et al. 1985; Hald et al. 2016; Ito et al. 1988; Kapperud and Rosef 1983; Kirk et al. 2002; Vogt et al. 2019).

In certain cases, identical strains of pathogenic organisms identified in human outbreak cases and in wild birds were also epidemiologically linked (Alley et al. 2002; Collins et al. 2019; Kwan et al. 2014). With the advent of newer, high-resolution typing methods using genomic data, the presence of identical strains in wild birds and humans is consistent with transmission events (Collins et al. 2019; Ford et al. 2019; Söderlund et al. 2019), but, overall, the evidence for a causal relationship for many pathogens remains circumstantial, as the direction of potential transmission between wild birds and humans is difficult to ascertain (Tsiodras et al. 2008). Nonetheless, the increasing burden of human illness due to enteropathogenic organisms of unidentified origin (e.g., *Salmonella*, *Campylobacter*) has prompted researchers to increasingly examine wild birds as a potential source of these particular zoonoses (Fonseca et al. 2020; Lynch et al. 2009). For other zoonoses, such as Lyme disease (caused by the *Borrelia burgdorferi* sensu *lato* species complex) or West Nile virus, wild birds represent a known reservoir species and may thus pose an indirect risk to human health in the presence of competent vector species (Chancey et al. 2015; Newman et al. 2015). Most people rarely come into direct contact with wild birds or wild bird specimens (except for those involved in bird-banding activities or wildlife rehabilitation); thus, it believed that the risk of transmission of most zoonotic diseases from birds to humans is primarily through indirect transmission, via exposure to contaminated, shared environments (Tsiodras et al. 2008). Fungal and bacterial diseases such as histoplasmosis and "parrot fever" (caused by *Chlamydophila psittaci*) may be acquired from wild birds through inhalation of aerosolized particles (Andersen and Vanrompay 2000; Deepe Jr. 2018). Zoonotic diseases acquired through direct contact (i.e., ticks, mites, *Erysipelas*) likely only represent a risk to those who regularly handle wild birds (Tsiodras et al. 2008). The many theoretical environmental pathways of transmission are complex and the major known and suspected routes are illustrated in Fig. 1. The gregarious nature and ability of certain bird species to produce copious amounts of fecal material, as starlings (*Sturnus vulgaris*) do, may contribute to environmental contamination with pathogens harbored by wild birds, particularly in agricultural contexts (Clark 2014). In these types of contexts, wild birds may directly contribute to the burden of infection/colonization of pathogens among livestock species (e.g., cattle, poultry), with potential downstream implications for human health (Cabe 2021; Clark 2014; Hald et al. 2016). In general, the species of wild birds most likely to contribute to environmental contamination are those which are often found in large numbers in urban areas shared by humans and wildlife, especially aquatic environments (Clark 2014; Minette 1986). As such, waterfowl, pigeons, and certain passerine (i.e., songbird) species have been the focus of much research investigating zoonotic disease risks associated with wild birds (Tsiodras et al. 2008).

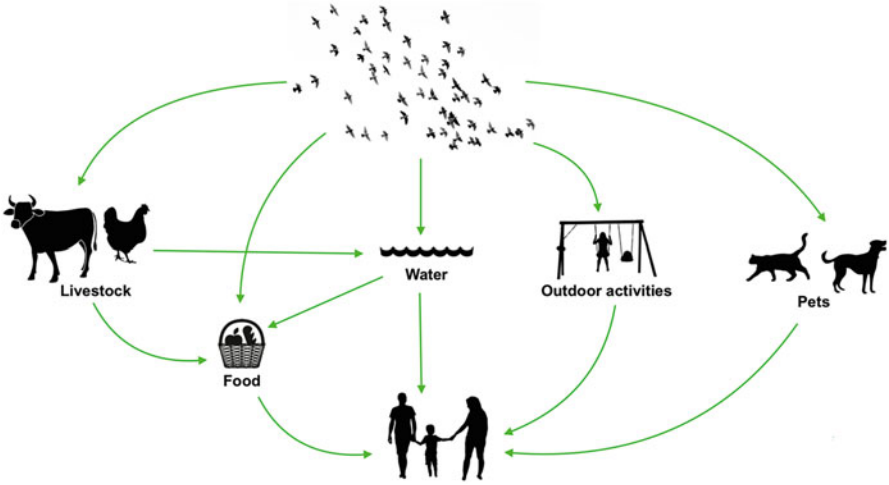

Fig. 1 Major known and suspected pathways for indirect feco-oral transmission of major bacterial pathogens (*Salmonella*, *Campylobacter*, *Escherichia coli*) from wild birds to humans

The following section will focus on zoonoses believed to have a major impact on human health (i.e., *Salmonella*, *Campylobacter*, *Escherichia coli*, *Chlamydophila psittaci*), for which wild birds are known reservoirs (i.e., West Nile virus, *Borrelia* spp.), or which may be acquired through direct contact with wild birds (i.e., mites, ticks). Bacterial, viral, fungal, and parasitic zoonoses with a minor, theoretical, or potential emerging risk of infection will also be briefly discussed (e.g., avian influenza, *Cryptococcus*, *Sarcocystis*). Although wild birds may contribute to the transmission and dissemination of antimicrobial resistance (Greig et al. 2015), this particular topic will not be addressed in this chapter.

33.4 The Usual Suspects

33.4.1 *Salmonella*

33.4.1.1 The Pathogen

Salmonella is a genus of Gram-negative rod-shaped bacteria belonging to the Enterobacteriaceae family of organisms. *Salmonella* are broadly divided into two major groups, referred to as typhoidal *Salmonella* (human-human transmission only) and non-typhoidal *Salmonella* (animal-human transmission). Over 2500 serovars of non-typhoidal *Salmonella* have been identified, which are determined based on the presence of H and O surface antigens. Certain serovars are host-adapted and rarely cause serious disease in their host species, but are likely to cause clinical illness in another species. Infection with non-typhoidal *Salmonella* typically results in mild gastrointestinal illness, but the immunocompromised, the elderly, and the young are

more likely to suffer serious, and potentially life-threatening, infections. Some individual animals and humans maintain a persistent carrier state and actively shed *Salmonella* in their feces, without suffering from any overt signs of clinical illness.

33.4.1.2 Epidemiology in Birds and Humans

The focus of this section will be on non-typhoidal *Salmonella* (i.e., *Salmonella enterica* subsp. *enterica*), henceforth *Salmonella*, and its relevance to humans and wild birds. *Salmonella* is responsible for a major global burden of illness in humans across the world. A recent global estimate suggests that *Salmonella* infections result in nearly 94 million cases and 155,000 deaths every year (Majowicz et al. 2010). *Salmonella* is considered an endemic disease that is predominantly acquired through the consumption of contaminated food or water, although outbreaks often occur as well. The serovars most commonly implicated in human illness are *S.* Typhimurium and *S.* Enteritidis, but a diversity of serovars have been implicated from a variety of food and animal sources (e.g., *S.* Heidelberg, *S.* Infantis, *S.* Enteritidis). The predominant serovars causing illness in humans vary by country and continent and can change over time. Most recently, *S.* Newport has emerged as a major cause of human illness worldwide (Elbediwi et al. 2020).

It appears that certain strains of *Salmonella* are specifically adapted to wild birds (most commonly *S.* Typhimurium) and rarely affect other animal species or humans. Mass mortality events related to *Salmonella* and wild birds (particularly songbirds, in association with garden bird feeders) have been recorded all over the world, beginning in the 1950s (Mather et al. 2016). The scale of these mortality events can be massive, with one study recording a total of 11,888 individual birds affected (Hall and Saito 2008). The overall burden of these mortality events on bird populations is unknown; although some suggest rapid recovery of populations following such events, there is some evidence that the frequency of mortality events is continuing to increase every year (12% annual increase in the United States over a 20-year period) (Hall and Saito 2008). Mortality events associated with bird feeders typically peak between January and April, reflecting the stress of cold winter months and low food availability, along with high densities of different bird species and poor hygiene at feeders that facilitate feco-oral transmission of *Salmonella*. Most commonly, pine siskins (*Spinus pinus*), American goldfinches (*Spinus tristis*), northern cardinals (*Cardinalis cardinalis*), house sparrows (*Passer domesticus*), and greenfinches (*Chloris chloris*) are affected, but other species from the orders Piciformes (e.g., woodpeckers) and Columbiformes (e.g., pigeons) have also been affected (Hall and Saito 2008). Despite widespread documentation of salmonellosis affecting birds at bird feeding stations, a recent study examining over 200 bird feeders during the winter months in both urban and rural settings in Poland failed to recover any *Salmonella* (Frątczak et al. 2021), highlighting the variability in the geographic occurrence of this organism in wild bird populations. Overall, the prevalence of *Salmonella* among different wild bird species ranging from waterfowl to passerines and gulls is typically less than 5% (Andrés et al. 2013; Dos Santos et al. 2020; Navarro-Gonzalez et al. 2020), but the prevalence is variable and can be as high as 20–60% (Feare et al. 1999; Martín-Maldonado et al. 2019), depending on factors

such as bird species and diet, geographic region, season, and proximity to anthropogenic sources (i.e., landfills, sewage) (Benskin et al. 2009; Vogt et al. 2020). One recent study comparing wild and captive Andean condors (*Vultur gryphus*) in Argentina only recovered *Salmonella* in the captive condors (with a prevalence of 2.8% ($n = 2/71$) and not in wild condors ($n = 0\%$, $n = 0/56$) (Wiemeyer et al. 2021).

Currently available evidence suggests that wild birds represent a reservoir of *Salmonella* for a small proportion of all human *Salmonella* cases (Lawson et al. 2014), with the majority being attributable to livestock sources and food sources such as raw or undercooked eggs (Thorns 2000). One study comparing the molecular epidemiology of wild bird-associated *Salmonella* strains using PFGE (pulsed-field gel electrophoresis) found that human cases with these strains mirrored the seasonal peak and spatial occurrence in wild birds in England between 1993 and 2012 (Lawson et al. 2014). Additional cases of human outbreaks of *Salmonella* linked to wild birds have been documented over the past several decades (Kapperud et al. 1998; Nesse et al. 2005; Penfold et al. 1979; Thornley et al. 2003). More recently, the use of highly discriminatory methods using whole-genome sequencing data and phylogenetics has revealed highly similar or indistinguishable *Salmonella* strains in wild birds and sporadic human cases or outbreaks of disease (Bloomfield et al. 2017; Collins et al. 2019; Ford et al. 2019; Fu et al. 2022; Mather et al. 2016; Söderlund et al. 2019). Case-control studies have also identified contact with wild birds as a potential risk factor for human *Salmonella* cases (Collins et al. 2019; Ford et al. 2019). Together, these findings provide compelling, but not definitive, evidence of wild birds as a potential source of *Salmonella* for humans, since the directionality of potential transmission has not yet been firmly established.

Wild birds are also thought to play a role in the dissemination and introduction of virulent strains of *Salmonella* into new geographic regions, due to their ability to travel and migrate long distances. Another major suspected route of indirect transmission of *Salmonella* from wild birds to humans is the contamination of water by aquatic bird species (Khalefa et al. 2021), and use of water for recreational purposes by humans, or irrigation of crops that are later consumed raw or lightly cooked (Fig. 1). There is evidence from Australia and Sweden that companion animals may also bridge the gap between wild birds and humans, particularly with outdoor cats that hunt weakened, ill songbirds that are infected with *Salmonella*, potentially causing salmonellosis in cats, colloquially known as "songbird fever" (Simpson et al. 2018; Söderlund et al. 2019). Based on an assessment of phage types and serotypes of almost 40,000 *Salmonella* isolates from livestock and nearly 800 wild bird carcasses in Great Britain, there appears to be minimal transmission (<1% overlap) between livestock and wild birds in Great Britain (Pennycott et al. 2006).

33.4.1.3 Disease in Birds

Most birds infected with *Salmonella* are asymptomatic carriers and do not become clinically ill. All bird species have the potential to become infected and clinically ill in the presence of predisposing factors (starvation, cold weather, high population densities), host susceptibility factors (stress, poor immunity, and young birds,

in particular), and *Salmonella* strain virulence. Affected birds may appear blind (due to neurological dysfunction), disoriented, and unable to fly, with ruffled feathers and increased respiratory rates. Birds that are clinically affected typically do not survive.

33.4.1.4 Disease in Humans

Salmonella infection in humans typically results in a mild gastroenteric illness (i.e., vomiting, diarrhea) lasting under 24 hours. Immunocompromised individuals and the young and elderly are particularly vulnerable to *Salmonella* and may suffer more serious consequences of infection, including systemic, multi-organ illness resulting from bloodborne infections (i.e., septicemia) that can result in hospitalization or fatality, depending on where the infection seeds in the body (Al Kaabi et al. 2021).

33.4.1.5 Public Health Importance

The overall burden of *Salmonella* in humans that is attributable to wild birds is currently unknown since the indirect transmission pathways are so difficult to characterize, namely, the interaction of wild birds with environmental reservoirs and sources, companion animals, and livestock (Fig. 1). As a result of these many possible routes of transmission and the considerable global burden of salmonellosis from foodborne sources (Fatica and Schneider 2011), it is plausible that *Salmonella* contributes to one of the greatest burdens of disease in people, among the various zoonoses transmitted from wild birds to humans. Evidence from case-control studies assessing indirect contact with wild birds as a risk factor for human *Salmonella* infections is not conclusive; one study found an increased odds of exposure among cases compared to controls (odds ratio: 6.9, 95% confidence interval: 2.3–21.0; Collins et al. 2019), but another failed to find an association (MacDonald et al. 2018).

33.4.1.6 Public Health Measures

The most common and likely route of direct and indirect transmission is feco-oral; thus, good hygiene is most useful in the prevention of salmonellosis. Although discouraging domestic cats from hunting wild birds by placement of a bell on their collar is likely to be of some benefit, the most effective preventive measure for this disease is to clean bird feeders frequently (every 2 weeks), using gloves, especially during the cold winter months. In general, it is recommended to avoid overfeeding wild birds and creating an unhealthy reliance on anthropogenic food sources, especially for food items that are not biologically appropriate, which may contribute to poor nutrition (e.g., bread). In warmer months, children and adults should avoid submerging their heads in shallow beach water that may be contaminated with feces from waterfowl and gulls. Those working in wildlife rehabilitation or conducting bird-banding activities should practice good hygiene (i.e., handwashing) after handling birds and before consuming food. The risk from handling wild birds is generally low, however, since mechanical transmission from feathers, feet, or the oral cavity does not appear to be a major mode of transmission (Navarro-Gonzalez et al. 2020).

33.4.2 *Campylobacter*

33.4.2.1 The Pathogen

Campylobacter is a genus of Gram-negative spiral organisms that require specific conditions in order to replicate; they are microaerophilic, meaning they require low oxygen (~5% O_2) conditions in order to grow. *Campylobacter* are also referred as "thermophilic," since they grow best at temperatures between 40 and 42 °C and will not replicate below temperatures of 30 °C; if they are exposed to temperatures below this, they may enter a state of senescence, or inactivation, where they do not replicate, but may still cause infections in humans and animals. Due to their fastidious nature and specific growth needs, *Campylobacter* can be difficult to culture, but there is no consensus about which culture method is optimal (Jokinen et al. 2012; Vaz et al. 2014). It is clear, however, that delays in processing of samples can result in the death of the organism and false-negative test results. *Campylobacter* undergo high rates of recombination and have high genetic diversity; thus, historical typing methods such as PFGE are being superseded by novel typing methods like the 40-locus binary typing scheme (i.e., comparative genomic fingerprinting) developed by Taboada et al. (2012), and high-resolution typing methods based on sequencing data (Llarena et al. 2017). *Campylobacter* is considered a commensal organism of the gastrointestinal tract of birds, since colonization is common (likely due to the higher body temperature of birds, as compared to mammals), and the vast majority of infected birds are clinically healthy. Infection with *Campylobacter* typically causes mild gastrointestinal illness in people. *Campylobacter jejuni* is by far the most common species identified in humans, with *Campylobacter coli*, *Campylobacter lari*, and other *Campylobacter* species occurring at a lower prevalence (Man 2011).

33.4.2.2 Epidemiology in Birds and Humans

Campylobacteriosis has been documented as the leading cause of foodborne illness in many countries around the world (Man 2011). *Campylobacter* infections in people typically occur as sporadic events, but outbreaks do occur, often in relation to untreated water and consumption of undercooked poultry products. It is believed that the human burden of illness due to *Campylobacter* is systematically underestimated due to the presentation of sporadic cases, typically self-limiting illnesses, and the nature of passive surveillance programs (Thomas et al. 2013). A seasonal pattern in the incidence of human *Campylobacter* cases has been widely documented, with the greatest number of cases occurring during the summer months. It has been hypothesized that this pattern is related to increased human exposures to potential sources of *Campylobacter* during warmer months and during outdoor activities (e.g., swimming) and picnics and the ability of the organism to replicate in warmer temperatures.

Campylobacter has been isolated from a wide variety of wild bird species. Prevalence estimates are highly variable, ranging from 0% to 93% (Kürekci et al. 2021; Lillehaug et al. 2005). The occurrence of *Campylobacter* is likely related to a host of factors, including the species of interest, feeding habitats and the ecological niche occupied, migration patterns, flock size, season, and geographic region of sampling

(Benskin et al. 2009; Vogt et al. 2020). Birds such as crows and gulls that frequent landfills and that live in close proximity to livestock and domestic animals are often found with a higher prevalence of microorganisms, including *Campylobacter* (Hald et al. 2016; Ito et al. 1988; Whelan et al. 1988). Even birds that exploit the same food resources (e.g., all bird species which feed on insects) may vary in their carriage of *Campylobacter*, as demonstrated by Waldenström et al. (2002), who demonstrated differences in the prevalence of this organism among ground-foraging insectivores (20.3%, $n = 14/69$), arboreal insectivores (0.6%, $n = 3/464$), and aerial insectivores (0%, $n = 0/42$). Seasonal peaks in the carriage of *Campylobacter* have been documented in spring and fall seasons, but the timing of peak prevalence is not always consistent and likely depends on a host of factors, such as bird species and behavior, health status, and feeding habits, among others (Broman et al. 2002; Taff et al. 2016; Vogt et al. 2020; Waldenström et al. 2002). Migration and larger flock sizes promoting inter- and intra-species mingling during colder seasons are thought to increase the risk of feco-oral transmission and contribute to *Campylobacter* infection, in addition to increased survival of *Campylobacter* in cooler temperatures (Moriarty et al. 2012).

There is some evidence suggesting that the carriage of less common *Campylobacter* species by wild birds is affected by exposures to this organism in their immediate environment. For instance, *Campylobacter coli* is rarely isolated from wild birds but is commonly isolated from pigs; two reports document an association with this species of *Campylobacter* and wild birds sampled near swine farms or swine manure (Hald et al. 2016; Vogt et al. 2019). Similarly, the occurrence of *Campylobacter lari* in predominantly marine bird species such as gulls might be related to the common occurrence of this species of *Campylobacter* in shellfish and aquatic environments (Motarjemi and Adams 2006; Waldenström et al. 2002). Further research is needed to clarify whether the presence of *Campylobacter lari* in aquatic environments is predominantly driven by marine birds or if it originates primarily from food sources and exposures in this environment.

Due to the fastidious nature of *Campylobacter*, which is prone to destruction by UV radiation and desiccation, the type of sample used is a fundamental consideration in the interpretation of prevalence estimates and risk assessments of wild birds. One study comparing the utility of fecal samples from Bonelli's eaglets (*Aquila fasciata*) with cloacal swabs did not recover any *Campylobacter* from dried fecal samples in the nest, but cloacal swabs from the same nestlings yielded a prevalence of 11% (95% CI: 4–24%) (Martín-Maldonado et al. 2019). Another comparison of different sampling techniques from a number of wild duck species found that the isolation of *Campylobacter jejuni* was significantly greater in cecal specimens compared to cloacal swabs (Luechtefeld et al. 1980).

Campylobacter is typically acquired through indirect feco-oral transmission of the organism from animal feces to humans, via contaminated food or water, or accidental exposure during outdoor activities (Fig. 1). Wild and domestic birds, livestock, and pets are considered major reservoirs of *Campylobacter*. The following have been identified as risk factors for human infection: consumption of raw or undercooked poultry, consumption of unpasteurized milk, exposure to untreated water, animal contact (livestock, pets), and outdoor activities (e.g., open water

swimming) (Cody et al. 2019; Lévesque et al. 2013; Rukambile et al. 2019). Not all human infections result in clinical illness. Children, due to their tendency of hand-to-mouth behavior, are thought to be at a higher risk of *Campylobacter* infection from environmental sources of animal fecal material, including playgrounds (French et al. 2009). The immunocompromised and the elderly are also at a greater risk of infection with *Campylobacter*. Several human outbreaks have specifically been linked to wild birds, including the consumption of milk from bottles with bird-pecked tops (Riordan et al. 1993) and raw peas that were contaminated with fecal material from sandhill cranes (Gardner et al. 2011; Kwan et al. 2014). Overall, these scenarios appear to be exceedingly rare, and the contribution of wild birds to the human burden of *Campylobacter* appears to be minor (<5% of human cases), based on a body of work, including a systematic review, comparing bird isolates to human clinical cases using multi-locus sequence typing (MLST) (Cody et al. 2015, 2019; Kovanen et al. 2019; Lévesque et al. 2013; Mäesaar et al. 2020; Marotta et al. 2020). A recent study comparing whole-genome sequencing data from wild bird isolates along with other animal and human sources in the Netherlands also demonstrated that wild birds contributed 0.4% (95% CI: 0.0–1.0%) to human cases (Mughini-Gras et al. 2021). Additional source attribution studies incorporating genomic data are needed to confirm these preliminary findings.

A major challenge with quantifying the contribution of wild birds to human *Campylobacter* cases, however, is the multitude of complex transmission pathways that exist (Fig. 1). The interaction of wild birds with poultry, livestock, and pets (other known reservoirs of *Campylobacter*) represents an unquantified pathway of transmission and amplification of the organism. Phylogenetic analyses of *Campylobacter* carried by wild birds have consistently demonstrated the presence of wild bird-specific strains that have rarely, or never, been recovered from humans or domestic animals (Aksomaitiene et al. 2019; Griekspoor et al. 2015; Kovanen et al. 2019; Weis et al. 2016). It is still unclear whether these strains have the potential to induce clinical illness in people or if they are generally nonpathogenic. These wild bird strains often make up the majority of *Campylobacter* strains found in waterways and rivers (Mughini-Gras et al. 2016; Mulder et al. 2020; Shrestha et al. 2019). In addition, wild birds have been shown to carry "generalist" *Campylobacter* strains found in a variety of animal sources and previously documented in human cases of clinical illness (Aksomaitiene et al. 2019; Hepworth et al. 2011; Weis et al. 2016). Based on these findings, it appears that wild birds represent a biological vector for transmission and dissemination of known pathogenic *Campylobacter* strains from other sources, but determination of the pathogenicity of host-adapted wild bird *Campylobacter* strains is needed.

33.4.2.3 Disease in Birds

Campylobacter is considered a commensal organism of all species of birds. Unlike *Salmonella*, *Campylobacter* has rarely been documented in association with clinical illness in wild birds. Although outbreaks of enteritis in domestic poultry have been attributed to *Campylobacter*, overt illness in wild birds has not been documented – only poor body condition – which could impact long-term survival (Taff and Townsend 2017; Waldenström et al. 2010). In one assessment, *Campylobacter*

infection did not affect the body condition, fledging success, or survival of American crow (*Corvus brachyrhynchos*) nestlings (Taff and Townsend 2017).

33.4.2.4 Disease in Humans

The majority of *Campylobacter* infections in people result in self-limiting gastrointestinal illness (e.g., vomiting, diarrhea), but a small proportion of cases (<1%) result in serious, long-term sequelae such as Guillain-Barré syndrome (Allos 2001). Additional medical conditions have been documented in association with *Campylobacter*, but a causal link has not yet been established for these conditions: esophageal cancer, colorectal cancer, irritable bowel syndrome, and Barrett's esophagus (Igwaran and Okoh 2019).

33.4.2.5 Public Health Importance

According to the World Health Organization, *Campylobacter* is the most common cause of bacterial enteritis across the world, and it is estimated to cause between 400 and 500 million infections every year (Igwaran and Okoh 2019). Unfortunately, despite a large body of evidence documenting the carriage of *Campylobacter* by a wide variety of wild bird species, their contribution to human cases remains unclear, since major research gaps regarding the pathogenicity of wild bird strains of *Campylobacter* remain, and assessment of potential spillover from wild birds to humans requires modeling of the entire transmission pathway and not only prevalence assessments (Smith et al. 2020).

33.4.2.6 Public Health Measures

Since consumption of poultry and poultry products accounts for the vast majority of *Campylobacter* infections in people, the most important measure to avoid infection is to ensure these products are properly cooked and stored and avoiding cross-contamination during meal preparation. Game meat (domestic and wild) is also considered a potential source of *Campylobacter* (Seguino et al. 2018); thus, hygienic meat handling measures also apply. Washing of fruits and vegetables prior to consumption, especially for those consumed raw, is important, since *Campylobacter jejuni* can survive up to 8 days on unwashed produce (Newell et al. 2016). Handwashing and good hygiene is recommended after handling of poultry, livestock, and pets and following outdoor activities in areas where wild birds are commonly found (e.g., parks). As with *Salmonella*, children should avoid submerging their heads underwater in shallow water that is also frequented by wild birds, and practice good hygiene after playing outdoors, including playground areas. Ensuring drinking water is treated is also recommended.

33.4.3 *Escherichia coli*

33.4.3.1 The Pathogen

Escherichia coli belong to a genus of Gram-negative, facultative anaerobic, rod-shaped bacteria. They comprise the normal microflora of the gastrointestinal

tract of mammals and birds, and most strains are harmless. In immunocompromised people, or when normal gastrointestinal barriers have been breached, commensal *E. coli* are capable of producing disease in the host. A subset of *E. coli* strains are considered pathogenic, even in healthy individuals. Pathogenic *E. coli* are phylogenetically distinct from commensal *E. coli* and typically possess a variety of virulence genes and mechanisms that allow them to cause disease in the intestinal tract or survive in different niches outside of the gastrointestinal tract (i.e., extraintestinal pathogenic *E. coli*). Pathogenic *E. coli* are characterized by different pathotypes, depending where in the body they produce disease, and the typical clinical disease they produce: **e**ntero**p**athogenic ***E. coli*** (EPEC), **e**ntero**h**emorrhagic ***E. coli*** (EHEC), and **u**ro**p**athogenic ***E. coli*** (UPEC). Classification of these different pathotypes is complex, and details are covered elsewhere (Kaper et al. 2004), involving a combination of virulence traits, genetic differences, and serotyping (e.g., O, H, and K antigens). Birds, especially domestic poultry, are susceptible to clinical illness as a result of infection with **a**vian **p**athogenic ***E. coli*** (APEC), but most wild birds colonized or infected with these *E. coli* do not exhibit any signs of clinical illness. In addition to APEC, this section will focus on major groups of pathogenic *E. coli* affecting humans that have been well-researched in wild birds, including **S**higa **t**oxin-producing ***E. coli*** (STEC, also known as **v**ero**t**oxin-producing ***E. coli***; VTEC) and EPEC, as well as lesser-examined pathogenic *E. coli*, like UPEC.

33.4.3.2 Epidemiology in Birds and Humans

Worldwide, *E. coli* are the most common agent causing urinary tract infections; an estimated 130–175 million human urinary tract infections occur every year, with 80% caused by UPEC strains (Russo and Johnson 2003). Women are more frequently affected by UPEC, and commensal *E. coli* (non-UPEC strains) can also be the cause of these infections. Rarely, urinary tract infections progress to kidney infection (pyelonephritis) and result in kidney failure and possibly death. EPEC strains are among the leading causes of diarrhea across the world and are predominantly associated with children (Alonso et al. 2017). In developed countries, EPEC is occasionally responsible for outbreaks in pediatric wards and day care centers. A considerable proportion of childhood diarrhea in developing countries is attributed to EPEC, and in some countries, outbreaks have resulted in mortality rates as high as 30% (Senerwa et al. 1989).

Shiga toxin-producing *E. coli* (STEC, also known as VTEC) are the predominant cause of bloody diarrhea in humans, and serotype O157:H7 is the most important and well-known STEC strain in North America, United Kingdom, and Japan, but other serotypes have also been identified (e.g., O26, O111), and more than 400 O:H types of STEC are associated with human infections (Alonso et al. 2017; Kaper et al. 2004). Children are particularly vulnerable to STEC infections, and the infection can progress to hemolytic uremic syndrome and may result in acute kidney failure and possibly death. STEC infections are the leading cause of hemolytic uremic syndrome in humans. Many serogroups have been associated with HUS outbreaks in people, including O26, O45, O103, O111, O121, and O145 (Kuehne et al. 2016). The major pathogenicity factor of STEC is Shiga toxin, or Shiga-like toxin (verocytotoxin),

conferred by genes *stx*$_1$, *stx*$_2$, and others (Kobayashi et al. 2009). Humans can acquire STEC from other infected humans, domestic animals (including livestock and pets), contaminated drinking water, or foodborne exposures (e.g., undercooked meats, contaminated produce). Cattle are considered the main reservoir of STEC, but wildlife, including wild birds and wild mammals, have been shown to carry pathogenic *E. coli*, including STEC (Espinosa et al. 2018).

Avian pathogenic *E. coli* (APEC) are considered a bird-adapted pathotype of *E. coli* and frequently colonize and infect domestic and wild birds without causing any clinical illness. APEC is particularly known for causing outbreaks in domestic poultry worldwide, with considerable mortality rates (~20%) and significant economic losses for the poultry industry (Bélanger et al. 2011). Also known as avian colibacillosis, APEC causes a variety of infections in birds, including systemic illnesses (e.g., septicemia, air sacculitis, death) and local syndromes (e.g., cellulitis). Although not all APEC are zoonotic, a subset of these pathotypes has been documented to cause illness in people; worldwide, O_2 is one of the serogroups most associated with zoonotic APEC strains (Moulin-Schouleur et al. 2007). Less is known about the epidemiology of APEC in wild birds, since this pathotype is rarely associated with clinical illness in wild birds, and the zoonotic potential of most APEC strains is suspected, but not confirmed (Jørgensen et al. 2019).

Virulence-associated genes (VAGs) found in various *E. coli* pathotypes have consistently been identified among wild bird populations. Unfortunately, the presence of such virulence genes alone does not confirm pathogenicity of *E. coli* strains, as further testing is typically required, and, oftentimes, the identification of VAGs in wild birds represents a preliminary scan for potentially harmful *E. coli* (Knöbl et al. 2011). In some cases, the presence of certain VAGs is often used to imply pathogenicity, such as with Shiga toxin genes (e.g., *stx*$_1$, *stx*$_2$), but not all STEC strains possessing these genes are pathogenic to humans, and additional genes are often required for cellular invasion (e.g., *eae*). Nonetheless, the characterization of potentially pathogenic *E. coli* in wild birds provides an important first step in assessing potential zoonotic risk from these species.

The overall prevalence of STEC in wild birds likely varies due to factors discussed in the previous sections (e.g., bird species, geographic region), but prevalences between 0% and 1% are commonly found (Alonso et al. 2017; Bolton et al. 2012; Borges et al. 2017; Gaukler et al. 2009; Sanches et al. 2017). Several studies of feral pigeons (*Columba livia domestica*) and certain setting of wild birds, such as wildlife rehabilitation centers, have demonstrated higher prevalences of STEC, between 10% and 15% (Morabito et al. 2001; Russo et al. 2021; Schmidt et al. 2000). A meta-analysis of studies examining the prevalence of STEC among North American breeding bird species reported an overall prevalence of 20% (±6.3% standard error; $n = 9185$ individuals, 36 studies) (Smith et al. 2020). Studies characterizing the probable pathogenicity of *E. coli* from wild birds based on their phylogroup (i.e., A, B1, B2, D) have documented the presence of both pathogenic and nonpathogenic strains in wild birds, and their occurrence appears to be species-dependent (Borges et al. 2017; Kuczkowski et al. 2016; Oh et al. 2011; Rybak et al. 2022). There is some research to suggest that wild birds in captivity are more likely to carry pathogenic *E. coli* or virulence genes than free-living wild birds (Blyton

et al. 2015; Díaz-Sánchez et al. 2012). There is limited available literature regarding the prevalence of other *E. coli* pathotypes, but, like STEC, it appears that the prevalence of EPEC among wild birds is also highly variable (2–70%) (Borges et al. 2017; Oh et al. 2011; Sanches et al. 2017).

Transmission of pathogenic *E. coli* (VTEC/STEC) between wild birds and livestock in farm environments is likely, based on overlap in strains determined using molecular typing (e.g., PFGE, single-nucleotide polymorphisms) (Navarro-Gonzalez et al. 2020; Nielsen et al. 2004; Rapp et al. 2021), serotyping (Fahim et al. 2019), and studies of experimental infection and transmission (Kauffman and LeJeune 2011). Exchange between cattle and starlings is thought to be common, since these livestock species are often housed with access to the outdoors, and wild birds often congregate in large numbers in barns and defecate near or onto animal feed, facilitating feco-oral transmission of the organism to cattle. In contrast with wild birds, however, the prevalence of STEC in cattle has been shown to be several orders of magnitude larger; one study of wild birds and cattle in California assessed the prevalence in cattle to range from 4.5% to 65%, depending on the season, whereas the prevalence in birds in the same study was $<1\%$ for all STEC strains (both O157 and non-O157) (Navarro-Gonzalez et al. 2020). There is some evidence supporting zoonotic transmission of pathogenic *E. coli* between wild birds and humans for APEC strains, based on serotyping (Kobayashi et al. 2009) and sequence typing (Handrova and Kmet 2019; Johnson et al. 2008). Recent assessments using comparative genomics are suggestive of inter-species transmission of pathogenic *E. coli* between humans, wild birds, dogs, and environmental sources (e.g., water) for sequence type 131 (a UPEC strain) (Li et al. 2021) and sequence type 410 (Schaufler et al. 2016). Concerns about migration and long-distance dissemination of pathogenic *E. coli* clones by wild birds are substantiated in part by the identification of a sequence type 131 O25 of human origin in wild birds living on a remote Russian island lacking human presence (Hernandez et al. 2010). Conversely, it should not be assumed that wild birds necessarily are a major driver of human infections with certain pathogenic *E. coli*; recent work addressing gaps about whether feral pigeons are responsible for human STEC infections (specifically related to the stx_{2f} gene) using a whole-genome MLST scheme demonstrated no overlap between pigeon and human strains (van Hoek et al. 2019).

33.4.3.3 Disease in Birds

Outbreaks of mortality related to *E. coli* have rarely been documented in wild birds, but in some instances, these outbreaks been associated with bird feeders, similar to *Salmonella* (Pennycott et al. 2002). *E. coli* infections in wild birds have also been associated with enteritis and diarrhea, caused by pathotypes such as EPEC or ETEC. More commonly, *E. coli* are responsible for opportunistic infections in domestic birds, often resulting from host stress, poor hygiene (e.g., APEC in poultry), or hypovitaminosis A (especially in parrots). Affected birds may exhibit depression, fever, yellowish/greenish droppings, and localized (e.g., cellulitis) or generalized infections (e.g., septicemia, air sacculitis, death). Clinically healthy wild birds have been demonstrated to carry *E. coli* that are considered pathogenic to humans.

33.4.3.4 Disease in Humans

Depending on the pathotype, clinical signs of *E. coli* infection in people are variable. As discussed above, two general syndromes occur: intestinal disease and extra-intestinal disease (e.g., meningitis, urinary tract infections). The severity of these infections can vary depending on host factors (e.g., stress, immune status), and pathogenic *E. coli* cause illness in immunocompetent individuals. A subset of STEC cause bloody diarrhea (e.g., *E. coli* O157:H7) and are more likely to result in complications in children and the elderly, the most important of which is hemolytic uremic syndrome, which can result in acute renal failure and death.

33.4.3.5 Public Health Importance

The degree to which wild birds contribute to the human burden of *E. coli* illness is complicated by the difficulties in determining whether *E. coli* isolated from wild birds are pathogenic or nonpathogenic, since there is no single gold standard test for determination of pathogenicity status (Knöbl et al. 2011). In addition, *E. coli* are often considered secondary invaders; thus, the pathogenicity of an *E. coli* strain may depend on host factors (e.g., stress) and environmental factors (e.g., hygiene), as well as the location of infection. The bulk of existing research in wild birds currently assesses only a subset of *E. coli* known to be pathogenic to humans (predominantly STEC), but other pathotypes may also cause disease in people. In particular, the zoonotic potential of APEC found in wild birds merits further research. Nonetheless, the identification of similar or identical strains of *E. coli* in wild birds, human clinical cases, other animals, and environmental samples using comparative genomics offers some evidence of zoonotic transmission (Li et al. 2021; Schaufler et al. 2016).

33.4.3.6 Public Health Measures

Similar to other agents of foodborne illness discussed above, practicing good hygiene and careful preparation and cooking of food are important for the prevention of exposure to pathogenic *E. coli.* Similarly, treatment of drinking water is recommended. Due to its extremely low infectious dose (<100 cells) (Kaper et al. 2004) and ability to persist for several weeks in water and in outdoor environments (McGee et al. 2002), caution is recommended regarding recreational activities in water during the summertime. Avoiding ingestion of untreated water or underwater submersion in outdoor recreational areas close to agricultural regions following heavy precipitation is advised. Although *E. coli* have rarely been recovered from the exterior of wild birds (i.e., feet and feathers) (Navarro-Gonzalez et al. 2020), the route of transmission is generally feco-oral; thus, handling of wild birds is not considered a high-risk activity for transmission of this organism, but good hygiene (i.e., handwashing) should always be practiced.

33.4.4 *Chlamydophila psittaci*

33.4.4.1 The Pathogen

Chlamydophila psittaci (formerly *Chlamydia psittaci*) is a Gram-negative, obligate intracellular bacterium for which birds are considered a major reservoir, but this organism is also present in domestic and wild mammalian species (Perez-

Martinez and Storz 1985). This organism is the causative agent of the rare, but important, zoonotic disease known as psittacosis, or "parrot fever" in humans. It was originally believed that only parrots transmitted this organism, but it has since been determined that over 450 bird species can carry *C. psittaci* (Sukon et al. 2021), including domestic poultry (chickens and turkeys), and the preferred name for the disease in humans is now "ornithosis." Ornithosis results in an atypical pneumonia in some people, but most infected people remain asymptomatic (Harkinezhad et al. 2009). Similarly, birds can remain asymptomatic with *C. psittaci* infection, but they can also develop severe, systemic respiratory illness (avian chlamydiosis).

33.4.4.2 Epidemiology in Birds and Humans

Human cases of ornithosis are distributed worldwide and typically occur as sporadic cases, although outbreaks have been reported in association with poultry processing plants (Hinton et al. 1993). Additional outbreaks have been reported in communities (Williams et al. 1998) and in association with the handling of an injured wild bird in a veterinary clinic (Branley et al. 2008). This disease can be a difficult one to diagnose, due to a lack of sensitive and specific testing methods and limited awareness of this rare zoonotic disease (Chaber et al. 2021). Most human cases of ornithosis are self-limiting, while others require hospitalization, but infections rarely cause death. Ornithosis usually presents as an atypical pneumonia that is unresponsive to conventional treatments. Although ornithosis has typically been described as an occupational risk for those working with wild and domestic birds (e.g., pet store employees, bird-banders, zookeepers, poultry workers), the risk factors for infection with *C. psittaci* appear to differ from the risk factors for clinical illness due to *C. psittaci*. Contact with birds (particularly parrots and pigeons) is a well-recognized risk factor for exposure to *C. psittaci* (Harkinezhad et al. 2009), but this factor is poorly predictive of whether someone will develop ornithosis; thus, additional research is needed to clarify what additional factors need to be present for the development of clinical disease (Olsen et al. 1998; Williams et al. 1998).

Like other pathogenic bacterial agents, the prevalence of *C. psittaci* varies by geographic region and host species (Stokes et al. 2020). One study of the genetic variability of *C. psittaci* among pigeon in different regions of Switzerland based on MLST found distinct sequence types in different areas, suggesting limited exchange of the organism between different pigeon populations (Mattmann et al. 2019). Prevalences between 0% and 95% of *C. psittaci* have been recorded in a wide range of bird species (Prukner-Radovcić et al. 2005; Stokes et al. 2021). In addition to parrots, pigeons and other birds of the order Columbiformes are generally considered to be major reservoirs of this organism (Bracewell and Bevan 1986). Most infected wild birds are asymptomatic carriers, but some persistently infected individuals can shed the organism in their feces intermittently or develop clinical illness during periods of stress (e.g., breeding, migration) (European Commission 2002). Outbreaks of avian chlamydiosis have been documented in wild birds (Franson and Pearson 1995; Grimes et al. 1966), but the frequency of these events appears to be on the decline (Andersen and Vanrompay

2000), along with evidence of decreasing prevalence of *C. psittaci* infections among pigeons in Slovenia over a 13-year period (Dovč et al. 2004).

A total of nine genotypes of *C. psittaci* have been identified, which are considered host specific: genotype B in pigeons, genotype A in psittacines, genotype M56 in rodents (Liu et al. 2019). There is some evidence that certain *C. psittaci* strains are not zoonotic or do not readily infect non-host species; Johnson and Grimes (1983) demonstrated that *C. psittaci* originating from ruminants does not infect wild birds, and Olsen et al. (1998) found that strains carried by wild songbirds (passerines) are rarely infectious to humans. Further research is needed to clarify the significance of *C. psittaci* in wild birds and their zoonotic potential. Additional research is also needed to confirm findings of higher prevalences of *C. psittaci* infection among wild or domestic birds in captivity versus those that are free-living in natural environments (Amery-Gale et al. 2020; Liu et al. 2019; Soon et al. 2021). However, challenges with diagnosis of this disease/infection also apply to birds, due to a lack of sensitive and specific testing methods (Luján-Vega et al. 2018) and intermittent shedding of the organism by persistently infected birds. Thus, it is recommended to obtain multiple samples from birds (e.g., pharyngeal swabs, cloacal swabs, and fecal samples) to ensure maximum testing sensitivity.

33.4.4.3 Disease in Birds

The majority of birds remain asymptomatic with *C. psittaci* infection, but it is believed that periods of stress can result in individuals progressing to clinical disease. Signs of infection include respiratory signs, conjunctivitis, purulent rhinitis, yellow-green droppings, polyuria, and lethargy. Particularly among domestic fowl, outbreaks may result in high morbidity and mortality (Sachse et al. 2015), but outbreaks are rare among wild bird populations.

33.4.4.4 Disease in Humans

Ornithosis typically presents as a flu-like illness, often with the following clinical signs: fever, malaise, headache, myalgia, and chills. People may or may not experience a dry cough. Disease may progress to pneumonia. Ornithosis is rarely fatal.

33.4.4.5 Public Health Importance

Overall, ornithosis is considered a rare disease in humans, in spite of probable underreporting of mild cases and missed diagnoses. It has been estimated that 1% of community-acquired pneumonia is caused by *C. psittaci* (Hogerwerf et al. 2017). However, since severe cases require prompt antimicrobial treatment, obtaining an accurate diagnosis using multiple tests (e.g., culture, serology, PCR) is paramount to the reduction of morbidity and mortality in affected people (Vande Weygaerde et al. 2018).

33.4.4.6 Public Health Measures

Transmission of *C. psittaci* is typically through inhalation of dust containing the organism or via ingestion of contaminated material (fecal material, secretions). The organism has been shown to survive in feces and bedding for up to 30 days (Sachse et al. 2015); thus, cleaning and disinfection are very important to remove the

environmental burden of *C. psittaci* among birds in captivity (including wild birds). Ensuring good ventilation and lowering the humidity of indoor environments housing birds will also help to decrease the risk of transmission, as will the use of personal protective equipment while cleaning bird mews. People who often work in close contact with wild or domestic birds are at increased risk of infection, but not necessarily clinical illness (Olsen et al. 1998; Williams et al. 1998), but good hygiene measures and frequent handwashing for those handling and in close contact with birds are still recommended. Most importantly, an awareness of this disease is likely to be most useful for those in occupations with frequent contact with birds, should they become ill, so that they can flag this disease for their attending physician, if necessary. Human-to-human transmission is rare; thus, quarantine or isolation of affected individuals is not indicated.

33.5 Ectoparasites of Wild Birds with Zoonotic Risks

Wild birds may also be carriers of mites and ticks that possess zoonotic potential. Mites such as the poultry red mite (*Dermanyssus gallinae*) have been found on wild birds and are capable of causing a rash in humans, often on the legs (George et al. 2015). *Ixodes* spp. ticks (hard ticks) can sometimes be found parasitizing wild birds and are competent vectors of Lyme disease, caused by the *Borrelia burgdorferi s.l.* species complex. Wild mammals such as deer and mice are considered the major wildlife reservoirs of *Borrelia* spp., but wild birds represent another competent reservoir of these organisms. Following the bite of an infected tick, many people initially experience a flu-like illness with a bull's-eye rash (erythema migrans) at the site of the tick bite and later progress to arthritis with swelling of the joints, cardiac signs, nerve pain, headaches, and chronic fatigue (Steere et al. 1998). Diagnosis and treatment of Lyme disease in humans is challenging; thus, prevention of exposure to infected ticks is considered key. Tick checks and prompt removal (including the head and mouth parts of the tick) following contact with wild birds are recommended, since it generally takes >24 hours for transmission of *Borrelia* spp. to occur (Hojgaard et al. 2008).

33.6 Wild Birds as Reservoirs of Viral Diseases

A number of viral diseases affect wild birds, including reportable diseases such as Newcastle disease virus. The two major viruses highlighted in this section represent viruses for which wild birds are a significant reservoir and may or may not cause clinical disease in people, but they pose a real or theoretical risk due to their widespread, global distribution among wild bird populations.

33.6.1 West Nile Virus

West Nile virus is a member of the *Flavivirus* genus. Avian species represent a major reservoir of these viruses, for which mosquitoes (primarily *Culex* spp.) are required

for transmission to humans and horses, both of which are considered dead-end hosts (no viral replication occurs). Raptors (hawks, owls) and corvid species (crows, ravens, jays) are particularly susceptible to infection with West Nile virus (Nemeth et al. 2007). Following the initial introduction to the virus to various parts of the world in recent decades, widespread mortality was observed in wild bird populations (Habarugira et al. 2020). Characteristic neurological signs in affected birds include head tilt, tremors, loss of coordination, weakness, convulsions, and possibly death. Overall, there is evidence of population recovery in many, but not all, bird species (Kilpatrick and Wheeler 2019). Most people infected with West Nile virus experience a mild, flu-like illness that is self-limiting. Other people, especially immunocompromised individuals, are more likely to suffer serious effects, such as meningitis, encephalitis, optic neuritis, or paresis.

33.6.2 Avian Influenza Virus

Avian influenza belongs to the Orthomyxoviridae family of viruses. There are three classes of avian influenza viruses, A, B, and C; the most important type in the context of zoonoses are type A viruses. These viruses can infect both humans and birds, but they are considered a disease of birds, not humans, and the disease is thus colloquially referred to as the "bird flu." Wild birds are considered a reservoir of these viruses and have the potential to introduce new strains over long distances due to their migratory capabilities. Avian influenza viruses have a high propensity for rapid genetic mutation, and there is a concern that strains of these viruses can suddenly develop into highly pathogenic strains (Stephenson and Democratis 2006). Highly pathogenic avian influenza virus subtype H5N1 has caused outbreaks in both people and domestic fowl in many parts of the world since the zoonotic strain was first detected in 1997 (Stephenson and Democratis 2006). Evidence of transmission between poultry and humans exists, but the risk of transmission from wild birds to humans remains theoretical (Koopmans et al. 2004; Tsiodras et al. 2008). Clinical signs of infection in people and birds are typical of influenza viruses, including respiratory signs, keratoconjunctivitis, fever, and diarrhea. Some cases may progress to more serious, potentially life-threatening illness, such as encephalitis.

33.7 Zoonoses of Wild Birds with Minor, Theoretical, or Unknown Risks

A variety of bacterial, fungal, and parasitic pathogens have been isolated from wild birds, including, but not limited to, *Yersinia* spp., *Listeria monocytogenes*, *Cryptosporidium* spp., *Cryptococcus neoformans*, *Histoplasma capsulatum*, and *Mycobacterium avium* (avian tuberculosis) (Kozdrun et al. 2015; Tsiodras et al. 2008). For some of these pathogens, it appears that immunosuppression is a major risk factor for disease (*M. avium*, *C. neoformans*, *H. capsulatum*), along with exposure to soil contaminated with bird or bat droppings (*C. neoformans*, *H. capsulatum*). For other

organisms, it is unclear whether wild birds are drivers of disease transmission or if they primarily act as sentinels of environmental contamination from other primary sources (e.g., livestock); thus, further research using high-resolution molecular typing methods is needed to clarify what role birds play in the transmission of these pathogens to humans.

Botulism is another disease of wild birds that is responsible for die-offs that can number into the hundreds of individual birds (Lima et al. 2020). The bioaccumulation of the botulism toxin in the food chain, from algae to fish, and then to fish-eating birds, causes paralysis of respiratory muscles and, ultimately, death. The toxin produced by *Clostridium botulinum*, the causative bacterial agent, is also capable of causing serious illness in people and their pets (i.e., life-threatening paralysis), following ingestion of contaminated material (i.e., affected deceased birds or fish containing the botulinum toxin).

Hunters should be aware of *Sarcocystis* spp. parasitic organisms that appear as small grains of rice in the breast meat of affected birds (usually waterfowl); although cooking the meat destroys the parasite, rendering it inactive, it is recommended to discard meat containing large cysts (Costanzo 1990).

Abstract

Bats are increasingly implicated as hosts of zoonotic and potentially zoonotic pathogens. As a whole, chiropterans now represent the largest known reservoir of emerging viruses (Calisher et al. 2006; Wong et al. 2007). Among the 60 viral species currently associated with bats, 59 are RNA viruses of importance in the current generation of emerging and reemerging human infections (Wong et al. 2007). Lyssaviruses, paramyxoviruses, filoviruses, and coronaviruses are among viral those pathogens impacting the health and well-being of both people and nonhuman animals around the globe. In comparison to the studies conducted on viral infections, much less attention has been paid to the nonviral pathogens of zoonotic importance within bat populations (Frick et al. 2010; Reichard and Kunz 2009; Van Brussel and Holmes 2021). This is changing, however, as more research is now being conducted to detect and describe bacteria ranging from vector-borne to enteric pathogens, as well as protozoan parasites, and fungal agents in a variety of bat hosts. This chapter focuses on zoonotic pathogens that bats can harbor and potentially transmit to humans.

Zoonoses · Bats · Chiropters

34.1 Introduction

Bats are increasingly implicated as hosts of zoonotic and potentially zoonotic pathogens. As a whole, chiropterans now represent the largest known reservoir of emerging viruses (Calisher et al. 2006; Wong et al. 2007). Among the 60 viral species currently associated with bats, 59 are RNA viruses of importance in the current generation of emerging and reemerging human infections (Wong et al. 2007). Lyssaviruses, paramyxoviruses, filoviruses, and coronaviruses are among those pathogens impacting the health and well-being of both people and nonhuman animals around the globe. In comparison to the studies conducted on viral infections, much less attention has been paid to the nonviral pathogens of zoonotic importance within bat populations (Frick et al. 2010; Reichard and Kunz 2009; Van Brussel and

Holmes 2021). This is changing, however, as more research is now being conducted to detect and describe bacteria ranging from vector-borne to enteric pathogens, as well as protozoan parasites, and fungal agents in a variety of bat hosts.

The many emerging infectious diseases associated with chiropteran species can have major impacts on both ecosystem and public health (Calisher et al. 2006; Mühldorfer 2013; Wibbelt et al. 2010; Wood et al. 2012). As such, the scope of this chapter is to provide an overview of those potential bat-related zoonoses and their clinical relevance to people. With increased disease surveillance and a trend toward more human contact with bat populations, it is likely that additional zoonotic diseases will continue to be identified. Bat infection dynamics are driven by a complex interplay of ecological, immunological, behavioral, and anthropogenic factors (Hayman et al. 2013). Interdisciplinary work will be needed in the future to better understand the drivers of disease emergence in bat populations and ultimately mitigate the threats that face both people and bats themselves.

34.2 Viral Zoonoses

34.2.1 Rhabdoviridae

34.2.1.1 Rabies and Rabies-Related Viruses

Among bat-associated viral zoonoses, rabies (RABV) is certainly one of the most widespread in a broad range of bat species and around the world, with several new lyssaviruses identified in recent years. In several countries considered to be free of terrestrial rabies, rabid bats and human cases of bat-associated rabies have been identified in the last decades, such as in Australia where three human cases have occurred and in the United Kingdom, with one human case in Scotland (Banyard et al. 2011; Fooks et al. 2003). In Latin America, more human rabies cases are now related to bat exposure (especially vampire bats) than to dog bites (Condori-Condori et al. 2013). There are 19 known Lyssaviruses identified, 17 of them being present in bats: Aravan, Australian, Bokeloh, Duvenhage, European bat 1 and bat 2, Gannoruwa, Irkut, Khujand, Kotalathi, Lagos bat, Lleida, Malto, rabies, Shimoni, Taiwan, and West Caucasian (Fooks et al. 2021; Van Brussel and Holmes 2021).

Although the opportunity for lyssavirus cross-species transmission seems rare, adaptation in a new host and the possibility of onward transmission to humans require continued investigation (Fooks et al. 2021). Host switching of RABV from bats appears to be more frequent in the Americas, while events involving other Old World (Africa, Europe, and Asia, or Afro-Eurasia) lyssaviruses appear to be rare (Fooks et al. 2021).

In Latin America, a review of the literature through 1990 reported 330 cases of bat-transmitted human rabies (Schneider et al. 2009). These cases, along with PAHO data to the end of 2006, revealed 637 reported cases of bat-transmitted human rabies in Latin America. Of 199 human cases transmitted by bats during the period 1996–2006, 146 (73%) were transmitted by vampire bats, 16 (8%) by nonvampire

bats, and 37 (19%) with no species reported (Schneider et al. 2009). Between 2009 and 2018, 70% (134) of the 192 human cases reported in South America were related to bat exposure, mainly vampire bats, especially in Peru (Meske et al. 2021). For instance, in Peru, during 2002–2007, 293 (77%) of the rabies cases diagnosed were associated with vampire bats, whereas 87 (23%) were related to dog rabies virus variants (Condori-Condori et al. 2013). It was also shown that vampire bat rabies variants spread gradually and involve different vampire bat subpopulations with different transmission cycles. Bovine paralysis caused by rabid vampire bat bites also has a major economic impact on cattle production in Mexico and several South American countries (Streicker et al. 2012). Emergence of rabies in insectivorous bats in several countries in Latin America (such as Argentina, Brazil, Chile, Peru, and Uruguay) has also been reported.

A study took advantage of recent outbreaks of vampire bat rabies among livestock in the Sao Paulo region of Brazil to test whether seroprevalence in *D. rotundus* reflects the incidence of rabies in nearby livestock populations (Megid et al. 2021). Sixty-four *D. rotundus* were captured during and after outbreaks from roost located in municipalities belonging to three regions with different incidences of rabies in herbivores. Sixteen seropositive bats were then kept in captivity for up to 120 days, and their antibodies and virus levels were quantified at different time points using the rapid fluorescent focus inhibition test (RFFIT). Antibody titers were associated with the occurrence of an ongoing outbreak, with a higher proportion of bats showing titer >0.5 IU/ml in the region with a recent outbreak. However, low antibody titers were still detected in bats from regions not reporting a rabies outbreak for the last 3 years prior to sampling. It clearly shows that serological surveillance of rabies in vampire bats can be used as a tool to evaluate the risk of outbreaks in cattle and human populations at risk.

Vaccination is the most effective measure to control rabies in cattle. Similarly, reduction of hematophagous bat populations, using anticoagulants, is a treatment that has also been used since the 1970s. However, this measure is temporary, and it destabilizes vampire populations, causing replacement of animals and consequently displacements of infectious foci (Benavides et al. 2020). Furthermore, using poisonous substances, such as anticoagulants, could affect beneficial animals such as scavengers or insectivores and frugivorous bats.

Since the 1990s, vaccination of bats against rabies has been considered as a useful tool by creating an immune barrier that prevents the spread of the virus, similar to what is done through oral rabies vaccination campaigns in foxes and raccoons (Aguilar-Sétien et al. 1998, 2002; Almeida et al. 2008). This concept has recently been reconsidered in several works (Cárdenas-Canales et al. 2020; Gilbert et al. 2020; Stading et al. 2017; Turmelle et al. 2010). This methodology would have the advantage of not using lethal procedures, while preventing the spread of virus.

In North America, rabies remains an important public health concern in the United States, with most human cases associated with bat rabies virus variants. Cases of rabies virus infection in bats are widely distributed across the continental United States (Patyk et al. 2012). Between 2001 and 2009, more than 205,439 bats were submitted for rabies virus diagnosis, and 6.7% of these bats were rabid. Increased odds of a submitted bat being rabid were associated with species that

exhibit inconspicuous roosting habits, bats originating in the Southwest, and bats submitted for diagnosis during the fall (Patyk et al. 2012). Between 2000 and 2020, 52 human rabies cases were reported in the USA, including 38 Indigenous cases of which 31 (82%) were bat related (Ma et al. 2021). Spillover from bat rabies variants to terrestrial mammals has also been reported (Leslie et al. 2006).

In Europe, bat rabies cases are principally attributed to two lyssaviruses, namely European bat lyssavirus-1 (EBLV-1) and European bat lyssavirus-2 (EBLV-2). Between 1977 and 2011, 961 cases of bat rabies were reported, with the vast majority (>97%) being attributed to EBLV-1, frequently isolated in The Netherlands, Northern Germany, Denmark, Poland, and also in parts of France and Spain (Schatz et al. 2013). At present (2021), 1338 cases have been reported (Rabies Bulletin Europe, accessed October 27, 2021). Most EBLV-2 isolates originated from the United Kingdom (UK) and The Netherlands, and EBLV-2 was also detected in Germany, Finland, and Switzerland. So far, there has been less than 50 cases of EBLV-2 detected in bats in Europe. Bat rabies due to EBLV-2 has been detected in Daubenton's bats (*Myotis daubentonii*) in Great Britain since 1996 (Folly et al. 2021). Across Europe, European bat lyssavirus 1 (EBLV-1) is commonly associated with serotine bats (*Eptesicus serotinus*) (Kohl et al. 2021). Despite the presence of serotine bats across large parts of southern England, EBLV-1 had not previously been detected in this population. However, in 2018, EBLV-1 was detected through passive surveillance in a serotine bat from Dorset, England. Subsequent EBLV-1-positive serotine bats have been identified in South-West England during 2018, 2019, and 2020 (Folly et al. 2021).

In addition, limited isolations of unique lyssaviruses from European insectivorous bats were reported in south-west Russia in 2002 (West Caucasian bat virus, WCBV), in Germany in 2010, and in France in 2012 (Bokeloh bat lyssavirus) (McElhinney et al. 2013; Picard-Meyer et al. 2013), and Lleida bat lyssavirus was identified in a bent-winged bat (*Miniopterus schreibersii*) in Spain (Aréchiga Ceballos et al. 2013). In June 2020, a cat from Arezzo (Italy) that died from a neurological disease was diagnosed with WCBV. The virus retained high identity across the whole-genome with the reference isolate found in 2002 from a Russian bent-winged bat (Leopardi et al. 2021). In a tunnel located near the cat's house, Leopardi et al. (2021) identified a group of bent-winged bats that showed virus-neutralizing antibodies to WCBV across four sampling occasions, but no virus in salivary swabs.

A few human cases related to bat exposure have also been reported from Europe. In Russia in 1985, only one other case of human encephalitis caused by this strain was confirmed, and two more cases of rabies were described in Finland in 1985 and in Scotland in 2002 caused by the EBLV-2 which killed two scientists specializing in bats research. Another bat-related case was also reported in 1977 from Ukraine, but the variant was not determined. The first human case of bat origin in France was reported in 2008 in French Guyana (Meynard et al. 2012). An autochthonous case was also reported in continental France in 2019. A man died of rabies in Limoges, in southwest central France, most probably after being bitten or scratched by a bat. The 59 year-old patient without specific past medical history died from encephalitis in August 2019. A colony of bats lived in an outbuilding of his house. No diagnosis

was made using standard procedures. When trying to identify the cause of this undocumented encephalitis, genetic analysis of postmortem samples showed that he had contracted a lyssavirus, European Bat Lyssavirus type 1 (EBLV-1) (Regnault et al. 2021). A human case caused by the Irkut virus was reported in 2007 from Far East Russia (Leonova et al. 2010).

In Africa, new lyssaviruses have been identified in bats, beside Lagos bat virus first isolated in Nigeria on Lagos Island in 1956 from African straw-colored fruit bat (*Eidolon helvum*) and Duvenhage virus first reported in 1970 in a human case in South Africa. Two more human cases of Duvenhage virus have occurred since then, one in 2006 when a man was scratched on the face by a bat and the last one in a Dutch woman who had visited a cave and had received two superficial wounds on the face from a bat in 2007 (Markotter et al. 1987). No human case caused by Lagos bat virus has been reported so far, but a few cases in cats ($n = 3$) and dogs ($n = 2$) have been reported from Africa (Coertse et al. 2021).

In Asia, limited reports on identification of lyssaviruses or antibodies to lyssaviruses have been published (Liu et al. 2013b). It is certainly a part of the world where new variants are likely to be identified in the near future, when better wildlife rabies surveillance will be set in this part of the world. Many aspects of the ecology of lyssaviruses in bats need still to be investigated, such as low prevalence of infection, potential survival to infection, and effective shedding of the virus. Recently a new Lyssavirus strain was identified as Taiwan bat Lyssavirus identifies in two Japanese pipistrelle bats (*Pipistrellus abramus*) in 2016 and 2017 (Hu et al. 2018). In Australia, three human cases of Australian bat lyssavirus have been identified, two in women rescuing flying foxes (1996, 1998) and one in a young boy who was infected in southern Australia (2013).

The incubation period of rabies in humans is typically 2–8 weeks but can be as short as 10 days and as long as 6 years. Initial signs include headache, slight fever, malaise, and pain at the bite wound. The disease, which lasts from 2 to 6 days without medical support, progresses to paralysis of the muscles of deglutition, hyperesthesia, and generalized convulsions. Death ensues shortly thereafter (Hoar et al. 1998). In bats, infection rate and mortality are usually low, although this has been studied in few species. Experimental studies in vampire bats indicate that a high viral load is necessary to induce mortality, with either no observable clinical signs or squeaking, tremor, paralysis, and loss of appetite (Aguilar-Setien et al. 2005). In cattle infected by vampire bats, rabies is mainly expressed by paralysis with a rather long incubation period (25 to 150 days or more) and lasts for 2 to 5 days before causing death (Hoar et al. 1998).

34.2.2 Paramyxoviridae: Henipaviruses

34.2.2.1 Hendra, Nipah, and Menangle Viruses

Several important zoonotic paramyxoviruses have been associated with animal and human deaths in Australasia since the end of the twentieth century. The henipaviruses are naturally harbored by Pteropid fruit bats (flying foxes) and some microbat species.

Hendra virus: In Australia, Hendra virus was first recognized in 1994 when 21 horses and two humans were infected, leading to the death of 13 horses and one human. As of December 2012, a total of 45 outbreaks of Hendra virus have occurred in north-eastern Australia, all involving infection of horses (Aljofan 2013). As a result of these events, more than 100 animals (105 horses and two dogs) in 63 natural spillover events have died or been euthanized by March 2021 (Annand et al. 2021). These cases have all occurred in Queensland and in northeast New South Wales. Case fatality rate in humans is 60% (4 of 7 recorded cases) and in horses 75%. Human infections with Hendra virus range from mild influenza-like illness to fatal respiratory or neurological disease. Infected people initially develop fever, headaches, myalgia (muscle pain), sore throat, and a dry cough. They could also have enlarged lymph nodes, lethargy, and vertigo. The incubation period ranges from 5 to 14 days. Hendra virus is transmitted to people through close contact with infected horses or their body fluids. To date, no human-to-human transmission of Hendra virus has been documented. No specific treatment is available, but a vaccine has been developed for immunization of horses and is available since the end of 2012. The following signs have all been associated with Hendra virus cases in horses, but not all these signs will be found in any one infected horse: rapid onset of illness, increased body temperature/fever and heart rate, discomfort/weight shifting between legs, depression, and rapid deterioration with either respiratory and/or nervous signs. Respiratory signs include respiratory distress, increased respiratory rates, and nasal discharge at death that can be initially clear until progressing to stable white froth and/or stable blood-stained froth. Nervous signs include wobbly gait, apparent loss of vision in one or both eyes, aimless walking in a dazed state, head tilting and circling, muscle twitching, urinary incontinence, and inability to rise. Horses get infected when very high concentrations of virus material are deposited directly under trees in what is call the "drip zone," and almost no virus is deposited once the horses leave the perimeter of the trees. This area of the trees where the spats and the urine of feeding flying foxes will be dropped potentially poses an extremely high risk for horses (Australian Veterinary Association: http://www.ava.com.au/hendra-virus). The natural reservoirs are the black flying fox (*Pteropus alecto*), the grey headed flying fox (*P. poliocephalus*), the spectacled flying fox (*P. conspicillatus*), and the little red flying fox (*P. scapulatus*) present in the urine and birthing fluids of these bats (Van Brussel and Holmes 2021). A new virus variant was recently identified (Annand et al. 2021; Wang et al. 2021). Since 2013, 98 flying foxes were tested and 11 were positive for the new HeV variant (Wang et al. 2021). No samples were positive for the original HeV. Ten of the positive samples were from grey-headed flying foxes (*Pteropus poliocephalus*); however, this species was overrepresented in the opportunistic sampling, as 83% of bats tested were *P. poliocephalus*.

Nipah virus (NiV): In Malaysia and Singapore, in late 1998 and early 1999 an outbreak of human disease characterized by febrile encephalitis among pig farmers, which appeared to be linked to cases of respiratory and neurological disease in commercially farmed pigs, was described as well as in 11 employees at a slaughter plant in Singapore (Aljofan 2013; Clayton et al. 2013). There were 265 patients, of

whom 105 died, reported as having NiV-induced viral encephalitis, mostly among adult males who were involved in pig farming or pork production activities. However, the reported number of patients who survived the acute NiV encephalitis was 160 with 7.5% prevalence of relapsed encephalitis (12/160 patients) more than 24 months after the outbreak. Of the 89 patients previously known to have non-encephalitic or asymptomatic Nipah virus infection, 3 (3.4%) developed late-onset encephalitis. Most patients presented with a severe acute encephalitic syndrome, but some also had significant pulmonary manifestations. The Malaysian outbreak was controlled by the culling of over one million pigs and strict quarantine measures on pig movements.

Nipah virus reemerged in 2001 in outbreaks of human disease in India and Bangladesh. Since 2001, outbreaks of NiV infection have occurred almost annually in Bangladesh, with many outbreaks featuring smaller clusters of cases (Clayton et al. 2013). A second outbreak in India, close to the Bangladesh border, was reported in 2007. Sequencing and genetic characterization of these isolates revealed that they were closely related to, but distinguishable from, the causative agent of disease in Malaysia. Since the emergence of NiV in Bangladesh and India, and an outbreak in the Philippines (meat consumption from sick horses) due to a virus closely related to the Nipah virus, at least 646 human cases have been identified, with an overall case fatality of (386/646) 59.7% (Hauser et al. 2021). Most cases are related to consumption of unwashed fruits or palm juice contaminated by fruit bats secretions (saliva, urine, and fecal materials). Outbreaks in Bangladesh and India were characterized by bat (*Pteropus medius*, the Indian flying fox)-to-human and human-to-human transmissions. *Pteropus* spp. serve as the wildlife reservoir for NiV across a wide area of South-east Asia, including countries from which no known outbreaks have emerged such as Cambodia, Thailand, Indonesia, and Papua New Guinea (Van Brussel and Holmes 2021). Seropositive bats for henipaviruses were also detected in Madagascar, Ghana, and a henipavirus, or henipa-like virus, also appears to circulate in both fruit bats and microbats in China (Clayton et al. 2013).

Menangle virus: The Menangle virus, another paramyxovirus, was first identified in 1997 after a piggery in Menangle (New South Wales) experienced a high number of stillbirths (Aljofan 2013; Hoar et al. 1998). Two workers at the piggery became ill with unexplained, flu-like symptoms but subsequently recovered. Investigations later found that the virus was transmitted from a nearby population of flying foxes, through pigs which act as a carrier of the virus. Bats appear to be an asymptomatic host, with infection caused through contact with body fluids of infected animals. Like for Hendra virus, the grey headed flying fox, the black flying fox, and the spectacled flying fox were identified as the likely reservoirs (Van Brussel and Holmes 2021).

New potentially zoonotic paramyxovirus: A novel morbillivirus from a vespertilionid bat species (*Myotis riparius*) in Brazil named myotis bat morbillivirus (MBaMV) was identified by metagenomics. MBaMV used *Myotis* spp. CD150 much better than human and dog CD150 in fusion assays, using live MBaMV that was rescued by reverse genetics. However, MBaMV replicated efficiently in primary human myeloid but not lymphoid cells, suggesting a potential zoonotic availability (Lee et al. 2021).

34.2.3 Filoviridae

34.2.3.1 Marburg and Ebola Viruses

Marburg virus: Marburg virus causes sporadic outbreaks of severe hemorrhagic disease in sub-Saharan Africa. Bats have been implicated as likely natural reservoir hosts based most recently on an investigation of cases among miners infected in 2007 at the Kitaka mine, Uganda, which contained a large population of Marburg virus-infected *Rousettus aegyptiacus* fruit bats (Amman et al. 2012).

In July and September 2007, miners working in Kitaka Cave, Uganda, were diagnosed with Marburg hemorrhagic fever. The likely source of infection in the cave was Egyptian fruit bats (*Rousettus aegyptiacus*) based on detection of Marburg virus RNA in 31/611 (5.1%) bats, virus-specific antibody in bat sera, and isolation of genetically diverse virus from bat tissues (Towner et al. 2009). The virus isolates were collected 9 months apart, demonstrating long-term virus circulation. The bat colony was estimated to be over 100,000 animals using mark and recapture methods, predicting the presence of over 5000 virus-infected bats. The genetically diverse virus genome sequences from bats and miners closely matched. These data indicate common Egyptian fruit bats can represent a major natural reservoir and source of Marburg virus with potential for spillover into humans.

A study conducted at Python Cave in Uganda, where an American and a Dutch tourist acquired Marburg virus infection in December 2007 and July 2008, found that about 2.5% of more than 1600 bats captured between August 2008 and November 2009 were actively infected with the virus, 7 of which yielded Marburg virus isolates (Amman et al. 2012). Moreover, Q-RT-PCR-positive lung, kidney, colon, and reproductive tissues were found, consistent with potential for oral, urine, fecal, or sexual transmission. The combined data for *R. aegyptiacus* tested from Python Cave and Kitaka mine indicate low-level horizontal transmission throughout the year. However, Q-RT-PCR data showed distinct pulses of virus infection in older juvenile bats (~6 months of age) that temporarily coincide with the peak twice-yearly birthing seasons. Retrospective analysis of historical human infections suspected to have been the result of discrete spillover events directly from nature found 83% (54/65) events occurred during these seasonal pulses in virus circulation, perhaps demonstrating periods of increased risk of human infection.

The incubation period ranges from 2 to 21 days, and the clinical outcome can be divided into three phases: initial generalized phase (day 1–4), early organ phase (day 5–13), and either a late organ or convalescence phase (day 13 onward). Pigott et al. (2015) reported ten natural outbreaks in Africa between 1975 and 2014, with three of them affecting more than ten people in Democratic Republic of Congo (Durba): 128 deaths out of 154 cases between October 1998 and August 2000; in Angola (Uige): 227 deaths out of 252 cases between October 2004 and July 2005; and in Uganda (Ibanda): 14 deaths out of 15 cases between August and October 2012.

Ebola virus: Evidence of Ebola virus antibodies was reported in various bat species in Africa (Pourrut et al. 2009) and of Ebola-Reston virus in *Rousettus amplexicaudatus* bats from the Philippines (Taniguchi et al. 2011). In Africa, 1030

animals were captured in Gabon and the Republic of Congo, including 679 bats, 222 birds, and 129 small terrestrial vertebrates, and were tested for evidence of infection by Ebola virus (Leroy et al. 2005). Of the infected animals identified during these field collections, immunoglobulin G (IgG) specific for Ebola virus was detected in serum from three different bat species (4/17 *Hypsignathus monstrosus*, 8/117 *Epomops franqueti,* and 4/58 *Myonycteris torquata*). Viral nucleotide sequences were detected in livers and spleens in other bats from the same populations (4/21, 5/117, and 4/141, respectively). No viral RNA was detected in kidney, heart, or lung in these animals after amplification by polymerase chain reaction (PCR), and no viral nucleotide sequences were revealed in any of the other animal species tested.

Twelve years after the Kikwit Ebola outbreak in 1995, Ebola virus reemerged in the Occidental Kasaï province of the Democratic Republic of Congo (DRC) between May and November 2007, affecting more than 260 humans and causing 186 deaths (Leroy et al. 2009). During the latter outbreak, several epidemiological investigations were conducted to identify the underlying ecological conditions and animal sources. Qualitative social and environmental data were collected through interviews with villagers and by direct observation (Leroy et al. 2009). The local populations reported no unusual morbidity or mortality among wild or domestic animals, but they described a massive annual fruit bat migration toward the southeast, up the Lulua River. Migrating bats settled in the outbreak area for several weeks, between April and May, nestling in the numerous fruit trees in Ndongo and Koumelele islands as well as in palm trees of a largely abandoned plantation. They were massively hunted by villagers, for whom they represented a major source of protein. By tracing back the initial human-to-human transmission events, it was shown that in May the putative first human victim bought freshly killed bats from hunters to eat. This study provided the most likely sequence of events linking a human Ebola outbreak to exposure to fruit bats, a putative virus reservoir. Such findings support the suspected role of bats in the natural cycle of Ebola virus and indicate that the massive seasonal fruit bat migrations should be considered in operational Ebola risk maps and seasonal alerts in the DRC (Leroy et al. 2009).

34.2.4 Coronaviridae

34.2.4.1 SARS- COVID19 and MERS-Coronaviruses

Severe acute respiratory syndrome (SARS) was first reported in February 2003 in China. When the World Health Organization declared the outbreak over on 5 July 2003, more than 8000 cases (and almost 800 fatal) had been reported in 32 countries worldwide (Field 2009; Wang et al. 2006). Initial symptoms are flu-like and may include fever, myalgia, lethargy symptoms, cough, sore throat, and other nonspecific symptoms, leading to sever pneumonia. The only symptom common to all patients appears to be a fever above 38 °C (100 °F). Shortness of breath may occur later.

A succession of phylogenetic and epidemiological findings suggested that SARS had a wildlife origin, and that “wet markets” in southern China were the origin of the

outbreak. Subsequently, two groups independently identified SARS-like coronaviruses (SARS-CoV) in species of bats in China. Li et al. (2005) reported serological and molecular evidence of a cluster of SARS-like coronaviruses in several species of free-living horseshoe bats (*Rhinolophus* spp., especially *R. sinicus*) in southern China. They contend that the virus responsible for the SARS outbreak in humans in 2003 emerged from this cluster of viruses, and that bats are the origin of the SARS coronavirus. *Rhinolophus* species are more likely to foster host shifts of coronaviruses than other bat species; this propensity, when combined with the potential for close contact between bats, civets, and humans in the wildlife trade in southern China, supports SARS-like coronaviruses as being the source of the SARS coronavirus (Field 2009; Van Brussel and Holmes 2021). The majority of the coronaviruses originated from African, Asian, and European bats (Corman et al. 2013). In addition to SARS-CoV, four human coronaviruses (HCoVs), termed HCoV-OC43, −229E, -NL63, and -HKU1, are known. Recently, a sixth HCoV was described, the MERS-CoV, which can cause coughing, fever, and pneumonia. This virus emerged in Saudi Arabia in 2012 and has been reported in some other Gulf States, France, Germany, Italy, Tunisia, Korea, and Britain [all cases to date can be epidemiologically linked to Saudi Arabia, Qatar, United Arab Emirates, and Jordan]. Since the disease was first identified in Saudi Arabia in April 2012, 2594 cases of Middle East respiratory syndrome coronavirus (MERS-CoV) have been detected in 27 countries of which 942 (36.3%) have died (ECD, as of October 4, 2024, consulted on October 27, 2021). Close relatives of this betacoronavirus termed MERS-CoV and of HCoV-229E exist in Old World bats, especially of the genus *Pipistrellus,* and HCoV-NL63 could be grown in immortalized bat cells, demonstrating the zoonotic potential of previously reservoir-bound bat CoVs (Van Brussel and Holmes 2021). The recent description of a bat CoV related to MERS-CoV in Mexican bats (Anthony et al. 2013) and in bats from Saudi Arabia (Memish et al. 2013) emphasized the relevance of investigating neotropical bats for CoVs.

SARS-CoV-2: This virus emerged in late 2019 in the city of Wuhan, Popular Republic of China. Several of the early cases of SARS-CoV-2 have been linked to the Huanan market in Wuhan, China. Given the SARS-CoV pandemic and the resulting increased interest in bat CoV, a bat CoV (RaTG13, 96.2% id) detected in *Rhinolophus affinis* in the Yunnan province was quickly identified as the closest relative. SARS-CoV and SARS-CoV-2 share 79.6% sequence identity only, although both viruses are using the ACE2 receptor for cell entry. The origin of this pandemic is still not clear, as suspicion of a bat origin is likely, but how it reached humans has not been validated. The lack of clarity from Chinese authorities about the first human cases cannot rule out a possible laboratory leak, as emergence from the Wuhan wet market cannot be proven nor confirmed. Five SARS-CoV-2-related coronaviruses have been identified in three *Rhinolophus* species (*R. malayanus*, *R. pusillus,* and *R. marshalli*) in Laos, with three of them that can bind to the human ACE2 receptor (Van Brussel and Holmes 2021).

It is so far the largest pandemic in recent history leading to several millions of deaths worldwide within less than 24 months. Several outbreaks were also reported in wild captive felids, in mink farms, and even in domestic carnivores (mainly cats and dogs) owned by people who got infected by the virus and likely were the source

of their pet infection (Haake et al. 2020). Experimentally, it has been demonstrated that SARS-CoV-2 replicates more efficiently in cats than in dogs and that cats can transmit the virus through aerosols. With approximately 470 million pet dogs and 370 million pet cats cohabitating with their human owners worldwide, the finding of natural SARS-CoV-2 infection in these household pets has important implications for potential zoonotic transmission events during the COVID-19 pandemic as well as future SARS-related outbreaks (Murphy and Ly 2021).

Identification of sequences of a group C betacoronavirus (β)-CoV in bat guano was recently reported (Wacharapluesadee et al. 2013). The detection of nucleic acid of this group C (β)-CoV and the previous isolation of viruses from bat feces and urine warrant some concerns that guano miners might be exposed to bat pathogens in fresh excreta as well as in soil substances. Therefore, bat guano miners should use preventive measures of personal hygiene and improved barrier protection to reduce the possibility of exposure to zoonotic pathogens.

34.2.5 Other Viral Pathogens

Many other viruses have been isolated or detected by molecular methods or by the presence of specific antibodies in bats, such as Hantaan virus in various bat species in Asia and Africa (Hance et al. 2006; Hoar et al. 1998; Wong et al. 2007), Japanese encephalitis virus in China (Liu et al. 2013a), Venezuelan equine encephalitis virus in vampire bats, and antibodies in bats from Guatemala (Hoar et al. 1998). In their review, Hoar et al. (1998) reported also detection of Chikungunya virus in African bats (*Scotophilus* sp.), Rio Bravo virus in Mexican free-tailed bats, and Rift valley fever virus in bats from the Republic of Guinea. In Europe, most viruses were found in Myotis spp., Pipistrellusspp., and Eptesicus spp. (Kohl et al. 2021).

In Uganda, four human cases of Kasokero virus isolated from *Rousettus aegyptiacus* bats living in the Kasokero cave occurred in laboratory workers (Kalunda et al. 1986). Infected laboratory workers had fever, headache, abdominal pain and diarrhea, sever myalgia, and arthralgia. Signs lasted 7 to 10 days and were followed by complete recovery. It was demonstrated that 67% of 74 bats from that cave were seropositive for Kasokero virus. Kyasanur virus has been isolated from bats in India, and the Vesicular Stomatitis Virus (New Jersey type), which causes flu-like symptoms in infected humans, has been isolated from bats in Panama and Guatemala (Hoar et al. 1998).

34.2.5.1 HepaDNAviruses, Hepatitis C-like and Hepatitis D (ex-Delta virus), and Bats

In recent years, several viruses related to human hepatitis viruses (Hepatitis A, Hepatitis B and D, Hepatitis C, and Hepatitis E) have been identified in bats as well as domestic animals (cats, dogs, and horses) (Bergner et al. 2021a; Drexler et al. 2012, 2013, 2015; Quan et al. 2013).

Hepatitis E virus (HEV) is one of the most common causes of acute hepatitis in tropical and temperate climates. Tropical genotypes 1 and 2 are associated with

foodborne and waterborne transmission. Zoonotic reservoirs (mainly pigs, wild boar, and deer) are considered for genotypes 3 and 4, which exist in temperate climates. In view of the association of several zoonotic viruses with bats, 3869 bat specimens from 85 different species and from five continents were analyzed for hepevirus RNA (Drexler et al. 2012). HEVs were detected in African, Central American, and European bats, forming a novel phylogenetic clade in the family Hepeviridae. Bat hepeviruses were highly diversified and comparable to human HEV in sequence variation. No evidence for the transmission of bat hepeviruses to humans was found in over 90,000 human blood donations and individual patient sera.

The hepatitis B virus (HBV), family Hepadnaviridae, is one of most relevant human pathogens. HBV origins are enigmatic, and no zoonotic reservoirs are known. Total 3080 specimens from 54 bat species representing 11 bat families were screened for hepadnaviral DNA (Drexel et al. 2013). Ten specimens (0.3%) from Panama and Gabon yielded unique hepadnaviruses in coancestral relation to HBV. Hepatic tropism in bats was shown by quantitative PCR and in situ hybridization. Infected livers showed histopathologic changes compatible with hepatitis. Human hepatocytes transfected with all three bat viruses cross-reacted with sera against the HBV core protein, concordant with the phylogenetic relatedness of these hepadnaviruses and HBV. Phylogenetic analyses carried out with generated virus sequences suggested that bat HBV was more closely related to primate HBV than to those of other mammalian orders (Bonvicino et al. 2014). These data suggest that bats may have been ancestral sources of primate hepadnaviruses.

Hepatitis delta virus (HDV) is an unusual RNA agent that replicates using host machinery but exploits hepatitis B virus (HBV) to mobilize its spread within and between hosts (Bergner et al. 2021a). In doing so, HDV enhances the virulence of HBV. Among 96,695 RNA sequence datasets, delta viruses were shown to infect bats, rodents, and an artiodactyl from the Americas but were absent from geographically overrepresented Old-World representatives of each mammalian order, suggesting a relatively recent diversification within the Americas (Bergner et al. 2021b). A field study also showed that common vampire bats (*Desmodus rotundus*) in Peru were infected by two divergent delta viruses, indicating multiple introductions into a single host species. One vampire bat-associated delta virus was detected in the saliva of up to 35% of individuals, formed phylogeographically compartmentalized clades, and infected a sympatric bat, illustrating horizontal transmission within and between species on ecological timescales (Bergner et al. 2021b). Consistent absence of HBV-like viruses in two delta virus-infected bat species indicated acquisitions of novel viral associations during the divergence of bat- and human-infecting delta viruses. Such data are supportive of an American zoonotic origin of HDV and reveal prospects for future cross-species emergence of delta viruses.

Hepatitis A: The hepatitis A virus (HAV) is a leading cause of acute viral hepatitis worldwide. It is transmitted mainly by direct contact with patients who have been infected or by ingesting contaminated water or food. The virus is endemic in low-income countries where sanitary and sociodemographic conditions are poor. Paradoxically, improving sanitary conditions in these countries, which reduces the incidence of HAV infections, can lead to more severe disease in susceptible adults.

The populations of developed countries are highly susceptible to HAV, and large outbreaks can occur when the virus is spread by globalization and by increased travel and movement of foodstuffs (Migueres et al. 2021). The existence of evolutionarily ancestral hepatoviruses in bats and shrews compared with the presence of more closely related viruses in rodents and primates is reminiscent of hantavirus host associations (Drexler et al. 2015). Of eight HAV-positive sera (7.3%), six were from West African *Eidolon helvum*, and one each from Central African *Rousettus aegyptiacus* and *Micropteropus pusillus* (Drexler et al. 2015).

34.3 Dengue (DENV) and Zika (ZIKV)

Bats are important natural reservoir hosts of a diverse range of viruses that can be transmitted to humans and have been suggested to be involved in the transmission cycle of Dengue (DEN) and Zika (ZIK) viruses. However, the exact role of bats in the epidemiology of Flaviviruses is still controversial.

34.3.1 Dengue Virus

The presence of antibodies against dengue virus (DENV) and/or viral RNA have led to the hypothesis that neotropical bats could have a potential role in the transmission cycles of DENV (Aguilar-Setién et al. 2008; de Thoisy et al. 2009; Machain-Williams et al. 2013; Sotomayor-Bonilla et al. 2014; Calderón et al. 2019, 2021). Considering some previous reports about the susceptibility of bats to DENV (Reagan and Brueckner 1952; Platt et al. 2000), the Aguilar-Setién group carried out a sampling of neotropical bats from DENV-endemic areas of the Pacific and Gulf coasts of Mexico, finding that out of 162 sampled bats of several species, 19 (12%) presented DENV antibodies (Aguilar-Setién et al. 2008). In this study, DENV serotype 2 was also detected by RT–PCR in four samples from three bat species: two frugivorous, *Artibeus jamaicensis* (2/9) and *Carollia brevicauda* (1/2), and one insectivorous, *Myotis nigricans* (1/11) (Aguilar-Setién et al. 2008). Supporting this finding, DENV RNA was reported in 14 species of neotropical bats sampled between 2001 and 2007 in French Guyana (de Thoisy et al. 2009). Other authors have also reported the presence of antibodies and/or RNA of DENV in bats from different countries in the Americas (Calderón et al. 2019, 2021; Machain-Williams et al. 2013; Sotomayor-Bonilla et al. 2014). Furthermore, an experimental infection of *Artibeus* bats with different viral loads of DENV-2 was performed (Perea-Martínez et al. 2013). Unexpectedly, a high percentage (43%) of bats developed macroscopic lesions consisting of bruises (hemorrhage) on the chest and/or on the wings (Fig. 1). Histological analyses showed structural alterations in the spleen and bleeding in the liver and intestine, but the virus was not detected by RT-PCR in any of the analyzed tissues except for one infected bat kidney, by seminested RT-PCR. In sera, the viral RNA was detected by seminested RT-PCR in 39% of bats, but only 8% of bats seroconverted. Overall, these data indicate that DENV-2 replicates poorly in these

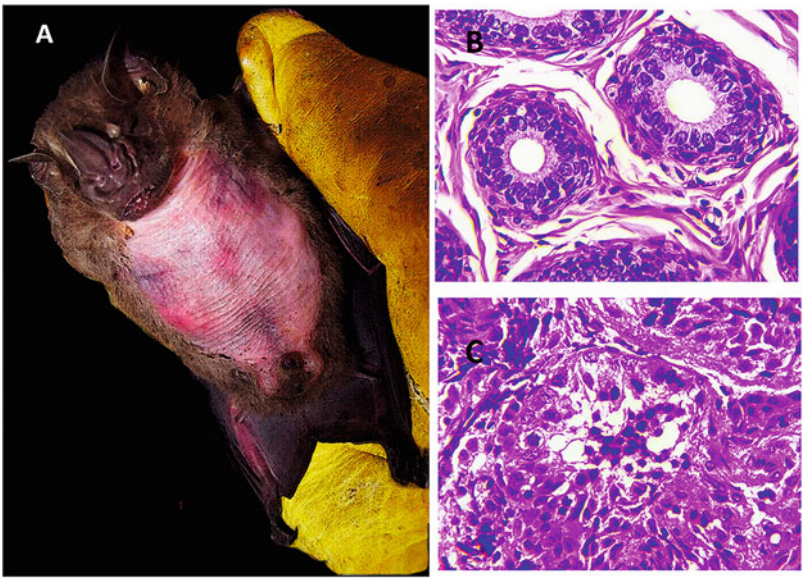

Fig. 1 Some of the macroscopic and microscopic changes founded in experimentally infected bats with DENV or ZIKV. (**a**) Hemorrhages in a bat experimentally infected with DENV B and C: Epididymis H&E 600 X . (**b**) Control *Artibeus* bat non infected; (**c**) *Artibeus* bat inoculated with ZIKV

bats, suggesting they are not suitable hosts to this virus (Perea-Martínez et al. 2013). It is possible that the observed macroscopic lesions (hemorrhage) and histopathological alterations could not be due directly to DENV as experiments were made using bats captured in the wild and other factors as other microbiological and/or physical agents could intervene in such pathologic manifestations.

Supporting the poor replication of DENV in experimentally infected *Artibeus* bats, no evidence of sustained replication of DENV was documented in experimentally inoculated *Artibeus jamaicensis* bats with DENV serotypes 1 or 4 (Cabrera-Romo et al. 2014).

Additionally, in vitro studies using several neotropical bat cell lines and experimental infection of *Artibeus* bats with DENV confirmed that these species of bats are inadequate hosts and likely do not play an important role in DENV transmission (Bittar et al. 2018; Cabrera-Romo et al. 2014; Moreira-Soto et al. 2017).

34.3.2 ZIKA Virus

For ZIKV, anecdotal experimental infections and field studies performed in the 1950s–1960s have documented the susceptibility and presence of clinical signs in African and American bat species (Reagan et al. 1955; Shepherd and Williams 1964; Simpson et al. 1968). Based on these previous studies and considering the

neotropical bat species richness as well as limited information of ZIKV hosts to date, 1872 bats were sampled (blood for ZIKV detection by qRT-PCR) within the ZikAlliance consortium, belonging to different neotropical species and countries (Peru, French Guyana, and Costa Rica) between 2010 after the emergence of Zika virus into the Americas (2015) and 2019 before the arrival of the disease. Sampling included 33 genera from 6 bat families. None of these 1872 bats was positive for either Zika antibodies or RNA. This lack of detection was consistent with another serosurvey of Brazilian bats (Bittar et al. 2018). However, a sampling bias cannot be excluded, due to the diversity of bat species in Latin America.

In 2019, ZIKV experimental infection was performed in a breeding colony *of Artibeus jamaicensis* bats. ZIKV antigens were detected in several organs (salivary glands, testes, SNC, and lung), and antibodies identified by ELISA were observed in less than half of the nine studied animals (Malmlov et al. 2019). ZIKV antigens were detected by PCR in only three samples (two urine samples and one nervous tissue) (Malmlov et al. 2019). Some ZIKV inoculated animals presented histopathological alterations in testes and CNS. These results raised the possibility that bats may have a role in ZIKV ecology which could even endanger bat populations. Another ZIKV experimental infection of *Artibeus* bats captured in the wild was conducted in Mexico (Aguilar-Setién et al., unpublished data). The results were consistent with Malmlov et al. 2019, findings, as ZIKV RNA was detected by rtPCR in only two urine samples, and none of the experimentally infected animals presented antibodies against ZIKV, measured by the more specific virus neutralization test (L'Huillier et al. 2017). As in the first study, in the present also histopathological alterations were found in infected animals mainly in testicles, ovaries, and SNC of some infected animals. Additionally, as it was reported for DENV, we observed that some infected animals showed hemorrhages on the chests, wings, and one animal presented on the bladder, as with DENV, without this being shown to directly attribute to ZIKV (Fig. 1).

Despite the difficulties in detecting ZIKV RNA in free-living bats, a recent Mexican study has detected ZIKV RNA in 9% (2/22) of *Artibeus* bats in Merida, Yucatan (Torres-Castro et al. 2021). Similarly, in our ZIKV experimental infection study, we had to exclude a few individuals that tested positive prior to inoculation for ZIKV RNA in urine samples (Aguilar-Setién et al., unpublished results).

As with the DENV, the set of obtained results with ZIKV seems to indicate that the bats studied are inadequate ZIKV hosts and maybe do not play an important role in ZIKV transmission. Nevertheless, a consistent fact in the two studies of experimental infection of bats with ZIKV carried out to date is the appearance of histopathological alterations mainly in the reproductive tract which opens the possibility that this virus could affect the reproduction of these animals.

34.3.3 Bats as Potential Reservoirs or Vectors of DENV and ZIKV

Some reports that inform concerning the presence of antibodies and/or DENV or ZIKV RNA speculate about how Chiropters could be contaminated with these Flaviviruses. The most logical explanations are that DENV Or ZIKV vectors feed on bats or that bats were contaminated consuming DENV or ZIKV vectors. Vicente-Santos et al.

(2017) in a peri-domestic study found only limited exposure of bats to a DENV likely due to closeness to humans and consumption of DENV vectors (Vicente-Santos et al. 2017). Nevertheless, information on vectors of arbovirus feeding on bats and consumption of these vectors by bats is scarce. *Aedes* mosquitoes are the main vectors of ZIKV and DENV. Some studies demonstrated that *Aedes funereus* mosquitoes fed on flying foxes (*Pteropus* sp.) (Ryan et al. 1997). In an experiment, *Artibeus* bats were bitten by *Aedes aegypti* mosquitoes in an attempt to infect these mammals with DENV (Cabrera-Romo et al. 2014), suggesting that *Aedes* mosquitoes could feed on bats. However, it is not known how often this happens and in which bat species. DENV and ZIKV have been isolated from mosquitoes other than *Aedes* such as *Culex* and *Mansonia* (Musso and Gubler 2016). DENV serotype 2 (DENV-2) was reported for the first time in Sao Paulo, Brazil, in *Culex spp*. and *Culex vaxus* pools, while ZIKV was identified in *Anopheles cruzii*, *Limatus durhamii,* and *Wyeomyia confusa* pools suggesting the possibility of a sylvatic enzootic cycle in these areas (Barrio-Nuevo et al. 2020). However, it is not known if these mosquito species feed on bats or are consumed by bats (Barrio-Nuevo et al. 2020).

Regarding the relationship of mosquitoes other than *Aedes* and bats, Tiawsirisup et al. (2012) collected mosquitoes from five genera inside a bat cave in Thailand to investigate the sylvatic circulation of Japanese Encephalitis Virus (JBEV). These collections included *Culex quinquefasciatus*, which was shown to mainly feed on Leschnault's rousette (*Rousettus leschenaulti*) bats. In the State of New York, *Culiseta morsitans* mosquitoes, the known vector of Eastern Equine Encephalitis Virus (EEEV), were found to have unfrequently fed on Eastern pipistrelle bats (*Pipistrellus subflavus*), as these blood meals comprised only 1% of the total blood meals identified from this mosquito species (Molaei et al. 2006). In Africa, blood of Egyptian roussette (*Rousettus aegyptiacus*) bat was detected in *Coquillettidia fuscopennata* mosquitoes in the Congo basin region (Crabtree et al. 2013). Insectivorous bats play an important role to reduce harmful insect populations and may constitute an appropriate biological control system for many mosquito-borne zoonotic viruses with a direct impact on human health (Hutson et al. 2001; Puig-Montserrat et al. 2020). In Canada, *Myotis lucifugus* was shown to feed predominately on mosquitoes suggesting that this species could play an important role in biological control of these important viral vectors; in Australia, foraging ranges of insectivorous bats *Vespadelus vulturnus* were shown to shift relative to changes in mosquito *Aedes vigilax* abundance (Facione et al. 1991). It is not known if bats could be contaminated by eating mosquitoes harboring arboviruses. Logically, in frugivorous bats, this source of contamination is less likely; however, it has been shown that frugivorous species could shift their diets to some degree of insect consumption to meet their protein requirements (Dinerstein 1986; Herrera et al. 2002).

The susceptibility of bat-adapted ectoparasitic diptera to DENV or ZIKV is not well known. In Hidalgo Mexico, Flavivirus sequences in 38 pools of specific ectoparasites (Diptera: Streblidae, *Strebla wiedemanni,* and *Trichobius parasiticus*) of common vampire bats (*Desmodus rotundus*) were detected by RT-PCR using primers specifically directed against the NS5 gene, a gene highly conserved among Flaviviruses. Phylogenetic inference analysis performed using the maximum likelihood algorithm showed that six sequences clustered with DENV (Abundes-Gallegos

et al. 2018). In order to verify the susceptibility of the bat ectoparasitic fly *Strebla wiedemanni* to DENV infection, we performed an experimental infection of organ explants of *S. wiedemanni* using as control *Melophagus ovinus* (a sheep ectoparasitic fly) organ explants, and C6/36 cells culture was performed. Viral titers (UFP/mL) were determined at 0, 48, and 96 hours post infection (PI). Infected organs were observed by electron microscopy and under the confocal microscopy indirect immunofluorescence (IIF) using specific conjugates against DENV. The infected organs of both species of ectoparasites replicated DENV at similar titers to those obtained with the C6/36 cell cultures ($\geq 10^6$ UFP/mL). Electron microscopy and IIF showed DENV replication in the digestive tract, tracheoles, and milk glands (MG) of both fly species. Areas with a high affinity for the DENV were observed in the fatty bodies of the MG of *M. ovinus* (Aguilar-Setién et al. 2017). The replication of DENV in organs of *S. wiedemanni* and *M. ovinus* was thus demonstrated in this work. Such data could suggest parallel cycles with maintenance of DENV in other nonclassical vectors and mammal hosts but will need to be confirmed (Table 1).

The results obtained from sampling different species of bats show a low and infrequent presence of DENV and ZIKV antibodies and/or viral RNA ranging from negative results (Bittar et al. 2018; Cabrera-Romo et al. 2016) to less than 15% (Aguilar-Setién et al. 2008; Calderón et al. 2019, 2021; de Thoisy et al. 2009; Irving et al. 2020; Sotomayor-Bonilla et al. 2014), confirming bat exposure to DENV and ZIKV in different geographic areas, where bats may be either accidental hosts or dead-end hosts.

Concerning experimental infections of bats with DENV and ZIKV, results indicate that bat species studied replicated poorly these Flaviviruses suggesting that they are not suitable hosts and do not play an important role in the epidemiology of these zoonotic viruses. Nevertheless, some histopathological alterations were observed mainly in the reproductive tract of bats infected with ZIKV suggesting a clinical impact on infected bats.

Most field or experimental studies were conducted using either blood samples (sera for serological tests) or different tissues such as spleen, heart, kidney, or liver for viral RNA detection. However, urine samples were rarely analyzed. Some studies in humans showed that ZIKV RNA can be detected in urine samples at higher levels and for a longer time period after the onset of infection compared to blood and other fluids (Duarte et al. 2017; Lamb et al. 2016; Van den Bossche et al. 2015). In the two experimental infections of *Artibeus* bats with ZIKV, viral RNA was only detected in four urine samples and in one nervous tissue sample, but not in other organs, despite the fact that ZIKV antigens were detected by immunohistochemical tests in testes or lungs of these bats. It suggests that urine samples may be most appropriate to seek for flaviviruses in bats. Fagre et al. (2021) recently demonstrated that subgenomic flavivirus RNA (sfRNA) of the 3′ untranslated region (UTR), which persists in tissues due to XRN-1 stalling during RNA decay, was more effective to detect ZIKV RNA in bats than the more commonly used amplification of NS5 gen sequences; as in experimentally infected bats with ZIKV, viral RNA was detected in most tissues when primers directed against the 3′ untranslated region (UTR) (sfRNA) were used, while none was positive when using primers directed against NS5 gen (Fagre et al. 2021).

Table 1 Family and genera of neotropical bats sampled for ZIKV anitibodies and viral RNA by the ZikAlliance Consortium*. All animals resulted negative

Family	Genera
Phyllostomidae	*Anoura*
	Artibeus
	Carollia
	Chiroderma
	Dermanura
	Desmodus
	Glossophaga
	Linchonycteris
	Lionycteris
	Lonchaphylla
	Lonchorhina
	Lophostoma
	Mimon
	Mycronycteris
	Phylloderma
	Phyllostomus
	Platyrrhinus
	Rhinophylla
	Sturnira
	Tonatia
	Trachops
	Uroderma
Molosidae	*Cynomops*
	Eumops
	Molossus
Vespertilonidae	*Eptesicus*
	Rhogeessa
	Myotis
Emballonuridae	*Peropteryx*
	Rhynchonycteris
	Saccopteryx
Noctilionidae	*Noctilio*
Mormoopidae	*Pteronotus*

ZikaAlliance Consortum: Blood sampled were taken in Costa Rica French Guyana, México and Peru by: Aguilar-Setién A, Salas Rojas M, Gálvez Romero G, Almazán Marín C, Moreira Soto A, Alfonso-Toledo J, Obregón Morales C, García Flores M, García Baltazar A, Serra-Cobo J, López-Roig M, Reyes Puma N, Piche-Ovares M, Romero-Vega M, Barrantes-Murillo D, Soto-Garita C, Alfaro-Alarcón A, Corrales-Aguilar E and Drexler JF

Japanese encephalitis: A recent study in Indonesia suggests a reservoir role for Japanese encephalitis virus in bats from western Kalimantan (Diptyanusa et al. 2021). As the presence of pig holdings is uncommon in West Kalimantan, another reservoir host might have played a role in the local transmission of JE virus in this

area. A total of 373 blood samples from bats were tested for JE virus, among which 21 samples (5.6%) showed positive results, mainly from *Cynopterus brachyotis* (lesser short-nosed fruit bat) found in residential areas. In Chinese bats, a high-genetic homogeneity among the bat JEVs isolated in different geographical areas from various bat species at different time periods was observed. All eight bat JEV isolates belonged to genotype III, indicating that bats might be involved in the natural cycle of JEV (Liu et al. 2013a).

34.4 Bacterial Zoonoses

34.4.1 Enteropathogenic Bacteria

34.4.1.1 *Salmonella*, *Shigella*, *Yersinia*, and *Campylobacter*

Enteric pathogens such as *Salmonella*, *Shigella, Yersinia,* and *Campylobacter* species have occasionally been found in bats (Mühldorfer 2013). A variety of different *Salmonella* serotypes have been isolated from apparently healthy and diseased bats. Almost all of them are serotypes with a broad host-range. *Salmonella* Enteritidis and *Salmonella* Typhimurium have been frequently identified, which belong to a small group of *Salmonella* serotypes mainly associated with disease in humans and animals. Both serotypes have been isolated from organ tissues of three individual bats of the family *Vespertilionidae* that were found dead or severely injured near human habitations (Mühldorfer 2013). It was also reported in vampire bats (Hoar et al. 1998). In Trinidad, of 377 tested bats, representing 12 species, 4 bats (1.1%) were positive for *Salmonella* spp., 49 (13.0%) were positive for *E. coli*, and no bats were positive for *E. coli* O157 or *Campylobacter* spp. (Adesiyun et al. 2009). Isolated serotypes of *Salmonella* included Rubislaw and Molade, both from *Noctilio leporinus*, a fish-eating bat, Caracas recovered from *Molossus major*, and *Salmonella* Group I from *Molossus ater*, both insect-eating bats. Of the 49 isolates of *E. coli* tested, 40 (82%) exhibited resistance to one or more antimicrobial agents. The presence of *Campylobacter* and *Salmonella* was examined in 631 fresh fecal samples of wild insectivorous bats from the Netherlands, using a specially developed method for the simultaneous isolation of low numbers of these pathogens in small-sized fecal samples ($\leq$ 0.1 g) (Hazeleger et al. 2018). Salmonella was not detected, but thermotolerant *Campylobacter* species were confirmed in 3% ($n = 17$) of the bats belonging to six different bat species, at different sites, in different ecosystems during the whole bat flying season. Molecular typing of these 17 isolated strains indicated *C. jejuni* ($n = 9$), *C. coli* ($n = 7$), and *C. lari* ($n = 1$), including genotypes also found in humans, wildlife, environmental samples, and poultry.

Shigella, causing a dysenteric infection in humans, was isolated from a *Molossus bondae* bat in Colombia (Arata et al. 1968). *Shigella* strains of serogroups B to D have been isolated from mega- and microbats of diverse feeding habitats (Mühldorfer 2013). *Shigella flexneri* in particular was detected in more than 3% of bats investigated.

A high prevalence of different *Yersinia* species (~35%) was detected in the feces of 70 insectivorous *Myotis myotis* collected from natural populations in Poland (Mühldorfer 2013). Most of the *Yersinia* species isolated from bats are widely distributed in the environment and rarely associated with disease in mammals and birds. Cases of systemic *Y. pseudotuberculosis* infection have been described once in an adult insectivorous bat (*M. myotis*) found dead in Germany after hibernation (Mühldorfer 2013) and a bat in England (Hoar et al. 1998), respectively. More recently, *Yersinia enterocolitica* was also isolated from the intestines of 3 out of 11 dead *Miniopterus schreibersii* bats in the Republic of Georgia after a massive die off in a cave (Imnadze et al. 2020).

In the same country, several zoonotic pathogens were detected in bats (Bai et al. 2017), as 218 bats belonging to eight species collected from four regions of Georgia were examined for *Bartonella* (see below), *Brucella*, *Leptospira*, and *Yersinia* using molecular approaches. *Brucella* DNA was detected in two *Miniopterus schreibersii* bats and in two *Myotis blythii* bats, all of which were from Imereti (west-central region). *Leptospira* DNA was detected in 25 (13%) bats that included 4 *M. schreibersii* bats and 21 *M. blythii* bats collected from two regions. The *Leptospira* sequences represented five genetic variants with one of them being closely related to the zoonotic pathogen *L. interrogans* (98.6% genetic identity). No *Yersinia* DNA was detected in the bats. Mixed infections were observed in several cases. One *M. blythii* bat and one *M. schreibersii* bat were coinfected with *Bartonella, Brucella*, and *Leptospira*; one *M. blythii* bat and one *M. schreibersii* bat were coinfected with *Bartonella* and *Brucella*; and 15 *M. blythii* bats and 3 *M. schreibersii* bats were coinfected with *Bartonella* and *Leptospira* (Bai et al. 2017).

34.4.2 Vector-Borne Bacteria

34.4.2.1 *Borrelia*, *Bartonella*, and *Neorickettsia*

Several *Borrelia* and *Bartonella* species and the causative agent of Potomac horse fever disease *Neorickettsia risticii* have been detected in blood and organ tissues of bats (Mühldorfer 2013). The majority of infected animals appear to be healthy; only two vespertilionid bats (*Pipistrellus* sp. and *Natalus tumidirostris*) revealed severe borrelial spirochetemia.

In recent years, many new *Bartonella* species have been isolated or detected from bats around the world, including the United Kingdom, Kenya, Guatemala, Peru, the Republic of Georgia (Bai et al. 2012, 2017), Taiwan (Lin et al. 2012), France, and Mexico (Stuckey et al. 2017a, c). In the Republic of Georgia, *Bartonella* DNA was detected in 77 (35%) bats from all eight species and was distributed in all four regions. The prevalence ranged 6–50% per bat species. The *Bartonella* DNA represented 25 unique genetic variants that clustered into 21 lineages (Bai et al. 2017). Phylogenetic analyses of *Bartonella* strains derived from bats identified several distinct phylogroups indicating the presence of a variety of novel *Bartonella* species in bats. It is notable that bats of the same species as well as bats of the same geographic origin and ecological niche (i.e., *Desmodus rotundus*, members of the

family Vespertilionidae) shared closely related strains of *Bartonella* (Stuckey et al. 2017b). It is not known if these *Bartonella* species are zoonotic. Furthermore, soft ticks (family Argasidae) and other ectoparasites commonly found on bats or in bat habitats are infected with *Bartonella*, *Borrelia,* and *Rickettsia* species, posing a potential risk of intra- and interspecies transmission cycles between bats, humans, and domestic animals (Mühldorfer 2013).

In a European study, 221 bat fecal and 118 bird pellet samples were collected from Hungary and the Netherlands and screened for a broad range of vector-borne bacteria using PCR-based methods (Hornok et al. 2018). *Rickettsia* DNA was detected in 13 bat-fecal DNA extracts, including the sequence of a rickettsial insect endosymbiont, a novel *Rickettsia* genotype, and *Rickettsia helvetica*. Fecal samples of the pond bat (*Myotis dasycneme*) were positive for a *Neorickettsia* sp. (*N. risticii*) and for hemoplasmas of the *Mycoplasma haemofelis* group. Therefore, bats can pass rickettsia and hemoplasma DNA in their feces (Hornok et al. 2018).

34.4.3 Other Bacterial Pathogens

A variety of pathogenic *Leptospira* species have been identified in bats in Asia, Europe, Australia, and the Americas (Bessa et al. 2010; Cox et al. 2005; Hoar et al. 1998; Mühldorfer 2013; Vashi et al. 2010). To date, *Leptospira* infection has been evidenced in over 50 bat species belonging to eight of the nine investigated bat families, encompassing various geographical regions in the tropics and subtropics, as well as Europe, although to a limited extent (Dietrich et al. 2015). The prevalence of leptospiral infections in bats varied from almost 2% to 35% depending on the sample size of the respective study. The family Phyllostomidae comprised the majority of microbats infected with *Leptospira*, whereas in obligate insectivorous species (i.e., families Vespertilionidae and Molossidae) leptospiral infection with pathogenic strains has occasionally been found. In Australia, native flying fox populations (genus *Pteropus*) were suggested as possible carriers of pathogenic *Leptospira* responsible for infections in humans and other animals because of high bacterial detection rates in kidney (11%) and urine samples (39%) and high seroprevalences (18%, 28%) (Mühldorfer 2013). Similarly, bats from Madagascar and Comoros islands harbor a notable diversity of *Leptospira* spp., a finding similar to the diversity found in a comparable investigation of bats in the Amazon region (Lagadec et al. 2012; Matthias et al. 2005). Leptospirosis incubation is 1–32 days (median 9 days) and median duration is 14 days. Most symptomatic patients develop a mild illness consisting of fever, chills, headache, and myalgia. Severe forms of the disease may manifest in acute renal failure, hepatitis, jaundice, myocarditis and meningoencephalitis, and outbreaks of severe pulmonary hemorrhagic leptospirosis have occurred resulting in high morbidity and mortality (Leshem et al. 2011). More recent data of *Leptospira* infection in bats have been reported (Cilia et al. 2021; Dietrich et al. 2015). Direct transmission of bat-borne *Leptospira* to humans has already been suggested, but never evidenced, following a case of serologically confirmed human leptospirosis after bat exposure (Dietrich et al. 2015).

A few other zoonotic agents, such as *Coxiella burnetii*, the agent of Q fever, or *Mycobacterium bovis,* were isolated from bats in Morocco and southern USSR and from captive Indian fruit bats in England, respectively (Hoar et al. 1998). Agglutinin antibodies against *Brucella* were detected in 5 of 53 vampire bats captured in areas of Brazil where incidence of brucellosis in cattle was high (Ricciardi et al. 1976). Similarly, *Coxiella burnetii* DNA was detected in bats, as four samples (3.4%, 95% CI, 0.9–8.3) out of 119 bats were positive for the htpAB gene of *C. burnetii* [spleen (2), liver (1), and heart (1)] (Ferreira et al. 2018). Several *Pasteurella* species (i.e., *P. multocida*, *P. pneumotropica,* and *Pasteurella* species B) have been identified as primary pathogens in bats responsible for a variety of localized and systemic infections in European bat species; most *Pasteurella* strains isolated from organ tissues of 29 vespertilionid bats represented *P. multocida* ssp. *septica* (85%) and capsular type A (75%) (Mühldorfer 2013).

34.5 Protozoan Parasites

34.5.1 *Trypanosoma*, *Toxoplasma*, *Coccidia*, and *Leishmania*

Few parasites of bats are known to be pathogenic to humans and are usually transmitted mechanically via an intermediate vector (Hoar et al. 1998). Many species of trypanosomes can infect bats, but one of main concern is *Trypanosoma cruzi*, the agent of Chagas disease. Bats have long been associated with blood-borne protozoal trypanosomes of the *Schizotrypanum* subgenus, which includes the zoonotic parasite *Trypanosoma cruzi*, agent of Chagas disease (Hodo et al. 2016). Another member of the subgenus, *Trypanosoma dionisii*, infects bats of Europe and South America, and genetic similarities between strains from the two continents suggest transcontinental movement of this parasite via bats. Hearts and blood from eight species of insectivorous bats from 30 counties across Texas were collected (Hodo et al. 2016). Using PCR and DNA sequencing, 593 bats for trypanosomes were tested, with 1 bat positive for *T. cruzi* (0.17%), 9 for *T. dionisii* (1.5%), and 5 for *Blastocrithidia* spp. (0.8%), a group of insect trypanosomes. The *T. cruzi*-infected bat was carrying TcI, the strain type associated with human disease in the USA. In the T. dionisii-infected bats, three unique variants associated with the three infected bat species were detected. A new genotype of *T. cruzi*, associated with bats from anthropic areas and which could be a potential source of infection to humans, has been described (Marcili et al. 2009). Chagas disease is commonly transmitted by reduviid bed bugs. In humans, the disease is characterized by high fever, adenitis, anemia, and facial edema in the acute form and myocarditis in the chronic form. Pathogenicity of bat trypanosomes for humans is not clearly established. *T. cruzi* has been detected in vampire bats, *Desmodus rotundus*, which can be of concern in terms of zoonotic transmission, as these bats feed on mammals, including humans (Ramírez et al. 2013).

Infection of bats with *Toxoplasma gondii* has been reported based on serological studies and more recently on its isolation from bats in Brazil (Cabral et al. 2013; Sun et al. 2013). Therefore, consumption of undercooked bats could be a source of

human infection. In bats, systemic toxoplasmosis caused by *T. gondii* was diagnosed in two juvenile, captive flying-foxes (*Pteropus conspicillatus* and *P. scapulatus*), which died following respiratory distress. One animal displayed clinical signs suggestive of neurological disease (Sangster et al. 2012).

Coccidia of the genus *Eimeria* have been isolated from several species of bats in many parts of the world (Hoar et al. 1998). Many new *Eimeria* species have been reported (McAllister et al. 2012). Prevalence in bats is usually low (<1 to 5%), and it is not known if they are pathogens for humans (Hoar et al. 1998).

Leishmaniasis is a zoonotic disease caused by parasites of the genus *Leishmania*. It has expanded beyond its natural range and is becoming increasingly urban (Shapiro et al. 2013). Using PCR and PCR-RFLP, *Leishmania (Viannia) braziliensis* was detected in two bats (Chiroptera) in Mato Grosso do Sul, Brazil, an endemic area. The animals testing positive were found in both a rural site and an urban site. These results indicate the need for further research into the viability of *Leishmania* in bats. It could have implications for public health in that part of Brazil, given the large populations of urban bats, their mobility, and their ability to roost at close proximity to humans within residences and other buildings (Shapiro et al. 2013). In Spain, samples from spleen, hair, and blood were analyzed to detect *L. infantum* DNA in bats from the Community of Madrid (Azami-Conesa et al. 2020). Infection by *L. infantum* was detected in 59.2% of the bats studied ($n = 16/27$), with the spleen being selected as the site for detection, yielding 14/16 positive results (87.5% sensitivity), followed by hair ($n = 7/16$) and blood ($n = 6/16$), the first report of *L. infantum* detection in the common urban bat (*Pipistrellus pipistrellus*) in Europe.

34.6 Fungal Pathogens

34.6.1 *Histoplasma*, *Coccidioides*, and Other Fungal Infections

Despite the emergence of white nose syndrome caused by *Pseudogymnoascus destructans,* which destroyed an estimated 6 to 7 million bats in North America in recent years (first reported in 2007 in some New York state caves), the main zoonotic fungal diseases related to bats is histoplasmosis and to a lesser extent coccidioidomycosis and a few other fungal infections also identified in bats (Hoar et al. 1998).

Histoplasmosis: Histoplasmosis is caused by *Histoplasma capsulatum*, a dimorphic fungus that is endemic in the Americas and parts of Asia and Africa (Hoar et al. 1998). There are two varieties that are pathogenic to humans, var. *duboisii* and var. *capsulatum*. The former exists only in Africa, while var. *capsulatum* is most prevalent in regions of North, Central, and South America, but has also been reported from parts of Africa, Southern and Eastern Europe, Eastern Asia, and Australia (Cottle et al. 2013). It grows as a mold in soil enriched with bird or bat guano; human infection occurs after inhalation of the dust generated when such soil is disturbed. Visiting caves, collecting or being exposed to bat guano, are the main sources of human contamination from bats (CDC 2012; Cottle et al. 2013; Hoar et al. 1998; Jülg et al. 2008; Kajfasz and Basiak 2012; Schwarz and Kauffman 1977). The

threat of *Histoplasma capsulatum* infection in bat-inhabited caves should be emphasized to travelers and also to physicians, as 3 of 4 travelers were hospitalized after returning from visiting bat-infested caves in Ecuador and having contact with bat guano (Kajfasz and Basiak 2012). Bats usually are healthy carriers and shed the fungus in their feces. In humans, clinical manifestations in humans vary according to host immunity and exposure intensity, ranging from asymptomatic infection (in most healthy persons exposed to a low inoculum; about 80% of the time) to life-threatening pneumonia with respiratory failure (Cottle et al. 2013; Hoar et al. 1998). Between these extremes, clinical presentations include acute or subacute pulmonary disease, pericarditis, rheumatological syndromes with erythema nodosum, progressive disseminated disease, and mediastinal complications. Acute pulmonary histoplasmosis in returning travelers typically presents as a flu-like illness with high-grade fever, chills, headache, nonproductive cough, pleuritic chest pain, and fatigue. Chest radiographs often show diffuse reticulonodular infiltrates and mediastinal lymphadenopathy. Symptom onset is usually 1 to 3 weeks following exposure, and most individuals recover spontaneously within 3 weeks. Disseminated disease is a rare complication, more likely to occur in persons with severely impaired cellular immunity (Cottle et al. 2013). The African species, *H. capsulatum* var. *duboisii,* is associated with cutaneous lesions and occasionally infection of long bones (Hoar et al. 1998).

Coccidioidomycosis: *Coccidioides immitis*, causing coccidioidomycosis, also known as valley fever in California, has been isolated from bat guano (Krutzsch and Watson 1978). Coccidioidomycosis is a systemic disease caused by *Coccidioides immitis* and *C. posadasii* spp., which are predominant in arid zones of the American continent, mainly in the Southwestern United States and the northern states of Mexico, as well as other regions with different environmental conditions (Welsh et al. 2012). Some countries of Central and South America are also endemic zones. Most infected patients are asymptomatic. Disseminated disease develops in less than 5% of clinically affected individuals. Culture, biopsy, and DNA probes are used for fungus identification. Prognosis is related to low antibody detection and a positive intradermic skin reaction to coccidioidin. Immunosuppressed patients and pregnant women require special attention in diagnosis, therapy, and prognosis. Amphotericin B in its different forms, itraconazole, and fluconazole, is the most frequently used treatment. Both fungi have been detected in bats and bat guano (Krutzsch and Watson 1978; de Cordeiro et al. 2012). In Brazil, *Coccidioides posadasii* was recovered from *Carollia perspicillata* bat lungs (de Cordeiro et al. 2012). Immunologic studies detected coccidioidal antibodies and antigens in *Glossophaga soricina* and *Desmodus rotundus* bats.

Candidiasis: Candida albicans, which causes mucocutaneous candidiasis ("thrush" or oropharyngeal candidiasis) in the mouth or throat of humans, was isolated from liver, kidney, spleen, and intestinal content of several bats captured in Nigeria (Oyeka 1994). The most common symptoms of oral thrush in humans are white patches or plaques on the tongue and other oral mucous membranes. It was indicated that bat consumption is common in that country and people could get infected by improper handling of bats or consumption of raw or undercooked bat meat (Oyeka 1994). In a recent study conducted in Brazil, 7 (12.3%) of 57 bats

showed yeasts in their feces. Five species of the genus *Candida* were isolated: *C. guilliermondii*, *C. krusei*, *C. lusitaniae*, *C. parapsilosis*, and *C. pelliculos* (Botelho et al. 2012).

Other fungal infections: Other fungal infections have been described in bats, some of which could potentially be transmitted to humans. Bats are susceptible hosts and reservoirs for *Histoplasma capsulatum, Paracoccidioides brasiliensis,* and *Sporotrichum schenckii* (Raymond et al. 1997). *Sporothrix schenckii, Scopulariopsis* sp., and *Cryptococcus neoformans* have been isolated from bats or bat guano in the Americas (Hoar et al. 1998; Kajihiro 1965). Blastomycosis is a granulomatous disease of mucous membranes. *Blastomyces dermatitidis* has been isolated from the lungs of an asymptomatic insectivorous bat (*Rhinopoma hardwickei hardwickei*) from India, and insectivorous bats orally inoculated with *B. dermatitidis* transiently shed viable organisms in their feces. Mexican free-tailed bats (*Tadarida brasiliensis*) intraperitoneally injected with *B. dermatitidis* developed systemic blastomycosis and excreted viable fungi in their feces. Apparently, bats can serve as both hosts and vectors for *B. dermatitidis* and may be potential sources for human infection (Raymond et al. 1997).

34.7 Conclusion

Bats themselves have an undeniable impact on our planet; with over 1200 chiropteran species identified to date, bats comprise one-fifth of all mammalian species globally and provide critical ecosystem services ranging from pollination to insect control (Wibbelt et al. 2010). Their vast numbers, capability of flight, and a variety of ecological, immunological, and socioeconomic factors also enable bats to transmit an increasingly recognized spectrum of pathogens (Calisher et al. 2006; Mühldorfer 2013; Wibbelt et al. 2010; Wood et al. 2012). The potential for the emergence of zoonoses will continue to increase, as demonstrated by the COVID19 pandemic, as human development encroaches on bat populations. As such, future research will be needed to monitor infection and better understand those underlying drivers of disease.

Contents

Abstract

Vector-borne zoonoses (VBZ) are diseases caused by a range of pathogens that affect animals and humans. A plethora of vectors, such as mosquitoes, ticks, fleas, phlebotomine sand flies, lice, and kissing bugs, may transmit numerous bacteria, protozoa, helminths, and viruses to animals and humans. The burden of VBZ is still considerable in poor rural areas in tropical and subtropical regions. Indeed, some of these diseases represent a current public health concern in low- and middle-income countries as well as in wealthy ones. A number of factors, such as increases in travel and trade, climate and land-use changes, and socioeconomic and political upheavals, may drive or alter the dynamics of VBZ in animals and humans. In this chapter, we review selected aspects of VBZ affecting animal and human populations worldwide. Unresolved issues regarding the epidemiology and control of this group of zoonoses are also discussed.

35.1 Introduction

Vector-borne zoonoses (VBZ) constitute a group of diseases caused by a wide range of pathogenic organisms, including bacteria (e.g., *Rickettsia conorii*, *Rickettsia rickettsii*, and *Borrelia burgdorferi*), protozoa (e.g., *Babesia divergens*, *Babesia microti, Plasmodium knowlesi*, and *Trypanosoma cruzi*), helminths (e.g., *Dirofilaria immitis, Dirofilaria repens, Onchocerca lupi*, and *Thelazia callipaeda*), and viruses (e.g., Crimean-Congo hemorrhagic fever virus, West Nile virus, and tick-borne encephalitis virus) (Colwell et al. 2011; Dantas-Torres et al. 2012b; Kilpatrick and Randolph 2012; Otranto et al. 2013; Bezerra-Santos et al. 2021; Mendoza-Roldan et al. 2021a). These pathogenic agents may be transmitted to animals and humans through the bite (during blood feeding) of a variety of arthropods, such as mosquitoes (family Culicidae), fleas (order Siphonaptera), lice (order Phthiraptera), phlebotomine sand flies (subfamily *Phlebotominae*), black flies (family Simulidae), biting midges (family Ceratopogonidae), kissing bugs (subfamily Triatominae), fruit flies (subfamily Steganinae), and ticks (order Ixodida). Some diseases such as plague, a flea-borne disease that claimed the lives of thousands of people since the Byzantine Empire (Gage and Kosoy 2005; Raoult et al. 2013; Bezerra et al. 2022), have been part of humankind for long time and have changed the course of our history. In recent years, a number of new VBZ have also been described (Dantas-Torres et al. 2012b), with direct implications for the diagnosis of this group of zoonoses, whose clinical features may overlap (Paddock et al. 2008).

The epidemiology and distribution of VBZ are influenced by several factors, but the presence of animal hosts and arthropod vectors in a given area is a *sine qua non* condition for the enzootic and zoonotic cycles to occur. For instance, small mammals and reptiles may act as hosts for a number of pathogens (e.g., *Babesia microti*, *Borrellia burgdorferi*, *Rickettsia* spp.) potentially causing disease in humans and may also serve as hosts for arthropod vectors, such as ticks (Dantas-Torres et al. 2012a; Mendoza-Roldan et al. 2021b). Importantly, the complex interactions between animal hosts, arthropod vectors, and people occurring in the enzootic and zoonotic transmission cycles of vector-borne pathogens partly explain the difficulties faced by public health authorities trying to control this group of diseases.

The burden of VBZ is still heavier in poor rural areas in tropical and subtropical regions, where arthropod vectors find a more suitable environment for their perpetuation and where access to health care services is often limited. For example, leishmaniasis and Chagas disease are still one of the leading causes of disability worldwide and responsible for thousands of deaths, mainly in rural and peri-urban areas of several low-income countries (Alvar et al. 2006; Bern et al. 2008; Christou 2011; Lozano et al. 2012). Furthermore, climatic, socioeconomic, and political

changes have caused a profound impact on the epidemiology and distribution of VBZ, some of which currently represent a public health concern in industrialized countries as well (Vorou et al. 2007; Otranto et al. 2013). In the present chapter, we provide an overview on selected aspects of VBZ affecting animal and human populations around the world. Unresolved issues regarding the epidemiology and control of this group of zoonoses are also addressed.

35.2 Morbidity and Mortality

From a global perspective, VBZ such as leishmaniasis, Chagas disease, and African trypanosomiasis are still causing a considerable burden in terms of morbidity and mortality in a number of countries. Particularly, the burden of such VBZ is still heavier in low- and middle-income countries as compared with high-income countries. On the other hand, several VBZ such as tick-borne encephalitis and Lyme disease are also increasing in many industrialized countries (Bhate and Schwartz 2011). Nonetheless, it is difficult to estimate the actual burden of VBZ, mainly in developing countries due to the absence of surveillance and/or deficiencies in the national case notification system. Furthermore, many cases of VBZ remain without a definitive diagnosis, particularly in remote rural areas where the access to basic health care services is still incipient.

Human leishmaniasis is a group of phlebotomine sand fly-borne diseases caused by several species of *Leishmania*, which are prevalent in at least 98 countries and three territories in all continents, except Oceania (Alvar et al. 2012); the *Leishmania* species circulating presently in Australia is apparently restricted to kangaroos. The global burden of leishmaniasis in terms of morbidity and mortality has recently been reassessed. It has been estimated that approximately 0.2–0.4 million visceral leishmaniasis cases and 0.7–1.2 million cutaneous leishmaniasis cases occur each year in countries where these diseases are endemic (Alvar et al. 2012). Remarkably, more than 90% of all visceral leishmaniasis cases reported worldwide occur in six countries: India, Bangladesh, Sudan, South Sudan, Brazil, and Ethiopia. In a similar manner, Afghanistan, Algeria, Colombia, Brazil, Iran, Syria, Ethiopia, North Sudan, Costa Rica, and Peru are responsible for 70–75% of the cutaneous leishmaniasis cases estimated to occur annually. It has also been estimated that 20,000–40,000 leishmaniasis deaths occur each year worldwide. Nevertheless, the number of cases and deaths that remain underreported is probably higher than currently estimated.

Trypanosomiases are neglected tropical diseases caused by *Trypanosoma* species, which might be transmitted by different arthropod vectors. American trypanosomiasis (Chagas disease) is caused by *Trypanosoma cruzi*, which is primarily transmitted by kissing bugs. In spite of the efforts toward the elimination of the vectorial transmission of *T. cruzi* in endemic areas, Chagas disease is still a leading cause of morbidity and mortality worldwide. Indeed, it is estimated that 10–20 million people are infected with *T. cruzi*, mostly in Latin America, causing between 20,000 and 50,000 deaths per year (Tarleton and Curran 2012; Leony et al. 2019). Differently, African trypanosomiasis (sleeping sickness) is caused by species of *Trypanosoma* (*Trypanosoma brucei*

rhodesiense and *Trypanosoma brucei gambiense*), which are transmitted by tsetse flies (*Glossina* genus). The disease is restricted to sub-Saharan Africa, where 70 million people are estimated to be at risk of infection. Importantly, the number of cases of sleeping sickness in Africa decreased about 82% in recent years (e.g., 37,991 cases in 1998 and 6743 cases in 2011), which is the result of the control efforts toward the elimination of the disease from this continent (Simarro et al. 2012).

Tick-borne bacterial diseases such as Lyme disease, Rocky Mountain spotted fever, Mediterranean spotted fever, granulocytic anaplasmosis, monocytic ehrlichiosis, and Q fever constitute emerging public health concerns worldwide (Christou 2011; Dantas-Torres et al. 2012b). For instance, Lyme borreliosis is on the rise in Europe, where more than 50,000 cases are reported each year. Similarly, over 250,000 cases of Lyme borreliosis were reported between 2000 and 2010 in the United States (Dantas-Torres et al. 2012b). Furthermore, human granulocytic anaplasmosis has been increasing in incidence and expanding its distribution in the United States in recent years (Christou 2011; Matos et al. 2022).

Arboviruses (i.e., arthropod-borne viruses) such as yellow fever virus, dengue fever virus, Japanese encephalitis virus, West Nile virus, tick-borne encephalitis, Chikungunya virus, Zika virus, Rift Valley fever virus, and Crimean-Congo haemorrhagic fever virus are responsible for considerable morbidity and mortality worldwide (LaBeaud et al. 2011). For instance, the World Health Organization official estimates indicate that 50–100 million dengue infections occur annually around the globe, but a more recent estimate increased this figure to 390 million dengue infections per year (Bhatt et al. 2013). Moreover, around 200,000 cases and 30,000 deaths by yellow fever are estimated to occur each year in tropical areas of Africa and Latin America, respectively. Similarly, more than 67,000 cases of Japanese encephalitis are estimated to occur each year throughout most Asia and parts of western Pacific, with a case-fatality rate ranging from 10–30% (Hu et al. 2012). Furthermore, more than 5300 West Nile virus disease cases occurred in 2012 in the United States, representing the highest number of cases reported to the Centres for Disease Control and Prevention since 2003 (http://www.cdc.gov/ncidod/dvbid/westnile/index.htm).

The recent introduction and subsequent emergence of several exotic VBZ (e.g., West Nile virus, Chikungunya virus, and Zika virus) worldwide appears to be influenced by several biotic and abiotic factors, including increased travel and trade, which ultimately favoured the introduction and/or the expansion of arthropod vectors. Nonetheless, the emergence or re-emergence of endemic VBZ (e.g., Lyme disease, tick-borne encephalitis, leishmaniasis, and malaria) has been attributed to climate changes, land-use, and social changes, which have greatly impacted on the ecology of vector species (Colwell et al. 2011; Kilpatrick and Randolph 2012; Dantas-Torres 2015).

35.3 Drivers and Dynamics of VBZ

At the local level, the probability (or the risk) of being exposed to and, thus, becoming infected by a vector-borne pathogen depends on the contact with competent vectors, which in turn may be influenced by several factors (e.g., living

Fig. 1 *Phortica variegata*, the vector of *Thelazia callipaeda*, feeding on a human eye

conditions, labor and leisure activities, knowledge of the disease transmission and control). From a broader perspective, the dynamics of VBZ in a given area are driven by several biotic (e.g., reservoir and vector population densities) and abiotic factors (e.g., land-use and social changes, increased travel and trade), which may vary in time and space.

In the past century, a number of exotic VBZ were introduced and established into new areas. For instance, canine thelaziasis is a VBZ caused by the spirurid nematode *Thelazia callipaeda*, which is transmitted by the fruit fly *Phortica variegata* (Fig. 1) (Otranto et al. 2013). The disease was initially thought to be restricted to the former Soviet Union and to countries in the Far East (the People's Republic of China, South Korea, Japan, Indonesia, Thailand, Taiwan, and India), but nowadays it is widespread in Europe (Otranto et al. 2013), and it has also been reported in the USA (Schwartz et al. 2021). Cases have been reported in almost all European countries (e.g., Italy, Belgium, France, Greece, Portugal, Spain, and Switzerland) as well as in the Balkans (Caron et al. 2013; Otranto et al. 2013, 2021). The emergence of thelaziosis in several European countries has been attributed to several factors, such as movement of infected animals, local changes in vector ecology and distribution, as well as to increased awareness of medical physicians, veterinary practitioners, and parasitologists. Indeed, the increasing in trade and travel is considered as a major driver of exotic vector-borne pathogen introductions into non-endemic areas (Kilpatrick and Randolph 2012; Dantas-Torres 2015). For instance, infected livestock and people as well as migratory or dispersing birds are potential carriers for the introduction of exotic pathogens (e.g., Crimean-Congo haemorrhagic fever, Chikungunya virus, and West Nile virus) into new regions (Kilpatrick and Randolph 2012).

Upon arrival in a new area, an exotic pathogen needs to find suitable reservoir hosts and arthropod vectors to establish locally. For example, the immigration waves of Europeans from leishmaniasis endemic countries (e.g., Portugal, Spain, and Italy) into the New World, since the arrival of the Conquistadores, resulted in multiple introductions of *Leishmania infantum*, the causative agent of zoonotic visceral leishmaniasis, into this region (Kuhls et al. 2011; Dantas-Torres et al. 2012c). The establishment of *L. infantum* in the New World was likely facilitated by the presence

of highly susceptible human populations and competent animal hosts, such as foxes, domestic dogs, and other wild animals co-habiting the same environment (Desjeux 2004; Dantas-Torres et al. 2012c). In the same way, the existence of a ubiquitous competent vector (*Lutzomyia longipalpis sensu lato*), migration waves from rural to urban areas, and increased trade have probably favored the rapid spread of zoonotic visceral leishmaniasis in some Latin American countries such as Brazil (Desjeux 2004; Kuhls et al. 2011; Dantas-Torres et al. 2012c).

The presence of an established vector population and of susceptible hosts that are immunologically naïve to the introduced pathogen might result in explosive epidemics of VBZ (Kilpatrick and Randolph 2012). Indeed, the emergence of endemic VBZ might be driven by several factors, which may bring large contingents of non-immune people into contact with vectors and associated pathogens. Road building, oil prospecting, mining, farming, irrigation, forestry development, tourism, as well as political upheavals, military conflicts, and natural disasters (e.g., the hurricane Katherine) have been associated with the emergence of several VBZ such as dirofilarioses, leishmaniasis, malaria, yellow fever, and tick-borne encephalitis (Desjeux 2004; Colwell et al. 2011; Kilpatrick and Randolph 2012; Antinori et al. 2013). For example, the largest outbreak of cutaneous leishmaniasis recorded in Colombia occurred during 2005–2009 in soldiers of the Colombian Army, when roughly 40,000 cases were detected (Vélez et al. 2012). In this outbreak, military incursions into the jungle, with the mission to combat illicit crops and the guerrilla, resulted in exposure of soldiers and military dogs to infected phlebotomine sand flies. Similarly, the emergence of malaria by *Plasmodium knowlesi* in south-eastern Asia has been associated with males who had a history of visiting or staying for some days in jungle areas, where wild macaques and anopheline mosquitoes maintain the natural cycle of the parasite (Singh et al. 2004; Lee et al. 2011; Antinori et al. 2013).

While deforestation (for road building, establishment of grazing areas, crop plantations, etc.) may be associated with the emergence of VBZ, reforestation has also been linked with changes in local abundance of animal hosts and arthropod vectors of certain pathogens. For instance, the emergence of Lyme disease in north-eastern United States in the mid-twentieth century has been partly attributed to the rise in deer (*Odocoileus virginianus*) and tick (*Ixodes scapularis*) populations as a result of reforestation occurring during the twentieth century (Barbour and Fish 1993). On the other hand, forest fragmentation in eastern regions of Canada and the United States and changes in predators' communities have been associated with increases in the relative abundance of wildlife hosts of *Borrelia burgdorferi* and in the infection prevalence in nymphal ticks (Logiudice et al. 2008; Levi et al. 2012). Certainly, forest fragmentation and/or reforestation may exert profound changes in wildlife host communities, with potential effects on arthropod vectors and associated pathogens. The effects of these changes in the dynamics of several VBZ may be unpredictable (Dantas-Torres 2015).

Socioeconomic and political changes may also increase the risk of VBZ (Otranto et al. 2017). For example, the upsurge of tick-borne encephalitis in central and eastern European states has been correlated with poverty and household expenditure

on food, after the collapse of the Soviet Union (Sumilo et al. 2008). Indeed, changes in land-use, reduced use of pesticides, increased unemployment, and poverty might have resulted in increased interactions between people and infected ticks. The linkage between poverty and VBZ is well documented for some neglected diseases, such as leishmaniasis, African trypanosomiasis and Chagas disease. For example, the cracked walls and damp earth floors, together with an absence of sanitation and inadequate garbage collection in impoverished urban and peri-urban settings create phlebotomine sand fly breeding sites and increase the risk of leishmaniasis (Alvar et al. 2006). In the same way, people living in poor rural communities in Latin America, in proximity to forest areas and under precarious housing conditions and underlying poverty are at risk of VBZ, such as Chagas disease (Briceno-Leon 1987).

35.4 Clinical and Diagnostic Considerations

Patients (whether animal or human) suffering from a given VBZ may present with a suit of clinical signs and symptoms, ranging from a single, localized skin ulcer to severe, life-threatening systemic disease. For instance, canine and human patients affected by American cutaneous leishmaniasis caused by *Leishmania braziliensis* may present localized skin ulcers or mucocutaneous lesions. In turn, those suffering from zoonotic visceral leishmaniasis by *L. infantum* may exhibit systemic clinical signs (e.g., weight loss, fever, lymph node enlargement, and hepatosplenomegaly) with a potential fatal outcome (Lainson and Shaw 2005; Dantas-Torres 2009). Other leishmanial species such as *Leishmania amazonensis* may induce a range of clinical signs in dogs and humans and eventually produce a visceral form of leishmaniasis that may be confounded with *L. infantum* infections (Lainson and Shaw 2005; Dantas-Torres 2009),

Human patients affected by spotted fever rickettsioses may present with unspecific clinical signs and symptoms (e.g., flu-like illness) in the early stages of the disease (Dantas-Torres 2007), potentially leading to misdiagnosis, delays in treatment initiation, and death. Certainly, the variety of clinical signs and symptoms animals and humans may present when suffering from VBZ make the clinical diagnosis a challenging task for physicians and veterinary practitioners working in both endemic and non-endemic areas. In endemic areas, they may be more used to typical clinical presentations of endemic VBZ, but atypical cases in immunosuppressed individuals and co-infections may further complicate the clinical diagnosis.

Vector-borne nematodes may cause ocular infestations in animals and humans (Otranto and Eberhard 2011; Otranto et al. 2013). For instance, thelaziosis is a VBZ of animals (e.g., dogs and cats) and humans caused by *T. callipaeda*, whose adults live primarily under the nictitating membrane of the eye and may induce lacrimation, epiphora, conjunctivitis, keratitis, and even corneal ulcers (Otranto and Eberhard 2011). However, several other vector-borne nematode species may invade the eyes of animals and humans and must be included in the differential diagnosis. As examples, a rare nematode (*Pelicitus* genus) was retrieved from the eye of a human patient from the Amazon region in Brazil (Bain et al. 2011) and an enigmatic

Dirofilaria sp. molecularly close to *Dirofilaria immitis* was characterized from a human patient from northern Brazil (Otranto et al. 2011a). In addition, cases of *Onchocerca lupi* ocular infestations was originally diagnosed in a patient from Turkey (Otranto et al. 2011b) and afterwards in Germany, Tunisia, and Iran (Otranto et al. 2012a; Rojas et al. 2021). Remarkably, *O. lupi* is a little known, but emerging parasite of dogs in parts of the United States and Europe (Labelle et al. 2013; Otranto et al. 2012b), whose zoonotic potential was underestimated until recently. Finally, human infestations by *Dirofilaria* spp. often result in pulmonary nodule formations, which may be erroneously diagnosed as malignant neoplasm, hence representing a further challenge to physicians (Genchi et al. 2011).

A number of rickettsial organisms have been described in recent years and some of them have been implicated in human disease (Dantas-Torres et al. 2012b; Oteo and Portillo 2012). For example, *Rickettsia massiliae* was originally described from ticks in 1994 from France and recently found to be a ubiquitous emerging pathogen of humans (Vitale et al. 2006; Parola et al. 2008; García-García et al. 2010). All published cases of *R. massiliae* infections were clinically similar to Mediterranean spotted fever suggesting that many cases of *R. massiliae* infections are likely to be misdiagnosed as by *Rickettsia conorii* infections (Parola et al. 2008). The same is true for *Rickettsia parkeri*, which has been described as a human pathogen in the United States and South America, where the disease is likely to be misdiagnosed as other infectious illnesses, including Rocky Mountain spotted fever, dengue fever, and leptospirosis (Romer et al. 2011).

The above-mentioned examples illustrate how difficult the clinical diagnosis of VBZ may be and underline that medical physicians and veterinary practitioners, as well as public health authorities should be prepared to react promptly in face of atypical cases in endemic and non-endemic areas. It is vital to avoid delays in the treatment initiation, which may eventually result in the death of the patient (Dantas-Torres et al. 2012b).

35.5 Advancements in VBZ Diagnosis

There have been several advancements in the field of VBZ diagnosis in the past few decades. The refinement of serological tests and the development of molecular biology tools, along with the decipherment of the genomes for several pathogens, have improved considerably our capacity to diagnose VBZ in animals and humans, allowing the detection and characterization of new, emerging pathogens (Otranto 2015). Moreover, the adoption of a holistic diagnostic approach has culminated in the discovery of new human pathogens, including several bacterial species. For instance, *R. rickettsii*, the causative agent of Rocky Mountain spotted fever, was for many years the only rickettsial agent to be definitely associated with human diseases in the United States. In 2004, the use of a comprehensive diagnostic approach (including serological testing, immunohistochemical staining, cell culture isolation, and molecular methods) led to the description of the first cases of rickettsiosis by *R. parkeri*, a spotted fever group first identified 65 years ago in Gulf Coast ticks (*Amblyomma maculatum*) collected from the southern United States (Paddock et al. 2004).

Remarkably, *R. parkeri* has been detected in *A. maculatum* and *A. triste* in several South America countries, which suggests that the distribution of this *Rickettsia* in the western hemisphere is probably wider than currently known. Furthermore, a case report from Argentina suggested that *R. parkeri* infections in this region are likely to be misdiagnosed as other infectious diseases, including Rocky Mountain spotted fever and dengue fever (Romer et al. 2011). The use of molecular tools has been proven essential for the correct aetiological diagnosis of tick-borne spotted fever rickettsioses in the United States and other countries of the western hemisphere.

Human malaria has traditionally been associated to four human-adapted *Plasmodium* species: *Plasmodium falciparum*, *Plasmodium malariae*, *Plasmodium ovale*, and *Plasmodium vivax*. Recently, a fifth species (namely, *P. knowlesi*) was implicated in several cases of human malaria across south-eastern Asia (Antinori et al. 2013). These cases were initially misidentified as *P. malariae* infections by microscopy, but refined molecular study revealed a large focus of naturally acquired human infections by *P. knowlesi* in Malaysian Borneo (Singh et al. 2004). Importantly, the initial suspicion that another *Plasmodium* species was involved in human malaria in Malaysian Borneo was based on clinical (e.g., fever with chills and rigor, headache, cough, and vomiting), epidemiological (e.g., mostly adults), and laboratory data (e.g., high parasitaemia, over 5000 parasites per μl) (Singh et al. 2004). Once again, the "*P. knowlesi* example" underlines the importance of using a comprehensive approach, coupling clinical and epidemiological data with modern diagnostic test results toward a correct diagnosis of VBZ.

The use of molecular biology in epidemiological studies has also advanced our understanding of the transmission dynamics and origin of several pathogens causing VBZ. For long time, *Leishmania chagasi* was considered to be the agent of zoonotic visceral leishmaniasis in the New World and referred to as a distinct species from *L. infantum*. However, molecular analyses confirmed the Old World origin of the so-called *L. chagasi*, which is now widely accepted as a synonym with *L. infantum* (Kuhls et al. 2011). Another example of the utility of molecular tools in the diagnosis of VBZ is represented by the first ever described case of zoonotic ocular infestation by *O. lupi* in a patient from Turkey (Otranto et al. 2011b). The nematode detected in a subconjunctival mass was detected on the superonasal quadrant of bulbar conjunctiva, but cut during the surgical removal. The nematode was initially identified as belonging to the genus *Onchocerca* and later on molecularly characterized as *O. lupi*. After this first occurrence, additional cases were detected in human patients as well as in dogs and cats worldwide (Rojas et al. 2021).

The development of rapid tests including point-of-care assays is also an important advancement in terms of diagnosis of VBZ such as leishmaniasis and Chagas disease (Barfield et al. 2011; Grimaldi et al. 2012; Leony et al. 2019; Rodrigues et al. 2022). For instance, a new rapid test (PATH-Lemos rapid test) for the point-of-care diagnosis of Chagas disease was compared with a commercially available rapid test (Chagas STAT-PAK, Chembio). As compared to the reference test (the Ortho *T. cruzi* ELISA, Johnson & Johnson), the PATH-Lemos rapid test demonstrated an optimal sensitivity of 99.5% and specificity of 96.8%, respectively, while the Chagas STAT-PAK showed a sensitivity of 95.3% and specificity of 99.5% (Barfield et al. 2011). More recently, a study assessed the performance of chimeric proteins for the detection of anti-*T. cruzi*

IgG antibodies in dogs, with promising results in terms of sensitivity and specificity (Leony et al. 2019). Some of these chimeric proteins were used to develop an immunochromatographic rapid test for the serological diagnosis of *T. cruzi* infection in wild and domestic canids (Rodrigues et al. 2022). These results show that both rapid tests present high levels of sensitivity and specificity, representing reliable tools for screening and diagnosis of Chagas disease. As another example, a new rapid test for plague detection in humans and other mammalian hosts has recently been developed, with high sensitivity and specificity (Bezerra et al. 2022).

Undoubtedly, these advancements will influence the clinical practice of medical physicians and veterinary practitioners. Hopefully, these tools will also be made available for point-of care use in poor rural settings in VBZ-endemic countries in order to improve the diagnostic standard for VBZ in these areas.

35.6 Unresolved Issues

The epidemiology and distribution of VBZ is changing due to several factors, such as unplanned urbanization, illegal deforestation, changing demographics, economic crisis, increased global movement of animals and people, changes in human behavior, land use and practices (Colwell et al. 2011; Kilpatrick and Randolph 2012; Dantas-Torres 2015). As a consequence, our understanding regarding several aspects (from aetiology to control) of VBZ has also changed in recent years. For example, the refinement and widespread use of genetic tools has greatly improved our capacity of detecting and identifying microorganisms in animals, humans, and arthropods. Indeed, a number of microorganisms have recently been detected in arthropods (e.g., ticks) and some of them have been implicated in human disease (Dantas-Torres et al. 2012b). On the other hand, the pathogenic potential of several recently described organisms remain largely unknown and further research is fundamental to predict the emergence of novel VBZ in animals and humans.

The diagnosis of VBZ in animals and humans has advanced considerably in the past decades. For example, rapid immunochromatographic diagnostic tests and PCR-based tools have been developed (Dantas-Torres et al. 2012c), even if most of these tools are still largely restricted to research institutes and reference diagnostic centers. Indeed, the effective implementation of these new diagnostic tools in the field may still be far from reality in some VBZ-endemic areas. Considering the diversity of pathogenic agents that may potentially infect animals and humans in tropical and subtropical regions, the use of accurate diagnostic methods is fundamental to improve clinical practice. Similarly, a precise and rapid etiological diagnosis is pivotal to expedite treatment decisions.

It is acknowledged that the control of VBZ in animals and humans is a difficult task due to the inherent complexities involved in the transmission cycles of these diseases. When a VBZ is established in a given area, it is very difficult to eradicate the pathogen and/or the vector or even to reduce the burden of disease. An appropriate example is the case of zoonotic visceral leishmaniasis, which is still causing considerable morbidity and mortality in endemic areas. In Brazil, for example, a control program against zoonotic

visceral leishmaniasis has been in place since more than 50 years ago with limited or no impact on the incidence of the disease in dogs and humans (Romero and Boelaert 2010; Dantas-Torres et al. 2019). For any VBZ to be controlled, it is fundamental to reduce the contact between susceptible hosts (animals and people) and vectors. A number of tools for reducing the contact of animals with arthropods (e.g., phlebotomine sand flies, mosquitoes, and ticks) have been developed in recent years, such as collars and spot-on pipettes containing active compounds with insecticide and repellent activity (Dantas-Torres et al. 2012c). Insecticide impregnated bed nets may reduce the exposure of humans to arthropod vectors and thus contribute to VBZ control (Kroeger et al. 2003). Unfortunately, most people living in poor rural communities, tropical and subtropical regions of the world cannot handle the costs of preventive tools. In such cases, public health authorities should elaborate and implement governmental programs for the control of VBZ in order to reduce the burden of these diseases in animals and humans living in poor rural communities.

Continuous education for medical physicians and veterinary practitioners is pivotal for controlling VBZ, as they are in the front line and should be up-to-date regarding recent advances in VBZ and base their clinical practice on the highest quality scientific evidence available. Improving VBZ detection and reporting in developing countries is central to have more precise burden estimates in these countries, which in turn is important to define priority in terms of control and management. In this context, the adoption of a One Health approach toward the management of VBZ has also been emphasized in recent years (Day 2011; Dantas-Torres et al. 2012b; Bezerra-Santos et al. 2021; Mendoza-Roldan et al. 2021a) and will be a critical step toward the control of these diseases. Indeed, it is imperative to reduce the gap of communication between, medical physicians, veterinarians, and public health authorities dealing with VBZ worldwide, particularly (but not exclusively) in low- and middle-income countries. Certainly, this is a simple but important step toward reducing the burden of VBZ in animals and humans around the world.

Abstract

Lyme borreliosis (LB) and relapsing fever (RF) are zoonotic diseases that are caused by spirochetal bacteria belonging to the genus *Borrelia*. The agents are generally maintained in natural transmission cycles by vector ticks (exception: body louse) and reservoir hosts. Lyme borreliosis (synonym in North America: Lyme disease, LD) is the most frequently reported tick-borne disease in Europe and North America. It mainly affects skin, large joints, nervous system or heart and is considered a multi-system disorder. Relapsing fever manifests as recurrent febrile attacks accompanied by headaches, muscle and joint aches, interrupted by afebrile intervals. It mainly occurs in tropical and subtropical regions including North and South America, Africa, Asia, and South European countries. In this chapter we describe the genus Borrelia, the huge diversity that has become apparent in recent years, the geographical distribution of its species, and the complex genome that is reflected in the complex ecology and disease symptoms. We also give information on diagnostics and its challenges, therapy, and prophylactic measures.

36.1 Introduction

Lyme borreliosis (LB) and relapsing fever (RF) are zoonotic diseases that are caused by spirochetal bacteria belonging to the genus *Borrelia*. The agents are generally maintained in natural transmission cycles by vector ticks (exception: body louse) and reservoir hosts. Lyme borreliosis (synonym in North America: Lyme disease, LD) was named after the town Old Lyme in Connecticut, United States, where a cluster of

juvenile arthritis cases (Steere et al. 1976, 1978, 2016) led ultimately to the discovery of the spirochetal agent of LB, *Borrelia burgdorferi* (Burgdorfer et al. 1982). The bacterium was described as species in 1984 (Johnson et al. 1984). In Europe, it had been suspected since the turn of the last century that a tick-borne agent(s) was the cause of medical conditions that are now recognized as LB (reviewed by Stanek et al. 2002).

Descriptions of conditions reminiscent of relapsing fever go back to antiquity and Hippocrates' times, but only in 1843 was the name "relapsing fever" coined by David Craigie during an epidemic in Edinburgh. The first microscopic observation of the etiological agent of louse-borne relapsing fever, now known as *Borrelia recurrentis*, was in 1868 by Otto Obermeier in the blood of febrile patients and reported to the Berlin Medical Society ("Berliner medicinischen Gesellschaft") in 1873 (reviewed by Warrell 2019, see references therein). The spirochetal agent of louse-borne relapsing fever was originally named *Protomycetum recurrentis*, *Spirochaeta obermeieri*, or *Spirochaeta recurrentis* (Lebert 1876; Cutler 2010) and then *Borrelia recurrentis*, when the genus was renamed after the French microbiologist Amédée Borrel by Swellengrebel in 1907 (Bergey 1925; Skerman et al. 1980). "Tick fever" – now known as tick-borne relapsing fever – was initially described in East Africa in 1904 and later documented in other parts in Africa (Elbir et al. 2013; Trape et al. 2013). New species are still being discovered (Fingerle et al. 2016), and the taxonomy of soft tick vectors is still under investigation (Trape et al. 2013). Louse-borne RF had probably the most severe impact on humankind of all *Borrelia* species causing huge epidemics during times of war, migration, poverty, and poor hygiene (reviewed by Warrell 2019, for a historical report see Lebert 1876).

Lyme borreliosis is the most frequently reported tick-borne disease in Europe and North America. It can affect tissues and organs and is considered a multi-system disorder. It may affect the skin, joints, nervous system, and other internal organs (Steere 2001; Stanek et al. 2011). A typical manifestation of LB is erythema migrans (also called bull's-eye rash), which is a skin manifestation that appears as a roundish red lesion (often around a central clearing) that slowly grows in diameter. Other manifestations are lymphocytoma (lymphadenosis benigna cutis), meningopolyneuritis (also known as Garin-Bujadoux-Bannwarth syndrome), unilateral or bilateral facial palsy, meningitis, cranial neuropathies, acrodermatitis chronica atrophicans, Lyme arthritis, and Lyme carditis. Lyme neuroborreliosis is a condition that appears to be more frequent in Europe than in North America but with a more similar clinical picture than often assumed (Stanek et al. 2012; Koedel et al. 2015).

Relapsing fever manifests as recurrent febrile attacks accompanied by headaches, muscle and joint aches interrupted by afebrile intervals (Cutler 2010; Warrell 2019). It mainly occurs in tropical and subtropical regions including North and South America, Africa, Asia, and South European countries (Rebaudet and Parola 2006). *Borrelia* species that have been reported to cause relapsing fever in humans include *B. duttonii*, *B. crocidurae*, *B. hispanica*, *Ca.* B. kalaharica in Africa, *B. persica* in Asia, *B. hermsii*, and to a lesser extent *B. turicatae* and *B. parkeri* in Western North America (Hinnebusch et al. 1998; Rebaudet and Parola 2006; Schwan et al. 2007; Elbir et al. 2013; Fingerle et al. 2016). *Borrelia recurrentis* causes louse-borne relapsing fever, which is often more severe than tick-borne relapsing fever (Warrell 2019). Upon antibiotic treatment, a condition called Jarisch-Herxheimer reaction can

be provoked (less often and less severe also in other RF species) and trigger organ failure that may cause death of the patient. Nowadays, *B. recurrentis* is mainly found in the Horn of Africa (Hoch et al. 2015).

One tick-borne RF species is an exception to the rule: *Borrelia miyamotoi* is vectored by ticks of the genus *Ixodes*, occurs in the temperate zones of the Northern Hemisphere, and can cause untypical RF illness (Fukunaga et al. 1995; Scott et al. 2010; Platonov et al. 2011; Hovius et al. 2013; Telford et al. 2015; Boden et al. 2016).

In this chapter, we describe the genus *Borrelia,* the huge diversity that has become apparent in recent years, the geographical distribution of its species, and the complex genome that is reflected in the complex ecology and disease symptoms. We also give information on diagnostics and its challenges, therapy, and prophylactic measures.

36.2 The Genus *Borrelia*

The genus *Borrelia* (emended Margos et al. 2018) was first described by Swellengrebel 1907, with *Borrelia anserina* as the chosen type species (Skerman et al. 1989). The species is an avian pathogen that can cause clinical disease in fowl and has a worldwide distribution (CAB International 2002). The genus currently comprises 60 proposed and named species (Table 1), several of which have "Candidatus" status, which means that cultured isolates are not available (Stackebrandt et al. 2002) (see also List of Prokaryotic Names with Standing in Nomenclature (LPSN), https://www.bacterio.net/). There are 22 species with validly published names under the International Code of Nomenclature of Prokaryotes (ICNP) within the RF group of spirochetes, 20 species with validly published names within the LB group of spirochetes (also termed *Borrelia burgdorferi* sensu lato (s.l.) species complex), and one species (*B. turcica* Güner et al. 2004) within a third group, sometimes called reptile-associated group (Margos et al. 2018). Apart from these species, there is a large diversity of species that have not yet been named officially or do not have validly published names and their pathogenic potential is largely unknown (Mitani et al. 2004; Lin et al. 2005; Takano et al. 2011; Fedorova et al. 2014; Ivanova et al. 2014; Ehounoud et al. 2016; Fingerle et al. 2016; Loh et al. 2017; Kumagai et al. 2018; Qiu et al. 2019; Binetruy et al. 2020; Muñoz-Leal et al. 2020; Norte et al. 2020; Bermúdez et al. 2021; Weck et al. 2022). A phylogeny based on 16S rRNA sequences shows (Fig. 1 from Margos et al. 2020c) that some of these *Borrelia* lineages cluster within clades of previously characterized *Borrelia* species or form their own clades: for example, *Candidatus* B. kalaharica, *Ca.* B. texasensis, and *Borrelia* sp. from Tanzania fall in the argasid-transmitted RF clade; *Ca*. B. aligera (not shown), *B. chilensis,* and *Ca*. B. ibitipoquensis (not shown) fall in the *Ixodes*-transmitted LB clade; while *Ca*. B. africana and *Ca*. B. ivorensis form their own clade (Mitani et al. 2004; Lin et al. 2005; Ivanova et al. 2014; Ehounoud et al. 2016; Fingerle et al. 2016; Muñoz-Leal et al. 2020; Norte et al. 2020). A significant diversity exists in borreliae described from metastriate ticks that form unique, deeply branching lineages within the genus; these include *Ca*. Borrelia tachyglossi from echidnas (Loh et al. 2017), several novel species from snakes (Takano et al. 2010), Testudines (Takano

Table 1 Overview of currently known *Borrelia* species with type strains and other characteristics

Name	Type strain	Pathogenic to; disease	Reservoir hosts	Vector species	Nomenclatural status	Geographic distribution	Reference	Association
Borrelia afzelii	VS461	Human; LB	Rodents, insectivores	*I. ricinus, I. persulcatus, I. hexagonus*	Validly published under the ICNP, correct name	Europe, Asia	Canica et al. 1993; Validation list no. 48. Int J Syst Bacteriol 1994; 44:182–183	LB
Borrelia americana	SCW-41	Unknown	Birds, rodents	*I. minor, I. pacificus*	Validly published under the ICNP, correct name	North America	Postic et al. (2007), Rudenko et al. (2009)	LB
Borrelia bavariensis	PBi	Human; LB	Rodents	*I. ricinus, I. persulcatus*	Validly published under the ICNP, correct name	Europe, Asia	Margos et al. (2009, 2013)	LB
Borrelia bissettiae	DN-127	Potentially human; LB	Rodents	*I. ricinus, I. spinipalpis, I. pacificus*	Validly published under the ICNP, correct name	North America	Postic et al. (1998), Margos et al. (2016)	LB
Borrelia burgdorferi sensu stricto	B31	Human; LB	Rodents, birds, insectivores	*I. ricinus, I. hexagonus, I. scapularis, I. pacificus, I. minor, I. affinis*	Validly published under the ICNP, correct name	Europe, North America	Johnson et al. (1984)	LB

[a]Species marked with 'a' are putative species that have been mentioned in the literature (see, e.g., reviews by Jakab et al. (2022), Trevisan et al. (2021)) but have not been properly described nor do they appear in the LPSN list; *ND* not designated

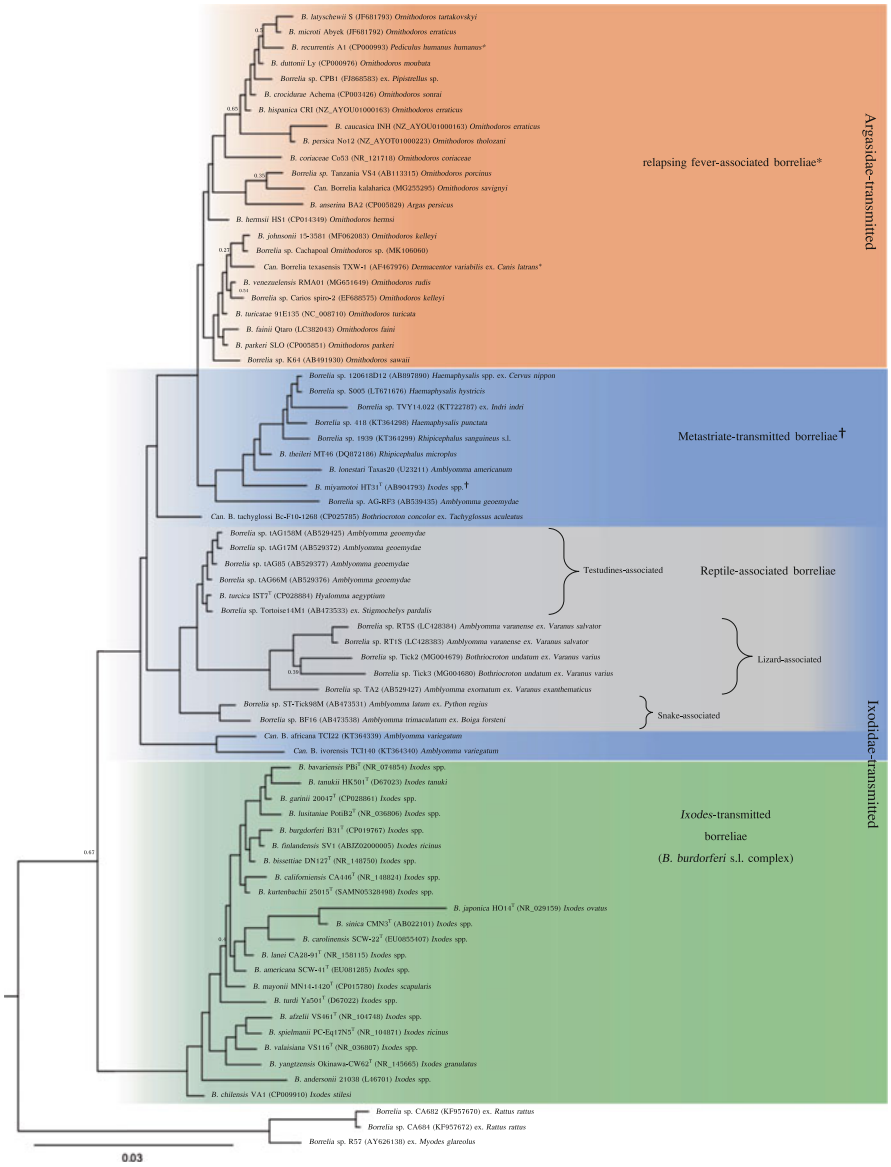

Fig. 1 Phylogenetic trees of *Borrelia* species based on the 16S rRNA locus. (Figure taken from (Margos et al. 2020c) with permission)

et al. 2011), lizards (Panetta et al. 2017; Kaenkan et al. 2020; Supriyono et al. 2019), and two putative species associated with *Haemaphysalis* spp. and Asian deer (Kumagai et al. 2018). Given the growing diversity in the genus *Borrelia* illustrated in Fig. 1, it would not be surprising if more species were found in the future (Elbir et al. 2013; Fingerle et al. 2016; Stete et al. 2018).

Historically, bacterial systematics relied on morphological and biochemical differences for differentiating bacterial taxa (Gajdacs 2019). Later on, bacterial taxonomy was complemented with DNA-DNA hybridization, melting temperature differences and 16S rRNA sequence analyses for characterization of species/strains. In the late 1990s and early 2000s, multilocus sequence typing (MLST), multilocus sequence analysis (MLSA), and genome comparison were accepted for taxonomic purposes (Stackebrandt et al. 2002; Gevers et al. 2006; Stackebrandt and Ebers 2006). For *Borrelia*, in 2008 an MLST/MLSA system has been deployed, which uses sequence fragments of eight chromosomally located housekeeping genes (Margos et al. 2008, 2009). The MLST database is maintained at the University of Oxford, Department of Zoology, and is part of the bacterial isolate genome sequence database (BIGSdb) (Jolley and Maiden 2010).

36.3 *Borrelia* Ecology: Hosts and Vectors

Borrelia are parasitic bacteria that depend on transmission between tick vectors and vertebrate hosts for survival; there are no free-living forms. As shown in Table 1, for *B. burgdorferi* s.l., a large array of vertebrates, including rodents, insectivores, lizards, and birds, can serve as reservoir hosts. However, the breadth of the ecological niches varies between species (Margos et al. 2019b). Some species, such as *B. burgdorferi* sensu stricto (s.s.), can use a wide variety of reservoir hosts (e.g., rodents, insectivores, birds), while others, such as *B. spielmanii*, have a narrow reservoir host spectrum, including dormice or potentially hedgehogs (reviewed by Wolcott et al. 2021). The same is true for vector association; while some species are adapted to use a wide range of vectors (e.g., *B. garinii* can utilize *Ixodes ricinus*, *I. persulcatus*, *I. pavlovskyi*, *I. uriae*), others are restricted to one vector species (e.g., *B. valaisiana* is mainly adapted to *I. ricinus*) (Margos et al. 2012a; Masuzawa 2004).

The genus *Borrelia* has increased considerably in diversity in recent years, and in addition to the classic division in relapsing fever group and *B. burgdorferi* s.l., there are lineages that take an intermediate position in phylogenies. These "intermediate" forms encompass several species that are associated with hard ticks and species that are associated with reptiles (snakes, tortoises, lizards). Transovarial transmission was suggested a regular feature in the ecology of RF spirochetes (at least for the soft tick-associated *Borrelia* species) but has not been proven for all species and not for intermediate, reptile-associated species (Kalmar et al. 2015). Given this ecology, i.e., transovarial transmission, it has been suggested that ticks not only function as vector but also as reservoir host for RF spirochetes (Piesman and Schwan 2010; Schwan and Raffel 2021; Schwan 2021). Thus, adaptation to vector tick species was thought to be an ecological driver, and several species are named after the tick species they were discovered in, e.g., *Borrelia hermsii*, *Ornithodoros hermsi*; *Borrelia coriaceae*, *O. coriaceus* (Trevisan et al. 2021; Jakab et al. 2022). As shown in Table 1 and reported by some researchers (Assous and Wilamowski 2009), this is not always the case, and some relapsing species do not match the name of its vector (e.g., *B. duttonii* – *O. moubata*) or may be able to use several tick species as vector (e.g., *B. crocidurae* – *O. erraticus, O. sonrai*). A notable exception in the RF group is

Borrelia recurrentis, which is transmitted by the human body louse *Pediculus humanus humanus* (Warrell 2019); there is no transovarial transmission in the louse, and humans are the only known host for this species. Although reservoir hosts may not be required for maintaining RF spirochetes in natural transmission cycles, as all ticks must to take blood meals from hosts for developing into the next stage or for egg production, spirochetes of the RF and the intermediate groups can also infect hosts, which may then function as reservoirs (Piesman and Schwan 2010).

Adaptation to different reservoir hosts or vectors are considered main drivers for diversification of species of the genus *Borrelia* and for determining the spatial range and structure of populations (Piesman 2002; Kurtenbach et al. 2006; Ogden et al. 2008; Hoen et al. 2009; Vollmer et al. 2011; Margos et al. 2012a, b; Elbir et al. 2013; Medlock et al. 2013; Mechai et al. 2015; Newman et al. 2015; Estrada-Peña et al. 2016; Talagrand-Reboul et al. 2018; Norte et al. 2020). As borreliae can be found in ticks that are not vector species and in animals that are not reservoir hosts, definitions for the terms **vector** and **reservoir host** have been established (Kahl et al. 2002): vector species and reservoir hosts have to fulfill the criteria that (i) they can become infected with borreliae, (ii) borreliae are maintained and can amplify, and (iii) transmission to the next host/vector must be successful. That means that not every tick or vertebrate that harbors *Borrelia* is also a "true" vector or reservoir host for that particular species. Thus, ideally, vector competence and reservoir host competence need to be experimentally confirmed (Margos et al. 2019b; Eisen 2020; Wolcott et al. 2021). The most reliable method for proving reservoir competence of a host and vector competence for a tick species is to perform transmission experiments, although this is laborious and logistically challenging. In xenodiagnosis, a common method in parasitology (Schenone 1999), naïve tick larvae feed on a host that has been challenged with *Borrelia* either by tick bite or needle inoculation. The viability of *Borrelia* in the resulting nymphs is evaluated; only reservoir hosts will transmit the bacteria to ticks (Ginsberg et al. 2005). If those nymphs are experimentally shown to infect a new host, then the vector competence of the tick is proven.

Although life history traits of ticks may vary, what all tick species have in common is that during their life cycle they produce eggs, larvae, nymphs, and adults. Larvae, nymphs, and adult female ticks require a blood meal to molt into the next developmental stage or to produce an egg batch, respectively (Sonenshine and Roe 2014; Gray et al. 2016). In some species, adult males may attach to hosts to facilitate feeding of females, but they do not require a blood meal (Wang et al. 1998). The number of nymphal stages may vary between taxa; often soft ticks have several sequential nymphal stages before molting into adult ticks. Soft ticks take fast blood meals within minutes, while *Ixodes* ticks require days to finish their blood meal (Vial 2009; Sonenshine and Roe 2014). Phenotypically, ticks can be nidicolous (endophilic) or non-nidicolous (exophilic). Between blood meals nidicolous ticks remain in close proximity to burrows or nests of their hosts; often they are more host specific than non-nidicolous ticks. Non-nidicolous ticks occupy open habitats and quest (i.e., search or wait for hosts) in the open (Apanaskevich and Oliver 2014). Ticks may vector a large variety of pathogens, including protozoa, bacteria, and viruses, and the differences in vector biology may significantly impact the epidemiology of transmitted microorganisms.

In the life cycle of *Borrelia*, ticks that have a generalist feeding behavior attach to a range of animals (including rodents and birds) and can serve as vectors for more than one *Borrelia* species. A good example for a hard tick species in Europe is *Ixodes ricinus* Linnaeus, 1758, which is known as vector for *B. afzelii* Canica et al 1993, *B. bavariensis* Margos et al. 2013, *B. burgdorferi s.s.* Johnson et al. 1984, *B. garinii* Baranton et al. 1992, *B. lusitaniae* Le Fleche et al. 1997, *B. miyamotoi* Fukunaga et al. 1996 (a RF species), *B. spielmanii* Richter et al. 2006, and *B. valaisiana* Wang et al. 1997 (Comstedt et al. 2011; Eisen 2020; Margos et al. 2012a; Masuzawa 2004). Transovarial transmission, which is well-known to occur in RF spirochetes, is infrequently reported in *B. burgdorferi* s.l. and may depend on the *Borrelia* sp.-*Ixodes* sp. combinations involved (Nefedova et al. 2004; Rollend et al. 2013; van Duijvendijk et al. 2016). Therefore, since experimental transmission of tick-borne agents in the laboratory is time-consuming and complex, researchers have (under the assumption of absence of transovarial transmission in *B. burgdorferi* s.l.) used infections in field-captured larvae collected feeding on hosts as a surrogate indicator of reservoir host competence.

The majority of RF spirochetes can be maintained in vector populations by transovarial transmission for prolonged periods of time because of the long life span of some soft tick species (Piesman and Schwan 2010; Schwan and Raffel 2021). Thus, ticks may be considered as infected hosts (Barbour and Hayes 1986). Certainly, the ticks need vertebrate animals for their blood meals and transmit *Borrelia* bacteria they carry to animals, which may then serve as reservoirs (Felsenfeld 1965; McCall et al. 2007; Cutler 2010; Elbir et al. 2013). Often, soft ticks are indiscriminate in their host choice and take blood meals from whatever hosts are available (Vial 2009).

As apparent in Fig. 1, the different clades of *Borrelia* use different tick genera as vectors. For the LB group of spirochetes ticks of the genus *Ixodes* serve as vectors, and it may appear in Fig. 1 that there is only one vector species per *Borrelia* species, but this is not always the case; see Table 1 (Comstedt et al. 2011; Margos et al. 2012a; Masuzawa 2004). Of the genus *Ixodes*, the most important vectors for human pathogenic *Borrelia* species (sometimes also termed bridge vectors) are the generalist species *I. ricinus* in Europe, *I. persulcatus* Schulze 1930 in Eastern Europe and Asia, and *I. scapularis* Say 1821 and *I. pacificus* Cooley & Kohls 1943 in North America (Swanson et al. 2006). Many of the RF species are transmitted by soft ticks of the genus *Ornithodoros;* one species, *B. recurrentis*, is adapted to the body louse; the type species, *B. anserina*, is associated with *Argas* spp., and one species, *B. miyamotoi*, is transmitted by *Ixodes* species that also transmit LB species, i.e. *I. pacificus*, *I. scapularis*, *I. ricinus*, and *I. persulcatus* (Fukunaga et al. 1995; Scoles et al. 2001; Richter et al. 2003; Warrell 2019; Trevisan et al. 2021; Jakab et al. 2022).

There can be a substantial fluctuation from year to year in tick and host abundance and *Borrelia* infection prevalence (Randolph et al. 2002; Ostfeld et al. 2006; Bregnard et al. 2020), and long-term data are required to address questions of increase/decrease of populations (Coipan et al. 2013; Bregnard et al. 2020; Okeyo et al. 2020).

36.4 *Borrelia* species: Geographic Distribution and Disease-Causing Species

Generally, the LB group of spirochetes is roughly distributed in a belt-like fashion between latitude 40 and 60, matching the presence of reservoir hosts and vector species (Fig. 2). However, *B. garinii* also occurs in seabird transmission cycles in the Southern and Northern Hemispheres, and in recent years, several species have been described to occur in South America (e.g., *B. chilensis*, *Ca*. B. ibitipoquensis, *Ca*. B. paulista) (Ivanova et al. 2014; Muñoz-Leal et al. 2020; Weck et al. 2022). Specifically, the adaptation of *Borrelia* species to reservoir host and vector species is reflected in the geographic distribution of individual species or populations (Margos et al. 2019b). In the *B. burgdorferi* s.l. complex, there are (i) species that are found in Europe only, including *B. spielmanii* and *B. valaisiana;* (ii) one species, *B. lusitaniae*, is found in Europe and Northern Africa; (iii) species that are found in Europe and Asia, e.g., *B. afzelii*, *B. bavariensis, B. garinii,* and *B. turdi*; (iv) species that are restricted to Asia, e.g., *B. japonica, B. sinica, B. tanukii,* and *B. yantzensis;* (v) species that have been found in North America, including *B. americana, B. andersonii, B. californiensis, B. carolinensis, B. kurtenbachii, B. lanei, B. maritima,* and *B. mayonii;* and (vi) species that are found in North America and Europe, e.g., *B. burgdorferi* s.s. and *B. bissettiae*.

Not all species that belong to the *B. burgdorferi* s.l. complex cause disease in humans. Six of the currently known 22 species are assured human pathogenic. Five of the species pathogenic to humans occur in Europe, including *B. afzelii*, *B. bavariensis*, *B. burgdorferi* s.s., *B. garinii*, and *B. spielmanii* (Fingerle et al. 2008; Stanek et al. 2011). Two species are the cause of human LD in North America,

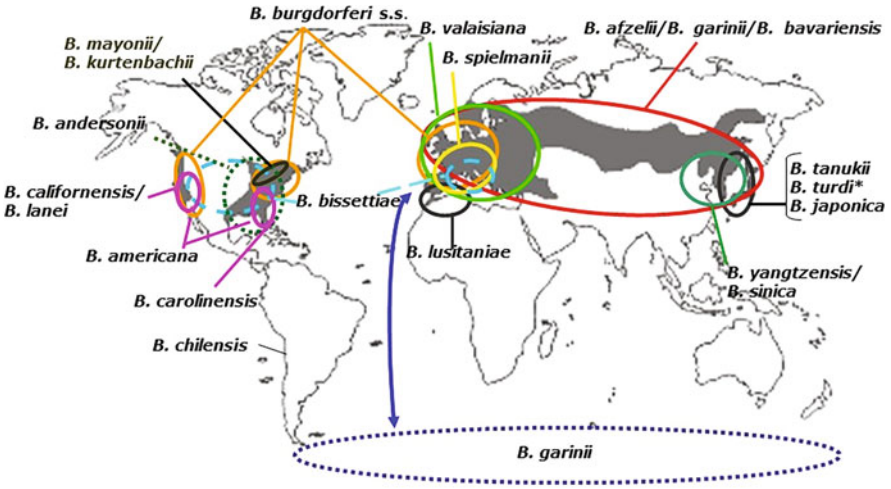

Fig. 2 Geographic distribution of Lyme borreliosis spirochetes. Image taken with permission from (Margos et al. 2019b), Frontiers in Ecology and Evolution

B. burgdorferi s.s. and *B. mayonii* (Spielman 1994; Steere et al. 2004; Pritt et al. 2016). The latter species was only discovered in 2016 in patients visiting the Mayo Clinic in Wisconsin (Pritt et al. 2016). Subsequently, additional symptomatic *B. mayonii*-infected patients have been discovered (Kingry et al. 2018).

In Europe, two additional species have been discussed as human pathogens; these are *B. lusitaniae* and *B. bissettiae*. *Borrelia lusitaniae* is commonly found in questing ticks in Mediterranean countries (Zhioua et al. 1999; De Michelis et al. 2000; Younsi et al. 2005; Dsouli et al. 2006; Amore et al. 2007; Norte et al. 2021). So far, two cases have been described suspecting *B. lusitaniae* as a human pathogen (Collares-Pereira et al. 2004; de Carvalho et al. 2008). One patient presented with vasculitis-like syndrome, the other with chronic skin lesion. *Borrelia bissettiae* has rarely been found in questing ticks in Europe (Hanincova et al. 2003; Coipan et al. 2016; Blazejak et al. 2018). However, one human isolate of *B. bissettiae* was obtained from a patient with symptoms resembling mild neuroborreliosis (Fingerle et al. 2008; Margos et al. 2016). In North America, *B. bissettiae* is commonly found in questing ticks at a regional scale and in certain habitat types (Postic et al. 1998; Picken and Picken 2000; Brown et al. 2006; Eisen et al. 2009; Fedorova et al. 2014), but no patient isolates have been obtained from humans (Girard et al. 2011).

Borrelia valaisiana has been reported to be nonpathogenic for humans (Margos et al. 2017b). Reservoir hosts are bird species, such as thrushes (*Turdus* spp.); its vector is *I. ricinus*; and it is being found as frequently as *B. garinii* in certain regions (Rauter and Hartung 2005). Although commonly found in questing ticks, to date not a single human isolate of *B. valaisiana* has been acquired (Margos et al. 2017b). For the remaining species (Table 1), the human pathogenic potential is unknown. Reasons may be that:

(i) Many of these species are transmitted by ticks that do not bite humans, and therefore, the species come not into contact with humans.
(ii) Or their genetic make-up may explain their lack of human pathogenicity.

Human disease-causing RF spirochetes often occur in subtropical and tropical regions (Fig. 3). Relapsing fever spirochetes have been divided into old and new world species (see Table 1). In North America, human disease-causing soft tick-associated species are mainly *B. hermsii* and *B. turicatae,* to a lesser extent *B. parkeri* (Piesman and Schwan 2010). Information on RF spirochetes in Central or South America is scarce and patchy (Lopez et al. 2016). In Africa, human disease is caused mainly by *B. duttonii*, *B. crocidurae*, and *B. recurrentis* (Elbir et al. 2013; Trape et al. 2013). For the louse-borne-associated species, *B. recurrentis*, foci of disease had been described in Peru and Africa, but nowadays, it seems to persist mainly in countries of the Horn of Africa (Warrell 2019). *Borrelia persica*, *B. latyschevii*, and *B. caucasica* cause human disease in the Middle and Central East, and *B. hispanica* is known to cause human and animal disease in Southern Europe and North Africa (Rebaudet and Parola 2006; Margos et al. 2020b). *Borrelia theileri* and *B. anserina* have a worldwide distribution and can cause disease in bovine and avian species, respectively (Trevisan et al. 2021; Jakab et al. 2022). *Borrelia miyamotoi* is a hard tick-associated relapsing fever species that uses the

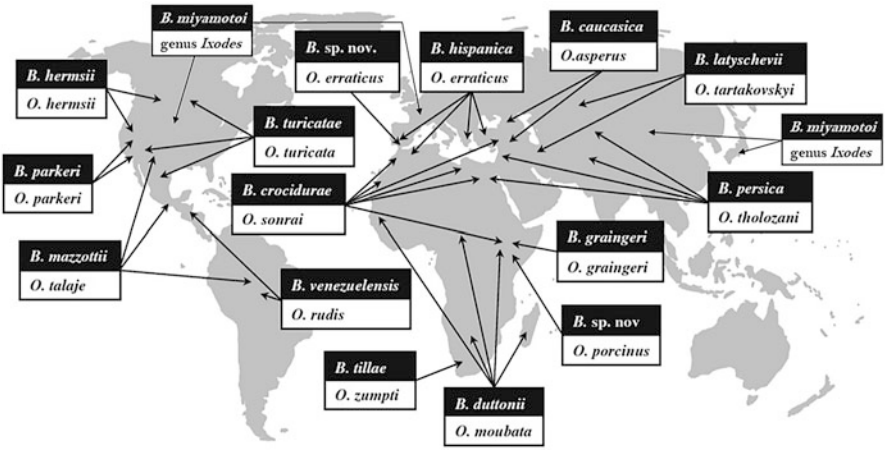

Fig. 3 Geographic distribution of relapsing fever spirochetes and their respective vectors. (Image with modifications taken with permission from Rebaudet and Parola 2006)

same vectors as LB species in North America, Europe, and Asia (Fukunaga et al. 1995; Scoles et al. 2001; Richter et al. 2003; Mun et al. 2006). It can cause human disease that neither represents typical relapsing fever nor typical LB (Platonov et al. 2011; Krause et al. 2013; Telford et al. 2015; Boden et al. 2016).

36.5 Cell Biology

Borreliae are helical bacteria. The cell body measures 0.2–0.3 μm in width and 10–30 μm in length (Barbour and Hayes 1986). *Borrelia* cell surface membranes differ in lipopolysaccharide (LPS) and protein richness from that of typical gram-negative bacteria (Takayama et al. 1987; Radolf et al. 1994). *Borrelia* possess a diderm cell envelope consisting of an outer-surface membrane and a cytoplasmic membrane, which are separated by a periplasmic space. The cytoplasmic membrane is covered by a peptidoglycan layer. Depending on the species, 7–30 flagella are inserted near the end of the protoplasmic cylinder of the cell extending into the periplasmic space (Hovind-Hougen 1974, 1995; Karimi et al. 1979; Cutler et al. 1997; Rosa et al. 2005; Guyard et al. 2013). These endoflagella give the bacteria a unique form of motility, permitting them to move in viscous media. They can flex and bend, propel forward and backward, and rotate (non-translational mode of motility) (Barbour and Hayes 1986; Charon et al. 2012), and this motility is crucial for host/vector infection (Sultan et al. 2013) (Fig. 4).

Borreliae possess outer membrane proteins (OMPs), which are integral membrane proteins that function as transporters for nutrients or other essential molecules (Kenedy et al. 2016). It was shown by freeze fracture electron microscopy that the outer membrane contains relatively few transmembrane proteins (Radolf et al. 1994; Shang et al. 1998). Such studies provided evidence that blebs, which are shed from *Borrelia*

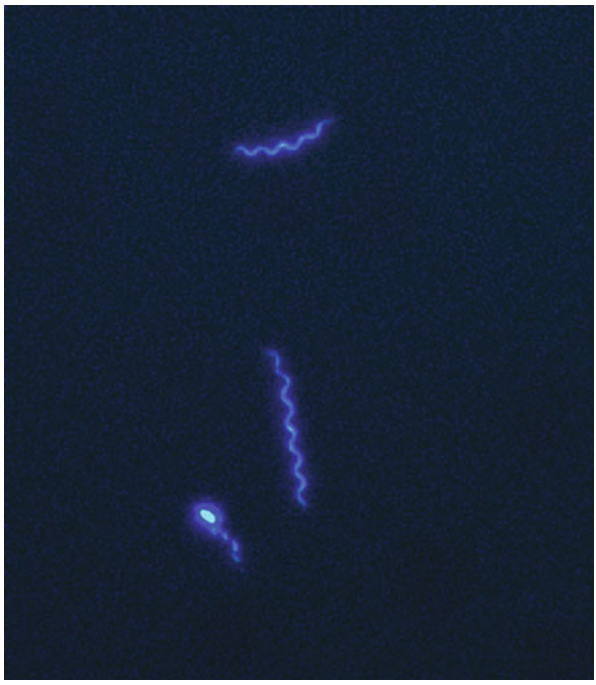

Fig. 4 *Candidatus* Borrelia kalaharica isolated from blood, DAPI stain (courtesy Dr. Volker Fingerle, German National Reference Centre for Borrelia, Oberschleißheim, Germany)

cells, are surrounded by a membrane(s), resembling the outer membrane, and/or the cytoplasmic membrane, suggesting that blebs are pinched-off sections of the cells.

Inserted in the outer-surface membrane via lipid moieties are outer-surface proteins (Osp's) (Berström and Zückert 2010); >150 potential Osp's have been identified in *B. burgdorferi* s.s. (Fraser et al. 1997). They have been named alphabetically in order of their identification, e.g., OspA, OspB, OspC, etc. Many of these proteins have functions in the interaction of the bacteria with their environment (host or vector).

Many OMP and Osp's are important for the interaction with host and vector in the life cycle of *Borrelia*, and intensive research efforts are being made to understand their function (e.g., Berström and Zückert 2010 ; Lin et al. 2012, 2014; Petzke and Schwartz 2015; Kuleshov et al. 2020; Rosa and Jewett 2021). Particularly interesting are the variable major surface protein (Vmp): the variable large and small surface proteins (Vlp and Vsp, respectively) of RF spirochetes and variable major surface protein-like proteins (vls) of LB spirochetes, which allow the bacteria to switch their surface antigens in a programmed manner, also known as antigenic variation, and escape from the hosts' immune response. In this system(s), an expression cassette lies adjacent to silent cassettes that contain variable sequences that can be imported (or parts of it) into the expression cassette changing the dominant antigen epitope of the protein (Barbour et al. 2006; Dai et al. 2006; Norris 2006; Chaconas et al. 2020; Kuleshov et al. 2020). The Vlp and Vsp's of RF spirochetes are similar to VlsE (expressed variant) and OspC of LB spirochetes, respectively (Lescot et al. 2008).

Vmp encoding regions have been located on a variety of plasmids, including lp23, lp24, lp29, and lp41 (Lescot et al. 2008; Kuleshov et al. 2020).

The in vitro cultivation of *Borrelia* has facilitated or permitted progress on topics, such as biology, genetics, genomics, and genetic manipulation of the bacteria. Other than many pathogenic bacteria, *Borrelia* are fastidious bacteria that do not grow well on plates but require a very rich liquid culture medium (Barbour and Hayes 1986). As microaerophilic bacteria, they require either growth in closed glass vials or under an atmosphere of 6% CO_2 (Margos et al. 2015a). For LB spirochetes, some laboratories use in-house prepared MKP medium (Preac-Mursic et al. 1986; Ruzic-Sabljic et al. 2006; Ruzic-Sabljic et al. 2014), but often a commercially available medium (BSK-H) is used that may be supplemented already with rabbit serum (BSK-H complete). For relapsing fever spirochetes, the use of BSK medium in various modifications has also been reported (Cutler et al. 1994; Replogle et al. 2021), while other reported the growth of *B. recurrentis*, *B. miyamotoi*, and *B. hispanica* in modifications of MKP medium (Margos et al. 2015a; Marosevic et al. 2017; Margos et al. 2020b). Growth in vitro varies for LB, reptile associated, and RF species; the former grow slower, and generation times may be as long as 8–12 h (Barbour and Hayes 1986; Güner et al. 2003).

36.6 Genomics

The genome of *B. burgdorferi* s.s. isolate B31 was the first to be completely sequenced within the genus *Borrelia* (Fraser et al. 1997). The genome turned out to be relatively small with a genome size of 1.5 Mbp. In addition, it is surprisingly fragmented (Fraser et al. 1997): it consists of a linear chromosome of about 910 kbp and of 12 linear and 9 circular plasmids, contributing another 600 kbp of DNA sequence (Fraser et al. 1997; Casjens et al. 2010, 2012). The structure of the genome, i.e., comprising of a linear chromosome as well as circular and linear plasmids, was found in all species investigated so far, although the number of plasmids may differ within and between species (Barbour 2016; Becker et al. 2016; Kingry et al. 2016, 2017a, b; Margos et al. 2017a, 2019a, b, 2020a; Casjens et al. 2018; Becker et al. 2020; Kuleshov et al. 2020). The main chromosome of B31 contains 820 open reading frames (803 protein coding sequences, 17 pseudogenes; 5 rRNA, 32 tRNA, 3 ncRNA), 10% of which match hypothetical proteins and 29% have no match in a database. The G+C content of the chromosome is around 28% (Fraser et al. 1997; Mongodin et al. 2013). The plasmids in B31 range in size from 5 to 60 kbp, containing additional 700 coding sequences, of which >90% have no convincing database match outside the genus *Borrelia* (Fraser et al. 1997; Casjens et al. 2000). The chromosomes of various LB species are very similar in size to B31 and show a high degree of synteny, although some chromosomes may have right end extensions (Casjens et al. 2012; Margos et al. 2019a). Not all *Borrelia* species/strains have as many plasmids as B31 (Margos et al. 2017a, 2019a; Casjens et al. 2018), so far the smallest genomes, with 7 plasmids, have been found for *B. garinii* isolate Far04 and *B. maritima* CA690 (Margos et al. 2020a).

Genomes of relapsing fever spirochetes are similar in size as LB spirochetes and range between 1.2 Mbp and 1.6 Mbp (Lescot et al. 2008; Elbir et al. 2014; Marosevic et al. 2017; Kuleshov et al. 2020). Chromosome size ranges between 906 kbp and 930 kbp and plasmid sizes from 6 kbp to 165 kbp. The number of protein coding genes on the chromosome ranges between 800 (20 pseudogenes) and 850 (22 pseudogenes); numbers of RNAs are 3 rRNA and 32 tRNA; G+C content is around 27.5%.

The linear components of the genomes, main chromosome and linear plasmids, are terminated by covalently closed hairpin structures, called telomeres (Barbour and Garon 1987; Hinnebusch et al. 1990; Casjens et al. 1997). These are created involving a telomere resolvase, ResT, an enzyme encoded on plasmid cp26 in LB spirochetes (Chaconas and Kobryn 2010; Kobryn and Chaconas 2014) and on plasmid lp23 in *B. recurrentis* and *B. duttonii* (Lescot et al. 2008). Plasmid-encoded genes are essential for the completion of the complex transmission cycle of *Borrelia* in nature (Lin et al. 2014; Iyer et al. 2015) but may be lost under in vitro culture conditions (Schwan et al. 1988; Norris et al. 1995; Labandeira-Rey and Skare 2001; Biskup et al. 2011). Some plasmids that encode genes for proteins that are essential for bacterial growth (e.g., cp26 containing the gene for the telomere resolvase ResT, an enzyme important for resolving the telomeres) are not lost in culture.

Initially plasmids have been named according to whether they are linear or circular and according to size, e.g., lp54 for a 54 kbp linear plasmids and cp26 for a 26 kbp circular plasmid (Casjens et al. 2000). However, since several cp32 or lp28 plasmids of similar size may be found in a single isolate and size differences of plasmids from the same plasmid family have been detected in different isolates, nowadays plasmids are typed according to their PFam32 locus. This locus was suggested to be homologous to plasmid partitioning protein (ParA) encoding genes in other bacteria (Casjens et al. 2012). However, the function of the PFam32 protein and related proteins (PFam49, PFam52, PFam57/60) in autonomous plasmid replication and maintenance needs to be confirmed in *Borrelia* (Chaconas and Kobryn 2010; Schwartz et al. 2021). Although this system of plasmid designation is well established and consistently used in LB spirochetes, it has not been fully integrated into genome analyses of RF spirochetes (Kuleshov et al. 2020; Kingry 2021).

Perhaps resulting from the parasitic life style, *Borrelia* have few genes for biosynthesis of cell components (Fraser et al. 1997; Lescot et al. 2008). The majority of chromosomal genes encode proteins for housekeeping and metabolic functions. Many of the plasmid-located genes encode outer-surface proteins (Osp's) that are required for interaction with host or vector. In *B. burgdorferi* s.l., analyses of plasmid sequences showed that extensive sequence rearrangements have taken place, and plasmid numbers and structures vary not only between species but also between strains of a single species (Casjens et al. 2012, 2017, 2018; Schwartz et al. 2021). Plasmids of the cp32 family have been shown to contain sequences that resemble prophages, and these may perhaps facilitate rearrangements and/or exchange of genetic material (Eggers and Samuels 1999; Eggers et al. 2001; Schwartz et al. 2021). Information on content and structure of the *B. burgdorferi* s.l. genome has been largely gained from strains of the species *B. burgdorferi* s.s. (Casjens et al. 2010, 2012, 2017). Although for other *Borrelia* species genomes have been sequenced, due to the complexity of the genomes and sequence similarity in some

plasmids, the complete set of plasmids has not been finalized for all of them (Becker et al. 2016, 2020; Elbir et al. 2017; Kingry et al. 2017a; b; Marosevic et al. 2017; Casjens et al. 2018; Kuleshov et al. 2018, 2020; Tyler et al. 2018; Kingry 2021; Schwartz et al. 2021; Kneubehl et al. 2022). However, the use of new sequencing technologies gives hope that this may be achieved in the near future (Margos et al. 2017a, 2020a; Kuleshov et al. 2020; Hepner, personal communication).

36.7 Epidemiology, Burden of Disease

The risk to become infected with *Borrelia* largely depends on contact of humans with vectors infected with human-pathogenic *Borrelia* species. This in turn directly correlates with the distribution of vector ticks, as well as the distribution, increase, and spread of the human population.

Almost all cases of LB are reported from the Northern Hemisphere focusing on the United States (USA) and Europe. Cases are also reported from Asia. There is considerable epidemiological uncertainty regarding LB incidence and prevalence (Lindgren and Jaenson 2006; Hofmann et al. 2017; Rauer et al. 2020). Not only varies the yearly incidence of reported LB cases greatly across Europe and within individual countries, the same is true for the United States: the basis of reported cases differs between reports, some taking into consideration clinically diagnosed cases, while others also report probable or suspected cases of LB (Lindgren and Jaenson 2006; Mueller et al. 2012; Wilking et al. 2015; Wilking and Stark 2014; Schwartz et al. 2017; Enkelmann et al. 2018; Woudenberg et al. 2020; Kugeler et al. 2021). In Europe, the reported incidence of LB cases for 100,000 inhabitants ranged from 0.6 in Ireland to 69 in Sweden and to 300 in Austria (Lindgren and Jaenson 2006). In Germany, incident cases reported to the Robert-Koch Institute lead to an estimation of about 85,000 cases of LB annually, while numbers extracted from a German health insurance company amounted >200,000 cases each year in Germany (Mueller et al. 2012). However, incidences based on health insurance data include false diagnoses, consultation of several health practitioners or misassignment of codes, etc. (Mueller et al. 2012; Kugeler et al. 2021). Thus, the lower numbers may be underreporting, while higher numbers are overestimations, and the true number of LB cases lies probably somewhere in between.

In the United States, a similar situation is reported. LB is a nationwide notifiable disease in the United States since 1991, with 25,000–30,000 confirmed cases annually reported to public health systems (Schwartz et al. 2017). In 1996 and 2008, marked increases of case numbers were noticed, which was likely due to the changes in diagnostic procedures (1996) and the introduction of modified case definition (2008) (Schwartz et al. 2017). A more recent analysis based on case numbers in health insurance data, Kugeler et al. estimated that during 2010–2018 approximately 476,000 persons were diagnosed with LB annually (which also includes false-positive diagnoses) in the United Stated (Kugeler et al. 2021).

Why is it problematic to get accurate numbers for LB cases? The answer lies partly in the complexity of the biological system: the longevity of ticks and some *Borrelia* reservoir hosts, the resulting long-term duration of transmission cycles that may

fluctuate between years, the infrequency of long-term studies on vector populations and *Borrelia* incidence, partly in inaccuracies with the official reporting systems, and, even with clear clinical case definitions, uncertainties in diagnostic methods (Hofmann et al. 2017; Kugeler and Eisen 2020; Rauer et al. 2020). In microbiological diagnostics, the gold standard usually is the cultivation of the causative agents. *Borrelia* are fastidious bacteria that need very rich culture medium and grow very slowly under in vitro conditions (generation time 8–12 h) (Barbour 1984; Preac-Mursic et al. 1986; Margos et al. 2015a). Compared with other bacterial infections, the numbers of spirochetes in human biopsies or tissues are often very low making adaptation of the bacteria to culture conditions difficult, because adaptation to artificial medium is a strong selection process (Norris et al. 1997). Clinical and laboratory data (often based on the detection of anti-*Borrelia* antibodies and borrelial DNA by PCR) as well as the history of a tick bite need to be taken into consideration. Importantly, the interpretation of test results requires ample diagnostic experience (Aguero-Rosenfeld et al. 2005; Stanek et al. 2011; Stanek et al. 2012). As already mentioned above, guidelines for diagnosis of LB (Mygland et al. 2010; Stanek et al. 2011; Hofmann et al. 2017; Rauer et al. 2020) and the reporting of LB cases are inconsistent in European countries; LB is a mandatory notifiable disease only in a few EU countries, and case definitions may differ in various countries (Sykes and Makiello 2017).

For RF spirochetes, disease burden is difficult to estimate for other reasons. Diagnostic procedures are comparatively easy as the bacteria can be detected in Giemsa- or DAPI-stained blood smears or be detected by PCR (see section "Diagnostics"). What can be problematic in malaria endemic regions is a lack of diagnostic routine, and therefore, RF may be misdiagnosed as malaria or other febrile diseases (Nordstrand et al. 2007). In North America, tick-borne RF cases caused by *B. hermsii*, *B. turicatae,* or *B. parkeri* are rare; between 1999 and 2011 483 cases have been reported mainly in California, Colorado, and Washington (https://www.cdc.gov/relapsing-fever/distribution/index.html). Few cases of *B. miyamotoi* infection have been reported in geographic regions, where the pathogen is present (Krause et al. 2015). There is only patchy data on RF spirochetes and its vectors from Central and South America, making it difficult to estimate disease burden (Lopez et al. 2016).

While climate change and its consequences as well as anthropogenic land use changes will most certainly have an effect on the habitats of vector and reservoir hosts, encroachment of humans into natural habitats is another factor that increases the risk of infection. As most soft ticks (vectors of RF spirochetes) have a nidicolous lifestyle, changing environmental conditions that will affect their hosts may have an impact on these vectors (Vial 2009). For LB spirochetes, the vector-pathogen-host life cycle is a highly complex ecological system, in which ixodid ticks, *Borrelia*, and vertebrate hosts interact at various environmental conditions. Consequently, each change in this system, driven by natural phenomena or by human intervention, affects the ecological balance and may alter the risk of human infection (Hartemink et al. 2008; Tsao 2009; Estrada-Peña et al. 2016). Anthropogenic impacts such as climate change, land cover changes, and geographical expansion of hosts (also incidental or dead-end hosts such as humans) are considered to be the main reasons for the increase in tick abundance, distribution of ticks in new habitats, and therefore the risk of infection (Bregnard et al.

2020). However, in contrast to reports of increasing tick populations as well as *Borrelia* prevalence and incidence (https://www.euro.who.int/data/assets/pdf_file/0008/246167/Fact-sheet-Lyme-borreliosis-Eng.pdf), two meta-analysis conducted in Europe for the periods 1984–2003 and 2010–2016, respectively, showed an increase in *Borrelia* prevalence in ticks from Western to Eastern Europe, but the overall mean prevalence remained the same 13.7% for the first period and 12.3% for the second period. Interestingly, the prevalence in adult ticks was higher (18.6%) in the first period than in the second period (14.9%), while in nymph, it remained stable (Rauter and Hartung 2005; Strnad et al. 2017). Long-term studies (6–10 years) on *Borrelia* prevalence in questing *I. ricinus* in Holland and Latvia showed that tick infection rates with *Borrelia burgdorferi* s.l. remained stable or even decreased over the study period (Coipan et al. 2013; Okeyo et al. 2020). Furthermore, reports based on seroprevalence studies (note: seroprevalence is an indication of exposure of the population to *Borrelia*) did not find an increase in incidence (Semenza and Menne 2009; Vanthomme et al. 2012; Cuellar et al. 2020; Woudenberg et al. 2020). In fact, a retrospective study conducted in Finland on the *Borrelia* seroprevalence of the population from 1962 to 1972 revealed a seroprevalence of 20%, much higher than that reported for 2011 (3.9%) (Cuellar et al. 2020).

Several studies on the transmission of *Borrelia* to humans after a tick bite suggest a low risk of developing LB even after being bitten by a *Borrelia*-infected tick (Fryland et al. 2011; Huegli et al. 2011; Wilhelmsson et al. 2016; Markowicz et al. 2021b). In these studies, around 5% of people being bitten by a tick received an infection (established by analyzing seroconversion); participants that developed symptoms ranged between 2% and 3%. Perhaps the situation in Europe is similar to that in the United States, where from 2008 to 2015 annual cases of LB (LD) have been stable in high incidence regions, where *Borrelia*-infected *I. scapularis* ticks have been endemic, while cases have increased in neighboring regions (Schwartz et al. 2017). Thus, published increases in incidence or annual cases may be due to different data sources; changes in reporting procedures; invasion of ticks, hosts, or *Borrelia* into low incidence regions; or increased awareness of general practitioners or the lay public (Kugeler and Eisen 2020).

As *Borrelia* are strictly dependent on their reservoir hosts and vector ticks, it is important to understand their ecology to discern the risk of humans to acquire the agent and develop LB or RF. There is clearly a need to study these complex ecological networks, over long periods of time, especially in the frame of climate change, as tick life cycles can take several years to be completed and most *Borrelia* reservoir hosts are long-lived.

36.8 Clinical Manifestations in Humans

36.8.1 Lyme Borreliosis

Lyme borreliosis (Lyme disease) typically affects skin, joints, heart, or nervous system and has traditionally been divided into different stages (Steere 1989):

Stage I: early, localized infection
Stage II: early, disseminated infection
Stage III: late infection

In clinical practice, the staging system may be used as a support to guide the choice of treatment regimen; however, over the years, it has become evident that most patients do not develop all stages, and overlaps between stages are not uncommon (Evans 2000).

The clinical manifestations and their relative frequencies differ between Europe and North America, probably depending on the geographical distribution and organotropism of the various human pathogenic *B. burgdorferi* sensu lato (s.l.) species (van Dam et al. 1993; Balmelli and Piffaretti 1995; Piesman and Gern 2004). The early, localized skin lesion called erythema migrans (EM) is the most common manifestation on both continents but tends to be associated with more systemic symptoms and earlier dissemination in North American patients, where *B. burgdorferi* sensu stricto (s.s.) generally is the causative species (Radolf et al. 2021). Since *B. burgdorferi* s.s. is prone to disseminate to joints and heart, Lyme arthritis and carditis are seen more frequently in North America. On the other hand, neurologic and late skin manifestations are more frequently seen in Europe, where the neurotropic species *B. garinii* and *B. bavariensis*, along with the dermatotropic *B. afzelii*, are the predominating species. Furthermore, asymptomatic seroconversion or subclinical infection appears to be at least as common as development of clinical disease in Europe (Wilhelmsson et al. 2016; Carlsson et al. 2018), whereas in North America, only a minor proportion of infected persons are asymptomatic (Steere et al. 2003).

36.8.1.1 Dermatoborreliosis

EM, the most frequently occurring manifestation of Lyme borreliosis, constitutes approximately 77–83.4% of all clinical cases (Berglund et al. 1995; Steere and Sikand 2003; Stanek and Strle 2018). It appears several days to weeks after the tick bite and presents as a maculopapular rash at the site of the bite. However, many patients do not recall the preceding tick bite (Strle et al. 2002; Wormser 2006), since these are not painful and therefore frequently pass unnoticed. As the red or bluish-red rash slowly enlarges, it may be associated with local symptoms, such as itching, burning, or pain, and with systemic symptoms, such as fatigue, headache, and migrating myalgia (Strle et al. 1996). Typically, the EM adopts an annular shape with a central clearing but can also be more homogenous. The diagnosis is based on the clinical appearance. Serology is positive in less than 50% of patients presenting with single EM (Strle et al. 1996) and is therefore not needed or recommended. For a reliable diagnosis, the EM should be at least 5 cm in diameter. Untreated EM may disappear spontaneously but can also persist and expand over weeks to months and reach a considerable size, involving several body parts like, for example, the trunk and extremities. Multiple EM lesions occur and are a sign of spirochetal dissemination (Stanek and Strle 2003) (Fig. 5).

Borrelial lymphocytoma (BL) and acrodermatitis chronica atrophicans (ACA) are other skin manifestations of European Lyme borreliosis, which are rarely, if ever, seen in North American patients. BL is a solitary bluish-red swelling appearing in the vicinity of the tick bite after weeks to months (Stanek and Strle 2003). It is typically located at the ear lobe or the nipple and is more common in children than in

Fig. 5 Erythema migrans. (**a**) shows the leg of an infected person. The EM is pale and covers a substantial area of the leg. (**b**) shows the arm of an infected person. The EM is of typical annular shape (courtesy Dr. Volker Fingerle, German National Reference Centre for Borrelia, Oberschleißheim, Germany)

adults. For diagnosis, serology is essential (Stanek et al. 2011). In addition, PCR and histological examination of a skin punch biopsy can be used in ambiguous cases. ACA is a late dermatologic manifestation that develops slowly over months to years and is almost exclusively associated with *B. afzelii* infection (Ohlenbusch et al. 1996; Stanek and Strle 2018). The onset is insidious with a slight bluish-red discoloration and edema, most often located at the extensor sides of the hands, feet, elbows, or knees (Stanek and Strle 2003). Polyneuropathy and arthritis may occur in the same area as the affected skin. Gradually, the edema disappears and skin atrophy is developed. ACA is more often diagnosed in women than in men, and the patients are usually >40 years of age (Asbrink and Hovmark 1988). The condition is easily misinterpreted as a sign of vascular insufficiency, especially when located at the lower extremities. Unlike EM and BL, ACA does not resolve without antibiotic treatment (Asbrink and Hovmark 1988). Practically all patients presenting with ACA have high levels of specific IgG antibodies in serum, but PCR and histology of a skin biopsy may be used as complementary diagnostic methods.

36.8.1.2 Neuroborreliosis

Neuroborreliosis (NB) is typically characterized by subacute meningitis and involvement of cranial and peripheral nerves (Pachner and Steere 1985). In Europe, NB is the second most common manifestation of Lyme borreliosis, constituting approximately 16% of all cases (Berglund et al. 1995). The neurologic symptoms usually occur 1–12 (mostly 4–6) weeks after the tick bite (Mygland et al. 2010). Borrelial meningitis, in contrast to most other bacterial meningitis, usually causes relatively mild or intermittent headache and moderate neck pain, although in some patients, these symptoms may be more intense (Kristoferitsch 1991). Any cranial nerve can be involved, but the facial nerve is by far the most frequently affected, resulting in unilateral or sometimes bilateral peripheral facial palsy. If present, radiculoneuritis usually causes severe, radiating pain that typically exacerbates at night. Fever, nausea, and vomiting may occur in children but are usually absent in adults (Stanek and Strle 2003). Other manifestations involving the central nervous system, such as encephalitis and myelitis, are rare (Kristoferitsch 1991; Stanek et al. 2011). Occasional cases of NB presenting

with confusion, cerebellar ataxia, hemiparesis, stroke-like symptoms, and cerebral vasculitis have also been reported (Mygland et al. 2010; Topakian et al. 2008). NB is typically a subacute illness, with 95% of cases diagnosed as early NB (duration of symptoms <6 months at the time of diagnosis). Less than 5% of NB patients present with a symptom duration exceeding 6 months (classified as late NB) (Mygland et al. 2010). The diagnosis is based on the patient's medical history, clinical signs, and symptoms, along with simultaneous laboratory analysis of serum and cerebrospinal fluid (CSF). The inflammatory parameters in serum are usually normal or only slightly elevated, whereas the CSF shows moderate to prominent inflammation mirrored by mononuclear pleocytosis, intrathecal production of *Borrelia*-specific antibodies, and elevated levels of pro-inflammatory cytokines and chemokines (Mygland et al. 2010; Pietikäinen et al. 2016; Lepennetier et al. 2019).

36.8.1.3 Articular Borreliosis

Borrelial arthritis (Lyme arthritis) is the most common clinical sign of disseminated borreliosis in North America, constituting about 10% of all cases, but appears to be less common in Europe, where only 3–7% of borreliosis cases present with arthritis (Berglund et al. 1995; Steere 1989; Stanek and Strle 2018). Onset of borrelial arthritis occurs weeks to months, most commonly 2–3 months, after the tick bite (Steere et al. 1987; Herzer 1991). The condition is characterized by acute mono- or oligoarticular inflammation of large joints, most commonly in one knee. Sometimes an elbow, shoulder, ankle, or hip may be affected. The joints become swollen and warm but are generally only moderately painful and not erythematous (Steere et al. 1987). Joint involvement is usually asymmetric and intermittent with inflammatory attacks, lasting from a few days to several weeks, or sometimes several months. The clinical course is variable, usually recurrent, and may continue for several years (Stanek and Strle 2003). Arthritis may be associated with other manifestations of borreliosis, such as EM, ACA, or NB (Berglund et al. 1995).

The diagnosis is based on the medical history, clinical features, and laboratory analyses, most importantly serology, but detection of *Borrelia* DNA in synovial tissue or synovial fluid is also recommended in ambiguous cases and in areas with high seroprevalence. C-reactive protein is usually within the normal range, while the white blood cell count in synovial fluid is elevated with a dominance of polymorphonuclear leukocytes (Stanek and Strle 2003; Nocton et al. 1994).

36.8.1.4 Carditis

Carditis has a reported relative frequency of 4–10% in North American Lyme borreliosis patients and 0.5% in European patients (Berglund et al. 1995; Wormser 2006; Strle and Stanek 2009). The condition often occurs within 2 months after the tick bite and typically presents with acute onset of changing atrioventricular blocks grade I–II as a result of conduction disturbances (Steere et al. 1980). There may be signs of perimyocarditis, and it is often accompanied by other manifestations of borreliosis, such as EM, NB, or arthritis. The diagnosis is based on the patient's medical history, clinical signs, and symptoms together with serology, electrocardiography, and cardiac imaging. Other evident explanations for cardiac disease should be investigated and excluded (Strle and Stanek 2009).

36.8.1.5 Rare Manifestations

Eye manifestations are rare and are either a result of inflammation in various eye tissues (e.g., conjunctivitis, keratitis, iridiocyclitis, retinal vasculitis, optic neuritis) or of extraocular involvement (such as paresis of cranial nerves and orbital myositis) (Mikkilä et al. 2000). Diagnosis is challenging and should include medical history, other clinical signs and symptoms indicative of borrelia infection, and serology.

Sporadic case reports of patients with, for example, myositis, osteomyelitis, nodular fasciitis, scleroderma, and symptoms from other organ systems, such as the liver, urinary tract, or respiratory tract, have been interpreted as manifestations of borreliosis, although these associations still remain to be firmly established (Stanek and Strle 2003) (Table 2).

36.9 Relapsing Fever

Louse-borne relapsing fever (LBRF), caused by *B. recurrentis*, and tick-borne relapsing fever (TBRF), caused by several different *Borrelia* species, present with similar clinical symptoms, of which recurrent episodes of high fever are the most characteristic (Cutler 2015). However, LBRF generally has an epidemic occurrence, causing outbreaks in vulnerable populations during poor sanitary conditions, for example, in refugee camps due to wars or natural disasters, while TBRF causes sporadic human cases in geographical areas, where the disease is endemic (Jakab et al. 2022). The incubation time is 4–18 days (mean 7 days), mostly somewhat shorter for LBRF (Jakab et al. 2022; Kahlig et al. 2021; Radolf and Samuels 2021). Thereafter, a varying number of fever episodes, typically lasting for 2–7 days, are separated by afebrile periods of up to 10 days (Jakab et al. 2022). The fever is usually accompanied by chills, headache, back pain, myalgia, arthralgia, and abdominal pain. Clinical examination may also reveal jaundice or a petechial skin rash. Subconjunctival hemorrhages and epistaxis are common in LBRF (25% of cases), and there may also be signs of gastrointestinal, respiratory, or intracranial bleeding or even disseminated intravascular coagulopathy (Warrell 2019). White blood cell count is usually within the normal range or slightly elevated. During a crisis episode, leukopenia and thrombocytopenia may occur, and aminotransferase levels can be elevated. Especially the TBRF *Borreliae* show a certain neurotropism and may cause neurologic symptoms, such as facial palsy, radiculopathy, meningoencephalitis, and confusion. Moderately elevated levels of mononuclear leukocytes and albumin are found in the cerebrospinal fluid, while glucose levels typically remain normal.

The relapsing fever spirochete *B. miyamotoi* has rather recently been demonstrated to be pathogenic to humans (Platonov et al. 2011). Unlike other TBRF, the causative agent is transmitted by hard ticks within the Ixodidae family. *Borrelia miyamotoi* disease (BMD) generally presents as a systemic illness with fever, although recurrent fever episodes may not be quite as distinct as in other TBRF. Associated symptoms may be headache, fatigue, chills myalgia, and arthralgia. Skin rashes occur but are uncommon (Platonov et al. 2011; Molloy et al. 2015). Biochemical analyses often reveal leukopenia, thrombocytopenia, and elevated aminotransferases. BMD may also present with meningoencephalitis, including neurologic

Table 2 Lyme borreliosis: clinical manifestations and diagnostic approach

Organ system	Clinical manifestation	Case definition	Antibody detection	Puncture or biopsy for PCR/culture/histology
Early phase – Incubation period days to months				
General symptoms	Flu-like, subfebrile, headache, muscle/joint pain, lymphadenitis	No respiratory/gastrointestinal symptoms. Rarely transient arthritis. Diagnostically unclear	Unclear	No
Skin	Erythema migrans (EM)	Erythema centrifugal spread, partly central fading, at skin level, not overheated, >5 cm[a] in largest diameter. Consult dermatologist if atypical. Often seronegative. Multiple EM possible	Only unclear cases: if necessary immediately (baseline) and control[b]; sensitivity 20–>50	Only if atypical: skin biopsy
	Borrelia lymphocytoma	Bluish-red painless nodule or plaque, children on earlobe or scrotum, adults mainly mammillary region. Rarely multiple	Obligatory. If necessary, follow-up[a] Sensitivity 70–90%	Skin biopsy; histology (B and T lymphocytic infiltrates), PCR
Nervous system	Meningopolyneuritis (Bannwarth syndrome), meningitis, rarely myelitis, encephalitis	Bannwarth: radicular pain especially at night (fluctuating, drilling, burning), cranial nerve paresis (especially N. facialis). Children mainly show meningitis and facial palsy. Rarely encephalitis, myelitis, or cerebral vasculitis	Obligat. CSF/serum – pair. Demonstration of *Borrelia*-specific intrathecal antibody production and lymphocytic pleocytosis. If necessary, follow-up[b]; sensitivity 70–>90%	CSF. If necessary, detection of CXCL13 from CSF
Heart	AV block, myocarditis, pancarditis	Rare. Typically acute onset of atrioventricular block of varying degrees	Obligatory. If necessary, follow-up[b]	Unclear

Other	Conjunctivitis, anterior and posterior uveitis, papillitis, episcleritis, keratitis	Rare	Obligatory. If necessary, follow-up[b]	Unclear
Late phase – Incubation period months to years				
General symptoms	As in acute phase	Mostly less pronounced	No	No
Skin	Acrodermatitis chronica atrophicans	Initial swelling, gradual livid discoloration, later skin atrophy (perivascular plasma cell-rich infiltrates); ulnar striations, juxta-articular dermal fibroid nodules, possibly peripheral polyneuropathy and deformities in the area of affected skin	Obligatory. High IgG antibody levels, broad band spectrum in IgG blot. IgM not diagnostic; sensitivity 95–100%	Skin biopsy; histology, culture, PCR
Nervous system	Meningitis, myelitis, encephalitis, encephalomyelitis, peripheral neuropathy	Very rare, chronic course. Mostly myelitis with spasticity and ataxia; encephalopathy with cognitive impairment and chronic encephalomyelitis Peripheral polyneuropathy only in ACA	Obligatory. CSF/serum pair for detection of intrathecal antibody formation including signs of inflammation. IgM not diagnostic; sensitivity 95–100%	CSF. If necessary, detection of CXCL13 from CSF
Musculoskeletal system	Arthritis, bursitis, myositis	Mono- to oligoarthritis of large joints, mostly knee joint; effusion voluminous, recurrent or persistent. No axial skeletal involvement. Myositis very rare	Obligatory. High IgG antibodies, broad band spectrum in IgG blot; IgM not diagnostic; sensitivity 90–100%	Synovia/synovial fluid, culture rarely positive, PCR. Punctate diagnostics (granulocytic pleocytosis)
Vessels	Vasculitis	Rare. May lead to ischemia	Obligatory	Unclear

[a]For diameter <5 cm: history of tick bite, at least 2 days between tick detachment and appearance of an expanding rash
[b]Question: seroconversion, significant increase in titer. *CSF* cerebrospinal fluid

and cognitive deficits, especially in immunosuppressed individuals (Gugliotta et al. 2013; Hovius et al. 2013), although there are indications that also immunocompetent persons may be affected (Henningsson et al. 2019).

The mortality of untreated TBRF has been reported to be 2–10%, and with antibiotic treatment, mortality is less than 2% (Jakab et al. 2022). The mortality of untreated LBRF appears to be higher, up to 47.1% according to evidence-based data; however, reported case fatality rates may have been affected by other factors, such as malnutrition and insufficient healthcare (Kahlig et al. 2021). Mortality is highest during a crisis episode or within 24 hours after initiation of antibiotic treatment, when up to 80–90% of LBRF and 1–39% of TBRF patients may develop a Jarisch-Herxheimer reaction (Kahlig et al. 2021; Butler 2017; Radolf and Samuels 2021).

36.10 Animals and Borreliosis

As indicated in Table 1, there are very few *Borrelia* species known to cause disease in wild and domestic animals, and juvenile animals may be more at risk of developing symptoms than adult animals (Elelu 2018). *Borrelia* species known or suspected to cause clinical symptoms in animals include *B. anserina*, causing avian borreliosis in poultry, and *B. hispanica* and *B. persica*, which can cause various disease symptoms in domestic cats and dogs, including lethargy, pale mucosa, anorexia, cachexia, or mild abdominal respiration (Margos et al. 2020b; Baneth et al. 2016, 2022). *Borrelia anserina* was an important disease in poultry breeding early in the last century (Ataliba et al. 2007; McNeil et al. 1949; Hoffman and Jackson 1946; Hoffman et al. 1946). Symptoms described include fever, depression, ruffled feathers, anemia, and greenish diarrhea (Cooper and Bickford 1993; McNeil et al. 1949). Improvement of poultry houses and sanitation does prevent establishment of tick populations, and this has diminished the threat of avian spirochetosis in industrial breeding (Ataliba et al. 2007). It may, however, still be present and reemerge in small flocks or free-range husbandry systems.

Borrelia theileri can infect cattle, sheep deer, and other ruminants (McCoy et al. 2014; Qiu et al. 2021) and has been suspected to cause bovine borreliosis, although more recent research questions whether this condition is caused by *B. theileri* or coinfecting *Babesia* spp. (reviewed by Elelu 2018). *Borrelia coriaceae* has been hypothesized to cause epizootic bovine abortion, a condition widely distributed in Western United States. However, other research suggests that an intracellular bacterium (class δ-proteobacteria, order *Myxococcales*) that is also transmitted by *Ornithodoros coriaceus* is the etiological agent of epizootic bovine abortion (King et al. 2005; Teglas et al. 2011).

Although it is often considered that *B. burgdorferi* s.l. are not pathogenic for wild mammal hosts (Wright and Nielsen 1990), juvenile *Peromyscus leucopus* or dusky-footed woodrats (*Neotoma fuscipes)* may develop symptoms associated with *B. burgdorferi* s.l. infection, including joint, cardiac, and muscle lesions (Moody et al. 1994; Brown and Lane 1994). There is conflicting information of dogs developing disease symptoms following Bbsl infection; the main symptom appears to be arthritis and fever 2 to 5 months after exposure (Krupka and Straubinger 2010;

Pantchev et al. 2015; Krämer et al. 2020). The association of *B. burgdorferi* infection in dogs with so-called Lyme nephropathy (an immune-mediated glomerulonephritis) is controversially discussed (Littman et al. 2006). Antibodies to *B. burgdorferi* have been detected in cats, horses, and cattle, but no or rare associations with disease have been reported (Hahn et al. 1996; Shaw et al. 2001; Butler et al. 2005).

36.11 Diagnosis

36.11.1 Hard Facts and Fake News

Laboratory testing is only supportive in the presence of clinical manifestations of Lyme borreliosis (Stanek et al. 2011). Therefore, the decision for laboratory testing requires a thorough clinical evaluation of the symptoms, and it should not be performed in case of uncharacteristic symptoms. As for other infectious diseases, two different approaches can be used to confirm *Borrelia* infection: the direct identification of the pathogen, like culture or PCR, or indirect methods, reflecting the immune response of the host. The latter includes the measurement of specific antibodies or detection of chemokines or cytokines, reflecting the host's immune response after stimulation with pathogen-specific antigens. Each of these methods has their advantages and limitations for particular infectious agents. *Borrelia burgdorferi* s.l. is a fastidious microorganism, which requires special conditions for cultivation, and it has a relatively long generation time. Moreover, low concentration of the spirochetes in clinical samples hampers the sensitivity of this method, and this also refers to PCR-testing. The performance of both methods is at highest when analyzing skin samples from erythema migrans ranging from 35% to 81% (van Dam 2011); however, the diagnostic utility is limited, as the diagnosis of this manifestation is clinical in the majority of cases, and no laboratory confirmation is required. Regarding Lyme neuroborreliosis and Lyme arthritis, the sensitivities are not satisfactory from cerebrospinal fluid (CSF) and synovial fluid or synovial tissue in the diagnostic routine. Direct detection of *B. burgdorferi* s.l. in blood or serum is not recommended for any manifestation of Lyme borreliosis, because the concentration of the spirochetes in blood is low, and if spirochetemia occurs, it is limited to a short duration of time. This is in contrast to tick-borne relapsing fever borreliae, like *Borrelia miyamotoi*, *B. duttonii,* and *B. recurrentis*, which are visible in a blood smear during the febrile phase of the infection (Hoch et al. 2015).They are readily visible in Giemsa- and/or DAPI-stained smears. In countries where malaria is endemic, febrile conditions may be misdiagnosed when blood smears are not taken on time. Recently, it was demonstrated that among patients who were regularly tested by PCR after a tick bite in a course of a research study, 16 developed an erythema migrans and only one of them showed a positive blood PCR result (Markowicz et al. 2021b). In conclusion, direct detection of *B. burgdorferi* s.l. plays a minor role for diagnosing Lyme borreliosis, and it is rather used for research studies. There is promising evidence that other methods like metagenomics sequencing (Branda et al. 2021) may be superior to traditional PCR testing in the future, and these findings require further research.

The most common method for indirect identification of *B. burgdorferi* s.l. in clinical samples is serologic testing. Detection of *Borrelia*-specific IgG and IgM consists of a screening test, e.g., ELISA, and a confirmatory test for borderline and positive results of the screening test. Immunoblot can be used as the second-tier test, and it has the advantage of demonstrating reactivity to various *Borrelia*-specific proteins, whereas the first-tier test usually reacts with one or two proteins only. The number of reactive bands determines the final interpretation of the immunoblot result. Based on European guidelines, at least two positive bands lead to the positive interpretation for IgG, whereas for IgM, the reactivity to the outer protein C (OspC) is sufficient for a positive result (Dessau et al. 2018). Serology may be negative in the early stage of infection; therefore, it is not recommended for erythema migrans. The detection of IgG plays an important role for the confirmation of late, disseminated manifestations of Lyme borreliosis (Stanek et al. 2011), and it is characterized by a high negative predictive value. Therefore, lack of specific IgG rules out a late disseminated disease. Specific *Borrelia* antibodies can be found in healthy persons frequently exposed to ticks during occupational or recreational activities (Cetin et al. 2006) and in subjects after a successful treatment of different manifestations of Lyme borreliosis. Therefore, it is essential to discriminate between persons in whom positive serology points at an acute or chronic infection fulfilling the clinical criteria and persons with background seroprevalence, which does not require treatment with antibiotics. Although IgM antibodies occur in the early stage of the infection, the test results must be also put in the clinical context (Hillerdal and Henningsson 2021). Like IgG, IgM can persist after the infection and treatment, and the dynamics of decline is dependent on the individual immune reaction. Possible explanation for the persistence of IgM in healthy subjects are cross-reactive antigens of human or environmental origin sharing the same epitope with OspC of *B. burgdorferi* s.l. (Markowicz et al. 2021a), which is the key antigen in the early stage of *Borrelia* infection. Other possible explanation for nonspecific IgM is polyclonal stimulation of B cells (Goossens et al. 1999; Tuuminen et al. 2011). In conclusion, *Borrelia* IgM is only relevant in the presence of clinical signs of an early *Borrelia* infection, and unspecific test reactivities for IgM must be interpreted with caution.

36.11.2 Laboratory Diagnosis of Particular Manifestations of Lyme Borreliosis

36.11.2.1 Early Skin Manifestations

Erythema migrans is the most frequent manifestation of Lyme borreliosis, and it is caused by a local affection of the skin by *B. burgdorferi* s.l. Its typical appearance does not require laboratory testing, and the diagnosis is made upon clinical examination. PCR or culture from skin biopsy is possible in case of atypical skin lesions with a suspicion of Lyme borreliosis. The same recommendations apply to multiple erythema migrans. Borrelial lymphocytoma requires laboratory confirmation by serologic testing. Positive serology or seroconversion observed in a paired sample is mandatory. The recommended time interval between the two tests is 2–4 weeks.

Histologic examination of the skin and PCR or culture from the skin biopsy can be considered as additional diagnostic procedures.

36.11.2.2 Lyme Neuroborreliosis

The most common manifestations of Lyme neuroborreliosis include meningoradiculoneuritis, lymphocytic meningitis, and cranial neuritis, and the pathophysiological processes are localized in the CSF and the meninges (Ogrinc et al. 2022). Thus, the analysis of the CSF is essential for the laboratory diagnosis (Mygland et al. 2010). First, demonstration of CSF inflammation is mandatory. Lymphoplasmacellular pleocytosis occurs in the first days after onset of symptoms, with an expected cell count of 10–1000 leucocytes/mm^3. Since the inflammation in the CSF is not specific for Lyme neuroborreliosis, the etiology of the infection should be confirmed by the intrathecal synthesis of *Borrelia*-specific antibodies. With this method, the fractions of Borrelia-specific antibodies in blood and in the CSF are compared, and their relation is expressed as the antibody index (AI). Value >1,5 indicates intrathecal synthesis (Tumani et al. 1995). Noteworthy, the synthesis of such antibodies is delayed in comparison to the pleocytosis, and – in contrast to the total cell count – the AI can be still elevated even for years after successful treatment. Therefore, this parameter is not suitable for monitoring the efficacy of treatment. Further laboratory findings in the CSF can be high protein concentration, whereas the glucose ratio is usually normal (Hansen et al. 2013).

In recent years, it became evident that the B cell attracting chemokine CXCL13 can be used for the laboratory diagnosis of Lyme neuroborreliosis (Rupprecht et al. 2014; Henningsson et al. 2018). High concentrations of CXCL13 in the CSF can be measured in the early phase of the infection, and they occur before the AI becomes positive. Moreover, the concentration decreases more rapidly than the cell count after treatment. High concentration of the chemokine in the CSF is often able to distinguish between Lyme neuroborreliosis and other inflammatory conditions of the central nervous system. However, CXCL13 is not specific for Lyme neuroborreliosis, and it can occur in other diseases like lymphoma, neurosyphilis, or multiple sclerosis (Dersch et al. 2015; Fischer et al. 2009). There are numerous studies demonstrating that the cutoff values are dependent on the test system and on the selection of study groups. Given these circumstances, CXCL13 can be used as a complementary method for diagnosing Lyme neuroborreliosis, but it should not replace the methods mentioned above.

36.11.2.3 Late, Disseminated Manifestations

Clinical suspicion of late disseminated manifestations of Lyme borreliosis like Lyme arthritis and acrodermatitis chronica atrophicans requires confirmation by serologic testing. High specific IgG levels are expected in these cases. Typically, a broad range of antigens is reactive in the immunoblot. A PCR from tissue – skin or synovial fluid or synovial tissue – may be helpful as an additional test, but negative test results do not exclude the infection due to limited sensitivity (Hofmann et al. 2017; Jaulhac et al. 2019; Rauer et al. 2020).

36.11.2.4 Rare Manifestations

Ocular and cardiac manifestations require confirmation of specific serum antibodies. Possible ophthalmic affections like conjunctivitis, uveitis papillitis, keratitis, and episcleritis are diagnosed during routine ophthalmologic examinations. Lyme carditis usually presents with varying degrees of atrioventricular block, rarely with pericarditis and myocarditis. Routine cardiologic examinations including electrocardiogram should be performed. In case of rare manifestations of Lyme neuroborreliosis, e.g., chronic meningitis, encephalomyelitis, the same diagnostic approach is recommended as was described for Lyme neuroborreliosis (Hansen et al. 2013; Kristoferitsch et al. 2018).

36.12 Methods with Insufficient Evidence to Support the Diagnosis of Lyme Borreliosis

There are numerous test methods that are not useful for the diagnosis of *Borrelia* infection. One reason are misconceptions – e.g., for microscopic examinations of blood in LB, despite known biological evidence that *B. burgdorferi* s.l. does not cause high levels of spirochetemia (Aase et al. 2016). An exception is *B. mayonii*, a novel *Borrelia* species restricted geographically to the Midwestern United States (Pritt et al. 2016). With regard to some diagnostic approaches, which are used for other diseases like interferon gamma release assay or lymphocyte transformation assay, there is increasing evidence questioning their utility for clinical practice (Baarsma et al. 2022; Dessau et al. 2014; van Gorkom et al. 2018). A recent case control study involving 271 patients did not show that the performance of these methods was higher compared to serologic testing, and the results highlighted their low specificity (Baarsma et al. 2022). Therefore, such methods require additional optimalisation and validation by independent experts using well-characterized human specimens before being fit for conventional, clinical use. Finally, testing of ticks removed from the skin for presence of *B. burgdorferi* s.l. is not recommended. Although it was shown, that the risk for infection with *Borrelia* is higher when the spirochete was detected by PCR in such ticks (Markowicz et al. 2021b), there is no evidence to recommend antibiotic prophylaxis after a bite of an infected tick, since only a small fraction of individuals bitten by *Borrelia*-positive ticks will develop symptoms of Lyme borreliosis (Wilhelmsson et al. 2016).

36.13 Diagnosis of Tick-Borne Relapsing Fever

In contrast to Lyme borreliae, the agents of tick-borne relapsing fever cause spirochetemia, making the microscopic identification in blood smears diagnostically useful. Giemsa- or DAPI-stained spirochaetes (Fig. 4) confirm the diagnosis in patients with corresponding clinical picture in endemic regions (Hoch et al. 2015). The examination is essential for travelers returning from regions, where malaria is

endemic, because the symptoms of both diseases are similar. Serologic tests for tick-borne relapsing fever are based on the detection of antibodies against glycerophosphodiester phosphodiesterase (glpQ), which is a protein present in relapsing fever spirochaetes but not in *B. burgdorferi* s.l. (Schwan et al. 1996). However, the assay is not able to discriminate between particular relapsing fever *Borrelia* species due to cross-reactivity.

36.14 Conclusions for Laboratory Diagnostics

Due to substantial limitations of direct detection of *B. burgdorferi* s.l. from clinical samples, the serologic testing remains the main method for the laboratory diagnosis of Lyme borreliosis. Importantly, serology should be only used in the presence of clinical symptoms, suggestive of Lyme borreliosis. Erythema migrans is the only manifestation, which is diagnosed clinically. For other manifestations, the presence of specific antibodies should by confirmed by two-tier testing. Examining serum and CSF is required to diagnose Lyme neuroborreliosis, by demonstrating pleocytosis and the intrathecal synthesis of specific antibodies. CXCL-13 is elevated in the CSF and can be helpful for the diagnosis. Since antibodies to *Borrelia* can be detected in healthy individuals, reflecting the background seroprevalence after tick exposure, and since antibodies are common after successful treatment, there is still an urgent need for identifying a marker of an active *Borrelia* infection from blood. This would help to reduce unnecessary treatment and overuse of antibiotics and to avoid missing other underlying diseases. Before new diagnostic approaches can be introduced to the laboratory routine, profound validation studies by independent experts are mandatory. Results of such investigations need to be reproduced on various well-characterized samples and patient populations in order to demonstrate which groups of patients can benefit from them.

36.15 Notes on Antibiotic Therapy

Lyme borreliosis is principally considered to be an efficiently treatable disease with a good prognosis, especially the early forms of the disease. Therefore, every clinical manifestation of Lyme borreliosis should be treated with antibiotics. In this context, it is worthwhile mentioning that even without antibiotic therapy, early manifestations of Lyme borreliosis do not lead inevitably to a late manifestation but can heal spontaneously (Hofmann et al. 2017; Mygland et al. 2010; Cerar et al. 2010; Lantos et al. 2021; Pfister et al. 1989; Koedel et al. 2015). Post-therapeutic complaints without tangible signs of a still ongoing infection (like signs of inflammation in cerebrospinal fluid) may be experienced due to a defective healing process (especially following longer diseases with organ damage) or in the sense of a postinfectious syndrome. In these cases, further antibiotic interventions are not indicated, but a symptomatic therapy would be required.

The main goals of antibiotic therapy include to shorten the clinical course of disease, to prevent complications including defective healing, and to prevent the development of later forms of the disease (Hofmann et al. 2017; Lantos et al. 2021; Rauer et al. 2020; Jaulhac et al. 2019).

36.16 Antibiotic Selection

Many in vitro studies have shown that the different *B. burgdorferi* s.l. species are susceptible to some second- and third-generation cephalosporins, tetracyclines, penicillins, and macrolides, while they are intrinsically resistant to fluoroquinolones, rifampicin, trimethoprim-sulfamethoxazole, and first-generation cephalosporins (Preac Mursic et al. 1996; Hunfeld et al. 2003, 2004, 2005; Morgenstern et al. 2009; Veinović et al. 2013, 2021; Baradaran-Dilmaghani and Stanek 1996). So far, there is no evidence for emergence of secondary antibiotic resistance in *B. burgdorferi* s.l. to the antibiotics recommended.

The choice of antibiotics as well as the mode and duration of administration depend on the clinical manifestation, the age of the patient, the severity of the disease, drug-allergy and side-effect profile, and possible coinfections with other tick-borne pathogens. Notably, although there are differences with respect to *B. burgdorferi* s.l. species and clinical manifestations between Europe and North America, therapy recommendations and therapy outcome are remarkably similar (Hofmann et al. 2017; Lantos et al. 2021; Rauer et al. 2020; Jaulhac et al. 2019).

The preferred medications for therapy of early manifestations – except Lyme neuroborreliosis (LNB) – are doxycycline, amoxicillin, cefuroxime axetil, and phenoxymethylpenicillin, while macrolides, e.g., azithromycin, seem to be less effective in vivo and therefore are recommended as second-line treatment. Late forms can be treated orally with doxycycline or amoxicillin and intravenously with ceftriaxone, cefotaxime, or penicillin G. (Hofmann et al. 2017; Lantos et al. 2021; Jaulhac et al. 2019; Luft et al. 1996). LNB is usually treated intravenously with ceftriaxone, cefotaxime, or penicillin G but can also be treated orally with doxycycline (Rauer et al. 2020; Arnason and Skogman 2022; Stupica et al. 2021; Bremell and Dotevall 2014; Borg et al. 2005; Ljøstad et al. 2008).

The duration of treatment is between 5 and 30 days, depending on the clinical manifestation and the antibiotic used. A significant prolongation is normally not advisable as the risk of severe side effects, such as pseudomembranous colitis, increases disproportionately (Nguala et al. 2021).

The minimum duration necessary for successful antibiotic treatment for the different antimicrobial agents has never been assessed in detail. For erythema migrans, it has been shown that a 10-day course of oral doxycycline was not inferior compared to 2 weeks (Stupica et al. 2012; Wormser et al. 2003). However, relevant studies regarding a shorter treatment for immunocompromised patients or for antibiotics other than doxycycline are not available.

Actually, most guidelines recommend antibiotic therapy for 10–21 days in case of early localized disease and a 2–4-week course for disseminated and late-stage

manifestations (Hofmann et al. 2017; Lantos et al. 2021; Rauer et al. 2020; Jaulhac et al. 2019; Pancewicz et al. 2015).

The success of therapy can only be assessed weeks to months after the end of therapy, especially in the case of long-standing disease manifestations (Table 3).

36.17 Therapy During Pregnancy and Lactation

In principle, pregnant and nursing women are treated with the same antibiotics and same duration as nonpregnant women. However, doxycycline should not be administered in the third trimester and macrolides not during the first trimester. In pregnancy and lactation, oral therapy with amoxicillin is the first choice. Alternatively, penicillin G and ceftriaxone can be used, the latter especially in cases of neurological manifestations (Hofmann et al. 2017; Rauer et al. 2020; Jaulhac et al. 2019; Lakos and Solymosi 2010; Maraspin et al. 2011). In cases of proven penicillin allergy, azithromycin or cefuroxime axetil may be prescribed according to strict indications. Under clinical supervision, ceftriaxone can also be given intravenously, since the risk of cross-allergy with third generation cephalosporins is only about 1% (Buonomo et al. 2014).

36.18 Therapy of Children

Children from the age of 8 years, after enamel formation is complete, can be treated with doxycycline. In children under 8 years of age, the therapy of choice is amoxicillin (Table). This antibiotic is required to be given in three daily doses, which may be difficult in kindergarten and school children. Alternatively, cefuroxime axetil, azithromycin, or clarithromycin can be used (Nizič et al. 2012).

36.19 Therapy of Immunocompromised Individuals

Although only limited data on treatment of LB are available for immunocompromised patients, the recommended antibiotic treatment approach – same antibiotics, dosage and duration – appears to be effective also in this group of individuals (Merkac et al. 2015; Fürst et al. 2006; Maraspin et al. 1999, 2006). One study on patients receiving tumor necrosis factor-alpha (TNF-α) inhibitors reported treatment failure in 25% (4/16); however, re-treatment resulted in an overall favorable outcome also for these patients (Maraspin et al. 2019).

36.20 Long-Term Antibiotic Therapy

Several randomized clinical trials did not provide relevant support for prolonged antibiotic treatment in patients who suffer from persistent symptoms after recommended antibiotic treatment attributed to “persistent” Lyme borreliosis

(Berende et al. 2016; Klempner et al. 2001; Krupp et al. 2003; Fallon et al. 2008). Treatment beyond 30 days for late manifestations is therefore not recommended (Hofmann et al. 2017; Lantos et al. 2021; Rauer et al. 2020; Jaulhac et al. 2019).

36.21 Not Recommended Therapeutic Interventions

Therapeutic interventions that cannot be recommended include, but are not limited to, fluconazole, vancomycin, gyrase inhibitors, metronidazole, hydroxychloroquine, long-term-, combination-, or pulsed-antibiotic therapy, photon therapy, electrotherapy, intravenous bismuth or H_2O_2, colloidal silver, hyperthermia, hypothermia, or stem cell transplantation (Hofmann et al. 2017; Koedel et al. 2015; Rauer et al. 2020; Figoni et al. 2019).

36.22 Treatment of Tick-Borne Relapsing Fever

Relapsing-fever *Borrelia* can be treated very effectively using appropriate medication, although well-designed studies regarding optimal length of therapy, dosing, or efficacy of different antimicrobial agents with regard to the different RF species are scarce to nonexistent. There are no reports of acquired antibiotic resistance, but rifampicin, sulfonamides, fluoroquinolones, aminoglycosides, and metronidazole are intrinsically poor or not effective. Tetracyclines, penicillins, and other ß-lactam antibiotics are most suitable for therapy, the latter especially in pediatric patients, where the use of tetracyclines is usually not recommended for children under 8 years. The efficacy of macrolides is less well-established, but they are an alternative in the second and third trimesters of pregnancy or intolerance for ß-lactams and tetracyclines. Chloramphenicol is also effective but is rarely used outside developing countries, mainly because of the well-tolerated alternatives. In general, the use of tetracyclines is favored because they are the most effective, and the lowest recurrence rate has been observed (Guerrier and Doherty 2011; Jakab et al. 2022). Oral tetracycline (4 × 500 mg per day) or doxycycline (2 × 100 mg per day) or intravenous doxycycline (2 × 100 mg per day) is usually used. Alternatively, intravenous or intramuscular penicillin G (600.000 IU daily) is available as standard therapy, meanwhile mostly replaced by ceftriaxone (1 × 2 g per day) especially in patients with central nervous system involvement. Erythromycin (4 × 500 mg per day) given orally or intravenously is a further alternative.

In louse-borne, RF therapy can be administered as a single dose, while in cases of TBRF, a single dose is usually not sufficient. This is at least partly due to the stronger CNS affinity of TBRF *Borrelia*. Particularly in compartments with limited antibiotic penetration capacity, such as the CNS, there are often niches in which the pathogens persist in spite of antibiotic treatment resulting in relapses. Relapse rates of up to 20% (despite antibiotic therapy) are observed in TBRF (Jakab et al. 2022).

Table 3 Lyme borreliosis: therapy

Manifestation	Drug/administration	Dosage per day		Duration in days
		Adults	Children	
Erythema migrans, Borrelial Lymphocytoma	Doxycycline/p.o.[a]	1 × 200 mg or 2 × 100 mg	4 mg/kg (max. 200 mg) in 1–2 doses	10–21
	Amoxicillin/p.o.	3 × 500–1000 mg	50 mg/kg (max. 2 g), in 3 doses	14–21
	Cefuroxime axetil/ p.o.	2 × 500 mg	30 mg/kg, in 2 doses	14–21
	Azithromycin/p.o.[b]	500 mg	5–10 mg/kg	5–10
Neuroborreliosis[d]	Doxycycline/p.o.[a,c]	1 × 200 mg or 2 × 100 mg	4 mg/kg (max. 200 mg) in 1–2 doses	14–21
	Ceftriaxone/i.v.	1 × 2 g	50–100 mg/kg (max. 2 g) in 1 dose	14–21
	Cefotaxime/i.v.	3 × 2 g	150 mg/kg in 3 doses	14–21
	Penicillin G/i.v.	4 × 5 Mio IU	0.25–0.5 Mio IU /kg in 4 doses (max. 4 × 5 Mio IU)	14–21
Carditis[e]	Doxycycline/p.o.[a]	1 × 200 mg or 2 × 100 mg	4 mg/kg (max. 200 mg)	14–21
	Amoxicillin/p.o.	3 × 500–1000 mg	50 mg/kg (max. 2 g), in 3 doses	14–21
	Ceftriaxone/i.v.	1 × 2 g	50–100 mg/kg (max. 2 g) in 1 dose	14–21
	Cefotaxime/i.v.	3 × 2 g	150 mg/kg in 3 doses	14–21
Lyme Arthritis, Acrodermatitis Chronica Atrophicans	Doxycycline/p.o.[a]	1 × 200 mg or 2 × 100 mg	4 mg/kg (max. 200 mg)	21–30
	Amoxicillin/p.o.	3 × 500–1000 mg	50 mg/kg (max. 2 g), in 3 doses	21–30
	Ceftriaxone/i.v.	1 × 2 g	50–100 mg/kg (max. 2 g) in 1 dose	14–28
	Cefotaxime/i.v.	3 × 2 g	150 mg/kg in 3 doses	14–28

i.v. intravenous; *p.o.* oral; *IU* international units; *NA* not available

[a]Relative contraindication for age <8 years. Not for adolescents or adults under 50 kg body weight; absorption of doxycycline may be affected by 2- or 3-valent cations (dairy products, calcium-containing fruit juices), magnesium in antacids, iron preparations, medicinal activated charcoal, and cholestyramine. Keep a time interval of 2–3 h between intake and meals

[b]Only for patients intolerant to doxycycline, amoxicillin, and cefuroxime

[c]Only in uncomplicated cases; possibly 300 mg/day needed

[d]For late neuroborreliosis therapy for 14–28 days

[e]In first-degree atrioventricular block and PR <30 ms oral therapy for 14–21 days

According to a recent review, the recommended treatment duration is usually 7–10 days, in the case of central nervous system involvement 10–14 days.

36.23 Jarisch-Herxheimer Reaction

During therapy, within a few hours after taking the first dose of antibiotics, a sometimes life-threatening Jarisch-Herxheimer reaction (JHR) can occur as a result of cytokine release (especially TNF-alpha). An initial chill phase with restlessness, intense rigors, sharp rise in temperature and blood pressure, tachycardia, tachypnea, delirium, gastrointestinal symptoms, cough, and limb pains is followed by a flush phase with massive sweating, drop in blood pressure, and a slow decline in temperature. Treatment with intravenous tetracycline carries the highest risk for a JHR; in children JHR is less common (Bryceson et al. 1970; Warrell 2019). In louse-borne RF, a JHR is observed in around 50% (up to 100%) of patients and in TBRF in about 20% (up to 40%) of all cases (Jakab et al. 2022; Butler 2017). Therapy is only symptomatic.

TBRF-related case fatality rate is around 6.5%, range of 2–10% (Goddard 2018). Mortality in TBRF appears to be primarily due to neurologic complications and ARDS.

36.24 Prophylaxis

Lyme borreliosis (Hofmann et al. 2017; Lantos et al. 2021; Figoni et al. 2019; Eisen and Dolan 2016; Pages et al. 2014; Due et al. 2013): Since no vaccine for humans is available, prophylaxis is limited to measures to reduce the risk of tick bites and to remove already attached ticks as early as possible. The risk of being bitten can be reduced by wearing light-colored clothing that covers the body, avoiding tick-infested areas and using repellents on the skin and clothing. After spending time outdoors, the body should be searched promptly and the tick removed as early and gently as possible, as the risk of transmission increases with the duration of the ticks' blood meal. To do this – if necessary with the aid of a magnifying glass – grasp the tick, e.g., with pointed, sturdy tweezers, as close as possible to the skin and slowly pull it out. Commercially available tools, such as a tick card or tick loop, can also be used according to the manufacturer's instructions; if no tools are at hand, simply use your fingernails. Finally, the wound must be thoroughly disinfected. If tick parts remain are still visible in the wound during the final inspection, it is merely the tick's proboscis, which is an intracutaneous foreign body with no specific risk of infection. A visit to the doctor is necessary if typical symptoms occur. Prophylactic antibiotic administration cannot be recommended in Europe at present. In the United States, a single dose of oral doxycycline within 72 h of tick removal for adults and children is recommended but only if the tick bite was from an identified tick vector species and occurred in a highly endemic area and the tick was attached for $\geq$36 h. In general, serological monitoring, self-performed point-of-care (POC) tests, and an examination of the tick

for *Borrelia* are not indicated. During the following 6 weeks, the tick-bite area should be checked for development of an erythema migrans. In that case, medical advice should be sought and the tick-bite should be mentioned.

Repellents for the prevention of tick bites for direct application on the skin include DEET (N,N-Diethyl-meta-toluamide), icaridin, IR3535 (ethyl-3-(N-n-butyl-N-acetyl) aminopropionate), or *Eucalyptus citriodora* oil hydrated/cyclized (EC oil (H/C))(p-menthane-3,8-idol). They should only be applied to uncovered areas of the skin strictly according to the manufacturer's instructions and should not be applied together with sunscreen (Schalka et al. 2014). Permethrin that kills ticks on contact provide highly effective protection and can be used to impregnate clothing. However, its tolerability in case of regular long-term use has never been assessed (Faulde et al. 2015; Vaughn et al. 2014).

Soft Tick-Borne Relapsing Fever (CDC; ECDC): Measures in countries where TBRF is endemic should mainly focus on preventing human-tick contact. Recommended measures include avoiding tick-infested areas, avoiding sleeping in rodent-infested areas, wearing light-colored clothing that covers the body and tucking trouser legs into socks, using tick repellents (see above) for the skin and permethrin-impregnated clothing, and using permethrin-impregnated sleeping bags or bed nets tucked under the mattress when sleeping on the ground or camping. Furthermore, rodenticides and acaricides to treat "cracks and crevices" or natural predators, like domestic cats, are recommended, as well as reducing rodent-friendly environments inside and around buildings.

Due to the short feeding period and the immediate transmission of the pathogen, recommending early removal of soft ticks is inefficient.

Abstract

The burden of the two different diseases, "cystic echinococcosis" (CE), due to several species of *Echinococcus* among the *E. granulosus sensu lato* cluster, and "alveolar echinococcosis," due to *E. multilocularis,* has long been underestimated. Other species, *E. oligarthra* and *E. vogeli,* may also cause disease in humans, similar to CE and AE, respectively. CE is usually maintained by a synanthropic domestic cycle (dog/domestic ungulates); a cycle in wild animals (fox/small mammals) allows *E. multilocularis* to subsist in nature, and environmental factors play a critical role. The larval stage of *Echinococcus* spp., the "metacestode," is characterized by a germinal layer surrounded by a laminated layer and an adventitial layer. The germinal layer forms isolated cysts (CE) or aggregated microcysts (AE), which are filled with a water-like liquid ("hydatid fluid"). The diagnosis of both diseases in humans relies on imaging: ultrasound examination (also useful for mass screening), computed tomography, and magnetic resonance imaging, which provides pathognomonic images; incidental diagnosis is frequent. WHO-US-based classification of CE cysts (CE-1 to CE-5) and staging system for AE (PNM classification) are used to choose among a variety of therapeutic options available, including surgery to remove the lesions and nonsurgical image-guided interventions to sterilize CE cysts or treat complications in CE and AE. Benzimidazoles – with a strict monitoring to ensure optimal efficacy and avoid adverse events – are still the only antiparasitic agents available. For CE as well as AE, there is a need to find new antiparasitic compounds and evaluate therapeutic strategies.

37.1 Introduction

Echinococcosis and *Echinococcus*. Echinococcosis is the disease caused by cestode helminths of the genus *Echinococcus (E.)* (Kern et al. 2017). Actually, this generic term applies to two rather different diseases, due respectively to *E. granulosus*, "cystic echinococcosis" (CE), also previously designated as "hydatid disease," hydatidosis, or "hydatid cyst," a condition already recognized at Hippocrates' times, and to *E. multilocularis*, alveolar echinococcosis (AE), a tumor-like disease only identified 170 years ago (Virchow 1855). In addition, both species differ by their usual animal

reservoir, i.e., mostly domestic animals, for *E. granulosus*, and mostly wild animals, for *E. multilocularis*. However, for more than a century, since the characterization of the "*Taenia echinococcus*" by the German scientist Carl Theodor Ernst von Siebold and the diagnosis of the first human cases of AE in the 1850s, there was no distinction between the two species (Vuitton et al. 2011). Other species of *Echinococcus* may also cause disease in humans, albeit far more rarely and only in South America; they are *E. oligarthra* (also wrongly called *E. oligarthrus* or *oligarthus*) and *E. vogeli*, both responsible for "neotropical" echinococcosis (NE) (D'Alessandro and Rausch 2008). The clinical symptoms of "polycystic echinococcosis," due to *E. vogeli*, are very close to those of AE, and species diagnosis relies on the south-American residence of the patient and on molecular identification (Grenouillet et al. 2013). The very rare cases of *E. oligarthra* infection present as single cysts (D'Alessandro and Rausch 2008). The clinical presentation of both NE is thus similar to that of AE and CE, respectively, and these two species will not be described in detail in this chapter. Finally, a new species of *Echinococcus* was disclosed recently in wild animals and in dogs on the Tibetan plateau, China, *E. shiquicus* (Xiao et al. 2005); however, no disease in humans has been attributed to this species until now.

37.2 The *Echinococcus* Genus: a Single Genus for an Increasing Number of Species, and Two Rather Different Diseases in Humans

A New Taxonomy. A taxonomic revision of the members of the genus *Echinococcus* (Cestoda: Taeniidae) has been proposed, which follows molecular phylogeny. The full description of the genomes of *E. multilocularis* and *E. granulosus* is now available (Tsai et al. 2013) as well as the complete mitochondrial genome for all species (Nakao et al. 2013). *E. multilocularis* still appears as a single species, although variations in its genome, best detected by using the *EmsB* microsatellite marker, may identify strains and has allowed epidemiologists to track its geographical spreading in the northern hemisphere (Knapp et al. 2010). Conversely, *E. granulosus* has been split into several species, which were previously considered as strains, numbered from G1 to G10, and characterized by their most usual intermediate animal host. The phylogenetic relationships of the various "strains" of *E. granulosus* with *E. oligarthrus*, *E. vogeli*, *E. multilocularis*, and *E. shiquicus* have also been studied (Nakao et al. 2007). It is now acceptable to differentiate, within the previously named "*E. granulosus*," *E. granulosus sensu stricto* (ex-sheep strain), *E. equinus* (ex-horse strain), *E. ortleppi* (ex-cattle strain), and *E. canadensis* (ex-camel, pig, and cervid strains) (McManus 2013). *E. felidis* was also described as a distinct species, although it is phylogenetically closely related with *E. granulosus sensu stricto* (Hüttner et al. 2008). Although the definition of two species within *E. canadensis* is still debated (Nakao et al. 2015), it is now accepted to include *E. granulosus sensu stricto, E. equinus, E. ortleppi,* and *E. canadensis* within the *E. granulosus sensu lato* cluster (Wen et al. 2019). The basal positions of the

phylogenetic tree are occupied by the so-called "neotropical" endemic species, *E. oligarthra* and *E. vogeli*, whose definitive hosts are derived from carnivores that emigrated from North America after the formation of the Panamanian land bridge (Nakao et al. 2007). Nowadays, the accepted nomenclature of species should be used in any scientific publications regarding the *Echinococcus* genus. An international consensus on the terminology to be used in English in this field, in order to avoid inappropriate words and expressions used in the past, has been found after a 2-year process of "formalized consensus," and published in 2020 (Vuitton et al. 2020). Adaptation of the international terminology to the French language has been recently published (Bellanger et al. 2021a). It was also established that only three names are now formally accepted for the human diseases associated with infections by *Echinococcus* spp. metacestodes: Cystic echinococcosis (CE) due to *E. granulosus s.l.*, alveolar echinococcosis (AE) due to *E. multilocularis*, and neotropical echinococcosis (NE) due to *E. vogeli* or *E. oligartrha*.

As no restriction to a single animal host has been identified for the various "new" species described from the previously named "*E. granulosus*," and no marked differences have been identified between the clinical presentation of CE depending on the species, for the following description, "*E. granulosus*" will be used as a general name for all three new "zoonotic" species, *E. granulosus sensu stricto*, *E. ortleppi*, and *E. canadensis*. *E. equinus* has never been recognized to infect humans; it thus cannot be considered as "zoonotic"; and the pathogenicity of *E. felidis* to humans is unknown (Vuitton et al. 2020).

Cystic Versus Alveolar: Similar Structure of the Metacestode, but Different Lesions, Depending on the Immune Response of the Intermediate Host. The larval stage of *Echinococcus* spp., also called "metacestode," is characterized by the ***germinal layer***, a syncitial monolayer of parasite cells surrounded by the ***laminated layer***, an acellular layer of polysaccharides which is the interface between the parasite and the host's cellular immune response while allowing exchanges between them (Vuitton and Gottstein 2010). The germinal layer forms "buds," then "vesicles" (cysts), which are filled with a water-like liquid ("hydatid fluid" or "cyst/vesicle fluid"). These cysts may be single (typically for CE) or multiple and aggregated (typically for AE, hence the adjective "alveolar," i.e., composed of alveoli), and small (from 1 mm to 1 cm, typically for AE) or large (from 1 cm to 20 cm, typically for CE) (Eckert and Deplazes 2004). Fertility is characterized by the growth and budding of "protoscoleces" from the germinal layer, and their release into the cyst fluid. In all species of *Echinococcus*, the "protoscolex" is that multicellular organism that ensures the transformation of the larva into an adult worm in the intestine of the definitive hosts after a process of evagination when the cysts are ingested, with the offal of domestic intermediate hosts (for CE) or with the rodent intermediate hosts as prey (for AE) by the appropriate carnivores. Hundreds to thousands of worms then settle in the small intestine of the definitive host where they attach through their hooks and suckers, reach maturity, characterized by egg-containing last segments within 2–3 weeks, and release them into the environment with the feces for an average of 1 month (Eckert et al. 2001; Torgerson et al. 2011; Kern et al. 2017). Each species of *Echinococcu*s was in the past carefully described based on the shape and

length of its segments, hooklets, and suckers, since the morphology of the adult stage (worm) was thought to be species-specific: The molecular taxonomy has now shown that different species can have similar morphology, and subtle differences are not important for species differentiation, which is now based on molecular biology (Thompson and Eckert 1983; Eckert et al. 2001; Lymbery 2017). The most striking differences lie in the histological aspect of the respective metacestodes. In CE, cells of the host's immune response have nearly totally disappeared when the cyst is disclosed in an intermediate host, either animal at slaughtering or human at diagnosis, and the cyst with its germinal and laminated layer is surrounded by paucicellular fibrous area, the **adventitial layer** (Vuitton et al. 2020). The cyst may contain hundreds of protoscoleces. After damage to the germinal layer (rupture or fissure) occurs, the cyst may either degenerate or produce "daughter cysts," usually inside and more rarely outside the germinal layer, which gives a "multivesiculated" appearance to the lesions, quite different from the "multi-cystic" aspect of NE or from the "alveolar" aspect of AE (Rogan et al. 2006; da Silva 2019) (Fig. 1). Protoscoleces may also be disseminated into the peritoneal or pleural cavity when a liver or lung cyst ruptures or after surgical opening (Kern et al. 2017; Vuitton et al. 2020). In AE, the laminated layer is surrounded by a layer of epithelium-like macrophages ("epithelioid cells"), then concentric layers of cells of the immune response, including macrophages, lymphocytes, eosinophils, and giant cells, of cells involved in fibrosis development, such as fibroblasts and myofibroblasts, and of collagen bundles and various components of the extracellular matrix (Ricard-Blum et al. 1992; Ricard-Blum et al. 1996; Grenard et al. 2001). This "granulomatous" periparasitic infiltrate is usually bordered by T-lymphocytes, at the immediate proximity of the liver or lung parenchyma. In AE, the extent of the periparasitic infiltrate and the presence or absence of protoscoleces in the parasite vesicles depend on the susceptibility of the

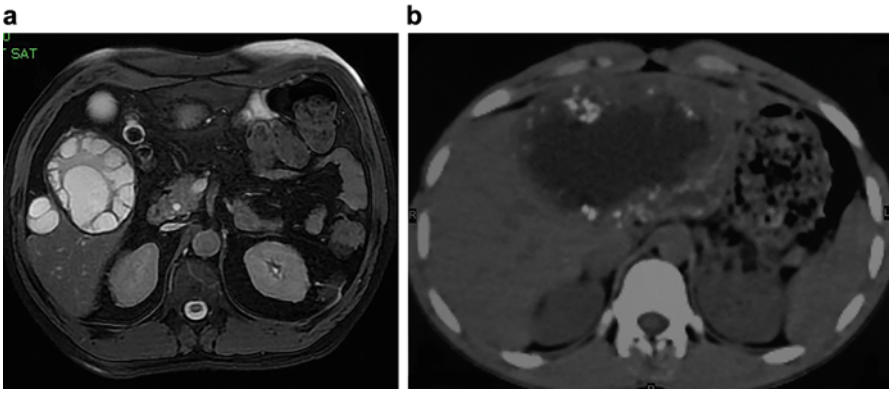

Fig. 1 Cystic (CE) and alveolar (AE) echinococcosis typical images. (**a**) CE: daughter cysts in a liver cyst, as shown at magnetic resonance imaging; (**b**) AE: necrotic cavity (pseudocyst) in the center of a huge lesion invading the right and left liver, as well as the liver hilum; at the periphery of the hypodense necrotic cavity, hyperdense calcifications are well shown in the pseudotumoral lesion by computer tomography (CT)

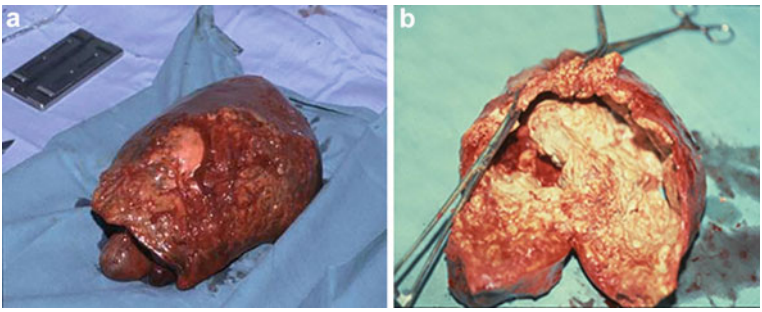

Fig. 2 Alveolar echinococcosis; macroscopical view after surgical hepatectomy. (**a**) Fibrous aspect of the lesions at the surface of the liver. (**b**) Necrotic cavity in the center of a very advanced lesion

host to the development of the metacestode, and may thus be different in the various species of intermediate hosts (Vuitton 2003; Vuitton and Gottstein 2010). Necrosis may also be observed in the periparasitic infiltrate; in degenerating lesions, especially after years of evolution in humans, massive necrosis may occur in the center of lesions, with the constitution of necrotic cavities, which give a "pseudocystic" appearance to AE lesions; however, such pseudocysts have irregular walls and are filled with solid and liquid necrotic debris, and are thus in no way similar to the real "cysts" of CE (Kern et al. 2017; Vuitton et al. 2020) (Figs. 1 and 2).

37.3 The Parasite Life Cycle and the Burden of *Echinococcus* spp. in Animals

E. granulosus sensu lato. The adult cestode develops in the small intestine of the definitive host, a carnivore (Kern et al. 2017; Romig et al. 2017; Wen et al. 2019) (Fig. 3). The last segments (proglottids) of this worm (3–5 mm long) contain oncospheres (eggs); they are released into the intestine, and the oncospheres are dispersed on the grass with the feces of the host. When the oncospheres are eaten by the intermediate host (usually a mammal), the hexacanth embryo, released into the duodenum, passes through the intestinal wall and most usually settles in the liver or in the lung as "cysts" (also called "hydatids" by parasitologists). Domestic animals such as sheep, goats, cattle, horses, camels, swines, caribous, or reindeers serve as intermediate hosts, with some but not strict specificity depending on the species within *E. granulosus sensu lato* (Vuitton et al. 2020). Commonly, dogs are infected by eating raw infective offal containing parasite cysts. Humans become accidentally infected either by touching dogs with contaminated hair, or by ingesting vegetables, water, or soil infected by dog feces (Fig. 3). Less commonly, the cycle involves a wild carnivore such as the wolf, jackal, or coyote and a wild herbivore such as wild elk, caribou, reindeer, or other cervids. As mentioned above, the animal species specificity of the various parasite species is not strict. Cattle, for instance, may be infected by *E. granulosus sensu stricto* or by *E. canadensis* as well as by *E. ortleppi*.

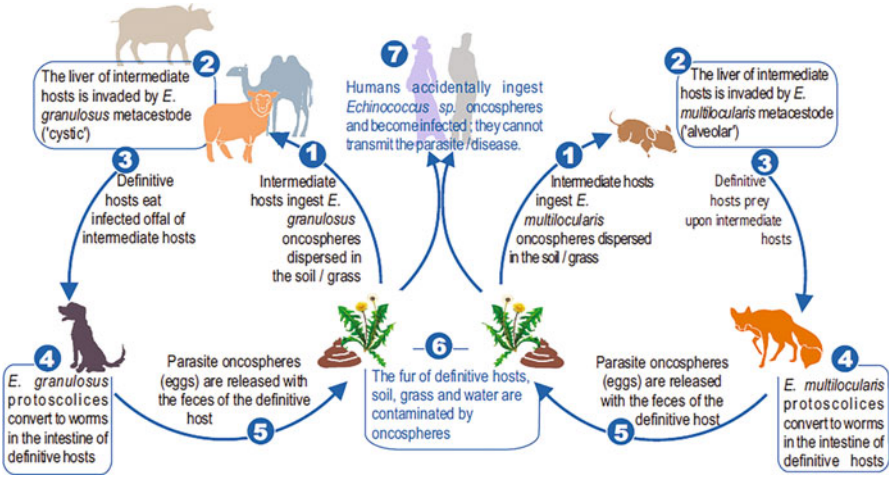

Fig. 3 Parasite cycles of *E. granulosus* (left cycle) and *E. multilocularis* (right cycle)

CE is usually maintained by the synanthropic domestic cycle (dog/domestic ungulate) and represents a persistent zoonosis in rural livestock-raising areas where humans cohabit with dogs fed on raw livestock offal. Infection of dogs by the worms of *E. granulosus* does not cause specifically identified disease or symptoms. Infection of domestic ungulates by the metacestode (larval form) of *E. granulosus s.l.* is characterized by single or multiple cysts, usually in the liver or the lung of the animals. The burden of *E. granulosus* infection in domestic animals has long been neglected and was considered to be minimal, since generally the infected animals do not present any overt disease. Moreover, in rural family-type farming, the fact that cysts might affect offal was not considered to be of great economical importance. However, more recent evaluation estimates the annual livestock production loss of at least US $141,605,195 and possibly up to US $2,190,132,464 (Budke et al. 2006).

Risk factors for domestic animal infection by *E. granulosus* metacestodes have been reviewed in an exhaustive analysis of the current literature (Otero-Abad and Torgerson 2013). Prevalence of CE differs between study locations or different livestock origin; there are seasonal variations in CE prevalence, as found by abattoir meat inspection; high altitudes and increasing annual rainfall are significant risk factors, as well as the age of the host for many farm species: higher CE prevalence is observed in old animals compared to young ones, and the number of cysts in a farm animal also increases with age. The gender of the intermediate host has also been identified as a possible determinant of CE, with females more at risk in most studies. Among host species, on a farm, small ruminants have frequently been observed with the highest rates of infection; but cattle have also been identified in many studies as bearing the highest prevalence of CE of those observed in farm species. Farm location and, especially, management factors are important determinants for infection: e.g., pigs reared in intensive conditions had significantly lower CE prevalence compared to pigs

reared in free-range conditions or on family-owned farms, while sheep and goats from mixed-farming systems showed higher rates of hydatid infection compared to small ruminants from pastoral systems (Otero-Abad and Torgerson 2013).

Livestock represents the parasite reservoir, while the infection of definitive hosts, mainly dogs, is responsible for the maintenance of the parasite cycle in animals and for the transmission to humans. The most important risk factor is the potential access of dogs to raw (uncooked) and infected offal, and thus depends on their food sources, access to the location where animals are slaughtered, access to livestock carcasses, rural location of dogs, whether dogs are free to roam (with a higher risk for stray dogs, in rural as well as in periurban areas, close to dumps or open-air abattoirs), the type of dog, its age (younger dogs being more at risk), and also the knowledge of the owners about echinococcosis and their socioeconomic background; dog's gender does not seem to be a significant risk factor (Otero-Abad and Torgerson 2013). Conversely, indoor or chained dogs are less at risk. Avoiding home slaughtering and preventing consumption of livestock offal by dogs, by proper disposal of carcasses by incineration/burial, or as more recently proposed, by boiling cyst-containing livers or lungs (Li et al. 2014), protects dogs, thus humans, from infection.

E. multilocularis. A cycle in wild animals allows *E. multilocularis* to subsist in nature (Fig. 3). The adult cestode usually develops as a worm (2–4 mm long) in the small intestine of the fox (Deplazes and Eckert 2001; Conraths and Deplazes 2015). The last segments are released into the intestine; the oncospheres (eggs) they contain are dispersed on the ground with the feces where they contaminate the grass. Oncospheres are surrounded by an envelope which allows them to resist very low temperatures (to −40 °C), but they die at +60 °C. When eggs are eaten by the intermediate host, usually a wild rodent, i.e., voles of a number of different species, depending on the endemic area, and in the lagomorph *Ochotona curzoniae* , on the Tibetan plateau of China (Vuitton et al. 2003), the hexacanth embryo is released into the duodenum, passes through the intestinal wall, and enters the liver where it usually settles. AE lesions consist of a mass of small vesicles produced by a single or several embryos, which may occupy a considerable part of the liver. The metacestode may then directly invade all organs and tissues close to the liver, or disseminate in microthrombi to any possible organs through the hepatic veins, heart, and pulmonary and systemic arteries. The life cycle is completed when the intermediate host, containing infected larvae with protoscoleces, is eaten by foxes. Dogs are the most common definitive hosts in some areas, such as China (Vuitton et al. 2003; Guo et al. 2021). Less commonly, other carnivores including raccoon dogs, coyotes, and cats can also serve as definitive hosts (Torgerson et al. 2011; Romig et al. 2017).

As for *E. granulosus* infection, gut infection by worms of *E. multilocularis* species does not result in clinical symptoms or disease, in foxes as well as in dogs or other definitive hosts. As most of the intermediate hosts are wild rodents and lagomorphs, there is no special veterinary or economic impact from the infection of the intermediate hosts by the metacestode. However, in all endemic areas, including Europe and Asia, larval infection with symptoms close to those observed in humans has more and more often been recognized in a number of domestic animals, such as horses, pigs, boars, or even dogs which appear to also serve occasionally as

intermediate hosts (Vuitton et al. 2003; Scharf et al. 2004; Ueno et al. 2012; Böttcher et al. 2013). In addition, AE cases observed in zoo animals, such as monkeys or lemurs, have received much attention in the recent years in Europe and Japan (Rehmann et al. 2005; Umhang et al. 2016), and AE was also observed in exotic pets, such as chinchillas (Staebler et al. 2007).

Environmental factors play a critical role in *E. multilocularis* infection in foxes, resulting in a heterogeneous geographical distribution of the parasite (Giraudoux et al. 2013; Romig et al. 2017). From continental to regional scales, AE forms discrete patches of endemicity within which transmission hotspots of much larger prevalence may occur. Each transmission ecosystem has its own characteristics, and lies on a subtle interplay between altitude, climate, landscape characteristics, land use, and predator/prey relationship (Giraudoux et al. 2013; Romig et al. 2017; Knapp et al. 2018; Guo et al. 2021). Regional meteorological conditions, such as low temperatures or high annual precipitations, have been reported as being associated with the infection rates. The importance of the availability and predation level on potential intermediate hosts for the successful transmission of *E. multilocularis* is well demonstrated. Changes in land use, such as promotion of permanent pastures, deforestation, or privatization of the land, are prone to influence *E. multilocularis* infection in small mammals and foxes, by favoring periods of high densities of small mammals with exclusive preying of foxes on these potentially infected mammals (Giraudoux et al. 2003; Wang et al. 2004, 2006a, 2016; Giraudoux et al. 2019). Involvement of dogs in the life cycle of *E. multilocularis*, as it occurs in rural western China, has been shown to be responsible for higher prevalence of AE in humans than fox infection alone (Wang et al. 2016; Cai et al. 2021). On the other hand, despite a higher prevalence in foxes from rural areas when compared with urban areas of Europe, there is a high infection pressure frequently reported in the periphery of the cities, and fox – as well as coyotes – urbanization has become a new threat, also by considerably increasing the human population at risk (Deplazes et al. 2004; Robardet et al. 2008; Robardet et al. 2011; Catalano et al. 2012; Luong et al. 2018).

37.4 Epidemiology of Echinococcosis in the World

CE in the World. The disease is prominent in rural areas where humans, dogs, and sheep/goat and cattle coexist closely, with poor housing conditions and low level of sanitation and is most common in the regions of the world where raising livestock is a major industry. The estimated minimum global human burden of human CE averages 285,000 disability-adjusted life years (DALYs) or an annual loss of US $194,000,000 (Budke et al. 2006). CE is found in the entire Mediterranean littoral including North Africa; former USSR; East Africa, with highest prevalence found in Turkana region, in Kenya, and in Sudan; and South America, particularly Uruguay, Argentina, and Chile, but also parts of Peru and Brazil (Deplazes et al. 2017). Highest prevalence is observed in Western China, where an average of 1–5% of the population may harbor a cyst when screened systematically using ultrasound examination of the liver (Torgerson et al. 2011). Recent data from China and

Kyrgyzstan suggest a "hot spot" distribution for CE, with some territories or communities being at higher risk than others (Paternoster et al. 2020). The disease is present in Nepal, India, Pakistan, and Bangladesh; it is still frequent in North Africa, Turkey, and all Middle-East countries, where it had been identified since Greek/Roman Antiquity. It is re-emerging in several countries where it had been partially controlled after the Second World War, and especially in all endemic ex-USSR territories, e.g., Bulgaria, Romania, Europe, and all central Asia republics (Torgerson et al. 2011; Deplazes et al. 2017; Mustapayeva et al. 2020; Paternoster et al. 2020; Tamarozzi et al. 2020b; Mustapayeva et al. 2021; Colpani et al. 2021).

Because of active control campaigns, New Zealand and Australia, which were highly endemic in the past, are now far less infected, and an increasing proportion of CE human cases are in immigrants from endemic areas (Torgerson et al. 2011; Deplazes et al. 2017). This is also true for the United States as well as for most of countries of the European Union, including Italy, Spain, and Portugal, which were still highly endemic in the past. Nevertheless, recent epidemiological studies show that CE remains endemic in these countries, especially in Italy where, out of the 436 patients with CE seen in a reference center, 248 (56.9%) were born in Italy, while 188 (43.1%) were foreign-born (Zammarchi et al. 2020; Vola et al. 2022). Strict regulations on slaughtering and control campaigns have contributed to decrease very significantly the transmission to humans despite persistent low level infection in domestic animals which can still be tracked by veterinary inspection, especially in Spain, Greece, Southern Italy, and France (especially in Sicily, Sardinia, and Corsica) (Brundu et al. 2014; Deplazes et al. 2017; Bosco et al. 2021). The diagnosis should thus be evoked for any suspect cystic lesion of the liver when it occurs in immigrants or travellers. A special situation occurs in the United Kingdom, where low level of infection by *E. granulosus sensu stricto* in sheep and in humans is still present in Wales, but most of animal infection is due to *E. equinus*, with horses as intermediate hosts and apparently no transmission to humans (Romig et al. 2006). Nonpublished results from abattoir surveillance including species genotyping seem to indicate a potential resurgence of *E. ortleppi* infection including human cases in Europe, e.g., in France, which should raise attention of public health authorities (Grenouillet et al. 2014; Basmaciyan et al. 2018).

AE in the World. Although always limited to the Northern hemisphere and restricted to specific geographical areas characterized by their ability to sustain the proper functioning of *E. multilocularis* lifecycle among its definitive and intermediate hosts, AE endemic regions have never ceased to extend, from the discovery of the first human case in 1852 in southern Germany. Initially only diagnosed in the mountainous areas of Jura and Alps in central Europe (from Eastern France to Western Austria), and in Russia, from Moscow area and Siberia to the far Eastern region of Kamchatka, AE cases were subsequently recognized during the first half of the twentieth century in Alaska, in Turkey, and in northern Japan, where the parasite was "artificially" introduced by foxes imported from the Kuril islands to Rebun island, then to Hokkaido, to fight agriculture pests [see references on the history of AE epidemiology in (Vuitton et al. 2011; Eckert and Thompson 2017)]. Since the 1940s, the epidemiological situation seemed quite stable, with AE considered to be a

rare disease, even in the endemic area. The rare occurrence and low prevalence of AE in so-called "endemic areas," at usually less than 10/100,000 in regions with the highest contamination pressure (infection of 70% of foxes) was explained both by the rare encounter of humans with infected fox feces, and by the natural resistance of humans as intermediate host for the parasite (Vuitton 2003; Vuitton and Gottstein 2010). This might also explain why, despite mild-level infection in all Central/Northern states of the United States and Southern provinces of Canada, so few AE cases had been observed in North America (Massolo et al. 2014).

However, the situation has changed radically since the 1980s. Western China is now likely to be the world region with the highest number of human AE cases (Vuitton et al. 2003; Craig and Echinococcosis Working Group in China 2006). Nine provinces and autonomous regions are concerned, including Qinghai, Xinjiang, Gansu, Sichuan, Tibet, and Ningxia in Western China where human cases and animal epidemiology are very well documented, and where both types of echinococcosis are found. In Inner Mongolia in North-Western China, as well as Heilongjiang and Jilin in North-Eastern China, *E. multilocularis* infection of animals and human AE cases have been observed, but the epidemiological situation is less known. Prevalence of the disease may reach 10% of the population in some "high risk" districts of Gansu and Ningxia, 100 times higher than in the previously known endemic areas of Europe. China is, with Turkey and central Asia, the only region in the world where CE and AE are known to coexist in some communities, and sometimes in the same patient (Wen et al. 1992; Yang et al. 2006a; Ran et al. 2019), or in the same definitive host (Vuitton et al. 2003). Estimates show that in China there are about 380,000 cases of echinococcosis (including CE and AE), and 50 million people are at risk of *Echinococcus* spp. infection (Wang et al. 2012). From the analysis combining human capital method with DALYs to analyze the indirect CE economic burden on a total of 2'018 CE patients attending the hospitals in Xinjiang, China, between 2004 and 2008, the per-person direct medical cost for the treatment of echinococcosis was estimated to be US$ 1493.12 and the per-person direct nonmedical cost to be US$ 19.67. The indirect economic cost was US$ 1435.96 per person, and the disability-adjusted life-years (DALY) lost was approximately 1.03 DALY/person (Wang et al. 2012; Kern et al. 2017).

Since the 1990s, the recognized extent of the endemic area has progressed a lot in Europe, with fox *E. multilocularis* infection disclosed in all countries, except the United Kingdom, Spain, and Portugal. It also now reaches Western France, Northern Germany, and Eastern Austria, regions that were not previously known to host *E. multilocularis*-infected foxes. Emergence (or recent recognition?) of the disease in the Baltic States is the most striking epidemiological finding of the beginning of the twenty-first century (Marcinkutė et al. 2015). Lithuania in particular now definitely appears to be a major endemic area, with 80 patients diagnosed between 1997 and 2006 for a total population of 3,535,547 inhabitants, 57% of foxes, several farmer dogs, and various intermediate hosts found infected by *E. multilocularis* (Vuitton et al. 2015; Deplazes et al. 2017). Meanwhile, in Japan and in Europe, fox *E. multilocularis* infection has reached the city, thanks to the increased number and the "urbanization" of foxes, which poses new and unresolved questions for the

prevention of AE (Deplazes et al. 2004; Robardet et al. 2008); and dogs and cats are increasingly recognized to be significant definitive hosts (Robardet et al. 2011; Knapp et al. 2018; Da Silva et al. 2020).

Finally, the second decade of the twenty-first century has seen the emergence of North America, especially Canada, as an endemic area for human AE; ecological studies point to the role of semiurban coyotes in the vicinity of cities in Alberta; and to the responsibility of European strains of *E. multilocularis* (and not the autochthonous "Alaskan" strains) in human infection, often revealed in immunodeficient patients (Catalano et al. 2012; Massolo et al. 2014, 2019; Liccioli et al. 2015; Mori et al. 2019).

In fact, the immunodeficient status of the human population in a given endemic area has become one of the parameters which must be taken into account in epidemiological studies. Changes in the sensitivity of the human hosts to *E. multilocularis* infection and larval development are also involved in the increased incidence of AE; this is particularly obvious in the emergence of cases in North America, and this contributes to the increased incidence of cases seen in European endemic areas since the beginning of the twenty-first century (Vuitton et al. 2019; Wen et al. 2019). Such AE cases found in immunosuppressed patients appear to be more and more frequent; a systematic study from the French registry of human AE cases has shown that their incidence was significantly higher than the overall increased incidence of AE cases observed in the French endemic areas in the last two decades (Chauchet et al. 2014). A recent study in a Swiss endemic area has confirmed that new diagnoses have increased fourfold in immunocompetent and ten-fold in immunocompromised patients in the past decade (Lachenmayer et al. 2019). Cases in patients with primary immune deficiency or AIDS are rare (Sailer et al. 1997; Zingg et al. 2004; Chauchet et al. 2014; Haskologlu et al. 2020); most of cases of "opportunistic AE" are observed in patients with immunosuppressive treatments (chemo- and/or immunotherapy) for malignant or chronic inflammatory diseases, or to avoid organ rejection after transplantation (Chauchet et al. 2014; Lachenmayer et al. 2019).

37.4.1 Diagnosis and Follow-up of Echinococcosis in Humans

Clinical Presentation of CE. CE presents usually as a cyst ("hydatid cyst"), in the liver or in the lung, which may remain clinically silent for a long time and is often discovered incidentally during routine abdominal ultrasound (US) examination or chest X-ray/CT scan. All other anatomical locations are possible but rarer, as shown in a large collection of cases by the Australian Hydatid Register in 1976 where the most frequent locations of 1802 cysts were liver (63%), lung (25%), muscles, (5%), bones (3%), kidney (2%), spleen, brain (1%), and heart, breast, prostate, parotid and pancreas (<1%) (Torgerson et al. 2011). Similar figures are given from more recent series of cases in China and in Europe (Wen and Yang 1997; Vola et al. 2022). For the diagnosis of liver cysts, the following signs and symptoms may be observed: right upper quadrant discomfort; urticaria; episodes of itching; right upper quadrant

palpable mass. Clinical symptoms are usually absent until the cyst has reached 10 cm in diameter; a cyst is rarely palpable until it has reached 15–20 cm. Physical examination of the liver may be normal or may disclose an enlarged and regular liver. If the cyst is located in the anterior liver, a round, painless tumor can be palpated (Kern et al. 2017).

A complication is most often at the origin of hepatic CE diagnosis (Kern et al. 2017). The observed signs and symptoms are mainly jaundice by compression of or rupture into the bile ducts, or anaphylactic shock, eosinophilia, urticaria, and/or acute abdominal pain in case of cyst rupture in the peritoneal cavity. Cyst rupture may be favored by any abdominal trauma, often related to sport practice in children of endemic areas. Compression of the common bile duct, portal or hepatic veins, or inferior vena cava is uncommon. Rupture of the cyst (usually into the bile ducts) is more common: depending on the case series, at diagnosis, 30–40% of hepatic cysts diagnosed in hospital settings have ruptured or become infected (Fica et al. 2012). Among lung cysts referred to surgeons, complicated cysts are also frequent, including lung abscess, pleural involvement, pneumonitis and fibrosis in 10.38%, 13.21%, 7.55%, and 11.32% cases, respectively (Ghoshal et al. 2012). However, when a cyst is found at mass screening in asymptomatic subjects, in more than 75% of cases its latent asymptomatic evolution without complications may last more than 10 years (Frider et al. 1999; Wang et al. 2006b). In a recent study in India, 26% of liver cysts were either ruptured or infected when referred to surgeons (Malik et al. 2010). Cysts located near the diaphragm can erode it and extend into the pleural and pericardial cavities, the lung, or the bronchi through perforation. Cysts close to the peritoneal cavity may rupture into the peritoneum or into the duodenum, stomach, colon, or right renal pelvis. These ruptures may lead to extrahepatic CE by the dissemination of *E. granulosus* germinal layer fragments and of protoscoleces, and favor the development of "daughter cysts" in or out the initial cyst (Rogan et al. 2006; Vuitton et al. 2020). More commonly, the rupture of cyst occurs into bile ducts, and is revealed by cholestatic jaundice, cholangitis, or biliary pain. Some ruptures into bile ducts may be clinically silent and are thus only disclosed during an operation.

Cough, hiccups, and chest pain are the main symptoms of lung cysts when there are not diagnosed by chance on a chest X-ray (Ghoshal et al. 2012). Cyst rupture is also a frequent opportunity for diagnosing lung cysts: rupture in the bronchi may be followed by elimination of cyst fluid and materials (membranes, protoscoleces) by cough.

In endemic areas, mass screening programs have been implemented for the past 30 years, using US and serology, and have become a common circumstance of diagnosis. Such mass screening campaigns have shown that liver cysts had a very slow and limited growth: in more than half of the cysts there were no modifications in cyst size during the 10- to 12-year period of observation, in one third growth was slight (<3 cm) and in only one case (7%) the cyst grew by 4 cm. Mean cyst growth in all cases with a prolonged follow-up was 0.7 cm (Frider et al. 1999; Wang et al. 2006b). While serology alone has been used in serosurveys to detect the presence of CE, the presence of false positive and false negative results has been demonstrated to cause an unacceptable rate of false positive and false negative results and should be avoided (see below) (Torgerson and Deplazes 2009).

Imaging Diagnosis of CE. The two key procedures for indirect diagnosis are US and serology. US can be used to recognize cysts as small as 1 cm in diameter, and may be used for diagnosis in hospital settings as well as for mass screening (Macpherson et al. 2003; Casulli et al. 2020). It usually shows one or several round masses with a well-defined contour, which may be empty or filled with echogenic structures corresponding to daughter cysts. US can be used to recognize the detachment of the endocyst that appears as a wavy line inside the cavity. When cysts become infected, they are diffusely hyperechogenic and no longer exhibit characteristic features. Several classifications of US images in CE have then been proposed with various degrees of complexity, after the first US characterization of CE cysts by Gharbi et al. (1981). The WHO-Informal Working Group on Echinococcosis (IWGE) has promoted a unified cyst classification (Fig. 4), which is currently used as a standard to compare data from mass screenings and results of therapeutic interventions (WHO Informal Working Group 2003). This classification groups the cysts according to their activity (Hosch et al. 2008); however, stage CE3a, characterized by the detachment of membranes may either progress to development of daughter cysts (CE2) or to degeneration (CE4 and 5) (Stojković et al. 2018). In addition, when the classification is used to assess any therapeutic intervention, the diameter of cysts (in cm) rather than semiquantitative values should be given (Wang et al. 2003).

On computed tomography (CT), unilocular cysts with their spherical or oval structure of near-water density are easily recognized. Conversely, multilocular cysts may have several CT patterns depending on the space occupied by daughter cysts inside the cyst. Abscesses or necrotic tumors may mimic CE cysts. In such circumstances, with negative serological results, only aspiration cytology can establish the diagnosis of hydatid cyst (Hira et al. 1988; Rinaldi et al. 2014). CE cyst aspiration with a fine needle under ultrasound guidance is currently considered as medically

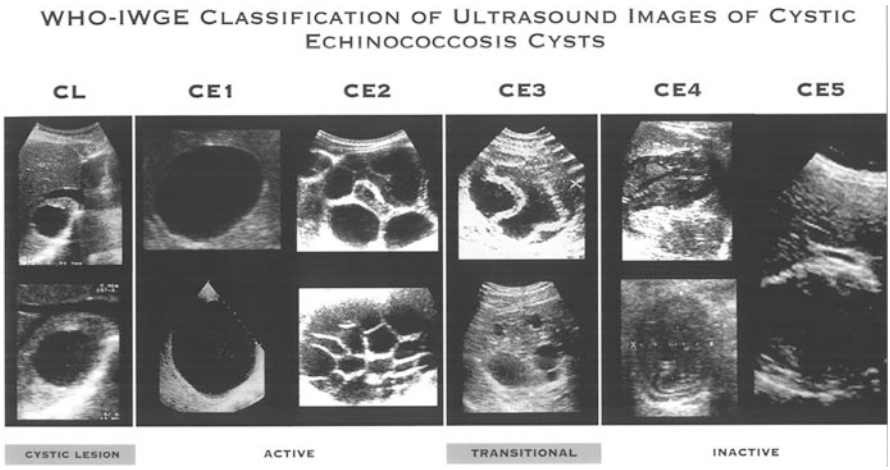

Fig. 4 International classification of Cystic echinococcosis cysts based on ultrasound images (according to WHO-Informal Working Group on Echinococcosis; in WHO-IWGE, 2003)

and ethically acceptable (Echinococcosis 2001). The appropriate procedure aimed at preventing and/or treating any anaphylactic complication and protoscolex spillage should be followed. A point-of-care examination of cystic fluid to determine the presence of PSCs or of *Echinococcus* spp. antigens can be employed to determine whether the puncture should be followed by other steps of the Puncture, Aspiration, Injection and Re-aspiration (PAIR) if the diagnosis of CE is confirmed (see below).

Magnetic resonance imaging (MRI) was shown to reproduce the ultrasound-defined features of CE better than CT and could be of use if for any reason US is not available (Stojkovic et al. 2012). FluoroDeoxyGlucose (FDG)-positron emission tomography (PET) seems to have little value for the routine diagnosis or follow-up of CE but may be of help for differential diagnosis with malignant lung tumors (Kurt et al. 2008)(56); however, peripheral FDG uptake was described in a case with liver cyst, with a typical "doughnut aspect" (Demir et al. 2008).

Clinical Presentation of AE. Before the 1980s in the European endemic area, AE was frequently recognized at an advanced stage and misdiagnosed as liver neoplasia: jaundice was the most frequent presenting symptom, in nearly 50% of the cases; it was either progressive jaundice related to hilum involvement, associated with pruritus, or intermittent jaundice with pain and fever related to superimposed bacterial biliary infection (Bresson-Hadni et al. 2000). Hepatomegaly, generally massive, was also a possible revealing symptom in about a quarter of the cases. This is still the situation in endemic areas of China (Ayifuhan et al. 2012; Aji et al. 2018) except in those regions where a systematic mass screening of the population is implemented.

During the past 30 years in Europe and Japan, changes in the revealing symptoms have occurred, because of disclosure of less severe and asymptomatic cases (Sato et al. 1997; Bresson-Hadni et al. 2000; Piarroux et al. 2011). From the French registry of human AE cases, more than 60% AE cases recorded in the last decade were asymptomatic when diagnosis was made (Bresson-Hadni et al. 2021b) (Siles-Lucas et al. 2017). Less than 25% of cases are revealed by jaundice; and hepatomegaly is observed in only 15% of the cases. Discomfort in the right upper quadrant is a revealing symptom in about 30% of cases. The contrast between a hepatomegaly mimicking a liver carcinoma or advanced cirrhosis and a good clinical status raises the suspicion of AE in endemic areas. Erratic clinical signs and symptoms generally due to metastasis or extrahepatic location of the parasite may also be observed at presentation (Kern et al. 2017). Diagnosis may be made during a surgical operation or an US, CT, or PET examination for another reason, or as the result of mass screening in an endemic area. Asymptomatic cases are more frequently disclosed in immune suppressed patients, especially when organ location/dissemination of cancer, lymphoma or leukemia is looked for during patient's follow-up, when pre-treatment evaluation is performed for systemic inflammatory/autoimmune diseases, or during the follow-up of patients after organ transplantation; evolution of AE seems faster in these patients; clinical symptoms, if any, may mimic liver abscess; and both imaging and serological diagnoses may be more difficult to interpret (Gruener et al. 2008; Chauchet et al. 2014; Vuitton et al. 2019; Lachenmayer et al. 2019).

The most frequent complications of AE are bacterial or fungal infection of the bile ducts and/or of the central necrotic area of lesions, with sepsis and septic shock (Piarroux et al. 2011; Kern et al. 2017; Ambregna et al. 2017). Locoregional extension or a hematogenous spread of parasitic tissue with distant metastases may cause a variety of symptoms ranging from dyspnea and bile-tinged sputum to seizures and stroke as well as skin nodules or bone pain or fractures. Unlike what happens with CE, anaphylactic reactions as revealing symptoms are extremely rare; the occurrence of such symptoms is always associated with systemic dissemination of parasitic fragments through the vessels. Bleeding from oesophagogastric varices related to portal hypertension, secondary to biliary cirrhosis or to chronic parasitic Budd-Chiari syndrome or portal thrombosis have become rare because of a more systematic prevention and treatment of such varices (Piarroux et al. 2011; Kern et al. 2017).

Imaging Diagnosis of AE. US and CT remain the basic imaging techniques in AE. US is the current screening method of choice for diagnosis and regular follow-up imaging in AE, as well as for mass screening (Bartholomot et al. 2002; Yang et al. 2006b; Kantarci et al. 2012; Liu et al. 2014; Kern et al. 2017). In two-third of the cases, the lesion is characterized by irregular limits and heterogeneous content with juxtaposition of hyperechogenic and hypoechogenic areas. The hyperechogenic fibrous tissue often contains scattered calcifications. Less typical US aspects include: 1) small hemangioma-like hyperechogenic nodules which correspond to a lesion at its earlier stage (currently more frequent in asymptomatic immunosuppressed patients; 2) pseudocystic lesions which correspond to huge AE lesions with massive necrosis; the surrounding hyperechogenic ring and the irregular lining should suggest the diagnosis of AE; 3) small calcified lesions which can correspond to either an abortive form of the disease or to a small-size developing AE (Bresson-Hadni et al. 2006). US combined with color Doppler can also provide useful information on biliary and vascular involvement (Liu et al. 2014; Kern et al. 2017). The limits of US examination lie in the calcification of the lesion which may prevent a proper evaluation of the lesion and its real extent. The various features of liver AE at US examination have been analyzed to propose a classification of the images (Kratzer et al. 2015); unlike the WHO-IWGE classification of CE US images, this classification, however, is not widely used although it could provide a better comparison of various series of AE patients, and help ultrasonographists to have a more systematic approach to US diagnosis. Contrast-Enhanced Ultrasonography (CEUS) is used only in specialized centers. Preliminary results showed that Levovist®-CEUS did not provide useful information (Ehrhardt et al. 2007); but using Sonovue® as a micro-bubble contrast agent could bring a very significant improvement both for the diagnosis and the follow-up of AE patients, by delineating the periparasitic micro-vascularized content of the lesions (Tao et al. 2011). Comparison of various imaging approaches to the "activity" of the lesions showed that CEUS could be a suitable substitute for FDG-PET, with the advantage of being readily portable, widely available, nonirradiating and far less expensive (Yangdan et al. 2021). Such comparisons should certainly be confirmed by further studies.

The typical CT aspect is a tumor-like lesion with irregular lining and heterogeneous content with a mosaïc of various densities: scattered, hyperdense calcifications and hypodense areas corresponding to necrosis and/or active parasitic tissue. No

significant enhancement is observed within the lesion after bolus administration of intravenous contrast medium; however, enhancement of the periphery of the lesions is sometimes observed. An intrahepatic bile duct dilation in the controlateral lobe of the liver is the hallmark of infiltration of the hilum by the parasitic process. Hypertrophy of the controlateral lobe is also usual. Following the classification of the US aspects of the liver lesions of AE (Kratzer et al. 2015), the same team has characterized CT images, with the definition of 5 types of "primary morphology," and 6 "patterns of calcification" (Graeter et al. 2016); this classification has the ambition of describing all possible morphological types of lesions at CT and may be useful to radiologists, especially in terms of comparison between lesion types observed in various settings (Graeter et al. 2020). No particular relationship has been found with the international PNM classification and staging which, on the other hand, had the ambition of proposing a prognosis, thus, a different objective. However, the description of the calcification patterns points out the morphological variety of such calcifications, which was not underlined in the past and could have pathophysiological significance: actually, the presence of microcalcifications (also described as "faethery calcifications" or "cloudy calcifications") at CT is strongly correlated to hypermetabolic activity of AE hepatic lesions at FDG-PET/CT independently of the presence of macrocalcifications (Brumpt et al. 2019).

MRI imaging may facilitate the diagnosis in uncertain cases with noncalcified lesions. It is the best technique to characterize the different components of the parasitic lesion and to study the extension to adjacent structures. It shows the typical aspect of multiple small cysts, best observed on T2-weighted images: such aggregations of microcysts are pathognomonic of AE, and may be used to assess diagnosis, especially in patients with small lesions with hemangioma-like or metastasis-like aspects at CT, and in those with a negative serology such as immunodeficient patients (Chauchet et al. 2014). Like the above mentioned "microcalcifications" inside the lesions, microcysts present on MR T2-weighted images may be regarded as a surrogate marker of the metabolic activity of the lesions (Azizi et al. 2015). Cholangio-MR imaging has now advantageously replaced the classical per-cutaneous cholangiography. It is an important part of the preoperative evaluation, as it provides information on the relationship between AE lesion and the biliary tree, and it may be completed by Endoscopic Retrograde Cholangio-Pancreatography (ERCP), which is often the first step of perendoscopic interventions, as described below (Tamarozzi et al. 2014; Ambregna et al. 2017).

PET using [18 F] FDG has been evaluated to assess the viability of the lesions, at diagnosis and in the follow-up of inoperable AE patients under long-term benzimidazoles therapy (Ehrhardt et al. 2007). Although FDG uptake does not actually reveal the metacestode, but is mostly associated with the periparasitic infiltrate by immune cells, this indirect approach may be useful and increased FDG uptake by an AE lesion in the liver is best correlated with parasitic metabolic activity when "delayed" FDG uptake images are analyzed, i.e., 3 h after FDG injection (Caoduro et al. 2013). It may be stressed that the similar increase of FDG uptake at PET-CT observed in AE and in a variety of solid primary or secondary tumors and malignant hematological disorders may be a source of difficult differential diagnosis, especially in those cases

with AE as an opportunistic infection when an abnormal lesion is found in the liver during the follow-up of patients with malignant diseases (Chauchet et al. 2014).

37.5 Immunological and Molecular Diagnosis of Echinococcosis

Serological tests may confirm the diagnosis of echinococcosis, although there is currently no standardized, highly sensitive and specific as well as inexpensive test available for antibody detection of CE or AE. Cross-reactivity is observed between both cestodes, and most tests for CE can be used for the diagnosis of AE and vice versa. In those endemic countries where both diseases may be found in the same area, a differential diagnosis could theoretically be useful; but most often, distinction is made by imaging. Cellular tests have no value for the routine diagnosis of both diseases (Bresson-Hadni et al. 1989). The intradermal Casoni test is no longer used because of its lack of sensitivity and specificity as well as because of safety issues (risk of anaphylactic shock).

Serological Tests. Detection of specific antibodies in serum uses antigens obtained from *E. granulosus* (hydatid fluid or protoscoleces) or *E. multilocularis* (protoscoleces or parasitic extracts), and/or more purified antigens or recombinant proteins from either *Echinococcus* sp. (Yang et al. 2008; Zhang et al. 2012; Craig et al. 2015; Kern et al. 2017; Gottstein et al. 2019; Vola et al. 2019; Tamarozzi et al. 2021). From the available literature and clinical experience, it may be stated that: 1) complement fixation tests are no longer used because of their poor sensitivity and specificity; 2) indirect hemagglutination and latex tests, using crude *Echinococcus* extracts, are both relatively inexpensive and sensitive, but poorly specific; 3) immunoelectrophoresis or immunosyneresis are specific, but poorly sensitive and time-consuming; they are no longer used; 4) ELISA tests, using crude antigens from *E. granulosus* or *E. multilocularis*, are sensitive, but poorly specific; 5) ELISA tests using specific antigenic fractions or recombinant antigens such as antigen 5 or antigen B of *Echinococcus granulosus*, *E. multilocularis* Em2 or Em18 fractions, and recombinant Em3/10/Em 18, are more specific; 6) Western blots use either crude extracts from *E. granulosus* or *E. multilocularis* (more sensitive) or purified fractions or recombinant antigens (more specific). Combination of antigens in a single test (as the $Em2^{plus}$, commercialized by Bordier Affinity Products, Crissier, Switzerland, or the rapid DOT-immunogold assay, commercialized by Xinjiang Key Lab, Urumqi, P.R. of China) (Feng et al. 2010), rules of interpretation for the Western blot (e.g., from *E. multilocularis* extract, as that commercialized by LDBio, Lyon, France) (Liance et al. 2000) or a combined Western Blot and Line blot assay (Deininger and Wellinghausen 2019), have attempted to combine positive and differential diagnosis. By evaluating the "best" serological tests on ultrasound and/or CT-confirmed lesions, overall sensitivity reaches 80% for liver hydatid cysts (it is lower for lung cysts, averaging 70%) and 95% for alveolar echinococcosis (it is lower in immune suppressed patients, averaging 85%); specificity may reach 90% for both (Ito and Craig 2003). However, diagnostic efficiency of serology is limited both by 1) the reduced capacity of some infected patients to develop specific antibodies (or some isotypes), for genetic or acquired reasons (such as immunosuppression) and 2) the absence of release of specific antigens by the cysts in CE, which

decreases sensitivity, and by the existence of infected nondiseased persons in endemic areas, which decreases specificity. Positive serological results in individuals at mass screening account for at least five different situations: 1) "patent," overt disease with symptoms, 2) "latent," nonapparent disease; 3) calcified dead lesions in the liver; 4) CE cyst in the lung or other organs and rare cases of isolated extrahepatic AE despite no US lesions in the liver; and, 5) no parasitic lesions at all (Bartholomot et al. 2002; Yang et al. 2007; Yang et al. 2008). Negative serology with patent CE or AE lesions have been found in all mass screening surveys and is the rule in all published hospital case series (Yang et al. 2007; Zhang et al. 2012). Serology should thus never been used as a "first intent" test, but always combined with ultrasound imaging in mass screening, and only be used as a confirmation test for a suspected diagnosis based on imaging techniques in clinical settings.

Molecular Tests. Molecular identification of both *E. granulosus* and *E. multilocularis* is mostly based on PCR using mitochondrial DNA probes, but also on nuclear sequences, including microsatellites. It may be used, if echinococcosis is suspected despite negative serology, on liver needle aspiration (for CE) and/or liver biopsy (for AE) (Dybicz et al. 2013), and it may be performed retrospectively, on formalin-fixed paraffin-embedded (FFPE)samples (Schneider et al. 2008; Simsek et al. 2011; Grenouillet et al. 2013). The use of such techniques is particularly precious in immunodeficient patients with negative serology and confusing images.

Time of storage could be critical for obtaining successful PCR. Recommendations were recently proposed (Knapp et al. 2022) for initial screening of either frozen or FFPE samples, using a short marker such as the 16S-84 bp target (Knapp et al. 2014), then different specific PCR systems in a second step for identification of *E. multilocularis* (Georges et al. 2004; Schneider et al. 2008) or *E. granulosus* (Stefanić et al. 2004; Trachsel et al. 2007). Additionally, the pan-Echinococcus 12S-268 bp target (Roelfsema et al. 2016) can be used to test for the putative occurrence of other species (e.g., *E. ortleppi* or *E. canadensis* in Europe). Molecular biology techniques also allow genotype studies both for CE (Boubaker et al. 2013; Alvarez Rojas et al. 2014) and AE (Massolo et al. 2019; Knapp et al. 2020). In addition, molecular biology techniques are useful in epidemiological studies to identify the actual species of *E. granulosus* involved in human contamination from the animal cycle (Romig et al. 2017; Massolo et al. 2019) Several techniques have been described to identify worms or eggs of *Echinococcus* spp. in the feces of definitive hosts. The most recent techniques aimed at avoiding the recurrent problem of RNAses and other inhibitors present in the fecal samples, while identifying the species of the animal host; the use of such techniques is currently revolutionizing epidemiological studies of *E. multilocularis* infection in the animal hosts (Umhang et al. 2016; Knapp et al. 2018, 2021; Da Silva et al. 2020; Herzig et al. 2021).

37.6 Antiparasitic Drugs and Echinococcosis

Two Orphan Drugs for Two Neglected Diseases. Compared to most of parasitic diseases and/or zoonoses, for which an appropriate and efficacious medical treatment is available, echinococcosis can rarely be cured by antiparasite chemotherapy

alone, safely and within an acceptable time schedule, and the available drugs are extremely limited (Pawlowski et al. 2001; Junghanss et al. 2008; Brunetti et al. 2010; Brunetti et al. 2011; Manciulli et al. 2018). In addition, there have been nearly no well-designed clinical trials for any medical treatment modality in either form of echinococcosis (Kern 2006). Only two benzimidazole compounds, used since the beginning of the 1980s, have proven effective against CE and AE: mebendazole (MBZ) (4.5 g/day) and albendazole (ABZ) (10–15 mg/kg/day) (WHO Informal Working Group on Echinococcosis 1996; Brunetti et al. 2010; Vuitton and Bresson-Hadni 2014). Both drugs have a poor bioavailability, mostly due to poor intestinal absorption; the most practical way to improve absorption is to combine ABZ with a fatty meal. ABZ (i.e., ABZ sulfoxide, the active compound originating from hepatic metabolism), however, may reach higher plasma levels than MBZ (Horton 2003; Junghanss et al. 2008; Vuitton and Bresson-Hadni 2014). For this reason, and because it is approved by the drug agencies of most countries, opposite to MBZ, ABZ is the most widely used drug for the treatment of echinococcosis. Both MBZ and ABZ must be given continuously, without interruption, for the period of treatment assigned to each case depending on the type of disease and treatment association; discontinuous administration of both drugs, as initially recommended by the pharmaceutical company and most of country drug regulation agencies, should not be used any longer (Tamarozzi et al. 2020a). Praziquantel (PZQ) is the only other drug of use in echinococcosis, since it is the only one with a demonstrated effect on *Echinococcus* sp. oncospheres, thus of possible use for deworming definitive hosts, dogs and fox (by baiting) and interrupting the parasite cycle (Gemmell et al. 1977). PZQ also exerts a toxic effect on *E. granulosus* protoscoleces (Richards et al. 1988), and may be used as adjuvant therapy together with albendazole in CE with systemic dissemination and/or specific locations, such as bone (Taylor and Morris 1989; Mohamed et al. 1998; Monge-Maillo et al. 2017; Monge-Maillo et al. 2019; Cattaneo et al. 2019); however, there are no sound clinical trials to support the use of such a combined therapy. Nitazoxanide has also been used for the treatment of CE, although its use has mostly been reported as a salvage therapy in bone CE, with contrasting results (Monge-Maillo et al. 2017; Monge-Maillo et al. 2019; Cattaneo et al. 2019).

Adverse Effects of Benzimidazoles. Adverse events of benzimidazoles occur in 6–20% of treated patients; they look more frequent when associated treatments are needed for other conditions, especially immune suppressants (Horton 2003; Chauchet et al. 2014; Tamarozzi et al. 2020a). General complaints include headache, nausea, anorexia, vomiting, abdominal pain and itching, and weight gain; in a few cases, idiosyncratic/allergic reactions have been observed (Horton 2003). A significant, but usually reversible alopecia occurs in about 5% of cases, favored by cholestasis and/or portal hypertension. In the first weeks of treatment, more severe side-effects may be observed, including leukopenia, as well as an increase in liver enzymes which may result from drug efficacy as well as be evidence of drug toxicity (Teggi et al. 1997; Horton 2003; Brunetti et al. 2010). A regular monitoring of a possible hepatotoxicity is therefore recommended: if aminotransferases rise over 3–4 times normal levels, discontinuation of therapy should be considered; ABZ sulfoxide plasma levels measured; and ABZ reintroduced at a lower dosage, with regular

monitoring of plasma levels (Vuitton et al. 2016). Albendazole sulfoxide levels should be regularly monitored when albendazole is used for a long period of time, as is the case in patients with AE or disseminated multiorgan CE; as the drug interfere with a variety of other drugs (Horton 2003) and other xenobiotics such as tobacco, cannabis or even liquorice, as recently stressed (Bresson-Hadni et al. 2021a), variations in drug systemic concentrations may explain adverse effects as well as lack of efficacy; measurement-guided modifications of ABZ dosage may widely improve both safety and efficacy of treatments (Vuitton and Bresson-Hadni 2014; Tamarozzi et al. 2020a; Bresson-Hadni et al. 2021a). ABZ has been shown to be teratogenic in rats and rabbits, and therefore, it should be avoided during pregnancy (at least during the first trimester) and lactation (Horton 2003). Although they are closely related drugs, MBZ may be better tolerated by patients with ABZ side-effects and vice versa; a switch to the other drug can thus be recommended before withdrawing chemotherapy definitively (Bresson-Hadni et al. 2011).

Candidate Drugs? All attempts at using other drugs for the treatment of echinococcosis have been unsuccessful until now, including promising drugs such as nitazoxanide, the effects of which were not convincing in humans after a preclinical trial (Stettler et al. 2004; Reuter et al. 2006; Kern et al. 2008). Several candidates have been proposed, from experimental *in vitro* and *in vivo* studies (Hemphill et al. 2007; Hemphill et al. 2014); none of them has reached phase I/II trials in humans. Several candidates from traditional medicine, including Chinese traditional medicines and others, have been studied from in vitro, experimental or clinical observations, but unfortunately have never been moved to approved treatment modalities (Siles-Lucas et al. 2018; Karpstein et al. 2021; Wang et al. 2021). Amphotericin B as salvage treatment for AE patients with intolerance or resistance to benzimidazoles effectively halted parasite progression in a small series of patients, but its IV administration precludes its use for the treatment of a chronic disease (Reuter et al. 2003).

The Advent of Biotherapies? Because of the exquisite sensitivity of *Echinococcus* larvae to the immune response of the host, efficacy of immune therapy may be anticipated; because of the efficacy of such therapies in cancer and the similarities between malignant tumors and the lesions of AE, as well as the severity of this disease, much attention has been given to a possible modulation of the immune system in order to inhibit the growth of *E. multilocularis*-induced lesions. The proof of concept was given two decades ago for interferon-alpha, with nearly complete prevention of *E. multilocularis* infection in experimental mice, and impressive regression of hepatic lesions in a patient with AE (Harraga et al. 1999; Godot et al. 2003); however, no clinical trials have been implemented to confirm these preliminary successes with interferons. More recently, experimental studies have focused on a possible intervention of immunological "check-points" in the tolerance of the host toward *Echinococcus* spp. metacestodes in order to develop biotherapeutic tools against AE and/or use biotherapies already developed for other purposes. The late stage of AE is characterized by a status of immune (T-cell) exhaustion, mostly due to the involvement of check-points similar to those observed in malignant tumors. Specific studies have addressed two inhibitory checkpoint systems, namely PD-1/PD-L1 (La et al. 2015; Wang et al. 2018; Bellanger

et al. 2020; Jebbawi et al. 2021) and TIGIT (Zhang et al. 2019, 2020, 2021). Experimental studies are very promising; however, use of check-points inhibitors (which are already used or at the preclinical stage in other indications) has not reached the preclinical stage yet for AE.

37.7 Treatment and Follow-up of CE Patients

Surgical Treatment of CE. The objective of surgery is to remove all parasitic cysts (Kern et al. 2017). For liver cysts, hepatic resection (hepatectomy) is usually only recommended for central cysts of a left lateral segment (segmentectomy). All other types of hepatic interventions are "cystectomies." Controversies still exist about the preferred operating technique of cystectomy among all proposed operations. Partial cystectomy, with an appropriate management of the residual cavity, is often preferred in endemic areas, since such a technique is easier to achieve by local surgical teams. However, without concomitant treatment by ABZ, recurrence and/or dissemination of cysts is frequent despite the measures implemented to prevent spillage of protoscoleces or of germinal layer fragments, since the cyst should be opened to perform such an operation. For any "opened cyst"-procedure, protection of the peritoneal cavity during cyst evacuation should be ensured. Partial cystectomy includes the sterilization of the cyst by injection of protoscolicidal agents, e.g., chlorhexidine, H_2O_2, 80% alcohol, or 0.5% cetrimide, then the evacuation of the cyst content. Recurrence of hepatic cysts and peritoneal dissemination of cysts are generally underestimated (2–25%), since very few series of patients with a prospective follow-up were ever reported in poor-resources endemic countries. In Kenya, among 663 patients with a surgical management of the disease, there were one intraoperative and one postoperative death, respectively, and 47 patients had repeated operations because of postoperative complications and/or recurrences (Cooney et al. 2004). To better avoid recurrence, currently various types of total cystectomy allow surgeons to completely remove the parasite without the risks of liver resection (Jerraya et al. 2015): after the liver overlying the cyst has been incised, attempts are made to excise the laminated layer intact; this may be done by following the virtual gap which exists between the inner and outer fibrous layer surrounding the cyst (Peng et al. 2006). Such a total (periadventitial) cystectomy, as proposed by Chinese surgeons, should be used whenever possible, if a surgical treatment for a noncomplicated cyst is necessary (Peng et al. 2002; Aydin et al. 2008; Mohkam et al. 2014; Chen et al. 2014; Lv et al. 2015; Zhang et al. 2020; Julien et al. 2021). The word "pericystectomy" should no longer be used to designate such an operation which removes all three layers of the cyst, including the adventitial layer, as well described by the international echinococcosis terminology which also proposes a systematic description of surgical operations for liver cyst resections according to the AORC nomenclature system (A for "Approach," O for "Opening," R for "Resection," and C for "Completeness," as shown in Fig. 5); such a standardized description should facilitate comparisons between case series, and avoid part of the biases usually unavoidable in retrospective studies (Vuitton et al. 2020;

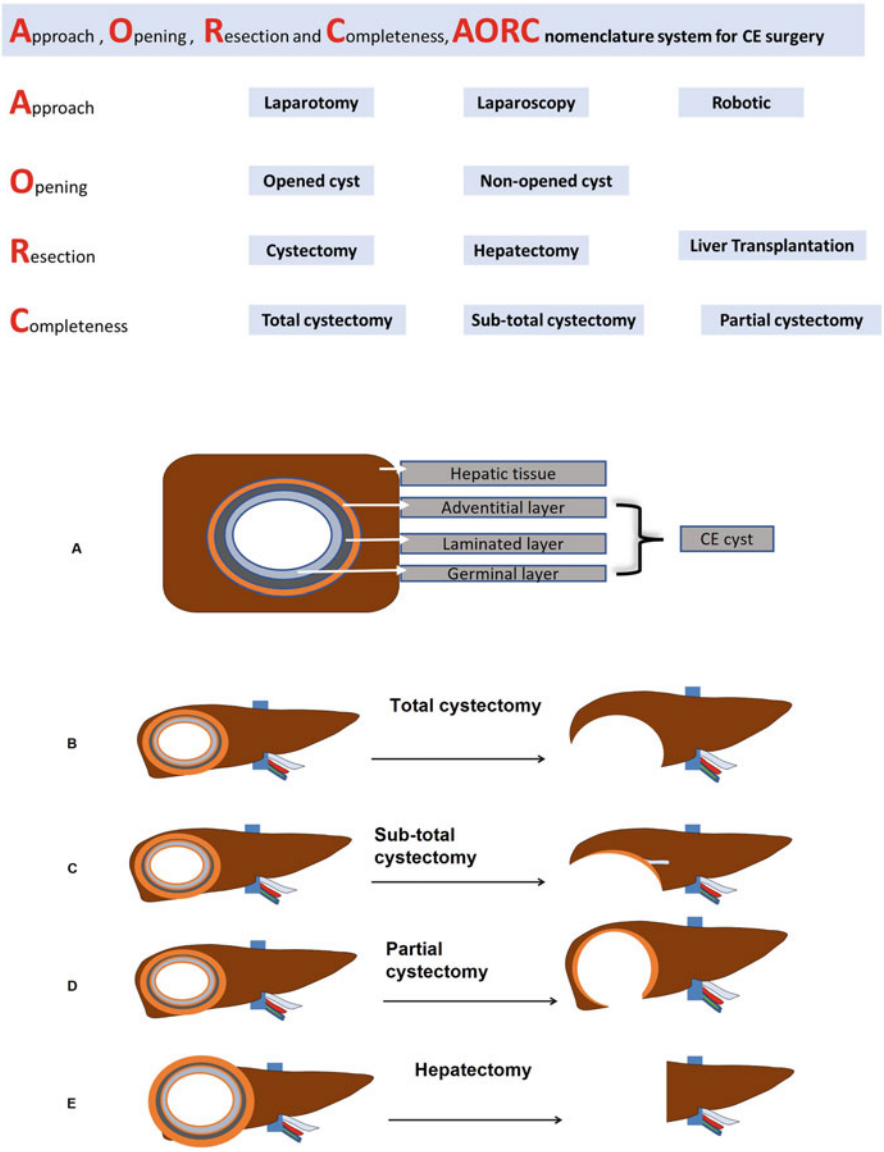

Fig. 5 The AORC (Approach/Opening/Resection/Completeness) nomenclature system for the description of surgical operations in the treatment of cystic echinococcosis (according to Vuitton et al. 2020, Parasite)

Bellanger et al. 2021a). Partial cystectomy, which removes the germinal and laminated layer of the cyst (previously named "endocystectomy"), remains widely used by surgeons; a standardized approach to this technique has been given in details; this technique includes cyst opening as part of the procedure, which needs a careful

protection of the surgical field and a long-term follow-up to check for recurrence (Al-Saeedi et al. 2019). The laparoscopic approach is now considered to be safe and is used by many surgical teams in endemic areas (Tuxun et al. 2014; Bektasoglu et al. 2019); robotic resection of hydatid cysts has also been reported (Magistri et al. 2019; Zhao et al. 2020; Yaghi et al. 2021); indocyanine green may help enhance the border between the peripheral adventitial layer and the liver parenchyma and assist surgeons to complete radical resection and reduce complications (Li et al. 2020). A meta-analysis based on 6 studies totally consisting of 1028 patients could not demonstrate a superiority of either of the surgical approaches (Sokouti et al. 2017). Another recent meta-analysis showed a higher rate of postoperative complications in the laparoscopic group, as well as lower rates of recurrence (Al-Saeedi et al. 2021). Depending on the series, recurrence rates especially were higher, similar, or lower in the laparoscopic group when surgical series were compared retrospectively (Bektasoglu et al. 2019; Bayrak and Altıntas 2019; Maitiseyiti et al. 2020). However, different types of procedures were used in the so-called "comparative" retrospective series; most studies lack important data such as cyst stage, dimension and location; and we miss prospective studies, randomized control trials, and long-term follow-up to define a strategy for the selection of cysts/patients to either of the approaches.

In any other locations (in the lung, brain, or any organ), cysts should be removed totally whenever possible (Duishanbai et al. 2011; Ghoshal et al. 2012; Ahmadinejad et al. 2020). For complicated liver cysts, a variety of techniques may be used, including surgical or perendoscopic biliary drainage (Dziri et al. 2009; Tamarozzi et al. 2014; Rinaldi et al. 2014); protoscolicidal agents should never be injected in the cyst when biliary communication is suspected; formalin and hypertonic saline must no longer be used in any cases because of the risk of caustic sclerosing cholangitis. Peritoneal dissemination and/or recurrence are difficult to treat. Liver transplantation (LT) has been exceptionally performed in patients with severe complications (Kern et al. 2017).

Nonsurgical Interventional Treatment of CE: Puncture–Aspiration–Injection–Reaspiration (PAIR). Since 1986, PAIR has been an alternative to surgery (Ben Amor et al. 1986; Gargouri et al. 1990). After percutaneous puncture under ultrasonographic guidance, a complete aspiration of the cyst is performed; the residual cavity is then filled with a scolicidal agent, usually ethanol, which is reaspired 10 min later. At the beginning of the 2000s, a review of cases treated with this technique by the WHO-IWGE and meta-analyses have concluded to the efficiency, safety and usefulness of the procedure (Echinococcosis 2001; Smego et al. 2003; Velasco-Tirado et al. 2018). A more recent meta-analysis of the comparison between PAIR and laparoscopic surgery, based on 57 studies including a total of 2832 patients has concluded to a superiority of PAIR regarding peri- and postintervention mortality and morbidity and a superiority of laparoscopic surgery regarding recurrence (Sokouti et al. 2019). However, such results are hampered by the different indications of the two techniques if the international rules for treatment decision are followed, by the specific techniques used for percutaneous puncture-associated treatment and for laparoscopic surgery, and by the different levels of expertise of the various teams involved in the collected studies. According to the

current consensus PAIR is indicated in medium-sized CE1 and CE3a cysts, and contraindicated for very large-sized cysts, and if there is communication of the cyst with the biliary tree, assessed using cysto-cholangiography, cholangio-MRI or by checking for bilirubin in the cyst content (Junghanss et al. 2008; Brunetti et al. 2010; Rinaldi et al. 2014; Kern et al. 2017). In particular, a retrospective study suggested that cysts larger than 7.5 cm have a high probability of having a biliary fistula (Kilic et al. 2008). A very limited number of anaphylactic shocks and less secondary dissemination than after surgery have been reported (Neumayr et al. 2011). Drainage may be associated with PAIR for large cysts and cysts associated with cysto-biliary communication; such a technique ("Standard Catheterization technique," S-CAT in the international echinococcosis terminology (Vuitton et al. 2020)) should be distinguished from the conventional PAIR when meta-analyses are performed; a prospective study comparing conventional PAIR and S-CAT showed that S-CAT had higher rates of major complications and length of hospital stay (Akhan et al. 2020). Other percutaneous technique have been described, which use larger tubes and vacuum aspiration, to treat cysts with daughter cysts ("Modified Catheterization techniques," Mo-CAT in the international terminology); however these procedures often have very long catheter times and selection of cases should be strict to compare favorably with surgery (Schipper et al. 2002; Kern et al. 2017; Akhan et al. 2017). Laparoscopic aspiration and sterilization of the cysts are also feasible but may be associated with spillage and recurrence, if the patients are not treated with ABZ before/after the procedure. As mentioned above, per-laparoscopic cystectomy is an option which is more and more adopted by properly trained surgical teams. Per-thoracoscopic interventions may also be performed to remove pulmonary or mediastinal cysts (Aydin et al. 2012; Alpay et al. 2012). Perendoscopic interventional procedures, including ERCP, dilation and/or stenting, have become the treatment of choice to treat postoperative biliary fistulae after cystectomy (Dziri et al. 2009; Tamarozzi et al. 2014; Jerraya et al. 2015). While PAIR has shown to be a curative procedure in cysts of appropriate stages, its diffusion has been hampered by the fear of complications, namely anaphylactic shock (Neumayr et al. 2011). While as discussed above the rate of anaphylactic complications is very low during PAIR, this remains a possibility. As such, all procedures should be performed in a hospital setting with the assistance of an intensive care specialist (Brunetti et al. 2010). Some authors have proposed the elimination of the injection step and the association of varying courses of albendazole to the treatment course (Firpo et al. 2017). However, no prospective study has been made on this variation to date.

Antiparasite Treatment and Follow-up of CE Patients. Benzimidazoles, which are parasiticidal on *E. granulosus in vitro*, are indicated for patients with multiple cysts in two or more organs and for patients with peritoneal cysts. ABZ may also be used to treat small-size cysts, since it was shown to be more effective on such cysts and when, given the natural history of CE, surgery might be disproportionate, especially in children. ABZ alone has a better effect on CE cysts than placebo or MBZ (Franchi et al. 1999). One prospective controlled trial of ABZ and PZQ (25 mg/kg/day) versus ABZ alone concluded that the combined treatment was more effective than ABZ alone (Mohamed et al. 1998). However, in randomized controlled trials, complete

disappearance of all cysts was never reached. Treatment schedules usually include "treatment cycles" of 3 month-continuous administration of ABZ, with imaging evaluation for signs of cyst degeneration after each cycle and decision to stop or prolong the treatment (Brunetti et al. 2010; Kern et al. 2017). Preintervention and postintervention antiparasitic treatment with BZM may reduce the risk of recurrence; there is no optimal scheme, but the current option is to give ABZ during 1 month before and 1–2 months after surgery (Kern et al. 2017). The most recent review of studies which compared surgery alone and surgery associated with BZM therapy was based on 22 studies with levels of evidence 2–4 which were qualitatively analyzed, and 11 randomized controlled trials which were quantitatively analyzed by meta-analysis (Velasco-Tirado et al. 2018). It confirmed that treatment outcomes were better when surgery is combined with BZM drugs given preoperation and/or postoperation. Association of ABZ with PAIR increases clinical and parasitologic efficacy (Smego et al. 2003; Velasco-Tirado et al. 2018). As a proof-of-concept, a retrospective study of PAIR without injection of protoscolecidal agent but followed by at least 1 month of ABZ administration has been performed: it showed results similar to those obtained with the classical PAIR in terms of response rate, relapse rate, and morbidity (Firpo et al. 2017); such a simplified procedure could extend the use of PAIR for the treatment of CE. A prospective comparative study should, however, be necessary to provide an optimal schedule of ABZ treatment, whatever the procedure, with and without injection. ABZ should not be administered when PAIR is performed during pregnancy (Horton 2003; Brunetti et al. 2010).

The main objective of administration of ABZ perioperatively is to prevent the development of protoscoleces after per-operative spillage. Based on experimental data (Ceballos et al. 2010, 2011, 2013), 1 month of treatment is a minimum to reach full protoscolecidal efficacy for ABZ; and adding PZQ could be a way to reduce the length of administration; however, perioperative use of PZQ to prevent protoscolex seeding, is based on a limited number of studies (Velasco-Tirado et al. 2018). A clinical study confirmed that after 28 days of administration of ABZ preoperatively, protoscoleces could still be found in some of the hydatid cysts at surgery or PAIR, and pointed out the high variability of individual albendazole sulfoxide concentrations, both in the plasma and in the cyst (Skuhala et al. 2014).

It may be anticipated that the multidisciplinary approach, which is now commonly used for AE patients, will soon also become a routine for the management of CE patients. Patients treated for CE, either by combined surgery, PAIR, S-CAT or Mo-CAT and ABZ, or by ABZ alone, should have a follow-up every 6 months during the first year after the initiation of treatment, including at least US examination. Blood cell count and amino-transferase levels should be measured every week during the first month of benzimidazole treatment, then twice a year. Recurrences (especially in the liver, the peritoneum and/or the pelvic cavity, for liver cysts) may occur several years after treatment: a retrospective study of long-term follow-up of CE patients with a care management in a single center of Spain showed 11.5% of recurrence with a median duration of recurrence's diagnosis of 12.35 years; the recurrence rate was even higher for non-liver or -lung locations (Velasco-Tirado et al. 2017). The long-term follow-up, including at least US once a year, for at least 3 years

after interruption of the antiparasite drug and/or after cystectomy, then every 2 years for 10 years, is thus needed to detect any cyst recurrence. It is clear from the experience of the National Reference Centers of many countries that such a long-term follow-up of the patients (especially children and teen agers) is not yet the rule among the surgeons of the endemic areas.

In the case of inactive cysts, the WHO-IWGE had suggested avoiding treatment ("Watch and wait" approach) on the basis of a low tendency to reactivation (Brunetti et al. 2010), and this has recently been confirmed in studies carried out at referral centers, showing that only around 1% of cysts that are spontaneously inactive eventually become active again (Stojkovic et al. 2016; Lissandrin et al. 2018).

37.8 New Biomarkers for the Follow-up of CE Cysts

We previously discussed the many limitations of serology for the diagnosis of CE cysts. It should be noted that all types of serology using the current antigens have had disappointing performances in the follow-up of CE patients (Tamarozzi et al. 2013; Stojkovic et al. 2017). Antibodies against *E. granulosus* can persist for years after cyst inactivation, whether this is spontaneous or induced by treatment. Moreover, several factors have been proven to influence serological results (Lissandrin et al. 2016; Tamarozzi et al. 2021). In the case of surgically treated patients, many studies evaluating serology as a follow-up tool report patients as being treated surgically but do not clarify the original cyst stage, or whether surgery has achieved complete removal of the cyst.

Since cyst viability determines whether the patient should undergo treatment and given the scarce availability of MRI-spectroscopy outside of select centers, biological markers of viability are being studied. Recently, some promise has been shown by cytokine assays, specifically targeting IL-4, that were able to distinguish active from inactive cysts with sufficient precision, showing a 76–95% specificity in the detection of reactivated cysts (Petrone et al. 2015, 2021). Another recently proposed marker consists of parasite-derived micro-RNAs (miRNAs). Two research groups have shown that panels of miRNAs were able to distinguish active from inactive cysts at diagnosis, pointing toward a potential role in the follow-up of patients as well as in the diagnosis in centers where US expertise is lacking (Mariconti et al. 2019). New biomarkers were recently developed for the early prediction of pediatric CE postsurgical outcomes, but defining their place in the follow-up strategy still requires additional evaluations (Ben Salah et al. 2022).

Finally, long-term follow-up of patients with a hydatid cyst disclosed at mass screening has shown that a significant percentage, especially among children, had a degenerating evolution or did not change with time (Frider et al. 1999; Solomon et al. 2017; Larrieu et al. 2019); and a "watch and wait" attitude is likely indicated in such cases with small cysts and most of uncomplicated subjects with CE4 and CE5 cysts (Junghanss et al. 2008; Brunetti et al. 2010). Cysts which have reached CE4 and even CE5 stages through ABZ treatment have been shown to move back to CE3 stage in a significant number of cases, more frequently than CE4 and CE5 cysts found at

screening; this is a reason to recommend a strict follow-up of these patients (Stojkovic et al. 2016; Stojković et al. 2018). Conversely, spontaneously inactive cysts (i.e., CE4–5 cysts that are inactive at diagnosis, in the absence of a treatment history) may be considered for a "watch and wait" approach, on the basis of a low tendency to reactivation. This has recently been confirmed in studies carried out at referral centers, showing that only around 1% of cysts that are spontaneously inactive eventually become active again (Stojkovic et al. 2016; Lissandrin et al. 2018).

37.9 Treatment and Follow-up of AE Patients

A Multidisciplinary Approach for the Treatment of Patients with AE. The therapeutic management of AE patients clearly requires a multidisciplinary approach, in which benzimidazole therapy is a common denominator (see below). A complete evaluation of the disease extension (including thoracic and brain CT) is necessary before any therapeutic decision (Vuitton 2009; Vuitton et al. 2016; Kern et al. 2017). Depending on the size of the lesion(s), its location in the liver and vascular and biliary involvement, invasion or not of adjacent organs, presence or absence of distant metastases, the options may be a curative resection or a prolonged ABZ treatment (associated with an interventional radiological or per-endoscopic procedure, if necessary, because of complications). Currently, "partial debulking" liver resections followed by continuous administration of a benzimidazole must be avoided (Kadry et al. 2005; Buttenschoen et al. 2009a, b). The PNM system of classification of AE cases, designed on the model of the TNM classification of cancers, helps clinicians to choose the appropriate treatment and the clinical teams to evaluate their results comparatively (Table 1) (Kern et al. 2006). A comprehensive algorithm, based on the possibility or not of complete resection of the lesion (assessed from imaging data and presence/absence of comorbidities) has been proposed for the care management of AE cases (Wen et al. 2019) (Fig. 6).

Surgical Treatment of AE. The only efficient treatment is partial hepatectomy when the lesions are located in liver segments accessible to resection; because the intrahepatic common bile duct is usually involved, it is often necessary to remove the bifurcation and to reconstruct the biliary tract using a Roux-en-Y loop (Kadry et al. 2005; Buttenschoen et al. 2009a; Ayifuhan et al. 2012; Kern et al. 2017; Wen et al. 2019; Yang et al. 2019). Currently, in endemic areas of Europe, 1/3 of patients with AE may benefit from a curative resection of their "parasitic tumor." In very severe cases, with life-threatening complications and no other options, liver transplantation may be proposed. Allogeneic liver transplantation is associated with a risk of recurrence, or of progression of extrahepatic locations, because of immunosuppression (Koch et al. 2003). Such a risk may be alleviated by early ABZ treatment after transplantation; and unexpected long-term survival of more than 20 years have been published in patients with residual lesions after liver transplantation (Bresson-Hadni et al. 2011). Continuous administration of ABZ is essential to prevent recurrences in the liver or in other organs (Zavoikin et al. 2020). *Ex vivo* liver resection followed by

Table 1 PNM classification and staging of alveolar echinococcosis (according to WHO-Informal Working Group on Echinococcosis; in Kern et al. 2006)

A. PNM classification of AE cases (at presentation)
P Hepatic localization of the parasite
P X Primary tumor cannot be assessed
P 0 No detectable tumor in the liver
P 1 Peripheral lesions without proximal vascular and/or biliary involvement
P 2 Central lesions with proximal vascular and/or biliary involvement of one lobe
P 3 Central lesions with hilum vascular or biliary involvement of both lobes and/or with involvement of two hepatic veins
P 4 Any liver lesion with extension along the vessels and the biliary tree
N Extra hepatic involvement of neighboring organs [diaphragm, lung, pleura, pericardium, heart, gastric and duodenal wall, adrenal glands, peritoneum, retroperitoneum, parietal wall (muscles, skin, bone), pancreas, regional lymph nodes, liver ligaments, kidney]
N X Not evaluable
N 0 No regional involvement
N 1 Regional involvement of contiguous organs or tissues
M The absence or presence of distant metastasis [lung, distant lymph nodes, spleen, CNS, orbital, bone, skin, muscle, kidney, distant peritoneum and retroperitoneum]
M X Not completely evaluated
M 0 No metastasis
M 1 Metastasis

auto-transplantation (ELRA) is an alternative which has been developed to allow easier resection of large-sized lesions with vascular involvement (Wen et al. 2011; Aji et al. 2018; Wen et al. 2019). Until now, the experience with this type of technique comes only from Chinese hepatic surgery teams, which confronted cases in relatively young patients with large sized-lesions, biliary and vascular complications, and difficulties to ensure life-long ABZ treatment, a situation currently rarely encountered in European endemic areas (Beldi et al. 2019). Long-term evaluation has been now been published by several Chinese teams. Performed by highly experienced teams specialized in hepatic surgery, with sound imaging and technological support (He et al. 2015; Qin et al. 2016, 2021; Chen et al. 2021), this type of operation, evaluated on more than 200 cases in several distinct centers within

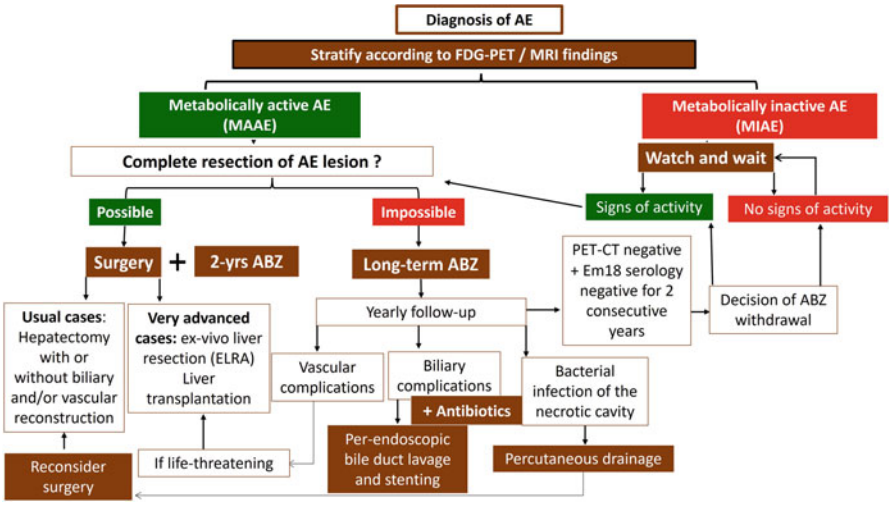

Fig. 6 Therapeutic algorithm for the care management of patients with alveolar echinococcosis (according to Wen et al., Clin Microbiol Rev., 2019)

the 10 years after its introduction in the surgical arsenal to treat severe AE cases, has results similar to or better than allotransplantation (Aji et al. 2018; Hwang et al. 2018; Shen et al. 2019; Yang et al. 2020). If the selection of patients has been careful to avoid primary liver dysfunction in the perioperative period, the obvious advantages are to avoid the resort to a liver donor and to life-long immunosuppressive antirejection treatment, and to only require the usual 2-year ABZ treatment when the resection of the lesions has been complete and thus curative (Wen et al. 2019).

Nonsurgical Interventional Treatment of AE. When curative resection is not possible, palliative surgery should be replaced by percutaneous or perendoscopic procedures. They consist of percutaneous radiological drainages of huge centroparasitic abscesses or of dilated intrahepatic bile duct above a hilum stenosis (Bresson-Hadni et al. 2006; Vuitton et al. 2016); this may be a first step before surgery (Yang et al. 2019). The best option is to push the drain beyond the stenosis to obtain an external/internal biliary drainage. Such drains may be maintained for years; combined with chemotherapy, they have allowed prolonged survival in initially very severe AE cases; shrinking of the initial necrotic "pseudocystic" cavity after percutaneous puncture and drainage may also make reconsider hepatic resection after a few months of treatment with ABZ (Vuitton et al. 2016; Kern et al. 2017; Wen et al. 2019). Biliary endo-prosthesis/stent insertion is an alternative which is currently more and more frequently used for the drainage of the bile ducts, often associated with temporary antibiotics administration to treat bacterial superinfection (Tamarozzi et al. 2014). Evaluated by a European survey, perendoscopic procedures were shown to be an efficient and safe alternative to surgery to treat AE biliary complications; insertion of multiple plastic stents delays stent occlusion and leads to effective and prolonged bile duct patency (Ambregna et al. 2017). Preoperative use of

perendoscopic procedures to treat bile duct obstruction by the AE lesions has become an important step in the care management of AE patients with jaundice and/or cholangitis by improving the nutritional status and reducing perioperative morbidity (Tamarozzi et al. 2014; Kern et al. 2017; Ambregna et al. 2017; Wen et al. 2019).

Antiparasite Treatment and Follow-up of AE Patients. MBZ and ABZ have only a parasitostatic effect *in vitro* and cannot kill *E. multilocularis* in most AE cases; however, their benefit for patients' survival and quality of life has been well assessed in the 1990s (Ammann 1991; Ammann et al. 1994; Ishizu et al. 1997). There are no comparative studies, but ABZ is currently preferred because it reduces the cost by >40%, is easier for patients to take and is now licensed for AE in many countries (Reuter et al. 2000; Piarroux et al. 2011). In case of curative surgery, ABZ should be initiated before the operation and maintained for at least 2 years to avoid recurrence (Brunetti et al. 2010; Kern et al. 2017). In inoperable cases, long-term chemotherapy (i.e., for life) may significantly prolong survival (10-year survival of approximately 80%, compared with less than 25% in historical controls) (Brunetti et al. 2010). Even in very severe cases, on the waiting list for liver transplantation, ABZ may have a dramatic efficacy in at least 15–20% of patients; antiparasitic treatment is thus always indicated (Ocak et al. 2021). A more personalized medical treatment of inoperable AE patients seems now to be possible, thanks to the combination of sequential FDG-PET evaluation with delayed acquisition of images, 3 h after FDG injection (Caoduro et al. 2013), the presence/absence of microcysts at MRI (Azizi et al. 2015), and of specific serological markers such as antibodies against *E. multilocularis* Em18 antigen, the decrease of which is best associated with absence or lack of viability of the metacestode (Tappe et al. 2009; Crouzet et al. 2010; Tappe et al. 2010; Bardonnet et al. 2013). New markers are currently under active research to better assess the "activity/viability" of the parasitic lesions (Gottstein et al. 2014; Valot et al. 2017; Bellanger et al. 2021b).

Taking antiparasitic drugs for years, and often for life, iterative stays at the hospital for complications and/or follow-up, major surgical operations, deeply impact on the patients' quality of life. A recent study has tried to evaluate the patients' quality of life after liver resection versus long-term ABZ treatment: it showed no statistically significant differences in patients with AE dependent on the applied treatment strategy (Schmidberger et al. 2019); however, there was a slight advantage in the physical and mental scores of the patients treated with surgery; furthermore, for 13 of the 25 surgically treated patients, some aspects of the health-related quality of life improved significantly after surgery. Discontinuation of BZM after many years of treatment could be tried in selected cases when all "activity markers" are negative (Ammann et al. 1998; Reuter et al. 2004; Bresson-Hadni et al. 2011; Bardonnet et al. 2013; Gottstein et al. 2014). In liver-transplanted patients, ABZ must be initiated before the operation, reintroduced as soon as possible after transplantation, and maintained for at least 2 years if all AE lesions were removed with the liver, and life-long in case of metacestode remnants or new AE foci discovered during follow-up (Bresson-Hadni et al. 2011).

Whatever the type of treatment, including or not surgery, all patients with AE should have a regular follow-up (every 3 months, then 6 months, then year, depending on the clinical status and the occurrence or not of complications). The follow-up should include US and serology, blood cell count and aminotransferase levels, and ideally FDG-PET, during the period of benzimidazole treatment; a yearly follow-up should be maintained for at least 5 years after benzimidazole withdrawal (Vuitton and Bresson-Hadni 2014; Kern et al. 2017). Monitoring of ABZ sulfoxide is also essential, both to evaluate patient's adherence to treatment, to suspect interference with associated drugs or other xenobiotics, and to properly adjust ABZ dosage in case of apparent resistance to treatment or of adverse effects (Vuitton 2009; Bresson-Hadni et al. 2021a).

37.10 Prevention and Control

As regard to the single individual, prevention of CE relies only on hygienic measures, such as washing hands before eating, avoiding contact between mouth and nonwashed hands, thorough washing of raw vegetables, and use of a safe water source; chlorination does not inactivate contaminating eggs (Craig et al. 2017; Lightowlers et al. 2021).

Control programs for CE are complex, with multiple targets, and require considerable investment of time (minimum 10 years of "attack phase" followed by a "consolidation" and "maintenance" phase) and resources, together with a consensual coordination of various actors (professionals and decision-makers in human and animal health, police, legislation, education, etc.) (Craig et al. 2017). The principal points of intervention have been individuated in: i) veterinary public health actions such as control of livestock movements and slaughter, including inspection of organs and proper disposal of infected viscera and dead animals; ii) registration of owned dog and control of stray dog population; however, dog culling practices should be carefully evaluated (Johansen and Penrith 2009); iii) accurate estimation of baseline epidemiological data in the animal and human population; iv) regular treatment of dogs with praziquantel, at least every 6 weeks; v) education of the owners about safe feeding of dogs and animal husbandry, and of the whole community about the purpose and importance of the program; vi) making CE a notifiable disease and introduce an appropriate supporting legislation (Barnes et al. 2012; Craig et al. 2017). So far, only four CE control programs have been successful, all on islands (Iceland, New Zealand, Tasmania, and Falkland Islands); and after an apparent success, one failed in Cyprus. Although purely education has not been found efficacious in reducing infection prevalence with the noticeable exception of the Iceland program, this is a pivotal measure in all control programs, as CE is generally not perceived as a serious condition for both animals and humans by communities and policy makers, and populations do not adhere to control measures aimed at animals to prevent a disease in humans (Huang et al. 2011). The introduction of livestock vaccination using the highly effective EG95 vaccine could be a very useful tool to shorten control program length (Lightowlers et al. 2021).

As regards the single individual, prevention of AE relies on similar measures as for CE: *E. multilocularis* eggs are extremely resistant to any chemical and to low temperatures (e.g., those reached by family-use freezers); they are only sensitive to heating, hence the advice to cook any fruit/vegetable collected in pastures/meadows or in family gardens exposed to fox and/or dog feces. Regular praziquantel treatment of dogs follows the same rule as for CE control, at family level, and was used in Alaska on highly endemic islands such as St Lawrence (Rausch et al. 1990). For decades, it was, however, considered that *E. multilocularis*, being a parasite which circulated in wild life, was globally beyond control (Roberts and Aubert 1995). A few control programs have targeted endemic rural areas, with variable results depending on the endemic country (e.g., Alaska vs. Europe vs. Japan); the most ambitious program of control has been established in PR China, focusing both on CE and AE which often coexist in the same areas of Western China (Craig et al. 2017); however, despite a major governmental involvement, especially because of the nomadic style of life of most of the populations at risk, results are not always at the level of the investment (van Kesteren et al. 2015). Most of the recent control programs have concerned urban foxes, using fox baiting with PZQ, with results that apparently varied according to contamination pressure in the rural areas surrounding the targeted city (Deplazes et al. 2004; Comte et al. 2013); a meta-analysis of studies in highly endemic areas of Europe or Japan showed that monthly fox baiting with PZQ resulted in a sharp and statistically significant decrease in parasite prevalence; nevertheless, when foxes were not fully dewormed, the parasite showed a strong capacity to rapidly recover its initial prevalence (Umhang et al. 2019). Conversely, consequent effort of fox culling in a city located in a French endemic area for *E. multilocularis* not only failed to decrease the fox population but resulted in an increase in *E. multilocularis* prevalence from 40% to 55% while remaining stable in an adjacent control area; this paradoxical finding was likely due to increased immigration of infected foxes from the rural surroundings (Comte et al. 2017).

37.11 Conclusion

Echinococcoses are highly neglected diseases although they affect populations nearly everywhere in the world, including developed and technically advanced countries with high-level public health systems. An efficient antiparasitic treatment of short duration with few adverse events still looks far from reach. However, even based on non-satisfactory levels of evidence, the therapeutic strategy and patients' life expectancy have considerably improved in the last 30 years. Among the major advances of the last decade, we may list (1) a genome-based definition of *Echinococcus* species involved in zoonotic and human diseases, with a totally revised taxonomy and the development of molecular biology-based epidemiology and transmission studies; (2) a consensus between the major actors in the field (researchers and clinicians) on a revised terminology which will enhance mutual understanding and international cooperation; (3) progress in deciphering immunological mechanisms involved in alveolar echinococcosis, leading to possible

immune interventions to complement antiparasitic drug approach; (4) better immunological and imaging tools for the follow-up of patients, both for CE and AE; (5) ambitious surgical techniques with proven efficacy, such as ex vivo liver resection and auto-transplantation, for advanced cases of AE, and better definition of the advantages, risks, and indications of the various interventional techniques for CE.

Prevention remains largely limited to individual measures, and even in those countries, such as China, which have implemented nation-wide programs, control of echinococcoses faces numerous obstacles because of the multifactorial aspects of *Echinococcus* spp. transmission in animals and humans. Echinococcoses were thought to be diseases of the rural environment and doomed to disappear because of societal changes, and improved hygiene and standard of living. However, cystic echinococcosis is still present in developed as well as developing countries; and since the beginning of the twenty-first century, *E. multilocularis* infection of definitive hosts has considerably increased in cities and extended its endemic areas, including in North America which was little concerned before. In addition, alveolar echinococcosis may now be listed among the opportunistic infections, and more and more individuals with therapeutic immune suppression are and will become vulnerable to *E. multilocularis* infection. Physicians should be better informed of this eventuality, and more studies are needed to assess the best strategy to tackle this emerging public health problem with a "One Health" perspective.

Abstract

In 2016, a new classification for hantaviruses has been established by the International Committee on Taxonomy of Viruses (ICTV). Hantaviruses are ranked as family *Hantaviridae* comprising seven genera. So far, pathogenic hantaviruses are exclusively detected in the genus *Orthohantavirus*. Orthohantaviruses are pathogens of emerging importance, and members are meanwhile described all over the globe. The knowledge on respective small mammal hosts and their associated viruses has been rapidly increasing in the last years and now includes beside rodents also insectivores, bats, and with these several associated new viruses. Usually, animals are asymptomatic reservoir carriers despite a few studies showing effects on rodent population levels. In humans, clinical symptoms of orthohantavirus infections are depending on the virus type. Orthohantaviruses in the Americas cause hantavirus cardiopulmonary syndrome (HCPS), whereas members in Eurasia cause hemorrhagic fever with renal syndrome (HFRS) of different severity. However, as the clinical outcome is often inapparent, recorded case numbers are also underestimated. The epidemiology of orthohantaviruses is multifaceted as multiple biotic and abiotic factors seem to bias the causal link to hantavirus oscillations. In conclusion, hantavirus research on orthohantavirus pathogenesis and epidemiology is complex, because the genus is characterized by a broad range of virulence and host species association.

Orthohantavirus · Zoonosis · Infection · Host species · HFRS · HCPS

38.1 Introduction

The genus *Orthohantavirus* within the family of *Hantaviridae* of the order *Bunyavirales* is a heterogeneous genus and difficult to characterize as a whole. The virulence of orthohantaviruses differs enormously, from apathogenic to highly virulent members with high case fatality rates. In addition, the pathogenic potential of most members is unknown, because they were identified from animal host species. Two different diseases—hemorrhagic fever with renal syndrome (HFRS) and hantaviral cardiopulmonary syndrome (HCPS)—are associated with human infection (Vaheri et al. 2013). However, the infection may also represent as a mixture of both diseases (Chand et al. 2020; Hjelle et al. 1996; Gizzi et al. 2013; Schütt et al. 2004; Rasmuson et al. 2011; Linderholm et al. 1997; Vollmar et al. 2016; Sironen et al. 2017; López et al. 1996; Du et al. 2014). Furthermore, factors responsible for orthohantaviral virulence are not known, and genetically close related members of an apathogenic orthohantavirus were identified as highly pathogenic agents as observed within the species of Dobrava-Belgrade orthohantaviruses (DOBV) (Klempa et al. 2008).

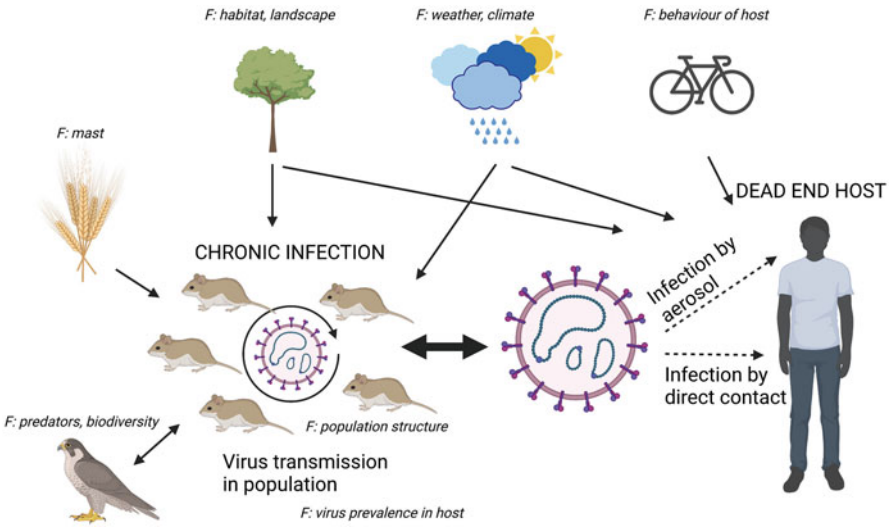

Fig. 1 Transmission cycle of orthohantaviruses and biotic and abiotic factors (F, *in italics*) that may drive viruses, rodents, and infections of humans

Therefore, characteristics associated with a certain orthohantavirus member are not necessarily valid for members of the same species or apply to the whole genus.

The natural hosts for orthohantaviruses are small mammals. For long time, rodents were thought to be the only hosts of these viruses. Orthohantaviruses are spread through the saliva, urine, and feces of animals and are typically transmitted to humans by inhalation of virus-contaminated aerosols (Fig. 1). In rare cases, direct contact of humans and rodents leads to human diseases (Heyman et al. 2012). For one orthohantavirus, the Andes virus human-to-human transmission was described, either via bodily fluids or long-term contact (see reviewed in (Toledo et al. 2021)).

In the last years, identification of further orthohantaviruses in novel host species, detection of viral genomes in patients, and the use of novel molecular and cell culture methods revealed interesting findings concerning phylogeny, epidemiology, virulence, pathogenesis, and replication of orthohantaviruses.

38.2 An Overview on Hantaviruses

38.2.1 Taxonomy

After years with a fast-growing list of hantavirus species, subspecies, genotypes, or strains, a novel taxonomy was introduced in 2016 (Laenen et al. 2019). Hantaviruses formerly graded as genus within the family of *Bunyaviridae* are now classified as family of *Hantaviridae* within the order *Bunyavirales.* The family *Hantaviridae* comprises four subfamilies and seven genera with 53 species. Table 1 shows an overview on the actual classification of the family *Hantaviridae* published in 2019 (Abudurexiti et al. 2019).

Table 1 Members of the genus Orthohantavirus (Order Bunyavirales, Family Hantaviridae, Subfamily Mammantavirinae, Genus Orthohantavirus)

Species	Virus	Disease	Host species	Geographical distribution
Andes orthohantavirus	Andes virus (ANDV)	HCPS	*Oligoryzomys longicaudatus*	Argentina, Chile, Brazil, Uruguay
	Castelo dos Sonhos virus (CASV)	HCPS	*Oligoryzomys moojeni Oligoryzomys utiaritensis*	Brazil
	Lechiguanas virus (LECV=LECHV)	HCPS	*Oligoryzomys flavescens*	Argentina
	Oran virus (ORNV)	HCPS	*Oligoryzomys longicaudatus*	Argentina
Asama orthohantavirus	Asama virus (ASAV)		*Urotrichus tapoides*	Japan
Asikkala orthohantavirus	Asikkala virus (ASIV)		*Sorex minutes*	Europe
Bayou orthohantavirus	Bayou virus (BAYV)	HCPS	*Oryzomys palustris*	USA (East Coast)
	Catacamas virus (CATV)		*Oryzomys couesi*	Honduras
Black Creek Canal orthohantavirus	Black Creek Canal virus (BCCV)	HCPS	*Sigmodon hispidus*	USA (South-East, Florida)
Bowe orthohantavirus	Bowe virus (BOWV)		*Crocidura douceti*	Guinea
Bruges orthohantavirus	Bruges virus (BRGV)		*Talpa europaea*	Belgium
Cano Delgadito orthohantavirus	Caño Delgadito virus (CADV)		*Sigmodon alstoni*	Venezuela
Cao Bang orthohantavirus	Cao Bang virus (CBNV)		*Anourosorex squamipes*	Vietnam
	Lianghe virus (LHEV)		*Anourosorex squamipes*	China
Choclo orthohantavirus	Choclo virus (CHOV)	HCPS	*Oligoryzomys fulvescens*	Panama
Dabieshan orthohantavirus	Dabieshan virus (DBSV)		*Niviventer confucianus*	China
Dobrava-Belgrade orthohantavirus	Dobrava virus (DOBV)	HFRS	*Apodemus flavicollis*	Slovenia, Croatia, Greece, Czech Republic, Slovakia, Hungary, Turkey
	Kurkino virus (KURV)	HFRS	*Apodemus agrarius*	Germany, Slovakia, Russia, Hungary, Slovenia, Croatia, Estonia
	Saaremaa virus (SAAV)		*Apodemus agrarius*	Estonia

(continued)

Table 1 (continued)

Species	Virus	Disease	Host species	Geographical distribution
	Sochi virus (SOCV)	HFRS	*Apodemus ponticus*	Russia
El Moro Canyon orthohantavirus	Carrizal virus (CARV)		*Reithrodontomys sumichrasti*	Mexico
	El Moro Canyon virus (ELMCV)		*Reithrodontomys megalotis*	Colorado
	Huitzilac virus (HUIV)		*Peromyscus beatae*	Mexico
Fugong orthohantavirus	Fugong virus (FUGV)		*Eothenomys eleusis*	China
Fusong orthohantavirus	Fusong virus (FUSV)		*Microtus fortis*	China
Hantaan orthohantavirus	Amur virus (AMRV)	HFRS	*Apodemus peninsulae*	Far eastern Russia, China
	Hantaan virus (HTNV)	HFRS	*Apodemus agrarius*	
	Soochong virus (SOOV)	HFRS	*Apodemus peninsulae*	Korea
Jeju orthohantavirus	Jeju virus (JJUV)		*Crocidura shantungensis*	South Korea
Kenkeme orthohantavirus	Kenkeme virus (KKMV)		*Sorex roboratus*	Far eastern Russia
Khabarovsk orthohantavirus	Khabarovsk virus (KHAV)		*Microtus fortis*	Far eastern Russia
	Topografov virus (TOPV)		*Lemmus sibiricus*	Sibiria
Laguna Negra orthohantavirus	Laguna Negra virus (LANV)	HCPS	*Calomys laucha*	Paraguay, Argentina, Bolivia
	Maripa virus (MARV)	HCPS	*Oligoryzomys microtis*	French Guiana
	Río Mamoré virus (RIOMV)	HCPS	*Oligoryzomys microtis*	Bolivia, Peru; Brazil
Luxi orthohantavirus	Luxi virus (LUXV)		*Eothenomys miletus*	China
Maporal orthohantavirus	Maporal virus (MAPV)		*Oligoryzomys delicatus*	Western Venezuela
Montano orthohantavirus	Montaño virus (MTNV)		*Peromyscus beatae*	Mexico
Necocli orthohantavirus	Necocli virus (NECV)		*Zygodontomys cherriei*	Colombia
Oxbow orthohantavirus	Oxbow virus (OXBV)		*Neurotrichus gibbsii*	USA
Prospect Hill orthohantavirus	Prospect Hill virus (PHV)		*Microtus pennsylvanicus*	USA

[a]antibody detection in patients with fever of unknown origin (FUO) and HFRS-like symptoms, no genome detection (Klempa et al. 2010; Gamage et al. 2017; Pattamadilok et al. 2006)
[b]single cases of apparent infections described (Reynes et al. 2017; Hofmann et al. 2021; Zelena et al. 2019)
Adapted from Abudurexiti et al. (2019)

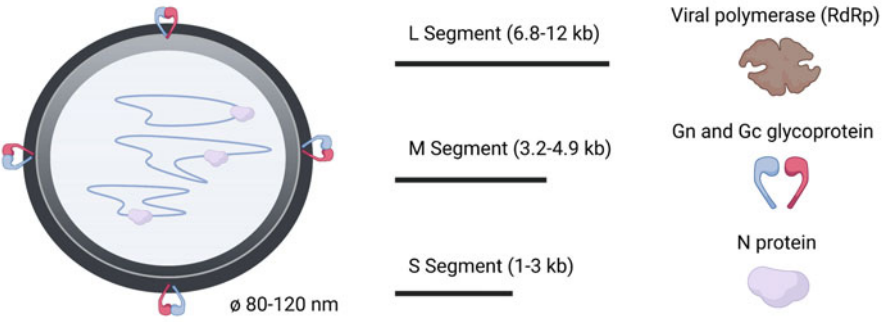

Fig. 2 Graphical structure and genome of a typical orthohantavirus. Virions are shaped spherical or oval with the glycoproteins Gn and Gc on the surface. The virions contain a tripartite negative sense RNA, wrapped by the nucleocapsid (N) protein. The large L segment encodes for the RNA-dependent RNA polymerase (RdRp, L protein), the medium (M) segment encodes for the two glycoproteins Gn and Gc, and the small (S) segment encodes for the N protein. (Image adapted from (Mittler et al. 2019, Schlegel et al. 2014))

Historically, orthohantavirus infections have been described more than 70 years ago in the 1950s as over 3000 UN soldiers suffered from the so-called Korean hemorrhagic fever (Lee 1982; Gajdusek 1956). These infections were caused by Hantaan virus (HTNV), the prototype of the genus orthohantavirus. This was the first orthohantavirus isolated and investigated in detail (Lee 1982).

Viruses of the family *Hantaviridae* have spherical or oval virions with a diameter of 80 to 120 nm (Fig. 2). The genome is a tripartite negative sense RNA. The large (L) segment encodes the viral RNA-dependent RNA polymerase (RdRp, L-protein), the medium (M) segment encodes a viral glycoprotein precursor (GPC), which is cleaved into two glycoproteins Gn and Gc. The small (S) segment encodes for the viral nucleocapsid protein (N). In some orthohantaviruses, e.g., Tula and Puumala virus, the S segment further has an open reading frame (ORF) for a nonstructural protein (Ns) (Plyusnin 2002; Binder et al. 2021). The three viral RNA segments are complexed with N proteins and form nucleocapsids. These are packed together with

an RdRp in the virus particle. The virions have a lipid envelope in which the two glycoproteins Gn and Gc are embedded. Criteria for the taxonomy of *Orthohantavirus* genus and its species are based for instance on the differences of amino acid sequences of the S and M segments (Maes et al. 2009; Laenen et al. 2019). As virus isolation is not trivial, for many described orthohantaviruses, only limited data gained directly from the reservoirs/hosts are available.

All known human pathogenic orthohantaviruses are members of the genus *Orthohantavirus* and carried by small mammals. The genus *Orthohantavirus* is built up currently of 38 species and 58 assigned viruses (Table1). However, it is not excluded that members hosted by shrews, bats, or moles of other genera of the family of *Hantaviridae* also possess pathogenic potential to humans or animals.

38.2.2 Molecular Typing and Host Virus Coevolution

Due to the late onset of specific symptoms, orthohantaviral antigens and viral RNA can only very rarely be found in human patients. Therefore, often the small mammal carriers are used to study the molecular epidemiology of these viruses. Despite the long knowledge of human cases, first viral genome data were only available in the early 1990s (Avsic-Zupanc et al. 1992; Xiao et al. 1993a, b; Pilaski et al. 1994). Reports of successful isolation of orthohantaviruses in Europe for a more proper molecular virus characterization or even pathogenicity studies are sparse. Only recently the first isolation of a Central European PUUV strain was reported (Binder et al. 2020) and may allow now the isolation and afterward in-depth characterization of, e.g., reservoir-adapted PUUV strains.

For PUUV, there exist different geographic clusters. Several northern European (e.g., north-/south-/Scandinavian, Finish, Danish) PUUV strains are separated from those found in central Europe (e.g., from Belgium, France, Germany, and Slovakia) or the Alpe-Adria area (e.g., from Austria, Slovenia, Croatia) (Avsic-Zupanc et al. 2007; Plyusnina et al. 2007, 2009; Nemirov et al. 2010; Ettinger et al. 2012). Isolation-by-distance analysis of PUUV S segment sequences (N and NSs) confirmed the strict spatial clustering in Europe (Binder et al. 2020).

Natural reassortments of segments were shown for example between members of the species Dobrava-Belgrade orthohantavirus (Kirsanovs et al. 2010) and for PUUV and DOBV (Klempa 2018). In Germany, the picture of genetic diversity of PUUV is quite more complex as at least eight geographically and phylogenetically distinct PUUV subclusters can be found here (Mertens et al. 2011c; Essbauer et al. 2007; Ulrich et al. 2008; Hofmann et al. 2008; Ettinger et al. 2012; Jeske et al. 2021).

A strict coevolution of rodent hosts and virus species was previously postulated for orthohantaviruses as these viruses group into three main clades that correspond with the rodent subfamilies (Morzunov et al. 1998; Plyusnin et al. 1996; Hughes and Friedman 2000; Plyusnin and Morzunov 2001). Meanwhile, there are several findings that do not completely support this hypothesis. One example is the detection of orthohantaviruses in nonrodent hosts that puts this theory in question (Ramsden et al.

2009). Phylogenetic analysis of TULV showed that the evolution seems to be not host-related, although different geographic genetic subclusters were shown in Europe (Schmidt-Chanasit et al. 2010; Plyusnina et al. 2007; Schlegel et al. 2012; Saxenhofer et al. 2019; Schmidt et al. 2021).

In South America, a comprehensive analysis of orthohantaviruses revealed that there exist three phylogenetic clades, the Andes/-like viruses, the Laguna Negra/-like viruses, and the Rio Mamore/-like viruses. A long coevolution of host and virus seems also to be present, and viruses of one clade are found in several host species (Firth et al. 2012). A detailed phylogenetic analysis of entire coding regions of orthohantavirus genomes showed that there exist four phylogroups in mammalian hosts, and ancient reassortment between these was postulated (Guo et al. 2013). Divergence of viruses and hosts differs for some orthohantavirus indicating a cross-species transmission during orthohantavirus evolution.

38.3 Epidemiology of Human Diseases

Today, the presence of orthohantavirus species was demonstrated in Asia, Europe, the Americas, Africa, and Australia. Pathogenic orthohantaviruses were found in Asia, Europe, and the Americas, so far.

The annual global number of orthohantavirus infections is difficult to calculate as, e.g., surveillance systems and case definitions differ between countries (Wang et al. 2021; Khismatullina et al. 2016; Knust et al. 2012). A precise estimation is also hampered by annual fluctuations in case numbers but also due to dramatic changes of case numbers by rodent control measures in China in the last decades (Sun and Zou 2018). According to actual reported cases, the most affected countries are China and Russia with averaged 14,000 and 7000 HFRS cases per year, respectively.

About 300 HCPS cases were reported in the Americas per year (Montoya-Ruiz et al. 2014; PAHO 2022; Kruger et al. 2015). However, due to the high case fatality rate, these HCPS cases are of high importance, and outbreaks of ANDV infections require special awareness due to possible person-to-person transmission (Martínez-Valdebenito et al. 2019; Martínez et al. 2020; Toledo et al. 2021).

38.3.1 Europe

In Europe, a bundle of orthohantavirus species associated with rodents and causing diseases in humans are found. First, Puumala virus (PUUV) carried by the bank vole (*Myodes glareolus*) is a virus with a broader distribution in this area. A mild form of HFRS is caused by PUUV, and lethality is below 1%. From 2014 to 2018, Finland, Sweden, and Germany reported 81% of all cases in Europe (Fig. 3). Latest numbers summarized case numbers from 29 countries are from 2018, with 1826 annual cases (Heyman et al. 2008, 2009b, 2011). Interestingly, in years with many PUUV cases and a high abundance of the virus in the hosts, a spillover of PUUV to

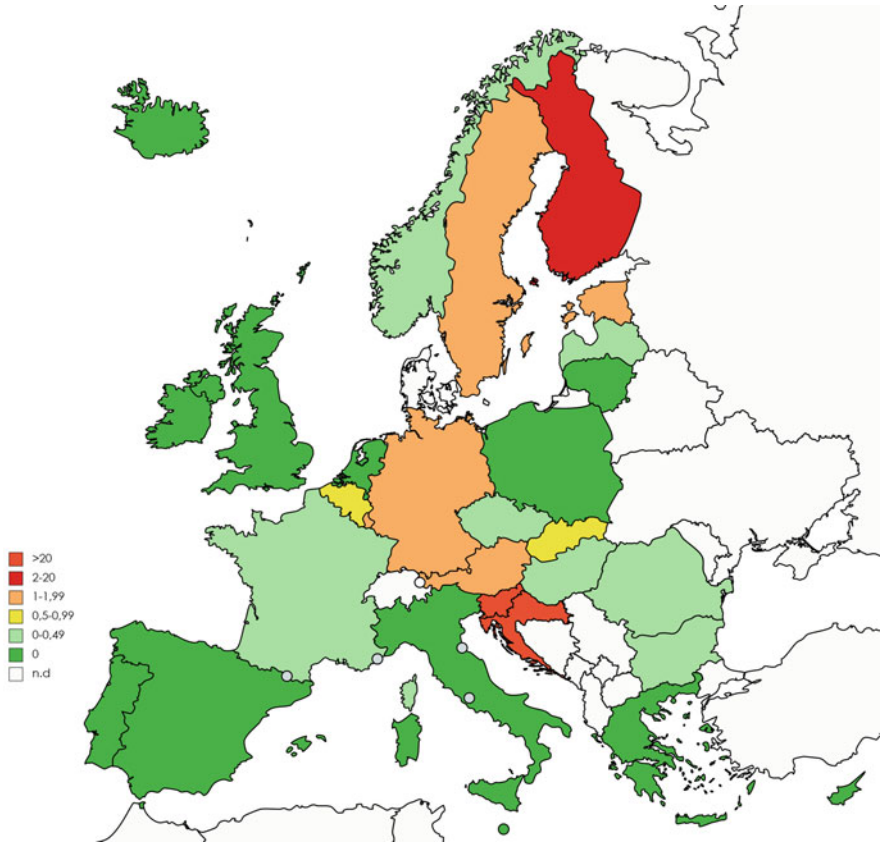

Fig. 3 Average incidence values of reported orthohantavirus infections in Europe from 2015 to 2019. (Adapted from the ECDC 5-year report 2015–2019. (ECDC 2022))

other habitat-sharing species such as *Apodemus sylvaticus* or *A. flavicollis* can be observed. The impact of the transmission of the virus from spill over from infected rodents to humans is unknown (Heyman et al. 2009b; Klingström et al. 2002a; Essbauer et al. 2006; Schlegel et al. 2009; Binder et al. 2020).

Second, species Dobrava-Belgrade orthohantavirus with its four subtypes Dobrava, Kurkino, Saaremaa, and Sochi virus is transmitted by several *Apodemus ssp.* (e.g., *A. flavicollis and A. agrarius*) (Klempa et al. 2013b). Members of the species *Dobrava-Belgrade orthohantavirus* cause HRFS with various severity from subclinical forms to life-threatening diseases (Avsic-Zupanc et al. 1999; Markotić et al. 2002; Mertens et al. 2011c) and are endemic in some central- and several southeast European countries.

Third, Tula virus (TULV) was detected in several vole species (Subfamily *Arvicolinae*: *Microtus agrestis* and *M. arvalis*) (Plyusnin et al. 1994; Vapalahti et al. 1996; Schmidt-Chanasit et al. 2010; Schmidt et al. 2021). Only limited reports

on the relevance of TULV for mild human diseases are present (Schultze et al. 2002; Klempa et al. 2003; Hofmann et al. 2021). Humans might have contact to TULV and develop specific antibodies as, e.g., found in a seroepidemiological study in Germany in forest workers (Mertens et al. 2011b).

Fourth, Seoul virus (SEOV) was giving attention in Europe. For a long time, it was unclear whether SEOV could cause disease in humans. Single reports of SEOV infections were described from 2004 up to 2021 in Europe (Heyman et al. 2004; Heyman et al. 2009a; Yasuda et al. 2021). In 2012, SEOV was detected in wild *R. norvegicus* in the United Kingdom and France. These virus sequences resembled SEOV originating from rare mild HFRS cases acquired by handling laboratory rats in the Netherlands, United Kingdom, and Belgium (Jameson et al. 2013a; Jameson et al. 2013b). In the following years, small outbreaks of SEOV were detected in *Rattus* populations, mainly pet rats, and in several European countries (Shepherd et al. 2021).

38.3.2 Asia

The continent that is mostly affected by orthohantavirus infections is Asia. High numbers of cases were reported from China, Far East Russia, and Korea (34-37). In contrast to Europe, where Nephropathia epidemica (NE) caused by PUUV—the milder form of HFRS—predominates, HFRS represents a severe public health problem in Asia. For instance, cases of HFRS were reported in nearly all Chinese provinces, with Heilongjiang in the northeast of China being the most severe endemic area with the highest annual incidence for HFRS (Guo et al. 2013). Causing agents of HFRS in Asia are HTNV and SEOV.

SEOV was first isolated from city rats (*Rattus norvegicus*) in Korea in 1981 and from laboratory rats (*Rattus norvegicus*) in Japan in 1982 (Lee et al. 1981; Lee 1982). Currently, SEOV repeatedly causes disease outbreaks in various provinces in China. Approximately, a third of the yearly cases of febrile illnesses with bleeding and kidney involvement (hemorrhagic fever with renal syndrome) are expected to be caused by SEOV annually. However, it was shown that infections with SEOV seem to demonstrate milder courses than HFRS caused by HTNV (Zhang et al. 2011).

In Russia, about 90% of infections were reported in the Volga Federal District and are described as NE caused by PUUV (Garanina et al. 2009). Several outbreaks in the Central Federal District were attributed to members of the species *Dobrava-Belgrade virus* (Klempa et al. 2008). In contrast, in the Far East region, HFRS cases caused by HTNV, SEOV, and Amur virus were observed (Yashina et al. 2000; Miyamoto et al. 2003; Peintner et al. 2021). The seasonality of HFRS cases in Russia also reveals geographic differences and seems to depend on the host reservoir species (Yashina et al. 2000). The seasonal pattern of reported hantavirus disease in humans in China and Korea shows a pronounced peak of case numbers in winter and a second minor peak in summer (Liu et al. 2012; Song et al. 2006; Huang et al. 2012).

Only a few HFRS cases were reported in other Asian countries, e.g., Indonesia, Sri Lanka, India, Thailand, and Vietnam (Jonsson et al. 2010; Huong et al. 2010). No human cases of HFRS were reported in Japan over the last 30 years, although cases were reported since 1960 and seropositive rodents were still present as demonstrated by several epizootiological surveys (Kariwa et al. 2007).

38.3.3 Americas

Hantaviruses became prominent in the United States as an outbreak of severe disease with lung manifestation (hantavirus pulmonary syndrome, HPS; hantavirus cardiopulmonary syndrome, HCPS) and death occurred in the Four-Corners Region in 1993 (Nichol et al. 1993). Sin Nombre virus (SNV) was the causative agent of this outbreak (Nichol et al. 1993; Childs et al. 1994; Duchin et al. 1994; Ksiazek et al. 1995). After the detection of SNV, many orthohantaviruses causing HCPS were detected in the North, Central, and South Americas. Most prominent, two years later in 1995, Andes virus (ANDV) was described during a severe HCPS outbreak in south-western Argentina (López et al. 1996). Remarkably, ANDV is the only orthohantavirus for which a human-to-human transmission has been demonstrated several times (Wells et al. 1997; Padula et al. 1998; Toro et al. 1998; Martinez et al. 2005; Lázaro et al. 2007; Ferres et al. 2007). A study published in 2020 describes an outbreak of HCPS by person-to-person transmission with 34 confirmed cases including 11 fatal outcomes in Argentina (Martínez et al. 2020). The outbreak was caused by one person infected via rodent-transmission and driven by three symptomatic spreaders during a social event. Spreading was probably more likely by patients with high viral loads. Control measures such as self-isolation and quarantine were imposed by local public health officials and seemed to be effective as further viral spread was prevented.

So far, the two species SNV and ANDV are the most common causes of HCPS in North, Central, and South America. Meanwhile, HCPS cases and several other hantaviruses were reported from the United States, Canada, and at least ten South and Central American States such as Argentina, Bolivia, Brazil, Chile, Ecuador, French Guiana, Panama, Paraguay, Uruguay, and Venezuela (CDC 2022; Koma et al. 2012). In general, case numbers of HCPS in Argentina, Brazil, and Chile are highest (Martinez et al. 2010; Macneil et al. 2011). In North America, HCPS in humans is also induced by, i.e., Bayou virus (Morzunov et al. 1995; Khan et al. 1995; Hjelle et al. 1996; Ksiazek et al. 1997; Torrez-Martinez et al. 1998), Black Creek Canal virus (Rollin et al. 1995; Ravkov et al. 1995; Khan et al. 1996), New York virus (Hjelle et al. 1995; Morzunov et al. 1998), and Monongahela virus (Song et al. 1996; Morzunov et al. 1998; Rhodes et al. 2000). In summary, in Northern, Central, and South America, at least 30 orthohantavirus types or genotypes have been recognized in HCPS patients or carried by *Sigmodontine* reservoir rodents. The pattern of strains as well as the genetic diversity and the distribution is multifaceted, and for many of the strains, the impact on humans to cause disease is unresolved (Macneil et al. 2011; Firth et al. 2012). Phylogeographic analyses of South American hantaviruses suggested a spread from the south-central part such as Paraguay, Brazil, Bolivia to the northern, southern, and eastern parts of this continent (Firth et al. 2012).

38.3.4 Africa and Australia

Intense studies in small mammals were initiated to find viruses and hosts in Africa. Sangassou virus (SANGV) was the first reported African orthohantavirus detected in *Muridae* collected in Guinea (Klempa et al. 2006; Klempa et al. 2012). It is the best characterized African orthohantavirus and was also isolated to grow *in vitro* in laboratory cell culture (Klempa et al. 2012). A second African murid-associated orthohantavirus is Tigray virus found in white-footed rat from Ethiopia (Meheretu et al. 2012). In addition, several further hantaviruses were described in shrews from Guinea (Klempa et al. 2007) and Côte d'Ivoire (Kang et al. 2011) and in bats from Sierra Leone (Weiss et al. 2012) and Côte d'Ivoire (Sumibcay et al. 2012; Meheretu et al. 2019), but are not yet classified by ICTV. In the last years, several studies investigated the impact of African orthohantaviruses on human health (Meheretu et al. 2021; Diagne et al. 2020; Raharinosy et al. 2018). For SANGV, a role in fever of unknown origin (FUO) and HFRS has been postulated in Guinea (Klempa et al. 2010). In a few seroepidemiological studies, a low human seroprevalence (1%–2%) was shown for African orthohantaviruses (Gonzalez et al. 1984; Klempa et al. 2010; Klempa et al. 2013b). A broad serological study on nonrodent-associated orthohantaviruses in Africa also revealed that shrew-transmitted orthohantaviruses indeed are also able to infect humans, at least in Gabon and Côte d'Ivoire (Heinemann et al. 2016). Nevertheless, further studies are needed in order to understand the impact and relevance of African orthohantaviruses for humans.

For Australia, the knowledge is even more meager than for Africa. The presence of orthohantaviruses in Australia was speculated for a long time (Bi et al. 2008), but no human cases have been reported so far. In June 2021, a complete genomic sequence of an orthohantavirus isolated from brain tissue of a black flying fox (*Pteropus alecto)* collected in Australia was published in GenBank and called Robina virus (TaxonomyBrowser 2022). An article with details on this important first detection of an Australian orthohantavirus is not yet published, but will be of interest for the whole field of orthohantavirus research.

38.4 Hantaviruses in Nonrodent Hosts, in Livestock, and in Pet Animals

38.4.1 Nonrodent Orthohantaviruses: Insectivores and Megabats as Reservoir Species

For many years, voles and mice were believed to be the only reservoir hosts for orthohantaviruses. Worldwide, intense search for *Hantaviridae* family members in bats as well as insectivores such as shrews and moles are performed, and several viruses have been discovered in the last decades. Table 2 summarizes orthohantaviruses that have been described in insectivores and megabats and that are already classified by ICTV. However, until now for nonrodent-associated orthohantaviruses, the impact on human health is not known (Carey et al. 1971; Zeller et al. 1989; Kang et al. 2009; Schlegel et al. 2012; Kim et al. 1994; Jung and Kim 1995).

Table 2 Overview on orthohantaviruses detected in different families of insectivores (Eulipotyphla) and in the family of megabats (Pteropodidae)

Order *Eulipotyphla, Soricomorpha*, Family *Soricidae* (shrews)			
Asikkala orthohantavirus	Asikkala virus (ASIV)	*Sorex minutus*	Europe
Bowe orthohantavirus	Bowe virus (BOWV)	*Crociduradouceti*	Guinea
Cao Bang orthohantavirus	Cao Bang virus (CBNV)	*Anourosorex squamipes*	Vietnam
	Lianghe virus (LHEV)	*Anourosorex squamipes*	China
Jeju orthohantavirus	Jeju virus (JJUV)	*Crocidura shantungensis*	South Korea
Kenkeme orthohantavirus	Kenkeme virus (KKMV)	Sorex roboratus	Far eastern Russia
Seewis orthohantavirus	Seewis virus (SWSV)	*Sorex araneus*	Switzerland, Czech Republic, Germany, Slovakia, Finland, Hungary, Siberia
Yakeshi orthohantavirus	Yakeshi virus (YKSV)	*Sorex isodon*	China
Order *Eulipotyphla*, *Soricomorpha*, Family *Talpidae* (moles)			
Asama orthohantavirus	Asama virus (ASAV)	*Urotrichus tapoides*	Japan
Bruges orthohantavirus	Bruges virus (BRGV)	*Talpa europaea*	Belgium
Oxbow orthohantavirus	Oxbow virus (OXBV)	*Neurotrichus gibbsii*	USA
Rockport orthohantavirus	Rockport virus (RKPV)	*Scalopus aquaticus*	Rockport, Texas, USA
Order *Chiroptera* Family *Pteropodidae* (megabats)			
Robina orthohantavirus	Robina virus (ROBV)	*Pteropus alector*	Australia

38.4.2 Evidence of Orthohantaviruses in Pet, Livestock, and Laboratory Animals

To the present knowledge, rodents are the main carriers of orthohantaviruses that have an impact on human health. Rodents may serve as prey for different birds, cats, or dogs. Further, rodents are around or in housings and also often found in buildings for livestock as buildings give some protection, hay is a good material for nesting, and food sources from livestock animals also serve rodents (Fig. 1). Therefore, it is important to know if orthohantaviruses can also be transmitted to nonrodent animals in laboratories, pets, or farm animals. Pet rats have been reported as a possible source of SEOV infections in the United Kingdom (Jameson et al. 2013a; Jameson et al. 2013b; Featherstone et al. 2013). Besides that, there exist only limited data on serological studies of different animals as for livestock such as cattle or pigs or birds of prey (Table 3). A combined study of animals' holders/handlers and animals was performed in an Austrian zoo (Juncker-Voss et al. 2004) and in the United

Table 3 Overview on investigations of orthohantavirus in pets, farm, and livestock animals (except rodents, shrews, bats)

Order	Animal species	Virus	Country	Detection	Ref.

Kingdom (Taori et al. 2013). Furthermore, orthohantavirus antibodies were detected in cattle (Danes et al. 1992). Serological studies further gave evidence that cats in comparison to dogs have a significantly higher orthohantavirus antibody-reactivity (Dobly et al. 2012). Table 3 summarizes the present knowledge of orthohantaviruses in pet, livestock, and laboratory animals. However, detection of orthohantavirus genome or isolation of replication-competent viruses from pets, farm, and livestock animals is missing so far and needs further investigation.

38.4.3 Do Orthohantavirus Infections Have an Impact on Animals?

As shown above, several serological studies show that animals developed antibodies against an orthohantavirus infection. Only a few studies have been performed—and mostly on rodents—in order to investigate if orthohantaviruses have an influence on the hosts. There is also a high variation of orthohantavirus prevalence in the respective rodent hosts. For example, the PUUV prevalence in rodents seems to be quite different depending on time, region, and the local orthohantavirus outbreak situation (Essbauer et al. 2006, 2013; Mertens et al. 2011c; Augot et al. 2008). Orthohantavirus infections in rodents are chronic and may have an impact on the population levels and the physiological status (Pearce-Duvet et al. 2006; Tersago et al. 2008, 2012; Luis et al. 2012). However, in summary, as described for the factors influencing the orthohantavirus epidemiology, there is also lack of data on the impact of the agents on their natural hosts.

Infection trials with some primates have shown different results, depending on the attenuation of the virus strains (Table 3). Surprisingly, infection experiments also showed that Prospect Hill virus (PHV), a North-American vole-associated virus that is nonpathogenic for humans, induced disease in *Cynomolgus macaques* (Yanagihara et al. 1988). Several nonhuman primate species seem also to be susceptible to a PUUV/TULV infection, but virus could not be isolated so far (Mertens et al. 2011a) (Table 3).

38.5 Seasonal Outbreaks, Exposition Risk Factors

The annual patterns of reported human PUUV cases in North and Central Europe are different. An investigation from 2001 to 2017 indicates a highly variable space-time disease incidence pattern. These infection rates are oscillating and show large outbreaks every 2 to 3 years with peaks in early summer (Faber et al. 2019). In Scandinavia, 3- to 4-year cycles seem to occur (Olsson et al. 2003; Vapalahti et al. 2003; Pettersson et al. 2008). Autumn and winter peaks of human cases are recorded in Fennoscandia (Rose et al. 2003; Evander and Ahlm 2009). Cycles in Central Europe do not follow a regular pattern. Varying local orthohantavirus outbreaks are reported in different years for Germany, France, and Belgium as reviewed in Essbauer et al. (2013) and Schmidt et al. (2021). Even as these countries are neighbors, outbreaks seem not to be synchronous (Essbauer et al. 2006, 2007; Faber et al. 2010; Mailles et al. 2005; Heyman et al. 2007; Ulrich et al. 2008; Koch et al. 2007; Hofmann et al. 2008; Ettinger et al. 2012). In France, most human infections are reported during late spring and summer (Vapalahti et al. 2003; Sauvage et al. 2002). In comparison, in Belgium and Germany, seasonal peaks are quite variable, and some years have exclusively summer peaks but in others also winter peaks occur (Heyman et al. 2012; Essbauer et al. 2013; Faber et al. 2010; Piechotowski et al. 2008). So far, the seasonal pattern of orthohantavirus cases in Germany and also neighboring countries seems quite unpredictable (Binder et al. 2019, 2020). In Germany, for DOBV, there might also exist two peaks, one in summer and one in winter (Hautala et al. 2002). The latter might be explained by the behavior of host, as late in season *Apodemus sp.* search for shelter in houses or garages, and therefore, humans might have enhanced contact to hosts and excreta.

In general, in Scandinavian countries (Finland, Sweden, and Norway) and Russia, PUUV incidences are much higher as in Central Europe (Fig. 3). High-endemic PUUV regions exist in most countries as, e.g., the Northern counties in Sweden (Olsson et al. 2003), the Jura for France (Augot et al. 2008), parts of South Belgium (Mailles et al. 2005) in Germany, i.e., the Swabian Alb, Main-Spessart region, Lower Bavaria, and the administrative districts of Osnabrück (Ulrich et al. 2008; Hofmann et al. 2008; Ettinger et al. 2012). Additionally, to the high oscillations, it should be mentioned that may be new regions are populated by host species. For example, several unusual urban outbreaks in the cities of Cologne, Aachen, and Osnabrück were recognized (Essbauer et al. 2007; Mailles et al. 2005; Abu Sin et al. 2007). Another example presents cities at the Swabian Alb, e.g., in 2010 and 2012, many cases were registered in the urban district of Stuttgart (Boone et al. 2012; Hautala et al. 2002). Changes in leisure behavior of city dwellers exerting more outdoor activities may also be responsible for the rise in urban cases.

The actual knowledge on factors driving orthohantaviruses in Europe was reviewed (Reusken and Heyman 2013); however, there remain many open questions on the tuning of outbreaks. Hence, several longitudinal studies were initiated in the last decade to better understand and predict outbreaks (Heyman et al. 2012; Essbauer et al. 2013; Reusken and Heyman 2013; Ulrich et al. 2008).

38.6 Hantavirus Disease

Diseases caused by pathogenic orthohantaviruses are called hemorrhagic fever with renal syndrome (HFRS) and hantaviral cardiopulmonary syndrome (HCPS) (Vaheri et al. 2013). HFRS is caused by Eurasian members, whereas HCPS is caused by orthohantaviruses of the American continents. The clinical picture of diseases is characterized by predominant involvement of kidney in HFRS and lung in HCPS. However, cases with pulmonary symptoms in infections with Eurasian orthohantaviruses and renal impairment by HCPS-causing American orthohantaviruses were also observed (Chand et al. 2020; Hjelle et al. 1996; Gizzi et al. 2013; Schütt et al. 2004; Rasmuson et al. 2011; Du et al. 2014; Linderholm et al. 1997; Vollmar et al. 2016; Sironen et al. 2017). Despite high genetic homology of orthohantaviruses, virulence of pathogenic members differs enormously, and severity of disease demonstrates an enormous variance between individuals. HCPS is associated with case fatality rates (CFR) of 21% to 39% (Alonso et al. 2019; Fonseca et al. 2018), whereas HFRS by Eurasian orthohantaviruses exhibits CFRs between 0.08% and 12% depending on the causative species (Vaheri et al. 2013; Klempa et al. 2013a). Highest CFRs between 6% and 15% are observed for SOCV, DOBV, and HTNV, whereas infections with PUUV or KURV are associated with milder courses and lower CFRs $< 1\%$ (Klempa et al. 2003). In addition, symptomatic infections with SEOV are observed in Europe, Asia, and the Americas (Zhang et al. 2011; Hofmann et al. 2008; Shepherd et al. 2021). Several case reports also describe mild signs of HFRS symptoms caused by TULV, which was formerly assigned to be nonpathogenic (Hofmann et al. 2021).

Symptomatic infections start with sudden onset of high fever and flu-like symptoms such as headache, myalgia, and gastrointestinal symptoms after several days to a few weeks after virus exposition. After this initial phase of infection, the organ-specific manifestation of the infection starts.

HFRS is associated with acute kidney injury with often massive proteinuria. Laboratory parameters that are changed involve the elevation of numbers of leukocytes, increased levels of serum creatinine, C-reactive protein, and lactate dehydrogenase activity. In contrast, numbers of platelets and serum albumin are decreased. Urinalysis reveals hematuria and proteinuria. The proteinuria is nonselective indicating a tubular and glomerular damage. In light-microscopic analysis, hantavirus disease presents as tubular-interstitial damage without obvious glomerular changes (Ferluga and Vizjak 2008). However, analysis of glomerular integrity by electron microscopy revealed structural changes of the glomerular filtration barrier (Nusshag et al. 2020; Collan et al. 1978; Boehlke et al. 2014). In addition, analysis of urine samples revealed the elevation of marker proteins for tubular and glomerular injury (Nusshag et al. 2020; Outinen et al. 2022). Besides the virus-specific virulence, differences in the clinical course between individuals are observed. Behavioral factors such as smoking or pre-existing conditions (Bergstedt Oscarsson et al. 2016; Gherasim et al. 2015; Latronico et al. 2018; Kitterer et al. 2016; Tervo et al. 2015) and genetic conditions such as HLA-haplotype influence the risk for severe courses of orthohantavirus infection (Ma et al. 2020; Mäkelä et al. 2001; Mustonen

et al. 1998). Gender-specific differences were also described. Middle-aged persons are mostly infected, and men are overrepresented (Krautkrämer et al. 2013; Faber et al. 2019; Klein et al. 2011; Hjertqvist et al. 2010; Klingström et al. 2008). Infections of children are often reported in the Americas with HCPS (Ferrés and Vial 2004), but recently also an immunocompromised boy died in Asia of a PUUV infection (Enyi et al. 2022). In Central Europe, a study revealed that infections with the Sochi virus gained an unexpectedly high fatality rate among children under 15 years of age (Dzagurova et al. 2018).

Long-term effects of an orthohantavirus infection are mostly determined by the severity of the organ involvement during the peak of the infection, but for the majority of patients, most symptoms are gone latest three months after disease onset. Due to the involvement of the kidney, many patients develop a long-term hematuria, hypertension, or proteinuria (Latus et al. 2015). Orthohantavirus-specific IgG will remain in the patients up to years after the infection. However, there is a correlation of PUUV survivors and an increased probability to develop lymphatic malignancies (Klingström et al. 2014), but no further studies were performed so far to reveal if this is PUUV specific or valid for all orthohantavirus infections.

In summary, orthohantavirus-induced diseases exhibit a broad range of symptoms and virus-specific determinants as well as individual patient-specific factors control the severity of the clinical course. It is central to gain more insights in the underlying cellular mechanism of pathogenesis for the development of antiviral strategies.

38.6.1 Pathogenesis

While most governmental research on orthohantavirus focuses on the distribution and virulence of the disease, it is also of utter importance to understand more about the biological abilities of the virus family and the mode of action of the pathophysiology. Some labs specialized on the investigation on orthohantavirus biology and were able to draw a comprehensive picture in the last decade. Understanding the molecular biological features of an infection ultimately paves the way to an effective prevention of an infection such as a vaccination or a targeted therapy dampening the symptoms of an infection.

38.6.1.1 Cell Biology

Like other viruses, orthohantaviruses are dependent on a host cell to replicate. Orthohantaviruses, entering the body either via the digestive or pulmonary system, are absorbed by cells expressing among others the integrin β3 surface receptor (CD61) such as endothelial and epithelial cells, T cells, DC cells, macrophages, and follicular dendritic cells (Noack et al. 2020).

All receptors for orthohantavirus entry were identified in *in vitro* cell culture systems. First, integrin β3 was described to mediate the entry of pathogenic orthohantaviruses (Gavrilovskaya et al. 1999; Gavrilovskaya et al. 1998). In the last years, more and more receptors and cofactors have been identified using different cell

culture models such as CD55, gC1qR, protocadherin-1, or TIM-1 (T-cell immunoglobulin and mucin domain 1) (Krautkrämer and Zeier 2008; Popugaeva et al. 2012; Buranda et al. 2010; Choi et al. 2008; Jangra et al. 2018; Mayor et al. 2020). In addition, studies demonstrated the permissibility of human and rodent cell types without integrin β3 expression (Higa et al. 2012; Raftery et al. 2014; Müller et al. 2019). In conclusion, receptor usage and entry mechanism of orthohantaviruses remain elusive. Entry may differ between cell types, host reservoir, and human cells, and between virus species. Therefore, further investigations are necessary.

Upon attachment and receptor engagement, virions ultimately fuse with the cell membrane in clathrin-coated pits by macropinocytosis of the host by changing the structure of the Gc surface protein (Torriani et al. 2019; Bauherr et al. 2020). In its open form, it is able to dimerize and expose its aromatic and polar residues who enable the fusion with the cell membrane (Bignon et al. 2019; Cifuentes-Muñoz et al. 2011). In the early endosome, the virions get uncoated, and viral ribonuclear particles (RNP) get into the cytoplasm where they are further stripped off protecting particles (Fig. 3). Orthohantaviruses provide their own RNA-dependent RNA polymerase (RdRp) that starts the initial transcription of viral RNA. However, to do so, the RdRp is depended on a yet to be defined host cell factor. Together, these two proteins perform so-called cap-snatching on 5′fragments of cellular mRNA to generate primers that are used for the initiation of the transcription of the viral genome (Jeeva et al. 2018). Subsequently, translation of the M-fragment starts at the rER, while S- and L-segments predominantly get translated at free ribosomes. An early and large quantity translation of the glycoprotein GPC is crucial to enable a continuous translation, trafficking, and assembly of other viral proteins and RNPs. Protein maturation, such as the glycosylation of the Gn/Gc glycoproteins, takes place at the Golgi apparatus. For this, the C-terminal peptides are crucial to enable efficient protein trafficking to the Golgi (Sperber et al. 2019). Gn proteins form spontaneously tri- and oligomers, while Gc proteins mostly assemble in mono- or dimers. Subsequently, Gn/Gc protein complexes self-assemble in virus like particles at a yet to be identified subcellular localizations (Acuña et al. 2014). Viral budding occurs after assembly of viral particles in the cytosol. Here, the Gn/Gc glycoproteins interact with proteins of the ESCRT machinery that releases the enveloped viruses into the extracellular fluid (Rheinemann and Sundquist 2021).

During all these steps of orthohantaviral replication cycle, the nucleocapsid (N) protein plays an outstanding role. This protein is a viral multifunctional protein that does not only facilitate stabilization of viral RNA, but also plays leading roles in genome packaging, intracellular protein transport, RNA chaperoning, DNA degradation, and intervention with the host immune response (Reuter and Krüger 2018). For instance, by remodeling Golgi structures, it establishes RNA synthesis factories (Davies et al. 2019). In addition, N protein impairs adhesion and migration capacity of infected renal cells and may contribute to renal pathogenesis (Hägele et al. 2019). All these features are mediated by its ability to interact with RNA and other viral and cellular proteins and thus qualify as a promising target for antiviral drug development (Arragain et al. 2019; Reuter and Krüger 2018).

38.6.1.2 Immune System and Cell Death Evasion

Frontline in the fight against a viral infection is the interferon (IFN) 1 system. Cells in direct contact with the virus excrete interferons as signal molecules to alert the immune system. Indeed, experiments in IFN1-deficient mice showed a high burden of orthohantavirus in all organs briefly after infection (Dowall et al. 2020). Mammalian cells identify an orthohantavirus infection by the RIG-1 receptor, a cytoplasmic receptor for dsRNA, that in turn activates the IFN1 cascade (Kell et al. 2020). Orthohantavirus, however, evolved different strategies to escape mammalian immunity. For Andes virus, viral NSs protein that antagonizes a cellular type 1 IFN response by inhibiting MAVS signaling is a key player in this evasion (Vera-Otarola et al. 2020). The effectiveness of an immune evasion of various old world or new world orthohantavirus species rests in the protein structure of their Ns or NSs proteins, respectively. Especially, NSs position 386 proved crucial in its effectiveness and may further explain the only human-to-human transmissibility of the Andes virus (Simons et al. 2019).

Mammalian cells developed a secondary line of defense against viral infection. For instance, exosomal miR145-5p, produced by orthohantavirus-infected endothelial cells, actively blocks viral replication (Wang et al. 2020). Furthermore, activated neutrophils secrete myeloperoxidase, neutrophil elastase, and IL-8, that may also drive the renal syndromes observed among patients (Strandin et al. 2018). In addition, genetic predisposition may alter the effectiveness of an immune response against orthohanta infection. It was shown that high expression of the immune modulators complement factor CFHR1 negatively and SIRBP1 positively affects the outcome of an orthohantavirus infection (Ribeiro et al. 2019).

The goal of a functioning immune system is to remove infected cells from the tissue. In case the immune system fails to extrinsically execute cell death in infected cells, concerned cells can also initiate cell death on their own, called intrinsic apoptosis (Peintner and Borner 2017). Interestingly, orthohantavirus also developed mechanisms to block the correct execution of extrinsic and intrinsic cell death (Solà-Riera et al. 2019). Central in the execution of cell death is the proteolytic protease caspase 3. It was experimentally proven, that the orthohantaviral N protein heterodimerizes with activated caspase 3 and so prevents cell death (Davies et al. 2019).

Extrinsic apoptosis induced by granzyme B or TRAIL is perturbed in orthohantavirus infected hosts by a downregulation of its surface receptor DR5 (Solà-Riera et al. 2020; Solà-Riera et al. 2019). This publication also observed an upregulation of the antiapoptotic protein Bcl2 after the infection with ANDV. This upregulation blocked the permeabilization of the outer membrane of mitochondria, a central event in intrinsic apoptosis. Hence, no activation of caspases leading to cell death was observed (Solà-Riera et al. 2020).

38.6.1.3 Recent Scientific Breakthroughs

The heterogeneity concerning the clinical picture (HFRS and HCPS) and the broad range of disease severity among orthohantaviruses even between members of the same species is one of the most interesting questions. Identifying determinants of

organ-specificity and pathogenicity is a prerequisite for the development of therapeutic strategies. Research on orthohantaviruses is hampered by the lack of a suitable small animal model and *in vitro* cell culture research was performed in non-target cells for a long time. Fortunately, the number of studies using relevant cell culture systems is increasing in the last years. Establishment of cell lines from host animal species and use of primary human target cells facilitate the characterization of steps of the orthohantaviral replication cycle. Infection of host species cell lines allows to determine the host range of rodent species for orthohantavirus infection (Essbauer et al. 2011; Binder et al. 2019). Studies in human primary cells revealed virus- and cell type specific differences in the susceptibility of target cells and functional effects that may contribute to hantavirus pathogenicity (Bourquain et al. 2019; Raftery et al. 2014; Hägele et al. 2019).

Another major hindrance of research on orthohantaviruses is the work under BSL2 and 3 conditions, which demands well-equipped laboratories to perform experiments. Also, long-term culture of virus in cell culture may change the characteristics of viruses, as frequently observed in other viruses (Strandin et al. 2020). This problem may partly be circumvented by using VSV- (vesicular stomatitis virus) or SIV- (simian immunodeficiency virus) pseudotyped viruses (Old World: (Slough et al. 2019; Higa et al. 2012), New World: (Cifuentes-Muñoz et al. 2010)). Using this recombinant virus, it was able to highlight the importance of the Gn/Gc glycoproteins in regulating viral infectivity. These tools may also be used to perform safe neutralization tests to screen for new monoclonal antibodies against the virus (Ogino et al. 2003). However, characterization of postentry steps or testing antiviral substances will still require wild-type viruses.

38.6.2 Therapy and Vaccination

Rationale of all research on human pathogens is the development of a reliable vaccine to prevent, or an effective drug treatment to fight, an infection. Hence, many laboratories aim to develop convincing treatment options against orthohantavirus infections.

Several potential drugs and drug targets have been identified over the last years. Early studies with ribavirin, for instance, proved to improve the prognosis of cardio pulmonary syndrome patients (Safronetz et al. 2011). Recently, chemical compounds of phenyl-benzotriazole derivatives or baloxavir acid were proved to massively downregulate viral burden *in vitro* (Sanna et al. 2020; Ye et al. 2019). To design more targeted drugs against surface properties of the capsid, labs use fluorescence activated cell sorting (FACS) to identify molecules from a compound library that block the entry of the virus in the target cell (Buranda et al. 2018). By analyzing the interaction of the N protein with viral RNA using advanced EM imaging, new structures on the N protein were identified that could serve as future drug binding areas (Arragain et al. 2019).

Beside all these efforts to develop potent antivirals, the gold standard of the fight against virus infections is a reliable vaccination. It is known that the intramuscular or

subcutaneous injection of cell culture produced recombinant viral Gn/Gc or N proteins induce a specific immune response in laboratory mice (Li and Klein 2012; Yu et al. 2013). Soon, it became evident that the most promising targets of antibodies are the Gc and Gn glycoproteins on the surface of orthohantaviruses, since an early binding of antibodies at these glycoproteins prevents their structural shift, which enables the binding to the host cell (Rissanen et al. 2020). Further research on the protein structure of this glycoproteins enabled the design of tailor-suited monoclonal antibodies (Levanov et al. 2019; Abdulla et al. 2021). At present, only few vaccinations made it to the market. An oral-administered vaccination targeted against SNV is used to vaccinate deer mice (*Peromyscus maniculatuts*) in North America to lower the viral burden of rodents in endemic areas (Warner et al. 2020). Vaccinations in humans are mostly driven in Asian countries or the United States and are excellently summarized elsewhere (Liu et al. 2020).

The efficacy of mononuclear antibodies against orthohantavirus is further boosted by special adjuvants. Especially, low endotoxoic lipopolysaccharide contributed to the enhancement of the immune response and—as a welcomed side effect—prolonged shelf life of the vaccine (Kurashova et al. 2020).

Summarized, there are many potential vaccinations in the pipeline targeting the different orthohantavirus species around the globe. Some of them are already being tested in preclinical studies (Dzagurova et al. 2020; Ma et al. 2020); however, there are no postexposure prophylactic vaccines in development yet (Logue et al. 2020). Furthermore, orthohantavirus is a very diverse family of virus in the order of *Bunyavirales,* and it will be very sumptuous to create a specific vaccination for each single family member. Therefore, some labs try to find a universal vaccine that targets all members of *Bunyavirales* (Ter Horst et al. 2019).

38.7 Perspective

The knowledge of the distribution and the complexity of the family of *Hantaviridae* is expanding in an unprecedented speed. Now species are found in hosts on all continents and many countries operate a tight monitoring network to identify local hotspots. Although hantaviruses are not officially endemic everywhere, practitioners should be aware, that their patients might get infected on trips abroad or within the country. Furthermore, institutes for public health need to continue their screen of hantavirus in wild animals. By monitoring the host species composition and the viral load of hosts, an impact for the human local community can be derived.

However, for many of the new described orthohantavirus species, the consequence and pathogenicity on humans are unknown. It is the effort of many researchers to generate virus isolates and grow them in cell culture systems so understand more about the biology and transmission of the virus.

Currently, there are big efforts to design an efficient pan-orthohanta vaccine. The recent successful development of SARS-CoV2 vaccines based on mRNA-technology may probably facilitate the progress for a hantaviral vaccine. However, till such a licensed vaccine is approved for the market, prevention of infection will

remain on rodent control, avoidance of contact with rodent excreta, and properly cleaning and disinfecting areas contaminated by rodent excreta.

In conclusion, despite 30 years of intense studies and growing awareness on hantaviruses, there are still a lot of open questions that will attract the curiosity of scientists for the coming years.

East African, and *T.b. gambiense* for the West African sleeping sickness. A third species, *T.b. brucei*, causes Nagana disease in cattle. HAT is fatal if left untreated. In recent years, considerable progress has been achieved in terms of treatment (introduction of a new drug flexinidazole) and control (successful reduction of cases).

39.1 Historic Introduction

Human African trypanosomiasis (HAT) or sleeping sickness is one of Africa's classic tropical diseases. The first case reports go back to the fourteenth century. Until recently, the impact of HAT on health in Africa has been devastating. Many areas had long been rendered uninhabitable for people and domestic livestock. Millions may have died in Central Africa around Lake Victoria and in the Congo basin within the last 100 years.

In 1895, the British scientist Sir David Bruce (1855–1931) suggested an association between trypanosomes and the "cattle fly fever," a major problem for livestock in southern Africa. In 1902, Robert M. Forde and Everett Dutton from the Liverpool School of Tropical Medicine identified trypanosomes in the blood of a patient during a research expedition in The Gambia, and in 1903, the Italian Aldo Castellani isolated trypanosomes from the cerebrospinal fluid. In the same year, tsetse flies were identified as the vector.

Up to the 1960s, control programs had been quite successful. However, recent epidemics in the Democratic Republic of Congo, Northern Angola, South Sudan, Uganda, and other countries resulted in a major resurgence of HAT. At the turn of the twentieth century, the achievements in sleeping sickness control during colonial times had been nearly completely reversed. Fortunately, recent successes of programs run by national institutions and various dedicated nongovernmental organizations finally succeeded in a reduction of transmission in many accessible areas of central Africa. However, nobody knows the true prevalence of HAT in Africa, as many countries are still in a state of war and civil unrest with a desperate population that cannot be reached by health interventions.

Today, about 60 million people in 36 African countries are exposed to the potential risk of HAT in about 300 currently existing active foci. Today, only a few hundred new cases are reported yearly to WHO, but they are doomed if left untreated. For expatriates and international travelers, sleeping sickness has always been a rare disease, although occasional clusters of cases in tourists to Tanzania, Zambia, and Malawi are regularly reported.

There is hardly any other tropical disease that demonstrated more clearly the hypocrisy characterizing our time. On one side, trypanosomes are kept in culture and

studied extensively in numerous research laboratories. Their genome is sequenced, and many molecular, biochemical, and immunological phenomena have been discovered as a result of basic science research; scientific interest in the disease is usually restricted to its research aspects. On the other hand, diagnostic and, especially, therapeutic tools were increasingly unavailable, because patients in rural Africa were not commercially viable consumers. Global concern about the crisis of HAT in Africa is a question of scientific ethics and international solidarity. HAT can be seen as the classic example of a Neglected Tropical Disease (NTD).

Fortunately, there have been considerable developments in recent years. In 2012, WHO set out to eliminate HAT as a public health problem. In the first stage, a reduction of new cases below 2.000 per year was reached in 2020. Now, it is planned to interrupt transmission of West African HAT by 2030. This, however, will only be possible by integration of HAT control in the general package of basic and public health measures. The control of the East African HAT is even more complex due to its extensive animal reservoir, a classic example of the necessity of a modern "One Health" approach.

39.2 Taxonomic Classification

HAT is caused by subspecies of the protozoan hemoflagellate *Trypanosoma brucei*, which is transmitted to man and animals by tsetse flies (*Glossina* spp.). The distribution of the vector restricts sleeping sickness to the African continent between 14° North and 29° South.

Human disease occurs in two clinically and epidemiologically distinct forms: West African and East African sleeping sickness (Table 1). A third subspecies of the parasite, *T.b. brucei*, causes the Nagana disease in cattle, but is nonpathogenic in

Table 1 The principal features of West and East African sleeping sickness

Disease	West African sleeping sickness	East African sleeping sickness
Parasite	*Trypanosoma brucei gambiense*	*T.b. rhodesiense*
Vector	Transmitted by riverine tsetse flies (*palpalis* group)	Transmitted by savannah tsetse flies (*morsitans* group)
Clinical course	Insidious onset, slow progression, death in stage II after many months or years	Acute onset, chancre frequent, rapid course, death frequently in stage I (cardiac failure)
Diagnosis	Parasitemia scanty, Winterbottom's sign, serology	Parasitemia usually higher and easily detectable, serological tests unreliable
Treatment	See Table 3	
Epidemiology	Tendency for endemicity, man as main reservoir with evidence for several other mammal species, severe public health problem in many West and Central African countries	Wild (antelopes, e.g., bushbuck) and occasionally domestic animals as reservoir and source of case clusters and epidemic outbreaks

humans. In Uganda, the only country where all three forms occur, the areas of *gambiense* and *rhodesiense* sleeping sickness are currently about to overlap.

Trypanosoma brucei (phylum Sacromastigophora, order Kinetoplastida) is an extracellular protozoan parasite. Like *Leishmania*, it possesses a centrally placed nucleus and a kinetoplast, a distinct organelle containing extranuclear DNA. The kinetoplast is the insertion site of an undulating membrane, which extends over nearly the whole cell length and ends as a free flagellum.

The three subspecies of *T. brucei* are morphologically indistinguishable. However, they differ considerably in their interaction with their mammalian host and the epidemiological pattern of the diseases they cause. Formerly, *T.b. gambiense* and *T.b. rhodesiense* isolates were characterized either by isoenzyme analysis or by animal inoculation. The advent of molecular techniques created expectations of more reliable tools for their differentiation. However, genomic characterization has revealed several more subdivisions rather than the three expected. Whereas West African isolates proved relatively homogeneous, East African isolates from humans and animals did not simply conform to what is still called *T.b. rhodesiense* and *T.b. brucei*, but showed a complex relationship with evidence of so far undiscovered genetic exchange in the vector. Further molecular research may soon lead to a comprehensive phylogenetic tree and a deeper insight into trypanosomal evolution and biology.

39.3 Biology

Although congenital, blood-borne and mechanical transmission have been reported and may play an occasional role, the main mode of transmission is through the bite of infected tsetse flies (*Glossina* spp., order Diptera). These are biologically unique insects, which occur only in Africa in 31 distinct species and subspecies. Less than half are potential vectors of HAT. Their distinctive behavior, ecology, and chosen habitat explain many epidemiological features of sleeping sickness. Tsetse flies can live for many months in the wild, but give birth to only about eight larvae per lifetime. Both sexes feed on blood. They require warm temperatures, shade, and humidity for resting and larviposition, which makes their distribution highly localized. Recently, the mapping and monitoring of possible HAT transmission foci has become possible with the use of satellite imaging techniques.

During the blood meal on an infected mammalian host, the tsetse fly takes up trypanosomes ("short-stumpy form") into its mid-gut, where they develop into procyclic forms and multiply. After about 2 weeks, they migrate to the salivary glands as epimastigotes, where they finally develop into infective metacyclic forms. At the next blood meal, they are injected into a new vertebrate host where they appear as "long-slender" trypomastigotes and multiply by binary fission. In contrast to *Leishmania* and *T. cruzi*, *T. brucei* is an exclusively extracellular parasite.

The cyclic changes of the trypanosome into different developmental stages are accompanied by variations in morphology, metabolism, and antigenicity. Several

unique metabolic pathways have been described in trypanosomes, distinct from their host and thus qualifying as potential drug targets.

The blood stream forms of *T. brucei* are covered with a dense coat of identical glycoproteins, numbering up to about 500 aminoacids per molecule. Being highly immunogenic, they stimulate the production of specific antibodies, mainly of the IgM subclass. Once the surface glycoproteins have been recognized by host antibodies, the parasite will be attacked and destroyed through complement activation and cytokine release, giving rise to local and systemic inflammatory reactions.

However, about 2% of *T. brucei* in each new generation change the expression of their specific surface glycoprotein. The "coat" will then be different in the new clone (thus, "variant" surface glycoprotein: VSG). This phenotypic switch is done mainly by programed DNA-rearrangements, moving a transcriptionally silent VSG gene into an active, telomerically located expression site. Each *T. brucei* parasite already has the information for hundreds of different VSG genes, and within a whole trypanosome population, the potential repertoire for such different VSG copies seems to be virtually infinite.

Every new VSG copy is antigenically different, thus stimulating the production of a new IgM population. This antigenic variation is the major immune evasion strategy of the parasite, enabling the trypanosome to persist in its vertebrate host. It also reduces parasite load and prolongs the infection. But the inevitable outcome is immune exhaustion of the host (supported by additional immunosuppressive metabolites of the parasites), penetration of trypanosomes into immune-privileged sites such as the central nervous system, and finally death.

39.4 Pathogenicity and Pathology

HAT progresses much more rapidly (over weeks or months) in the East African or *rhodesiense* variety compared with a more insidious onset and protracted course that can last years in *gambiense* (West African) infection. Generally, there are many more circulating organisms in *rhodesiense* compared with *gambiense* infections, making direct parasitological diagnosis easier in East African sleeping sickness. The number of organisms in the blood also varies widely depending on the immunological response to infection. These numbers come and go in waves, because antibodies that develop to one antigenic type of trypanosome can lyse them, but are not effective in stopping multiplication of a smaller number of organisms that have a different antigenic type, and it takes time for immune systems to respond to this new variant. Host inflammatory responses mediated by cytokines are prominent and, together with immunological responses, may contribute to pathophysiology. There are two stages of infection, which are important to distinguish because stage determines the choice of treatment and subsequent risks.

A few days after an infective tsetse bite, a small papule may develop, more often in *rhodesiense* than in *gambiense* infections. As organisms multiply locally, they excite inflammatory responses, an erythematous tissue reaction with edema and lymphadenopathy can follow. This "trypanosomal chancre" is commonly found in

rhodesiense, but rarely in *gambiense* infections. Organisms then invade quickly the hemolymphatic system where they multiply. Symptoms of fever, rigors, headaches, and arthralgias follow. These may be less prominent in *gambiense* infections. Lymphadenopathy is detected frequently, especially in the posterior triangle of the neck. This "Winterbottom's sign" is diagnostically useful, because lymph juices from these glands can show parasites and help to establish a diagnosis.

After local multiplication at the site of inoculation, the trypanosomes invade the hemolymphatic system, where they can be detected after 7–10 days. During this period of spread, they are exposed to vigorous host defense mechanisms, which they evade by antigenic variation. This continuous battle between antigenic switches and humoral defense results in a fluctuating parasitemia with parasites frequently becoming undetectable, especially in *gambiense* HAT. The cyclic release of cytokines during periods of increased cell lysis results in intermittent, nonspecific symptoms: fever, chills, rigors, headache, and joint pains. These can easily be misdiagnosed as malaria, viral infection, typhoid fever, or many other conditions. Hepatosplenomegaly and generalized lymphadenopathy are common, indicating activation and hyperplasia of the reticuloendothelial system.

Trypanosomes cross the blood–brain barrier within weeks after infection in *rhodesiense* and months in *gambiense* infections. This indicates the beginning of the "sleeping sickness" phase, which is associated with personality changes, headaches, withdrawal from the environment, and other signs of neurological involvement. Patients find it harder to carry out any but the simplest of tasks and show a kind of "mental tunnel vision." There are changes in circadian rhythm as well, such as nocturnal insomnia and daytime somnolence. Unless treated, these symptoms progress and are associated with apathy, inanition, and eventually secondary infections such as pneumonias that precede death.

39.5 Clinical Manifestations

Sleeping sickness is a dreadful disease, causing great suffering to patients, their families, and the affected community. The infection often has an insidious onset, but *T. brucei*, whether the East or West African subspecies, will invariably kill if the patient is not treated in time. The natural course of HAT can be divided into different and distinct stages. Their recognition and differentiation are important for the clinical management of the patient.

39.5.1 The Trypanosomal Chancre

Tsetse bites can be quite painful, usually leaving a small and self-healing mark. In the case of a trypanosomal infection, the local reaction can be quite pronounced and longer lasting. A small raised papule will develop after about 5 days. It increases rapidly in size, surrounded by an intense erythematous tissue reaction with local edema and regional lymphadenopathy. Although some chancres have a very nasty

appearance, they are usually not very painful unless they become ulcerated and superinfected. They heal without treatment after 2–4 weeks, leaving a permanent, hyperpigmented spot.

Trypanosomal chancres occur in more than half the cases of *T.b. rhodesiense*. In *T.b. gambiense*, they are much less common and often go undetected in endemic populations.

39.5.2 Hemolymphatic Stage (HAT Stage I)

A reliable sign, particularly in *T.b. gambiense* infection, is the enlargement of lymph nodes in the posterior triangle of the neck (Winterbottom's sign). Other typical signs are a fugitive patchy or circinate rash, a myxedematous infiltration of connective tissue ("puffy face syndrome"), and an inconspicuous periostitis of the tibia with delayed hyperesthesia (Kérandel's sign).

In *T.b. rhodesiense* infection, this hemolymphatic stage is very pronounced with severe symptoms, clinically often resembling *falciparum* malaria or septicemia. Frequently, patients die within the first weeks after the onset of symptoms, mostly through cardiac involvement (myocarditis). In the early stage of *T.b. gambiense* infection, symptoms are usually infrequent and mild. Febrile episodes become less severe as the disease progresses.

Patients presenting with an appropriate history of travel in endemic areas, perhaps a history of being bitten by tsetse flies and systemic symptoms of fever should raise suspicion of HAT.

39.5.3 Meningoencephalitic Stage (HAT Stage II)

Within weeks in *T.b. rhodesiense* and months (sometimes years) in *T.b. gambiense* infection, cerebral involvement will invariably follow; trypanosomes cross the blood–brain barrier.

The onset of stage II is insidious. The exact time of central nervous system involvement cannot be determined clinically. On histology, perivascular infiltration of inflammatory cells ("cuffing") and glial proliferation can be detected, resembling cerebral endarteritis. As the disease progresses, patients complain of increasing headache and their families may detect a marked change in behavior and personality. Neurological symptoms, which follow gradually, can be focal or generalized, depending on the site of cellular damage in the central nervous system. Convulsions are common, usually indicating a poor prognosis. Periods of confusion and agitation slowly evolve toward a stage of distinct perplexity when patients lose interest in their surroundings and their own situation. Inflammatory reactions in the hypothalamic structures lead to a dysfunction in circadian rhythms and sleep regulatory systems. Sleep pattern become fragmented and finally result in a somnolent and comatose state. Progressive wasting and dehydration follow the inability to eat and drink.

In children, HAT progresses even more rapidly toward this meningoencephalitic stage. Parents often notice insomnia and behavioral changes long before the diagnosis is established.

There is no pathognomonic clinical sign of late HAT, a wide range of possible neurological and psychiatric differential diagnoses is opened instead. However, the appearance of the patient with apathy, the typical expressionless face and swollen lymph nodes at the posterior triangle of the neck, is very suggestive for HAT in endemic areas.

39.6 Laboratory Diagnosis

HAT can never be diagnosed with certainty purely on clinical grounds. Definitive diagnosis requires the detection of the parasite in chancre aspirate, blood, lymph juice, or cerebrospinal fluid using various parasitological techniques.

39.6.1 Lymph Node Aspirate

Lymph node aspiration is widely used, especially for the diagnosis of *gambiense* HAT. Fluid of enlarged lymph nodes, preferably of the posterior triangle of the neck (Winterbottom's sign), is aspirated and examined immediately at × 400 magnification without additional staining. Mobile trypanosomes can be detected for a few minutes between lymphocytes.

39.6.2 Wet Preparation, Thin and Thick Blood Film

During all stages of the disease, trypanosomes may appear in the blood stream where they can be detected in unstained wet or in stained preparations. The yield of detection is highest in the thick blood film, a technique widely used for the diagnosis of blood parasites such as *Plasmodia* or microfilaria. Giemsa or Field staining techniques are appropriate.

Especially in *gambiense* HAT, parasitemia is usually low and fluctuating, often even undetectable. Repeated examinations on successive days are sometimes necessary until trypanosomes can be documented.

39.6.3 Concentration Methods

To increase the sensitivity of blood examinations, various concentration assays have been developed. Trypanosomes tend to accumulate in the buffy coat layer after centrifugation of a blood sample. The best results have been obtained with the mAECT (mini anion exchange column technique), where trypanosomes are concentrated after passage through a cellulose column, the QBC method (quantitative buffy

coat), which was originally developed for the diagnosis of malaria, or the CTC method (capillary tube centrifugation), which is widely used in the field.

39.6.4 Nucleic Amplification Techniques

Several specific primers have been described to detect trypanosomal DNA using the polymerase chain reaction (PCR). They had been successfully applied to samples from blood, lymph juice, and CSF, mostly under conditions of a research laboratory. Until today PCR assays are still inferior to conventional parasitological techniques.

39.6.5 Serological Assays

Serology is a useful tool to detect antibodies against trypanosomes. Various test methods have been described; some of them are now commercially available. They are mainly based on ELISA technique or immunofluorescence, but provide reliable results only in *gambiense* HAT.

For rapid screening under field conditions, the CATT (card agglutination test for trypanosomiasis) is an excellent tool in areas of *T.b. gambiense* infestation. It is easy to perform and delivers results within 5 min. A visible agglutination in the CATT suggests the existence of antibodies, but does not necessarily imply overt disease. Still, any positive serological result always requires parasitological confirmation before the initiation of treatment.

Recently, novel diagnostic tests similar to the rapid detection tests (RDT) for the diagnosis of malaria or COVID-19 have been developed by the nonprofit organization FIND (Foundation for Innovative New Diagnostics) and are currently undergoing evaluation under field conditions.

39.6.6 Nonspecific Laboratory Findings

Anemia and thrombocytopenia are caused by systemic effects of cytokine release, especially of TNF-α. Hypergammaglobinemia can reach extreme levels as a result of polyclonal activation of plasma cells. IgM levels detected in HAT are among the highest observed in any infectious disease.

39.6.7 Diagnosis of Stage II

Stage determination is crucial for the correct management of a patient. This cannot be done on clinical grounds alone. Therefore, cerebrospinal fluid must be examined in every patient found positive for trypanosomes in blood or lymph aspirate. In addition, a lumbar puncture should also be performed in all patients in whom HAT is

suspected clinically even if peripheral examinations had proved negative. A minimum of 5 ml of cerebrospinal fluid is required to examine for:

- *Leucocytes*: Cerebral involvement in HAT stage II is accompanied by pleocytosis, mostly lymphocytes, in the cerebrospinal fluid. By convention a number of five cells or more per mm^3 cerebrospinal fluid defines central nervous system involvement even if the patient does not (yet) have neurological symptoms. Pathognomonic for HAT is the appearance of activated plasma cells with eosinophilic inclusions in the cerebrospinal fluid, the morular cells of Mott
- *Trypanosomes*: The chances of detecting trypanosomes in the cerebrospinal fluid increase with the level of pleocytosis and the technique used. The highest yield is obtained by cerebrospinal fluid double centrifugation and rapid microscopy at the bedside
- *Protein*: In patients with HAT, a level of 37 mg of protein per 100 ml cerebrospinal fluid (dye-binding protein assay) or more is highly suggestive of the advanced stage. Stage II HAT is characterized by an autochthonous production of IgM antibodies in the cerebrospinal fluid, which can be selectively detected if suitable laboratory facilities exist (e.g., latex IgM test)

39.7 Treatment

39.7.1 General Considerations

HAT is curable, especially if the diagnosis is made at an early stage of the disease. In the harsh reality of the African situation, however, there are many major obstacles to successful patient management:

1. Sleeping sickness is a disease of rural, remote places. The active foci of sleeping sickness are usually in far away and insecure places, which are difficult to reach. Many treatment centers work under emergency conditions with extremely restricted resources. Numerous patients, without proper access to health care, are left unattended.
2. The diagnosis is difficult. Initial diagnosis and exact staging of trypanosomiasis requires sophisticated methods that are potentially harmful to the patient and thus justified only in the hands of experienced personnel. Repetitive training programs, constant supervision, and continuous quality control are necessary but, in reality, rarely available.
3. The treatment of trypanosomiasis is extremely costly although the drugs themselves are now covered by a donation program. Invariably, demand exceeds the locally available resources. External funding and sustainable donor commitments for rural Africa is generally decreasing.
4. The treatment can be complicated, dangerous, prolonged, and usually requires hospitalization. Most patients with late-stage trypanosomiasis are severely ill and malnourished. Adverse drug reactions during treatment are difficult to assess due

to concomitant pathologies. Their management requires considerable medical skill and good nursing care. Hospitals in rural Africa are often inadequately equipped and staffed to accomplish good patient care.

5. Many drugs are not easily available. Trypanosomicidal agents were on the verge of disappearance despite increasing demand. The range of drugs is diminishing, and hardly any new treatments are in sight. This is especially worrying in view of the reported spread of drug resistance.
6. HAT treatment is not standardized. Trypanosomiasis treatment regimens vary considerably between countries and treatment centers. Results from different centers are comparable to only a very limited extent. Few properly conducted and sufficiently powered clinical trials are available to evaluate duration, dosage, and possible combinations of drugs. Sufficient infrastructure for carrying out clinical research exists in only a handful of places.
7. The price for cure of HAT is high: dangerous drugs with limited availability and prolonged treatment schedules administered in many places by poorly trained personnel in rudimentary medical facilities. Little progress has been achieved in the last 30 years.

The treatment of HAT depends on the trypanosome subspecies and the stage of the disease (Table 2).

39.7.2 Stage I Drugs

39.7.2.1 Pentamidine

Since its introduction in 1937, pentamidine has become the drug of choice for *gambiense* HAT stage I, achieving cure rates as high as 98%. However, there are frequent failures in *rhodesiense* HAT. Lower rates of cellular pentamidine uptake in *T.b. rhodesiense* may explain these differences. Some cures of stage II infections have also been reported, but cerebrospinal fluid drug levels are usually not sufficiently high to guarantee a reliable trypanosomicidal effect in the central nervous system.

Pentamidine is usually given by deep intramuscular injection, often on an outpatient basis. If hospital care and reasonable monitoring conditions are available, an intravenous infusion, given in normal saline over 2 h, might be used instead. The

Table 2 The choice of drugs in the treatment of sleeping sickness until 2019

	Gambiense sleeping sickness		*Rhodesiense* sleeping sickness	
HAT Stage I	Pentamidine		Suramin	
HAT Stage II	1st line	NECT (nifurtimox eflornithine combination therapy)	1st line	Melarsoprol
	2nd line	Melarsoprol	2nd line	+ Nifurtimox

Table 3 Dosage and principal adverse reactions of antitrypanosomal agents

	Dosage regimen	Adverse drug reactions
Pentamidine	4 mg/kg body weight intramuscular daily or on alternate days for 7–10 injections	Hypotensive reaction (common) with tachycardia, dizziness, even collapse and shock, especially after intravenous administration, close monitoring of pulse rate and blood pressure after injection is mandatory Inflammatory reactions at the site of injection (sterile abscesses, necrosis) Renal, hepatic, and pancreatic dysfunction Neurotoxicity: peripheral polyneuropathy Bone marrow depression
Suramin	Day 1: Test dose of 4–5 mg/kg body weight Day 3, 10, 17, 24 and 31: 20 mg/kg body weight, maximum dose per injection 1 g	Pyrexia (very common) Early hypersensitivity reactions such as nausea, circulatory collapse, urticaria Late hypersensitivity reactions: skin reactions (exfoliative dermatitis), hemolytic anemia Renal impairment: albuminuria, cylindruria, hematuria (high renal tissue concentrations); regular urine checks during treatment are mandatory Neurotoxicity: peripheral neuropathy Bone marrow toxicity: agranulocytosis, thrombocytopenia
Melarsoprol	New regimen Day 1–10: 2.2 mg/kg body weight (not evaluated for *T.b. rhodesiense*)	Treatment-induced encephalopathy Pyrexia Neurotoxicity: peripheral motor or sensory polyneuropathy Dermatological reactions: pruritus, urticaria, exfoliative dermatitis Cardiotoxicity Renal and hepatic dysfunction
Eflornithine	Most commonly used dosage regimen 100 mg/kg body weight at 6-h intervals for 14 days	Gastrointestinal symptoms such as nausea, vomiting, and diarrhea Bone marrow toxicity: anemia, leukopenia, thrombocytopenia Alopecia, usually toward the end of the treatment cycle Neurological symptoms such as convulsions
Nifurtimox	5 mg/kg body weight three times daily for 30 days	Abdominal discomfort such as nausea, pains, and vomiting in half of the treated patients, often leading to a disruption of the treatment course Neurological complications: convulsions Impairment of cerebellar function, polyneuropathy Skin reactions
NECT	Nifurimox 5 mg/kg every 8 h over 10 days + Eflornithine 200 mg i.v. every 12 h over 7 days	As above, but less as compared to monotherapy

main advantage of pentamidine over other drugs is the short treatment course and ease of administration. Adverse effects are related to the route of administration or its dose and are usually reversible.

In clinical medicine, pentamidine is also used as second-line therapy for visceral leishmaniasis and especially in the prophylaxis and treatment of opportunistic *Pneumocystis jirovecii* pneumonia in AIDS. Since the start of the HIV pandemic, the price of pentamidine was increased more than tenfold by producers, making it unaffordable by health institutions in low-income countries. After an intervention led by WHO, a limited amount of pentamidine is now made available for use in HAT.

39.7.2.2 Suramin

In the early twentieth century, the development of suramin, resulting from German research on the trypanosomicidal activity of various dyes ("Bayer 205"), was a major breakthrough in the field of tropical medicine. For the first time, African trypanosomiasis, at least in its early stages, became treatable without causing major harm.

Suramin is still used to treat stage I HAT, especially *rhodesiense*. Like pentamidine it does not reach therapeutic levels in cerebrospinal fluid. Suramin is injected intravenously after dilution in distilled water.

Adverse effects depend on nutritional status, concomitant illnesses (especially onchocerciasis), and the patient's clinical condition. Although life-threatening reactions have been described, serious adverse effects are rare.

39.7.3 Stage II Drugs

39.7.3.1 Melarsoprol

Until the systematic introduction of the arsenical compound melarsoprol in 1949, late-stage trypanosomiasis was virtually untreatable. Since then, it has remained the most widely used stage II antitrypanosomal drug both for *T.b. gambiense* and *rhodesiense* infections. It has saved many lives, but has a high rate of dangerous adverse effects. Increasing frequency of relapses and resistance has been reported in some parts of Congo, Angola, Sudan, and Uganda.

Melarsoprol clears trypanosomes rapidly from the blood, lymph, and cerebrospinal fluid. Its toxicity usually restricts its use to late-stage disease. It is given by slow intravenous injection; extravascular leakage must be avoided.

A new, simpler regimen is based on recently acquired knowledge of the drug's pharmacokinetics. The most important adverse effect is an acute encephalopathy, provoked around day 5–8 of the treatment course in 5–14% of all patients. There is severe headache, convulsions, rapid neurological deterioration, or deepening of coma. Characteristically, the comatose patient's eyes remain open. Most probably, this is an immune-mediated reaction precipitated by release of parasite antigens in the first days of treatment. The overall case fatality under treatment ranges between 2% and 12%, depending on the stage of disease and the quality of medical and nursing care. Simultaneous administration of glucocorticosteroids (prednisolone 1 mg/kg body weight; maximum 40 mg daily) might reduce mortality, especially

in cases with high cerebrospinal fluid pleocytosis. However, in areas where tuberculosis, amebiasis or strongyloidiasis are highly prevalent, corticosteroids have dangers of their own!

39.7.3.2 Eflornithine (DFMO)

Initially developed as antitumur agent, eflornithine (alpha-difluoro-methylornithine) was introduced in 1980 as an antitrypanosomal drug, in the hope that it might replace melarsoprol for treatment of stage II trypanosomiasis. However, exorbitant costs and limited availability have restricted its use mostly to melarsoprol-refractory cases of *gambiense* sleeping sickness. *T.b. rhodesiense* is much less sensitive due to a much higher turnover rate of the target enzyme ornithine-decarboxylase and, therefore, cannot be treated with Eflornithine.

It can be taken orally, but intravenous administration is preferred as it achieves a much higher bioavailability and success rate. Eflornithine should be administered slowly over a period of at least 30 min. Continuous 24-h administration is preferable if facilities allow.

The range of adverse reactions to eflornithine is wide, as with other cytotoxic drugs in cancer treatment. Their occurrence and intensity increase with the duration of treatment and the severity of the patient's general condition.

In the late 1990s, no pharmaceutical company has produced eflornithine for use against HAT, despite demands by WHO. The discovery of its therapeutic effect in cosmetic creams against facial hair helped to restimulate production and thus had a beneficial "spin-off effect" for HAT. In 2001, agreements were signed between WHO and two major drug producing companies which led to a "Public-Private-Partnership" (PPP) and helped to assure a sufficient supply of eflornithine and other drugs essential for the treatment of HAT. The agreement was prolonged several times on a 5-year basis.

39.7.3.3 Nifurtimox

Ten years after its introduction for the treatment of American trypanosomiasis in 1967, nifurtimox was found to be effective in the treatment of *gambiense* sleeping sickness. It has a place as second-line treatment in melarsoprol-refractory cases or in combination chemotherapy.

Nifurtimox is generally not well tolerated, but adverse effects are usually not severe. They are dose-related and rapidly reversible after discontinuation of the drug.

39.7.3.4 Combination Treatments in HAT

Melarsoprol, eflornithine, and nifurtimox interfere with trypanothione synthesis and activity at different stages. There is also experimental evidence that combinations of suramin and stage II drugs might also be beneficial. Therefore, by reducing the overall dosage of each individual component, drug combinations could perhaps reduce the frequency of serious side effects, and the development of resistance, which are such common problems in the treatment of sleeping sickness.

In 2009, a large multi-center clinical trial was published demonstrating the advantages of a nifurtimox eflornithine combination therapy (NECT) over

eflornithine monotherapy in *gambiense* HAT. NECT is now considered to be the treatment of choice in the late stage of *T.b. gambiense* infection.

39.7.3.5 Recent Developments in the Treatment of HAT

A major breakthrough was achieved in the last 10 years. When the international nongovernmental organization *Médecins sans Frontières* received the Nobel Peace Prize in 1999, the award money was used to form a new institution: *Drugs für Neglected Disease Initiative* (DNDi), which set out to bridge the gap between basic science and drug development. One major outcome was a new drug to treat HAT: flexinidazole, a nitroimidazole for oral use. In November 2018, the European Medicines Agency adopted a positive opinion for fexinidazole, and WHO followed by updating the guidelines for the treatment of West African HAT in 2019. Fexinidazole is now recommended for individuals of $\geq$ 6 years and $\geq$ 20 kg, in first and second stage T.b. gambiense infection with $<$100 leukocytes/μl in the cerebrospinal fluid. NECT remains recommended for those with with $\geq$ 100 leukocytes/μl. The use of flexinidazole for *T.b. rhodesiense* infection is still not recommended, but currently under investigation.

39.8 Preventive Measures

39.8.1 Individual Protection

Tsetse flies have a very patchy distribution. Infested strips of land are often well known to the local population and should be avoided as much as possible. HAT among tourists and occasional visitors to endemic areas is a rare but regularly reported event. Pentamidine or suramin chemoprophylaxis is historical, and can no longer be recommended.

Insect repellents are of limited use, as tsetse flies are visually oriented. Long-sleeved, bright clothing (avoidance of black or dark blue) can decrease attractiveness to these insects and is the best defense against attacking tsetse flies.

39.8.2 Control in Endemic Areas

In the past, tremendous efforts were undertaken to control the threat posed by trypanosomiasis to humans, livestock, and economic development in rural Africa. Control programs are based on the five complementary pillars given in Table 4.

Table 4 Control of HAT

1	Diagnosis and treatment of patients
2	Active case finding
3	Vector control
4	Implementation and continuation of a surveillance system
5	Training, health education and community participation

The most important strategy is active case finding. This requires mobile teams, which regularly visit villages in endemic areas. Mostly based on the results of CATT screening, patients, preferably in the early stage of the disease, are identified and treated. Gradually, the parasite reservoir is depleted. As *Glossina* is a relatively incompetent vector with infectivity rates usually below 0.1% and susceptible to control measures such as insecticide application or trapping, the combination of various approaches can lead to a complete break of the transmission cycle. This was achieved in the past in many places. However, the recent resurgence of sleeping sickness in areas ridden by war and civil unrest, in combination with the decreasing availability of drugs on the international market and the general loss of interest in health in Africa, gives rise to the fear that HAT will soon be again out of control.

Waterborne Zoonoses

Cryptosporidium and Cryptosporidiosis: Trickle or Treat?

40

Lucy J. Robertson and Ian Woolsey

Contents

Abstract

Cryptosporidiosis usually manifests as gastrointestinal infection and is associated with considerable morbidity and, in some circumstances, mortality. Effective treatment that is suitable for all patients, including those that are particularly affected by infection, children and the immunocompromised, is lacking.

There are several species of *Cryptosporidium*, some of which are zoonotic. The most important of these zoonotic species is *Cryptosporidium parvum*, but others, including *C. cuniculus* (predominantly associated with rabbits), *C. meleagridis* (predominantly associated with poultry), and *C. ubiquitum* (predominantly associated with sheep and cervids), are also of public health importance. *C. hominis* is generally only infective to humans. Subtypes within species have also been identified, with varying host-specificities, and, in addition, some genotypes have been identified that may, potentially, be recognized as individual species as more information accumulates.

A. Sing (ed.), *Zoonoses: Infections Affecting Humans and Animals*,
https://doi.org/10.1007/978-3-031-27164-9_32

Cryptosporidium is particularly suited to waterborne transmission, but foodborne transmission has also occurred on multiple occasions and outbreaks have been documented. In this chapter various waterborne outbreaks are reviewed, particularly those associated with zoonotic transmission, and also Standard Methods for analyzing water and food samples for contamination with these parasites. Although most waterborne outbreaks of cryptosporidiosis are due to *C. hominis* (and are therefore not zoonotic), most foodborne outbreaks are apparently zoonotic. Zoonotic transmission also occurs when there is close contact between infected animals and humans, particularly veterinary students and young children on petting farms. Thus, cryptosporidiosis is an important zoonosis with the potential for causing community-wide outbreaks of disease due to both waterborne and foodborne transmission.

Keywords

Cryptosporidium · Cryptosporidiosis · Foodborne transmission · Waterborne transmission · Zoonoses

40.1 Introduction

Cryptosporidium spp. are protozoan parasites that have been reported from a large variety of different hosts globally, including humans. To date, at least 25 different species of *Cryptosporidium* have been identified and described, and of these around 50% have been reported as being infectious to humans. In addition, multiple subtypes have been identified, some of which have zoonotic potential (e.g., chipmunk genotype I; Bujila et al. 2021), and the zoonotic horse genotype (Widmer et al. 2020), but have currently not been assigned species status. Additionally, subtypes within species can have a significant bearing on adaption to host species. It is becoming increasingly apparent that within species currently considered zoonotic, some subtypes may have specific host-specificity and may even solely infect humans, and therefore have no zoonotic potential. For *C. parvum* these include *C. p. anthroponosum* (IIc) (Nader et al. 2019) and subtypes IIe and IIm, whereas infections in livestock (cattle, sheep, and goats – the main sources of human zoonotic infection) are dominated by subtypes IIa and IId worldwide (Widmer et al. 2020). Furthermore, while some subtypes are capable of infecting both humans and other animals, their proclivity for a particular host species can have a bearing on their zoonotic potential. For example, *C. ubiquitum* subtype XIIa is found in ruminants worldwide, but subtypes XIIb-XIIf are predominantly found in rodents. Not surprisingly, the most common subtype found in humans in most parts of the world is XIIa. In the USA, however, there is a different pattern, with XIIb-XIId most commonly found in humans, and these genotypes were also the most common ones in rodents in the USA and also found in drinking water sources. As people in the USA probably have limited direct contact with wild rodents, it would seem that here *C. ubiquitum* zoonotic transmission may well be through rodent-contaminated water supplies (Li et al. 2014).

However, most reported human infections involve *C. parvum* (an important zoonotic species, particularly associated with infections in calves) or *C. hominis*, which is found primarily in humans. Other species that are considered important as human pathogens include *C. meleagridis*, a zoonotic infection primarily associated with infections in turkeys, but also relatively commonly identified in children in South America, and *C. cuniculus*, another zoonotic species particularly associated with infections in rabbits (Table 1). The other species of *Cryptosporidium* with zoonotic potential tend to be associated only with sporadic cases of human infection (e.g., *C. ubiquitum* infections that are usually associated with infections in sheep and cervids, although in some locations rodents) or are particularly associated with infections in immunocompromised patients (e.g., *C. suis* infections, more commonly associated with infection in pigs, and *C. felis* infections, more commonly associated with infections in cats; however one case of probably zoonotic transmission of *C. felis* from a cat to its immunocompetent owner has been documented (Beser et al. 2015). Although prevalence data are patchy, *Cryptosporidium* infection has emerged as a global public health problem, and has been reported from all continents except Antarctica (Wang et al. 2018).

Waterborne transmission is important in cryptosporidiosis; numerous waterborne outbreaks of cryptosporidiosis have occurred worldwide due to oocyst contamination of drinking water sources. The largest waterborne illness outbreak of any kind in the USA occurred in 1993 when over 400,000 people acquired cryptosporidiosis in Milwaukee (Mac Kenzie et al. 1994). More recently, around 27,000 people suffered from waterborne cryptosporidiosis in Östersund, Sweden in 2010 (Widerström et al. 2014).

In this chapter, emphasis will be primarily directed toward those species of *Cryptosporidium* that are predominantly zoonotic (that is, not *C. hominis*, as this is associated almost exclusively with human infections), and that have also been associated with waterborne or foodborne infection. Thus, *C. parvum* will be the main focus of the chapter, but also *C. cuniculus*. In addition, more general information will be provided including on the life cycle, clinical symptoms, diagnosis, and treatment of *Cryptosporidium* infections, both from a medical and a veterinary perspective, transmission routes and the epidemiology of infection, waterborne and foodborne outbreaks of zoonotic cryptosporidiosis, and the detection of *Cryptosporidium* in these matrices.

40.2 General Information on *Cryptosporidium* and Cryptosporidiosis: Life Cycle, Clinical Presentation, Diagnosis, and Treatment

For all *Cryptosporidium* species, the life cycle is direct (no intermediate host). When viable oocysts are ingested by an appropriate susceptible host, they usually excyst in the small intestine (*C. baileyi* can be associated with intra-tracheal infection in chickens) where the resultant sporozoites invade epithelial cells – and locate epicellularly (within the cell, but not within the cytoplasm). Repeated cycles of

Table 1 Overview of the major relevant species of *Cryptosporidium* in domestic animals (livestock and pets), including clinical presentation and zoonotic potential[a]

Cryptosporidium species	Host animal	Clinical notes for host animal species	Zoonotic potential
C. andersoni	Cattle	Older post-weaned calves, yearlings, and adults – some failure to thrive. Infects abomasal gastric glands	Yes
C. baileyi	Poultry	Detected in many different anatomical sites including digestive tract, respiratory tract, and urinary tract. Has been associated with high morbidity and mortality	A few reports from immunocompromised patients
C. bovis	Cattle	Common in post-weaned calves – less pathogenic than *C. parvum*	No
C. canis	Dogs	Often asymptomatic: may be associated with diarrhea	Yes: sporadic cases diagnosed in both immunocompetent and immunocompromised patients
C. cuniculus	Rabbits	Symptoms mostly mild or lacking, but severe cases have been reported	Yes: first identified as pathogenic to human during a waterborne outbreak
C. felis	Cats	May be associated with persistent diarrhea	Yes: sporadic cases diagnosed in both immunocompetent and immunocompromised patients
C. erinacei	Hedgehogs and horses	No symptoms reported	Yes: Sporadic cases reported; one report in an immunocompetent male
C. galli	Poultry	Infects the proventriculus, and has been associated with acute diarrheal disease	No
C. meleagridis	Poultry	Mostly intestinal and generally associated with mild symptoms	Yes: cases in immunocompetent and immunocompromised reported. Occurs particularly in Peru
C. parvum	Cattle	Common in pre-weaned calves – acute onset diarrhea. Intestinal location	Yes: considerable
	Cervids	Information on species detected among farmed deer is lacking; diarrhea in young calves, possibly severe, but can also be asymptomatic	

(continued)

Table 1 (continued)

Cryptosporidium species	Host animal	Clinical notes for host animal species	Zoonotic potential
	Dogs	Often asymptomatic: may be associated with diarrhea	
	Horses	Foals seem more susceptible; both asymptomatic cases and clinical infections (diarrhea) reported	
	Pigs	Less common than in bovines and small ruminants; diarrhea and vomiting	
	Small ruminants	Relatively common in pre-weaned lambs, associated with diarrhea	
C. scrofarum	Pigs	Relatively common, mild symptoms	No
C. suis	Pigs	Relatively common, mild symptoms	Few reports from immunocompromised patients
C. tyzzeri	Mice	No clinical signs or macroscopic changes associated with experimental infection	One case report in a 25-year old female
C. ubiquitum	Small ruminants	Common in older lambs and sheep, often apparently asymptomatic	Yes: sporadic cases in both immunocompetent and immunocompromised
C. xiaoi	Small ruminants	Common in older lambs and sheep, often apparently asymptomatic	No

[a]Information in the table derived and adapted from Santín and Trout (2008), Robertson and Fayer (2012), Robertson et al. (2014), Rašková et al. (2013), Kváč et al. (2014), Kaupke et al. (2014), Ryan et al. (2014), Ren et al. (2012), Jiang et al. (2020)

asexual reproduction result in destruction of these cells and the production of enormous quantities of meronts. A sexual cycle, gametogony, results in oocyst production. The oocysts sporulate while within the host (unlike other genera of Apicomplexa such as *Eimeria* spp. or *Toxoplasma gondii*) and may excyst within the same host, resulting in re-invasion of the epithelial cells and continuation of the infection. Alternatively, the oocysts are excreted in the feces, and are immediately infectious for the next host. These small oocysts (for most species they are approximately spherical and around 3–5 μm in diameter, although there is interspecies variation) are also very robust and can survive for long periods under cool, moist conditions.

In the human host, cryptosporidiosis is an enteric disease, generally characterized by watery diarrhea, abdominal pain, nausea, and related symptoms. However, other

symptoms have been reported, including low-grade fever and headache. Immunocompromised individuals and children in developing countries are most affected by cryptosporidiosis, and the relationship of infection with growth faltering, malnutrition, and diarrheal mortality is in need of further exploration (Shirley et al. 2012). In some individuals, however, infection may be largely asymptomatic.

The spectrum of symptoms depends not only on the host (age, nutritional status, immunity), but also on parasite factors including the number ingested and species. While cryptosporidiosis is self-limiting in immunocompetent individuals, a high relapse rate has been reported in some studies, as well as post-infection sequelae, which can be both gastrointestinal and non-gastrointestinal; in particular, after an outbreak in Sweden in 2010–2011, a follow-up study found that 48% of cases reported symptoms up to 28 months after the initial infection compared to non-cases. In addition to abdominal pain, these included nausea, fatigue, headaches, and joint pain (Lilja et al. 2018). In a recent systematic review that included 3670 cases, the most common long-term sequelae were diarrhea (25%), abdominal pain (25%), nausea (24%), fatigue (24%), and headache (21%) (Carter et al. 2020). In immunocompromised patients, the symptoms are often more severe, and infection may become chronic, debilitating, and potentially life-threatening, with high volumes of diarrhea, spreading of infection beyond the primary site, and severe weight loss.

In animals, the symptoms of *Cryptosporidium* infection appear to depend highly on parasite adaptation to the host and host age/immunological status, although results from different studies vary, and for many species infections are largely asymptomatic (see Table 1). Nevertheless, infections of some domestic animals with some species of *Cryptosporidium* may result in severe infection, usually with acute diarrhea as the main symptom. In some animals, especially young animals and particularly in association with concomitant infections or conditions, this may even be fatal (Xiao and Cama 2018; Cruvinel et al. 2020; Garro et al. 2021).

For both human and animal infections, diagnosis usually depends on the demonstration of oocysts (or their antigens or DNA) in fecal samples. As the oocysts are very small, the use of a staining technique, particularly using antibodies labeled with a fluorochrome and screening with fluorescence microscopy (immunofluorescent antibody testing; IFAT), is recommended. IFAT is considered to be a gold standard, although other techniques such as modified Ziehl-Neelsen (mZN) or auramine phenol staining may also be used successfully. However, mZN detects between 70% and 87.5% of infections compared with immunofluorescent antibody stains (Ryan et al. 2018), although a pre-screening concentration stage (formol-ether or flotation on sucrose or salt) may enhance sensitivity. Immunochromatographic kits are another diagnostic option that are rapid and simple to use for diagnostics; however they may have limited sensitivity in light infections, tend to be expensive, have a relatively short shelf life, and, to date, have not been widely adopted. Some investigations have shown poor sensitivity particularly in infections with species other than *C. hominis* or *C. parvum* (Agnamey et al. 2011). However, some next-generation kits, including kits not requiring refrigeration seem to have better sensitivity (Johansen et al. 2021).

While molecular methods such as PCR were not the mainstay of the general parasitology diagnostic laboratory a decade ago, in wealthy countries with the necessary infrastructure this has now changed, and molecular assays for gastrointestinal parasites are now the norm and tend to be of superior sensitivity and specificity. Indeed, molecular techniques have been reported to detect more than double the number of infections that would be detected by mZN (Checkley et al. 2015; Zahedi and Ryan 2020). A nested PCR has been developed for the detection of all *Cryptosporidium* spp. that can be differentiated by sequencing the PCR amplicons, but this is only genus-specific and is unable to identify species (Robinson et al. 2020). However, a duplex real-time PCR assay has also been developed, able to differentiate between *C. parvum* and *C. hominis* (Robinson et al. 2020). In addition, several assays based on multiplex PCR assays are being approved by the US Food and Drug Administration (FDA) in recent years. The majority of these tests are panel assays that are suitable for automation and thus enable higher throughput and faster results. Additionally, they are suitable for the simultaneous detection of numerous enteric parasites, or even different enteric pathogens (with gastrointestinal bacteria and viruses included in the panel). These tests are expensive, currently between US$ 30 and 155 per sample with equipment costs running up to US$40,000, which is an obstacle to their implementation even for laboratories in developed countries. However, they are a very useful tool in epidemiological surveillance, research, and outbreak investigations (Ryan et al. 2017). Further work is required to assess how well these tests perform on different sample types (Ryan et al. 2018).

Successful treatments for cryptosporidiosis in both humans and animals remain elusive, although one treatment (nitazoxanide) has been FDA-approved for symptom alleviation in immunocompetent humans and has shown promise for treating cryptosporidiosis in animals. Current treatments for ruminant cryptosporidiosis include halofuginone lactate or paromomycin, both of which reduce oocyst shedding and decrease the severity of diarrhea (Innes et al. 2020). Failure of therapeutic agents being evaluated is often considered to reflect the specific taxonomic position of *Cryptosporidium*, which indicates that it is more closely related to organisms such as gregarines rather than to classical coccidia (Ryan et al. 2016). For immuncompromised patients with HIV-infection, the development of effective antiretroviral therapies has been of more value for decreasing mortality due to cryptosporidiosis than any parasite-targeted treatment, and currently supportive care and antiretroviral therapy form the basis of treatment for *Cryptosporidium* in patients with HIV/AIDs (Squire and Ryan 2017). In developing countries, however, antiretroviral therapy coverage is often limited and thus cryptosporidiosis in HIV patients, particularly in association with other insults to health, may prove fatal.

The identification of *Cryptosporidium* as one of the four main etiological agents associated with serious childhood diarrhea (Kotloff et al. 2013) indicates that there is still a need to develop an effective chemotherapy targeting this parasite. The burden of diarrhea caused by *Cryptosporidium* infection was assessed in The Global Burden of Diseases, Injuries, and Risk Factors study (GBD) 2016 along with more than 300 causes of death and disability. By systematically quantifying the morbidity and mortality associated with these causes, *Cryptosporidium* infection was identified as

the fifth leading diarrheal etiology in children under 5 years with acute infection causing more than 48,000 deaths and in excess of 4.2 disability-adjusted life-years (DALYs) lost globally in 2016. These estimates on the burden of *Cryptosporidium* infection were then supplemented via a meta-analysis approach to determine the effect on childhood diarrhea caused by *Cryptosporidium* infection on physical growth parameters. The significant burden of acute short-term diarrhea was found to be a substantial underestimation of the true burden of disease when height-for-age, weight-for-age, and weight-for-height were considered, with an additional 7.85 million DALYs associated with these longer-term effects on childhood development (Khalil et al. 2018).

40.3 Transmission Routes and Epidemiology of *Cryptosporidium* Infection

As *Cryptosporidium* oocysts are immediately infectious upon excretion (unlike the majority of classical coccidial oocysts), direct fecal oral transmission (animal-to-animal, animal-to-human, human-to-animal, and human-to-human), as well as re-infection of the excretor, is relatively common and has been well documented. Although it is often impossible to exclude entirely the possibility that transmission has occurred via a contaminated vehicle, person-to-person spread is particularly well described within families (often secondary cases after a primary outbreak infection), in institutions such as childcare nurseries, and in hospitals. With respect to zoonotic transmission, infection of veterinary students examining diarrheic calves has, in particular, been well-documented and also of children visiting petting farms where they have direct contact with young animals. There are some reports where pet-to-human transmission has been convincingly demonstrated (e.g., Beser et al. 2015). However, again infection from environmental contamination (that is, from oocyst contamination of a transmission vehicle such as food) or common source transmission to both hosts often cannot be entirely excluded in such settings.

As well as being immediately infectious, *Cryptosporidium* oocysts are also notoriously robust, being able to survive in damp, cool environments for weeks or months, and being resistant against a range of commonly used disinfectants, including chlorination at levels used by the water industry. This means that transmission via a vehicle, such as water or food, is also well-documented, particularly as this may lead to an outbreak situation in which hundreds or thousands of individuals may be infected. It should, however, be noted that oocysts do not survive prolonged freezing at below −15 °C, freeze-thawing, or desiccation and that they are also killed by cooking (EFSA 2018).

In general, clinical cryptosporidiosis occurs most often in the toddler age group (1- and 2-year olds), presumably due to lack of previous infection (and hence immunity) and due to the unhygienic behavior in this age group, especially mouthing of myriad objects. Although more commonly diagnosed in male children, possibly due to greater exposure to contaminated objects or perhaps an artifact associated with medical consultation, in adults it is women who tend to be more frequently

diagnosed with clinical cryptosporidiosis than men (Nichols 2008). This is probably due to greater exposure of women than men to children with cryptosporidiosis, who may be excreting infective oocysts, but might also reflect that drinking water consumption is often higher among women. A range of studies have explored risk factors for infection. Although these vary according to study conditions, particularly whether associated with an outbreak or with sporadic infections and whether the study has focused on a population in an industrialized or developing country, in general, the key risk factors identified include: ingestion of contaminated drinking or recreational water; contact with infected persons or animals, particularly calves and lambs; travel to areas where the disease is considered endemic; and contact with children under 6 years of age (particularly, but not exclusively, children with diarrhea) (Bouzid et al. 2013). Interestingly, several investigations have indicated a negative association between cryptosporidiosis and eating raw vegetables, while, in contrast, various outbreaks of cryptosporidiosis have been associated with consumption of fresh produce. It has been proposed that this apparently protective effect may be due to repeated exposure to low numbers of *Cryptosporidium* oocysts on raw vegetables thus allowing the development of protective immunity (Bouzid et al. 2013). Risk factors for infection will vary by region; in Ethiopia, for example, an in-depth exploration of risk factors associated with pediatric cryptosporidiosis identified use of public tap water and moderate acute malnutrition as relevant risk factors for cryptosporidiosis diarrhea, neither of which are likely to occur widely in most industrialized countries (Johansen et al. 2021). In a recent meta-analysis of risk factors for *Cryptosporidium* infections in low to middle income countries, significant reported risk factors were animal contact, household diarrhea, and open defecation; interestingly, however, poor quality drinking water was not found to be significant (Bouzid et al. 2018).

Associations have also been made between season and cryptosporidiosis (Lal et al. 2012), with infection peaks in spring and late summer/early autumn and least cases reported in winter, regardless of the country of study. It is suggested that the spring peak may reflect agricultural practices (calving and other young livestock), as well as greater potential for water contamination due to heavy rainfalls and spring snowmelt (Lal et al. 2012). In some instances, the late-summer peak may represent the return home of tourists who have been vacationing in more endemic areas, and perhaps associated with behaviors resulting in greater exposure risks, such as increased contact with recreational water.

The development and use of tools for molecular epidemiological studies have provided useful insights into the transmission of cryptosporidiosis. Small subunit (SSU) rRNA-based tools are now commonly used for genotyping *Cryptosporidium* identified in both human and animal infections, and also for oocysts isolated from water and other environmental samples (Xiao 2010). At the sub-genotyping level, one of the popular tools is the DNA sequence analysis of the 60 kDa glycoprotein (gp60) gene. This gene contains tandem repeats of the serine-coding trinucleotide TCA, TCG, or TCT at its 5′ end, along with extensive sequence differences in the non-repeat regions, and has been used to categorize *C. parvum* and *C. hominis* (the most common *Cryptosporidium* spp. causing infections in humans) to subtype

families (Xiao 2010). Besides the sequence heterogeneity of the gp60 gene, which makes it useful as a *Cryptosporidium* subtyping tool (it is one of the most polymorphic markers identified in the *Cryptosporidium* genome), it is also of biological relevance. The gp60 gene codes for a protein that is located on the surface of the apical region of invasive stages of the parasite, and thus provides a biological possibility of associating parasite characteristics, including clinical presentation, with subtype family.

The use of these and other molecular tools has revealed that, although cryptosporidiosis is generally considered an infection of global importance, there is a clear geographical distribution of *C. parvum* and *C. hominis* in human infections. Although both *C. parvum* and *C. hominis* are common in European countries, *C. parvum* is the dominant species in humans in the Middle East, while in the rest of the world, particularly in developing countries, *C. hominis* is usually the predominant species in humans (Xiao 2010). Furthermore, within-country geographic variations have also been noted, with *C. parvum* infections being more common than *C. hominis* in rural regions of the USA and Ireland (Xiao 2010). These data suggest that zoonotic cryptosporidiosis is more common in the Middle East and Europe than in developing countries, at least at present; this is also supported by some of the data from surveys of calves in some developing countries, where infection rates have sometimes been unexpectedly low (Chang'a et al. 2011; Robertson et al. 2020; Guo et al. 2021). Indeed, in Africa, zoonotic *Cryptosporidium* spp. transmission appears to occur a great deal less frequently than human–human transmission. In a recent review (Robertson et al. 2020), numerous possible reasons for this were suggested. These include that management practices predominant in Africa such as smaller herd sizes, outdoor housing, and the use of hay bedding (reducing close contact between animals and oocyst survival rates, respectively) are both associated with lower risk of transmission; that established cattle herds in Africa are predominantly of *B. indicus* breeds with evidence suggesting that these breeds may be more resistant to *C. parvum* infection, and year-round breeding also means that seasonal peaks in environmental contamination in spring, associated with lambing and calving do not occur. Furthermore, it was noted in Africa, and potentially low-income settings in general, that infants and children are likely to receive low level exposure via human transmission thus potentially inferring a certain degree of protection against later zoonotic infection (Robertson et al. 2020).

40.4 Waterborne Transmission of Zoonotic *Cryptosporidium* Species

Cryptosporidium lends itself to waterborne transmission due to various factors in its biology. These factors include the low infective dose (theoretically as low as a single oocyst, although human volunteer studies suggest tens of oocysts), the large numbers of oocysts excreted during infection – calves infected with *C. parvum* may produce as many as 6×10^7 oocysts per gram of feces, and a single infected calf may excrete 4×10^{10} oocysts during its second week of life and 6×10^{11} oocysts during

its first month of life (Uga et al. 2000; Nydam et al. 2001), and the robustness and longevity of the oocysts in damp, cool environments, including upon exposure to drinking water chlorination regimes. In addition, the small size of oocysts enables them to penetrate some of the physical barriers in water treatment. Together, these factors have resulted in numerous outbreaks of waterborne cryptosporidiosis, both associated with drinking water and also with recreational water. A review of 325 outbreaks of human disease attributed to the waterborne transmission of pathogenic protozoa (from the beginning of records up until around 2003) indicated that the majority of them (approximately 51%) were caused by *Cryptosporidium* infection (Karanis et al. 2007). Although the majority of these are suggested to be *C. parvum* infections, the lack of molecular characterization methods at the time of most of these outbreaks coupled with the fact that the majority of different species of oocysts are morphologically indistinguishable mean that it is likely that a large proportion of these outbreaks were actually due to *C. hominis* infections (and possibly some other species of *Cryptosporidium*). A follow-up review of more recent outbreaks (Baldursson and Karanis 2011) indicated that *Cryptosporidium* spp. continued to be the dominant etiological agent of waterborne outbreaks of protozoan disease between 2004 and 2010, with more than 60% of the 199 documented outbreaks due to *Cryptosporidium* infection. Although the review does not provide a species overview for these outbreaks (*C. hominis* or *C. parvum*), reference to the original papers cited in the review demonstrates that the majority of these outbreaks for which species information was available were due to *C. hominis*. However, even for outbreaks with *C. parvum*, this knowledge is insufficient to determine whether zoonotic transmission has occurred (from animals to humans, via water as the transmission vehicle), since contamination can also occur from human sewage even with *C. parvum* infections, and thus traditional epidemiological data analysis is needed in addition to molecular epidemiological data in order to determine the source of contamination. However, when the etiological agent is *C. hominis*, then zoonotic transmission is much less likely to have occurred (Nydam et al. 2005).

Nevertheless, some waterborne outbreaks of cryptosporidiosis have often been attributed to contamination of water catchments by animals, and although sometimes the indications implicating zoonotic transmission have been speculative (and later proven to be incorrect or unlikely), on other occasions the evidence has been substantial.

For example, grazing cattle or slaughterhouse effluent contaminating Lake Michigan were mentioned as two possible sources of *Cryptosporidium* oocysts in the large outbreak in Milwaukee, Wisconsin in 1993 (Mac Kenzie et al. 1994). But retrospective analysis of clinical isolates revealed that the outbreak was caused by the anthroponotic *C. hominis* (Sulaiman et al. 1998), and it is worth noting that among the most recent waterborne outbreaks in the UK (compiled by Chalmers (2012)), the majority do not indicate zoonotic transmission as *C. hominis* infection predominates.

However, during an outbreak in Scotland in 1988 substantial testing of water and environmental samples was conducted (Smith et al. 1989) – albeit with the less sophisticated methods available at that time – and they were less sensitive and

specific than those currently developed (sucrose flotation was used, for example, rather than immunomagnetic separation (IMS)), which indicated that irregular seepage of oocyst-containing water into a break-pressure tank was the most likely cause of the outbreak. This seepage was considered to have been exacerbated by heavy rains, and the occurrence of muck spreading and the spraying of cattle slurry prior to the outbreak in the vicinity of a fire clay pipe draining into the break-pressure tank indicated that this was the likely zoonotic source of oocysts (Smith et al. 1989). Another outbreak in the UK in 1992 was again associated with heavy rainfall and, in this instance, flooding of a field in which livestock (species not mentioned) grazed and thereafter drainage into a shaft associated with a groundwater drinking water supply (Bridgman et al. 1995) suggests again waterborne zoonotic transmission. It should be noted that although the traditional epidemiological investigations associated with both these outbreaks was extensive, they occurred before the introduction of reliable molecular tools that could be used to determine whether the etiological agent was potentially zoonotic, and, moreover, before *C. parvum* and *C. hominis* had been recognized as separate species.

Although zoonotic transmission of cryptosporidiosis from lambs has been definitively shown in various outbreaks associated with direct contact such as petting farms (Gormley et al. 2011; Robertson et al. 2014), and a range of waterborne outbreaks of cryptosporidiosis in the UK have implicated sheep as the source of the infection, a lack of studies in which oocysts from both grazing lambs or sheep and oocysts in water and in patient samples have been characterized has resulted in a lack of clarity over whether these really are the source of contamination (Robertson 2009). This is unfortunate, as sometimes the assumption that lambs or sheep are the source of contamination has resulted in measures being implemented that may have been unnecessary. These have included extensive boil water notices, relocation of sheep during the lambing season, and even contributed to the closure of some sheep farms, all measures that may result in anxiety and frustration for local communities (Robertson 2009). Thus, now that we have tools to help in deciding sources of contamination of water supplies, it is important to ensure that they are appropriately used.

While the focus of zoonotic transmission, including by the waterborne route, tends to focus on *C. parvum*, it should be noted that sheep are also frequently infected with *C. ubiquitum*, and this species has also been detected in a number of sporadic human cases globally (Cieloszyk et al. 2012; Elwin et al. 2012; Feltus et al. 2006; Leoni et al. 2006; Ong et al. 2002; Soba et al. 2006; Trotz-Williams et al. 2006). As this species has also been identified in storm water, wastewater, raw water, and drinking water (Jiang et al. 2005; Liu et al. 2011; Nichols et al. 2010; Van Dyke et al. 2012) and was the third most common species in raw water in Scotland, as well as the most common species identified in drinking water (Nichols et al. 2010), there is a clear potential for zoonotic waterborne transmission. Given that no such waterborne outbreaks have been described to date, it is possible that infectivity to humans is relatively limited. Likewise, deer also are relatively commonly infected with both *C. parvum* and *C. ubiquitum*, but there have been no documented cases of proven zoonotic transmission from deer. A study from Australia suggested that deer

were not likely to be a threat for zoonotic transmission of cryptosporidiosis in a specific protected drinking water supply watershed (Cinque et al. 2008); a study from the USA, however, reached the opposite conclusion and stated that deer in a particular watershed posed a potential threat regarding zoonotic cryptosporidiosis and therefore were appropriate targets for source water protection (Jellison et al. 2009). In addition, subtyping of *C. ubiquitum* samples from the USA has suggested that subtypes XIIb-XIId from wild rodents have the potential to infect humans via waterborne transmission (Li et al. 2014).

Another zoonotic species of *Cryptosporidium, C. cuniculus,* has, however, been associated with waterborne transmission. *C. cuniculus* is rarely, but sporadically, identified in human infections (e.g., of 3030 *Cryptosporidium*-positive fecal samples submitted for routine typing in the UK between 2007 and 2008, only 37 were diagnosed as *C. cuniculus* (1.2%); Chalmers et al. 2011) and transmission of *Cryptosporidium* to humans from farmed rabbits has not been recorded (Robertson et al. 2014). Indeed, an investigation exploring associations between farm animals and human patients with cryptosporidiosis did not indicate rabbits as a particular source of infection among farmed animals (Smith et al. 2010). However, a waterborne outbreak of cryptosporidiosis in England in 2008 affecting 29 people was identified to the species level in eight patients as *C. cuniculus*, and to the subtype level as subtype VaA18 (Chalmers et al. 2009). Furthermore, *Cryptosporidium* oocysts of the same species and sub-genotype were identified in the colon of a carcass of a rabbit (presumably wild) that was found in a tank at the implicated water treatment works. Thus, this outbreak, which was investigated using both traditional and molecular epidemiological tools, convincingly demonstrates a waterborne outbreak of zoonotic cryptosporidiosis.

Another of the most important zoonotic species of *Cryptosporidium* is *C. meleagridis*. This species is the third most common species in human cryptosporidiosis worldwide (Robertson et al. 2014). Studies on the prevalence and species distribution for cryptosporidiosis in humans in South America have identified that the prevalence of *C. meleagridis* infection is very similar to that of *C. parvum* (Cama et al. 2003, 2007, 2008). Although *C. meleagridis* infection is usually associated with infection in turkeys, the only documented case of zoonotic transmission from a bird source demonstrates that chickens rather than turkeys were the source of infection (Silverlås et al. 2012). Moreover, no waterborne transmission has been documented. However, as not all patients in epidemiological investigations that have been diagnosed with *C. meleagridis* infections have had contact with birds or even animals (Elwin et al. 2012), transmission via a contaminated vehicle (such as food or water) seems possible, or – alternatively – direct infection from another person with that infection.

As well as adequate water treatment, including sufficient barriers to ensure acceptable removal and/or inactivation of pathogens such as *Cryptosporidium*, one of the major mechanisms for ensuring safe water supply is implementing an appropriate catchment control policy. With respect to zoonotic *Cryptosporidium* infection, this may mean limiting or restricting access of domestic animals and wildlife to vulnerable sites, particularly watercourses, associated with drinking water supply

and possibly recreational use. Such restrictions might be of particular validity during periods of heavy rain, when wash-off contamination is likely to be highest. Environmental studies have demonstrated that contamination of surface waters with *Cryptosporidium* oocysts are significantly affected by land use, such as cattle husbandry and manure management practices, as well as seasonal and weather characteristics (Keeley and Faulkner 2008). However, such restrictions regarding grazing of domestic animals, for example, may have little impact if there is a large reservoir of infection in wild animals, and will also serve little purpose if the restricted animals are not infected with zoonotic pathogens. For example, a study in Canada that sought to investigate the contribution of dairy cattle to protozoan contamination of water sources (Budu-Amoako et al. 2012) concluded that the *Cryptosporidium* oocysts being shed were predominantly non-zoonotic *C. bovis* and *C. andersoni*, and therefore of little significance to public health. Given that pre-weaned calves are the most likely age group and species to shed *C. parvum* oocysts, it could be argued that measures to protect water catchments from young ruminants and their feces, including spreading of calf manure on fields where runoff cannot occur, should be directed toward this animal group (Robertson et al. 2014). However, it should be emphasized that water courses should be subjected to individual risk assessment and measures implemented accordingly; it should not be forgotten that even with adequate catchment protection and water treatment, unexpected events may occur that nevertheless may result in contamination (e.g., the entry of a rabbit with *C. cuniculus* infection into water treatment works). Therefore, it is necessary to follow outbreaks of diarrhea in the community, and – where appropriate – to analyze water samples for contamination.

40.5 Foodborne Transmission of Zoonotic *Cryptosporidium*

Although cryptosporidiosis is generally considered a waterborne, rather than foodborne, disease, the potential for foodborne transmission is widely acknowledged. Indeed, it has been estimated that 10% of all *Cryptosporidium* infections are foodborne (EFSA 2018). Globally, *Cryptosporidium* has been ranked the fifth most important pathogen out of 24 potentially foodborne parasites with only *Taenia solium, Echinococcus granulosus, Echinococcus multilocularis*, and *Toxoplasma gondii* exceeding it (FAO/WHO 2014) and caused 8.6 million cases of foodborne illness in 2010, 3759 deaths and 296,156 DALYs (Ryan et al. 2018). A European ranking of foodborne parasites (Bouwknegt et al. 2018) also placed *Cryptosporidium* as the fifth most important, although regionally second highest in both Northern and Western Europe; a similar exercise from India also placed *Cryptosporidium* in the second position (Robertson et al. 2015). Food contamination with *Cryptosporidium* oocysts may occur during production, processing, or preparation, and the longevity of the oocysts that is enhanced on moist and sheltered surfaces of fruit and vegetables (Gajadhar and Allen 2004; Ryan et al. 2018) means that they can survive various processing treatments, including chlorine baths and blast freezing (Duhain et al. 2012). This longevity can make trackback measures to an outbreak difficult as

there can be a long lag time between the contamination of a food item and its consumption, and, in addition, there may be a prolonged period of several days between infection and symptoms, and between symptoms and diagnosis. Washing of fresh produce may fail to remove contaminating oocysts, since they not only adhere to surfaces but may also infiltrate into leafy vegetables via stomatal openings (Macarisin et al. 2010a, b). However, a study looking at removal of *Cryptosporidium* oocysts (and other parasites) from artificially contaminated blueberries and raspberries found that simple rinsing under cold water for 1 min removed over 85% of contaminating *Cryptosporidium*, and washing in a vinegar solution or using a salad spinner to remove excess water increased removal efficiency to, on average, over 90% (Temesgen et al. 2021).

Fewer foodborne cryptosporidiosis outbreaks have been documented than waterborne outbreaks. Of the 40 reported cryptosporidiosis outbreaks (in which molecular characterization was performed) in the last 10 years, 27 have been waterborne while only 13 foodborne outbreaks have been reported (Zahedi and Ryan 2020). This could be because fewer foodborne outbreaks have occurred (because, for example, the oocysts survive less readily on food due to potential for desiccation, freezing, or heating, or because contamination of food is less likely to occur than contamination of water). Alternatively, this could reflect that fewer people tend to be infected in foodborne outbreaks (due to more restricted distribution of the contaminated product), and therefore the event may be less likely to be identified. Additionally, traceback is often hampered by the fact that the food item in question has been consumed and therefore not available for testing (Gajadhar and Allen 2004; Ryan et al. 2018). One interesting aspect of comparing foodborne outbreaks and waterborne outbreaks is that whereas waterborne outbreaks of cryptosporidiosis tend to be most frequently caused by the anthroponotic species *C. hominis*, foodborne outbreaks tend to be most frequently caused by the zoonotic species *C. parvum*. In a review considering geographical distribution of foodborne cryptosporidiosis (Robertson and Chalmers 2013), seven of the eight outbreaks in which molecular analyses were conducted on samples report *C. parvum* as the etiological agent, and only one *C. hominis.* A further outbreak of foodborne cryptosporidiosis from May 2012 in the UK (McKerr et al. 2015) was primarily epidemiologically associated with consumption of ready-to-eat pre-cut mixed leaves from a major supermarket chain and was also found to be due to *C. parvum*. Of the outbreaks in the last 10 years only 6 of the 27 waterborne outbreaks reported *C. parvum* as the etiological agent and only 1 case of *C. hominis* was reported in 13 foodborne outbreaks (Zahedi and Ryan 2020). Infection with *C. parvum* does not necessarily indicate zoonotic transmission from an animal source, since humans can also transmit *C. parvum*. However, epidemiological investigations into at least some of these outbreaks suggest that an animal source of *Cryptosporidium* is probable. Moreover, zoonotic transmission also seems likely for some of the outbreaks in which molecular analyses were not conducted, as evinced from traditional epidemiological investigations. For example, an outbreak in the USA in 2003 in which ozonated apple cider was the infection vehicle was demonstrated to be largely due to infection with two similar sub-types of *C. parvum* (for one patient, infection with *C. ubiquitum* was

recorded) (Blackburn et al. 2006). However, in two earlier outbreaks of cryptosporidiosis associated with consumption of apple cider, species identification had not been conducted (Millard et al. 1994; Anonymous 1997), although evidence from one of these outbreaks strongly suggested that animals were the probable source of infection, with calves with cryptosporidiosis grazing in the orchard from which the apples had been obtained. The first outbreak linked to apples reported outside the USA occurred in Norway in Autumn 2018. The species was *C. parvum,* GP60 subtype IIaA14G1R1, and was linked to one container of self-pressed apple juice suggesting an isolated contamination event suggesting contaminated ground at the orchard, contaminated fruit, or contamination during processing (Robertson et al. 2019). It was unclear whether human or animal contamination was most likely to be responsible for the contamination event.

Another foodborne outbreak of cryptosporidiosis was suspected to have been transmitted via the consumption of vegetables that had been sprayed with water possibly contaminated with cattle feces, with both human cases and implicated animals infected with the same subtype of *C. parvum* (Collier et al. 2011). Furthermore, it would seem likely that the outbreaks of cryptosporidiosis that have been postulated to have been caused by the consumption of inadequately pasteurized cow milk (Gelletlie et al. 1997; Harper et al. 2002) are due to zoonotic transmission, although this cannot be proven in the absence of insufficient information.

Why foodborne cryptosporidiosis should more likely be due to zoonotic transmission and why waterborne cryptosporidiosis should more likely be due to anthroponotic transmission is not entirely clear. It could, at least partly be the result of cryptosporidiosis being historically regarded as a waterborne parasite leading to under-assessment and underreporting of food as a transmission vehicle coupled with fewer international standards for testing food compared to drinking water (EFSA 2018). However, it would seem probable that greater effort is made to keep a barrier between human sewage and food production areas, but it is simply not possible to maintain this barrier between human sewage and water catchment areas. Furthermore, along the farm-to-fork food production chain there are various opportunities for contact between food products and animal feces from potentially infected animals, but relatively few opportunities for contact between human sewage and food products.

40.6 Detection of Zoonotic *Cryptosporidium* Oocysts in Water Supplies and on Food

Our understanding of the importance of the waterborne route of infection for *Cryptosporidium*, particularly exacerbated by the occurrence of community-wide outbreaks with hundreds or thousands of individuals infected, led to a need for analysis of water samples for these parasites. Such information provides a handle on the extent of contamination in different water sources and how this may be affected by factors such as weather patterns and season. Such data are also used as input for risk assessments, to evaluate whether water supplies are likely sources of infection in

outbreak situations, to determine the efficacy of different removal or inactivation measures, and to have a basis for recommending the type and extent of water treatments and interventions that are necessary for a particular water supply. However, analysis of water samples for *Cryptosporidium* oocysts is not easy. Unlike bacteria they cannot be readily cultivated, and there are no simple, easy-to-quantify indicators or appropriate surrogates. Thus, in order to detect and quantify *Cryptosporidium* contamination of water, the individual oocysts must be isolated and enumerated or their DNA (or some other marker) must be isolated and the quantity measured. In order to determine if the oocysts detected are zoonotic, molecular analyses must also be conducted, either downstream from detection or as a component of the detection method.

Over the past 30 years or so, different approaches and equipment have been investigated for their suitability at conducting this task. Method requirements include reproducibility, specificity, and sensitivity (given the low concentrations of these parasites usually occurring in water). Additionally, it is preferable for the method to be cheap, user-friendly, rapid, and with the potential to be implemented in a standard analytical laboratory.

The first documented Standard Methods for analysis of water for *Cryptosporidium* oocysts were probably the US EPA ICR (United States Environment Protection Agency Information Collection Rule) Method (US EPA 1996) and the "SCA Blue book method" (Anonymous 1990). These methods included collection of a water sample by filtration through a yarn-wound polypropylene filter; removal of all particulates from the filter using detergents and mechanical extraction; concentration of the particles by centrifugation (or settling); purification/isolation of putative parasites by buoyant density gradient centrifugation (usually using Percoll-sucrose, specific gravity of 1.10); detection of the parasites using immunofluorescent antibody testing (IFAT) in which the sample concentrate is incubated with fluorochrome-labeled monoclonal antibodies against the oocyst walls.

These methods have been improved over time, particularly with respect to the production of improved sampling techniques (different filter types and continuous-flow centrifugation) and the use of IMS for isolation of oocysts from the sample concentrate prior to detection (Anonymous 2006). Interlaboratory trials have been used for validation work for different techniques, and now the most commonly followed Standard Methods are probably US EPA Methods 1622 and 1623.1 (both of which are regularly updated and available for downloading from the US EPA homepage), and ISO Method 15,553 (Anonymous 2006). In addition, individual countries or regions have also produced versions of these methods or considered them.

State-of-the-art detection methods are coming online and include on-chip biosensors, electrochemical biosensors, capacitance, and nanotechnology such as the use of semiconductor quantum dot technology to fluorescently label oocysts. While there is no significant difference between this new technique and FITC, quantum dots are more photo-stable and generate 50% less interference with other fluorescence material in water samples. Oligonucleotide gold nanoparticles have been used for molecular detection without DNA amplification and these nanoparticles have

been employed in immuno-dot blot assays, increasing sensitivity of parasite detection 500-fold when compared to conventional ELISA. These results demonstrated good correlation with those of conventional PCR validation (Luka et al. 2021) making this method a promising candidate for future use in routine water screening assuming prices become economically competitive with current detection methods.

Methods for detection of *Cryptosporidium* contamination of foods has lagged behind that for water, although an ISO Standard that is directed toward analysis of leafy green vegetables and berry fruits has been published (ISO 18744; Anonymous 2016). This uses a similar sequence of steps as the water analysis method, but with elution of the parasites from the fresh produce by a washing procedure prior to concentration by centrifugation, isolation by IMS, and detection by IFAT. Immunomagnetic bead separation (IMS) methods have significantly improved the sensitivity of immunological methods. IFAT detection of *Cryptosporidium* on lettuce and raspberries after IMS has been used with increased sensitivity and specificity of up to 95.8% and 85.4%, respectively (Cook et al. 2006).

Approaches used for *Cryptosporidium* detection in different food matrices, including fresh produce, fruit juice, milk and dairy products, meat, and shellfish, have been extensively described (EFSA 2018; Chalmers et al. 2020); in general, the most sensitive methods require oocyst separation from the sample matrix followed by detection either by IFAT or PCR. As IFAT is the detection method described in the ISO Standard, this remains the method most commonly used and is considered the gold standard. However, there is a need for standardization and although ISO 18744 is considered a good starting point for sample surveys, further refinement to increase its range of applicability has been recommended (Chalmers et al. 2020). The methods are not considered suitable for routine analyses for food operators, and considering factors such as the variety of relevant food matrices, cost, and practicability, transition from IFAT to molecular detection has been recommended (Chalmers et al. 2020). The EFSA-funded IMPACT project is one progression toward this recommendation (Mayer-Scholl et al. 2021).

40.7 Conclusion

Cryptosporidiosis is an important protozoan disease that is associated with considerable morbidity and, in some circumstances, mortality on a global level. The main symptom is diarrhea. One of the most important facets of this infection from a clinical perspective is the absence of an effective treatment that is suitable for all patients, including children and the immunocompromised, two patient groups that are particularly affected by infection.

There are several species of *Cryptosporidium*, some of which have some degree of host-specificity, but many of which have the potential to infect humans and are considered zoonotic. The most important of these is *C. parvum*, but other species, including *C. cuniculus* (predominantly associated with rabbits), *C. meleagridis* (predominantly associated with poultry), and *C. ubiquitum* (predominantly associated with sheep and cervids, but also rodents) are also of relevance to public health.

In addition, *C. hominis* affects predominantly humans, but occasional infections in other animals have been reported. Various characteristics of *Cryptosporidium* mean that it lends itself to waterborne transmission, and many waterborne outbreaks have been documented, often affecting hundreds or thousands of individuals. The importance of the waterborne transmission route has instigated the development of Standard Methods for analyzing water samples for contamination with these parasites, and methods for food have also been developed. Although the majority of documented waterborne outbreaks of cryptosporidiosis are due to infection with *C. hominis* (and are therefore not zoonotic), the majority of foodborne outbreaks of cryptosporidiosis are apparently zoonotic, as evidenced by both traditional and molecular epidemiological investigations. In addition, zoonotic transmission has frequently been recorded when there is close contact between infected animals and humans, particularly veterinary students and young children on petting farms. Thus, cryptosporidiosis is an important zoonosis, with the potential for causing community-wide outbreaks of disease due to both waterborne and foodborne transmission.

Contents

Abstract

The flagellated protozoan *Giardia duodenalis* is the etiologic agent of giardiasis, a very common gastrointestinal infection of mammals, including humans, with a global distribution. The clinical manifestations of giardiasis are quite variable, and range from the absence of symptoms to acute diarrhea, characterized by dehydration, abdominal pain, flatulence, nausea, vomiting, fatigue, and weight loss to chronic infection. There is considerable genetic variation within *G. duodenalis*, and eight major genetic groups, or assemblages, have been identified (assemblages A to H). Of these, assemblages A and B infect both

humans and animals, whereas assemblages C to H are mostly host-specific, and rarely reported in humans. Multiple transmission routes are possible, including direct (person-to person, animal-to-person, and animal-to-animal), and indirect (through consumption of contaminated water and food) pathways. The increasing application of molecular techniques, from multi-locus typing up to whole genome analysis, showed that infection is highly prevalent in many animal species, yet zoonotic transmission contributes modestly to human giardiasis. Nevertheless, a few animal species (e.g., beavers) have been implicated in the transmission of *Giardia* to humans, particularly through contamination of water; well-conducted studies in epidemic settings may further clarify the role of animals. Water plays a very important role in the epidemiology of giardiasis, with widespread contamination of different water sources leading to waterborne outbreaks. To understand the complex epidemiology of giardiasis, a One Health approach is needed.

41.1 An Introduction to the Organism

Species within the genus *Giardia* are unicellular flagellates that infect the gut of different classes of vertebrates. There are currently eight recognized species in the genus (Table 1), including *Giardia agilis* in amphibians, *G. ardeae* and *G. psittaci* in birds, *G. microti*, *G. muris*, and *G. cricetidarum* in rodents, *G. peramelis* in marsupials, and *G. duodenalis* (syn. *G. lamblia*, *G. intestinalis*) in many mammals, including humans (Adam 2021). The life cycle of *Giardia* is direct and involves only two stages, the trophozoite, the stage that replicates in the host and cause symptoms, and the cyst, which is the infective stage shed with host feces (Fig. 1). Infection is initiated by ingestion of cysts either by the fecal-oral route (direct person-to person, animal-to-person, or animal-to-animal contacts), or indirectly through consumption of contaminated food or water. Exposure to the acidic environment of the stomach provides the necessary stimuli for the excystation of trophozoites from the cyst in the duodenum (Gardner and Hill 2001). Trophozoites undergo repeated mitotic divisions and are eventually triggered to develop into environmentally resistant cysts in response to changes in the small intestine environment, such as reduced cholesterol, increased bile content, and slightly basic pH, as well as in response to density and host-induced stress signals (Barash et al. 2017). Cysts shed with feces are immediately infectious and able to survive for weeks to months in the environment, leading to contamination of water and food (Feng and Xiao 2011). In humans, the infective dose is low, and 10–100 cysts might be sufficient to cause infection (Rendtorff 1954).

Table 1 The species currently recognized within the *Giardia* genus, their host distribution, and distinctive morphological characteristics. The eight assemblages comprised of *G. duodenalis*, and their host distribution, are indicated

Species	Host	Distinctive morphologic features (from light or electron microscopy)	Length/width of the trophozoite (μm)
Giardia agilis	Amphibians	Long and narrow trophozoites with club-shaped median bodies	20–30/4–5
Giardia ardeae	Birds	Rounded trophozoites, prominent notch in ventral disc and rudimentary caudal flagellum. Median bodies round-oval to claw-shaped	~10/~6
Giardia psittaci	Birds	Pear-shaped trophozoites, with no ventro-lateral flange. Claw-shaped median bodies	~14/~6
Giardia muris	Rodents	Rounded trophozoites with small, round median bodies	9–12/5–7
Giardia microti	Rodents	Trophozoites similar to *G. duodenalis*. Cysts contain fully differentiated trophozoites	12–15/6–8
Giardia cricetidarum	Hamsters	Small, rounded trophozoites, more similar to *G. muris*	12–18/8–12
Giardia duodenalis		Pera-shaped trophozoites with claw-shaped median bodies	12–15/6–8
Assemblage A	Mammals, including humans		
Assemblage B	Mammals, including humans		
Assemblage C	Domestic and wild canines		
Assemblage D	Domestic and wild canines		
Assemblage E	Ruminants, pigs		
Assemblage F	Cats		
Assemblage G	Rats		
Assemblage H	Marine mammals (seals)		
Giardia peramelis	Quanda (marsupial)	Similar to *G. duodenalis*	

41.2 Taxonomy of *Giardia*

Based on morphological characters, organisms in the genus *Giardia* are classified in the phylum Metamonada, subphylum Trichozoa, superclass Eopharyngia, class Trepomonadea, subclass Diplozoa, and order Giardiida (Thompson and Monis 2012).

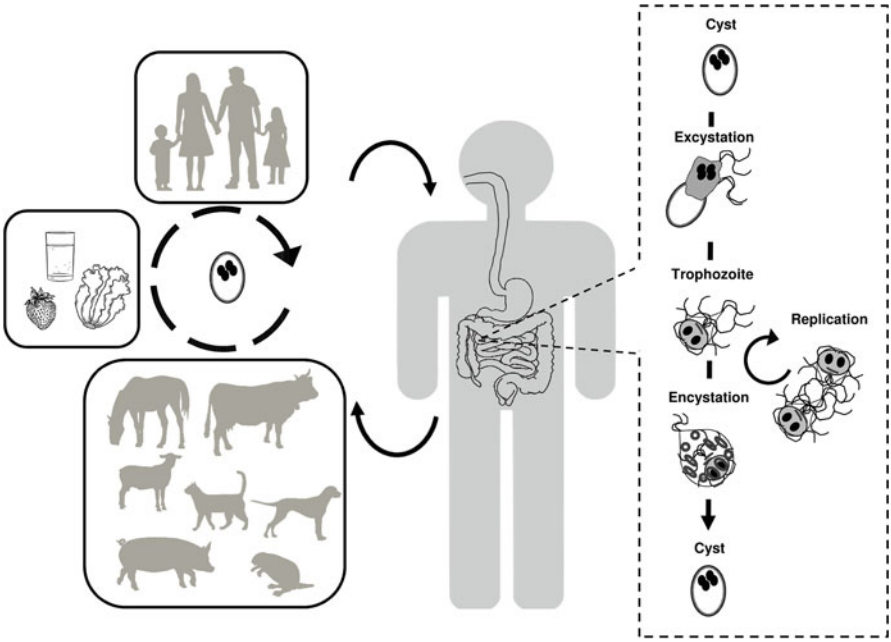

Fig. 1 Schematic representation of the transmission pathways of giardiasis and the life cycle of *Giardia*

The taxonomy of *Giardia* species has been, and still is, a subject of intense debate and controversy, and this has resulted in a confusing nomenclature with different names used for the same species (Monis et al. 2009). Early taxonomy, based on the assumption of strict host specificity (i.e., a different parasite species for each host), resulted in the description of 51 species of *Giardia*, including 30 from mammals (of which 2 from humans), 14 from birds, 4 from amphibians, 2 from reptiles, and 1 from fish (Thompson and Monis 2012). The taxonomy of *Giardia* species was reconsidered by Filice (1952), who concluded that no experimental evidence supported the validity of species named on the basis of host specificity. Filice proposed to recognize only three morphologically distinct species, namely, *Giardia muris*, *G. agilis*, and *G. duodenalis*, on the basis of the shape of internal median bodies as well as body shape and length (Filice 1952). This proposal rapidly became accepted, albeit, as acknowledged by Filice himself, many species were put under the *G. duodenalis* "umbrella," due to the lack of tools to discriminate between variants. With the development of advanced microscopic techniques, ultrastructural description of trophozoites allowed the description of two new species from birds, *Giardia ardeae* and *Giardia psittaci*, whereas *Giardia microti*, a parasite infecting various rodents, was recognized as a separate species due to the unique presence of fully differentiated trophozoites in the cysts. More recently, two additional species, *G. peramelis* in marsupials and *G. cricetidarum* in hamsters, have been described (Ryan and Zahedi 2019). Therefore, eight species are currently recognized in the genus (Table 1).

The development of techniques for the in vitro propagation of trophozoites in axenic conditions (Farthing et al. 1983) opened the possibility to characterize *Giardia* isolates from different hosts using genetic techniques. The first important series of experiments, based on polymorphisms of isoenzymes, revealed a large amount of genetic variability among *Giardia duodenalis* strains (Andrews et al. 1989). Importantly, cluster analysis of the isoenzyme data identified strongly supported groups of genetically related strains that, in most cases, were derived from specific hosts (Monis et al. 2003). DNA sequence analyses further confirmed the validity of these genetic groups, which were named assemblages to underline the fact that each group comprised of highly related but not identical strains. To date, eight assemblages are recognized, which have different host distribution: assemblages A and B are found in humans and other mammals, assemblages C and D are specific to dogs and other canids, assemblage E is found in livestock, assemblage F in cats, assemblage G in rats, and assemblage H in marine mammals (Cacciò et al. 2018; Table 1). These assemblages are separated by very large genetic distances, and are likely to represent distinct species, a conclusion reinforced by comparisons at the whole genome level of isolates from assemblages A, B, C, D, and E (Morrison et al. 2007; Franzén et al. 2009; Jerlström-Hultqvist et al. 2010; Ankarklev et al. 2015; Kooyman et al. 2019). A revision of the taxonomy and a new nomenclature at the species level has been proposed but not formally adopted (Monis et al. 2009), as controversies persisted. Therefore, the term assemblage will be used in this chapter.

As noted above, additional genetic variation exists among isolates within assemblages (i.e., intra-assemblage variability), which led to the description of sub-assemblages (Monis et al. 2003). Four sub-assemblages in assemblage A (AI, AII, AII, and AIV) and four in assemblage B (BI, BII, BIII, and BIV) were identified (Monis et al. 2003). Importantly, human isolates belonged to AI, AII, BIII, and BIV. Even the isolates belonging to sub-assemblages are not identical, and are better viewed as clusters of closely related isolates (Monis et al. 2003). However, the lack of a standardized nomenclature for the genetic variants found within sub-assemblages has created confusion, with different names used in different studies (Sulaiman et al. 2003; Lalle et al. 2005). These genetic variants are better described as genotypes, and, when multiple loci are investigated, as multi-locus genotypes (MLGs). To avoid further confusion, genotypes will be identified only at the level of the sub-assemblage to which they belong (e.g., AI, AII, BIV).

41.2.1 Molecular Typing of *Giardia duodenalis*

Like for many other pathogens, the introduction of molecular techniques has revolutionized the study of the epidemiology of giardiasis. Molecular tools are thought to provide higher sensitivity and specificity compared to microscopic or immunologic assays, and, more importantly, to allow a reliable identification of the parasite at the level of species, assemblage, sub-assemblage, and genotypes (Cacciò et al. 2008).

The first PCR assays targeted fragments of conserved eukaryotic genes, sometimes using degenerated primers (18S rRNA, glutamate dehydrogenase (*gdh*), elongation factor 1-alfa, triose phosphate isomerase (*tpi*); Monis et al. 1999), or genes
